Following the test procedure conducted by Young & Lui (2005), the load transfer plates were restrained against all degrees of freedom, except for the displacement at the top load transfer plate in the direction of the applied load. The loading method used in the FEM was identical to that used in the tests. The displacement control method was used for the analysis of the cold-formed high strength stainless steel square and rectangular hollow section stub columns. The load was applied to the specimen by specifying a displacement to the reference point of the analytical rigid plate that modeled the top load transfer plate.

The corner material properties of the rest of the sections were extrapolated from section 160 × 80 × 3 according to the measured initial Young's Modulus (E), the static 0.2% tensile proof stress ($\sigma_{0.2}$), the static tensile strength (σ_u) and the elongation after fracture (ε_f) based on a gauge length of 50 and 25 mm in the flat and corner portions, respectively. The measured and predicted stress-strain curves for flat and corner portions of each column were used in the analysis. Due to the absence of overall buckling for stub columns, only local geometric imperfection has been incorporated into the FEM in the form of the lowest buckling mode shape predicted in the linear perturbation analysis which is the first step of the finite element analysis as mentioned earlier. The local imperfection amplitude derived from the predictive model of Dawson & Walker (1972) as adapted by Gardner & Nethercot (2004b) for stainless steel was used in the finite element analysis. The local imperfection amplitude was defined in Eq. (1)

$$w_0 = 0.023\left(\frac{\sigma_{0.2}}{\sigma_{cr}}\right)t \tag{1}$$

where w_0 is the magnitude of the local imperfection, t is the plate thickness, $\sigma_{0.2}$ is the material 0.2% proof stress, and σ_{cr} is the elastic critical buckling stress of the plate that assuming simply supported boundary conditions.

3.2 *Verification of finite element model*

In the verification of the FEM, a total of 7 cold-formed high strength stainless steel square and rectangular hollow section stub columns were analyzed. A comparison between the experimental and FEA results was carried out. The main objective of this comparison is to verify and check the accuracy of the FEM. The comparison of the test results (P_{Exp}) with the ultimate loads (P_{FEA}) predicted from the FEA is shown in Table 2. It can be seen that a good agreement has been achieved between both results for all specimens. A maximum difference of 5% was observed between the experimental and numerical results for section 140 × 80 × 3. The mean value of the $P_{\text{Exp}}/P_{\text{FEA}}$ ratio is 1.03 with the small coefficient of variation (COV) of 0.020.

Table 2. Comparison of Experimental Results with Ultimate Loads Predicted from Finite Element Analysis.

Specimen	$h/t\varepsilon$	$b/t\varepsilon$	P_{Exp} (kN)	P_{FEA} (kN)	P_{Exp}/P_{FEA}
40 × 40 × 2	28.0	27.9	245.3	245.3	1.00
50 × 50 × 1.5	28.5	28.4	175.7	176.0	1.00
150 × 150 × 3	46.2	46.4	408.6	392.1	1.04
150 × 150 × 6	46.6	46.9	1927.4	1865.9	1.03
140 × 80 × 3	69.0	69.0	558.2	529.9	1.05
160 × 80 × 3	33.1	33.0	537.3	526.4	1.02
200 × 110 × 4	55.5	27.2	957.0	925.5	1.03
				Mean	1.03
				COV	0.020

The failure mode observed from the tests was also verified by the finite element model, as shown in Figure 2. It is shown that the FEM accurately predicted both the ultimate loads and the failure modes for cold-formed high strength stainless steel square and rectangular hollow section stub columns.

3.3 *Parametric study*

It was shown that the FEM accurately predicted the cross-section response of cold-formed high strength stainless steel square and rectangular hollow sections in compression. Hence, an extensive parametric study was carried out to investigate the effects of the cross-section aspect ratio ($\alpha = h/b \geq 1$), which directly related to the degree of interaction of constituent plate elements in square and rectangular hollow sections, on Class 3 slenderness limit and section capacities of cold-formed high strength stainless steel square and rectangular hollow sections in compression.

A total of 63 cold-formed high strength stainless steel square and rectangular hollow section stub columns with different cross-section aspect ratio were analyzed in the parametric study. The specimens consisted of 7 series with the cross-section aspect ratios α of 1.00, 1.13, 1.38, 1.80, 2.25, 3.00, and 6.00, respectively. For all the specimens, the web depth (D_c) between the midlines of the flanges was kept constant at 200 mm, the midline corner radius (r_c) was kept constant at 10 mm and the column length (L) was kept at 600 mm. The flange width (B_c) between the midlines of the webs ranged from 200 to 50 mm, such that the cross-section aspect ratios ranged from 1.00 to 6.00, were analyzed. The thickness (t) varied from 3.0 to 10.0 mm to cover from relatively compact sections to slender sections. The measured stress-strain curves of the flat and corner portions of the section 160 × 80 × 3 were used in the parametric study. The ultimate loads (P_{FEA}) predicted from FEA are summarized in Table 3.

Table 3. Ultimate Loads Predicted from the Finite Element Analysis of Parametric Study.

Specimen ($D_c \times B_c \times t$)	$P_{FEA}/\sigma_{0.2}A$						
	$B_c = 200$ $\alpha = 1.00$	$Bc = 180$ $\alpha = 1.13$	$Bc = 150$ $\alpha = 1.38$	$Bc = 120$ $\alpha = 1.80$	$Bc = 100$ $\alpha = 2.25$	$Bc = 80$ $\alpha = 3.00$	$Bc = 50$ $\alpha = 6.00$
$200 \times B_c \times 3.0$	0.48	0.50	0.54	0.59	0.62	0.66	0.66
$200 \times B_c \times 3.5$	0.53	0.55	0.60	0.65	0.69	0.72	0.71
$200 \times B_c \times 4.0$	0.59	0.61	0.66	0.72	0.75	0.77	0.76

$200 \times B_c \times 10.0$	1.20	1.22	1.23	1.25	1.28	1.28	1.29

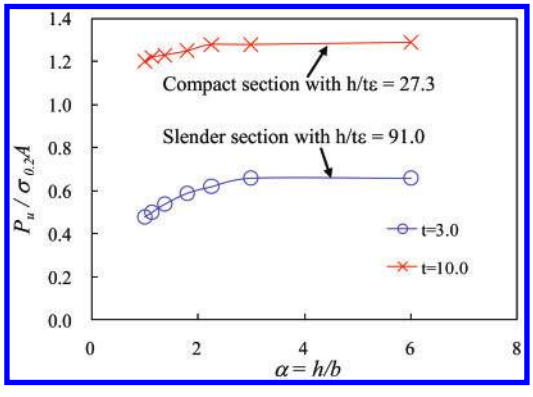

Figure 3. Effect of the interaction of constituent plate elements.

4 INTERACTION EFFECTS OF CONSTITUENT PLATE ELEMENTS

The cross-section response of the cold-formed high strength stainless steel square and rectangular hollow sections in compression is influenced by the interaction of constituent plate elements. The normalized section resistance ($P_u/\sigma_{0.2}A$) increases when the cross-section aspect ratio ($\alpha = h/b$) increases. This is attributed to the lower value of flange slenderness that provided a higher degree of restraint to the webs.

The effects of the cross-section aspect ratio (α) on the normalized section resistances for both the slender section with the normalized web slenderness ($h/t\varepsilon$) of 91.0 and the relatively compact section with the $h/t\varepsilon$ of 27.3 are shown in Figure 3. It is shown that the cross-section aspect ratio α has greater effect for the slender section than for the compact section. This is due to the fact that cross-section failed by either material yielding or inelastic local buckling in the case of stocky cross-section, and failed by local buckling below the yield stress for slender cross-section. The occurrence of local buckling will be delayed by the degree of restraint provided by the flanges to the webs. It is also shown that as the value of α increases the normalized section resistance also increases during the initial stage. Once α reached a value of approximately 3 ($\alpha = 3$) then the normalized section resistance hardly increase for both slender section having $h/t\varepsilon$ of 91.0 and the compact section having $h/t\varepsilon$ of 27.3, as shown in Figure 3.

5 ASSESSMENT OF CURRENT CLASS 3 SLENDERNESS LIMITS

The cross-section classification approach for stainless steel is similar to that adopted for carbon steel with the only difference lying in the adopted slenderness limits. The slenderness parameter $h/t\varepsilon$ specified in EC3 Code (2006) can be used to define the cross-section classification, where h is the flat width of the plate element considered, t is the plate thickness and ε is defined using Eq. (2).

$$\varepsilon = \sqrt{\frac{235}{\sigma_{0.2}} \frac{E}{210000}} \tag{2}$$

in which $\sigma_{0.2}$ is 0.2% proof stress and E is the Young's modulus. For square and rectangular hollow sections, the plate elements are simply supported and considered as internal elements where a buckling factor (k_σ) of 4 is used. Therefore, the relationship between slenderness parameter $h/t\varepsilon$ specified in EC3 Code (2006) and the slenderness parameter λ specified in the ASCE Specification (2002) is follows as in Eq. (3).

$$\frac{h}{t\varepsilon} = 56.83\lambda \tag{3}$$

For slender cross-sections (corresponding to Class 4 defined in EC3 Code) in compression, the section capacity is below the squash load as a result of local buckling. The numerical ultimate loads (P_{FEA}) obtained in this study together with the experimental results (P_{Exp}) reported by Young & Lui (2005) for the cold-formed high strength stainless steel square and rectangular hollow section stub columns were compared with the nominal section capacities ($\sigma_{0.2}A$) to assess the accuracy of the design provisions on Class

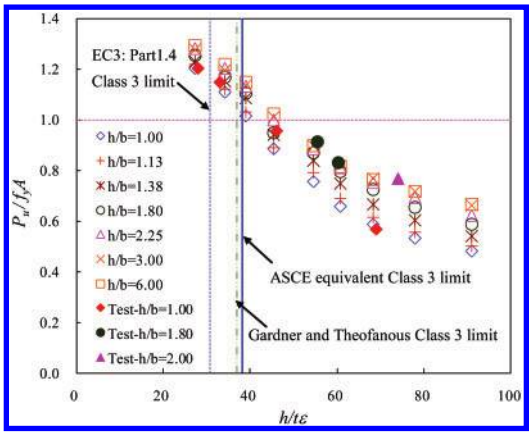

Figure 4. Current Class 3 slenderness limit for internal elements in compression.

3 slenderness limit. The cross-section ultimate loads (P_u) obtained from the tests and finite element analysis were normalized by the nominal section capacities ($\sigma_{0.2}A$) and plotted against the slenderness parameter $h/t\varepsilon$ of the web, which is the most slender plate element of the section in compression for all specimens, as shown in Figure 4. In ASCE Specification (2002), an equivalent Class 3 slenderness limit is defined in this study, when the reduction factor (ρ) for the calculation of effective width is less than 1.0, then the corresponding slenderness limit is defined as Class 3. The Class 3 slenderness limits for fully effective section specified in the current ASCE Specification (2002) and EC3 Code (2006) are 38.3ε and 30.7ε, respectively. The Class 3 slenderness limit of 37.0ε for fully effective section proposed by Gardner & Theofanous (2008) is also assessed using the cross-section ultimate loads obtained in this study. It is shown that the rectangular hollow sections ($\alpha > 1$) achieve the superior normalized section resistances to their square hollow sections ($\alpha = 1$) counterparts with the same web slenderness, particularly in the slender range of the graphs. It is also shown that the Class 3 slenderness limit for fully effective section proposed by Gardner & Theofanous is very close to that codified in ASCE Specification (2002), which is more suitable for square hollow sections instead of rectangular hollow sections. However, the Class 3 slenderness limit for fully effective section specified in the EC3 Code (2006) is quite conservative even for square hollow sections with the least normalized section resistances.

6 PROPOSED CLASS 3 SLENDERNESS LIMIT AND COMPARED WITH NUMERICAL RESULTS

In the current EC3 Code (2006) for stainless steel structures, the cross-section responses is considered to the behaviour of its most slender plate element, thereby neglecting the interaction of constituent plate

Table 4. Cross-section Dimensions and Ultimate Loads Predicted from the Finite Element Analysis for Proposing Class 3 Slenderness Limit.

Specimen ($D_c \times B_c \times t$)	$h/t\varepsilon$	$b/t\varepsilon$	α	P_{FEA} (kN)	$\sigma_{0.2}A$ (kN)	$P_{FEA}/\sigma_{0.2}A$
$200 \times 50 \times 5.9$	46.3	7.7	6.00	1534.2	1526.8	1.00
$200 \times 80 \times 6.0$	45.5	15.2	3.00	1764.5	1745.6	1.01
$200 \times 100 \times 6.1$	44.8	19.9	2.25	1938.9	1905.5	1.02
$200 \times 120 \times 6.2$	44.1	24.5	1.80	2112.6	2069.7	1.02
$200 \times 150 \times 6.4$	42.7	30.8	1.38	2372.9	2342.3	1.01
$200 \times 180 \times 6.7$	40.8	36.2	1.13	2698.6	2667.5	1.01
$200 \times 200 \times 7.0$	39.0	39.0	1.00	2984.1	2937.1	1.02

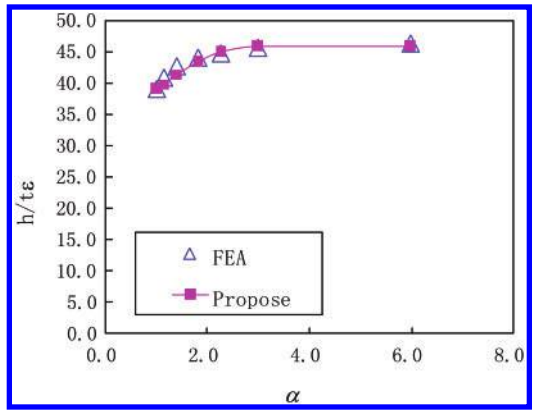

Figure 5. Proposed Class 3 slenderness limit for cold-formed high strength stainless steel square and rectangular hollow sections in compression.

elements, which are individually classified according to their width-to-thickness ratios, as compared with codified slenderness limits (Gardner & Theofanous 2008). However, it is shown that the effects of the interaction of constituent plate elements are quite obvious up to the cross-section aspect ratio (α) of 3. Therefore, a new Class 3 slenderness limit based on the whole cross-section response is proposed in this study for cold-formed high strength stainless steel square and rectangular hollow sections in compression, which takes into consideration of the interaction of constituent plate elements.

A total of 7 series square and rectangular hollow sections with the values of α equal to 1.00, 1.13, 1.38, 1.80, 2.25, 3.00, and 6.00, considered in the parametric study were re-analyzed using the finite element model developed in this study. For each series, the web depth between the midlines of the flanges (D_c), the flange width between the midlines of the webs (B_c) and the midline corner radius (r_c) are kept unchanged. The only change to the sections is the thicknesses (t). The aim of the investigation is to obtain the appropriate value for each series such that the normalized section resistances are close to 1.0 ($P_{FEA}/\sigma_{0.2}A = 1.0$). The cross-section dimensions and the ultimate loads

(P_{FEA}) predicted from FEA for the purpose of proposing a new Class 3 slenderness limit are summarized in Table 4. Based on this study, a new Class 3 slenderness limit, which is the function of the cross-section aspect ratio ($\alpha = h/b$), is proposed, as shown in Eq. (4).

$$\frac{h}{t\varepsilon} = \begin{cases} 30.5 + 10.2\alpha - 1.7\alpha^2 & 1 \le \alpha \le 3 \\ 45.8 & \alpha > 3 \end{cases} \quad (4)$$

where h and b are the flat widths of the web and flange elements, respectively, of the square and rectangular hollow sections ($h \ge b$); t is the plate thickness; ε is defined in Eq. (2) of this paper; α is the cross-section aspect ratio ($\alpha = h/b \ge 1$); and $\sigma_{0.2}$ is the 0.2% proof stress of the stainless steel. The limitations of the Eq. (4) are $1.0 \le \alpha \le 6.0$ and $448 \le \sigma_{0.2} \le 707$ MPa.

The slenderness parameters $h/t\varepsilon$ predicted using the proposed Class 3 slenderness limit as shown in Eq. (4) were plotted against the cross-section aspect ratio α in Figure 5. The $h/t\varepsilon$ data points shown in Table 4, where the normalized section resistance is close to 1 ($P_{FEA}/\sigma_{0.2}A = 1$) are used. It is shown that the proposed Class 3 slenderness limits agree well with the numerical results.

7 CONCLUSIONS

An accurate and efficient finite element model (FEM) was developed in this study for the analysis of cold-formed high strength stainless steel square and rectangular hollow section stub columns. The initial local imperfection and non-linear material properties of the flat and corner portions of the cross-section have been carefully incorporated in the FEM. It is shown that the FEM closely predicted the cross-section responses of the cold-formed high strength stainless steel square and rectangular hollow sections in compression. Hence, an extensive parametric study was carried out to study the interaction effects of constituent plate elements on cold-formed high strength stainless steel cross-section behaviour in compression.

It is shown that the interaction effects of constituent plate elements on the normalized section resistances are obvious, particularly for slender sections. It is also shown that as the value of cross-section aspect ratio (α) increases, the normalized section resistance also increases during the initial stage, and once α reached a value of approximately 3 then the normalized section resistance hardly increase for both slender section having $h/t\varepsilon$ of 91.0 and the compact section having $h/t\varepsilon$ of 27.3. The Class 3 slenderness limit in the EC3 Code, ASCE Specification and proposed by Gardner and Theofanous were also assessed using the results obtained from the parametric study. It is shown that the design provisions on Class 3 slenderness limit are more suitable for square hollow sections rather than rectangular hollow sections since they neglected the interaction of constituent plate elements.

Therefore, a new Class 3 slenderness limit is proposed in this study for cold-formed high strength stainless steel square and rectangular hollow sections in compression that takes into consideration of the interaction of constituent plate elements. It is shown that the proposed Class 3 slenderness limit agrees well with the numerical results for both square and rectangular hollow sections.

ABSTRACT: Experimental research was done to investigate the mechanical properties of austenitic stainless steel after exposed to fire. Three types of stainless steel coupons, including flat, curved and corner coupons, were tested after subjected to a designed heating and cooling fire, and the post-fire modulus of elasticity, yield strength, ultimate strength, ultimate strain and stress-strain curves of stainless steel corresponding to various historical maximum temperatures were measured and discussed. Finally, based on the experimental results of flat and curved coupons, a post-fire stainless steel stress-strain model was proposed, and the accuracy of the predicted results is acceptable.

1 INTRODUCTION

Stainless steel has been widely used in structural constructions due to its excellent performance, such as corrosion resistance, ease of maintenance and aesthetic appeal. Compared with carbon steel, stainless steel usually contains some special elements, such as chromium, nickel, molybdenum and titanium, which lead to the remarkable corrosion resistance and different mechanical properties of stainless steel. The shape of the stress-strain curve of stainless steel is a "round-house" type, and the pronounced yield plateau in mild steel stress-strain curve does not exist for stainless steel. Therefore, a systematic research on mechanical properties of stainless steel at ambient, elevated and after elevated temperatures is necessary.

To capture the stress versus strain relationship of stainless steel at ambient temperature, plenty of research has been done before. Ramberg & Osgood (1943) proposed a stress–strain relation equation, which can predict the stress–strain curve of stainless steel when stress is less than 0.2% proof stress. Mirambell & Real (2000), Rasmussen (2003) and Quach et al. (2008) extended Ramberg and Osgoods' model to perform an accurate prediction of stainless steel stress–strain curve when stress is higher than 0.2% proof stress. Van & Van (1992) and Cruise & Gardner (2008) investigated the corner mechanical properties of cold formed stainless steel.

For the research on mechanical properties of stainless steel at and after elevated temperatures, literature review indicates that limited work has been done, especially for the research regarding stress-strain models. Chen & Young (2006) proposed a stress-strain relation model for stainless steel at elevated temperatures. Felicetti et al. (2009) tested stainless steel bars (austenitic AISI 304L steel) after being heated up to 850°C, and the test results indicate that for hot-rolled stainless steel the yield strength degraded if the temperature was higher than 500°C, but the fire exposure had no apparent influence on the ultimate strength. Till now, no research has been done on the stress-strain model of stainless structural steel after fire exposure. Therefore, in this paper, tensile tests are conducted to investigate the post-fire properties of EN 1.4301 stainless structural steel, and a stress-strain relation model for austenitic stainless steel after exposed to high temperatures is proposed.

2 EXPERIMENTAL PROGRAM

2.1 *Test specimens*

Post-fire mechanical properties of austenitic stainless steel of grade 1.4301 (304) was investigated. Three types of test coupons, including flat, curved and corner coupons, were fabricated, in which, the flat coupons were cut from the middle of the flat surfaces of cold rolled square hollow section (SHS, $200 \times 200 \times 5.7$ mm) tubes, the curved coupons were cut from circular hollow section (CHS, 260×3 mm) tubes and the corner coupons were cut from the corners of the same cold rolled SHS tubes. The specimen configurations for tensile tests were adopted from

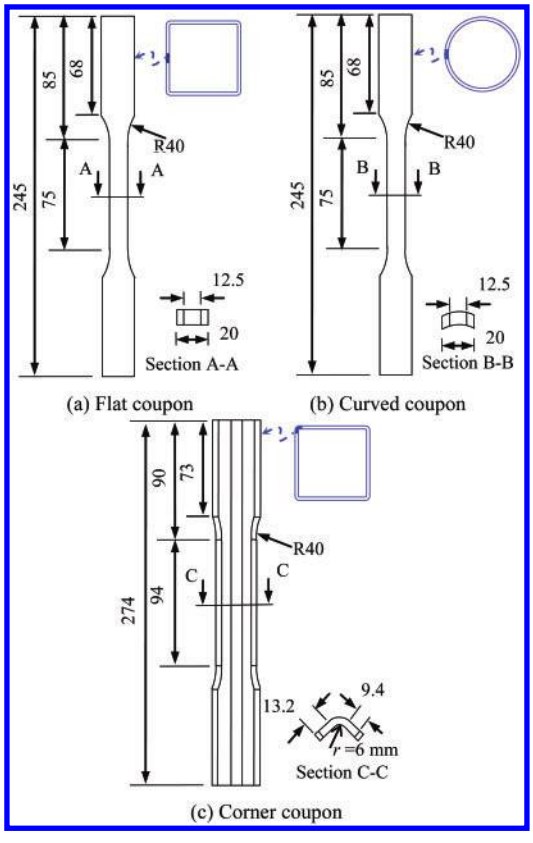

Figure 1. Dimensions of tensile coupons (Unit: mm)

AS 1391-2007 (2007). The specimen dimensions are shown in Figure 1.

2.2 *Test equipment and test procedure*

Heating was conducted in a temperature-controlled furnace. The coupons were heated from ambient temperature at a rate of 20°C/min to the historical maximum temperature (T), and then kept the maximum temperature stable until the expected heating time (t_h) was reached. Finally, the fire in the furnace was shut off to make the coupons cool down to ambient temperature with the furnace door closed. Figure 2 illustrates a typical temperature versus time relationship of coupons. The maximum temperature (T) and heating time (t_h) are listed in Table 1.

After cooled to ambient temperature, the coupons were taken out from the furnace and the tensile tests were conducted using a computer controlled test machine Instron 6027. Strain-controlled method was used and the coupons were loaded at a strain rate of 0.000 2/s. Two extensometers were placed on both sides of the coupon to measure the extension. The data, including post-fire full-range stress (σ)–strain (*varepsilon*) curves, modulus of elasticity (E_{0T}), 0.2% proof yield strength ($\sigma_{0.2T}$), 0.01% proof yield strength ($\sigma_{0.01T}$), ultimate strength (σ_{uT}), and ultimate strain

21	1000	60	

(ε_{uT}) corresponding to σ_{uT}, were recorded. The strain hardening exponent (n_T) was calculated according to the equation suggested by Ramberg & Osgood (1943).

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 *Experimental results*

Figure 3 illustrates the influence of fire exposure on the σ–ε curves. After fire exposure, the strength of the stainless steel undergoes deterioration, whilst the post-fire stress–strain curve maintains the same basic shape of the "rounded" type. The strength reduction in flat coupons and curved coupons is similar, but the corner coupon shows more significantly decrease in strength, as shown in Fig.3(c).

Furthermore, for corner coupons, the decreased ductility induced by cold-working seems to recover

after fire exposure. Strength increase due to work-hardening at room temperature can be explained by the effects of corner region subjected to a high degree of plastic deformation. So the transformation of austenitic to martensitic phases can occur. The martensitic structure provides a greater strength than the former austenitic structure. If the material is exposed to extreme temperatures, however, the strength enhancing martensitic phase reverts to the lower strength austenitic phase. It can be found in Figure 4 that after being heated to 1000°C, the stress–strain curve of the corner coupon is close to those of flat and curved coupons.

From the post-fire full-range stress–strain curves of the coupons, modulus of elasticity (E_{0T}), 0.2% proof yield strength ($\sigma_{0.2T}$), 0.01% proof yield strength ($\sigma_{0.01T}$), ultimate strength (σ_{uT}), ultimate strain (ε_{uT}), and strain hardening exponent (n_T) are extracted and summarised in Table 2. To quantify the influence of high temperatures on the post-fire properties of stainless steel, the ratios of E_{0T}/E_0, $\sigma_{0.2T}/\sigma_{0.2}$, σ_{uT}/σ_u, $\varepsilon_{uT}/\varepsilon_u$, $\sigma_{0.01T}/\sigma_{0.01}$ and n_T/n are calculated, and the results are discussed in the following sections, where E_0, $\sigma_{0.2}$, σ_u, ε_u, $\sigma_{0.01}$ and n are the parameters corresponding to the unheated coupons.

3.2 *Influence of heating time*

To investigate the influence of heating time (t_h) on the post-fire mechanical properties of stainless steel, flat coupons were heated to 800 °C, and kept the temperature constant until the heating time reached 40 min, 85 min, 130 min and 175 min respectively. Ratios of E_{0T}/E_0, $\sigma_{0.2T}/\sigma_{0.2}$, σ_{uT}/σ_u and $\varepsilon_{uT}/\varepsilon_u$ corresponding to various t_h are illustrated in Figure 5. It can be found that all the ratios are close to 1.0, and the influence of t_h is

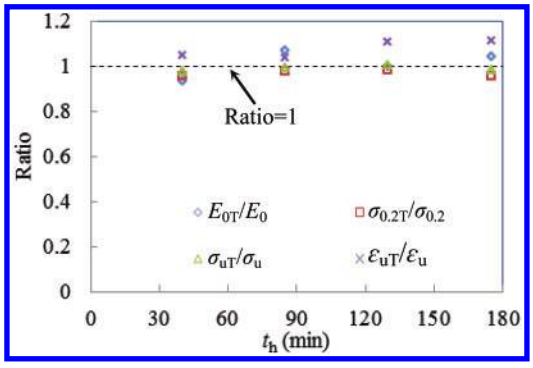

Figure 5. Influence of heating time (t_h) on E_{0T}/E_0, $\sigma_{0.2T}/\sigma_{0.2}$, σ_{uT}/σ_u, $\varepsilon_{uT}/\varepsilon_u$ of coupons with the same maximum temperature of 800 °C.

minor on the post-fire mechanical properties of stainless steel. It can be concluded that residual mechanical properties of stainless steel is not dependent on heating time if the heating time is long enough to achieve an even temperature inside the steel coupons.

3.3 *Influence of maximum temperature*

The influence of maximum temperature (T) on ratios of E_{0T}/E_0, $\sigma_{0.2T}/\sigma_{0.2}$, $\sigma_{0.01T}/\sigma_{0.01}$, n_T/n, σ_{uT}/σ_u and $\varepsilon_{uT}/\varepsilon_u$ are depicted in Figures 6(a-f), respectively.

It can be seen from Figure 6(a) that, when T ranges from 20°C to 700°C, E_{0T} shows a slight decline, and after T is higher than 700°C, E_{0T} remains almost the same as that of coupons at ambient temperature. In spite of the minor fluctuation, it is reasonable to assume that the change of E_{0T} can be ignored after exposure to high temperatures.

Figure 6(b) indicates the influence of T on $\sigma_{0.2T}/\sigma_{0.2}$, where the tested data from this paper and Felicetti et al. (2009) are included. It can be found that generally $\sigma_{0.2T}$ remains unchanged when T is lower than 500°C, and then an obvious decrease of $\sigma_{0.2T}$ can be observed when temperature is higher than 500°C. The same tendency as $\sigma_{0.2T}/\sigma_{0.2}$ can be observed for $\sigma_{0.01T}/\sigma_{0.01}$ as shown in Figure 6(c).

Generally, as shown in Figures 6(d-f), it can be found that the influence of T on n_T/n, σ_{uT}/σ_u and $\varepsilon_{uT}/\varepsilon_u$ is moderate, although significant variations in n_T and ε_{uT} are observed.

3.4 *Comparison between stainless and carbon steels*

Figure 7 depicts the typical measured σ–ε curves for stainless steel at ambient temperature and with a maximum temperature of 1000 °C. In Figure 7, the predicted σ–ε curves for carbon steel by Tao et al. (2013) are also shown. It can be found that, for the stainless steel, the reductions in yield strength and ultimate strength are 13.3% and 3.3%, respectively. The predicted reductions for the corresponding carbon steel are 21.3% and 9.8%, respectively. From the comparison, it can be concluded that stainless steel has superior post-fire performance than carbon steel.

4 POST-FIRE STRESS-STRAIN RELATION MODEL FOR STAINLESS STEEL

4.1 *Post-fire stress-strain model*

As mentioned before, for stainless steel after exposure to elevated temperatures, the tensile stress-strain curves remain the basic shape, as shown in Figure 3. Therefore it is reasonable to assume that the basic expression for ambient stainless steel can still be used for stainless steel after fire exposure. In this study the stress-strain relation equations for stainless steel at ambient phase proposed by Rasmussen (2003) is utilised to develop the post-fire stress-strain model. Five key parameters, including modulus of elasticity (E_0), 0.2% proof strength ($\sigma_{0.2}$), ultimate stress (σ_u), ultimate strain (ε_u) corresponding to σ_u and the strain hardening exponent (n), need to be decided to calibrate the stress-strain relation. As discussed before, among the five parameters, only $\sigma_{0.2}$decreases when the maximum temperature exceeds 500°C, whereas other parameters remain unchanged in general. Therefore the post-fire stress-strain model can be expressed by Equation (1) and depicted in Figure 8.

$$\varepsilon = \begin{cases} \dfrac{\sigma}{E_0} + 0.002\left(\dfrac{\sigma}{\sigma_{0.2T}}\right)^n & \sigma \le \sigma_{0.2T} \\ 0.002 + \dfrac{\sigma_{0.2T}}{E_0} + \dfrac{\sigma - \sigma_{0.2T}}{E_{0.2}} + \varepsilon_u\left(\dfrac{\sigma - \sigma_{0.2T}}{\sigma_u - \sigma_{0.2T}}\right)^m & \sigma > \sigma_{0.2T} \end{cases} \quad (1)$$

where,

$$n = \frac{\ln(20)}{\ln(\sigma_{0.2}/\sigma_{0.01})} \quad (2)$$

$$E_{0.2} = \frac{E_0}{1 + 0.002nE_0/\sigma_{0.2T}} \quad (3)$$

$$m = 1 + 3.5\frac{\sigma_{0.2T}}{\sigma_u} \quad (4)$$

The subscript T of the post-fire 0.2% proof yield strength ($\sigma_{0.2T}$) indicates that $\sigma_{0.2T}$ is the function of the maximum temperature (T). Because the 0.2% proof yield strength and the 0.01% proof yield strength decrease in the same pattern after fire exposure, as shown in Figures 6(b) and 6(c), $\sigma_{0.2T}/\sigma_{0.01T} \approx \sigma_{0.2}/\sigma_{0.01}$, therefore $\sigma_{0.2}/\sigma_{0.01}$ is used instead of $\sigma_{0.2T}/\sigma_{0.01T}$ in Equation 2.

In Equation 1, $\sigma_{0.2T}$ depends on the maximum temperature (T). Therefore, in this paper, $\sigma_{0.2T}$ is determined based on regression analysis to test data. The test results in this paper indicate that flat coupons cut from the centre part of the flat faces of the stainless SHS tubes and curved coupons cut from CHS tubes are much less work-hardened than the corner coupons, and the flat and curved coupons can be considered as one group without corner effect. Therefore,

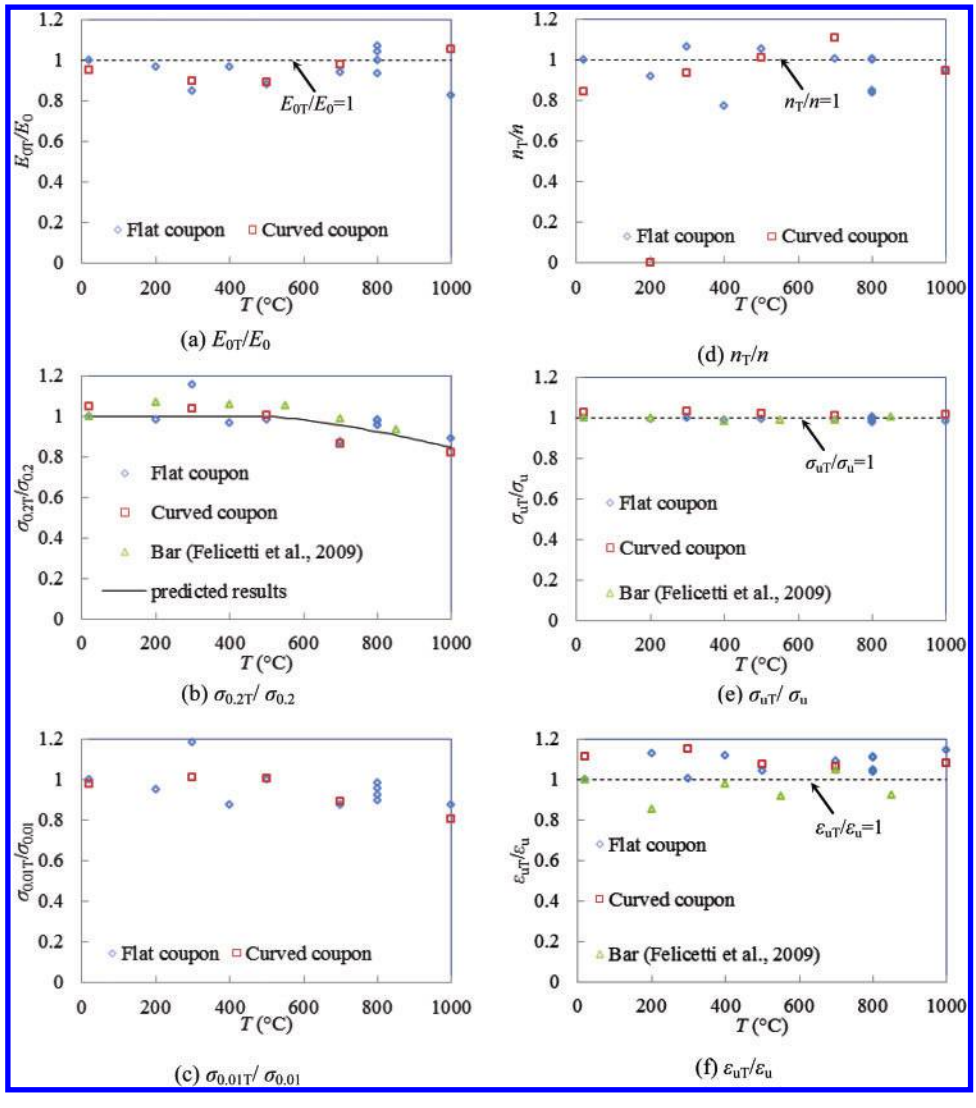

Figure 6. Influence of maximum temperature (T) on the post-fire mechanical properties of coupons.

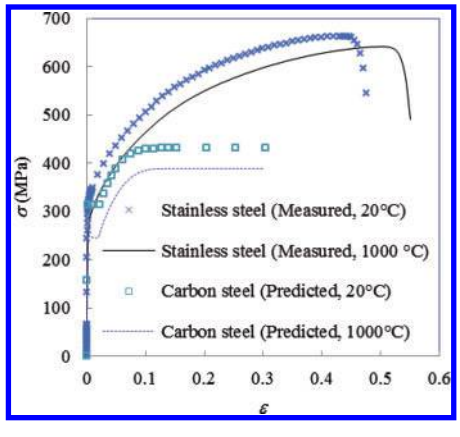

Figure 7. Typical σ–ε curves of stainless steel and carbon steel before and after exposed to fire.

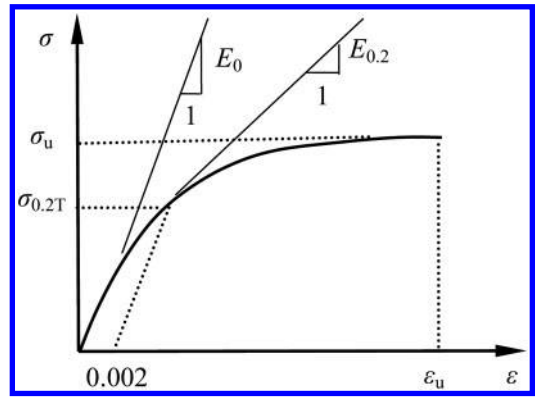

Figure 8. σ–ε model of stainless steel after exposed to elevated temperatures.

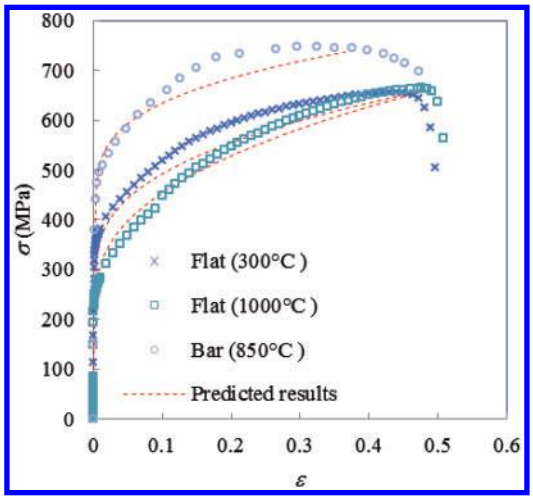

Figure 9. Comparison between tested and predicted σ–ε curves of stainless steel after exposed to elevated temperatures.

in this paper, to calibrate $\sigma_{0.2T}$ for stainless steel without considering corner effect, experimental data of flat coupon and curved coupon tests performed in this paper are adopted. Moreover, stainless bar test data reported by Felicetti et al. (2009) present the same variation tendency as flat and curved coupons. Due to the limited post-fire test data available, the test data of stainless bars are also adopted to calibrate $\sigma_{0.2T}$. Ratios of $\sigma_{0.2T}/\sigma_{0.2}$ corresponding to the three groups of test data are shown in Figure 6(b), and Equation (5) is proposed to predict the $\sigma_{0.2T}/\sigma_{0.2}$of stainless steel after exposure to elevated temperatures. It also can be found from Figure 6(b) that the predicted $\sigma_{0.2T}/\ \sigma_{0.2}$ curve is acceptable.

$$\frac{\sigma_{0.2T}}{\sigma_{0.2}}=\begin{cases}1 & T\le 500^{\circ}\mathrm{C}\\ 1-1.75\times10^{-4}(T-500)-2.71\times10^{-7}(T-500)^2 & T>500^{\circ}\mathrm{C}\end{cases} \quad (5)$$

4.2 *Verification of established model*

The experimental stress–strain curves of flat coupons, curved coupons and bar coupons are used to assess the accuracy of the proposed stress–strain model. For the stainless steel bar tests presented by Felicetti et al. (2009), the modulus of elasticity (E_0) and strain hardening exponent (n) are not reported, therefore, the proposed$E_0$and n according to Eurocode 3 (2006) are adopted, which are 200000 MPa and 6, respectively. Comparison between tested and predicted stress–strain curves is shown in Figure 9. In general, the proposed stress–strain model can predict the measured stress–strain curves of stainless steel very well.

5 CONCLUSIONS

Experimental study was carried out to investigate the mechanical properties of austenitic stainless steel after exposure to various temperatures, and the important post-fire mechanical property parameters, including stress–strain curve, modulus of elasticity, 0.2% proof yield strength, 0.01% proof yield strength, ultimate strength, ultimate strain and strain hardening exponent, were obtained. The comparison between stainless and carbon steel after exposed to fire demonstrates that stainless steel has superior post-fire performance than carbon steel. Based on the test results, a stress-strain model is proposed to obtain the full-range stress-strain curve for stainless steel without corner effect after exposure to elevated temperatures. The predicted stress-strain curves are generally in good agreement with test curves.

Study on ferritic stainless steel and its application on architecture structure

Ma Li & Wenbo Dong
Stainless Steel Technology Center, Baosteel Research Institute; Baoshan Iron & Steel Co.,Ltd., Shanghai, China

ABSTRACT: Ferritic Stainless Steels (FSS) are nickel-saving, corrosion-resistant, low cost steels. In this paper the feasibility of applying ferritic stainless steels on architecture structural fields is studied. Three typical ferritic stainless steels with 12%, 16% and 22% chromium content are chosen, and comparison of properties for these steels was made by performing physical testing, mechanical testing, corrosion resistance testing and welding experiment. The results show that FSS has not only excellent corrosion resistance but also good mechanical and physical properties. But following the increase of Cr, FSS exhibits a worse impact toughness in despite of a better corrosion resistance. Controlling a lower carbon, nitrogen and adding some stabilized elements titanium or niobium helps to improve the impact toughness, and other general properties are also developed to some extent. The impact toughness is also influenced by the thickness of the material, so the thickness should be limited to less than 4 mm for high chromium ferritic stainless steel on structural applications.

Keywords: Ferritic stainless steel; Structural; Impact toughness

1 INTRODUCTION

Stainless steels are being increasingly used as construction materials because of their attractive features such as excellent corrosion resistance, long service life span, low life cycle cost and unique aesthetic appeal. As a main type of stainless steels ferritic stainless steels(FSS) show lower cost, higher thermal conductivity, smaller linear expansion and better resistance to chloride stress corrosion cracking, atmospheric corrosion and oxidation compared to traditional austenitic stainless steels. FSS are essentially iron-chromium binary alloys containing about 12–30 percent of chromium, and According to the content of chromium they are divided into three series, the low-chromium, the medium- chromium and the high-chromium, and the corrosion resistance enhances with the increase of chromium content [1]. For engineers one of the important and practical aspects of materials selection in the design, development, and production of new components is the possibility of failure of the components under normal operation [2]. FSS are more easily to fracture in a brittle manner with little plastic deformation at low temperature, which may lead to sudden, unexpected, catastrophic failures [3−4]. Now FSS are only partially covered by European structural standards and used scarcely on structural applications because of the low temperature brittleness. Thus, in this paper the feasibility of applying FSS on architecture structural fields especially the impact toughness of FSS are studied.

2 EXPERIMENTAL

The experimental materials were cut from commercial hot bands, and the composition is shown in Table 1. Three series of commonly used ferritic stainless steels with 12%, 16% and 22% chromium content are chosen, and the effects of carbon content, nitrogen content and stabilization on the properties of these steels are studied. F1 and F2 are low chromium stainless steels with 12% chromium content and F2 has higher chromium and lower carbon and nitrogen than that of F1. F3 and F4 are typical medium chromium stainless steel with 16% chromium content and F4 has higher Cr content and lower carbon and nitrogen than that of F3, furthermore, in F4 Nb and Ti were also added to suppress the precipitation of chromium carbon nitride by forming stable carbide or nitride like Ti(C,N) and Nb(C,N) to avoid occurrence of intergranular corrosion. FSS5 is a high chromium stainless steel with lower C and N, more Ti and Nb, and a certain amount of Mo to get a better corrosion resistance. Comparative material 304 is a conventional austenitic stainless steel with 18% Cr and 8% nickel.

Comparisons of microstructure and properties for these steels were made by performing microstructure analysis, physical testing, mechanical testing and corrosion resistance testing. In order to obtain the influence of material thickness on the impact toughness, two section thickness of 4mm and 2.5mm samples were tested on the drop weight impact testing machine (INSTRON-9250) at temperature raging

Table 1. Composition of ferritic stainless steels /%.

Grade	C	Si	Mn	Cr	N	Nb	Ti	Mo	Ni
F1	0.028	0.3	0.3	12.3	0.027	–	–	–	–

304	7.93	72	502	16.2	17.3	193

from −60° to 2°, then the fracture surfaces after impact tests were observed by means of scanning electron microscopes (SEM). Mechanical properties were measured using a tensile test machine (INSTRON5985), and hardness tests were performed on Vickers hardness tester (Instron Wilson-Wolpert Turkon 2100B). At the same time corrosion resistance and physical performance index were obtained respectively with Princeton VMP3 type potentiostat, thermo dilatometer (DIL402C) and thermal conductivity meter, etc.

3 RESULTS AND DISCUSSION

3.1 *Physical properties*

The physical properties of five ferritic stainless steels are shown in Table 2 in comparison with those of typical carbon structural steel SS400 and conventional austenitic stainless steel 304. It is visible that these ferritic stainless steels show very similar physical properties and they have similar density, Specific Heat and Young's Modulus compared with those of SS400 and 304. Ferritic stainless steels also have smaller thermal expansion coefficient than that of SS400 and 304, which means that the thermal strain of FSS will be small due to the change of atmospheric temperature between day and night or during the welding process. In addition, the biggest different parameters among FSS, SS400 and 304 are Electric Resistance and Thermal Conductivity. Carbon steel SS400 shows best electrical and thermal conductivity and FSS takes the second place. The different physical properties of FSS, SS400 and 304 should attribute to the difference of the alloy component, the metallic crystal structure and the general arrangement of the atoms, and the electrical and thermal conductivity depend on the directional movement of free electrons and the vibrations of the metal's lattice of positive ions. Young's Modulus is an important parameter to determine the stiffness of structural members and metals with high Young's Modulus are relatively stiff and do not deflect easily. Young's Modulus is related to the bonding strength between the atoms in a metal or alloy and steels have similar high values

3.2 *Mechanical Properties*

The mechanical properties of ferritic stainless steels F1-F5, carbon structural steel SS400 and austenitic stainless steel 304 are shown in Table 3, where yield strength, tensile strength, elongation and hardness are measured. It can be seen that ferritic stainless steels show similar strength and elongation properties to those of carbon structural steel SS400, and they all show higher yield strength, lower tensile strength, lower elongation and lower work-hardening than austenitic stainless steel 304. The yield strength is a very important value for use in engineering structural design since it is the strength at which a metal or alloy shows significant plastic deformation, and the tensile strength is not used much in engineering design for ductile alloys since too much plastic deformation takes place before it is reached. During a plastic deformation the metal is deformed to such an extent and it can not fully recover its original dimensions, so it's more important for material having higher yield strength in the field of Structural Engineering Design. Above all it can be seen that ferritic stainless steels exhibit similar mechanical properties to those of carbon structural steel SS400, and can meet the requirement of architecture structural design.

Table 3. Mechanical properties of ferritic stainless steels.

Grade	Rp0.2, MPa	Rm MPa	A50 mm, %	Hardness, HV5
FSS1	300	480	29	142
FSS2	260	405	35	122
FSS3	285	465	31.5	133
FSS4	280	440	36	135
FSS5	330	515	34	170
SS400	300	450	33	-
304	265	650	52	154

3.3 *Corrosion Resistance*

Stainless steels are selected as engineering materials mainly because of their excellent corrosion resistance in many environments. The corrosion resistance of stainless steels is due to their high chromium contents, and the chromium forms a surface oxide film that protects the underlying matrix from corroding. The corrosion resistance in stainless steels is mainly dependent on the Pitting Resistance Equivalent (PRE = Cr% + 3.3Mo%), i.e., the chromium and molybdenum contents. But to increase the content of chromium even to 24% is not enough for complete prevention of rust, in some high chromium stainless the combination of chromium and molybdenum is necessary [5–6]. The PRE value and the pitting potential of FSS1-5 are shown in Fig1. It can be seen that the corrosion resistance of F1-5 improve with the increase of chromium content, and molybdenum added F5 shows a superior corrosion resistance to that of 304. At the same chromium content level, F2 with low carbon and nitrogen contents has a better corrosion resistance than that of F1 with higher carbon and nitrogen, and F4 with very low carbon and nitrogen, titanium and niobium stabilized has a better corrosion resistance than that of F3.

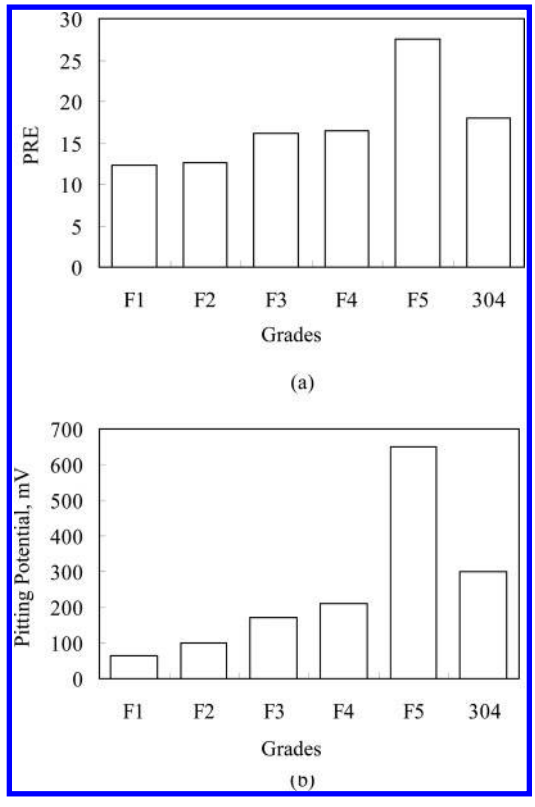

Figure 1. PRE and Pitting Potential of FSS: (a) PRE; (b) Pitting Potential.

3.4 *Impact Toughness*

FSS are more easily to fracture in a brittle manner with little plastic deformation at low temperature, which may lead to sudden, unexpected, catastrophic failures. Impact toughness is defined to measure the amount of energy that a material can absorb before fracturing. It becomes of engineering importance when the ability of a material to withstand an impact load without fracturing is considered. One of the simplest methods of measuring toughness is to use an impact testing apparatus. In this paper two section thicknesses of 4mm and 2.5mm samples were tested on the drop weight impact testing machine at temperature raging from −60° to 20°.

3.4.1 *Effect of Temperature*

Fig 2 shows the relative effect of temperature on the impact energy of F1-F5. The impact energy falls down with the decrease of temperature, and a distinct ductile to brittle transition temperature (DBTT) is observed. The DBTT of F1 to F5 is about −30°, 10°, −10°, −10°, and 10°. F1 shows best impact energy

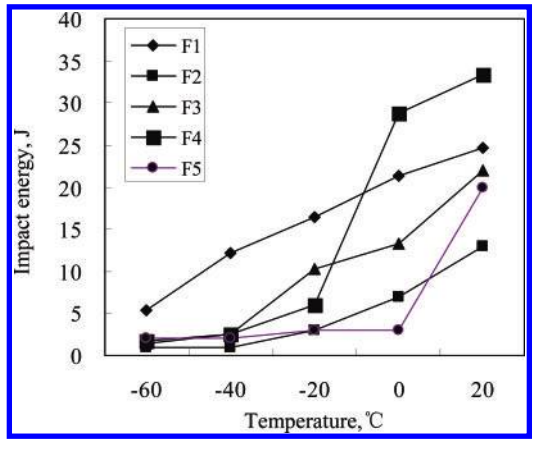

Figure 2. Charpy V-notch impact toughness of experimental material as a function of temperature (2.5 mm specimens)

because it is a semi-matensitic stainless steel with different microstructure from pure FFS. Then the fracture surfaces after impact tests were observed by means of scanning electron microscopes (SEM), and Fig 3 shows the different fracture manner of F4 steel in different temperature. When the impacted temperature is higher than the DBTT, ductile fracture occurs, otherwise brittle fracture happens. So FSS are strongly

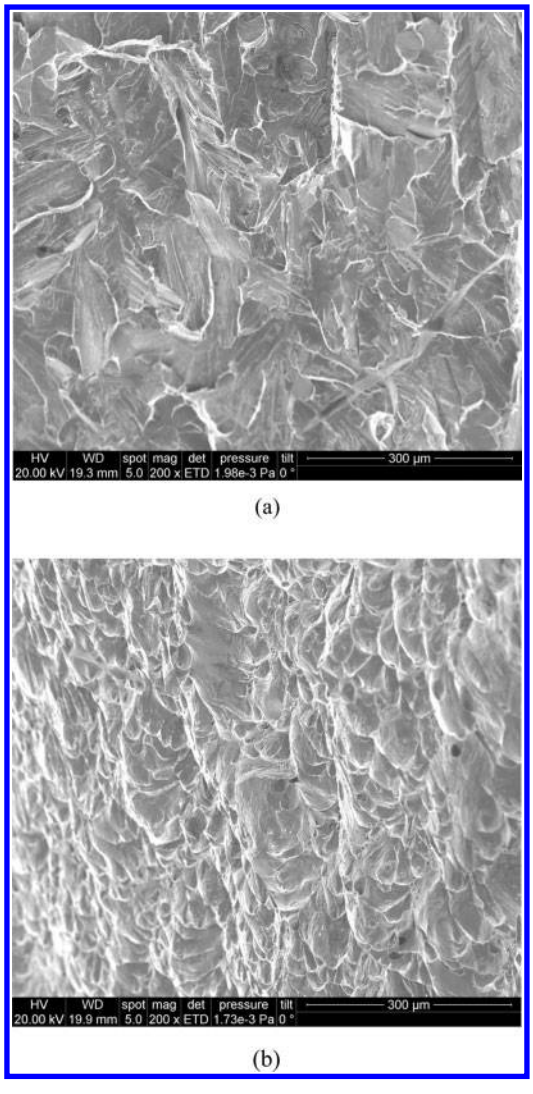

Figure 3. Scanning electron micrograph of specimen F4, ductile and brittle fractured: (a) −60°; (b) 20°.

recommended to be use in those environments where the service temperature is higher than the ductile to brittle transition temperature.

3.4.2 *Effects of alloy elements*

Fig 4 shows the relative effect of alloy elements on the impact energy of some FSS. Compared with F3, F4 has a lower C and N and adds some Ti and Nb as stabilization elements, which contributes to the improvement of impact toughness. The impact energy of F4 is distinct higher than that of F3 although the DBTT doesn't change.

3.4.3 *Effects of thickness*

Fig5 shows the effect of thickness on the impact energy of F4 steel. The 4mm specimen shows lower impact energy and a higher DBTT. This expressed that as the thickness of FSS increased, the steels become more

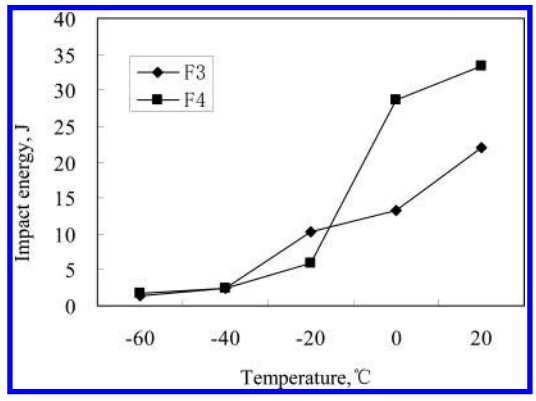

Figure 4. Charpy V-notch impact toughness of different alloy composition (2.5 mm specimens)

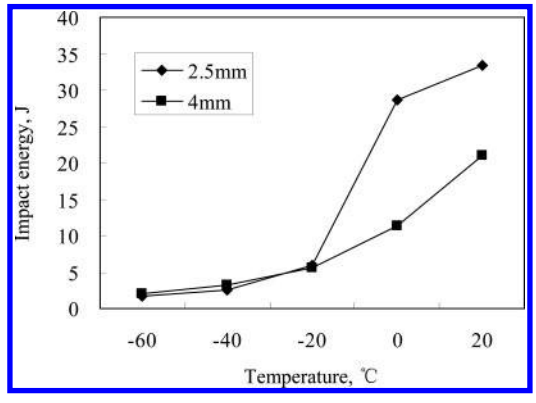

Figure 5. Charpy V-notch impact toughness of different thickness (F4).

brittle, and less energy is absorbed on impact during fracture.

3.4.4 *Effects of processing*

Fig6 shows the effect of processing on the impact energy of F5 high chromium stainless steel. F5 steels with same thickness of 2.5 mm are processed by different working methods. First materials are hot rolled to 2.5 mm and annealed directly, and the second materials are hot rolled to 5 mm, then annealed and cold rolled to 2.5 mm, finally annealed with same annealing technology. The cold rolled steel performs quite superior impact energy to that of hat rolled steel.

These results indicate that FSS has not only excellent corrosion resistance but also good mechanical and physical properties. Because FSS have body-centered cubic crystal structure, they are more easily to fracture in a brittle manner with little plastic deformation at low temperature.

Besides the crystal structure, the alloy composition, the thickness, and the processing are also factors influenced the impact toughness of FSS. Controlling a lower carbon, nitrogen and adding some stabilized elements titanium or niobium helps to improve the impact toughness. The thickness should be limited to

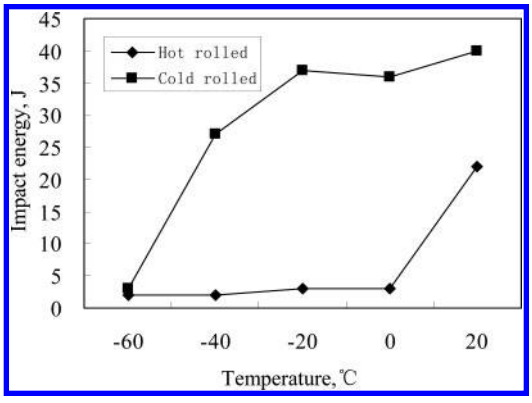

Figure 6. Charpy V-notch impact toughness of different processing (F5, 2.5 mm specimens)

less than 4 mm for high chromium ferritic stainless steel on structural applications. Adopting cold rolled steels to replace hot rolled steels is also a good choice for structural design.

4 CONCLUSIONS

Ferritic stainless steels show very similar physical properties and mechanical properties to those of carbon structural steel SS400, and can meet the requirement of architecture structural design.

With excellent corrosion resistance Ferritic stainless steels can be used in many environments, and some high chromium FSS show a superior corrosion resistance to that of austenitic stainless.

Although having the weakness of low temperature brittleness, FSS are also recommended to be use if the alloy composition, the thickness, and the processing methods are matched good with the environment.

Institut für Baustoffe, Massivbau und Brandschutz, Fachgebiet Massivbau, TU Braunschweig, Germany

ABSTRACT: In this paper, shear force design approaches referenced in literature are investigated on their potential to partially replace or to refine the shear design approaches provided by current codes. Using a comprehensive database providing experimental data, it is analysed how the different shear design approaches are able to adapt to experimental results. As a result, the advanced shear design approaches show calculated mean values almost equal to the experimental results, in combination with a very low variance. In addition, a probabilistic analysis verifies the required safety level demanded by the current standards. These results are confirmed by an example. As a consequence, it is noted that modern and advanced shear design approaches create the possibility to determine existing structural reserves.

1 INTRODUCTION

The German motorway network contains approximately 40,000 bridges with around 70% made of prestressed concrete and 20% of reinforced concrete. The majority of these bridges have been constructed in the decades after the Second World War and reached an average age between 40 to 60 years. Current investigations of existing concrete bridges reveal deficiencies in regard to material, construction, design and standard aspects.

Beneath the material degradation the main reasons for these deficiencies on the action side are the rapid growth of the traffic volumes on German motorways since the Second World War as well as the increase of the maximum permitted weight from 24 to in 1956 to 44 to today. In addition, a further rise of heavy good vehicles – numbers and maximum weights – is forecasted.

On the resistance side it has to be noted that the existing concrete bridges show in particular very low shear reinforcement ratios. Before 1966 e.g. no minimum shear reinforcement was required. In consequence, bridge structures with narrow cross-sections and high degrees of prestressing, but with hardly any shear reinforcement were designed and constructed. In the 1980s an increased load module, the SLW 60/30, was introduced into the load standards, as well as design specifications for imposed deformations (temperature constraint effects). As a result, bridges from the 1980's are much more able to handle today's traffic. Nevertheless, looking at the forecasted traffic growth in the near future their reserves are also nearly exhausted.

From today's point of view a way to deal with the existing bridges and their deficiencies must be found. First, it is possible to enhance their load carrying capacity by strengthening. However, a study of currently used strengthening methods shows that the strengthening in regard of shear is rather complex and usually requires interference with the existing structure as well as bridge closures (Empelmann et al. 2012). Alternatively, advanced and refined shear design approaches can be used to determine additional load carrying capacities allowing the further use of the existing bridges. In this paper the second idea is pursued.

2 BASICS

2.1 *Analysis of shear failure*

The design for a bending moment is based on the hypothesis of Bernoulli. However, this design approach is strictly valid only for non-cracked components that are also free of transverse forces. A general mechanical model for shear containing all different shear load-bearing mechanisms is desirable and currently being debated among experts.

In order to understand shear failure the consideration of experimental behaviour is mandatory. Figure 1 shows a test beam without shear reinforcement under transverse load. First, flexural cracks form at midspan. An increase of the load results in a parabolic shear crack. Simultaneously, there is a decrease in the rigidity followed up by a rearrangement of the load-bearing mechanisms. At first, the dowel effect of the longitudinal reinforcement and the load carrying capacity of the non-cracked concrete are activated. Altogether, a compression arch and tie-rod model is formed (Görtz 2004, Muttoni & Fernández Ruiz 2008).

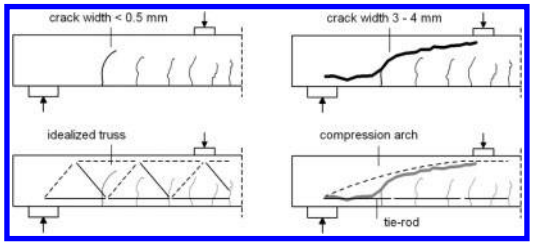

Figure 1. Cracking of a test beam under transverse load (up) and rearrangement into compression arch and tie-rod (down).

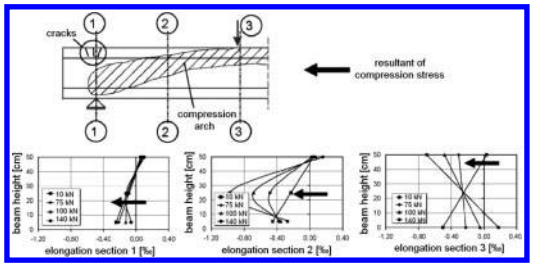

Figure 2. Definition of test beam sections and longitudinal strain in the defined sections (Hegger & Görtz 2006).

Shear reinforced members show a different behaviour. Not one single shear crack develops under transverse load but several parallel cracks. Figure 1 (left side) shows that the cracks are inclined at 35–45° to the members axis. The shear reinforcement is activated by the opening of these cracks. Depending on the amount of shear reinforcement the rearrangement into the arch and tie-rod model can be delayed due to the activation of a crack-bridging effect.

In addition, the analysis of tests shows a smooth transition between members without and with shear reinforcement. If the yield strength of the reinforcement is obtained, it comes to a sharp increase in the crack width and thus a failure of the crack friction, but not to a component failure. Figure 2 shows the longitudinal strain in three sections of a test beam. The locations of the resultants of the compressive stresses show the formation of the compression arch. In combination with the tie-rod in the longitudinal reinforcement, an increase beneath the yield strength of the reinforcement is provided. Failure of the beam occurs, analogous to the beam without shear reinforcement, through cracking into the compression zone.

2.2 *Current European Design Code – EC 2*

The verification of the shear resistance according to DIN EN 1992:2011 (EC 2) consists of three parts:

- resistance without shear reinforcement $V_{Rd,c}$,
- resistance of the shear reinforcement $V_{Rd,sy}$,
- resistance of the compression struts $V_{Rd,max}$.

Members without shear reinforcement are designed using the resistance $V_{Rd,c}$. The empirical formula is based on a comb model. The resistance is dominated by the crack friction and the dowel effect of the longitudinal reinforcement. The load bearing capacity of the concrete plays only a minor role. The relevant parameters of the empirical equation are the concrete strength f_{ck}, the longitudinal reinforcement ratio ρ_l and the geometric dimensions. The influence of a prestressing is included by a normal stress σ_{cp} in the members axis.

$$V_{Rd,c} = \left[0.10 \cdot k \cdot (100 \cdot \rho_l \cdot f_{ck})^{1/3} + 0.12 \cdot \sigma_{cp}\right] \cdot b_w \cdot d \quad (1)$$

To avoid a particularly strong deviation in the range of low shear slenderness, which is the distance between support and first single transverse load a in relation to the static height d, EC 2 provides an adaption factor β. Mechanically this adaption is justified by the formation of an additional load-bearing truss in the section near the support.

$$\beta = 2.0/(a/d) \text{ if } (a/d) < 2.0 \quad (2)$$

If the resistance $V_{Rd,c}$ is exceeded shear reinforcement is required, which then is determined on basis of a strut-and-tie-model analogy, i.e. with a completely different design model. The strut angle θ is modified based on the plasticity theory as a function of aggregate interlock. The influence of a prestressing is included by the normal stress σ_{cp}

$$1.0 \le \cot\theta \le \frac{1.2 - 1.4 \cdot \sigma_{cp}/f_{cd}}{1 - V_{Rd,cc}/V_{Ed}} \le 3.0 \quad (3)$$

For vertical shear reinforcement ($\alpha = 90°$) the load carrying capacity of the shear reinforcements $V_{Rd,sy}$ can be calculated using equation (4).

$$V_{Rd,sy} = a_{sw} \cdot z \cdot f_{ywd} \cdot \cot\theta \quad (4)$$

To prevent failure of the compression struts it has to be checked that the compressive strength of the concrete $V_{Rd,max}$ does not exceed. For bridge structures the strength of the compression strut is only decisive in a few cases, e. g. thin webs or large single loads. For vertical shear reinforcement ($\alpha = 90°$) the design formula is given in equation (5).

$$V_{Rd,max} = b_w \cdot z \cdot \nu_1 \cdot f_{cd}/(\cot\theta + \tan\theta) \quad (5)$$

It can be seen that the approach by EC 2 does not really reflect the experimental behaviour indicating a smooth transition between non-reinforced and shear reinforced members. Especially for existing bridges with low shear reinforcement ratios this inconsistent change of design models is problematic. In this case, advanced design approaches should be considered.

3 ADVANCED DESIGN APPROACHES

3.1 *Members without shear reinforcement*

Zink (Zink 2000) presents an advanced design approach for members without shear reinforcement.

Based on the experimental behaviour, his concept, in contrast to EC 2, contains three main components of the shear carrying capacity $V_{Rd,c}$.

$$V_{Rd,c} = V_0 \cdot k(a/d) \cdot k(l_{ch}/d) \tag{6}$$

Herein, the shear resistance is mainly determined by the resistance of the compression zone V_0. The most important parameter for the calculation of V_0 is the height of the non-cracked compression zone k_x, in which the influence of the longitudinal reinforcement ρ_l as well as the modulus of elasticity E_c is already implemented.

$$V_0 = \frac{2}{3} \cdot b_w \cdot k_x \cdot d \cdot f_{ct} \tag{7}$$

Especially in case of low static heights, two additional factors need to be considered. The tension-stiffening effect is, up to a limit value of the shear slenderness of $a/d < 4$, considered with the factor $k(a/d)$. The influence of crack friction, especially in the fracture process zone, is difficult to measure. The calculation of the factor $k(l_{ch}/d)$ and thus the stresses in the fracture process zone uses a tension block ($\alpha_v = 0.4$). Zink notes that the influence of the dowel effect is negligible and has already been considered by the factor $k(l_{ch}/d)$.

In addition, Zink directly determines a proportion of the shear carrying capacity V_λ in case of a prestressing force.

$$V_\lambda = P \cdot \lambda = P \cdot \frac{d}{a} \cdot \left(1 - \frac{k_x}{2}\right) \tag{8}$$

3.2 *Members with shear reinforcement*

The design approach of Görtz & Hegger (Görtz 2004, Hegger & Görtz 2006) is based on three separate load bearing components. In addition to the load bearing capacity of the shear reinforcement V_F, a concrete load bearing capacity V_C as well as a load bearing capacity in case of a prestressing V_P is added.

$$V_{Rd,c} = V_F + V_C + V_P \tag{9}$$

The capacity of the shear reinforcement V_F is based on an idealised strut-and-tiemodel. The strut angle θ corresponds to the inclination of the shear cracks β_r.

$$V_F = a_{sw} \cdot f_{ywd} \cdot z \cdot \cot \beta_r \tag{10}$$

$$\cot \beta_r = 1 + 0{,}15 \cdot \frac{\rho_w \cdot f_y}{f_{ctm}} - 0{,}18 \cdot \frac{\sigma_x}{f_{ctm}} \leq 2{,}15 \tag{11}$$

The basis for the determination of the concrete load capacity V_C is the approach by Zink (Eq. 6). Adaption of the results using the factor β is suggested by Görtz (Görtz 2004).

$$\beta = 3.0/(a/d) \text{ if } (a/d) < 3.0 \tag{12}$$

To guarantee a smooth and consistent transition between non-reinforced and shear reinforced members a factor κ is introduced to reduce the concrete load capacity in case of high shear reinforcement ratios.

$$V_C = \kappa \cdot V_{Rd,c} \tag{13}$$

$$0 \leq \kappa = 1 - \frac{\rho_w \cdot f_{ywd}}{3 \cdot f_{ct}} \leq 1 \tag{14}$$

Görtz & Hegger consider the influence of a prestressing force by the load capacity V_P Also here, a factor κ_p is established in order to reduce the additional load bearing capacity in case of high shear reinforcement ratios.

$$V_P = P \cdot \frac{d - k_x/2}{a} \tag{15}$$

$$0 \leq \kappa_p = 1 - \frac{\rho_w \cdot f_{ywd}}{f_{ct}} \leq 1 \tag{16}$$

4 COMPARISON OF SHEAR DESIGN APPROACHES AND TEST RESULTS

4.1 *Database*

The performance of the shear design approach of the EC 2, compared to the aforementioned advanced shear design approaches, is examined by evaluation of tests results. Therefore, a database of about 1000 results of shear tests by Görtz & Hegger (Kordina & Hegger 1987, Görtz 2004) was used, containing:

- 441 non-prestressed members without shear reinforcement,
- 195 prestressed members without shear reinforcement,
- 216 non-prestressed members with shear reinforcement,
- 151 prestressed members with shear reinforcement.

4.2 *Members without shear reinforcement*

The comparison of test results V_{exp} for reinforced members without shear reinforcement with the calculated values according to EC 2 $V_{EC\,2}$ (Eq. 1) and Zink V_{Zink} (Eq. 6) is shown in Figure 3 and Figure 4 in relation to the shear slenderness a/d. The calculations content the factor β (Eq. 2 and 12).

In summary, both approaches are able to map the experimental values relatively accurate for high shear slenderness. The shear design approach of Zink has advantages in case of low shear slenderness. As a consequence, the statistical evaluation of both design approaches shows for Zink a very low variance of 0.03 compared with the variance 0.31 for EC 2 (see Table 1).

Furthermore, the design approaches of EC 2 and Zink are compared for prestressed members without shear reinforcement. Table 2 shows the results of the statistical evaluation. The shear design approach of EC 2 shows more values on the safe side, i.e. above 1.0.

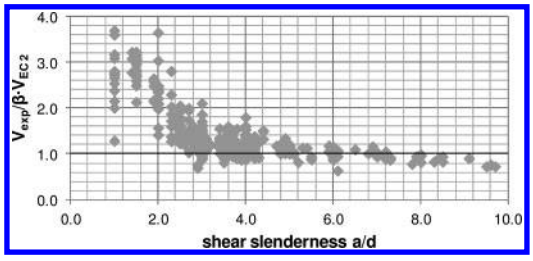

Figure 3. Comparison of test results without shear reinforcement with EC 2 design approach, adaption for low shear slenderness.

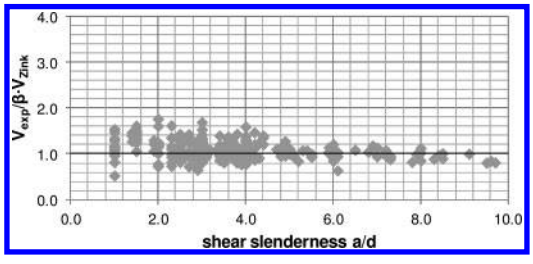

Figure 4. Comparison of test results without shear reinforcement with Zink design approach, adaption for low shear slenderness.

Table 1. Reinforced members without shear reinforcement.

	μ	Min	Max	σ	V
$\beta \cdot$ EC 2	1.39	0.63	3.70	0.56	0.31
$\beta \cdot$ Zink	1.08	0.53	1.77	0.17	0.03

Table 2. Prestressed members without shear reinforcement.

	μ	Min	Max	σ	V
EC 2	1.50	0.84	2.64	0.33	0.11
Zink	0.97	0.11	1.98	0.28	0.08

4.3 *Members with shear reinforcement*

Figure 5 shows the comparative values $V_{exp}/V_{EC\,2}$ plotted against the shear reinforcement ratio ρ_w, which is the cross-section of the shear reinforcement in relation to the concrete cross-section. In particular, in case of low shear reinforcement ratios differences between the experimental and theoretical values occur. This finding supports the statement that the shear capacity of reinforced components is not only generated by the shear reinforcement as indicated in the shear design approach of EC2.

The comparison of the same test results with the design approach by Görtz & Hegger in Figure 6, points out that using the additional load capacities V_C and V_P an excellent re-calculation of the test results is

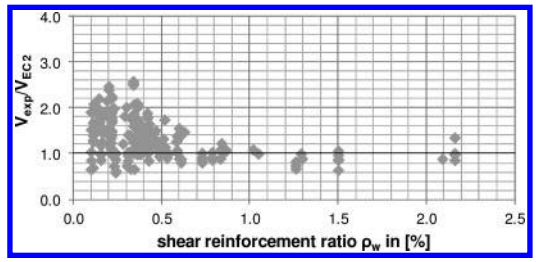

Figure 5. Comparison of test results with shear reinforcement with EC 2 design approach.

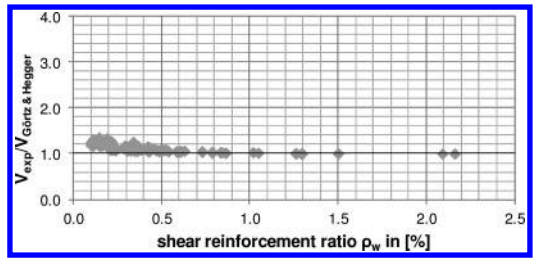

Figure 6. Comparison of test results with shear reinforcement with Görtz & Hegger design approach.

Table 3. Reinforced members with shear reinforcement.

	μ	Min	Max	σ	V
EC 2	1.35	0.59	2.58	0.42	0.17
Görtz & Hegger	1.12	1.00	1.36	0.08	0.01

Table 4. Prestressed members with shear reinforcement.

	μ	Min	Max	σ	V
EC 2	3.36	0.80	9.45	1.64	2.70
Görtz & Hegger	1.63	0.88	3.08	0.41	0.17

obtained. This statement is supported by the statistical evaluation shown in Table 3.

Table 4 sums up the results for prestressed test members with shear reinforcement. The shear design approach according to EC 2 provides a significantly high mean value and an excessive variance. This suggests that the influence of the prestressing has not been considered correctly. The approach by Görtz & Hegger shows better statistical values.

5 PROBABILISTIC ANALYSIS

5.1 *Basics*

The aim of the following probabilistic analysis is to show that the investigated shear design approaches achieve the currently required normative safety level.

Table 5. Basic variables for parameter study.

	mean	variance	distribution
1. load			
permanent load	g_k	10%	N
live load	q_k	25%	G
model uncertainty	1.0	5%	N
2. resistance			
dimensions	nom a	2%	N
concrete strength	$f_{ck}+8$	15%	LN
steel strength	f_y	5%	LN
steel area	a_{sl},a_{sw}	2%	N
3. prestressing			
prestressing force	P	5%	N

N: normal distr.; LN: log- normal distr.; G: Gumbel-distr.

Table 6. Results of probabilistic calculations.

Approach	μ_β	V
1. Members without shear reinforcement		
EC 2	3.79	0.004
Zink	3.93	0.115
2. Prestressed members without shear reinforcement		
EC 2	5.35	0.020
Zink	3.49	0.070
3. Members with shear reinforcement		
EC 2	3.28	0.000
Görtz & Hegger	3.49	0.004
4. Prestressed members with shear reinforcement		
EC 2	1.72	0.000
Görtz & Hegger	3.81	0.006

In the reliability considerations the safety index β is introduced as a key parameter. The DIN EN 1990:2010 requires a value of $\beta = 3.8$ in the ultimate limit state for a lifetime of 50 years. This corresponds to the probability of failure of $P_f = 10^{-4}$.

Each variable used in the investigated design approaches can be defined deterministically, by a fixed value, or probabilistically, with a statistical distribution. The challenge is to find generally accepted statistical distributions with their determining parameters. In literature a lot of different proposals can be found. In this paper the parameters provided by (Hansen 2004) and (JCSS 2006) are used (Table 5).

Especially the model uncertainty for shear is discussed controversial among experts (Song, J. et al. 2010; Sykora & Holicky 2011). In this paper, in order to capture the differences between the aforementioned shear design approaches, the model uncertainty is defined as the variance regained from the comparison with the test results of the database.

Finally, the equations of the introduced shear design approaches have to be transferred into limit state equations, which are examined by the program Comrel (RCP 2004).

Due to the large number of basic variables, which have an influence on the shear strength, and the large range of values, which have to be covered, it is useful to perform the probabilistic analysis as a parameter study. Different cross-sections (rectangles and t-members), different longitudinal and shear reinforcement ratios as well as different levels of concrete strength and prestressing were investigated.

5.2 *Results*

Table 6 sums up the results of the probabilistic calculations with the following conclusions:

For reinforced members without shear reinforcement both investigated shear design approaches achieve the required safety index of $\beta = 3.8$.

For prestressed members without shear reinforcement the shear design approach of EC 2 provides an average well above the required safety level. This confirms the finding that the shear design approach of EC 2 generates too many results below the experimental values ($\mu = 1.50$, Table 2). The approach by Zink has a slightly too low mean value of $\mu_\beta = 3.49$, which is also confirmed by the tendency to overestimate the influence of a prestressing.

Reinforced Members with shear reinforcement show little too low mean values for both investigated shear design approaches. Due to the low variance it can, however, be assumed that the design approaches work precisely.

Prestressed members with shear reinforcement present a low average safety index for the shear design approach of EC 2 ($\mu_\beta = 1.72 < 3.8$). This finding has to be put into perspective with the very high variance of the model uncertainty ($V = 2.70$, Table 4). The shear design approach according to Görtz & Hegger achieves a mean of $\mu_\beta = 3.81$ and only a very low variance of $V = 0.6\%$.

Figure 7 exemplarily shows the detailed results for prestressed members with shear reinforcement and the shear design approach by Görtz & Hegger.

Based on the results of Table 4 it is concluded, that the shear design approach by Görtz & Hegger provides more realistic values for prestressed and shear reinforced members. The values in Table 6 show that the required normative safety level is ensured. Because of these findings the exemplary calculation in the following chapter compares the shear strength of an existing bridge re-calculated using the shear design approaches of EC 2 and Görtz & Hegger.

6 EXAMPLARY BRIDGE STRUCTURE

As an exemplary calculation the superstructure of a four-lane prestressed concrete bridge is investigated. The bridge was built in 1968 with only a small amount of shear reinforcement. The structural system is a continuous beam of nine fields. The overall structure is 220 m long with span lengths of 20–26 m.

The re-calculation with EC 2 is performed in two steps. First, the shear resistance without shear reinforcement $V_{Rd,c}$ is determined. The second step

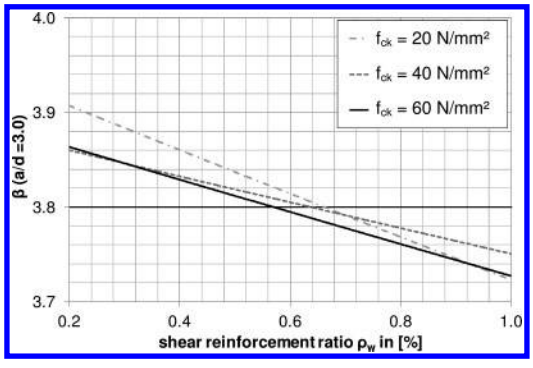

Figure 7. Safety index β for prestressed members with shear reinforcement – Shear design approach by Görtz & Hegger.

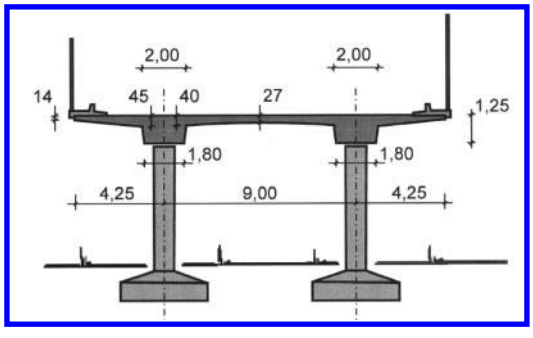

Figure 8. Bridge superstructure cross section.

contains the calculation of the shear reinforcements resistance $V_{Rd,sy}$.

$$V_{Rd,c} = 1{,}93\ MN \tag{17}$$

$$V_{Rd,sy} = 0{,}94\ MN \tag{18}$$

Based on the findings in chapters 4 and 5 of this paper the shear design approach by Görtz & Hegger was chosen for the alternative re-calculation. The three parts of the shear strength are determined to

$$V_F = 0{,}448\ MN \tag{19}$$

$$V_C = 0{,}849\ MN \tag{20}$$

$$V_p = 1{,}681\ MN \tag{21}$$

resulting into the total shear design strength of

$$V = 2{,}95\ MN \tag{22}$$

With the shear design approach according to EC 2 only shear design capacities of 0.94 and 1.93 MN can be determined. Whereas using the advanced shear design approach by Görtz & Hegger a load capacity of 2.95 MN (+53%) could be determined.

7 CONCLUSIONS

In this paper different shear design approaches are compared in regard to their load-bearing components as well as to their fitting with shear test results. It turns out that the shear design approach by EC2, which determines the shear capacity based on the capacity of the shear reinforcement only, is too conservative. Particularly, in case of low shear reinforcement ratios the load carrying capacity of the concrete is not to be underestimated, as well as in case of prestressing the load carrying capacity of the truss should be considered. This is demonstrated in the exemplary calculation of the shear strength of an existing bridge structure.

In consequence, it has to be noted that the assessment of the reliability and structural reserves of existing reinforced and prestressed concrete structures in terms of shear strength can be improved by using advanced shear design approaches.

Dismantleable joints of load-bearing reinforced concrete units of prefabricated concrete building system with controlled stiffness

J. Witzany, T. Čejka & R. Zigler
Czech Technical University in Prague, Faculty of Civil Engineering, Prague, Czech Republic

ABSTRACT: An essential characteristic of dismantleable prefabricated reinforced concrete building system with controlled properties of joints is contact connection of load-bearing reinforced concrete units, which allows, due to compensation elements inserted into the joints capable of absorbing energy, the limitation of the intensity of dynamic effects to a level that will not cause the failure of a building and its parts. Another significant property of these joints is also the elimination of outside noise (traffic, building activity, industrial activity) below the absolute threshold of hearing and thus the enhancement of the quality of the internal environment, allowing development in areas with increased noise levels, traffic, etc. The system may analogically be applied in areas with poorer foundation conditions, with underground traffic, in undermined zones, etc.

1 INTRODUCTION

Monolithic reinforced concrete and prefabricated systems with "rigid" joints do not allow the regulation of the system's response to dynamic effects, active damping of vibrations and the elimination of their propagation through load-bearing parts of the system.

Systems with controlled joint properties allowing damping of vibrations may also find their applications in buildings with strict conditions and requirements such as special production plants, health care, research and development facilities, etc.

2 CHARACTERISTICS OF PREFABRICATED SYSTEMS

Prefabricated systems – with "rigid" joints (welded reinforcement projecting from joint sections of prefabricated units or anchored by steel elements embedded in prefabricated units with successive grouting of joints with concrete) – are characterised by such a deformation and failure mechanism in which the limit state of the structure as a whole is preceded by the joint failure, or in which the structure passes from linearly elastic behaviour to non-linear elastic to plastic state usually by exceeding the proportionality limit in its joints. Rigid joints tend to be the weakest point of a load-bearing system with insufficient capacity to absorb strain energy due to extreme short-term loading (exceptional effects, explosions, vehicle impacts, etc.).

In the plastic deformation state of mainly joints of load-bearing prefabricated units with energy dissipation, energy absorption occurs; is this phase of the bond action (plastic action phase) it is necessary that the respective static bond is not completely eliminated from the load-bearing system. This presumes that the plastic deformation mechanism should prevail at critical points of the load-bearing system during energy dissipation. In the case of prefabricated reinforced concrete wall systems, the joints of prefabricated wall units loaded predominantly by shear forces are, as a rule, the principal agent in this respect, while in the case of reinforced concrete pier systems the principal agents are the joints of piers and cross beams loaded predominantly by bending and twisting moments.

The "stiffness" of a floor slab binding together individual vertical elements into a 3D load-bearing system is essential for securing the stability of a prefabricated reinforced concrete system, and the fulfilment of this requirement primarily depends on the rigidity and strength of joints between the prefabricated floor units (slabs). In terms of energy dissipation, the implementation of the plastic deformation mechanism in these critical zones must avoid a substantial reduction in the so-called springy force and any potential instabilities. In this phase of the joint (connecting bond) action, the fulfilment of the condition δtotal. > δplast. is essential, i.e. with a drop in loading a joint (connecting bond) partially "returns" to the initial position before the respective i-th load cycle. In case of standard reinforced concrete systems with rigid joints the effective reinforcement of the prefabricated system in the part with joints is of utmost importance for energy dissipation through plastic deformation of joints of prefabricated units. The type, quality and amount of reinforcement are vital for reaching the necessary joint ductility. The full exploitation of joint ductility – in the range of non-linearly elastic and plastic deformations – in standard prefabricated systems is connected with a gradual development of cracks and joint rupture preceding the failure – collapse of joints (Fig. 1).

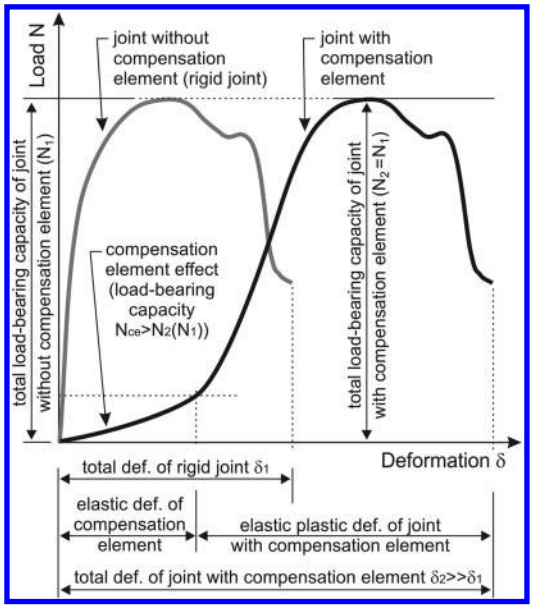

Figure 1. Load – deformation diagrams of rigid joints and joints with compensation (elastic) elements.

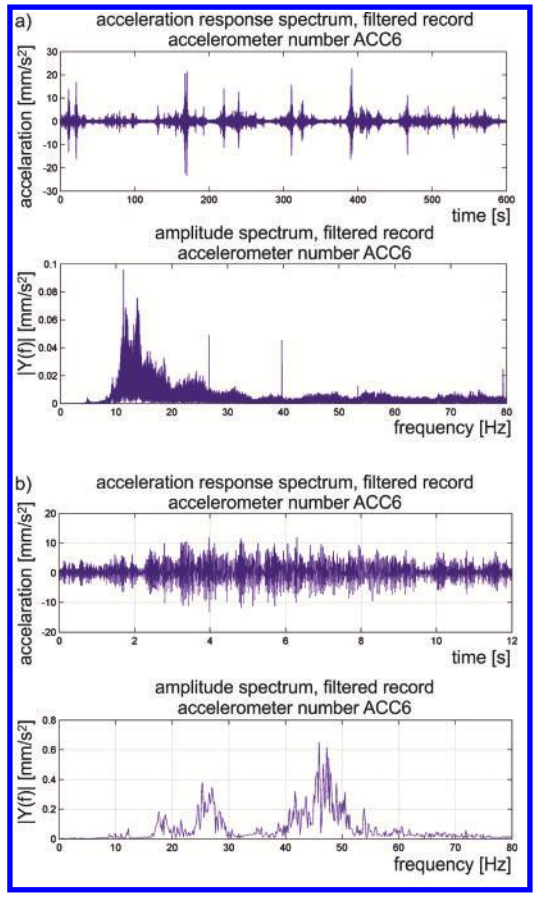

Figure 2. Records of vertical accelerations, a) passage of three cars, reinforced concrete skeleton, distance of 10 m from the source, b) metro, overground measurement, precast panel wall system, distance of 5 m from the source (Witzany & Makovička, in prep.).

The capacity of dissipative joints of prefabricated units which represent critical elements (zones) of a prefabricated load-bearing system in terms of its resistance to exceptional effects and impacts of seismic loads may be proved by means of a cyclic non-elastic test in which the so-called plastic deformation mechanism is verified under loading with repetitive shear force, or the bending or twisting moment (ČSN EN 1998 – Eurocode 8).

The results of numerous experimental studies (Witzany 1982) have proved that, depending on the method and amount of reinforcement, rigid (monolithised) joints of prefabricated reinforced concrete units are extremely sensitive to the effects of variable cyclic loads. Under cyclic (repetitive) loading amounting to 40 to 70% of the joint's limit load (i.e. around the limit of proportionality), the joint failure occurs by reaching the joint's deformation limit under the respective load – not under the limit load – which is called incremental failure. Time-variable, non-linear changes in the properties of joints – a drop in the joint rigidity due to the effect of loading with a dynamic component – in relation to the loading history and plastification, may be of crucial importance for the structural safety and service life of a load-bearing system in time (Makovička & Makovička 2011).

3 DYNAMIC LOADING OF PREFABRICATED STRUCTURES

Great emphasis is currently placed on the solution of issues of seismic loading and the response of structures to the effects of natural, technical and induced seismicity worldwide, these efforts are focused not only on buildings situated in zones of increased natural seismic activity, but also on buildings affected by growing volumes of overground as well as underground traffic and construction activity, and buildings exposed to the effects of technical and induced seismicity.

Technical seismicity due to traffic effects differs from natural seismicity particularly by higher frequencies which propagate into the surrounding environment and by frequent repetitions during which the fatigue limit of material may be exceeded. The frequencies of traffic shocks range between 10 to 200 cycles/sec being most frequently between 30 to 150 cycles/sec, while the amplitudes of shocks are small reaching no more than several tenths of a micrometre. Natural seismicity has approximately 100 times lower oscillation frequencies, while the amplitudes of shocks are, on the contrary, by several orders higher (Makovička & Makovička 2007). The acceleration of traffic shocks corresponds to values of catastrophic earthquakes of the 10th to 12th degrees on

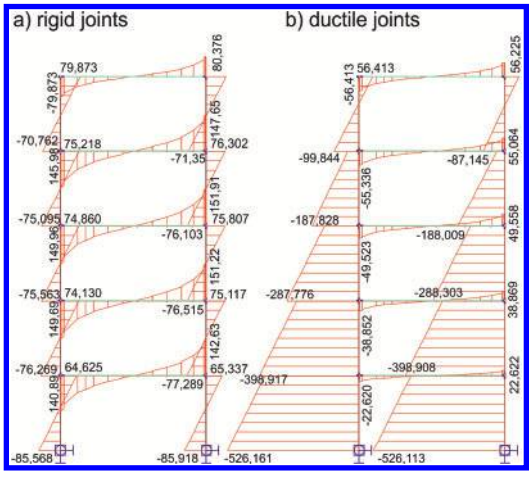

Figure 3. Comparison of the response of a reinforced concrete storey structure (frame) with rigid and ductile joints loaded by shearing force (100 kN) at the upper free end (bending moments [kNm]).

the Richter scale. Vibrations due to road traffic propagating through the environment into the surrounding buildings are usually in dominant frequencies ranging approximately from 5 to 25 Hz (Makovička & Makovička 2012). Vibrations due to overground railway traffic (trams, railway trains) have dominant vibrations roughly from 5 Hz to 50 Hz (Fig. 2)

High sensitivity of reinforced concrete prefabricated pillar or wall systems of particularly multi-storey buildings with "rigid" joints to the effects of induced deformations, strain and vibrations increases potential risks of the failure of the structural function of the load-bearing system exposed to long-term intensive vibrations and shocks, or seismic effects, and of a related loss of its static (dynamic) resistance (Witzany et al. 2009).

A simple example of a multi-storey frame on Figure 3 illustrates the effect of reduced rigidity on the static response of a structure.

4 DISMANTLEABLE JOINTS WITH CONTROLLED STIFFNESS

A characteristic feature of joints with controlled properties, i.e. an inserted compensation (elastic) element, is their ability of absorbing large amounts of strain energy exerted by the effect of exceptional loading, natural or technical seismicity, or long-term acting cyclic, variable loading effects (Fig. 4 and 5).

The required drop in rigidity and increased joint ductility of prefabricated units is achieved, in case of proposed solution of dismantleable joints of prefabricated reinforced concrete units, by inserting elastic components (compensation elements) in the area of the mutual contact of prefabricated units in the joint. The rigidity (ductility) of this elastic element must be

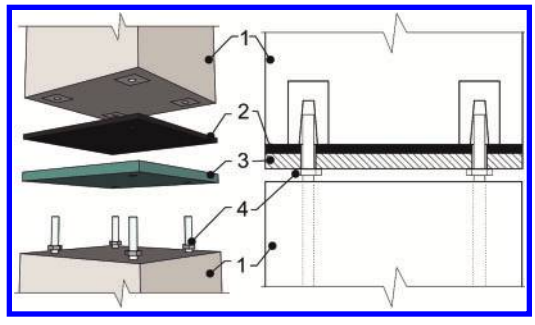

Figure 4. Design principle of dismantleable joint with a damping layer in the mutual contact zone (column – column joint). Legend: 1 – Column, 2 – Compensation (elastic) element, 3 – Spreading steel plate, 4 – Levelling nut.

determined with respect to structural demands resulting from loading and the effects transferred by jointed units and with respect to the requirement for the damping of vibrations and dynamic effects with specific characteristics.

The specific solution of dismantleable joints of prefabricated reinforced concrete system with controlled stiffness is currently the subject of patent procedure and therefore can not be publicly presented at the moment.

Numerical investigations on the shear capacity of reinforced concrete slabs under concentrated loads

K. Reissen & J. Hegger
Institute of Structural Concrete, RWTH Aachen University, Aachen, Germany

ABSTRACT: The shear capacity of reinforced concrete slabs without shear reinforcement has been investigated at the Institute of Structural Concrete at RWTH Aachen University. To determine the effective width for shear under concentrated loads, 13 full-scale tests on single-span slabs with varying slab widths and shear-span-to-depth ratios were performed. Since full-scale tests are time consuming and expensive, nonlinear three-dimensional finite-element models were developed and calibrated based on the available test data. By means of parameter studies, further influences on the shear capacity were analyzed (e.g. concrete strength, longitudinal and transverse reinforcement ratio, reinforcement in the compression zone, slab dimensions, shear-span-to-depth ratio) and a modified approach for the effective width for shear is proposed.

1 INTRODUCTION

Rising traffic loads have increased the requirements for the load-carrying capacity of bridges significantly (Naumann 2010). Furthermore, German design code rules have changed during the last decades reducing the calculated shear capacity of reinforced concrete members without shear reinforcement (DIN 1045: 1988, DIN 1045-1:2001, DIN EN 1992-2:2005). Therefore, the calculated shear capacity of many existing bridge deck slabs without shear reinforcement is not sufficient according to the present design rules. Since shear failure and excessive crack formation have not been observed in existing bridges to date, the bridges are evidently able to carry the heavier traffic loads. Therefore, the shear capacity of reinforced concrete slabs without shear reinforcement has been investigated within a research project, which was funded by the Federal Highway Research Institute of Germany (BASt) and carried out at the Institute of Structural Concrete at RWTH Aachen University.

To investigate the effective width for shear, 13 full-scale tests on single-span slabs were performed (Reissen & Hegger 2011, 2012, 2013). Full-scale tests are time consuming and expensive, so that further influences were analysed by means of numerical simulations with the Finite-Element-Software Abaqus (2009). Firstly, nonlinear three-dimensional models were developed and calibrated based on the test data of six tests. Secondly, parameter studies with varying concrete strengths, longitudinal and transverse reinforcement ratios, reinforcement in the compression zone, slab dimensions and shear-span-to-depth ratios were carried out.

Most of the present design rules for the shear capacity of members without shear reinforcement were developed based on empirical evaluations of shear databases consisting of beam tests. So far, only few tests on the shear capacity of slabs under concentrated loads have been conducted. Hence, the investigation of slabs under concentrated loads reveals new aspects of the shear-bearing behaviour. For instance, the shear-span-to-depth ratio and the transverse reinforcement ratio affect the effective width for shear and thus the shear capacity.

2 EXPERIMENTAL INVESTIGATIONS

With tests on beams and slabs under concentrated loads with a constant height of 0.28 m, different widths of 0.5 m, 1.5 m, 2.5 m and 3.5 m (S5 to S35) and different shear-span-to-depth ratios of 2.91 (A), 4.16 (B) and 5.41 (C) (Fig. 1, Table 1, Reissen & Hegger 2012, 2013), the effective width contributing to the shear resistance in the cracked state was investigated. Each specimen was tested in a three-point shear test by means of a 0.4 m square load according to wheel loads in the European codes (DIN EN 1991-2, 2010). The varying widths cover the transition from beams to slabs exposed to concentrated loads.

All specimens featured a uniform reinforcement ratio of 0.98%. The tensile reinforcement was realized by high strength steel bars Ø15/7.5 ($f_{yk} = 900$ MPa). The further reinforcement layers consisted of normal strength steel bars ($f_{yk} = 500$ MPa), Ø10/15 in the compression zone and Ø12/10 in lateral direction in the tension and compression zone (Fig. 2). Concrete cover was 2 cm resulting in an effective depth of $d = 0.24$ m.

Normal strength concrete was used in all tests. The mean cylinder strengths $f_{c,cyl}$, uniaxial tension strengths f_{ctm} and modulus of elasticity E_{cm} were

measured at the day of testing and are listed in Table 1. Additionally, the test programme (specimen width b, shear-span-to-depth ratio a/d) and the test results (reached ultimate loads F_u and corresponding shear forces $V_{F,u}$) are given.

3 NUMERICAL INVESTIGATIONS

3.1 *Material Model*

The numerical investigations were performed with the FE-Software Abaqus (2009). The implemented

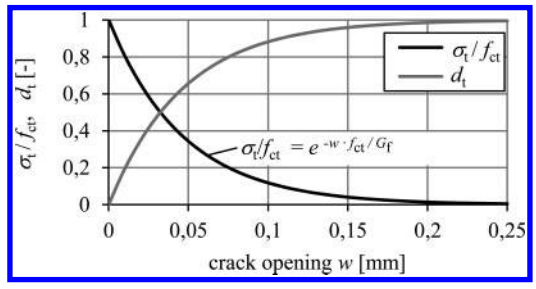

Figure 3. Stress-crack-opening relation in tension and corresponding tensile damage d_t.

plasticity theory based model Concrete Damaged Plasticity (CDP) was used consisting of the following three components to represent the inelastic behaviour of the concrete:

- The yield function determines whether the material responds elastically at a particular state of stress. It is defined by the uniaxial (f_c) and biaxial (f_b) concrete compressive strength, the uniaxial tensile strength f_{ct} and a parameter K_c describing the shape of the yield surface. The CDP model applies the yield function according to Lubliner et al. (1989) with modifications proposed by Lee & Fenves (1998) to account for different strength developments under tension and compression controlled by two damage variables for tensile and compressive damage, respectively.
- The hardening rule accounts for the modification of the yield function due to inelastic deformations.
- The flow rule defines the development of the inelastic deformations after leaving the elastic region. The Abaqus-Software applies a hyperbolic Drucker–Prager function, which depends on the dilation angle ψ of the concrete and the so-called eccentricity parameter ε.

Realistic modeling of the tensile behaviour is essential to investigate the typical shear-tension failure of plain concrete (Hegger et al. 2010). After the maximum tensile strength f_{ct} is reached under consideration of a linear stress–strain relation, the post-peak behaviour is defined by a stress-displacement relation according to Hillerborg's fictitious crack model (Hillerborg et al. 1976). The normalized transferred tensile stress σ_t/f_{ct} at a given crack width w is defined with the tensile strength f_{ct} and the fracture energy G_f by the exponential function according to Figure 3. The tensile damage variable d_t is defined as the inverted stress-crack-opening relation, where the tensile strength is normalized to the maximum tensile strength. Since d_t describes the stiffness degradation due to cracking, it will be used to illustrate the damage of the slabs in the following discussion.

3.2 *Model*

The concrete body of the slabs, the support and the load plate were modeled by 8-node volume elements

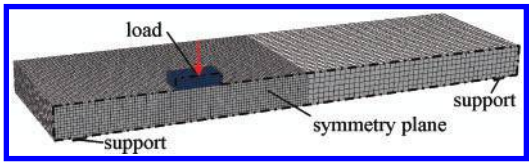

Figure 4. FE model of S25B.

(C3D8) considering the symmetry in transverse direction. Since the shear failure occurs between the load introduction and the nearest support, the corresponding region was meshed by a fine mesh with edge lengths of approximately 25 mm, while a coarser mesh with edge lengths of 50 mm was used in the remaining part to reduce the computing time (Fig. 4). The two parts were linked together by tying the nodal degrees of freedom in the plane between the dissimilar meshes with an applicable function in Abaqus named Tie Constraints. Comparative calculations using a continuously fine mesh revealed no significant influences on the load-bearing behaviour.

For modeling the reinforcement, two-node truss elements with elastic–plastic material behaviour were applied. The reinforcement bars were embedded in the surrounding concrete simulating a perfect bond by linking the nodal degrees of freedom.

All calculations were performed displacement controlled with an explicit solution technique for dynamic and highly nonlinear problems in Abaqus Version 6.9 (Abaqus 2009). The computing time corresponds to the critical increment size and for FE models with a great number of degrees of freedom, it is considerably shorter in comparison to the computing time under application of implicit solvers. In addition, convergence problems due to unstable crack propagation are avoided using the explicit solution technique. However, a linear load application would lead to too large acceleration changes between two increments. Therefore, the displacement was applied considering a so-called smooth-step function, where the first two derivatives at the beginning of the load application equal to zero.

The parameters of the material model were defined following reasonable values given in literature and by comparing the numerical results with test data concerning load–deflection behaviour, concrete and steel stresses, increase of slab thickness, ultimate load and failure mechanism:

- The tensile strength f_{ctm}, compressive strength $f_{c,cyl}$ and modulus of elasticity E_{cm} were derived from laboratory tests (Table 1). A reduction of f_{ct} to 70% of the mean test values considered a certain scatter of strength in the model.
- The tensile behaviour is strongly affected by the fracture energy G_f. While the shear capacities were considerably overestimated applying the fracture energy according to Model Code 2010 (CEB-FIP 2012), the numerical simulations are in good accordance with the experimental results, if the lower fracture energy according to Model Code 1990 (CEB-FIP 1993) is applied.
- To calibrate the parameters of the CDP model, parameter studies were performed based on reasonable values from literature. The variation of the parameters describing the yield function had no significant influence on the shear-bearing behaviour. Therefore, the relation of biaxial to uniaxial concrete compressive strength f_b/f_c was defined according to Grassl & Jirásek (2006) as $f_b/f_c = 1.16$ and the parameter K_c was chosen in accordance to Lubliner (1989) as $K_c = 0{,}66$. In contrast, the shear capacity was clearly affected by the variation of the parameters defining the flow rule. In the investigated range of variation of $\psi = 30°$ to $40°$, the shear capacity increased with increasing dilation angle due to increasing ductility. This increase was higher for the wider slabs, so that with a dilation angle of $\psi = 37°$ a good accordance between the numerical and experimental results could be achieved for nearly all tests. The eccentricity parameter ε was varied between 0.01 and 1.0 also resulting in an increase of shear capacity with increasing eccentricity parameter. The best results were achieved by the default value of $\varepsilon = 0.1$.

Furthermore, thorough parameter studies of further factors such as load introduction details, element type and mesh size indicated that reliable and reproducible results could be expected.

3.3 *Definition of shear-crack load*

As the numerical calculations with the explicit solution technique do not necessarily stop at failure, the numerical shear capacities had to be determined with the help of defined criterions. At first, the formation of a shear crack was detected with the help of the tensile damage variable d_t indicating a critical crack opening. The formation of the critical shear crack is accompanied by stiffness degradation in the load-deflection curve. A further possibility to verify the shear-crack load is given by the energy development. The ratio of external work to inner energy should equal 1.0 except for the beginning of the incremental load application. A further increase indicates energy conversion (e.g. in kinematic energy) due to instable crack propagation. With this, reliable shear-crack loads were defined as failure criterion, whereby possible redistributions of internal forces after shear cracking are not taken into account.

3.4 *Numerical results*

The experimental shear capacities and numerical shear-crack loads given in Table 2 reveal good accordance except for test S35C with a high shear-span-to-depth ratio of 5.41. In the following, comparisons between numerical results and test data are exemplarily shown for tests S35B and S35C explaining the greater deviation for S35C.

Table 2. Experimental ultimate loads and numerical shear-crack loads.

test	S5B	S15B	S25B	S35B	S35C	S35A
$F_{u,exp}$ [kN]	183	543	664	985	1166	1143
$F_{u,num}$ [kN]	167	510	702	983	901	1185
Δ [%]	−8.7	−6.1	+5.7	−0.2	−22.7	+3.7

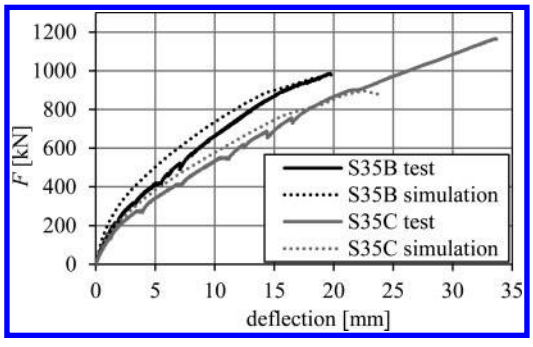

Figure 5. Experimental and numerical load-deflection curves for S35B and S35C.

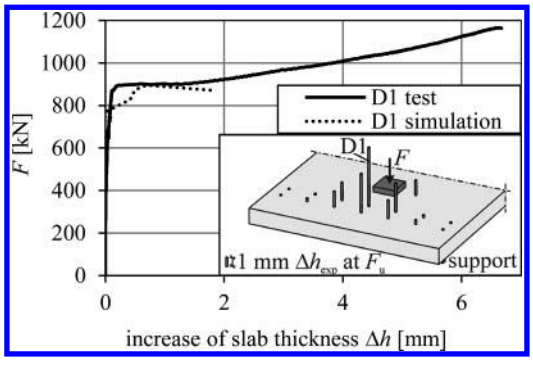

Figure 6. Experimental and numerical increase of slab thickness Δh for S35C at measuring point D1 and Δh_{exp} at ultimate load F_u.

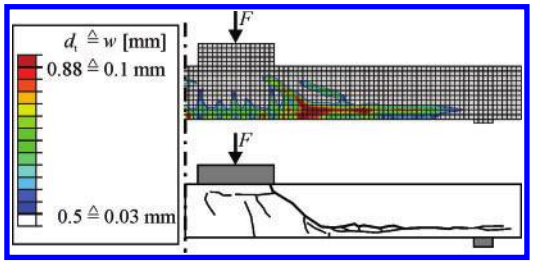

Figure 7. Crack pattern of S35C in symmetry axis in numerical simulation (above) and in test by saw cut (below).

In Figure 5, the experimental and numerical load-deflection curves for S35B and S35C are given. The initial stiffness in the linear-elastic range was slightly higher in the numerical simulations than in experimental tests leading to a parallel offset of the load-deflection curves. The experimental and numerical maximum shear capacities and deflections at maximum load are in good agreement for S35B (black curves). For S35C, the numerical maximum load coincides with stiffness degradation at approximately 900 kN in the test indicating the formation of a shear crack.

During the tests, the development of shear cracks within the slabs was detected by measuring the slab thickness. Figure 6 shows the experimental and numerical development of slab thickness increase Δh for S35C at measuring point D1 in front of the load plate depending on the applied load F and the experimental increases of slab thicknesses Δh_{exp} at ultimate load F_u for all measuring points. At approximately 800 and 900 kN, respectively, the measuring point D1 indicates the opening of a shear crack in the numerical simulation and in the test, respectively. In the test, the load could be further increased leading to a crack opening of several millimeters in front of the load plate at ultimate load, while the outer regions without shear crack were activated to carry the load. Obviously, this load redistribution could not be numerically reproduced. Except from that, the load-bearing behaviour, the shear-tension failure and the shear-crack formation are described appropriately. Figure 7 shows the crack pattern of S35C in the symmetry axis for the numerical simulation by the tension damage parameter d_t and in the test by a saw cut. Both the location and the inclination of the critical shear crack are in good agreement.

3.5 *Parameter study*

The described models served as basis to investigate further influences on the shear capacity of slabs without shear reinforcement under concentrated loads within a parameter study. The concrete strength, longitudinal and transverse reinforcement ratio, reinforcement in the compression zone, shear-span-to-depth ratio, slab height, width and span were varied based on the dimensions and reinforcement ratios of S35B considering concrete properties corresponding to strength class C30/37.

By comparison of the mean shear capacities $v_{Rm,c}$ according to DIN EN 1992-2 (2005) and the numerical shear capacities consisting of the shear forces due to the shear-crack load $V_{Fu,num}$ and the dead weight of the slab v_g, the effective widths b_{eff} were determined:

$$V_{\mathrm{Fu,num}} + v_{\mathrm{g}} \cdot b_{\mathrm{eff}} = v_{\mathrm{Rm,c}} \cdot b_{\mathrm{eff}} \Rightarrow b_{\mathrm{eff}} = \frac{V_{\mathrm{Fu,num}}}{v_{\mathrm{Rm,c}} - v_{\mathrm{g}}} \quad (1)$$

$$v_{\mathrm{Rm,c}} = [c_{\mathrm{m}} \cdot \kappa \cdot (100 \cdot \rho_l \cdot f_{\mathrm{ck}})^{1/3} - 0{,}12 \cdot \sigma_{\mathrm{cd}}] \cdot d \quad (2)$$

The shear capacity $v_{Rm,c}$ depends on the height of the uncracked compression zone (which is proportional to $(100 \cdot \rho_l)^{1/3}$, where ρ_l means the longitudinal reinforcement ratio), the tensile strength of the concrete (which is proportional to $f_{ck}^{1/3}$), the size-effect κ, the

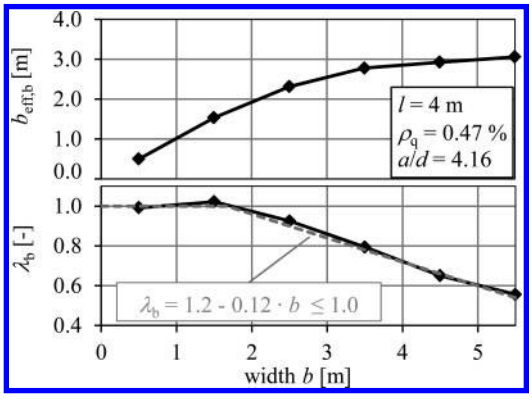

Figure 8. Effective width b_{eff} and factor λ_b depending on the slab width b.

influence of axial longitudinal stresses σ_{cd} and the effective depth d. The empirical factor $c_m = 0.18$ is based on an international shear database consisting of shear tests on beams.

By dividing these effective widths by the full slab width and a reference width, respectively, several factors λ_i could be derived representing the influences on the effective width of the various parameters. The effective width is than calculated as product of the slab width and the various factors as $b_{eff} = b \cdot \prod \lambda_i$.

It could be proved, that the influences of the concrete strength f_{ck}, the longitudinal reinforcement ratio ρ_l and the effective depth d, as they are described by equation (2), are also valid for simply supported slabs under concentrated loads. Furthermore, no influence of the reinforcement in the compression zone was detected. Hence, the results of the shear tests on beams without shear reinforcement (which normally do not have reinforcement in the compression zone) may be transferred to bridge deck slabs, which have reinforcement in the compression zone by default.

The effective width increases with increasing slab width (Fig. 8, above). However, this increase gets progressively smaller. For slab widths equal or smaller than 1.5 m, the full slab width is activated to carry the load indicating a beam bearing behaviour and resulting in a linear increase of the effective width with increasing slab width. In contrast, the effective widths of the models with a width of $b \geq 2.5$ m is smaller than the actual slab width indicating that not the full width of the specimens has been activated. These numerical results confirm the conclusions drawn from the experimental investigations (Reissen & Hegger 2011, 2012, 2013). Since the effective width b_{eff} is calculated by multiplying the factors λ with the full slab width b, the factor λ_b decreases with increasing slab width although the effective width increases (Fig. 8).

The shear-crack load and thus the effective widths and the factors λ_i also increase with increasing span (Fig. 9) and transverse reinforcement ratio in the tension zone (Fig. 10) due to higher potential for load distribution. Transverse reinforcement is essential to ensure lateral load distribution and to carry transverse

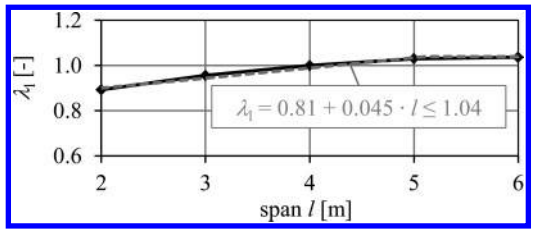

Figure 9. Factor λ_l depending on the span l.

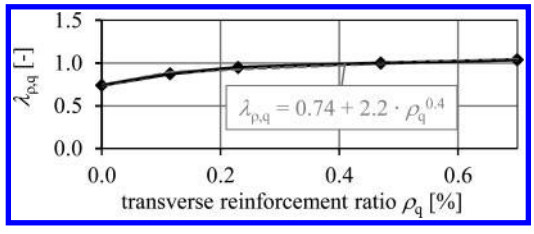

Figure 10. Factor $\lambda_{\rho,q}$ depending on the transverse reinforcement ratio ρ_q.

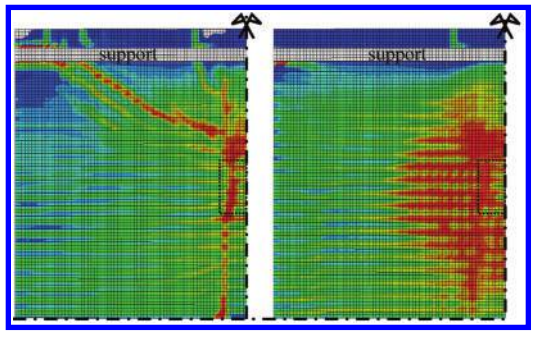

Figure 11. Crack pattern at soffit for different transverse reinforcement ratios of $\rho_q = 0\%$ (left) and $\rho_q = 0.47\%$ (right).

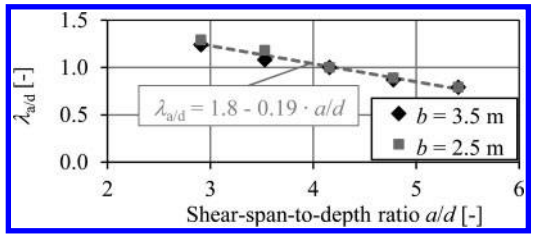

Figure 12. Factor $\lambda_{a/d}$ depending on the shear-span-to-depth ratio a/d.

stresses. While the formation of deep cracks in slabs without transverse reinforcement as shown in Figure 11 (left) leads to stiffness degradation and loss of shear capacity, sufficient transverse reinforcement ensures a fine crack distribution resulting in optimal load distribution as demonstrated in Figure 11 (right, $\rho_q = 0.47\%$).

The influence of the shear-span-to-depth ratio a/d has been investigated on numerical models with a width of 2.5 m and 3.5 m, respectively. Due to the

decreasing influence of the direct compression strut, the shear-crack load and thus the factor $\lambda_{a/d}$ decrease nearly linearly with increasing a/d (Fig. 12). Since shear-crack loads were used for the evaluation, possible redistributions of internal forces after shear cracking are not captured by this approach. Hence, with regard to structural design in the ultimate limit state, the following approach accounting for the identified influences of the slab width b, the transverse reinforcement ratio ρ_Q, the span l and the shear-span-to-depth ratio a/d provides slightly conservative results.

$$b_{\text{eff}} = b \cdot \lambda_{\text{b}} \cdot \lambda_{\text{pq}} \cdot \lambda_{\text{l}} \cdot \lambda_{\text{a/d}} \tag{3}$$

$$\lambda_{\text{b}} = 1.2 - 0.12 \cdot b \leq 1.0 \quad \text{for } b \leq 5.5 \text{ m} \tag{4}$$

$$\lambda_{\text{pq}} = 0.74 + 2.2 \cdot \rho_{\text{q}}^{0,4} \quad \text{for } 0 \leq \rho_{\text{q}} \leq 0.7\ \% \tag{5}$$

$$\lambda_{\text{l}} = 0.81 + 0.045 \cdot l \leq 1.04 \quad \text{for } l \geq 2 \text{ m} \tag{6}$$

$$\lambda_{\text{a/d}} = 1.8 - 0.19 \cdot {}^{a}\!/_{d} \quad \text{for } 2.91 \leq {}^{a}\!/_{d} \leq 5.41 \tag{7}$$

4 SUMMARY AND CONCLUSIONS

Nonlinear three-dimensional finite element models of single-span slabs under concentrated loads were developed and calibrated based on available test data using the software Abaqus. The applied plasticity theory based material model was able to reproduce the observed shear-tension failure of slabs without shear reinforcement appropriately. By means of parameter studies, further influences on the shear capacity were analyzed. Based on comparisons of the numerical shear-crack loads and the calculated shear capacities $v_{Rm,c}$ according to DIN EN 1992-2 (2005), a modified approach for the effective width for shear $b_{eff} = b \cdot \prod \lambda_i$ is proposed, where the factors λ_i account for the various influences. It could be proved, that the influences of the concrete strength f_{ck}, the longitudinal reinforcement ratio ρ_l and the effective depth d, as they are described by the shear capacity $v_{Rm,c}$, are also valid for simply supported slabs under concentrated loads. Furthermore, no influence of the reinforcement in the compression zone was detected. The shear-crack load and thus the effective width increases with increasing slab width, span and transverse reinforcement ratio due to higher potential for load distribution. Because of the decreasing influence of the direct compression strut, the shear-crack load decreases with increasing shear-span-to-depth ratio. Since the data bases to verify new approaches are limited, additional research is required to extend and further validate the proposed approach.

ACKNOWLEDGEMENTS

This report is based on parts of the research carried out at the request of the Federal Federal Ministry of Transport, Building and Urban Development, represented by the Federal Highway Research Institute, under research project No. 84.0110/2009. The authors are solely responsible for the content. We acknowledge the funding and the discussions with the project committee.

Furthermore, we would like to thank Mr. Paul Golus for his contribution to the presented numerical investigations.

ABSTRACT: The reported study presents results of two full-scale I-shaped shear-critical prestressed and reinforced concrete beams subjected to a four-point bending test with monotonically increasing load. Full-field three-dimensional displacements and deformations are measured with two stereo vision digital image correlation (DIC) systems over both zones where a shear force occurs. In this paper, a numerically generated optimized speckle pattern was applied on both beams in a controlled manner using a stencil printing technique. The experimentally observed displacement and deformation data are used to validate numerical finite element models. A satisfying correlation was found between experimental and numerical results concerning failure load and mode, displacements and deformations. From the numerical models, it was found that a significant portion of the applied shear force is carried in the area of both flanges of both specimens.

1 INTRODUCTION

After more than a century of research, shear remains an area within the scientific community where disagreement remains amongst researchers. From the early days of concrete construction, engineers have sought for models that accurately determine the shear resistance of a structural concrete member. In the earliest contributions, Ritter (Ritter, 1899) idealized the flow of forces within a structural concrete member by means of a truss model, as shown in Figure 1. The top and bottom cord resist the applied bending moment whereas the combination of concrete compressive struts and steel tension ties take up the applied shear force. Important progress has been made in the last fifty years when, under the influence of the theory of plasticity, the truss model was extended and systematized. This model is easy to understand and is still the basis for current international codes of practice.

From the last thirty years onwards, research has shifted from (semi-)empirical design approaches towards more rational theoretical (Vecchio and Collins, 1986, Ruiz and Muttoni, 2009, Sigrist, 2011) based on the mechanical behaviour of structural concrete members loaded in shear. Some of these models are mature enough to be incorporated into current international codes of practice. Despite the large research effort, shear remains an open problem and our understanding is clearly incomplete (fib, 2010).

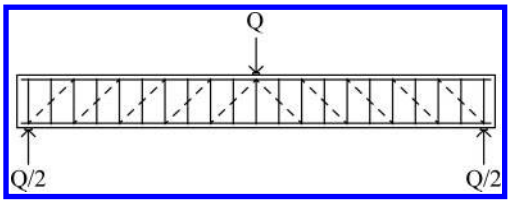

Figure 1. Truss model concept (compressive struts in dashed lines; vertical tension ties in full lines).

This paper aims to make a contribution to a better understanding of shear in prestressed and reinforced concrete structural elements by reporting the results of two preliminary tests of an extensive experimental program. In the first part of this paper, the specimen properties and experimental setup are summarized. Special attention is devoted to the use of the digital image correlation technique as a full-field measurement technique for measuring displacements and deformations. In the second part of this paper, the experimental data are used to validate numerical predictions obtained from nonlinear finite element models (FEM). A good correlation was found between the experimentally observed data and numerical predictions concerning failure load and mode, displacements and deformations. Finally, an investigation of the shear carrying mechanisms is performed based on the FEM output.

2 EXPERIMENTAL WORK

Two I-shaped girders, referred to as B105 and B111 and part of an extensive experimental program, were tested until failure occurred. Both beams are 7000 mm

long, 630 mm high and have a flange width of 240 mm. The web of both beams is 70 mm wide. Specimen B105 is prestressed at the prestressing yard of a local precast manufacturer by means of 8 straight 7-wire strands with a nominal diameter of 12.5 mm at the bottom and two 7-wire strands with a nominal diameter of 9.3 mm at the top. An initial strain of 3.76 10^{-3} (744 MPa) was given to each strand. At the day of testing, after immediate and time-dependent prestress losses, a mean strain value of 3.31 10^{-3} (655 MPa) was found using demountable mechanical strain gauge points glued onto the concrete surface. Specimen B111 is conventionally reinforced with two hot-rolled bars with a nominal diameter of 25 mm. Specimen B105 has an effective depth d equal to 511 mm whereas the effective depth of specimen B111 equals 580 mm. Single legged stirrups were provided with a nominal diameter of 6 mm and a center-to-center distance of 150 mm. The geometry of both specimens is shown in Figures 2(a)–(b).

2.1 *Materials*

Together with each specimen, concrete cubes (sides 150 mm), cylinders (height 300 mm; diameter 150 mm) and prisms (length 600 mm; sides 150 mm) were cast to determine the mean compressive strength f_{cm} based on cylinders, the mean compressive strength $f_{cm,cube}$ based on cubes, the mean secant modulus of elasticity E_{cm} and the flexural tensile strength $f_{ctm,fl}$. A summary of the results per specimen is shown in Table 1. Tensile tests were performed on the conventional longitudinal reinforcement as well as on the shear and splitting reinforcement to determine the modulus of elasticity E_s, the yield and ultimate stress f_{ym} respectively f_{tm} and the strain at failure ε_u. The same characteristics of the prestressing strands were taken from the manufacturer. The results are summarized in Table 2.

2.2 *Experimental setup*

Both specimens are subjected to a four point bending test, as shown in Figure 3. The tests are carried out in load-control using a hydraulic press (Instron, maximum capacity of 2.5 MN). The force from the hydraulic press is converted to two point loads by means of a steel construction profile (HEB 400) lying on two steel bearing cylinders. The total load is monotonically increased at 0.250 kN/s (i.e. applied shear force rate: 0.125 kN/s) until failure occurs. The distance between the support points is equal to 5000 mm. The distance outside the support is therefore equal to 1000 mm at each end. This setup firstly enables the authors to study shear outside the length needed for the prestressing force to gradually develop over the member's height and secondly to prevent failure due to debonding of the longitudinal reinforcement. Two linear variable differential transformers (LVDTs) were provided at 1200 mm from the support point at the bottom of the beam.

2.3 *Digital image correlation (DIC)*

As an optical full-field measurement method, digital image correlation (DIC) has proven to be an ideal tool for a wide range of applications, including the identification of the mechanical material behaviour through inverse modeling, structural health monitoring and the study of the deformation characteristics of a wide range of materials. The basic principle behind the technique is to calculate the displacements on the surface of an object by taking images of a black and white speckle pattern in the undeformed and deformed state. There are three main steps in the DIC method: (1) capture images, (2) correlation process and (3) post-processing phase.

In the reported study, both zones where a shear force occurs were investigated by using two stereo-vision DIC systems. Each zone under investigation measures approximately 1500 mm by 630 mm. Each system consists of two CCD 8-bit cameras (AVT Stingray F-201 B; 1628 pixels by 1236 pixels resolution) with lenses having a focal length equal to 12 mm mounted on a tripod. The cameras are located at a perpendicular distance of approximately 2700 mm from the web of the test specimen, refer to Figures 3(b)–(c). To ensure good lighting conditions and small exposure times, two 500 W quartz iodine lamps are provided per investigated zone as shown in Figures 3(b)–(c). The image acquisition rate of each camera is equal to 2 Hz with an

exposure time of 20 ms. All images of the four cameras are transferred to a desktop computer over FireWire and synchronized with the analog data (applied force and corresponding stroke) of the hydraulic press.

In this contribution, a subset-based method is applied to correlate two speckle patterns. This method considers a pixel and its neighborhood in the undeformed image f and searches the same subset in the deformed image g by adopting a maximization routine for a similarity function. The formalism is clearly explained in (Lava et al., 2009). In this study, maximization of the similarity function is obtained by adopting the zero-normalized sum of squared differences (ZNSSD) routine. The size of the subset can be chosen as desired prior to the evaluation. In this work, the dimensions of each subset were 27 by 27 pixels where each pixel has the physical dimension of approximately 1 mm.

Two specific problems are to be addressed when using DIC for the aforementioned experiments: (1) due to the large zone under investigation, a relatively large speckle size is required; and (2) reproducibility of the speckle pattern on a 3D surface needs to be accounted for to gain acceptance as a reliable measurement method. Here, a numerical technique is used to generate optimized speckle patterns for DIC, as proposed by (Bossuyt, 2012). This allows the authors to generate a pattern tailored to the experiments so that the speckle size and spatial distribution of the speckles are controlled. The generated pattern is applied onto each specimen by using a stencil printing technique. Figure 4(a) depicts a detail of the numerically generated speckle pattern whereas Figure 4(b) shows the same part of the speckle pattern applied onto specimen B105. Figure 4(c) shows the speckled zones in the experimental setup.

The correlation process and the post-processing of the data are done by using MatchID 3D (Lava et al., 2009). During the post-processing phase, strains are calculated by smoothing the displacement data over a certain zone to damp out the effect of noise and local uncertainties. This is a commonly adopted method (Lava et al., 2010). In the reported study, strains are averaged over 51 by 51 displacement data points. Taking into account the step size of 3 pixels and the physical dimension of one pixel, this means that strains are averaged over approximately 150 by 150 mm. This relatively large base length is justified when dealing with heterogeneous materials that exhibit a profound cracking behaviour such as concrete.

Relatively small displacements (order of magnitude 10^1 mm) and deformations (order of magnitude 10^3 μS) are expected during the experiments in view of the field of view and the spatial resolution involved. Therefore it is of the utmost importance to quantify the resolution of the measuring technique, i.e. the smallest signal above the noise level. Quantification of this noise level can be done by correlating two different images in undeformed state and assessing the predicted displacements and deformations. The noise on the displacement and strain data can be considered approximately normally distributed and can therefore be best expressed by the standard deviation of the considered displacement or strain component. For this setup, the standard deviation s of the in-plane horizontal U (x-axis) and vertical V (y-axis) displacement, refer to Figure 3(a), is found to be 21 μm and 11 μm respectively. The standard deviation of the out-of-plane displacement W (z-axis) is an order of magnitude higher, equal to 155 μm, but also less important for the reported experiments since primarily in-plane displacements and deformations will occur. The standard deviation of the horizontal ε_{xx}, vertical ε_{yy} and shear strain ε_{xy} is found to be equal to 112 μS, 241 μS and 140 μS respectively.

2.4 *Failure mode and load*

Both specimens failed due to diagonal tension due to rupture of the shear reinforcement in the web. The shear force applied at failure is 251.2 kN for specimen B105 and 141.5 kN for specimen B111. Using the shear strength provisions found in Eurocode 2 (CEN, 2004), based on the aforementioned truss analogy, the failure load can be estimated. According to Eurocode 2, the failure load of specimen B105 is equal to 131.8 kN (ratio of experimental to predicted failure load = 1.91) whereas the predicted failure load of specimen B111 is equal to 59.8 kN (ratio of experimental to predicted failure load = 2.37). These predicted failure loads were obtained by using average material strength properties and no partial safety factors.

Table 3. Comparison between experimentally observed and numerically predicted failure load and mode.

Specimen	Experiment		FEM		
	$V_{u,test}$ [kN]	mode [–]	$V_{u,pred}$ [kN]	mode [–]	$V_{u,test}/V_{u,pred}$ [–]
B105	251.2	DT*	247.9	DT	0.99
B111	141.5	DT	139.5	DT	1.01

*DT = diagonal tension due to rupture of the shear reinforcement.

3 FINITE ELEMENT MODEL (FEM) VALIDATION

A three-dimensional nonlinear finite element model was constructed using the commercially available software package ANSYS (v14). Due to double symmetry of the geometry and loading conditions, this model is reduced to a quarter of each specimen, minimizing the required computational time. The concrete matrix is modeled using eight-node hexahedron elements with linear shape functions. Each node has three translational degrees of freedom. Both longitudinal and shear reinforcement types are discretely modeled using truss elements. Experimentally determined material characteristics, as reported in Table 1 and Table 2, were used to define the material models for both concrete and reinforcement. To account for the influence of a multi-axial stress state on the overall structural behaviour of concrete, the three-dimensional failure surface, proposed by (Willam and Warnke, 1975), is adopted. Similar to the experiments, the simulations are carried out in load-control.

The ability of the FEM to reconstruct the experiment is validated by firstly assessing the numerically predicted failure load and mode. The results are summarized in Table 3. From Table 3, it can be seen that a good correlation between the experimental and numerical failure load and mode is obtained. Figures 5(a)–(b) show the experimentally observed cracking pattern at failure and the location of the shear reinforcement for specimens B105 and B111 respectively. The grey value of each shear reinforcement element represents the numerically predicted axial stress. These stress levels correspond well with the location and angle of the cracking pattern.

The load-displacement response curves, determined at 1200 mm from the support point at the bottom of each specimen, obtained with DIC and FEM, are shown in Figures 6(a)–(b). From Figures 6(a)–(b), it can be seen that the numerical model is capable of reconstructing the nonlinear behaviour due to cracking of the concrete matrix and subsequent yielding of the reinforcement.

Finally, a comparison is made between the experimentally and numerically computed horizontal strains. Therefore, the horizontal strain values as a function of

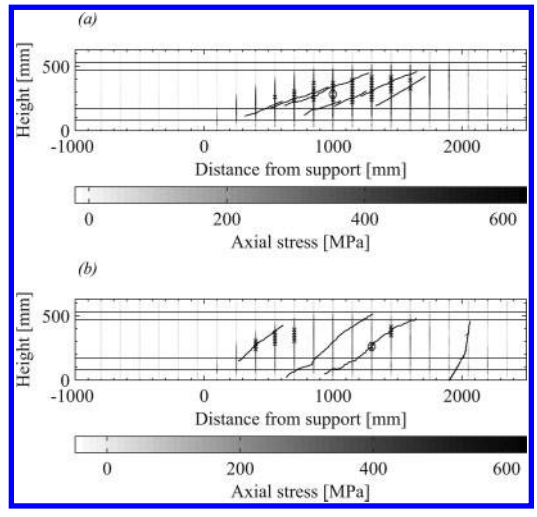

Figure 5. Experimentally observed cracking pattern at failure and numerically predicted axial stress in shear reinforcement elements. Location of rupture stress indicated with 'o'; location where the yield stress is exceeded indicated with 'x'; (a) specimen B105; (b) specimen B111.

the member's height are calculated at three different load levels (50%, 80% and 95% of the experimentally observed failure load). The results for specimen B105 are depicted in Figures 7(a)–(i). Similar results were found for specimen B111. A satisfying correlation is found at the top and the web of the specimen. At the bottom however, a discrepancy between the experimental and numerical values is observable.

4 FINITE ELEMENT MODEL ANALYSIS

In this section, the various shear force contributions of each specimen during the experiment are identified and quantified based on the output of the numerical model. The numerically predicted shear stresses τ_{xy} will, if integrated over the element surface on which they act, resist the applied shear force. The contributions of the top (refer to Figure 2(b), area ranging from $z = 630$ mm to $z = 470$ mm) and bottom flange (area ranging from $z = 0$ mm to $z = 170$ mm) and the web (area ranging from $z = 170$ mm to $z = 470$ mm) can thus be determined as a function of the applied load

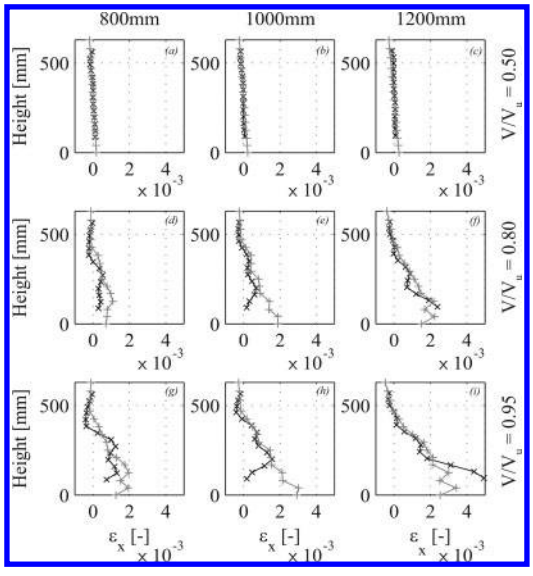

Figure 7. Experimentally (x) and numerically (+) computed horizontal strain values as a function of the height for specimen B105 at 800 mm (a, d, g), 1000 mm (b, e, h) and 1200 mm (c, f, g) from the support point for 50% (a, b, c), 80% (d, e, f) and 95% (g, h, i) of the experimentally observed failure load.

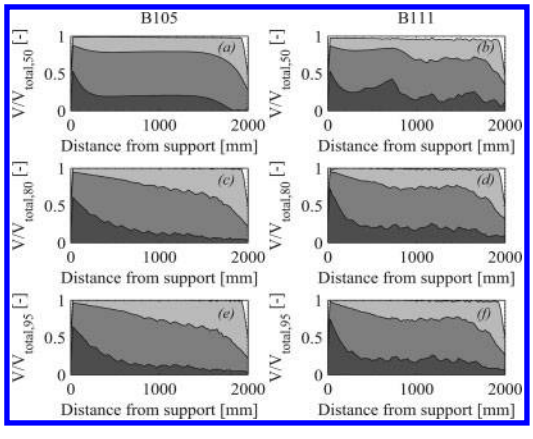

Figure 8. Numerically predicted shear force contributions of top (light grey) and bottom flanges (dark grey) and web (grey) of specimen B105 (a, c, e) and B111 (b, d, f) at various load levels.

and distance from the support point. Figures 8(a)–(e) depict the individual contribution of both flanges and the web of specimens B105 and B111 relative to the applied shear force at various load levels and as a function of the distance from the support point. From Figures 8(a)–(e) it can be noted that a relative large portion of the applied shear force is carried also in the area of both flanges of both specimens. However, this effect is usually neglected in codes of practice and could explain the poor failure load predictions as stated in Section 2.4.

5 CONCLUSIONS

This paper presents the results of two prestressed and reinforced concrete beams subjected to a four-point bending test until failure. During both tests, two stereo-vision digital image correlations (DIC) systems were used to continuously measure full-field displacements and deformations. The experimental data were used to validate nonlinear finite element models (FEM). A good correlation was found between the experimental observations and numerical predictions. Based on the numerical output, an investigation of the shear force contributions of top and bottom flanges and the web of each specimen was made. It was found that a significant portion of the applied shear force is carried in the area of both flanges of the specimens. This effect however, is usually neglected in current codes of practice.

The effect of steel fibres on the compressive ductility in lightweight aggregate concrete structures

J.A. Øverli
Department of Structural Engineering, Norwegian University of Science and Technology, Trondheim, Norway

T.M. Jensen
SINTEF Building and Infrastructure, Trondheim, Norway

ABSTRACT: The well-known brittleness in compression of lightweight aggregate concrete (LWAC) compared to normal density concrete can explain the limited use of the material for practical purposes. To study the ductility an experimental program was set up consisting of eight over-reinforced concrete beams subjected to four-point bending. The LWAC had a mass density around 1800 kg/m^3. Four different configurations of the beams were investigated, only LWAC in the compression zone, closed links with spacing 100 mm, 1% of steel fibre reinforcement, and a combination of closed links and steel fibres. The pre-peak behaviour was approximately the same for all configurations. As expected, the beams with only LWAC had a very brittle response after peak load. The others beams had different post-peak response, but all were able to carry load with quite large deflections after maximum loading. Especially the combination with both fibres and links experienced very ductile behaviour.

1 INTRODUCTION

The main objective for using lightweight aggregate concrete (LWAC) is normally to reduce cost by reducing the dead load of structures. E.g. with low weight the dimensions of the foundations in buildings can be reduced in areas with low bearing capacities, the inertia actions are reduced in seismic regions and it enables easier handling and transportation of precast elements. Even with the major advantage of reduced weight and the high strength-to-weight ratio of the material compared to conventional concrete, the use of LWAC is still limited as a mainstream construction material in the building industry.

The major disadvantage of LWAC is the brittleness in compression at the material level compared to normal density concrete. In overload situations adequate ductility is essential to ensure safety. Floating offshore structures and LNG-terminals are often post-tensioned. Thus the compressive ductility is of great importance. It is well known that confinement in the compression zone increases the ductility of concrete. Numerous researchers have investigated both experimental and theoretical, the effect of ordinary transverse steel reinforcement and the effect of adding fibres have on the confinement in normal density concrete (Attard & Setunge 1996, Cheong & Zeng 2002, Mander et al. 1988b, Sheikh & Toklucu 1993, Mander et al. 1988a). For lightweight aggregate concrete similar effects is reported (Balaguru & Foden 1996, Balendran et al. 2002, Campione & La Mendola 2004). The effect of confinement is also taken into account in design codes for concrete structures (Standard Norge 2008a). However, most studies on confinement focus on columns and cylinders subjected only to uniaxial loading (Kim & Harmon 2006, Kosaka et al. 1985, Mangat & Motamedi Azari 1985). Flexural behaviour of LWAC beams with focus on ductility has been reported, but only on under-reinforced beams (Sin et al. 2011, Ahmad & Barker 1991, Ahmad & Batts 1991, Altun & Aktaş 2013, Carmo et al. 2013). For heavily reinforced structures in bending or subjected to a combination of axial forces and bending moments, very little information is found in the literature.

The main objective in this study is to investigate the effect closed links and steel fibres have on the ductility in bending of LWAC structures. An experimental program was set up consisting of eight concrete beams, which were tested in flexure under a four-point loading system.

2 EXPERIMENTAL PROGRAM

The test program was designed to study the ductility enhancement in heavily over-reinforced lightweight aggregate concrete beams provided by steel fibres and steel confining transverse reinforcement. The main focus was on the ductility in the compression zone. Thus, the beams were heavily reinforced to ensure spalling in the compression zone of the cross section before yielding of the tensile reinforcement. The experimental setup and cross-sectional details is given

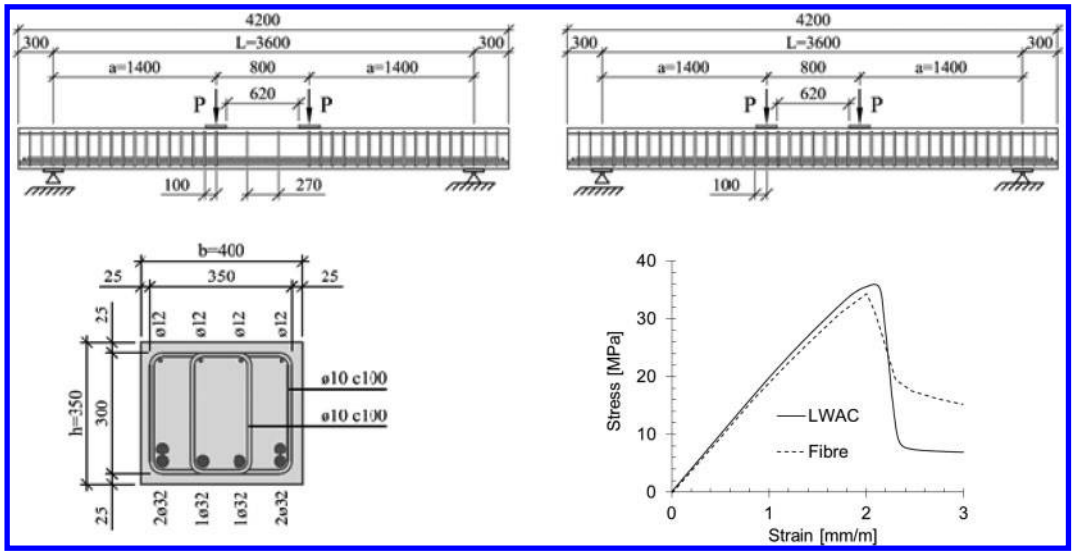

Figure 1. Experimental setup, and typical stress strain relationships for concrete.

in Figure 1. The experimental program consisted of eight simply supported concrete beams, which were tested in flexure under a four-point loading system. Hence, the central part of the beam is in pure bending which is the main focus in this work. The free span between the supports was 3.6 m. The two concentrated loads were applied symmetrical with a distance of 0.8 m. Four different configurations of the LWAC beams were investigated to study the response. Two beams only with LWAC (Beam 1) were considered beams for reference. Two beams each had closed links (Beam 2) and steel fibres (Beam 3) respectively. The final two beams had a combination of closed links and fibres (Beam 4).

To produce the concrete, lightweight expanded clay aggregate, commercially known as LECA, was used to achieve a density of the LWAC around 1800 kg/m^3. For beams with steel fibres, Dramix 65/60 was used, which is a cold drawn wire fibre of bright steel with hooked ends and a length of 60 mm. The fibre content was 78 kg/m^3, which corresponds to an amount of fibres of 1% by volume of concrete. After casting the beams were stored in the formwork under polyethylene sheets to prevent moisture loss. One day later demoulding took place and the beams were again covered with wet burlap sacks and polyethylene sheets to prevent rapid moisture loss.

To achieve an over-reinforced beam in bending, 6 deformed bars with diameter 32 mm were required. The transverse reinforcement consisted of 10 mm diameter deformed bars bent into closed stirrups with spacing 100 mm, see Figure 1. Typical obtained compressive stress strain relationship from cylinders for LWAC with and without fibres are also given in Figure 1.

The beams were suitable instrumented to measure displacements and strains. Deflections of the beams were measured at midspan and at the load transfer points by means of three vertical linear variable differential transformers (LVDT). To capture the concrete strains four LVDTs were placed horizontally at the top and bottom level at both sides of the cross-section, measuring over a distance of 0.5 m. Six strain gauges were used to measure steel strains both on the compressive and the tensile reinforcement.

The load was applied by a 1000 kN servo controlled hydraulic actuator, and distributed to the LWAC beam by a steel beam with two rolled supports. Up to a total load level of 200 kN the loading was applied in intervals of 33.3 kN. Above 200 kN the intervals was doubled to 66.6 kN. At each load level there was a 5 min break to study the formation of cracks. After reaching the peak load, the beams were continuously loaded until complete failure.

3 RESULTS

Table 1 gives the main results from the testing of the eight beams. In production of the beams one batch of concrete was required per beam. The achieved compressive strengths, f_c, for each batch are given in the table. The capacities, P_{calc}, are calculated according to the requirement for LWAC in Eurocode 2(Standard Norge 2008a) and compared to the load at spalling, P_{spall}. The spalling load is identified as the peak load when horizontal cracking in the compression zone occurs, followed by spalling of the concrete cover. For beams without steel fibres the spalling is much more severe than beams with fibres, where the cross-section remains much more intact. This is confirmed in Figure 2 where pictures of the failure zones in beams with and without fibres are shown. The failure zone without fibres is much more local and concentrated than with fibres where the zone is wider and deeper. A centre of rotation is formed close to the centre

of the longitudinal tensile reinforcement. The accordance between calculated and spalling loads from the tests is satisfactory. Due to a deformation controlled testing system, the peak loads in Table 1, P_{peak}, represents a second obtained maximum load level after the spalling load. The combination of shear links and fibres obtained an increase of approximately 10% from the spalling load.

The main goal in this study was to study the effect on the post-peak behaviour of adding fibres and using confinement reinforcement. Ductility is defined as the ability to sustain significant inelastic deformations after peak load without a significant loss in the capacity. It can be measured at various levels in a structure, on material, sectional, element or global level. A common way of quantifying ductility is to employ a ductility index, which on a local sectional level often is defined as the ratio of curvature at crushing of concrete to that of yielding of reinforcement, e.g. in seismic design where formation of yield hinges is important(Standard Norge 2008b). In this study the beams are over-reinforced meaning yielding of reinforcement cannot be used to find a ductility index. Thus, a displacement ductility index is found in order to assess the ductility. The index, μ_i, is calculated as the ratio between the centre point deflection when the spalling load level has been reduced to 90% after peak load, $\Delta_{0.9,spall}$, and the deflection at spalling load, Δ_{spall}. From Table 1 it can be seen that ductility ratio is at the same level for beams with either shear links or fibre. For the combination of links and fibre the ratio is approximately doubled. Thus, the effect of confinement reinforcement and fibres is an additive effect with respect to ductility in this test series.

Figure 3 shows the load displacement graph for the centre point of the beams. As expected the beams with only LWAC and no confinement experience very brittle behaviour after reaching load at spalling, i.e. no post-peak deformability. The responses for the beams demonstrate the strong influence of the different confinement configurations on the behaviour. In the beams with fibres transverse reinforcement or a combination of those two, the responses of the beams are very ductile. Especially the combination of fibres and shear links shows a continuous response and is able to maintain a high load level after peak load. The two beams with only steel fibres have the largest post-peak deviation. This is typical for fibre reinforced concrete. The variation is large due to the influence of casting process and workability of the concrete on the fibre distribution and orientation. Beams with shear reinforcement but no fibres, 2A and 2B, show a very clear unloading after the first peak load, associated with spalling of the concrete cover in the compression zone. However, the shear links are able to maintain a cross-section and after some redistribution of stresses a second peak point can be identified. This can clearly be seen in Figure 3b where loads and displacements for each beam are normalized with respect to the spalling load and the corresponding spalling displacement.

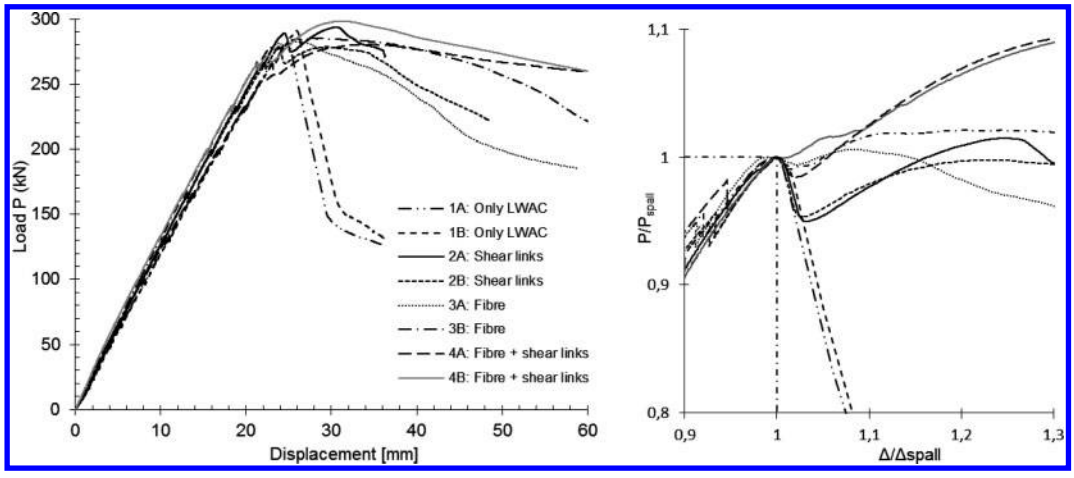

Figure 3. a) Load-displacement plots for all beams at mid span; b) Normalized load-displacement plot.

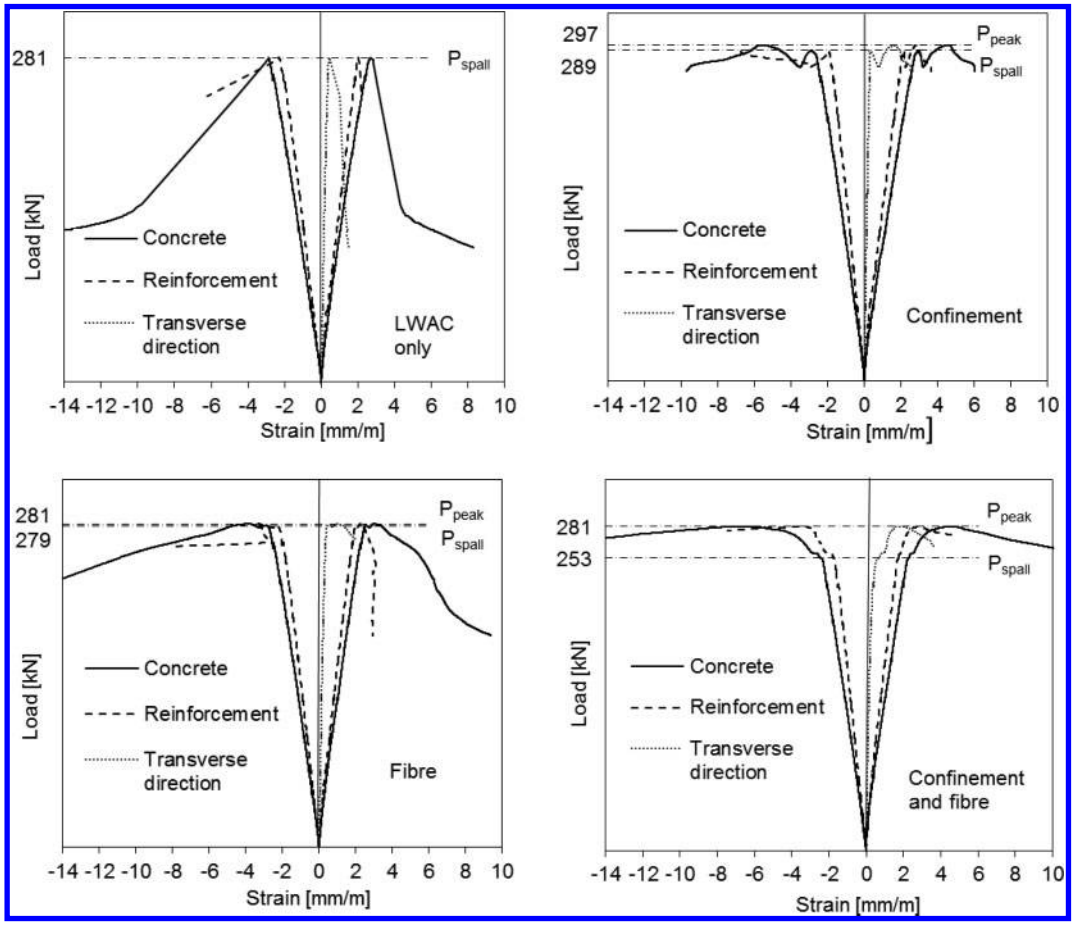

Figure 4. Strain development for the four different configurations of beams.

The strain development during loading is shown in Figure 4 with tensile strains having positive values. Only the results from the first beam (A-beam) in each of the four configurations in the test series are presented. Similar responses were obtained for the second beams. In the figure concrete strains are in longitudinal direction of the beam at top and bottom surface, reinforcement strains are in the top and bottom

reinforcement, and the transverse strains are in the horizontal part of the shear reinforcement close to the top surface. The strains in the reinforcement are measured locally with gauges while the concrete strains are average strains over a distance of 0.5 m. Hence, the reinforcement strains are more influenced by the location of cracks and the following spalling. The strain developments confirm the global load-displacement relationships. Up to the spalling load the strains are not significantly influenced by the introduction of fibre and shear reinforcement. The beam with only LWAC has a very brittle response after spalling, while the beam with both fibres and shear links experiences an increase in bending capacity with large strains in the compressive zone. This increase of ductility can be explained by the effect of confinement. The fibres and shear reinforcement are able to prevent some of the lateral expansion due to the large compressive strains. This introduces small lateral compressive stresses which increase the compressive ductility. From the strains in Figure 4 it is possible to estimate the lateral expansion coefficient, defined as the relationship between the lateral and the longitudinal strain. At load levels below the spalling load the coefficient is approximately 0.15, which is a typical value for lightweight concrete.

To be able to evaluate the design assumptions and the strains calculations, the deformed bar with diameters 10 and 32 mm were tested to characterize the properties(Standard Norge 2010). The bar with diameter 10 mm has an almost perfect linear-ideal plastic behavior with a yield strain of 0.0027. The bars with diameter 32 mm shows a more non-linear behavior where the yielding starts at a strain of 0.0027 before reaching perfect plastic at a strain of 0.0037. From Figure 4 it can be seen that before spalling of the compressive zone the reinforcement is elastic. Hence, the beams are over-reinforced as assumed in the design. However, with increasing load and ductility the tensile reinforcement yields before the ultimate failure.

4 CONCLUSIONS

This work is focusing on improvement of the compressive ductility of lightweight aggregate concrete. Testing of over-reinforced beams in this study shows a considerably increased flexural ductility of the beams when applying steel fibres and/or confinement reinforcement. Especially the combination of fibre and confinement reinforcement experienced a continuous response and the beams were able to maintain a high load level after reaching the maximum load. This study is only considered a first step to increase ductility in heavily reinforced and post-tensioned lightweight aggregate concrete structures by improving the confinement by employing fibres. The effect is confirmed in this work, but further studies are necessary to quantify the confinement effect of fibres and confinement reinforcement in LWAC.

Full-range behavior of FRP-to-concrete bonded joints with trilinear bond-slip law

H. Yuan & L. Wu
MOE Key Lab of Disaster and Control in Engineering, Institute of Applied Mechanics, Jinan University, Guangzhou, China

ABSTRACT: This paper presents a close-form analytical solution of both interfacial shear stress distribution and load-displacement response, which is capable of predicting the entire debonding propagation process including elastic, elastic-flow, elastic-flow-softening, elastic-flow-softening-debonding, flow-softening-debonding, and softening-debonding stages. Based on experimental result of high Young's modulus type of CFRP plate-to-concrete bonded joints, a nonlinear fracture mechanics method, in which the tri-linear local bond slip law is employed, is used to understand the stress transfer mechanism, interfacial crack propagation and ductility behavior in adhesive bonded joint. It is also shown how experimental load-displacement response of bonded joints can be used to identify interfacial properties, including the interfacial fracture energy and parameters of the local bond-slip relationship. The concept of serviceability limit state and ultimate limit state is considered.

1 INTRODUCTION

In the field of reinforced concrete structures, the use of FRP plates as an additional reinforcement appears to be a very promising technique, especially if such structures are in need of repair. However, a better understanding of the mechanical behavior of FRP plates is needed for the field use of this repair. The motivations of this research were that the assumption of perfect bond between the concrete and reinforcement may not apply to externally bonded FRP plates, and that strengthening and stiffening analysis of repaired members with high Young's modulus type of CFRP plate-to-concrete bonded joints requires a new model of local bond shear stress-slip relations. The objectives of this study are as follows

1. Develop a new model describing elastic, flow, softening and debonding along FRP-to-concrete interface.
2. Investigate the load-carrying capacity, effective bond length and full-range load-displacement relations.
3. Indicate how to identify the interfacial fracture energy and local shear stress-slip relation by comparing the analytical model with experimental results.
4. Study the effect of bond length and FRP plate stiffness per unit width on load-displacement response and effective bond length.

The most important and complicated failure mode for the FRP-strengthened structures is the delamination due to the unstable propagation of interfacial debonding initiating from the flexural and/or shear crack of concrete. In interfacial debonding failures, the stress state of the interface is similar to that in a shear test specimen in which a plate is bonded to a concrete prism and is subject to tension (Fig. 1). As a result, the adhesive bonded joint may be thought as a simple and typical model of FRP-strengthened structures to understand the stress transfer and debonding behavior. A large number of studies, both experimental and theoretical, have been carried out on bonded joints. Ueda et al. (1999) and Yoshizawa et al. (2000) conducted an experimental study on bonding behavior of FRP-concrete interface by using both types of single-lap and double-lap shear specimens. The test results show

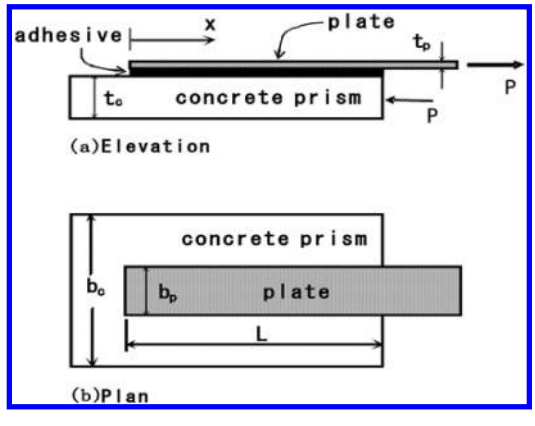

Figure 1. Pull-push shear test of a single-lap plate-to-concrete bonded joint.

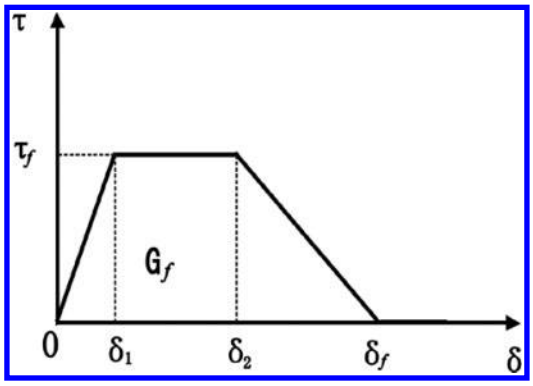

Figure 2. Local bond – slip model.

that the shear stress-slip relationship with a softening behavior can be used to represent well the initiation and propagation of interfacial cracks. However, the test results also shows that for the high Young's modulus type of CFRP plate-to-concrete bonded joints, the tri-linear model shown in Figure 2 which features a linear ascending branch followed by a linear platform, then followed by a linear descending branch provides a better approximation (Yoshizawa et al. 2000).

Of the available closed-form analytical studies, Täljsten (1996) analytically obtained the expression for the ultimate load using a linear ascending bond-slip model. Yuan et al (2000) and Wu et al. (2001, 2002) developed equations for the ultimate load, the interfacial shear stress distribution at the first attainment of the ultimate load and the effective bond length for various interfacial bond-slip models. Chen & Teng (2001) presented a review of most of the studies prior to theirs, assessed available models by comparison with experimental data gathered from the literature, and proposed accurate expressions for the ultimate load and the effective bond length. Yuan et al. (2004) presented an analytical solution for the prediction of the entire debonding propagation process in FRP-to-concrete bonded joints with bilinear local bond slip law. Recently, Yuan et al. (2012) studied the FRP-concrete interface with hardening and softening bond slip law. However, no analytical solution has been presented which is capable of predicting the entire debonding propagation process of tri-linear model with linear flow platform.

This paper presents a close-form analytical solution of both interfacial shear stress distribution and load-displacement response, which is capable of predicting the entire debonding propagation process including elastic, flow, softening, elastic-flow, flow-softening, elastic-flow-softening, elastic-flow-softening-debonding, flow-softening-debonding, and softening-debonding stages. Based on experimental result of high Young's modulus type of CFRP-to-concrete bonded joints, a nonlinear fracture mechanics method, in which the tri-linear local bond slip law with linear flow platform is employed, is used to understand the stress transfer mechanism, interfacial crack propagation and ductility behavior in adhesive bonded joint. It is also shown how experimental load-displacement response of bonded joints can be used to identify interfacial properties, including the interfacial fracture energy and parameters of the local bond-slip relationship. The concept of serviceability limit state and ultimate limit state is considered.

2 LOCAL BOND-SLIP MODEL AND EQUILIBRIUM EQUATIONS

2.1 *Fundamental assumptions*

Figure 1 shows a single-lap pull-push test of a plate-to-concrete bonded joint, in which the width and thickness of each of the three components (plate, adhesive layer and concrete prism) are constant along the length. The width and thickness of the plate are denoted by b_p and t_p respectively, those of the concrete prism by b_c and t_c respectively, and the bonded length of the plate (i.e. bond length) is denoted by L. The Young's modulus of the plate and concrete are E_p and E_c respectively.

In such a joint, the adhesive layer is mainly subjected to shear deformations, so mode II interfacial fracture is the expected failure mode. A simple mechanical model for this joint can be thus established by making the following assumptions for simplicity of problems:

- The two adherents (the plate and the concrete prism) are homogeneous and linear elastic;
- The adhesive is only subject to shear forces which are constant across the thickness of the adhesive layer;
- Bending effects are neglected;
- The normal stresses in both adherents are uniformly distributed over the cross-section; and
- The thickness and width of the adherents are constant throughout the bond line.

2.2 *Elastic-flow-softening-fracture model (Trilinear bond-slip model)*

The tri-linear model shown in Figure 2 provides a close approximation for high Young's modulus type of CFRP plate-to-concrete bonded joints. According to this model, the bond shear stress increases linearly with the interfacial slip until it reaches the peak stress τ_f at which the value of the slip is denoted by δ_1. Interfacial flow then starts with the shear stress being the constant peak stress τ_f (plateau) and interfacial slip increasing from δ_1 to δ_2. After interfacial slip attains δ_2, interfacial softening begins with the shear stress reducing linearly with the interfacial slip. The shear stress reduces to zero when the slip exceeds δ_f, signifying the shear fracture (or debonding) of a local bond element. The absence of any residual shear strength after debonding implies that friction and aggregate interlock over the debonded length of the joint is ignored. This

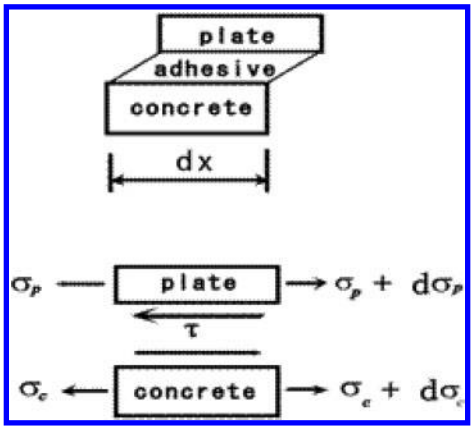

Figure 3. Deformation and equilibrium in a bonded joint.

bond-slip model shown in Figure 2 is mathematically described by the following

$$f(\delta)=\begin{cases}\dfrac{\tau_f}{\delta_1}\delta & when\ \ 0\le\delta\le\delta_1\\ \tau_f & when\ \ \delta_1<\delta\le\delta_2\\ \dfrac{\tau_f}{\delta_f-\delta_2}(\delta_f-\delta) & when\ \ \delta_2<\delta\le\delta_f\\ 0 & when\ \ \delta>\delta_f\end{cases} \quad (1)$$

2.3 *Equilibrium equations*

Considering the element shown in Figure 3, the equations of equilibrium for adherents can be written as

$$\frac{\mathrm{d}\sigma_p}{\mathrm{d}x}-\frac{\tau}{t_p}=0 \quad (2)$$

$$\sigma_p t_p b_p+\sigma_c t_c b_c=0 \quad (3)$$

where τ is the shear stress in the adhesive layer, σ_p is the axial stress in the plate and σ_c is the axial stress in the concrete prism. The constitutive equations for the adhesive layer and the two adherents are expressed as

$$\tau=f(\delta) \quad (4)$$

$$\sigma_p=E_p\frac{\mathrm{d}u_p}{\mathrm{d}x} \quad (5)$$

$$\sigma_c=E_c\frac{\mathrm{d}u_c}{\mathrm{d}x} \quad (6)$$

The interfacial slip δ is defined as the relative displacement between the two adherends, that is

$$\delta=u_p-u_c \quad (7)$$

After substituting Equations (3)–(7) into Equation (2) and introducing the parameters of local bond

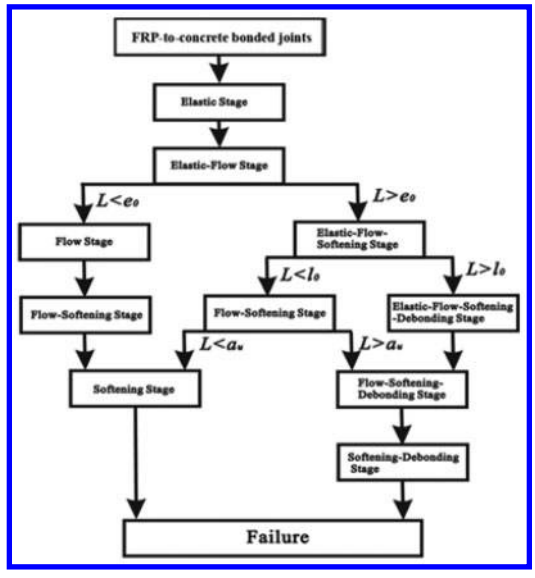

Figure 4. The flow chart with different bond lengths.

strength τ_f and interfacial fracture energy G_f yield the following

$$\frac{\mathrm{d}^2\delta}{\mathrm{d}x^2}-\frac{2G_f}{\tau_f^{\,2}}\lambda^2 f(\delta)=0 \quad (8)$$

and

$$\sigma_p=\frac{\tau_f^{\,2}}{2G_f t_p\lambda^2}\frac{\mathrm{d}\delta}{\mathrm{d}x} \quad (9)$$

where

$$\lambda^2=\frac{\tau_f^{\,2}}{2G_f}\left(\frac{1}{E_p t_p}+\frac{b_p}{b_c E_c t_c}\right) \quad (10)$$

Equation (8) is the governing differential equation of the bonded joint shown in Figure 1 and can be solved if the local bond-slip model relating the local interfacial shear stress to the local shear slip as represented by $f(\delta)$ in Equation (1) is introduced. The interfacial fracture energy, which is simply the area under the local bond-slip curve, is introduced because once it is known it can be used regardless of the exact shape of the local bond-slip curve where a particular quantity (e.g. the ultimate load) depends on the interfacial fracture energy but not on the shape of the bond-slip curve.

With the bond-slip model defined above, the governing equation (Eq. (8)) can be solved to find the shear stress distribution along the interface and the load-displacement response of the bonded joint. However, FRP-concrete interface with different bond length will lead to the difference of its failure process. Figure 4 gives the flow chart of failure process for different bond lengths. A detailed discussion will be given later.

3 THEORETICAL DERIVATIONS

The following values of critical length will be used to identify the different failure process

$$a_u = \frac{\pi}{2\lambda_2} \tag{11}$$

$$e_0 = \frac{1}{\lambda_1}\sqrt{\frac{2(\delta_2 - \delta_1)}{\delta_1}} \tag{12}$$

$$\tan(\lambda_2 a_0) = \frac{\lambda_1}{\lambda_2}\sqrt{\frac{\delta_1}{2(\delta_2 - \delta_1)}} \tag{13}$$

$$l_0 = e_0 + a_0 \tag{14}$$

where

$$\lambda_1^{\,2} = \frac{\tau_f}{\delta_1}\left(\frac{1}{E_p t_p} + \frac{b_p}{b_c E_c t_c}\right)$$

$$\lambda_2^{\,2} = \frac{\tau_f}{\delta_f - \delta_2}\left(\frac{1}{E_p t_p} + \frac{b_p}{b_c E_c t_c}\right)$$

Detail deduction of above equations will not be given here for length restriction of 6 pages.

3.1 *FRP-concrete interfacial bond length $L > l_0$*

The following stages of the debonding process will appear step by step only for a bond length which is longer than l_0. Equation (8) for each stage can be solved with appropriate boundary and continuous conditions. The debonding process includes elastic, elastic-flow, elastic-flow-softening, elastic-flow-softening-debonding, flow-softening-debonding, and softening-debonding stages.

3.2 *FRP-concrete interfacial bond length $L < l_0$*

The failure process of FRP-to-concrete bonded joints is discussed in the previous section for a bond length which is longer than l_0. However, FRP-concrete interface with shorter bond length will experience different failure process, which should be divided into three cases for clarity: (1) $L < e_0$; (2) $e_0 < L < a_u$, (3) $a_u < L < l_0$.

When the slip at the unloaded end reaches δ_1, the slip at loaded end doesn't reach δ_2 yet if the bond length is shorter than e_0. Its failure process will only experience elastic stage, elastic-flow stage, flow stage, flow-softening stage, softening stage.

If the bond length is larger than e_0 and shorter than a_u, its failure process will experience elastic stage, elastic-flow stage, elastic-flow-softening stage, flow-softening stage, softening stage.

If the bond length is larger than a_u and shorter than l_0, its failure process will experience elastic stage, elastic-flow stage, elastic-flow-softening stage, flow-softening stage, flow-softening-debonding stage, softening-debonding stage.

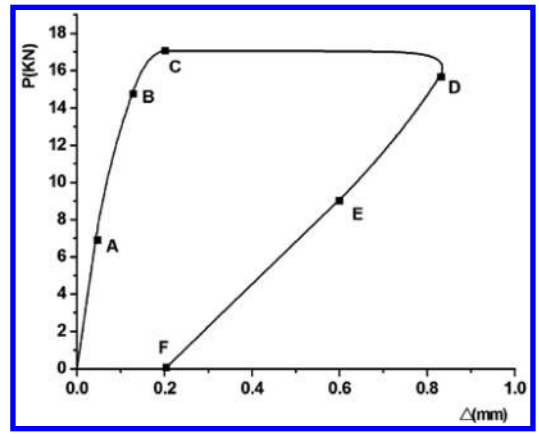

Figure 5. Theoretical load-displacement curve ($L > l_0$ and L = 150 mm).

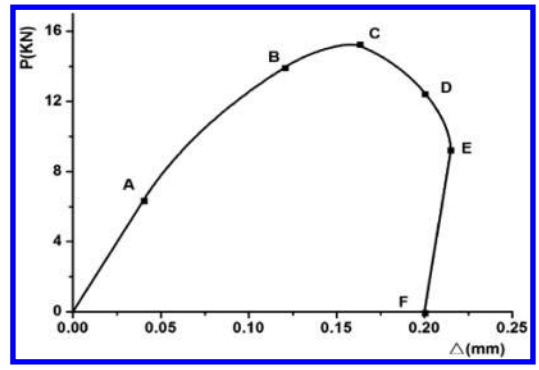

Figure 6. Theoretical load-displacement curve ($a_u < L < l_0$ and L = 40 mm).

4 NUMERICAL SIMULATIONS

To gain a clear understanding of the load-displacement response, interfacial shear stress distribution and crack propagation along the FRP-concrete interface, numerical simulations are conducted to simulate the loading condition depicted in Figure 1. The material and geometric properties are as follows: $t_p = 0.167$ mm (nominal thickness), $b_p = 40$ mm, $t_c = 60$ mm, $b_c = 300$ mm, $E_p = 390,000$ MPa and $E_c = 32,000$ MPa. The interfacial parameters were chosen as: $\delta_f = 0.2$ mm, $\delta_1 = 0.04$ mm, $\delta_2 = 0.12$ mm, $\tau_f = 10$ MPa, and $G_f = 1.4$ N/mm. Using above parameters yields that $e_0 = 32.2085$ mm, $a_u = 35.7747$ mm, $l_0 = 46.2260$ mm.

Figures 5–8 shows the theoretical load-displacement curves for different bond length($L > l_0$, $a_u < L < l_0$, $e_0 < L < a_u$, $L < e_0$). It shows that different bond length will result in different propagation process of

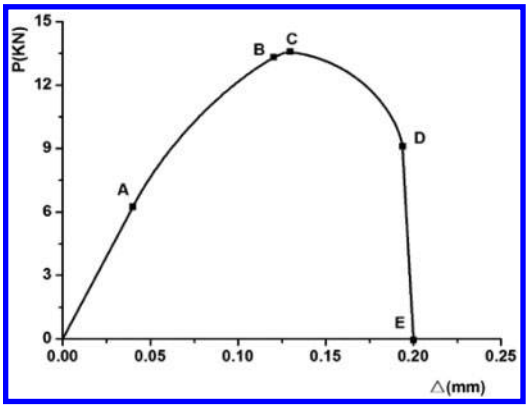

Figure 7. Theoretical load-displacement curve ($e_0 < L < a_u$ and L = 34 mm).

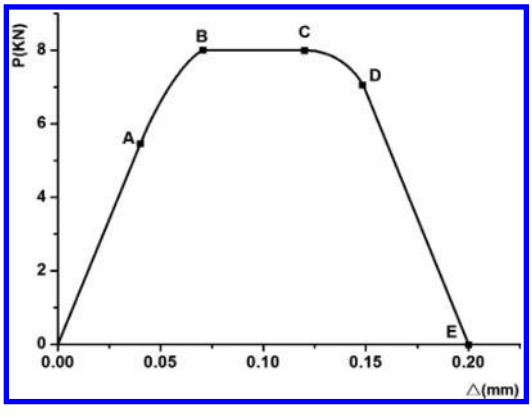

Figure 8. Theoretical load-displacement curve ($L < e_0$ and L = 20 mm).

debonding, and different bond length will also result in different load-displacement response. Generally, the bond length is larger than l_0. Therefore, the case of bond length $L > l_0$ will be discussed in the following. Other cases of bond length can be discussed similarly.

Figure 9 shows the shear stress distribution and debonding propagation along interface when the bond length is larger than l_0. All stages of the debonding process are given step by step. Figure 5 shows the full-range theoretical load-displacement curve when the bond length is larger than l_0. The elastic stage is represented by segment OA in Figure 5, elastic-flow stage represented by AB, elastic-flow-softening stage represented by BC, elastic-flow-softening-debonding stage represented by CD, flow-softening-debonding stage represented by DE, and softening-debonding stage represented by EF. Of particular importance are point A at the serviceability limit load, Point B at the initiation of softening and point C at the initiation of debonding. These three points can be obtained without difficulty from an experimental load-displacement curve. As the loading continues, the debonding length

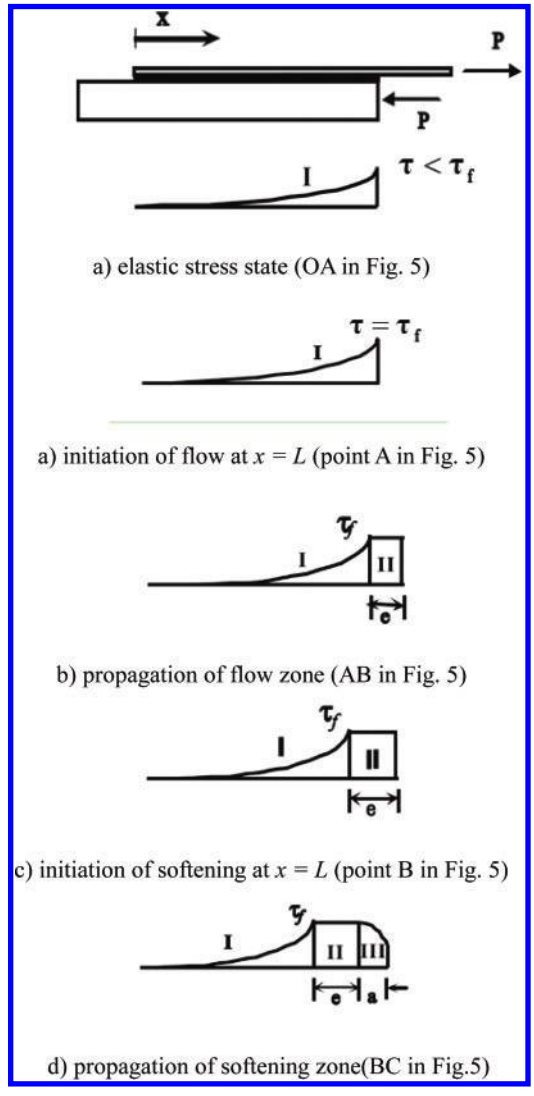

Figure 9. Interfacial shear stress distribution and propagation of debonding (bond length $L > l_0$).

is too long that the shear stress in elastic zone has begun to become incomplete, and the load P begins to decrease. Point D when the peak shear stress first reaches the unloaded end, point E when the flow zone just disappear and point F at complete debonding failure are generally not easy to obtain from experiment. The detail discussion may be made as follows.

As shown in Figure 9, section I is called the elastic stress zone, and there is no interfacial crack or micro-crack (flow and softening zone) along FRP-to-concrete interface. Section II and III are called the flow and the softening zone respectively, and the interface is micro-cracked but still able to transfer shear stress. In section IV an interfacial crack (debonding) without stress transfer occurs.

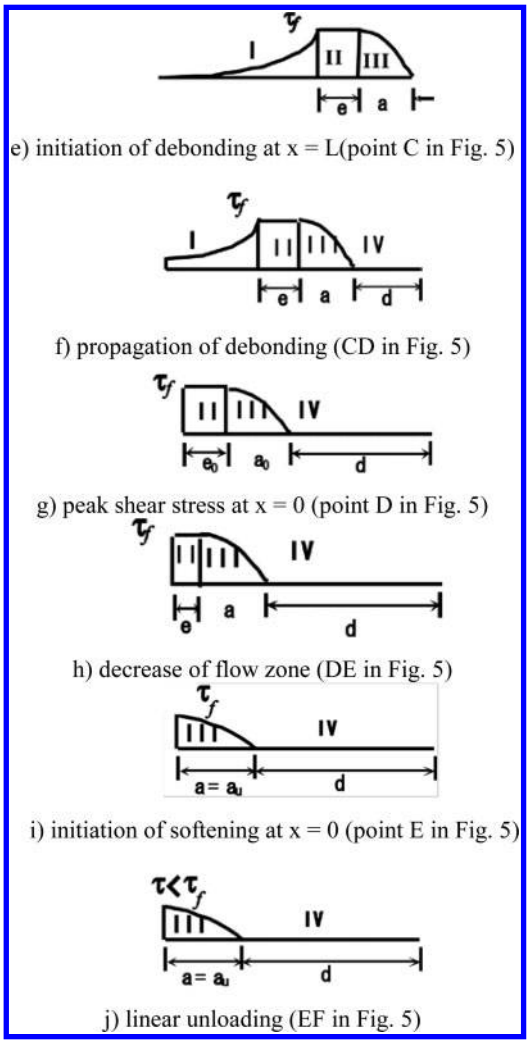

Figure 9. Continued.

5 CONCLUSIONS

In this paper, a nonlinear fracture mechanics approach has been introduced to derive theoretical solutions on interfacial stress transfer of the adhesive bonded joint. The analytical formulas indicate that the trilinear bond-slip model can be used to predict load-carrying capacity, and the model can predict the fracturing procedure such as initiation of micro-cracking and cracking (debonding), cracking propagation, load-displacement relation, shear stress distribution along FRP-to-concrete interface. The following conclusions can be made.

(1) The trilinear bond-slip model can better simulate the interfacial bond and debonding behavior.
(2) It is shown how measurement of the load-displacement relationship can be used for identifying the interface properties, including interfacial fracture energy and the local shear stress-slip relationship.
(3) The concept of serviceability limit state and ultimate limit state can be considered for the trilinear bond-slip model, which can be used to conduct serviceability state design and ultimate state design. Crack propagation stage and location on load-displacement curve are corresponded each other. Effect of bond length and FRP stiffness on load-displacement behavior, load-carrying capacity and effective bond length are studied in detail.
(4) The failure process with different bond length is given. The critical lengths for various failure process are obtained. Load-displacement curves and interfacial shear stress distribution for small bond length are also obtained.
(5) Bilinear bond-slip model is a particular case of the paper by letting $\delta_1 = \delta_2$, ie $e_0 = 0$.

A comparison of the variable strut inclination and alternative stirrup design methods

K.K. Mensah, C. Barnardo-Viljoen & J.V. Retief
University of Stellenbosch, Stellenbosch, Western Cape, South Africa

ABSTRACT: South Africa's adoption of EN 1992-1-1 *Eurocode 2: Design of concrete structures – Part 1-1: General rules and rules for buildings* will introduce the Variable Strut Inclination Method (VSIM) as an alternative analogy for stirrup design. The unbiased stirrup contribution of the EN 1992-1-1 VSIM has been shown to yield unsafe capacity predictions for relatively heavily shear-reinforced concretebeams. Conversely, the same model is excessively conservative for lightly reinforced beams. This contribution compares the performance of the EN 1992-1-1 VSIM to (1) the classical Ritter-Mörsch stirrup design analogy employed in the currently operational local design standard SANS 10100-1*The structural use of concrete*, and (2) the *fib* Model Code 2010 Modified Compression Field Theory (MCFT)-based design analogies (Levels of Approximation I & III). The VSIM seems to be in general agreement with the other design methods, but tends to offer higher capacity predictions at stirrup amounts in excess of 1 MPa.

1 BACKGROUND

South Africa (SA) is on the advent of adopting the European Standard EN 1992-1-1 *Eurocode 2: Design of concrete structures – Part 1-1: General rules and rules for buildings* as the equivalent standard for local use. Amidst a number of other changes, the adoption of EN 1992-1-1 as a local design standard will introduce the Variable Strut Inclination Method (VSIM) as an alternative analogy for stirrup design. The provision of stirrups or vertical reinforcement in design signifies an important and highly routine design situation that frequently occurs in practice to prevent sudden brittle failures in common reinforced concrete members. The assessment of the general performance of the VSIM as presented by EN 1992-1-1 therefore becomes one of the essential activities of the adoption process.

Investigations by Cladera & Mari (2007), later confirmed by Mensah (2012), have shown the unbiased stirrup contribution of the VSIM to be sensitive to the amount of stirrups provided in design. Figure 1 illustrates the trend of the ratio of the failure load from a laboratory test beam (V_{test}) to a corresponding unbiased VSIM prediction (V_{pred}) versus the nominal quantity of stirrups provided in design ($\rho_w f_{yw}$). The stirrup reinforcement ratio ρ_w is equivalent to the ratio of the area of the 2-legs of a stirrup (A_{sw}) over the product of the beam width (b_w) and stirrup spacing (s). f_{yw} represents the yield strength of the stirrups. The unbiased stirrup contribution of the VSIM seems to generally give excessively conservative capacity predictions when small amounts of stirrups are provided in design. Conversely, the model progresses to marginally conservative and eventually becomes unconservative as $\rho_w f_{yw}$ increases.

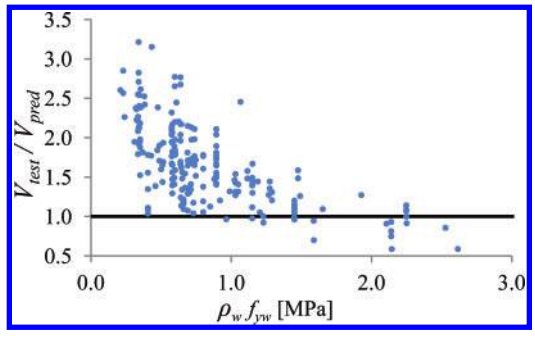

Figure 1. Relationship between V_{test}/V_{pred} and $\rho_w f_{yw}$.

Parametric correlation and regression analyses of the V_{test}/V_{pred} ratio against common variables affecting shear indicate that the VSIM is not significantly correlated to parameters such as concrete strength (f_c), beam width (b_w), shear span (a)-to-depth (d) ratio etc. It should be noted that the performance of the VSIM is to a large extent dependent on the limits governing the concrete compressive strut angle (θ). The limits for θ suggested by EN 1992-1-1 and used in this investigation are presented in Section 3.1

2 PROCEDURES FOR STIRRUP DESIGN

For member requiring stirrups, classical Ritter-Mörsch truss model idealisations have traditionally been used as conceptual basis for design. Historical approaches based on this analogy describe the post-cracking stirrup contribution to shear resistance ($V_{Rd,s}$) by a 45°

concrete strut angle (θ) truss with an empirically determined pre-cracking concrete contribution term ($V_{Rd,c}$). This is the approach followed by SA's currently operational concrete design standard SANS 10100-1 *The structural use of concrete – Part 1: Design*. The VSIM employed in EN 1992-1-1 is fundamentally a truss model that allows for a variable angle of the concrete compressive struts as derived based on the theory of plasticity (Bræstrup et al. 1976; Jensen & Lapko 2009). This model does not consider any direct contribution of the concrete to shear resistance. In EN 1992-1-1, the concrete compressive strut angle (θ) is assumed to vary between the confines of 21.8° and 45°.

The Modified Compression Field Theory (MCFT) is a rigorous procedure that can be used to predict the load-deformation response of a reinforced concrete element subjected to biaxial stressesThe MCFT, unlike the conventional constant angle and plasticity-based truss model approaches, accounts directly for the components of shear failure such as aggregate interlock and friction, dowel action and longitudinal steel, and shear carried across the uncracked concrete (ACI-ASCE Committee 445 Report 2009)The full procedure of the MCFT is described by Vecchio and Collins (1986), with applications in design standards described by Bentz & Collins (2006) and Kuchma et al. (2008) amongst a plethora of other publications.

The emerging *fib* Model Code 2010 (abbreviated MC 2010) (*fib* 2011) describes the four Levels of Approximation (LoA) that could be used to determine the shear resistance of a reinforced concrete member. Both the accuracy and computational effort required to make a prediction increase as the LoA increases. The first Level of Approximation (LoA I) is based on a simplified form of the LoA III approach and both are based on the MCFT (Bentz 2010). LoA II is based on the principles of plasticity modified with a strain term based on the MCFT to better model the behaviour of heavily reinforced concrete beams

LoA IV shear resistance predictions could be fulfilled by either LoA III or, if possible, higher order approximations proven to be of supreme accuracy. Response 2000 (Bentz, 2000) – hereafter referred to as R2k – is an MCFT-based sectional analysis program that can predict the load deformation response of concrete sections and members subjected to a combination of shear, flexure and axial load. R2k has proved to provide a more accurate and reliable prediction of the shear capacity of flexural members than any other method (Kuchma et al.2008). R2k cannot be used as a design method, but its accurate predictions could rather serve as the equivalent of physical test predictions.

2.1 *Comparison of stirrup design methods*

The 45° constant angle strut analogy that neglects the contribution of concrete to shear resistance has been proven to be over-conservative. It is for this reason that standards like SANS 10100-1 include an empirically determined concrete contribution term. Design procedures established in such a manner usually exhibit adequate performance within the range from which it has been derived. However, due to a lack of sound conceptual and scientific basis, the results of empirically derived design cannot be generalised and apply strictly within clearly defined boundaries. The VSIM and MCFT prediction models have evolved as the more economic and rational approaches to shear analysis, prediction and design.

Modern trends in structural design tend to prescribea variety of plasticity-based approaches for routine and conventional design situations, owing to their ease of use and quick execution times. The more computationally involving MCFT-based predictions usually suffice when more refined analyses are required or when they could yield significant economic benefits (usually for complex structures e.g. nuclear reactors, offshore structures, high-rise buildings). The approach taken by the *fib* MC 2010 for stirrup design offers a refreshing approach to the application of MCFT-based design procedures, specifically the simpler LoA I.

2.2 *Objectives of the investigation*

The inconsistentbehaviour of the VSIM at varied amounts of $\rho_w f_{yw}$ was highlighted in Section 1. To mitigate uncertainties and promote its economic use in SA, an extensive reliability investigation has been commissioned to calibrate the VSIM to suit local conditions and practice. The main outcomes of the process will be a set of rationally determined partial factors and design limits to support the optimal application of the VSIM in SA. As part of the general assessment of the performance of the VSIM, this contribution compares EN 1992-1-1 mean and design value predictions to those from, (1) the semi-empirical Ritter-Mörsch-based stirrup design analogy employed in the currently operational local design standard SANS 10100-1, and (2) the *fib* MC 2010 MCFT-based LoA I and LoA III design analogies.

The mean (unbiased) (V_{Rm}) and design (V_{Rd}) shear capacity predictions of the aforementioned procedures were compared for a beam of known cross-sectional and longitudinal geometry. Motivated by the systematic sensitivity of the VSIM portrayed in Figure 1, the design values of the different design methods were compared at parametric variations of $\rho_w f_{yw}$ for the chosen Test Case Furthermore, the performance of the V_{Rm} trend with $\rho_w f_{yw}$ for the various design approaches were compared to equivalent R2k predictions; with the R2k predictions serving as LoA IV or representative best estimate results across the parametric range considered. The objectives of this investigation are thus to;

1. Assess the trend of EN 1992-1-1 V_{Rm} predictions to the other approaches over the parametric range considered, and
2. Assess the trend of EN 1992-1-1 V_{Rd} predictions compared to the different approaches at varied amounts of $\rho_w f_{yw}$ in comparison to bullet 1. This analysis showcases the effect of the bias incorporated by partial factors and characteristic values for the different design methods across the parametric range considered.

3 DESIGN AND MEAN VALUE FUNCTIONS FOR THE VARIOUS APPROACHES

For capacity predictions, the shear resistance V_{Rd} of the web of reinforced concrete member may be generally described by:

$$V_{Rd} = V_{Rd,c} + V_{Rd,s} \le V_{Rd,max} \quad (1)$$

where $V_{Rd,max}$ is an upper limit to shear resistance aimed at avoiding premature web-crushing failures of the concrete compressive struts. The $V_{Rd,c}$, $V_{Rd,s}$ and $V_{Rd,max}$ components of Equation 1 for the different design approaches are reported in Table 1. The strut angle (θ) specified by each design approach is also presented in Table 1. It should be noted that Table 1 presents simplifications of the general design equations that are applicable to stirrup design. Salient features regarding the application of the various design procedures are discussed in the following Sections.

3.1 *EN 1992-1-1*

For resistance capacity predictions, θ for non-prestressed reinforced concrete members can be determined by (European Concrete Platform 2008):

$$\theta = \sin^{-1}\left[\left(A_{sw}\left(\frac{f_{ywk}}{\gamma_S}\right)/b_w s \nu_1 \left(\frac{\alpha_{cc} f_{ck}}{\gamma_C}\right)\right)^{1/2}\right] \quad (2)$$

where f_{ck} and f_{ywk} are, respectively, the characteristic compressive cylinder strength of concrete and the characteristic stirrup yield strength; γ_C and γ_S are the partial material safety factors for concrete and steel. EN 1992-1-1 recommends the vales of $\gamma_C = 1.5$ and $\gamma_S = 1.15$. Figure 2 shows, for different concrete strengths, the variation of θ across the parametric range of $\rho_w f_{yw}$ considered in this investigation. The detailed parameters of the investigation are given in Section 3.6. α_{cc} is a coefficient accounting for the scale effects of concrete and can be taken conservatively as 0.85. ν_1 is a compressive strength reduction factor recommended in EN 1992-1-1 as $0.6(1\text{-}f_{ck}/250)$. The maximum spacing of stirrups should not exceed $0.75d$ where d is the effective member depth. The minimum stirrup ratio is defined by:

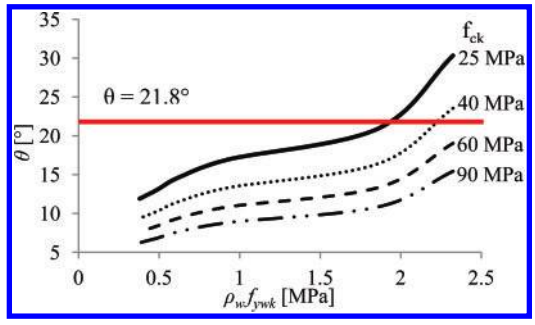

Figure 2. Variation of θ with $\rho_w f_{ywm}$ and f_{ck}.

$$\rho_{w,min} = 0.08\frac{\sqrt{f_{ck}}}{f_{yk}} \quad (3)$$

3.2 *SANS 10100-1*

SANS 10100-1 stipulates the same maximum spacing requirement as EN 1992-1-1, but suggests $\rho_{w,min}$ as 0.0012 when mild strength stirrups are used. $\rho_{w,min}$ assumes a larger value of 0.002 when high strength stirrups are used. The characteristic yield strength of SA's commercially available mild and high strength steel is 250 and 450 MPa, respectively. γ_C for shear is recommended as 1.4, whereas the same value of γ_S recommended in EN 1992-1-1 applies.

3.3 *fib MC 2010 LoA I*

Although the design function for the LoA I and LoA III design approaches is fundamentally the same, different values of k_v and k_c are applicable to either of the

methods. k_v indicates the ability of the web to resist aggregate interlock stresses which provide the concrete contribution to shear strength. For LoA I, k_v can be taken as 0.15 when the stirrups provided exceed $\rho_{w,min}$ as defined in Equation 3. k_c is a term that shall be taken as:

$$k_c = 0.5\left(\frac{30}{f_{ck}}\right)^{\frac{1}{3}} \quad (4)$$

where f_{ck} is expressed in MPa. The maximum spacing of stirrups should be taken as the lesser of $0.54d$ or 500 mm. The $\rho_{w,min}$ limit described by Equation 3 provides the minimum threshold ratio to which the *fib* LoA design functions apply to members with stirrups. However, for the design of new members MC 2010 requires that the 0.08 term from Equation 3 be replaced by 0.12. Both LoA I and LoA III apply the same values of γ_C and γ_S suggested for use by EN 1992-1-1.

3.4 *fib MC 2010 LoA III*

For LoA III, both k_v and θ are dependent on the calculated longitudinal strain ε_x at the mid-depth of the member. θ is defined in Table 1 and k_v is defined by:

$$k_v = 0.4/(1 + 1500\varepsilon_x) \quad (5)$$

provided the amount of stirrups exceeds $\rho_{w,min}$ from Equation 3. The expression for k_c for LoA III is similar to that given by Equation 4, save for the difference that 0.5 is replaced by 0.55. ε_x for non-prestressed members without axial forces is evaluated from:

$$\varepsilon_x = \frac{M_{Ed}/z + V_{Ed}}{2E_S A_S} \quad (6)$$

where M_{Ed} and V_{Ed} are the factored design forces for moment and shear, respectively. z is the inner lever arm and all design approaches commonly recommend its value as $0.9d$. E_s is the elastic modulus for steel and A_s represents the area of sufficiently anchored longitudinal tension reinforcement.

3.5 *Unbiased mean value predictions*

Characteristic values (f_{ck}, f_{ywk}) and partial factors (γ_C, γ_S) are introduced into design equations to incorporate some safety bias into the design process. For material and resistance models, the safety bias reduces the unbiased or best estimate resistance prediction of the analytical (or conceptual) function under investigation. Equations 1 through 6, as well as those presented in Table 1, can all be represented at their unbiased values by, where applicable, (1) expressing f_{ck} and f_{ywk} their mean values f_{cm} and f_{ywm}, respectively, and (2) not applying the partial factors γ_C and γ_S. The safety bias for the all other basic variables (A_{sw}, b_w, s etc.) is conventionally assumed as 1.0. For concrete strength, both EN 1992-1-1 and *fib* MC 2010 recommend the relationship:

$$f_{cm} = f_{ck} + 8\ MPa \quad (7)$$

For steel strength, Holický (2009) reports the following relationship:

$$f_{ywm} = f_{ywk} + 2\sigma_{f_{yw}} \ \ \& \ \ \sigma_{f_{yw}} = 0.1 f_{ywm} \quad (8)$$

where σ_{fyw} is the standard deviation of steel yield strength as observed from standard European steel production practice.

Table 3. Additional information required by R2k.

Parameter:	a/d [mm]	f_{yl} [MPa]	C [mm]	h [mm]
Quantity:	2.5	450	30	500

3.6 *Parameters for the test case*

V_{Rm} and V_{Rd} predictions were compared at parametric variations of $\rho_w f_{yw}$. The parametric variation of $\rho_w f_{yw}$ was achieved by varying the stirrup spacing, s, whilst keeping fixed the values of all other parameters. Since other design parameters do not show any systematic trends in comparing VSIM to experimental results, a typical section geometry should provide representative indication of the performance of the shear design method. The parameters of the beam cross-section required to make a prediction according to either of prediction methods presented in Table 1, are reported in Table 2. It should be noted that f_{ck} was converted to the equivalent characteristic cube strength f_{cu} to enable a SANS 10100-1 prediction.

LoA III additionally required the shear span (a)-to-depth ratio (a/d), specified in Table 3, to enable a resistance prediction. The traditional beam setup with a single central point load on simple supports was assumed for longitudinal geometry. R2k was also implemented for a best estimate analysis of the beam. R2k, however, provides a complete implementation of the MCFT for flexural members, and consequently required the specification of additional information to enable a resistance prediction. Some of the additionally required parameters are given in Table 3. f_{yl} represents the yield strength of the longitudinal tension reinforcement, C the clear concrete cover from

beam soffit to outermost seal of the stirrups, and h represents the beam height.

According to O'Brien et al. (2012), shear-flexure cracks that propagate towards the load (splitting the member in the process) become frequent above a value of a/d of 2.5. For lower values of a/d, direct strut action or compression forces are prevalent and such situations are best analysed by strut-and-tie approaches for efficient design. The approaches discussed here would be overly-conservative Beyond a value of a/d of 2.5, the influence of flexure becomes more pronounced in the moment-shear interaction and flexural failures gradually become of primary concern. The value of a/d of 2.5 therefore represents a regime where shear stresses are prominent and shear strength is critical. It is for this reason that the value of a/d of 2.5 was selected for the LoA III and R2k analyses.

4 RESULTS OF THE MEAN AND DESIGN VALUE ANALYSIS

4.1 *Mean values*

The mean predictions of shear capacity (V_{Rm}) provided by the different design approaches are shown in Figure 3. By treating R2k observations as test results or the best possible prediction, the unbiased predictions offered by the different design approaches all tend to become unconservative at increased amounts of $\rho_w f_{ywm}$. This trend of results, particularly for the EN 1992-1-1 model, agrees with the observation reported in Figure 1. The EN 1992-1-1 VSIM is the first to exceed the R2k predictions and become unconservative at a value of $\rho_w f_{ywm}$ of approximately 1.2 MPa. The LoA III predictions provide the best approximation of the R2k predictions. Consequently, the LoA III predictions exceed those of R2k at the highest value of $\rho_w f_{ywm}$ of about 2 MPa. The SANS 10100-1 model, although semi-empirical, provides a closer match to the more accurate LoA III and R2k predictions than both EN 199-1-1 and LoA I. This is an indication that the SANS model has been appropriately calibrated (empirically) for the parametric range considered in this investigation. The early rise in EN 1992-1-1 predictions, making it the foremost model to become unconservative as $\rho_w f_{ywm}$ increases, should be of concern as South Africa adopts EN 1992-1-1, and should ideally be appropriately calibrated to suit local adoption.

4.2 *Design values*

Figure 4 shows the design value shear strength predictions yielded by the different design approaches for the characteristic range of $\rho_w f_{ywk}$, since design values and safety bias are now of concern. The EN 1992-1-1 design function is initially conservative and comparable with the other design methods below a value of $\rho_w f_{ywk}$ of 1 MPa. The model however rapidly progresses to become the least conservative design method by providing the highest capacity predictions at $\rho_w f_{ywk}$ in excess of 1.2 MPa. On the other hand, the

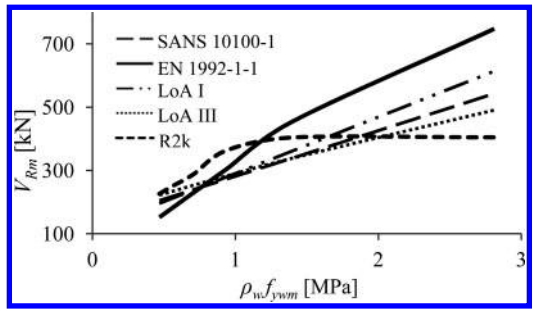

Figure 3. V_{Rm} for the various approaches and R2k *vs.* $\rho_w f_{ywm}$.

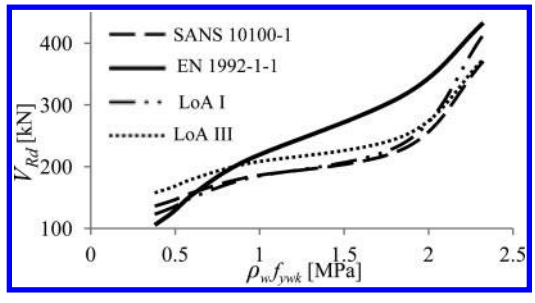

Figure 4. V_{Rd} for the various approaches *vs.* $\rho_w f_{ywk}$.

SANS 10100-1, LoA I and LoA III design approaches provided very similar capacity predictions over the parametric range, although the LoA III design values are slightly less conservative.

4.3 *General observations and comments*

The scatter of the different curves shown particularly by Figure 3, and to some degree for Figure 4 as well, indicate the wide-spread uncertainty and problems of the accurate prediction of shear resistance in structural design. Not only do the capacity predictions of the different methods vary from one another, they also vary from the actual value of resistance in a physical structure. Given these uncertainties, the issue of calibration of appropriate partial factors and characteristic values for shear design models becomes critical to ensure their safe and economic application in practice.

Although all the models deviate from the LoA IV R2k predictions in Figure 3, the EN 1992-1-1 VSIM portrays behaviour that is not only somewhat distinct from the others, but has the potential to become unsafe at lower quantities of $\rho_w f_{yw}$ than the other models. Proper calibration of the VSIM is thus essential for SA to adopt and apply EN 1992-1-1 reliably in practice. Mensah (2012)explores the prospects of calibration the VSIM as presented in EN 1992-1-1 to local SA conditions and practice.

5 CONCLUSIONS

The EN 1992-1-1 VSIM for the design of stirrups has been compared in this contribution to the

(1) semi-empirical Ritter-Mörsch based SANS 10100-1 approach, and (2) the fib MCFT-based LoA I and LoA III approaches. The investigation was motivated by two facts. The first is that South Africa intends to adopt EN 1992-1-1 as the local standard for the design of concrete structures. Following from the first, the second concern pertains to the economic and safety performance of the unbiased VSIM at parametric variations of the amount of shear reinforcement $\rho_w f_{yw}$. It was thus commissioned to compare the EN 1992-1-1 mean (V_{Rm}) and design (V_{Rd}) shear strength prediction trends at parametric variations of $\rho_w f_{yw}$ to those yielded by the previously established design approaches. A representative Test Case of selected cross-section and longitudinal geometry was used to for the investigation.

The EN 1992-1-1 VSIM is found to be in general agreement with the other design methods, but tends to offer higher capacity predictions at stirrup amounts in excess of 1 MPa. The practical implication is that the EN 1992-1-1 VSIM offers economic performance stirrup amount above 1 MPa as compared to SA's currently operational concrete design standard SANS 10100-1. The comparison to the *fib* LoA I & III approaches was included as part of the investigation to gain some insight of the relative performance of internationally available alternatives for stirrup design. The different prediction methods are not only conceptually different, but also offer different V_{Rm} and V_{Rd} trends as $\rho_w f_{yw}$ varies. This is a reflection of the existing contention in the fraternity on how to approach shear analysis, prediction and design.

Whatever the motivations for applying any given design approach, the method should be calibrated to incorporate sufficient conservative bias into the procedure. This would mitigate the various uncertainties associated with any given approach and support its safe and economic application in practice. The use of the EN 1992-1-1 VSIM is thus warranted for use in SA, but it should be calibrated to local conditions and practice to optimise its performance for designed structures.

Shear strength of reinforced concrete plastic hinges subjected to seismic action

R.V. Mehrabani & V. Sigrist
Institute of Concrete Structures, TUHH-Hamburg University of Technology, Hamburg, Germany

ABSTRACT: The shear strength of reinforced concrete beams is reduced by axial elongation of the plastic hinge regions during cyclic loading. In members with shear reinforcement this elongation may also affect the path of the shear cracks and the inclination of the compressive stress field. Thus, the effective concrete compressive strength decreases and/or the contribution of the concrete to the shear strength is reduced.

This paper presents a model to predict the longitudinal strain (axial elongation) in plastic hinge regions under seismic loading at the shear failure stage. The background for this is the Cracked Membrane Model and the shear design provisions of fib Model Code 2010, respectively. The calculation procedures are based on compatibility considerations and take the longitudinal strain at mid-depth of the beam cross sections into account. The theoretical results are compared to experimental data taken from literature and in general, good correlation is found.

1 INTRODUCTION

There are well established approaches for predicting the shear strength of reinforced concrete members in monotonic loading but there still is scientific discussion in that field. The behavior under load reversals is even more complex. Until now, most of the effort towards models for the shear strength of RC beams subjected to seismic (reversed-cyclic) loads has been spent on extending the classical 45-degree truss analogy and to provide a degradation function for the concrete contribution V_c or for both, the contributions of the concrete V_c and of the transverse steel V_s. For considering the degradation of the shear strength of RC members subjected to cyclic loading, ACI 318-08 (2008), the New Zealand Concrete Code (1982) and CSA A23.3-04 (2006) neglect the concrete contribution V_c in the earthquake design of ductile frame structures. The ATC seismic design guideline (1996), from a more analytical and conceptual perspective, proposes a shear capacity curve that comprises different ductility levels. AIJ (1990) code combines the shear contribution of the steel reinforcement in a truss mechanism with a concrete contribution from an arch mechanism based on a lower-bound solution of the theory of plasticity. In addition, this code imposes a reduction of the effective concrete compressive strength for the cracked concrete and limits the inclination of the concrete struts in the truss model; this leads to an overestimate of the shear strength degradation in the plastic hinge region (Choi & Park 2010, Lee & Watanabe 2003a).

Priestley et al. (1994) present a shear capacity curve for columns which is applicable to both low and high ductility levels. Sezen & Moehle (2004) improved a semi-theoretical shear strength model on the base of a diagonal tension failure mechanism. Choi & Park (2010) developed an analytical method to predict the inelastic deformation capacity of RC beams subjected to cyclic or monotonic loading. Biskinis et al. (2004) developed a model for the degradation of the shear resistance relative to the cyclic displacement ductility demand on the basis of the contribution of the web reinforcement V_s from the classical 45-degree truss analogy. However, most of the existing shear models which describe the degradation of the shear capacity due to inelastic flexural deformations are empirically developed without sound theoretical background. Therefore, a more rigorous prediction model that includes the most important parameters and reflects the actual failure mechanisms is required.

Recently, the Generalized Stress Field Approach (GSFA) (Sigrist 2011) was introduced for the design and analysis of beams in monotonic shear; this approach combines limit analysis methods and the concept of the Cracked Membrane Model (Kaufmann 1998) and improves the present situation in view of structural assessment. The basic ideas have been incorporated in fib Model Code 2010.

Evan if there are attempts to introduce models for the degradation of the shear resistance within the framework of the present Eurocode (a variable strut inclination model, neglecting V_c) it is quite clear that such models are not suitable for the design for cyclic loading (Biskinis et al. 2004). On the contrary, the GSFA that considers the strain state in determining the effective concrete compressive strength has the potential for improvements. Therefore, in this paper

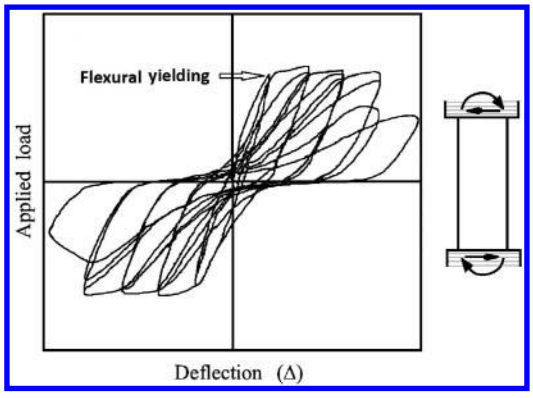

Figure 1. Load-deflection curve of a RC beam failing in shear after flexural yielding (Lee & Watanabe 2003a).

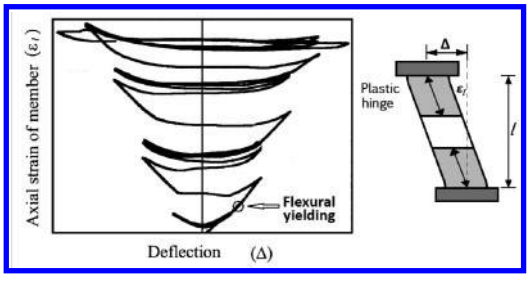

Figure 2. Axial strains versus deflections of a RC beam failing in shear after flexural yielding (Lee & Watanabe 2003a).

an (first) effort is made to extend the GSFA for plastic hinges of RC beams in reversed-cyclic shear.

2 SHAER DEGRADATION OF FLEXURAL PLASTIC HINGES

The results of previous studies show that the concrete shear resistance of RC members decreases with increasing displacement ductility demand μ (Priestley et al. 1994). Figure 1 shows the load-versus-deflection curve of a typical plastic hinge of a reinforced concrete beam with short span-depth ratio; the shear forces dominate the behavior. After the onset of yielding of the flexural reinforcement, plastic hinges were formed at both ends of the beam. Figure 2 shows the longitudinal axial strain at mid-depth of the beam versus the deflections of the beam. In the plastic hinges the longitudinal axial strain at mid depth of the section ε_l abruptly increases after the onset of flexural yielding and the residual strain of the longitudinal bars increases with each cycle. This increase of the axial strain widens the diagonal cracks and leads to an increase of the principal tensile strain ε_1 which results in a reduction of the effective concrete compressive strength $\eta_c f_c'$ until a shear failure occurs.

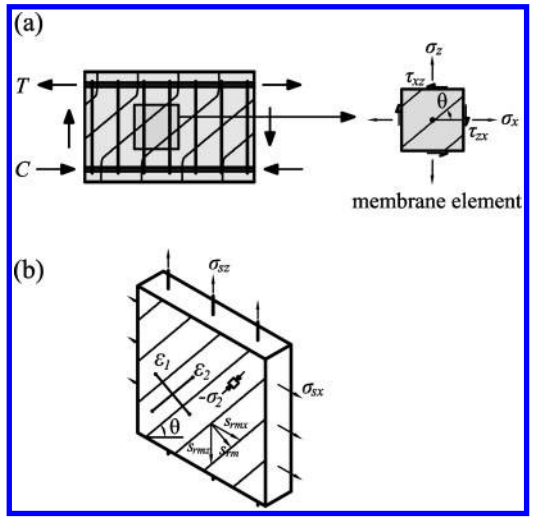

Figure 3. (a) Diagonally cracked RC beam segment and membrane element; (b) stresses in concrete and steel in a cracked membrane.

3 CRACKED MEMBRANE & STRESS FIELD ANALYSIS

3.1 *Cracked membrane*

Figure 3 shows a RC beam with flexural compression and tension forces and a diagonally cracked web. The web consists of a compound of orthogonally reinforced membrane elements subjected to the in-plane stresses σ_x, σ_z and τ_{zx}.

During the loading process cracks occur and subsequently, the applied stresses are resisted by the steel bars and the inclined concrete struts. From equilibrium for pure shear the shear stress τ_{zx} can be derived from nominal stress $\sigma_{sz}\rho_z$ or the principal concrete stress σ_2:

$$\tau_{xz} = \sigma_{sz}\rho_z \cot\theta \tag{1a}$$

$$\tau_{zx} = -\sigma_2 \sin\theta\cos\theta \tag{1b}$$

In Eq. (1) ρ denotes the reinforcement ratio of the stirrups $A_{sw}/b_w s$ The kinematic condition can be deduced from Mohr's circle of strains:

$$\tan^2\theta = \frac{\varepsilon_x - \varepsilon_2}{\varepsilon_z - \varepsilon_2} \tag{2}$$

ε_x, ε_z and ε_2 denote the average (smeared) strains in the respective directions. By adopting a bilinear stress-strain characteristic for the reinforcement, a stepped rigid-perfectly plastic bond shear stress-slip relationship to compute the deformations of the ties (Sigrist 1995) and an idealized quadratic parabola for the stress-strain response of concrete

$$\frac{\sigma_c}{f_{ce}} = 1 - (1 + \frac{\varepsilon_c}{\varepsilon_{c0}})^2 \tag{3}$$

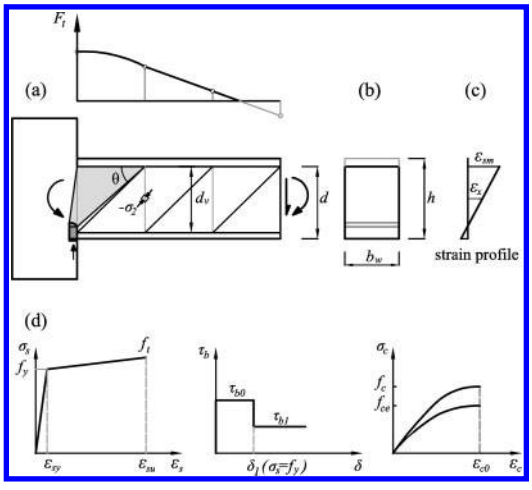

Figure 4. Discontinuous stress field and Generalized Stress Field Approach: (a) fan region and parallel stress bands of a RC fixed-end beam and variation of top chord force; (b) cross-section; (c) longitudinal strain at mid-depth of the beam; (d) constitutive laws for steel, bond shear stress-slip and concrete (Sigrist 1995).

the shear strength τ_R and the corresponding angle θ can be determined numerically; f_{ce} is the effective concrete compressive strength and defined as:

$$f_{ce} = \eta_c f_c' \left(\frac{30}{f_c'}\right)^{1/3} \leq \eta_c f_c' \tag{4}$$

where f_c' denotes the concrete cylinder strength and η_c the reduction factor accounting for strain influences which, based on investigations by Kaufmann 1998) and proposed by Sigrist (2011), can be taken to:

$$\eta_c = \frac{1}{1.2 + 55\varepsilon_1} \tag{5}$$

The principal tensile strain ε_1 perpendicular to the crack direction can be calculated with $\varepsilon_1 = \varepsilon_x + (\varepsilon_x - \varepsilon_2)\cot^2\theta$.

3.2 *Generalized stress field approach*

Figure 4(a) shows a discontinuous stress field for the RC fixed-end beam. The top chord force, F_t, changes hyperbolically within the fan region near the fixed end and linearly within band stress field outside of the fan region (Sigrist et al. 1995). F_t is defined as

$$F_t = -\frac{M}{d_v} + \frac{V}{2}\cot\theta \tag{6}$$

Stress fields are used for describing the stress state within a structure at ultimate. The Generalized Stress Field Approach combines limit analysis methods and the concept of the Cracked Membrane Model and

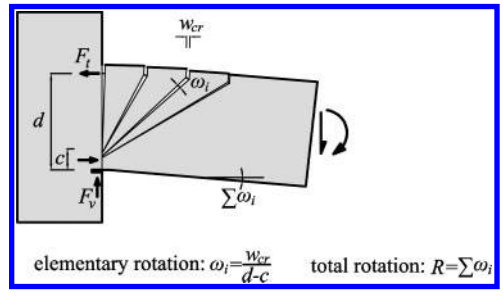

Figure 5. Determination of element rotation.

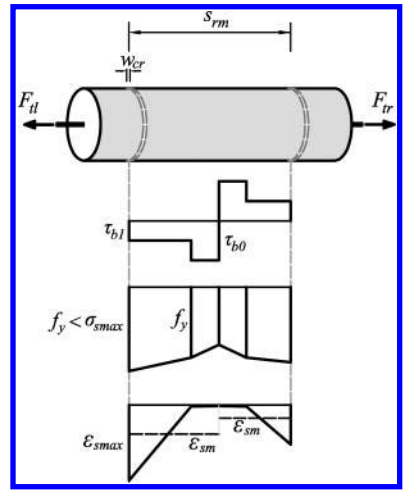

Figure 6. Tension Chord Model.

improves the present situation in view of structural assessment. GSFA comprises specific limits for the inclination angle θ, an upper limit for web crushing without yielding of the stirrups and a lower limit for rupture of stirrups; θ-values in between correspond to the so-called web crushing criterion. Longitudinal strains of webs are assumed to vary linearly over the depth and for reasons of applicability, the longitudinal strain at mid-depth of the web ε_x (Fig. 4) is taken as representative. With these determinations the shear strength τ_R of RC beams in the case of monotonic loading can be predicted.

4 PLASTIC HINGE REGION AND ELEMENT ROTATION

Rotations of plastic hinges are primarily due to the elongation of the tension chord. Accordingly, plastic rotations can be determined by calculating crack widths (Bachmann 1967). As shown in Figure 5, from the crack width w_{cr} elementary rotations $\omega_i = w_{cr}/(d - c)$ can be calculated. The sum of elementary rotations leads to the total rotation $R = \sum \omega_i$. Crack width can be calculated by the help of Tension Chord Model (Marti et al. 1998). By considering a tension chord element with unequal forces ($F_{tl} > F_{tr}$) and an

average crack spacing s_{rm} as shown in Figure 6, using the constitutive laws for steel and bond shear stress-slip of Figure 4(d) in which $\tau_{b0} = 0.6 f_c^{2/3}$ for the pre-yield range and $\tau_{b1} = 0.3 f_c^{2/3}$ for the post yield range may be used, crack width can be calculated. As a result, average steel strains ε_{sm} are found by dividing the crack width for each load stage by related values s_{rm}.

5 LONGITUDINAL AXIAL STRAIN OF REVERSED-CYCLIC PLASTIC HINGE

As mentioned above, longitudinal strains vary linearly over the member's depth and hence, axial strains at mid-depth of the beam can be calculated easily with help of the Tension Chord Model (Fig. 4(c)). In the case of reversed cyclic loading the determination of axial strains in plastic hinges is more complex. This is mainly because of the presence of residual axial strains due to previous cycles and also the effect of closing and opening of cracks during load reversal. Several researchers have studied the axial strain and elongation of reverse-cyclic plastic hinges (Lee & Watanabe 2003a,b, Peng et al. 2007, Eom & Park 2010). In most of these studies the efforts are focused on predicting the total elongation and axial strain in the plastic hinge or member. Alternatively, the axial strain is predicted directly by relations that are developed from deflections (or rotations) and the elongation or axial strain at mid-depth of the member without considering the interdependence of the chord elongation and the rotation.

In this contribution, the axial strain of the chord is predicted with help of the Tension Chord Model and, a simplified method for calculating the axial strain at mid-depth of the reversed-cyclic plastic hinge is proposed. As shown in Figure 2 only the elastic part of the axial strain recovers whereas the plastic part remains as a residual strain; hence, this portion adds to the axial strain of the next cycle. According to Lee & Watanabe (2003a,b) the decreasing rate of the axial strain in unloading is approximately the same as the increasing rate in elastic stage. Therefore, the recovered axial strain can be estimated to $2(\mu - 1)\varepsilon_{x,yield}$ where μ is the displacement ductility (Δ/Δ_y) and $\varepsilon_{x,yield}$ is the axial strain at flexural yielding at mid-depth of beam. This proposed simplified method neglects the effect of the load cycles that are imposed at the same deflection (rotation) magnitude. However, further work is needed to more precisely assess the axial strains; this research is continued by the authors.

The longitudinal elongation (axial strain) of plastic hinges at fixed beam ends is attributed mainly to 1) the plastic deformation of the flexural tensile reinforcement and 2) the fixed-end rotation due to pull out of the longitudinal reinforcement from the support. For the investigation of the shear capacity of RC beams on the basis of stress field approaches, the axial strain excluding the fixed-end rotation should be used; with help of the proposed method this separation is easily possible.

6 CALCULATION PROCEDURE

The reversed-cyclic shear response of RC beams is a complex issue. One of the complexities is the formation of cracks and, even more important, the development and variation of the crack inclination during the loading process. Many of the codes assume a fixed crack inclination, e.g. $\theta = 45°$ for high ductility demands. However, such a θ-value is for design at ultimate. Actually, the value of θ is very sensitive to load history and changes in the presence of imposed displacements. Therefore, for evaluating the shear degradation and the member's ductility a rigorous prediction of θ is required.

Previous studies have shown that after the onset of yielding of the longitudinal reinforcement in the plastic hinge, the crack inclination tends to be rather steep (Elmenshawi et al. 2009). If the main crack inclination is formed prior to first flexural yielding, principal concrete stresses and stress angles would vary to achieve equilibrium. The proposed model supposes the main cracks to be formed during the initial monotonic loading and crack inclination at first flexural yielding is close to the crack inclination at failure. This assumption may not be completely correct but it leads to a conservative prediction of the ductility capacity of a shear dominated plastic hinge of a RC beam in cyclic loading. The first step of the proposed method is, with help of the Cracked Membrane Model and the GSFA, to determine the crack inclination θ, related to the shear stress at the onset of first flexural yielding τ_y, numerically.

The average crack spacing in a fully cracked membrane is defined by

$$s_{rm} = s_{rmx} \sin\theta = s_{rmz} \cos\theta \tag{7}$$

and the distances in x-and z-directions are given by

$$s_{rmx} = \lambda_x s_{rmx0} \quad \text{and} \quad s_{rmz} = \lambda_z s_{rmz0} \tag{8}$$

The maximum crack spacing in either direction is calculated as

$$s_{rm0} = \frac{f_{ct} \varnothing (1-\rho)}{2\tau_{b0}\rho} \tag{9}$$

Finally, the crack spacing s_{rm} can be approximated on the basis of

$$\frac{f_{ct}}{2}(\lambda_x + \lambda_z) - \frac{\tau_{xz}}{2}(\cot\theta + \tan\theta) + \sqrt{\left[\frac{\tau_{xz}}{2}(\cot\theta - \tan\theta) - \frac{f_{ct}}{2}(\lambda_x - \lambda_z)\right]^2 + \tau_{xz}^2} \le f_{ct} \tag{10}$$

where the parameters λ_x and λ_z are limited by the conditions $0.5 \le \lambda_x \le 1$ and $0.5 \le \lambda_z \le 1$. Equation (10) was derived by Kaufmann (1998). Taking Equations (1) to (10) into account, the crack inclination θ related to the shear stress $\tau_{zx} = \tau_y$ can be calculated iteratively.

For this calculation procedure the constitutive laws of Fig. 4(d) are used. To achieve the smallest crack inclination θ, the lowest possible value for λ_z has to be considered.

As found in plastic hinge tests, the shear stress at first flexural yielding τ_y is about the maximum that the beam will experience in the next cycles; peak shear stresses of the cycles do not change much as the crack inclination θ related to first flexural yielding is the smallest inclination that can be predicted. Note that the smallest θ-value leads to the minimum required axial strain ε_x at failure.

The shear strength τ_R of a plastic hinge degrades due to longitudinal elongation. For a given value τ_R the computation of the principal tensile strain ε_1 is straight forward with help of $f_{ce} = \tau_R/(\sin\theta\cos\theta)$ and $-\varepsilon_2 = \varepsilon_{c0}$ as well as by adopting Equation (5). Axial strain ε_x at mid-depth of the beam at failure is found as

$$\varepsilon_x = \frac{\varepsilon_1 \tan^2\theta + \varepsilon_2}{1+\tan^2\theta} \tag{11}$$

7 VERIFICATION AND DISCUSSION

For verification, the proposed model is applied to the three RC fixed-ended beam tests BA2, BA4 and BA10 reported by Lee & Watanabe (2003a,b); these were tested at Kyoto University and subjected to reversed cyclic bending and shear. Shear span-to-depth ratio is $L_s/d = 2.3$. The test parameters are listed in Table 1. According to test report, shear forces dominated the behavior of the beams because of the short shear span and after the onset of yielding of the flexural reinforcement, plastic hinges were formed at both beam ends.

For these beams a crack spacing in the tension chords of $s_{rm} = 111$ mm is determined from the tensile reinforcement ratio and other parameters; furthermore, average axial strains at mid depth of the beams are calculated. The results are given in Figure 7. The horizontal axis of the diagrams shows the distance from the fixed end of the beam and the vertical the strain values. Three series of strains are plotted. The lowest values are the average axial strains at mid-depth, the highest values are the required axial strains at shear failure according to Eq. (11) and the values in between are the total (sum of the) average axial strains from the fixed end to the related points (Sigrist and Hackbarth 2010). For the required axial strains, the horizontal lines depict the calculated crack inclination θ of the parallel stress bands and the minimum points correspond to the crack inclination θ_y at first flexural yielding and the start of the fan region (Table 1); the branches of the curves on the left refer to crack inclinations θ bigger than θ_y. By comparing the required axial strains for shear failure and the total average strains it can be concluded that the average axial strains of the fan regions are very close to the predictions of the proposed model. This is an import outcome that illustrates the potential of the proposed model for evaluating the shear strength in reversed-cyclic (seismic) plastic hinges.

It is noteworthy that the predictions of the axial strains of RC beams that fail in shear after flexural yielding largely depend on the effective concrete compressive strength f_{ce}. Equation (5) that is used for determining f_{ce} is highly influenced by the principal

Table 1. Test properties and proposed inclinations.

Ref.	Specimen	f_c' (MPa)	f_{yl} (MPa)	f_{yz} (MPa)	ρ_l (%)	ρ_z (%)	θ_f (deg)	θ_b (deg)
Lee & Watanabe (2003a,b)	BA2	29.3	399	696	1.45	0.27	32	35
	BA4	29.3	399	692	1.45	0.80	40	42
	BA10	43.4	399	696	1.45	0.60	39	41

f_c' = concrete compressive strength; f_{yl} = yield limit of longitudinal reinforcement; f_{yz} = yield limit of shear reinforcement; ρ_l = tensile longitudinal reinforcement ratio; ρ_z = shear reinforcement ratio; θ_f = predicted inclination of fan; θ_b = predicted crack inclination of parallel stress bands.

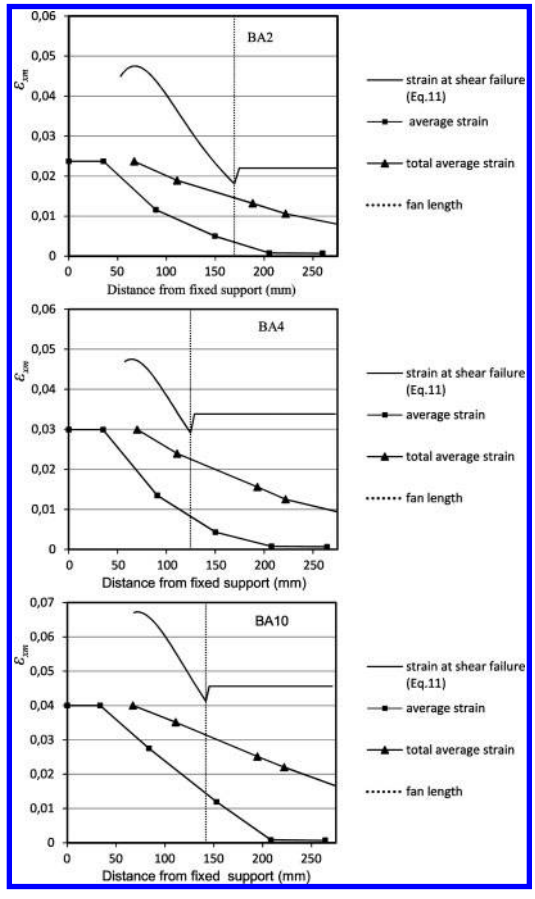

Figure 7. Predicted axial strains at mid-depth of the beams in plastic hinge regions.

tensile strain ε_1 perpendicular to the crack direction. This equation is based on test results of RC beams under monotonic loads with rather small values of ε_1 (Sigrist 2011); the ε_1-values in reversed-cyclic plastic hinges may be much bigger. Thus, additional work is needed to investigate strength reduction for reversed-cyclic plastic hinges of RC beams failing in shear at flexural yielding.

8 CONCLUSION

The research reported in this contribution presents a model that evaluates the longitudinal axial strain at the failure stage of plastic hinges in RC beams subjected to reversed-cyclic (seismic) loading. To predict the required axial strain of the beam for shear failure, this study is focused on the degradation of diagonally compressed concrete with help of a compatibility-based stress field model that takes the axial strain at mid-depth of the beam's cross section into account. The proposed model uses the crack inclination at first flexural yielding and predicts the longitudinal elongation capacity of the plastic hinge up to shear failure by extending the Cracked Membrane Model and the GSFA. From the comparison of the calculations with test results it can be concluded that the model has good potential to predict the required axial strain at shear failure and hence, to evaluate the shear capacity of reversed-cyclic (seismic) plastic hinges.

This contribution aims at giving an overview on these developments and at demonstrating that the model – even if originally developed for the design and analysis of members in static loading – forms a sound basis for the seismic assessment of structures. However, additional work is needed to investigate the concrete strength reduction for reversed-cyclic plastic hinges of RC beams failing in shear at flexural yielding.

Experimental and numerical investigations on the punching behavior of thick footings with and without shear reinforcement

D. Kueres, C. Siburg, K. Reissen & J. Hegger
Institute of Structural Concrete, RWTH Aachen University, Germany

ABSTRACT: Although punching of reinforced slabs has been investigated extensively in the last decades, there are only limited test data with realistic specimen sizes for punching of footings. Thus, a number of twelve reinforced concrete footings with and without shear reinforcement were tested to investigate the punching behavior. The thickness of most of the slabs was set to 0.45 m, whereas four specimens were tested with a higher slab thickness of 0.65 m to investigate the punching behavior of thick footings. Examining the influence of the shear slenderness, the edge lengths of the square slab were varied from 1.20 m to 2.70 m. The main test parameters investigated are the shear slenderness, size effects of the effective static depth, concrete compression strength, longitudinal reinforcement ratio and shear reinforcement.

1 INTRODUCTION

In the past, the punching behavior of reinforced concrete slabs was investigated mainly by means of small-sized specimens. As a result of these investigations, theoretical and empirical models were developed to describe the main influences on the punching behavior of flat slabs and footings (Andrä 1982, Brooms 2005, Muttoni 2008, Ricker 2009). However, tests showed that the punching behavior of footings differs significantly from the behavior of flat slabs (Dieterle & Rostásy 1987, Hallgren et al. 1998, Timm 2003).

Based on a research project funded by the German Research Foundation (DFG – Deutsche Forschungsgemeinschaft) that has been concluded already, a number of twelve reinforced concrete footings with and without shear reinforcement were tested at the Institute of Structural Concrete at RWTH Aachen University to examine these differences. The tests primarily investigated the influences resulting from shear slenderness, size effects of the effective static depth, concrete compression strength, longitudinal reinforcement ratio and shear reinforcement.

2 EXPERIMENTAL INVESTIGATIONS

The specified test program consisted of twelve punching tests on reinforced concrete footings with and without shear reinforcement. The edge lengths of the footings varied from 1.20 m to 2.70 m with effective static depths between 0.40 m and 0.60 m resulting in shear slendernesses of 1.25 to 2.00.

Based on a tested footing without shear reinforcement (Hegger et al. 2006a) with an effective static depth $d = 0.40$ m, a shear slenderness $a/d = 1.25$, a longitudinal reinforcement ratio $\rho_l = 0.85\%$ and a concrete compression strength $f_{c,cyl} = 20$ N/mm^2, the influencing parameters on the punching behavior of thick footings were investigated systematically.

The thickness of most of the footings was set to 0.45 m, whereas four specimens (DF26, DF28N, DF33 and DF35) were tested with a higher slab thickness of 0.65 m to investigate the punching behavior of thick footings. For two specimens (DF41 and DF42) the longitudinal reinforcement ratio was reduced to 0.30%. One footing (DF20N) was produced with a concrete compression strength $f_{c,cyl} = 35$ N/mm^2 and two other footings (DF38 and DF39) had a concrete compression strength $f_{c,cyl} = 50$ N/mm^2. Besides the punching behavior of footings without shear reinforcement it was examined how shear reinforcement affects the punching shear capacity of thick footings. Therefore, a number of five specimens (DF29, DF31, DF32, DF33 and DF35) were equipped with shear reinforcement and constructed structurally identical to the reference test series without shear reinforcement. Compared to the specimens DF33 and DF35, where the distance s_0 between the first vertical stirrup and the column was set to $0{,}3d$, three footings (DF29, DF31 and DF32) were tested with a smaller distance. Whereas the shear reinforcement ratio generally was high enough to reach the maximum punching shear capacity, specimen DF32 contained 25% less shear reinforcement than DF31 to investigate the influence of the amount of shear reinforcement.

2.1 *Test specimens*

Considering the results of a former DFG research project (Hegger et al. 2006a, 2006b, 2009, 2010) the twelve reinforced concrete footings were planned and

produced. In this context, Table 1 shows the varied test parameters as well as the failure loads for the investigated footings. The geometry and the reinforcement for a representative specimen are shown in Figure 1.

2.2 *Experimental setup*

To investigate size effects of the effective static depth particularly with regard to thick footings, it was necessary to test slabs with higher effective static depths. The experimental setup used in the former DFG research project was not designed for both the necessary geometry and the ultimate loads. Hence, a new experimental setup (Fig. 2) was developed.

The specimens were tested upside down with the base area up. A uniform pressure was created with 16 and 25 load points, respectively, depending on the footing dimensions. Twelve presses transferred their load through beams to two load points each. A further press with a piston area of half the size completed the load arrangement above the column. An equal distribution of the press forces was ensured since all presses were controlled by the same oil circuit. In order to avoid any formation of membrane forces in the test specimen, sliding and deformation bearings were placed between the footing and the cross beam.

2.3 *Test results*

2.3.1 *Bearing behavior and crack formation*

All tested specimens showed a punching failure located in the intersection of column and footing. The failure loads are given in Table 1. The comparison between the ultimate load V_{Test} and the load V_{Flex} according to Yield Line Theory (Gesund 1983) indicates that the flexural capacity was not reached which confirms the observations during the tests.

The crack patterns inside the footings were documented with the help of saw-cuts which are given in Figure 3. All specimens without shear reinforcement showed a discrete failure shear crack. The experimental investigations indicated that the angle of the crack is steeper in punching tests on compact footings than observed on more slender slabs (Fig. 3). While

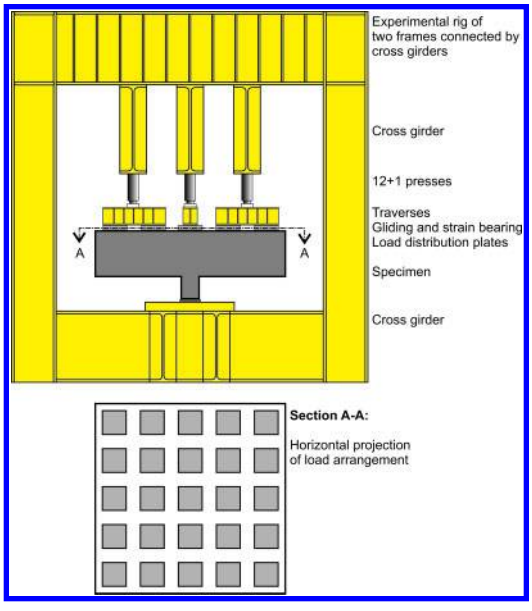

Figure 2. Experimental setup used for punching tests.

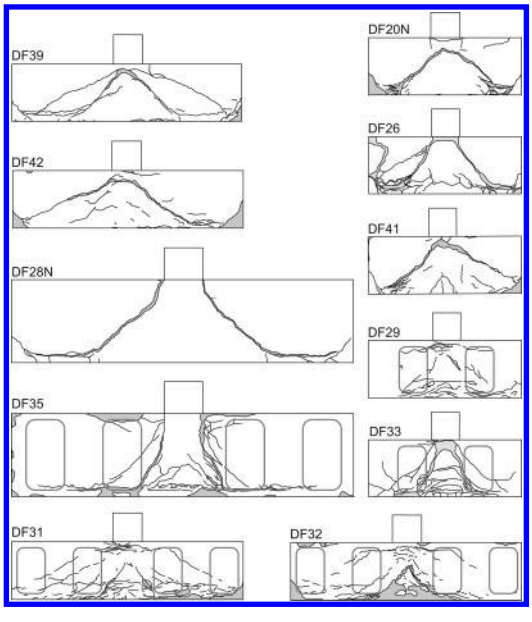

Figure 3. Saw-cuts of the specimen at edge of column.

footings without shear reinforcement showed a discrete crack, the crack patterns of footings with shear reinforcement were finely dispersed and seemed to be unattached by the shear slenderness.

2.3.2 *Influence of the shear slenderness*

Figure 4(a) shows the influence of the shear slenderness on the punching shear capacity of footings. The failure loads were normalized so that effects of the concrete compression strengths were eliminated. The shear slenderness significantly affects the punching shear capacity of slabs. Regardless of the longitudinal reinforcement ratio or concrete strength, the failure load decreases with increasing shear slenderness. Thus, the influence of the examined parameters was tested for different shear slendernesses.

2.3.3 *Influence of size effects of the effective static depth*

In Figure 4(b) the results of the experimental investigations to determine size effects of the effective static depth are presented. To visualize the relative reduction of the punching shear capacity of thick slabs, the failure test load was converted into a shear stress. The stress $v_{Ru,c}$ describes the shear stress along the decisive design location according to Eurocode 2 with German annex (DIN EN 1992-1-1 + NA 2011).

In the diagrams (Fig 4(b)), the dashed lines describe the factor k (DIN EN 1992-1-1 + NA 2011) which characterizes the size effect of the effective static depth as the result of punching tests on flat slabs. Whereas this factor is able to describe the relative reduction of the punching shear capacity of flat footings, current tests showed that the size effect of thicker slabs may be more distinct. This tendency can be observed for shear slenderness $a/d = 1.25$ and 2.00 as well as for specimens with and without shear reinforcement (Fig. 4(b)).

2.3.4 *Influence of longitudinal reinforcement ratio*

The punching shear capacity shows a dependency on the longitudinal reinforcement ratio. According to Eurocode 2 with German annex (DIN EN 1992-1-1 + NA 2011), this dependency can be described by a cubic root function which could be verified considering the current test data (Fig 4(c)).

2.3.5 *Influence of concrete compression strength*

Besides the longitudinal reinforcement ratio, the punching behavior of slabs shows a similar dependency on the concrete compression strength (DIN EN 1992-1-1 + NA 2011). In this context, Figure 4(d) presents the results of the experimental investigations. For footings with shear slendernesses $a/d \geq 1.50$ the normalized test load $V_{Test}/f_{ck}^{1/3}$ shows a slight rise for increasing concrete compression strengths. However, by use of habitual concrete strengths $f_{c,cyl} \leq 30$ MPa this normalization seems to be sufficiently precise.

2.3.6 *Influence of shear reinforcement*

For footings with vertical stirrups as shear reinforcement, higher loads than for comparable footings without shear reinforcement can be obtained. In this regard, Figure 4(e) shows the ratio of failure loads of specimens with and without shear reinforcement $V_{Test}/V_{c,Test}$. As can be seen, this load-increase up to the maximum punching resistance is hardly influenced by the shear slenderness and increases for slender slabs. Hence, shear reinforcement seems to be more effectively for higher shear slendernesses.

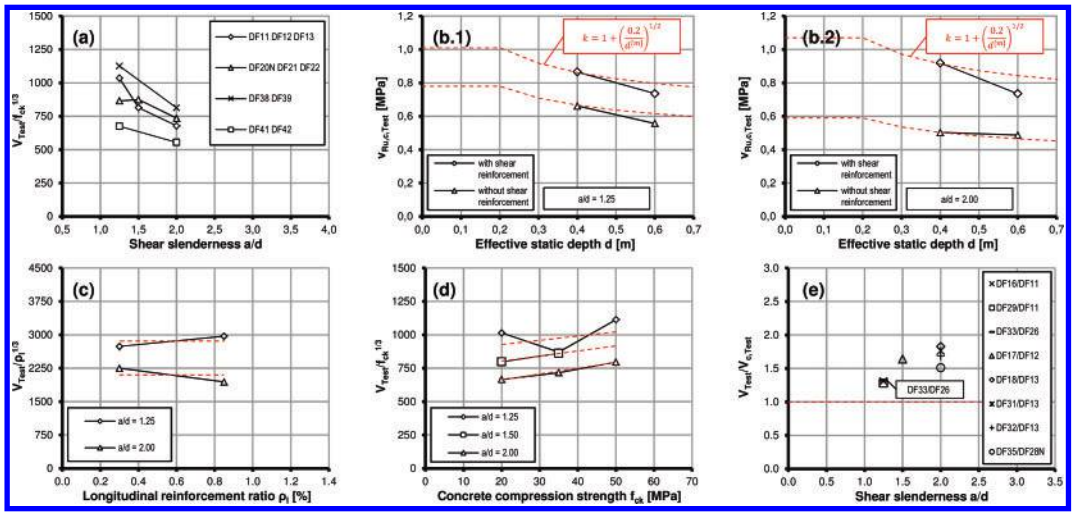

Figure 4. Influence of the shear slenderness (a), effective static depth (b), longitudinal reinforcement ratio (c), concrete compression strength (d) and shear reinforcement (e) on punching shear capacity of footings according to experimental investigations.

3 NUMERICAL INVESTIGATIONS

In addition to experimental investigations, nonlinear finite element analyses were carried out. The numerical investigations were performed by use of the FEM program ABAQUS/CAE 6.11.

3.1 *Computational model*

The tested specimens consist of concrete and steel reinforcement. To model the nonlinear behavior of these materials, physically nonlinear material models were used. In this context, the concrete was modeled by means of the CONCRETE DAMAGED PLASTICITY MODEL (Lubliner et al. 1989, Lee & Fenves 1998). To discretize the concrete, 8-noded, linear continuum elements with full integration were used. The nonlinear behavior of both, the longitudinal and shear reinforcement was considered by using the material law according to VON-MISES. The reinforcement bars were modeled with linear truss elements. The finite element model used for the numerical analysis for a representative specimen is shown in Figure 5.

For symmetry reasons it was practical to model only a quarter of the specimens. The load was applied incrementally so that the iterative NEWTON-RAPHSON method could be utilized. To evaluate the numerical results, the ultimate load at the time of abortion of the computations was used. Other abort criteria were not defined.

3.2 *Validation of the computational model*

To verify the computational model, the numerical results were compared with the experimental results. Hence, different criteria – such as failure loads, load-deflection curves, measured concrete and steel strains as well as crack patterns – were defined to evaluate the quality of the model.

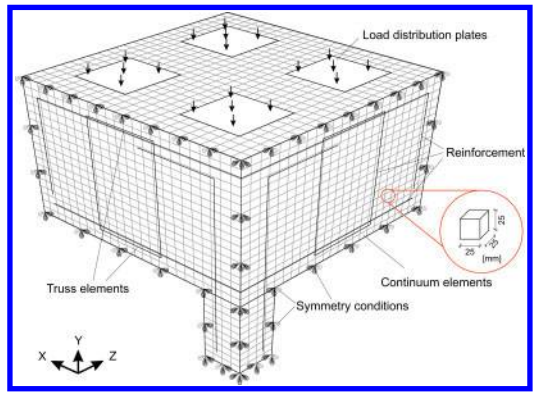

Figure 5. Finite element model used in analysis for specimen DF29.

The comparison between the actual failure loads and the calculated failure loads V_{Test}/V_{FE} is given in Table 1. Considering all analyzed footings, the arimethic mean was $x_m = 0.99$ with a coefficient of variation $V = 0.08$ which indicates that the results do not vary widely. Figure 6 presents the comparison of the measured and simulated load-deflection curves and concrete respectively steel strains for two representative specimens. As can be seen, the actual measured load-deflection curves and the simulated curves match well. Furthermore, the model has the ability to reproduce concrete strains (Fig 6(b)) as well as steel strains of the longitudinal reinforcement (Fig 6(c)) in radial and tangential direction in a sufficient way. In most cases steel strains of the shear reinforcement – especially in the first vertical stirrup – could not be simulated realistically (Fig 6(d)). In particular, if the stirrup is located in a shear crack, the load-strain curve shows a sharp bend. Since the CONCRETE DAMAGED PLASTICITY MODEL is

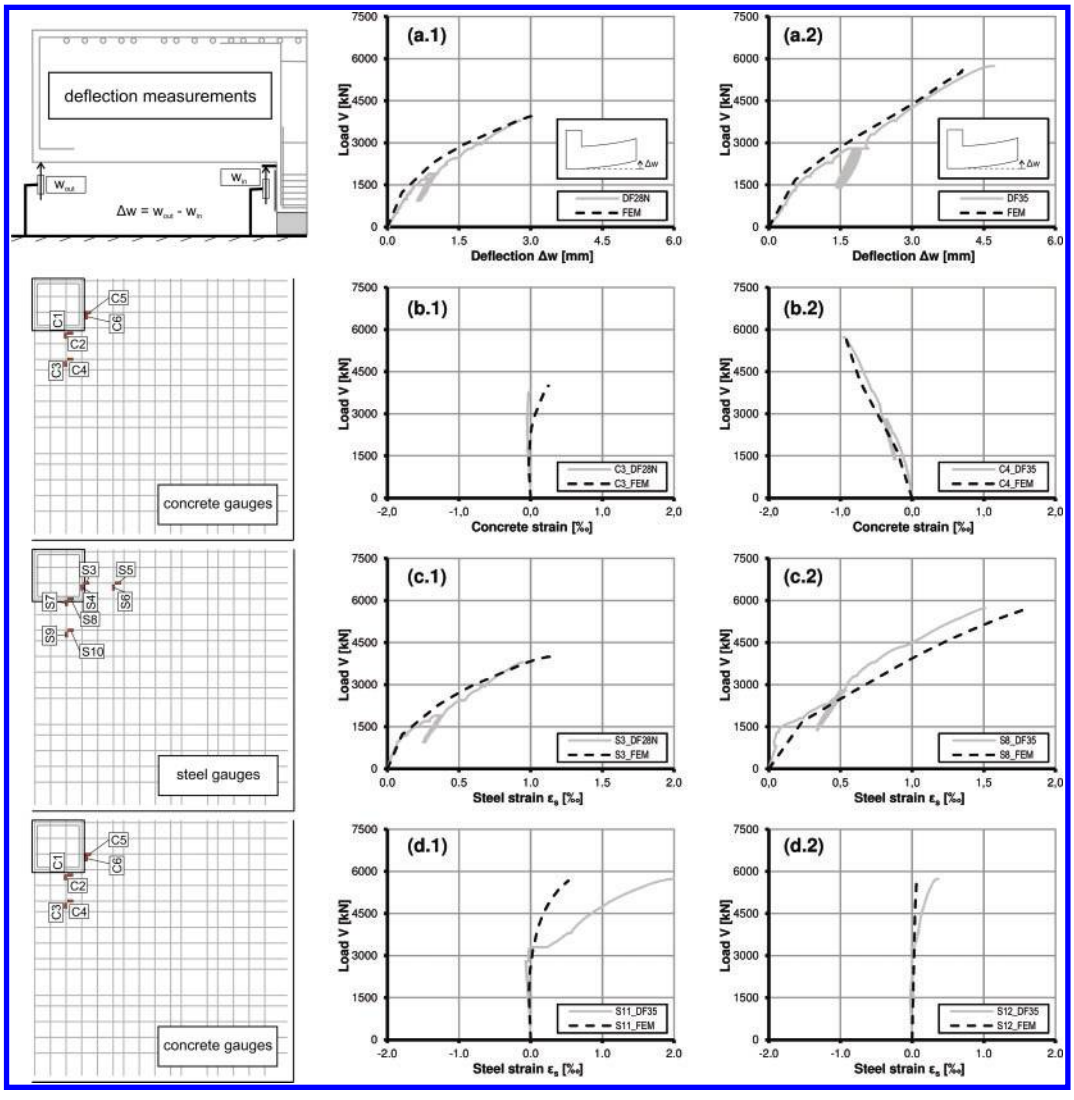

Figure 6. Representative load-deflection curves (a), concrete strains (b), strains of longitudinal reinforcement (c) and strains of vertical stirrups (d) of finite element model and test results for specimens DF28N and DF35.

not able to simulate discrete cracks, this bend cannot be reproduced.

3.3 *Parameter studies*

The validation of the computational model shows, that the punching behavior of thick footings can be simulated appropriately with the applies material models. Thus, the validated model can be used for further investigations.

In a first step, the influences of size effects of the effective static depth, concrete compression strength and shear reinforcement were examined. Further investigations considering the longitudinal reinforcement ratio as well as the shear reinforcement arrangement, amount and diameter have not been completed yet.

3.3.1 *Influence of size effects of the effective static depth*

Figure 7(a) presents the results of a parameter study regarding size effects of the effective static depth. The failure load was converted into a shear stress along the critical circular cut according to Eurocode 2 with German annex (DIN EN 1992-1-1 + NA 2011). Considering all examined shear slendernesses ($a/d = 1,25 - 3,25$) the punching shear capacity decreases with increasing thickness of the specimens. The factor k (DIN EN 1992-1-1 + NA 2011) seems to slightly underestimate this size effect which confirms the results of the experimental investigations.

3.3.2 *Influence of concrete compression strength*

The influence of the concrete compression strength on the punching behavior of footings was investigated by

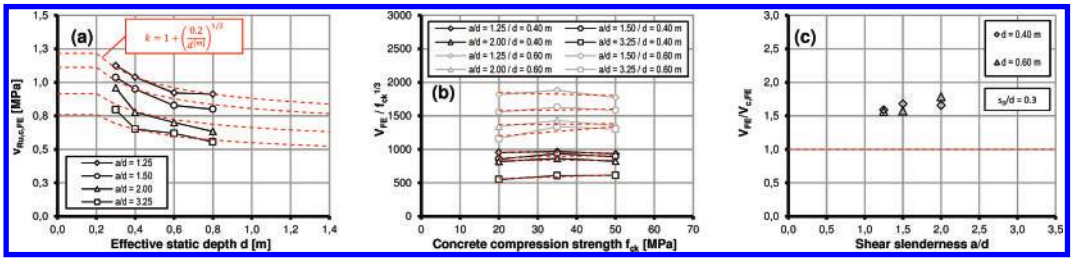

Figure 7. Influence of the effective static depth (a), concrete compression strength (b) and shear reinforcement (c) on punching shear capacity of footings according to numerical investigations.

further numerical calculations. For two effective static depths ($d = 0.40$ m and 0.60 m) concrete compression strengths between 20 and 50 MPa were examined. The results are given in Figure 7(b). As determined in the experimental investigations, the normalized test load $V_{\mathrm{Test}}/f_{\mathrm{ck}}^{1/3}$ shows a slight rise for increasing concrete compression strengths which seems to be negligible for habitual concrete strengths.

3.3.3 *Influence of shear reinforcement*

In analogy to the results of experimental investigations (Fig. 4(e)), Figure 7(c) shows the ratio of failure loads of specimens with and without shear reinforcement $V_{\mathrm{FE}}/V_{\mathrm{c,FE}}$ for different shear slendernesses. The distance s_0 between the first vertical stirrup and the column was set to $0{,}3d$. As already observed during the experimental investigations, shear reinforcement seems to be more effective with increasing slenderness.

4 CONCLUSIONS

Based on the experimental and numerical investigations the following findings can be summarized:

- The punching shear capacity is hardly influenced by the shear slenderness. Regardless of the longitudinal reinforcement ratio or concrete strength, the failure load decreases with increasing shear slenderness.
- For footings with different concrete compression strengths or longitudinal reinforcement ratios the observed effects are approximately equal to punching behavior of flat slabs.
- The influence of size effects of the effective static depth seems to be underestimated (according to DIN EN 1992-1-1 + NA 2011). This assumption should be verified through further investigations, especially with tests on thicker footings.
- The load-increase of footings with shear reinforcement is hardly influenced by the shear slenderness and increases for slender slabs.

ACKNOWLEDGEMENT

The tests and investigations presented were funded by the DFG (DFG-GZ HE 2637/11-2) to whom we express our sincere thanks.

Reliability of EN1992 crack model applied to South African water retaining structures

C.H. Mc Leod
University of KwaZulu-Natal, Durban, South Africa

J.V. Retief & J.A. Wium
University of Stellenbosch, Stellenbosch, South Africa

ABSTRACT: Development of a design code of practice for concrete water retaining structures (WRS) in South Africa is currently underway, along with the revision of the code of practice for reinforced concrete structures (SANS 10100). This paper discusses part of the research undertaken in the development of the proposed South African design code for WRS, namely, the subject of model uncertainty. Cracking due to loads and/or restrained deformations (such as shrinkage) under serviceability limit state (SLS) is usually the limiting condition for the design of water retaining structures. The basic crack model considered is that utilized by Eurocode EN1992-1-1 (2004) and EN1992-3 (2006). A reliability model for load-induced cracking to EN1992 is formulated using the First Order Reliability method and applied to typical South African WRS. The modelling and influence of model uncertainty applied to the EN1992 crack model for load-induced cracking is investigated and discussed. It is found that model uncertainty has a significant effect on the reliability model for cracking.

1 INTRODUCTION

The South African civil engineering industry currently uses the British code of practice, BS8007 (1989) in the design and construction of reinforced concrete water retaining structures (WRS). With the introduction of the Eurocodes and subsequent withdrawal of the British design codes, there is a need for a design code of practice relevant to South African reinforced concrete WRS (which will be the proposed SANS10100-3). In updating the related South African design code for reinforced concrete buildings, there is a move towards adopting the corresponding Eurocode. With regard to WRS, the relevant Eurocode is EN1992-3 (2004) which is read in conjunction with EN1992-1-1 (2004). Serviceability limit state cracking tends to be the limiting state in the design of WRS, rather than ultimate limit state loading. A reliability analysis was thus performed to assess the reliability of the EN1992 crack model applied to South African conditions. The study focused on load-induced cracking due to direct tension and pure bending. Indirect evidence suggested that model uncertainty was influential in concrete cracking. The reliability analysis was used to determine if this indeed was the case and thus warranting further investigation.

2 RELIABILITY MODEL

The reliability analysis of the EN1992 crack model was performed using the First Order Reliability Method (FORM). The FORM algorithm is well documented as given in, for example, Ang & Tang(1990), so is not repeated here. The analyses included a sensitivity analysis from which the influence of the model variables could be assessed. Theoretical partial safety factors for the model variables were also determined. A reliability calibration exercise was then performed using known combinations of partial safety factors and reliability level, and constituted the first step in ultimately identifying a set of factors that would ensure sufficient reliability across the range of concrete cracking applications. The analyses were performed using Microsoft EXCEL.

2.1 *EN1992 crack model*

Serviceability cracking is deemed to be controlled by meeting a specified crack width limit for a given structural configuration and reinforcement. The EN1992 crack model is based on the compatibility relationship (as given in Narayan *et al* (2005)):

$$w = S_r \,.\, \varepsilon_m \tag{1}$$

where w is the crack width, S_r is the crack spacing and ε_m is the mean strain. The crack spacing is determined from:

$$S_r = 2c + 0.25\, k_1 k_2 \varphi \,/\rho_{p,eff} \tag{2}$$

where c is the concrete cover, φ is bar diameter and $\rho_{p,eff}$ is the effective reinforcement ratio. The coefficients k_1 and k_2 take into account the bond properties

of the reinforcement and distribution of strain, respectively. The values of these coefficients are:

k_1 0.8 (high tensile reinforcement)
k_2 0.5 (bending stress) or 1.0 (tension stress)

The effective reinforcement ratio is the ratio between the area of reinforcement, A_s and the effective area of the concrete zone in tension, $A_{c,eff}$. The concrete tension zone is calculated using $b.h_{c,eff}$ where b is the section width and $h_{c,eff}$ is the effective depth of the concrete tension zone. The latter is the lesser of *h/2, 2.5(h − d)* or *(h − x)/3* where h is the section thickness, d is the effective depth of section and x is the depth of the neutral axis, c is concrete cover. The equation *2.5(h − d)* may be expressed as *2.5(c + φ/2)* where φ is bar diameter.

The mean strain is determined using:

$$\varepsilon_{sm} - \varepsilon_{cm} = \left[\sigma_s - k_t \frac{f_{ct,eff}}{\rho_{p,eff}} \left(1 - \alpha_e \rho_{p,eff}\right)\right] / E_s \qquad (3)$$

where σ_s is the steel strain, k_t is a coefficient dependent on the duration of load, $f_{ct,eff}$ is the effective concrete tensile strength, α_e is the modular ratio and E_s is the steel modulus. The coefficient k_t has a value of 0.4 for long-term loading.

2.2 *Representative structural configuration of WRS*

Possible worst cases of cracking due to tension and flexural loading were investigated to determine the associated structural configuration. The following load cases were established:

2.2.1 *Flexural load case*

Consider a 1 m length ofa 5 m high wall in a rectangular reservoir subject to a liquid load only, deemed to be a permanent load as defined by SANS10160 (2011). The wall acts as a vertical cantilever and will therefore be subject to flexure about a horizontal axis. The liquid load, L, is γ_w. H where γ_w is the density of water and H is the depth of water taken as equal to the height of the wall. The maximum bending moment, M, occurs at the base of the wall, such that $M = L.H^2/6$.

2.2.2 *Tension load case*

Consider the wal lwith a sliding base in a circular reservoir of diameter (D) 28 m, subject to a liquid load only such that the wall is subject to hoop stress in the horizontal plane only. The resulting tensile force, T, on the wall is L D/2.

2.3 *Performance functions*

The performance function, g(X), of the sensitivity FORM analysis using the EN1992 crack model may be written as:

$$g(X) = w_{lim} - \theta\, w \qquad (4)$$

where w_{lim} is the limiting crack width, θ is model uncertainty and w is the calculated crack width using equation (1), which in turn is expressed in terms of the model basic variables (discussed in Section 2.5). Model uncertainty is modelled as a random variable and is discussed further in Sections 2.5 and 2.7.

The performance function for the reliability calibration exercise may be defined as follows:

$$g(X) = \theta.w(X) - w_d(X_k, \gamma_x) \qquad (5)$$

where $w(X)$ is the random crack width and $w_d(X_k, \gamma_x)$ is the design crack width. The theoretical partial safety factors, γ_i, applied design values of the model basic variables, X_k, are calculated using [define x*]:

$$\gamma_x = \frac{x^*}{\mu_x} \qquad (6)$$

where x* is the theoretical design value of the variable and μ_x is its mean value. Both the random and the design crack widths are determined using the compatibility relationship expressed in equation (1).

2.4 *Level of reliability*

The level of reliability for serviceability has generally not been well-researched, as emphasis is normally placed on the ultimate limit state as this is usually the limiting state in the design of buildings. However, in WRS serviceability is dominant. SANS2394 (2004) gives some guidance on an appropriate level of reliability, recommending a reliability index, β, of 1.5 for irreversible serviceability limit states such as cracking and 0 for reversible serviceability limit states, for a reference period of 50 years. Therefore, in this research, a reference level of 1.5 is used for β. Given the importance of serviceability cracking in WRS, analyses were performed using β of 0.5 and 2.0 (as a reasonable upper limit for SLS), enabling the effect of reliability on the model to be assessed.

2.5 *Parameters of model*

Once the performance function was defined, statistical data for the model parameters was gathered. Sources such as the JCSS (2001) and Holicky (2001) were consulted. A summary of the data for the model basic variables is given in Table 1.

Referring to Table 1, the basic variables of the reliability crack model were found to be concrete cover

Table 1. Crack model basic variables.

Variable	Unit	pdf	Nominal Value	Mean	Std Dev.
Concrete tensile strength	MPa	LN	2.00	2.89	0.55
Liquid load	kN/m^2	N	49.05	49.05	2.45
Concrete cover	mm	LN	40	40	6
Section thickness	mm	N	450	450	4.5
			250	250	2.5
Model uncertainty	–	LN	1	1	0.2

Note: LN = log-normal pdf, N = normal pdf.

(c), section thickness (h), liquid load (L), effective concrete strength ($f_{ct,eff}$) and model uncertainty (θ).

All other parameters in the model were considered as deterministic. Analyses were performed using a reinforcement bar diameter of 20 mm over a range of reinforcement areas. A steel modulus of 200 GPa and an effective concrete modulus (long term) of 13.7 GPa were used. All values were chosen assuming good construction and management practice.

2.6 *Limiting crack width*

The limited crack width specified by EN1992 depends on the tightness class of section defined by the acceptable amount of leakage through a section. For a Tightness class 2, with cracks going through the section, a general crack width limit of 0.2 mm is recommended. This limit decreases to 0.05 mm depending on the hydraulic ratio, h_D/h where h_D is the depth of water and h is the section thickness. At a 0.2 mm crack width limit, h_D/h is 5,increasing to 35 at a crack width limit of 0.05 mm. Reliability analyses were performed for crack widths of 0.2 mm, 0.1 mm and 0.05 mm.

2.7 *Model uncertainty*

Model uncertainty in the reliability crack model needed to be quantified as much as possible. First, the sources of uncertainty in the model needed to be defined. In general terms, two main types of uncertainty can be defined, namely, inherent random variability and uncertainty due to incomplete knowledge including statistical uncertainty, as defined in literature, for example, Ang & Tang (1990) and the Joint Committee on Structural Safety (JCSS) (2001).

Uncertainty due to random variability is generally dealt with by means of the coefficients of variation of the random variables of the reliability model. Uncertainty also exists due to mathematical simplifications of physical and probabilistic models. In the case of the EN1992 crack model, simplications due to the formulation of the physical crack model from experimental research, such as in using fixed-value coefficients to allow for the effects of reinforcement bond, duration of loading and type of stress distribution. Uncertainty exists in the stochastic model on normalizing non-normal distributions and in the first order approximation of using FORM for the mathematical solution of the failure probability integral.

For the reliability crack model, model uncertainty is allowed for by treating it as a random variable, as is commonly accepted, having a log-normal distribution. On reviewing literature on model uncertainty relating to concrete cracking, it was found that there is a lack of data in this regard. However, Holicky & Retief (2009) presented a reliability model of tension cracking using the EN1992 crack model. Model uncertainty was treated as a random variable with a log-normal distribution having a mean of 1 and coefficient of variation of 0.1. Quan & Gengwei (2002) also treated model uncertainty as a random variable with a log-normal distribution having a mean of 1.05 and coefficient of variation of 0.3.

In this study, model uncertainty was treated as a random variable having a log-normal distribution with a mean of 1. Given that the model uncertainty is not really known in this case, values of 0.1 to 0.3 were chosen as upper and lower limits for the coefficient of variation, with the value of 0.2 to represent a best estimate value. In this way, the effect of model uncertainty on the reliability crack model could be investigated.

3 RESULTS

Results concerning the influence of model uncertainty on the crack model are presented for both tension and flexural cracking.

It was found that in the tension cracking model, the limiting equation for the effective depth of the concrete tension zone, $h_{c,eff}$, was determined by the section geometry chosen, specifically, bar diameter, concrete cover and section thickness. The equation $2.5(c + \varphi/2)$ tends to be limiting. However, particularly for smaller section thicknesses, either both $2.5(c + \varphi/2)$ and h/2 apply (giving the same numerical answer for the physical model), or h/2 only is limiting. Therefore two reliability models were set up for the tension cracking case.

The reverse-FORM analysis was performed over a range of 0.1 to 0.3 for the model uncertainty variation, V_θ. Crack widths of 0.2, 0.1 and 0.05 mm were chosen. Analyses were done for reliability indexes, β, of 0.5, 1.5 and 2.0.

3.1 *Sensitivity analysis*

A reverse-Form analysis was done such that the sensitivity factors, α_i, of the model basic variables were determined for a given level of reliability. The sensitivity factors give an indication of the relative influence of a particular variable on the reliability model. Results are discussed for each of the three reliability models as follows:

Flexural cracking

Table 2 is a summary of the results of the sensitivity factors obtained for model uncertainty in the case of flexural cracking.

The sensitivity factors for model uncertainty, α_θ, indicated that the influence of this variable depended mainly on the variation chosen and on the limiting crack width. In the case of flexural cracking, the influence of model uncertainty increases as V_θ increases and as the crack width limit decreases. The sensitivity factors indicate that model uncertainty has a small influence at a V_θ of 0.1. Model uncertainty becomes more influential at a V_θ of 0.3. The influence of model uncertainty was found to increase as reliability was increased.

Comparing model uncertainty to the remaining flexural model basic variables, liquid load was found to dominate with sensitivity factors of nearly -1.0.

Table 2. Flexural cracking – sensitivity factors for model uncertainty, α_θ.

		Sensitivity factor, α_θ		
		Crack width limit, w_{lim}(mm)		
β	V_θ	0.2	0.1	0.05
0.5	0.1	−0.085	−0.114	−0.151
	0.2	−0.167	−0.223	−0.292
	0.3	−0.248	−0.324	−0.416
1.5	0.1	−0.095	−0.127	−0.170
	0.2	−0.188	−0.251	−0.321
	0.3	−0.280	−0.370	−0.474
2.0	0.1	−0.099	−0.134	−0.180
	0.2	−0.199	−0.267	−0.352
	0.3	−0.298	−0.396	−0.505

Table 3. Tension cracking – $h_{c,eff} = 2.5(c + \varphi/2)$: Sensitivity factors for model uncertainty α_θ.

		Sensitivity factor, α_θ		
		Crack width limit, w_{lim}(mm)		
β	V_θ	0.2	0.1	0.05
0.5	0.1	−0.318	−0.298	−0.270
	0.2	−0.555	−0.528	−0.486
	0.3	−0.706	−0.679	−0.638
1.5	0.1	−0.324	−0.308	−0.284
	0.2	−0.561	−0.537	−0.501
	0.3	−0.708	−0.683	−0.645
2.0	0.1	−0.326	−0.311	−0.289
	0.2	−0.563	−0.540	−0.506
	0.3	−0.708	−0.683	−0.646

Section thickness was found to have a neglible influence with sensitivity factors approaching 0. Concrete cover has a neglible to small influence with factors from about −0.04 to −0.16, as the model uncertainty variation and β increased, and the limiting crack width decreased. The effective concrete tensile strength has similar values to concrete cover, namely, about 0.06 to 0.13, but is a positive influence on the model.

Tension cracking – $h_{c,eff} = 2.5(c + \varphi/2)$

A summary of the model uncertainty sensitivity factors for tension cracking with $hc,eff = 2.5(c + \varphi/2)$ is given in Table 3. The influence of model uncertainty in the case of tension cracking with $h_{c,eff} = 2.5(c + \varphi/2)$ increases by a factor of about 2.2 as V_θ increases. There is a small decrease in the sensitivity factors as the crack width limit decreases. Model uncertainty was not found to be sensitive to a changing level of reliability, as there was only a marginal increase in the sensitivity factors as β increased.

Comparing model uncertainty to the remaining basic variables of this tension model, the dominant variable depends on the value of V_θ. At the lower value of 0.1, the effective concrete tensile strength and concrete cover are the dominant variables with sensitivity factors of about 0.6 and 0.7, respectively.

As V_θ increases to 0.3, model uncertainty is dominant with sensitivity factors of about −0.6. The effective concrete tensile strength and concrete cover sensitivity factors are about | 0.5 |. Liquid load has a small influence,having sensitivity factors of about −0.23 to −0.30. Section thickness obviously has no influence as it does not appear in the crack width equation for this tension cracking model.

Table 4. Tension cracking – $hc,eff = h/2$: Sensitivity factors for model uncertainty, α_θ.

		Sensitivity factor, α_θ		
		Crack width limit, w_{lim}(mm)		
β	V_θ	0.2	0.1	0.05

Tension cracking – $h_{c,eff} = h/2$

Table 4 summarises the sensitivity factors obtained for tension cracking with $h_{c,eff} = h/2$.

The sensitivity factors indicate that model uncertainty is more influential in tension cracking with $h_{c,eff}$ of h/2 limiting, particularly at lower V_θ. This influence increases as V_θ increases. The crack width limit is a lesser influence on model uncertainty.

Comparing model uncertainty to the remaining basic variables, section thickness has a neglible influence and concrete cover has a very small influence with sensitivity factors of about −0.14. Liquid load has a small influence (sensitivity factors of about −0.33). Sensitivity factors for the effective concrete tensile strength are in the order of 0.54. Model uncertainty is the most influential variable for this case of tension cracking.

3.2 *Theoretical partial safety factors*

The theoretical partial safety factors, γ_i, as determined using Equation (6) were determined for the basic variables of the flexural and tension cracking models. Results at β of 1.5 are discussed for each of the three reliability models as follows:

Flexural cracking

Table 5 gives the γ_i determined for flexural cracking and shows that although the sensitivity factors indicated that load was the dominant variable, model

Table 5. Flexural cracking – partial safety factors.

Theoretical partial safety factors						
Crack width limit (mm)	V_θ	γ_c	γ_h	γ_L	γ_{ft}	γ_θ
0.05	0.1	1.02	1.00	1.07	0.95	1.02
0.05	0.2	1.02	1.00	1.07	0.95	1.08
0.05	0.3	1.02	1.00	1.07	0.95	1.18
0.20	0.1	1.00	1.00	1.07	0.97	1.01
0.20	0.2	1.00	1.00	1.07	0.97	1.04
0.20	0.3	1.00	1.00	1.07	0.97	1.08

Table 6. Tension cracking – partial safety factors.

Theoretical partial safety factors						
Crack width limit (mm)	V_θ	γ_c	γ_h	γ_L	γ_{ft}	γ_θ
Tension cracking – hc,eff = 2.5(c + φ/2)						
0.05	0.1	1.15	–	1.02	0.82	1.04
0.05	0.2	1.14	–	1.02	0.84	1.14
0.05	0.3	1.11	–	1.02	0.85	1.28
0.20	0.1	1.16	–	1.02	0.84	1.05
0.20	0.2	1.14	–	1.02	0.86	1.16
0.20	0.3	1.11	–	1.02	0.87	1.32
Tension cracking – hc,eff = h/2						
0.05	0.1	1.05	1.00	1.03	0.79	1.06
0.05	0.2	1.04	1.00	1.02	0.82	1.20
0.05	0.3	1.03	1.00	1.02	0.84	1.34
0.20	0.1	1.03	1.00	1.03	0.81	1.08
0.20	0.2	1.02	1.00	1.02	0.84	1.23
0.20	0.3	1.01	1.00	1.02	0.87	1.41

uncertainty requires the higher partial factor, particularly as the model uncertainty variation increases. The partial safety factors for model uncertainty also increase as the limiting crack width decreases.

Tension cracking

Table 6 is a summary of the γ_i determined for tension cracking using both formulation for $h_{c,eff}$. Model uncertainty factors (γ_θ) were found to depend on the model uncertainty variation, increasing as the variation increases as would be expected. The limiting crack width does not appear to significantly influence γ_θ. Concrete cover has varying influence depending on the limiting equation for $h_{c,eff}$. Section thickness and liquid load have partial safety factors of about 1.0 therefore can be modelled as deterministic.

3.3 *Reliability calibration*

Several sets of partial safety factors were chosen from the theoretical factors derived from the reverse-FORM analysis and a reliability calibration exercise was performed, such that γ_θ was calculated using fixed values

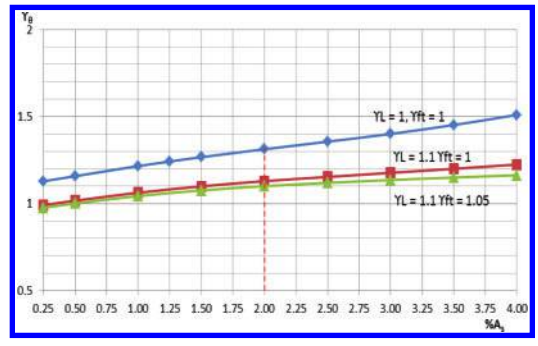

Figure 1. Variation of γ_θ with %A_s for β 1.5 and V_θ 0.2 for flexural cracking.

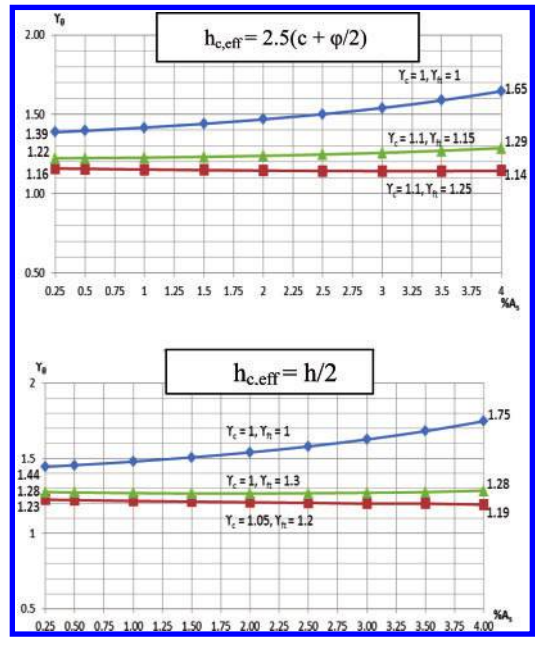

Figure 2. Variation of γ_θ with reinforcement area as %A_s for β 1.5 and V_θ0.2 for tension cracking.

for the other variable partial safety factors and different V_θ. Results are summarised as follows:

Flexural cracking

Referring to Figure 1, a reasonable value for model uncertainty γ_θ is about 1.2 using partial safety factors of 1.1 and 1.0 for load and the effective concrete tensile strength.

All other variables have partial safety factors of 1.0. If factors of 1.0 are used for all safety factors, then γ_θ is dependent on the reinforcement area (as %A_s). Values for γ_θ are also higher in this instance for a given %A_s.

Tension cracking

From Figure 2, for tension cracking with $h_{c,eff} = 2.5$ $(c + \varphi/2)$, γ_θ is independent of the reinforcement area and has a value of about 1.16, if factors of 1.1 and

1.25 are used for concrete cover and effective concrete tensile strength, respectively.

For $h_{c,eff} = h/2$ limiting, γ_θ is independent of the reinforcement area and has a value of about 1.28 if factors of 1.0 and 1.3 are used for concrete cover and effective concrete tensile strength, respectively. If values of 1.0 are used in both tension models, then as with flexural cracking, γ_θ values are significantly higher.

Comparing the three crack models, difficulty arises in choosing a single realistic design scheme that could be applied to all load cases without introducing undue conservatism into the design model, In addition, each model has different variables which have partial safety factors potentially greater than 1.0. If all variables except γ_θ are 1.0, then at a 4% A_s, partial safety factors of 1.51, 1.65 and 1.75 are obtained for γ_θ for flexural cracking and tension cracking with $h_{c,eff} = 2.5(c + \varphi/2)$ and h/2, respectively, using V_θ of 0.2. Further research is required if a reasonable design scheme is to be developed.

4 SUMMARY

The parametric range of model factors used in this analysis is based on indirect considerations to cover the range of validated probabilistic representations. The reliability analysis confirms that model uncertainty has a significant influence on the EN1992 crack model when applied to South African conditions for loading-induced cracking. Further research is therefore justified.

Model uncertainty is more influential in tension cracking. Its influence increases as V_θ increases and w_{lim} decreases.

New design approach for crack width calculation in reinforced concrete structures

Hamdy A. Elgohary
Structural Engineering Department-Faculty of Engineering, Mansoura University – Mansoura, Egypt

Majid M. Assas
Civil Engineering Department-College of Engineering & Islamic Architecture, Umm al Qura University Makkah, KSA

ABSTRACT: Present paper provides a developed approach to improve the calculations of crack width in reinforced concrete cracking. A new relationships account for the effect of several important factors has been obtained. The considered factors are the strain in steel reinforcement at the cracked section, bond stress between steel and concrete, geometry of the cross section and properties of concrete and reinforcement, actual strain distribution in concrete along the axis of steel reinforcement, and, where appropriate, the effect of shear force. The results obtained using the recommended approach show good agreement with the experimental results.

1 INTROUDUCTION

At the present time, reinforced concrete is considered as the primary material in construction. Therefore the development of theory and methods for improving the calculation of reinforced concrete structures is one of the most important tasks of structural engineering science.

Reinforced concrete is a material in which cracks are developed by resistance of force and deformation. The process of crack formation and development is quite complex. Consequently, the accurate determination of the crack width is not a simple process.

Assessing the accumulated results of experimental studies on the crack width, it should be noted that, to date, little empirical data for the crack width and crack spacing calculation when checking multilevel process of their formation and the length of the crack as the load increases in the variation of reinforcement and concrete class.

The lack of theoretical justification and analysis of experimental data led in time to give preference to empirical methods of calculation, including the width of cracks, which requires a continuous time-consuming and costly experimentation.

It follows that research on the detailed study of the crack width of reinforced concrete structures subject to incompatibility strains of concrete and reinforcement material discontinuity is a topical problem.

2 CURRENT METHODS

Study of crack formation in reinforced concrete structures is devoted in a large number of researches and studies. Most of the known proposals for the calculation of the crack spacing and crack width can be divided into groups depending on the approach used to obtain the recommended relationships.

The first group includes all recommended empirical and semi-empirical formulas obtained on the basis of extensive experimental studies and taking into account the influence of various factors on the process of cracking. The experimental investigations showed that cracking is generally proportional to the tensile stress in steel and bar diameter and inversely proportional to reinforcement percentage. The fundamental equation for this group was developed by Gergely and Lutz. In their study they included 612 observations for bottom cracks and 355 observations for side cracks. The obtained formula has the form:

$$w_{cr} = [(11 \times 10^{-6})\beta f_{st}) \sqrt[3]{d_c(\frac{A_e}{n})} \quad (1)$$

where
d_c – thickness of concrete cover measured from the extreme tension fiber to the centre of the nearest bar
A_e – effective area of concrete in tension surrounding the main tension reinforcement,
n – number of bars in tension
f_{st} – stress in tension steel at its centroid
β – ratio of the distances to the neutral axis from the extreme tension fiber and from the centroid of reinforcement.

In equation (1) other important parameters were not considered. As it has been found in the experimental investigations these parameters are also important.

These parameters are: concrete quality, thickness of concrete cover, member thickness, bond strength and concrete tensile strength. Equation (1) was used in ACI up to 1995 and then replaced by a modified condition. The crack width calculation in Saudi Building Code follows the same provisions of ACI.

The second group is based on the premise of Murashov's theory. This theory states that the crack width is determined based on the condition: elongation in concrete tension zone along the axis of steel reinforcement plus crack width should be equal to the elongation of steel reinforcement in the segment between cracks. The basic equation of this group is used in EC-2 and ECC with the form:

$$w_{cr} = (\varepsilon_{sm} - \varepsilon_{ctm}).S_{cr} \quad (2)$$

The third group includes studies in which the crack width is considered as the accumulation of relative movement between reinforcement and concrete along the axis of the steel reinforcement in the segment between two consequent the cracks (Berg 1962). The crack width has the form:

$$w_{cr} = 2\int_0^{0.5S_r} \varepsilon_r(x).d(x) \quad (3)$$

Where
$\varepsilon_r(x)$ – relative strain between reinforcement and concrete along the axis of the steel reinforcement at x,
S_{cr} – spacing between the cracks.

Equation (3) has been assumed based on the assumption that the ε_r curve has a continuous parabolic profile.

3 PROPOSED METHOD

In the present paper the main idea of the third group will be used taking into consideration the relative strain distribution obtained experimentally. The basic assumptions are:

1. Relationship between bond stress and relative strain will have the form:
   $\tau(x) = G\varepsilon_r(x)$ (4)
   Where $G = 0.3E_c$
2. The strain distribution in concrete and steel reinforcement along the distance between two adjacent cracks will be used as shown in Fig. 1 (Bondarenko 2004).
3. Stress in the steel reinforcement at the cracked section is determined from the equilibrium conditions of the moments about the point of application of the resultant compressed concrete for the segment shown in Fig. 2

From Figure 1 the relative strain can be determined from the relationship

$$\varepsilon_r(x) = \varepsilon_s(x) - \varepsilon_{ct}(x) \quad (5)$$

Where $\varepsilon_s(x)$ and $\varepsilon_{ct}(x)$ – strain in steel reinforcement and concrete at distance x, respectively.

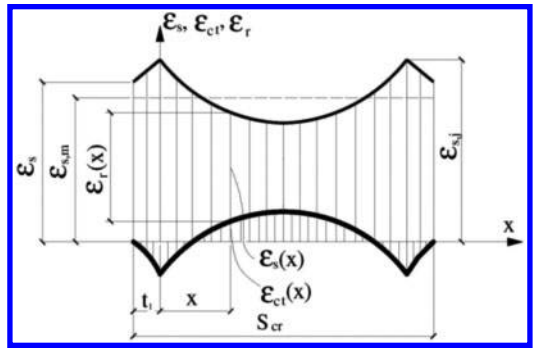

Figure 1. Experimental Strain Distribution in Steel and Concrete along segment between cracks.

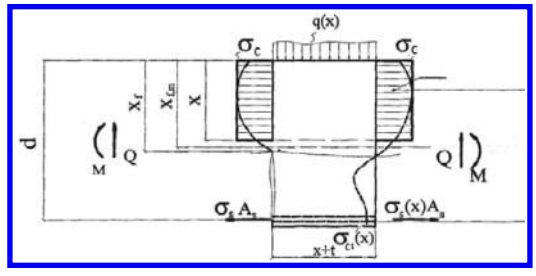

Figure 2. Stress Distribution at cracked Section and Section between cracks.

Steel strain at distance $t_1 + x$ from the crack will have the form

$$\varepsilon_s(x) = \varepsilon_s + \frac{\Delta T}{E_s A_s} + \frac{S_s}{E_s A_s}\int_0^x \tau(x)dx \quad (6)$$

Where $\tau(x)$ – the conventional shear stress

Concrete strain $\varepsilon_{ct}(x)$ can be determined from the equilibrium conditions of the segment of length $(t_1 + x)$ located between the cracked and uncracked sections shown in Figure 2.

$$\varepsilon_{ct}(x) = \delta\,\frac{\varepsilon_s E_s A_s Z_s - \varepsilon_s(x) E_s A_s Z_s(x) - Q(t_1+x)}{0.5A_{ct}(x).E_c Z_{ct}(x)} \quad (7)$$

Where $\delta = \frac{d-x}{h-x}$

Differentiating equation (5):

$$\frac{d\varepsilon_r(x)}{dx} + B\varepsilon_r(x) = \frac{\delta}{t}Q \quad (8)$$

Where $t = 0.5A_{ct}(x).E_c Z_{ct}(x)$ and B-parameter of bond between steel and concrete, depending on the perimeter of reinforcing bars, bond modulus, parameter K and the area of steel and the elastic modulus reinforcing steel and has the form

$$B = \frac{S_S.G}{K.A_S.E_S} \quad (9)$$

Where
S_s – perimeter of tension steel
A_s – tension steel area
E_s – modulus of elasticity of steel

$$K = \frac{1}{1+\beta} \quad \text{and} \quad \beta = \frac{\delta.\mu.\frac{E_s}{E_c}.Z.d}{0.32(h-X).(h+.03X)}$$

The solution of the nonhomogeneous first order differential equation (8) is:

$$\varepsilon_r(x) = C.e^{-Bx} + \frac{\delta.Q}{t.B} \tag{10}$$

The integration constant C can be found from the boundary conditions at $x = 0$, $\varepsilon_{ct}(x) = \frac{\partial_{ct}}{\nu_c E_c}$

$$C = \varepsilon_s + \frac{\Delta T}{A_s E_s} - \frac{б_{ct}}{\nu_c E_c} - \frac{\delta.Q}{t.B} \tag{11}$$

$t_1 = 1.5$ bar diameter (d), $\Delta T = 0.5.(\pi.d.t_c.f_c), t_c = 2d$

Using the condition the strain in concrete at the midpoint between two adjacent cracks will equal the ultimate value thus $\varepsilon_{ct}(0.5x - t_1) = \varepsilon_{ctu}$ and integrating for $\varepsilon_{ct}(x)$, the following relation for strain distribution in concrete along the reinforcement axis can be obtained:

$$\varepsilon_{ct}(x) = (1-K)\left\{C(1-e^{-Bx}) + \frac{\delta Q}{t}\right\} - \frac{б_{ct}}{\nu_c E_c} - \frac{\delta Q}{t}x \tag{12}$$

Or

$$-e^{-B(0.5S_{cr}-t_1)} = 1 + \frac{\varepsilon_{ctu}}{C.(K-1)} + \frac{б_{ct}}{C.\nu_c E_c.(K-1)} = C_1$$

On other hands

$$\ln C_1 = -B(0.5\,S_{cr} - t_1)$$

The crack width then will have the form

$$S_{cr} = \frac{2(B.t_1 - \ln C_1)}{B} \tag{13}$$

Crack spacing is the most important parameter required for crack width determination in concrete structures. Depending on loading level, several levels of cracking development up to failure will take place in concrete members under bending. Accordingly, the development of a new level of cracking corresponds to the load, satisfying the following condition

$$S_{cr,i} \le 0.5\,S_{cr,i-1} \tag{14}$$

Integration relative strain in both concrete and reinforcement leads to the following form for the crack width:

$$w_{cr} = 2\left\{\int_0^{t_1} \varepsilon_r(x)dx + \int_{t_1}^{0.5S_{cr}-t_1} \varepsilon_r(x)dx\right\}$$

After integration, we get:

$$w_{cr} = -\frac{2\Delta T}{G} + \frac{2C}{B}\left(1 - e^{-B(0.5S_{cr}-t_1)}\right) + 2\frac{\delta Q}{t.B}(0.5S_{cr} - t_1) \tag{15}$$

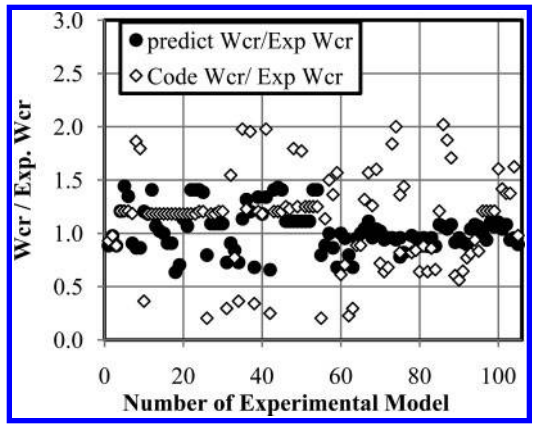

Figure 3. Comparison of Proposed Method Formula, EC-2 Equation and Experimental Results.

The obtained equations (13) and (15) account for the effect of several important factors, such as deformation of reinforcement in the section with a crack in the valve coupling parameters with concrete, and the geometric characteristics of the cross-section properties of concrete and reinforcement, deformation effects (occurring in concrete elements after violation continuity), the relative conditional focused mutual displacements of concrete and reinforcement, and, where appropriate, the effect of shear force Q.

4 VERIFICATION OF RESULTS

The recommended approach for determining the crack width is verified against experimental results to judge how the recommended approach can be applied for design practice. The test results obtained by (Ghattas 1994), (Korytnyuk 1974), (Maureen 1974) and (Shavykin 2009) we considered with total number of test samples 105. The crack width for all samples has been calculated using the recommended approach and by equation (15) and by EC equation. The relative crack width (predicted/experimental) calculated by the proposed equation and by EC-2 equations is shown in Figure 3. The results obtained by the proposed approach give average value of the relative crack width of 1.03, while EC-2 results give 1.13. This proofs that, unlike basic equation for all codes, the proposed method gives results with good agreement with the test results.

Multi-functional fiber reinforced concrete for sustainable structures

N. Banthia
University of British Columbia,Vancouver, British Columbia, Canada

ABSTRACT: Civil infrastructure around the world is in a state of utter disrepair and significant efforts are needed on the part of all stakeholders to render our failing infrastructure back to a serviceable and safe state. The root of the problem is at the apparent lack of durability in our construction materials, inability on part of the owners to provide timely maintenance, absence of advanced condition assessment tools and lack of long-lasting, cost effective repair materials and technologies. This paper will present data to support the argument that fiber reinforced concrete (FRC) is an ideal material for achieving these goals. The paper also discusses smart fiber reinforced concrete materials carrying carbon fibers and carbon nano-tubes that possess sensing abilities. These materials can help us develop intelligent infrastructure with elegantly integrated sensing and health monitoring abilities.

1 INTRODUCTION

Compared to other building materials such as metals and polymers, concrete is significantly more brittle and exhibits a poor tensile strength. Concrete carries flaws and micro-cracks both in the material and at the interfaces even before an external load is applied. These defects and micro-cracks emanate from excess water, bleeding, plastic settlement, thermal and shrinkage strains and stress concentrations imposed by external restraints. Under an applied load, distributed micro-cracks propagate, coalesce and align themselves to produce macro-cracks. When loads are further increased, conditions of critical crack growth are attained at the tips of the macro-cracks and unstable and catastrophic failure is precipitated. Under fatigue loads, concrete cracks easily, and cracks create easy access routes for deleterious agents leading to early saturation, freeze-thaw damage, scaling, discoloration and steel corrosion.

The micro and macro-fracturing processes described above can be favourably modified by adding short, randomly distributed fibers of various suitable materials. Fibers not only suppress the formation of cracks, but also abate their propagation and growth. The resulting material termed fiber reinforced concrete (FRC) is rapidly becoming a well-accepted mainstream construction material. Strain-softening characteristics that were typically obtained in these materials have now been replaced by strain-hardening capabilities in tension as demonstrated in Figure 1.

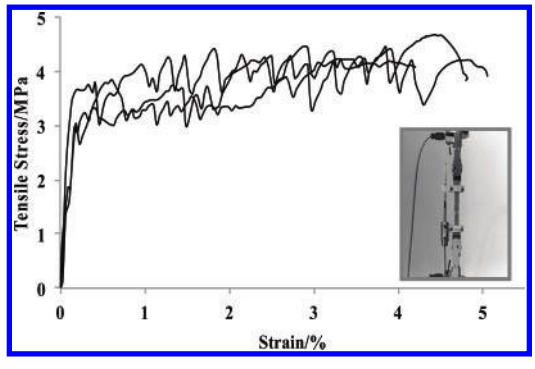

Figure 1. Strain Hardening Capabilities in High Performance FRC.

2 FIBER REINFORCED CONCRETE FOR DURABILITY

2.1 *Permeability under stress*

The decreasing life span of concrete structures is primarily due to corrosion of steel in reinforced concrete structures. Chloride penetration and carbonation are the primary reasons for such corrosion and any measures aimed at mitigating the ingress of chlorides or CO_2 into the body of concrete are expected to significantly enhance the durability of concrete structures. These deleterious agents enter the body of concrete through one of the three transport mechanisms: diffusion, capillary sorption and permeability—of

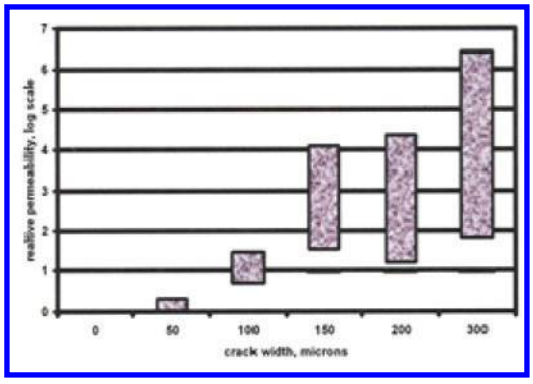

Figure 2. Effect of Crack Width on Permeability, Bentur [1].

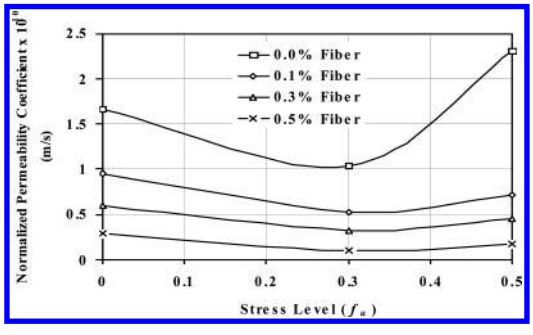

Figure 3. Normalized Permeability Coefficients [2,3].

these, the permeability is considered as the dominant mechanism. Any measures adopted to reduce permeability of concrete will therefore help in preserving durability. Results have indicated that permeability, in turn, is highly dependent upon cracking in concrete and an increase in the crack width will not only produce a highly permeable concrete (Figure 2) but also enhance the possibility of rebar corrosion Bentur [1].

Fiber reinforcement is the most effective way of controlling cracking and hence of permeability under stress. Indeed, tests conducted at the University of British Columbia [2] & [3] demonstrated such benefits. The results for cellulose fiber are shown in Figure 3. Notice that under conditions of no-stress, fibers reduce the permeability of concrete, and the reduction appears to be proportional to the fiber volume fraction. This is often explained on the basis of internal curing that occurs due to hydrophilic cellulose fiber. Data further indicate that stress has a significant influence on the permeability of concrete. When stress was first increased to $0.3f_u$, both plain and FRC showed a decrease in the permeability. However, when the stress was increased to 0.5fu, plain and FRC showed very different trends. At $0.5f_u$, the permeability of plain concrete increased substantially over that of the unstressed specimen, but for FRC, while there was an increase in the permeability over $0.3f_u$, the permeability still stayed below that of the unstressed specimen.

The above observations can be related to cracking. At $0.3f_u$, it is conceivable that in both plain and FRC, there is no discernible cracking that can affect the flow of water. However, at $0.5f_u$, the stress-strain response for both plain and FRC would become non-linear indicating the presence of cracking.

As given by the Poiseuille Law, Edvardsen [4], the flow of water through cracks is proportional to the cube of the crack width. In the case of FRC, one can expect the fibers to suppress cracking and hence maintain the rate of flow similar to an unstressed specimen. When combined with the phenomenon of 'pore compression', this implies that the permeability of FRC under stress can in fact be lower than that of an unstressed specimen.

2.2 *Diffusion control with fibers*

Chloride induced corrosion of reinforcing steel in concrete remains the most serious durability concern of our time. Need exists therefore to control transport mechanisms that allow an ingress of chlorides into concrete. Earlier studies have shown that fiber reinforcement of concrete reduces its permeability to water both with and without an applied stress. However, if fiber reinforcement also reduces diffusion of chlorides, is not known. Fiber reinforcement of concrete is known to reduce both environmentally-initiated and load-induced cracking and alter the transport properties, but a direct evidence of fibers mitigating rebar corrosion is lacking.

Sappakittipakorn and Banthia [5,6] performed Bulk Diffusion Tests as per ASTM C 1556 [7] and supplemented them by the Silver Nitrate Spray Tests on fiber reinforced concrete. By fitting the solution of Fick's second law to the results of the chloride profiles, the apparent and effective chloride diffusion coefficients were determined corresponding to the total and free chloride profiles, respectively. Their results are given in Figure 4.

Notice that the apparent diffusion coefficients are higher in the FRC samples possibly because of an increase of the volume of interfacial porosity at fiber-matrix interfaces that provided easier paths for chloride to transport. In the case of cellulose fibers, the hydrophilic nature of the fiber and the internal moisture entrapment most likely caused the upsurge. However, the effective diffusion coefficients are lower in the FRC as a consequence of the chloride binding effect. This ability of fibers to bind chlorides is an extremely useful property in combatting corrosion as was further demonstrated in tests described below.

2.3 *Corrosion control with fibers*

Sappakittipakorn and Banthia [5,6] designed tests to study the effect of fibers on the initiation of corrosion of reinforcing steel in concrete beams. Beams, 100 mm × 100 mm × 350 mm, were reinforced with three #10 carbon steel rebars similar to the specimen in ASTM G 109. One of the bars (working electrode)

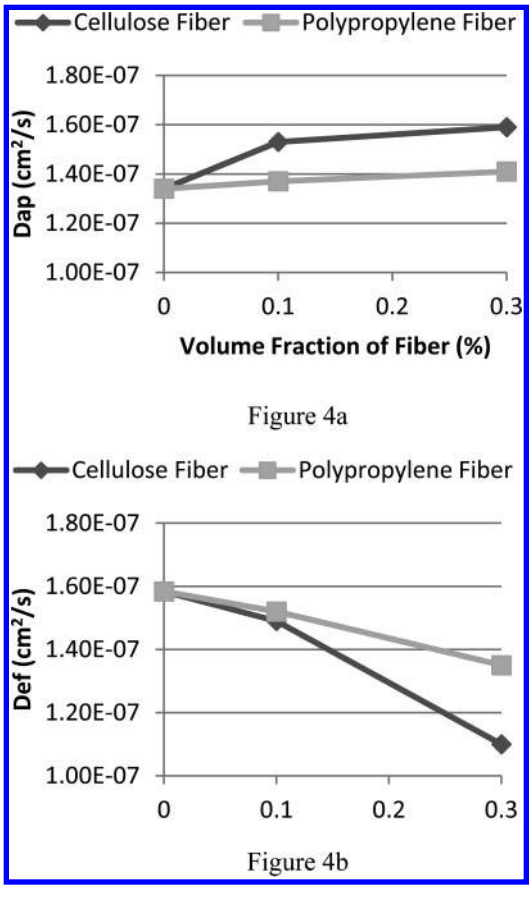

Figure 4. Apparent (a) and Effective (b) Coefficients of Chloride Diffusion for Various Volume Fractions of Fibers.

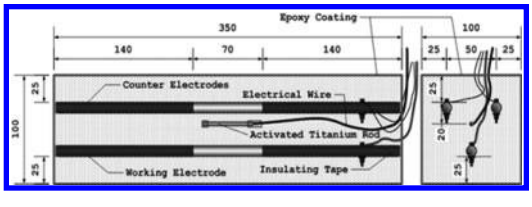

Figure 5. Schematic of a Specimen for Corrosion Control Tests; all dimensions are in millimeter.

was put in a tension zone and was corrosion monitored during the experiment. The other two were in a compression zone and were used as auxiliary electrodes. All of the bars were covered with a rubber paint at a distance of 140 mm from both ends so that the corrosion could take place only within the middle 70 mm of the bars. The concrete cover was uniform at 25 mm. The bars were electrically connected to wires for corrosion measurements. Each beam was coated with epoxy on all sides except for the side at the bottom, which was stressed in tension and exposed to chloride solution. A schematic of the beam specimens is shown in Figure 5.

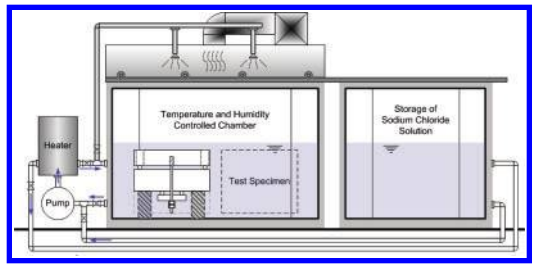

Figure 6. Chamber for Corrosion Tests.

Table 1. Time to Onset of Corrosion.

	Time to Corrosion Onset (weeks)		
Fiber	0% P_{ult}	25% P_{ult}	50% P_{ult}
0%	27	3	1
0.1% C	56	38	1
0.3% C	>56	51	1
0.1% P	41	8	1
0.3% P	47	13	1

C: Cellulose; P: Polypropylene

Two sets of beams were investigated: one with load and the other without. Across the middle of the tension surface, all the beams were pre-notched by the insertion of a thin steel sheet, 0.2-mm thick and 5-mm deep, prior to concrete casting. After a moist curing of 28 days, specimens designed for corrosion measurements were continuously loaded to two applied load levels of 15 and 30 kN; these are approximately 25% and 50% of the ultimate load (P_{ult}). To accelerate the corrosion, a conditioning tank (Figure 6) was used. Time to tidal zone marine environment was applied by using wet/dry cycles in 3.5% sodium chloride solution (4 days in dry and 3 days in wet conditions). In the wet cycle, the salt water in which the beams were submerged was circulated and controlled at 20–25°C. A steel frame was employed to maintain the loads on the beams, as shown in Figure 6. A torque was applied at the nuts on the threaded rods at both sides of the beam to control the flexural load.

To monitor the corrosion process, a potentiostat (Reference 600 from Gamry Instruments) was utilized to perform three electrochemical measurements, i.e., half-cell potential, galvanic current, and linear polarization resistance. The initiation of corrosion was assumed either when the electrical potential was below −350 mV (versus CSE) or when the galvanic current density and the corrosion current density were above 1 $\mu A/cm^2$ (6.45 $\mu A/in^2$). Based on these criteria, the times to onset of corrosion recorded with different monitoring methods were fairly consistent and are given in Table 1. As seen in Table 1, clearly, cracking induced in the concrete cover by loading accelerated the corrosion substantially. In the case of non-loaded specimens, there were no cracks involved, so that the corrosion developed very slowly. It was found that the

25% P_{ult} loaded samples responded in a manner similar to the non-loaded samples but the corrosion initiated sooner as a result of the crack. Because of the large crack in all samples subject to the 50% P_{ult} loading, the corrosion began sometime within the first week itself. The influence of the fiber was found in all samples if no extensive crack existed. The corrosion initiation was delayed at a rate proportion to the fiber dosage.

3 SMART FRCS FOR INTELLIGENT INFRASTRUCTURE

Fiber Reinforced Cement-based sensors, also described as smart (self-monitoring) structural materials, have recently been developed for use in structural health monitoring (SHM) systems. Cement-based sensors are designed to function based on the principle of piezoresistivity. Materials in which the electrical resistance changes in response to changes in the applied strain are referred to as piezoresistive materials. Piezoelectricity is referred to the coupling between internal dielectric polarization and strain and can be used for both sensing and actuation [8].

The most common fiber used as the conductive phase in cement-based sensors is carbon fiber (CF). Extensive research has been conducted to obtain the optimum volume fraction of carbon fibers, electrode type, effect of curing time, temperature, moisture and chloride on the performance of these sensors [9–16]. In a recent study [17], cement-based sensors were developed by incorporating carbon fibers either alone or in combination with multi-walled carbon nanotubes (MWCNT) in a cement paste matrix. Changes in the electrical resistivity of cement-based sensors under monotonic and cyclic compressive loading were monitored. Carbon fibers used in these studies were 6 mm long, 11 μm in diameter and had a volume resistivity of 2.3 × 10-6 Ω-m. The properties of the MWCNTs are shown in Table 2.

The experimental setup is displayed in Figure 6a. In order to evaluate the sensing ability of the developed sensors, load and strain values were compared against the Fractional Change in Resistivity (FCR).

$$FCR = \frac{\rho_t - \rho_0}{\rho_0} \tag{1}$$

where, ρ_t: Electrical resistivity at time t during the tests; ρ_0: Electrical resistivity at the beginning of the test (prior to loading)

And,

$$\text{Gauge Factor} = \frac{\Delta R / R_0}{\varepsilon} = \frac{\Delta\rho / \rho_0}{\varepsilon} = \frac{FCR}{\varepsilon} \tag{2}$$

where, ΔR (or $\Delta\rho$): Change in strain gauge resistance (or resistivity); R_0 (or ρ_0): Unstrained resistance (or resistivity) of strain gauge; FCR: Fractional Change in Resistivity; ε: Strain

Figure 7 (b) displays the response of the 15% CF sensors to cyclic loading at a rate of 0.002 cycles/s.

Table 2. Properties of Multi-Walled Carbon Nano-Tubes (MWCNT).

Outer Diameter (nm	10–2
Inside Diameter (nm)	3–
Purity	>95 wt%
Length (μm	10–3
Specific Surface Area ($m2/g$)	23
Specific Gravity	≈1.5
Electrical Conductivity (s/cm)	$>10^{-2}$

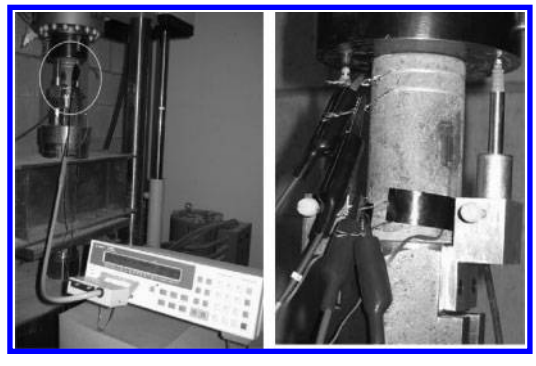

Figure 7(a). Experimental Setup Development of an FRC Sensor [17].

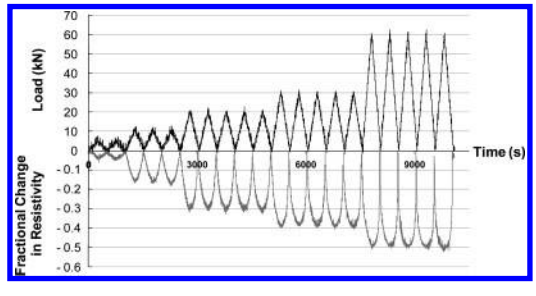

Figure 7(b). Response of 15% CF Sensor to Cyclic Compressive Loading.

Notice that the electrical resistivity of the sensors varied distinctly in response to the cyclic compressive loading: decreasing reversibly with the increasing branch of each compressive loading cycle and increasing reversibly with the decreasing or unloading branch of each cycle.

The averaged stress/strain and stress/FCR correlations for 15% CF and 15% CF + 1% MWCNT for five cycles of compressive loading are compared in Figure 8. The relationship between stress/FCR, although not as linear as that of the stress/strain, appears to have a sensible correspondence.

When gauge factors are computed, the 15% CF composites depicted gauge factors of 290 and 145 for strain values below and above 0.0007, respectively. The 15% CF + 1% MWCNT composites, on the other hand, demonstrated gauge factors of 410 and 110 for strain values below and above 0.0004, respectively. Notice that these gauge factors are well above those for

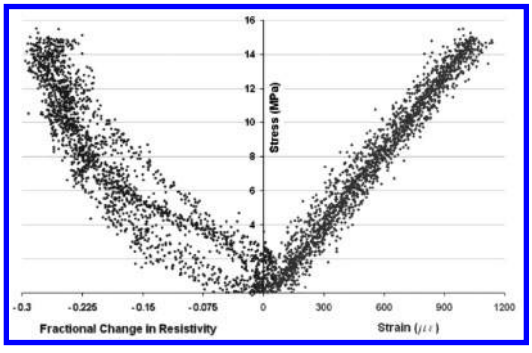

Figure 8(a). Stress/strain and stress/FCR relationships for 15% CF sensors.

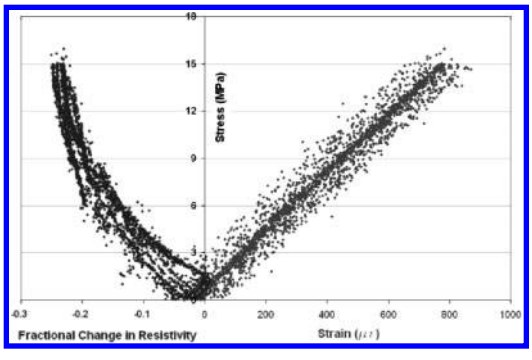

Figure 8(a). Stress/strain and stress/FCR relationships for 15% CF + 1% MWCNT Sensors (15% CF: $FCR = 185558\varepsilon^2 - 459.23\varepsilon + 0.118$ and for 15% CF + 1% MWCNT: $FCR = 331009\varepsilon^2 - 538.83\varepsilon - 0.0174$).

conventional strain gauges. Notice also a remarkable improvement in the gauge factor due to the addition of MWCNT.

4 CONCLUSIONS

With the current durability concerns for our concrete infrastructure, the use of sustainable fiber reinforced concrete for both new construction and repair appears highly promising. Fibers abate cracking and in turn reduce permeability under stress and delay corrosion. The paper also discusses smart fiber reinforced cementitious composites that are reinforced with conducting media such as carbon fibers and carbon nano-tubes and can inexpensive sensors, enabling effective structural health monitoring and active control.

Comparison of strain measurement techniques for the characterization of brittle, cementitious matrix composites

D. Arboleda, S. Yuan, J. Giancaspro & A. Nanni
University of Miami, Coral Gables, Florida, USA

ABSTRACT: Five strain measurement methodologies are described and experimentally compared based on their performance to measure axial strain of brittle matrix composite materials under uniaxial tensile loading, and setup requirements. A clip-on extensometer, electrical strain gages, a laser extensometer, and two Digital Image Correlation (DIC) techniques (edge detection of a painted rectangle and speckle interferometry), are the focus of this investigation. The composite is a novel, fabric-reinforced cementitious matrix (FRCM) system intended for strengthening concrete structures. Instrumentation is not standardized for testing of FRCM materials, so this study is particularly relevant for this field. Results indicate that for this class of composite, both the laser and clip-on extensometers are well suited for strain measurement, while strain gage measurements are only valid prior to the onset of cracking. Poor results obtained using the DIC technologies are likely attributable to out-of-plane displacement due to specimen curvature and fiber straightening during testing.

1 INTRODUCTION

1.1 *Motivation*

A critical process in the introduction of new materials for structural applications is the evaluation of the mechanical material properties through experimental means. One of the essential tasks for this effort is the definition of test configurations that give meaningful measurements intended to achieve the desired accuracy and resolution used to derive the stress-strain behavior. Characterization of the basic material properties used for design, such as strain and strength allowables, elastic moduli, and any transition in mechanical behavior is, thus, highly dependent upon the techniques utilized for measuring strain. The motivation for this study is the evaluation of a new composite intended for structural rehabilitation, following the International Code Council Evaluation Service (ICC-ES) Acceptance Criteria 434 (AC434 2013), which is modeled after AC125 for fiber reinforced polymer (FRP) composites and RILEM Technical Committee 201 for textile reinforced concrete (TRC). This material is a fabric reinforced cementitious matrix (FRCM) composite described in the following sections. During preliminary uniaxial testing, a clip-on extensometer was used to measure axial strain. The inherent variability of the material's characteristic response, due in part to its lack of homogeneity, gave rise to a search for a better understanding of the material behavior and response through different available test measurement methods, specifically, strain measurement techniques.

1.2 *Background*

Various full-field and point measurement methods are available for measuring strain or deformation based on mechanical, optical, acoustical, pneumatic, and electrical phenomena. Direct tensile testing of continuous fiber reinforced brittle matrix specimens typically involves measuring the specimen strain response with strain gages (Silva *et al*2000), LVDT's, and clip-on extensometers (Naaman & Shah 1979, Contamine *et al* 2011, Qian & Zhang 2012). Published standards (ASTM C1275) and AC434 specify only the use of extensometers satisfying ASTM E83 class B-1 requirements, which are based upon the relative error of the gage length. Optical and digital image correlation (DIC) methods have been used for crack size measurements and crack distribution analysis (Mobasher 2012), but not extensively used for strain measurement in this class of composites.

One optical strain measurement apparatus is the laser extensometer, which reflects a laser beam from reflective targets placed at the endpoints of the gage length being investigated.

Digital image correlation is a non-contacting, optical strain measurement technique intended to measure surface deformation. By correlating the changes in a series of images before and after deformation, the displacement field of the surface can be quantified (Pan *et al* 2009). Compared to other strain measurement methods, DIC is advantageous due to its relatively low cost, simplicity in setup, and wide measurement range. However, the analytical and computational necessities can be much more complex and time-consuming.

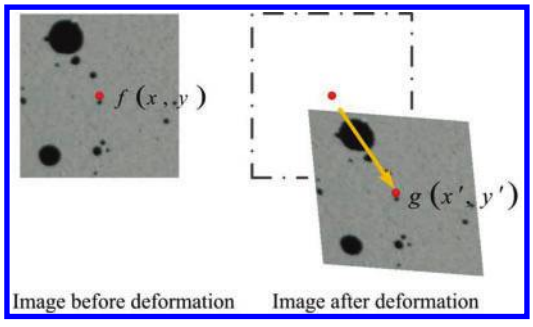

Figure 1. Correlation of pixel displacement by DIC (adapted from Pan *et al* 2009).

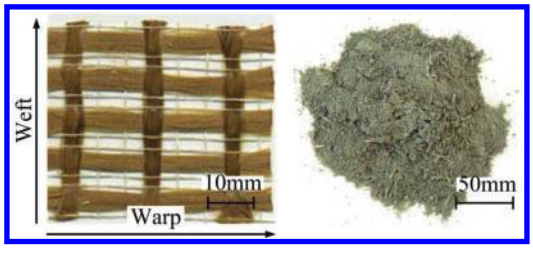

Figure 2. PBO-FRCM system: fabric (left), mortar matrix (right).

The basic principle of DIC is to analytically track the same point(s) through the deformation, as shown in Figure 1. For tracking the displacement, the specimen surface is painted with a grey background, followed by a random distribution of black spray-painted speckles. The arrangement of the specklesis separated into multiple subsets with a uniquely grey distribution that is identifiable, similar to a finger print. Using a correlation criterion to track the position change of each subset, the displacement map for the specimen is obtained.

A new approach developed by the authors is to paint a black rectangle on the specimen surface, then apply edge detection principles to measure the distance between the edges on the sub-pixel level. In this paper, both the speckle and rectangle-based approaches were used.

2 TEST SETUP

2.1 *Specimen description*

The FRCM system consists of two main elements, a cementitious matrix, which is typically a Portland cement-based grout system and a low dosage of dry polymers (less than 5% in weight), and a dry fiber network or fabric. For this study, a PBO-FRCM system was used, consisting of PBO fabric (polyparaphenylene benzobisoxazole) (Figure 2) and a stabilized inorganic matrix, intended for the strengthening of reinforced concrete structures(Arboleda *et al* 2012).

The PBO fabric is made of 10 mm and 20 mm spaced rovings in the warp and weft directions

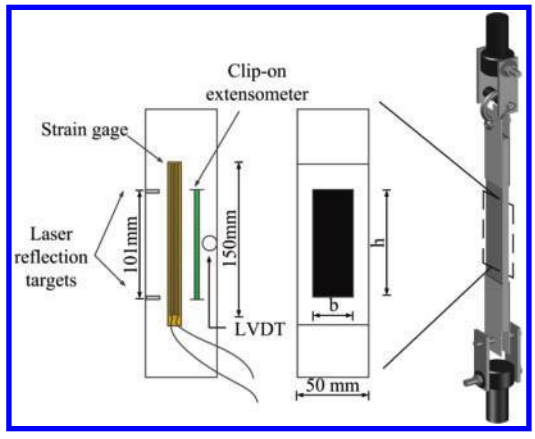

Figure 3. Specimen instrumentation set up.

respectively. The clear spacings are approximately 5 mm and 15 m min the warp and weft directions respectively, while the nominal thicknesses in the two fibers directions are 0.046 mm and 0.011 mm, respectively.

Tensile coupons measured 500 × 50 × 10 mm and were cut from larger panels. The larger panels were 410 × 563 mm, and were manufactured using a manual impregnation technique in a rectangular mold. In this process, a 5-mm thick layer of the cementitious matrix was placed, followed by a layer of the fabric, which was manually wetted with the wet cementitious material. The top layer of matrix was then applied to form the surface of the specimen. Panels were cured for 28 days at 20°C and 70% relative humidity before cutting. Individual coupons were cut using a diamond-tipped wet saw using a rigid fixture to ensure consistent specimen widths. 2 mm steel tabs were bonded with a polyurethane construction adhesive to each specimen 24 hours prior to testing.

2.2 *Experimental setup*

A49 kN test frame was used to apply the tensile load and recorded using a load cell with 9 kN capacity. A clevis grip set up was used to provide sufficient degrees of freedom in order to minimize secondary moment or torsion loading conditions at the supports due to specimen geometry. Test specimens were aligned at the grips and preloaded to 50 N.

To facilitate direct comparisons between the strain measurement approaches, the strain measuring devices were strategically arranged such that the laser extensometer, the clip-on extensometer, and the 150 mm long strain gage were arranged on one side of the specimen, whileone of the two DIC patterns (speckles or rectangle) were on the other side. This arrangement is shown in Figure 3.

The laser extensometer was mounted on a rigid frame (Figure 4) and directed at the test specimen at a target distance of 305 mm. The laser extensometer used a moving window of 256 scans averaged per reading. A mechanical, general-purpose, clip-on axial

Figure 4. Equipment set up.

Table 1. Instrumentation configuration for each specimen.

Specimen name	Laser gage length (mm)	Strain gage (mm)	Digital image pattern (mm)	Shutter speed (sec)	Focal ratio	LVDT
FRCM-1	102.2147	150	rectangle 101 × 35	1/10	f/3.2	Yes
FRCM-2	104.3457	N/A	rectangle 70 × 35	1/8	f/3.2	Yes
FRCM-3	106.0602	150	rectangle 52 × 35	1/6	f/3.2	Yes
FRCM-4	102.6998	150	speckle	1/40	f/3.2	Yes
FRCM-5	105.7580	N/A	speckle	1/40	f/3.2	No
FRCM-6	104.8385	N/A	rectangle 52 × 35	1/15	f/3.2	No
FRCM-7	101.1047	N/A	speckle	1/40	f/3.2	Yes

extensometer with an initial gage length of 100 mm was mounted directly on the test specimen using knife edges.

A 240-ohm strain gage with a 150-mm gage length was bonded along the axial direction on the specimen, and was connected to a quarter-bridge circuit.

Digital images were recorded by a charge coupled device (CCD) camera with a 40-mm micro lens and an image resolution of 3872 × 2592 pixels. The camera was mounted on a rigid frame (Figure 4), directed at the specimen, and calibrated by taking images of a checkerboard pattern of known dimensions at different angles (Zhang 1999). The camera shutter speed and focal ratio for each test are listed in Table 1. Shutter speed and aperture were manually selected based upon the lighting conditions which were controlled by using a lamp with a 35 Watt bulb supplying 1050 Lumens.

After executing the first two tests on specimens FRCM-5 and FRCM-6, and analyzing the data, it

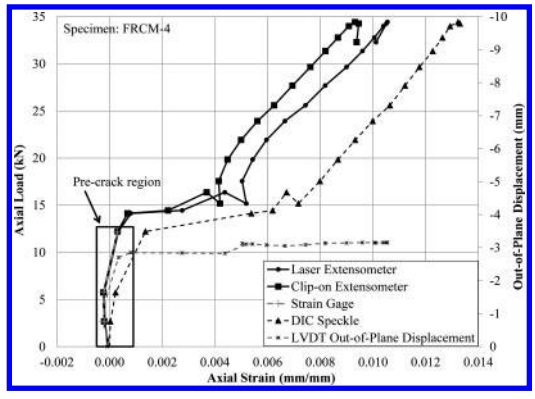

Figure 5. Comparison with speckle DIC.

became apparent that out-of-plane displacement due to specimen curvature and fabric straightening was occurring. This movement adversely affected the camera focus so the DIC data for those specimens was not usable. A new strategy was developed that included placing the camera on a bed of stainless steel ball bearings that attached to the specimen, allowing the camera to freely move with the out-of-plane movement of the specimen. In addition, two linear variable differential transformers (LVDT) were added at the specimen mid-section and top support to measure the out-of-planed eflection. A total of 7 specimens were tested with the instrumentation configurations shown in Table 1. All configurations included a 100 gage length clip-on extensometer.

The laser extensometer, clip-on extensometer, 150-mm strain gage, and load cell were connected to a data acquisition (DAQ) system, as were the two LVDTs. The test was programmed to run under displacement control at a rate of 0.25 mm/min with measurements recorded continuously at a rate of 1 Hz. To synchronize the digital images with the DAQ system, the test was paused every 0.25 mm of crosshead (stroke) displacement to take a series of images for subsequent DIC analysis.

3 RESULTS

3.1 *Summary*

Figure 5 shows a comparison between the speckle DIC and the other strain measuring methods in a dual axis graph with load vs. strain for each axial strain instrument on the left axis and out-of-plane vs. strain on the right axis.

Figure 6 shows the detail of the pre-cracked region which is the data collected before a crack occurs within the measurement gage. When a crack occurs outside the gage area, it is not recorded in the strain measurement.

Figure 7 shows a comparison between the rectangle DIC and the other strain measuring methods in a dual axis graph with load vs. strain for each axial strain

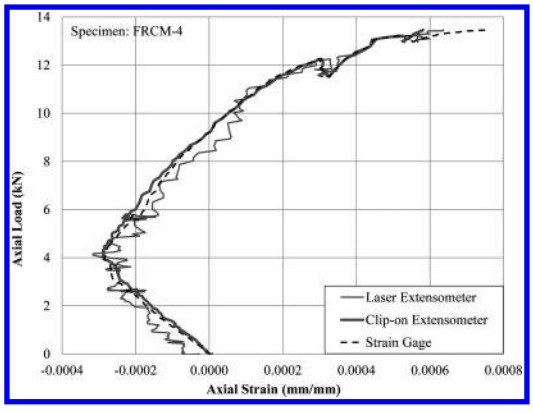

Figure 6. Detail of pre-cracked region of Figure 5.

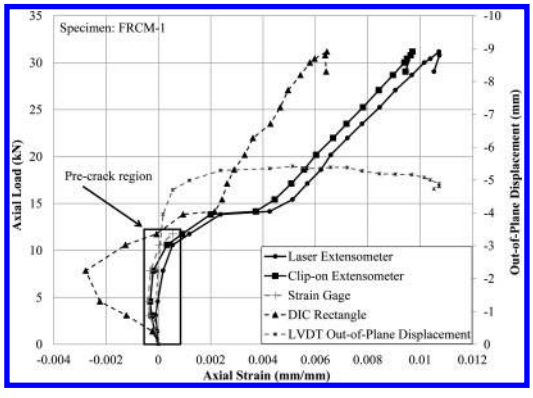

Figure 7. Comparison with rectangle DIC.

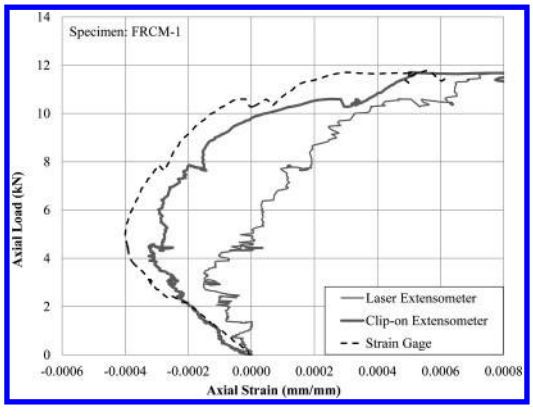

Figure 8. Detail of pre-cracked region of Figure 7.

instrument on the left axis and out-of-plane vs. strain on the right axis.

And finally, Figure 8 shows the detail of the pre-cracked region of the previous figure.

3.2 *Analysis*

Both Figure 5 and Figure 7 show that out-of-plane displacement occurred during the pre-cracking zone and then settled out as expected. It had the most significant effect in the DIC strain measurements.

The strain gage data is only useful until the initiation of a crack within the gage length. Before crack initiation, the correlation between the laser, clip-on, and strain gage is good. After the first crack occurs, the circuit is ruptured, rendering the strain gage inoperable. The laser and clip-on extensometers continue to provide consistent strain measurements with only a small offset between their strain readings. The width of each crack is not constant across the specimen and could explain this difference. Once the cracking zone of the matrix begins and the out-of-plane displacement stops, the slope of the remaining strain measuring devices are consistent with each other.

DIC methods to measure strain are based on the sub-pixel changes in the captured images. The length change indicated by the change in the number of sub-pixels is divided by the original length which is the original number of sub-pixels. The DIC methodology results show a relatively inconsistent strain result compared to the laser and clip-on extensometers. Since the DIC method is an optical method, maintaining a constant focal distance from the camera lens to the specimen is critical during the test. The LVDT data in Figure 5 and Figure 7 demonstrate that out-out-plane displacement occurred, thus, changing the distance from the camera lens to the specimen surface. A negative displacement implies the specimen surface is moving towards the camera. Any change in focal distance during loading(caused by out-out-plane specimen displacement) causes the camera to lose focus which leads to a blurred image. Moreover, that change in distance affects the perceived size of the image, which induces large errors in the subsequent strain computations.

For the DIC of the speckle pattern, a precise correlation was hard to achieve. Matlab code based on digital image correlation method was developed by Eberl et al. 2010. Matching is done by a normalized cross-correlation criterion. By detecting the extreme of the peak of C_{NCC}, the position of the deformed subset is found.

$$C_{NCC} = \frac{\sum f_i g_i}{\sqrt{\sum f_i^2 \sum g_i^2}} \quad (1)$$

Where, C_{NCC} is the coefficient of normalized cross-correlation, f_i is the gray intensity of the reference subset, and g_i is the gray intensity of the deformed subset. The Matlab code creates a list of images for analysis, and creates a grid of raster points. These raster points are considered as the center of each of the subsets. Then, during the point matching, the displacements of these raster points are detected. Finally, based on the displacement map, the full strain map is obtained.

For the DIC of the rectangle pattern, determining the change in length of the rectangle is based upon detecting the presence and location of edge pixels. Because the length change of the rectangle is smaller

than the resolution of one pixel, a sub-pixel precision edge detection algorithm was needed. In this analysis, a Gaussian curve fitting sub-pixel edge detection method was chosen (Shang *et al* 2010). The edge pixels of the image present a sharp change in grey value. The corresponding gradient curve of the edge pixels on the direction of gradient shows a gauss distribution. The Gaussian curve expression for one dimension is expressed as:

$$y = \frac{1}{\sqrt{2\pi}} e^{\frac{(x-\mu)^2}{2\sigma^2}} \quad (2)$$

Where y is the gradient value of the pixel, μ is the mean and σ is the standard deviation of the gradient value of the edge pixels.

A precise Gaussian curve is important for achieving sub-pixel accuracy. The least-squares method was applied to find the optimal Gaussian curve. Nine pixels near the edge (one pixel at the extreme gradient value and four on either side) were selected to determine a best-fit Gaussian curve. Based on the authors' judgment, the Gaussian curve was considered acceptable when the goodness of fit, R^2, was greater than or equal to 80%.Once the edge becomes blurry, the Gaussian algorithm is no longer applicable, and results in R^2 values near 0.

3.3 *Assessment of the techniques*

In addition to the analytical comparison presented earlier, other factors for comparison can be considered. These include requirements for specimen preparation, set up of equipment, and relative cost. This comparison is based upon the authors' experience as well as cost data acquired from the equipment manufacturers. In terms of specimen preparation requirements:

- Laser extensometer: to apply the reflective targets (tape),a smooth surface must be available at the gage length ends; the gage length surface should be free of any spurious reflections or covered to prevent laser beam interference.
- Clip-on extensometer: no specimen preparation is required.
- Strain gage: a smooth surface free of large discontinuities, voids, or elevations is necessary; surface preparation is extensive and includes removal of dust and other foreign debris particles, and neutralization of chemical residue on the surfaces of the specimen and strain gage; gage alignment, adhesive bonding, and wire soldering can be a time-consuming, delicate procedure requiring prior training and ample experience.
- DIC painted rectangle or speckle interferometry: a smooth surface free of voids and macrocracks is necessary; paint can be directly applied to the surface; for the rectangle DIC, a stencil or similar pattern should be utilized to achieve sharp external edges.
- LVDT: specimen preparation is not warranted, but requires the attachment of at least one contact point which can be cumbersome.

In terms of equipment set up requirements:

- Laser extensometer: the DAQ settings must be properly configured, and require adjustment depending on the brittle or ductile behavior of the specimen; a rigid base to support and align the laser to the specimen is needed.
- Clip-on extensometer: sufficient tension must be provided to prevent slippage of the knife edges or clip-on wireforms. DAQ input must be properly configured, though relatively simple.
- Strain gage: DAQ input must be properly configured, but the output signal conditioner can be complex and requires routine calibration with each strain gage.
- DIC rectangle or speckle interferometry: a rigid base and frame are needed to support the equipment and maintain alignment of the camera to the specimen; stringent lighting requirements, and software for image analysis is a necessity.
- LVDT: DAQ input can be properly configured in a simple manner.

For the cost analysis (based on having the test frame already equipped with DAQ and signal conditioning boards), the prices presented here have been normalized to the price of a strain gage (1sg) in order to show only a relative comparison since prices will vary from region to region and can be expressed in multiple currencies.

- Strain gage: 1sg per specimen and not reusable.
- Laser extensometer:750sg per device, and is reusable.
- Clip-on extensometer: 100sg per device, and is reusable.
- DIC painted rectangle or speckle interferometry: Camera with additional lens 50sg, plus Matlab license75sg (commercial or 5sg student version). This equipment is reusable.
- LVDT: 15sg and this equipment is reusable.

3.4 *Conclusions and recommendations*

The DIC method is difficult to apply for specimens which show bending or straightening behavior during the test. An improved strategy including fixtures and algorithms for minimizing the effects of out-of-plane displacement is needed for this method to work on this class of materials

Laser and clip-on extensometers are recommended as good and accurate strain measurement techniques with initial cost investment being the differential. These methodologies offer the most convenient set up ranging from little specimen preparation required to ease of equipment set up. Out-of-plane deformation should be addressed during specimen preparation if pre-cracked mechanical properties need to be studied.

LVDT's in the axial direction were not investigated in this study but are commonly used as noted in the literature. Attachment to the specimen can sometimes be cumbersome.

Department of Structural Engineering, the Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: Within a relatively large Norwegian research programme, denoted COIN (Concrete Innovation Centre) covering a broad range of concrete research topics, fibre reinforced dapped end beams (beams with corbel ends) have been tested to study the structural behaviour of fibre concrete in discontinuity regions (D-regions). Ordinary strength concrete with 1% (80kg/m^3) 60 mm long end hooked steel fibres has been used. The shear reinforcement and the splitting tensile reinforcement in the beam ends used in the traditional solution have been partially or fully removed. The typical strut and tie models commonly used in practical design of D-regions have been modified to include the effect of the fibres. A simplified reinforcement layout to be used together with steel fibres is proposed, and gives similar capacity and ductility as today's standard solution without fibres. Furthermore beams with fibres replacing all the transversal and splitting tensile bars, also give reasonable strength and ductility, and can therefore be recommended for structures with low load levels. In the current fibre project flowable concrete generally is preferred, and fibre distribution and orientation, and the influence of the casting process are major topics. Therefore fresh concrete testing has been carried out by the LCPC box and the 4C Rheometer, and sections are cut and the amounts of fibres recorded and compared to theoretical values. The research activity is continuing, and the results and conclusions are not final.

1 INTRODUCTION

Steel fibres may be used as replacement for shear, additional anchorage and splitting tensile bar reinforcement in the discontinuity regions (D-regions) of concrete structures, i.e. the regions where the beam theory (B-regions) does not hold. Only limited research is done with FRC for this type of problems, however the topic is important since design rules for FRC now are being to standardized for load carrying structures, see f.i. FIB Model Code (2011), and ongoing work for revision of Eurocode. One type D-region is the dapped ends (corbel ends) of prefabricated beams commonly used in precast concrete structures. Another problem considered within the same project is replacement of additional reinforcement around openings in beams, and replacement of these bars with fibres. The motivation for both topics are cost and work-hour savings, and potentially also better structural performance (i.e.less cracking).

These particular problems are not theoretically complicated problems; however, obtaining general design rules might be difficult due to the large number of important parameters involved: shear span to depth ratio, scale effect, concrete strength, fibre type, fibre content, fibre distribution and orientation, and finally amount of reinforcing bars. The work described in this paper must therefore be considered as a first attempt to establish a basis for the models, and one aim of the present paper is to compare test results with results from the proposed strut and tie model and illustrate the applicability of the theory on FRC structures.

In two experimental series, Backe-Hansen & Hamstad 2011 and Nordbrøden & Weydahl 2012, the shear reinforcement and the splitting tensile reinforcement in the dapped beam ends have been partially or fully removed to study the fibres effects on the structural behaviour. For simplicity reasons, only the second test series is presented in detail in this paper, however, the results from both series are included in the final evaluation of the proposed strut and tie model.

Due to well-known synergies between self-compacting concrete and fibres (Døssland 2008), the ambition in the on-going project is to use flowable concrete. Special attention is therefore being paid to the fresh concrete properties and the casting technique, and the fibre orientation and distribution in the critical sections have been studied on sawn parts of the structural elements.

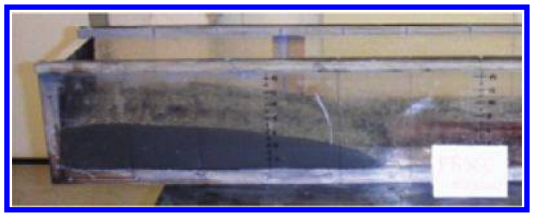

Figure 1. Flowable FRC (80 kg/m^3 steel fibres) in the LCPC box.

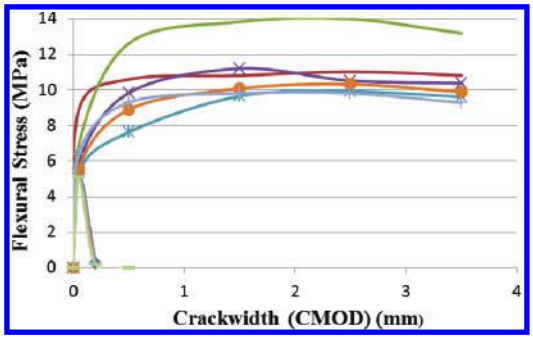

Figure 2. Stress-crackwidth (CMOD) relation for standard 3-point bending tests (EN14651).

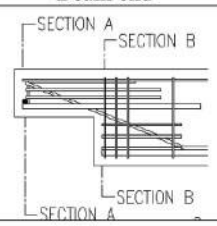
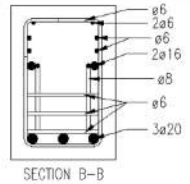
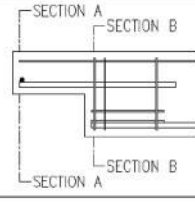
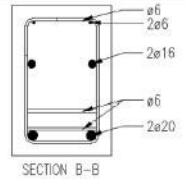
2 MATERIALS AND TEST PROGRAM

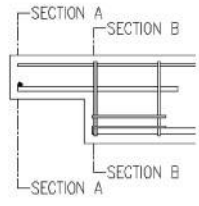
The concrete qualities used in the two series are B70 and B40 in series 1 and 2, respectively. In both concretes 1 volume % (80kg/m^3) end hooked 60 mm long steel fibres were used.

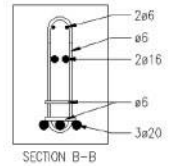


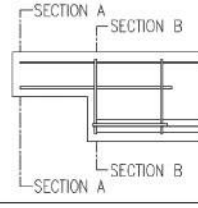


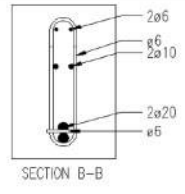


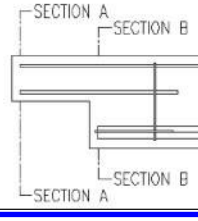


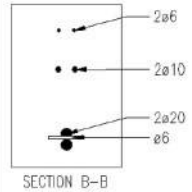












Fresh concrete testing was carried out, and the yield stresses measured from 4C-Rheometer (Thrane et.al. 2010) were 55 Pa for the plain concrete and 75 Pa for the fibre reinforced concrete, which are compatible with the values found from the LCPC box (Rousell 2007). The latter test is shown in Figure 1 below, and is also an illustration of the concrete's consistency and casting properties.

The residual tensile strengths were determined by three-point bending of notched standard beams according to EN14651 (150/150/550 mm), and the results for the six FRC-beams and 3 plain concrete beams for series 2 are presented in Figure 2. For this series the average strength values are: Residual bending strength at 2,5 mm crackwidth (CMOD): 10,9MPa, residual tensile strength at the same crackwidth: 4,0MPa, and finally the limit of proportionality in bending: 6,5MPa. The corresponding compressive cylinder strength is 52,3MPa.

The cross section and length of the beams were 200/300 mm and 2500 mm, and the vertical load was placed 2,5 times the effective height of the beam from the support. The load location was unsymmetrical so that each beam could be tested at both ends, i.e. two test results per beam.

The reinforcement layout of the beams in the second series is presented in Table 1 below. Beam A and B are the reference beams without fibres, while beam C, D and E are fibre reinforced beams with less reinforcing bars than A and B. As shown in the Table, the amount of transversal reinforcement is reduced with the beam names in alphabetic order. In the FRC beams the reinforcing bars are drawn towards the centre-line of the cross sections to improve the casting conditions, i.e. to prevent weak zones between the stirrups and the formwork walls, and to arrange for the wall effect which contributes towards favourable fibre orientation.

3 STRUT AND TIE MODELS (STM) APPLIED TO DAPPED BEAM ENDS

The STM is a simplified method where the load carrying model consists of compressive struts, tensile ties and nodes where the concentrated loads act.

There are in general no unique models for the various design situations, but since the method is commonly used procedures and proposals are presented in many text books and research literature, see f.i. Schlaich et.al.1987. Following the right procedures, the method is a lower bound method related to the theory of plasticity, and gives in general results on the safe side.

Figure 3a below shows the typical load situation, and the principal stress fields for the considered D-region problem. For ordinary reinforced concrete the traditional solution is to locate the tensile reinforcement in accordance with the tensile stress lines as shown in Figure 3b, and thereafter define the tensile ties in the STM in accordance with the tensile bars as shown in Figure 3c and 3d. For the traditional solution with both vertical stirrups and diagonal bars the shear capacity can simply be expressed as:

$$V_{Rd} = V_{Rd,incl} + V_{Rd,vert}$$
$$V_{Rd,incl} = A_{s\alpha}\, f_{yk} \sin\alpha \text{ and } V_{Rd,vert} = A_{sv}\, f_{yk} \quad (1)$$

In which V_{Rd} is the total shear capacity, $V_{Rd,incl}$ and $V_{Rd,vert}$ are the shear capacities due to the diagonal and vertical bars, respectively, and $A_{s\alpha}$ and A_{sv} are the areas area of diagonal and vertical shear reinforcement.

For FRC it is impractical to include the diagonal bars, so in this case the capacity may be calculated by combining the contribution from vertical stirrups and a fictitious fibre concrete tie with geometry in accordance with the distribution of principal tensile stresses as illustrated in Figure 3e. Thus the capacity can be expressed as:

$$V_{Rd} = V_{Rd,vert} + V_{Rd,fibre}$$
$$V_{Rd,vert} = A_{sv}\, f_{yk} \text{ and } V_{Rd,fibre} = f_{res2,5}\, b_w\, t_f \quad \sin\alpha \quad (2)$$

The following symbols have been used: $V_{Rd,fibre}$ is the shear capacity due to the diagonal fibre concretetie, α is the angle between the system axis and the fibre tie, $f_{res2,5}$ is the residual tensile strength determined from EN14651 at CMOD = 2,5 mm, and b_w and t_f are the assumed dimensions of the fibre tie.

4 TEST RESULTS

Figure 4 presents measured load versus mid-point deflection curves for the tested beams. It can be seen that the simplified reinforcement layout proposed to be used together with steel fibres (beam C and D) gives about the same capacity and ductility as the traditional reinforcement solution (beam A). It is also shown that the solution with fibres only (beam E, with longitudinal bars, but no tranversal reinforcement) gives reasonable strength, and can be recommended for structures with relatively low load levels.

Furthermore Figure 5 does show typical crack patterns and measured crack deformations for beam types A (traditional reinforcement), and C (simplified reinforcement layout). Figure 6 shows corresponding results for beam E (no transversal reinforcement).

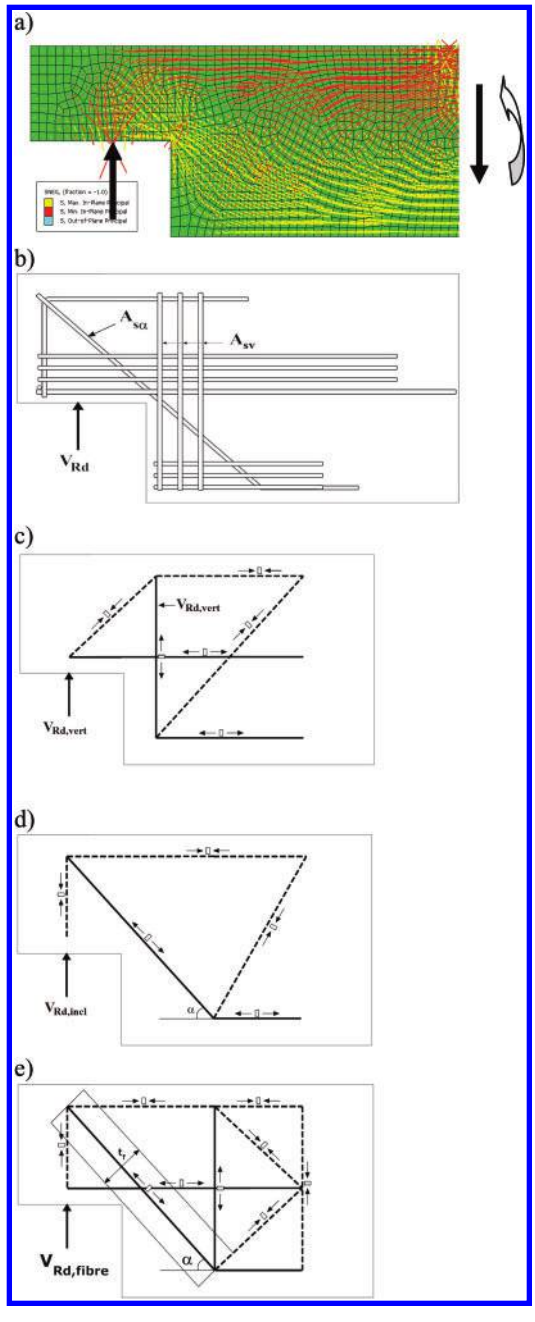

Figure 3. Strut and tie models. (a) Principal stresses from linear elastic FE analysis. (b) Traditional reinforcement layout, (c) Model for capacity contribution of vertical stirrups, (d) Model for capacity contribution from diagonal bars, (e) Model for the fibre contribution.

Comparing the crack patterns, it is seen that while the traditional solution contains several cracks distributed over a large area, only one or two cracks are present for the fibre reinforced beams. These experimental results are further evaluated by means of nonlinear

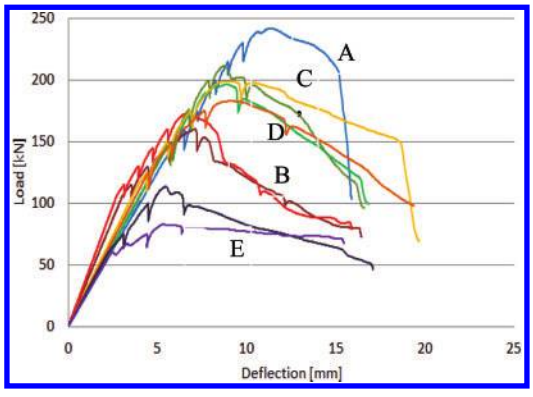

Figure 4. Load versus mid-point deflection for the tested beams in series 2.

FE analysis in an ongoing PhD work (Sarmiento to be published in 2015).

Finally, the overall agreement between the strut and tie model and the total amount of experimental results is presented in Figure 7 where it can be seen that the general agreement is satisfactory, and that the results generally are on the safe side.

As shown previously the fibre concrete's shear capacity contribution is described as:

$$V_{Rd,fibre} = f_{res2,5}\, b_w\, t_f\, \sin\alpha$$

Obviously there are uncertainties due to the involved parameters, but so far the parameters are based on Figure 3a with $\alpha = 35^o$.

The strength $f_{res2,5}$ is set to 0,37 times the residual bending strength at 2,5 mm CMOD although the fibre orientation is more favourable in the beam test of EN14651 than in the critical part of the dapped end beam as shown and discussed later in this paper.

5 FIBRE ORIENTATION

As previously stated, fibre distribution and orientation is a major topic within the current project, and therefore various sections have been cut and the amounts of fibres crossing the sections recorded and compared to theoretical values.

To relate the real fibre orientation to the corresponding theoretical values is an important part of the result evaluation, and therefore, the number of fibres crossing various sections of the tested specimens has been recorded by manual marking and image analysis. The orientation factor was calculated using the following expression:

$$\alpha = \frac{n_f \cdot A_f}{v_f} = \frac{N \cdot A_f}{A_c \cdot v_f}$$

where: n_f is the number of fibres per concrete unit surface; A_f is the cross-section of a fibre; v_f is the nominal fibre volume fraction; N_f is the number of fibres in the concrete cross-section with area A_c.

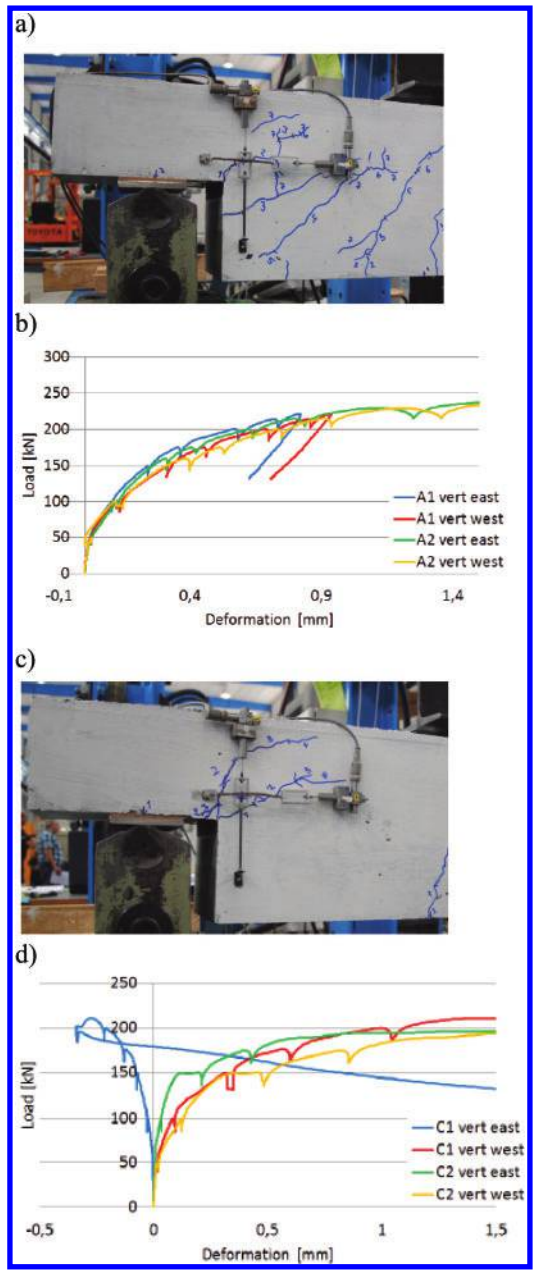

Figure 5. Crack pattern and measured vertical crack deformations for beam types A (a,b) (traditional reinforcement) and C (c,d) (simplified reinforcement layout and fibres)

Under isotropic conditions the orientation factor should be equal to 0,5, while it theoretically is 1,0 if all fibres are directed in one direction normal to the considered plane.

In beam series 1, 150 mm cylinders were drilled out in the critical zone as shown in Figure 8 below., Referring to the eight cylinder sectors the average orientation factors four of the tested beams were as follows: 1: 0,51, 2: 0,71, 3: 0,53, 4: 0,35, 5: 0,48, 6:

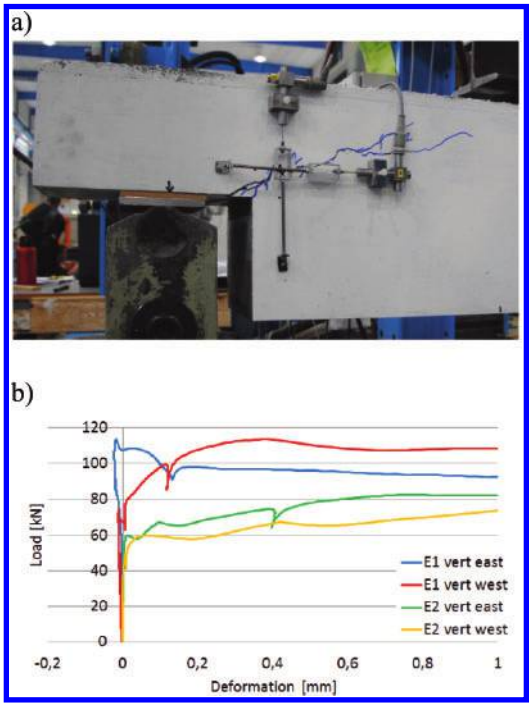

Figure 6. Crack pattern (a) and measured vertical crack deformations (b) for beam type E (no transversal reinforcement, only fibres)

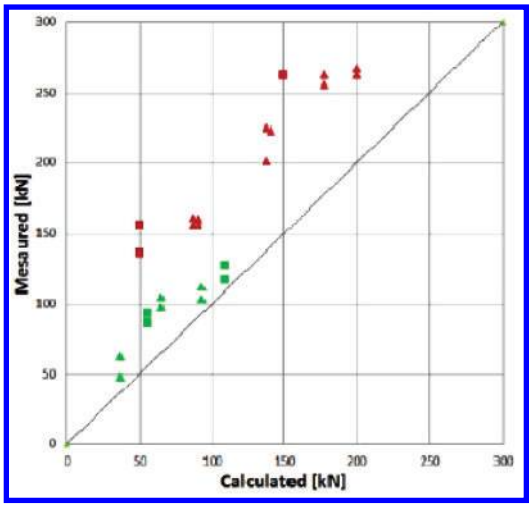

Figure 7. Experimental failure capacities versus strength calculated by the strut and tie models for all beams in both series.

0,56, 7: 0,55, 8: 0,51. The scatter is large, but as the overall average value is 0,51, the results indicate that the fibre distribution is isotropic.

For the second beam series the evaluation of the fibre distribution and orientation is not completed yet. However some interesting results can be referred. The standard beams (EN14651) used to determine the

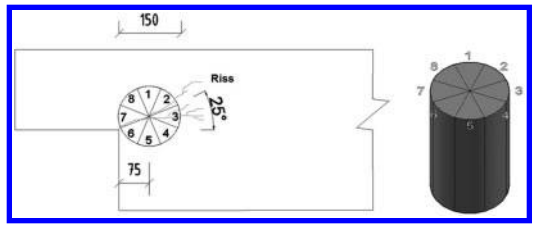

Figure 8. Drilled cylinders for fibre counting and determination of orientation factors.

residual tensile strength show a relatively favourable fibre orientation, in average $\alpha = 0{,}77$ for the longitudinal direction which is decisive for the residual strength. In general this is as expected based on previous experience with similar concretes even if the execution procedure of the standard is followed as closely as possible. Considering sections in the critical parts of the dapped end beams the orientation factor for the longitudinal direction is in average 0,43, for the beams with stirrups close to the height step, which corresponds reasonably well with the results on the cylinder shown previously in Figure 6. For beam E without stirrups, the fibre orientation is more pronounced in the longitudinal direction, $\alpha = 0{,}78$, which is more in agreement with the situation in the standard beams. Thus, it can be concluded that stirrups considerably influence the fibre orientation even if as in this case precautions are taken to reduce the problem by modifying the reinforcement layout. The strong fibre orientation in the longitudinal direction in beam E may also explain the direction of the cracks shown in Figure 6 which indicates that the horizontal plane is weaker than the vertical plane.

Currently these sawn sections are further evaluated by image analyses on several planes (directions) and CT scanning of sawn elements, and the data will be more thoroughly published later (Zirgulis to be published in 2014).

6 CONCLUSIONS AND PLANS FOR FURTHER WORK

Fibre reinforced dapped end beams have been tested to study the structural effect of fibres in D-regions, i.e. regions in structural elements where the beam theory doesn't hold. Ordinary strength concrete with 1% (80 kg/m^3) 60 mm long end hooked steel fibres have been used, and the shear reinforcement and the splitting tensile reinforcement in the beam ends used in the traditional solution have been partially or fully removed to study the effects of the fibres on the structural behaviour.

The proposed alternative simplified reinforcement layout to be used together with steel fibres gives similar capacity and ductility as today's standard solution without fibres. Furthermore does the solution with fibres only, also give reasonable strength, and can be recommended for structures with low load levels.

The typical strut and tie models commonly used in practical design of D-regions have been modified to include the effects of the fibres. In general the model is in good agreement with the experimental results, although a certain uncertainty is devoted to the input parameters in the model.

By recording the amount of fibres crossing sawn sections from the structural elements, it is shown that the fibre orientation in the standard beams (EN14651) is more favourable than in the critical zones of the dapped end beams. It is also shown that transversal reinforcement influences the fibre orientation considerably.

Three ongoing research activities continues the work described in this paper; (1)Nonlinear FE analysis of the tested elements, (2)More thorough registration of the fibre distribution and orientation, and finally (3) tests on beams with openings in the web.

ACKNOWLEDGEMENT

The paper is based on the work performed in COIN – Concrete Innovation Centre (www. coinweb.no) – which is a Centre for Research based innovation, initiated by the Research Council of Norway in 2006. The Centre is directed by SINTEF, with NTNU as research partner and with the present industrial partners: Kværner, Norcem, Norwegian Public Roads Administration, Rescon Mapei, Skanska, Unicon, Veidekke and Weber Saint Gobain.

Study of the properties of hybrid fibre reinforced concretes

T. Zych
Cracow University of Technology, Cracow, Poland

ABSTRACT: The results of research concerning the properties of fresh concrete (consistency and air content) and hardened concrete (water absorption, compressive strength, flexural strength, flexural toughness) of hybrid fibre-reinforced concretes are presented in this paper. Cases considered were as follows: five types of hybrid reinforcement;one combination of steel fibres: long (60 mm) hooked-end steel fibres and short (13 mm) straight steel fibres; three combinations of steel-polypropylene fibres: short (35 mm) hooked-end steel fibres (with single hooks), long (60 mm) hooked-end steel fibres (with single or double hooks) and (19 mm) fibrillated polypropylene fibres); one combination of polypropylene fibres: long (60 mm) bi-component macrofibres and (19 mm) fibrillated polypropylene fibres. These types of fibres are modern and popular. The results for concretes with hybrid fibres were compared with the obtained properties of concretes without fibres and with one type of fibre.

1 INTRODUCTION

Several types of fibres for cement composites, different in material and geometry (shape, dimensions) are produced. The most popular fibres are steel, polypropylene, glass. The addition of randomly distributed fibres into concrete improves its properties, mainly related to the behaviour under tension. Each type of fibres modifies concrete properties in different ways (Bentur& Mindess 1990, Hannant 2003). The effect of fibres, which are strong and stiff (having high tensile strength and modulus of elasticity), e.g. steel fibresdiffers from that observed in the case of fibres with low tensile strength and modulus of elasticity (flexible fibres), e.g. polypropylene fibres. Steel fibres can improve the mechanical properties (tensile strength, flexural strength, flexural toughness due to crack bridging, impact strength) whereas polypropylene fibres can prevent the cement matrix from shrinkage crack formation and propagation. Moreover, polypropylene fibres protect concrete against spalling under the impact of fire. As regards fibres different in geometry, short and long, their influence on the properties of concrete also varies (Markovic 2006). Short fibres can bridge microcracksmore efficiently than long fibres, because they are very thin and their number in concrete is much higher than that of the long thick fibres for the same fibre volume quantity. Taking into account that microcrack formation and crack bridging by fibres occurs in the first phases of tensile loading, short fibres can have a significant influence on the increase in tensile strength. However, long fibres can provide a stable post-peak response. When microcracks grow and join into larger macrocracks, long fibres become more and more active in crack bridging (Fig. 1). Ductility (toughness) can be

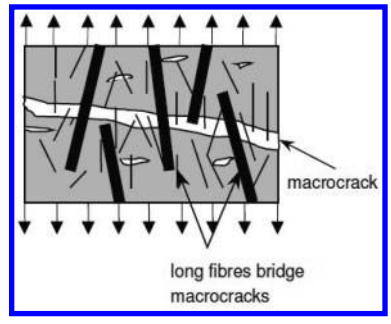

Figure 1. Short thin fibres and long thick fibres sewing cracks (Markovic 2006).

improved, and partly also tensile strength. During this time short fibres are less active, because they are pulled out.

To utilize the individual properties of each type of fibres, the combination of different types of fibres is applied. The benefits of combining fibres were recognized nearly 40 years ago (Walton & Majumdar 1975). However, experimental studies of the properties of concretes with hybrid fibres (combinations of different kinds of steel fibres, steel-polypropylene fibres, polymer fibres, etc.) have only been conducted by a number of research centersin the last few years.Because the hybrid reinforcementcan provide interesting application of fibre reinforced concretes, new researchis expected, but carried out by researchers using the same test method (to be able to compare the test results). The tests of flexural properties of hybrid fibre reinforced concretes, presented in the literature were conducted according to various standards (using notched or un-notched beams, with three-point or

four-point loading):American standard ASTM C1018 (1997), European standard EN 14651 (2007) (based on RILEM TC162-TDF), Italian standard UNI 11039 (2003),Japanese standard JCI-SF4 (1984), etc. (see References).

The paper presents the results of the investigations on the properties of fresh and hardened cement concretes withthe following types of hybrid reinforcement: steel-steel combination: long (60 mm) hooked-end steel fibres + short (13 mm) straight steel fibres,steel-polypropylene combinations: short (35 mm) hooked-end steel fibres (with single hooks) or long (60 mm) hooked-end steel fibres (with single or double hooks) + (19 mm) fibrillated polypropylene fibres, polypropylene-polypropylene combination: long (60 mm) bi-component macrofibres + (19 mm) fibrillated polypropylene fibres.

2 EXPERIMENTAL DETAILS AND TEST METHODS

2.1 *Materials*

Portland cement type I CEM I 42.5R (Gorazdze Cement SA), river sand 0–2 mm, crushed granite 2–8 mm and 8–16 mm, water and superplasticizer were used to make cement concrete – the matrix(M) of fibre reinforced concretes. The sand content was 33% of the aggregate content. Water-cement ratio was 0.45. The cementpaste content was 325 dm^3/m^3. The composition of concrete mixture is shown in Table 1.Different types of fibres were applied in the study – four types of steel fibres: 13 mm long, straight fibres (SF13), 35 mm or 60 mm long, hooked-end fibres with single hooks (SF35 or SF60), 60 mm long, hooked-end fibres with double hooks (SF60d) and two types of polypropylene fibres: 19 mm long, fibrillated fibres (PF19), 60 mm long, bi-component fibres (PF60). They are the most frequently used fibres in practice. The characterisics of applied fibres are shown in Tables 2-3 and Figures 2–3. Hooked-end steel fibres are glued in bundles. According to the producer fibrillated polypropylene fibres are two-side coated with a special substance that enlarges the surface of fibres and facilitates dispersion of fibres in the cement paste. Bi-component fibre consists of a core (high tensile strength, high E-modulus polymer) and a shell (Fig. 3). The structured and nano-modified shell (the embossed surface of the shell and surface activating additives) ensures excellent binding to the cement matrix.Fibres were applied as the mono-fibre reinforcement (SF35, SF60, SF60d, PF60) or hybrid reinforcement (SF60 + SF13, SF35 + P19, SF60 + P19, SF60d + P19, P60 + P19) of the concrete matrix (Table 4). The content of fibres was similar to that used in practice. Each type of steel fibres was added to the cement matrix in the amount of 30 kg/m^3 (0.38% by volume). The content of fibrillated polypropylene fibres was always 1 kg/m^3 (0.11% by volume). As regards bi-component polypropylene fibres, the content of fibres was 2 kg/m^3 (0.22% by volume) (minimum amount recommended by the manufacturer) in the case of mono-fibre reinforcement and 1 kg/m^3 in the case of hybrid reinforcement (the combination with 1 kg/m^3 of fibrillated polypropylene fibres).

2.2 *Preparation of specimens*

The research were conducted on fresh and hardened (28-day) cement concretes with and without fibres. All specimens were demoulded after 24 hours and cured in high humidity conditions RH > 90% and at the temperature of + 20°C until the age of 28 days.

2.3 *Test methods*

The following properties of fresh and hardened concretes, with and without fibres, were analysed: consistency, air content, water absorption after 28 days, 28-day compressive and flexural strength, load-deflection relation. Consistency was determined by the slump test (according to EN 12350-2). For measuring the air content in fresh concrete mixtures (after consolidation on the vibrating table)the pressure method (according to EN 12350-7) was used. Water absorption was tested according toPN-88/B-06250. Compressive strength test was conducted according to EN 12390-3. 100 mm and 150 mm cube specimens were used

Figure 4. Set-up for performing bending tests.

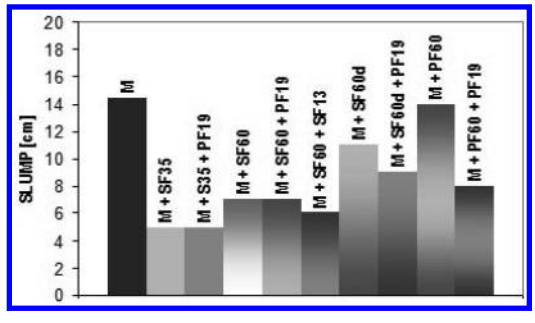

Figure 5. Slump (slump classes: S2- slump: 5-9 cm, S3- slump: 10-15 cm) of concrete mixtures with and without fibres.

to test water absorption and compressive strength, respectively. The behaviour of each concrete at bending was investigated using a 100 × 100 × 500 mm beam as a specimen. Three-point bending test (according to EN 12390-5) was used (Fig. 4). The distance between supports was 300 mm.The deflection rate was 1 mm/min. During the flexural strength examination, force-deflection relation was determined. The tests of mechanical properties of fibre reinforced cement concretes were carried out at Cracow University of Technology, Faculty of Civil Engineering; Zwick/Roell Z100 press was applied (Fig. 4). Water absorption for every type of concrete was tested on six specimens. Each mechanical property was assessed on three specimens.

3 RESULTS AND DISCUSSION

3.1 *Consistency*

The concrete mixtures tested characterize the classes of consistency of S2, S3 (Fig. 5). The influence of the presence of fibres on consistency depends on the type of fibres. As regards the mixtures with one type of fibre, the effect is more significant in the case of rigid steel fibres than polypropylene fibres. The dominant effect is noticeable for the mixture with steel fibres of

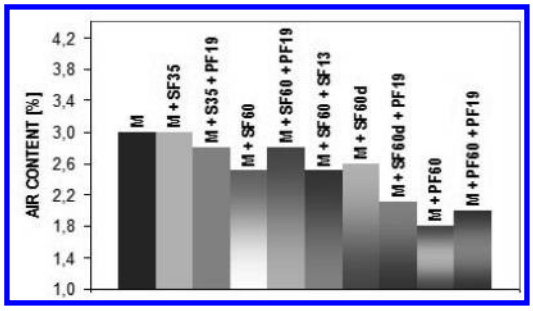

Figure 6. Air content of concrete mixtures with and without fibres.

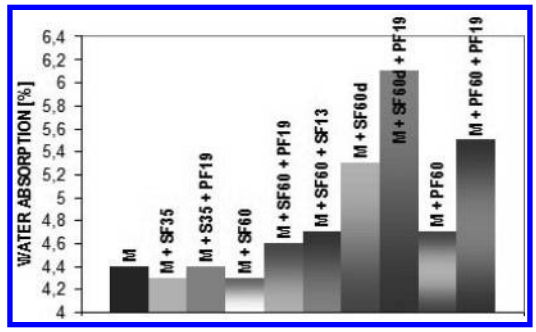

Figure 7. Water absorption of concrete with and without fibres.

the length of 35 mm (SF35) (the reduction of the slump from 14.5 cm to 5 cm for the fibre content of 30 kg/m^3). It can result from the large numberof fibres(about 14,500 fibres per kg), which is greaterthan 4600 and 3200 fibres per kgfor steel fibres of the length of 60 mm with single hooks (SF60) and double hooks (SF60d),respectively (Table 2). As regards the mixtures with hybrid fibres, polypropylene microfibres (fibrillated, 19 mm long) (PF19) (in the amount of 1 kg/m^3) have the insignificant influence when they are combined with SF35 or SF60 steel fibres. But polypropylene microfibres added together with SF60d steel fibres into the concrete matrix (M)reduce liquidity more than SF60d used as one type of fibres (the slump of 11cm for M + PF19 + SF60d and 9 cm for M+SF60d). Also in the case of the combination of short steel fibres of the length of 13 mm (SF13) with SF60 steel fibres, the mixture is less liquid than that with SF60 fibres (one type of fibres). The hugequantity of short fibres SF13 (about 314,000 fibres per kg) improves the compaction of the mixture. The influence of polypropylene fibres on consistency is negligible for macrofibres (bi-component fibres) (PF60) in the amount of 2 kg/m^3 and considerable for the combination of 1 kg/m^3 macrofibres and 1 kg/m^3 microfibres (PF60 + PF19). Although the amount of fibres – 2 kg per 1 m^3 is the same in both mixtures, consistency varies. The liquidity of the mixture with one type of fibres (macrofibres) and the mixture without fibres is hardly differ (the slump of 14 cm and 14.5 cm, respectively) whereas hybrid fibres reduce the slump from 14.5 cm to 8 cm. The greater effect of hybrid fibres than polypropylene macrofibres on liquidity can result from the huge quantity of microfibres (about 2,500,000 pieces of polypropylene microfibres as compared to about 100,000 pieces of polypropylene macrofibres, for the fibre content of 1 kg/m^3).

3.2 *Air content*

The values of air content are not larger than 2% for mixtures with polypropylene fibres (Fig. 6). The large number of fibres in the case of hybrid polypropylene reinforcement (PF60 + PF19) (see Section 3.1) and then the difficulty in the proper compaction of the mixturecan cause high air content (air content is larger than for mono-fibre polypropylene reinforcement (PF60)). The influence of rigid steel fibres on air content is noticeable. The higher the number of steel fibres (see Section 3.1), the higher the air content. The largest value of the air content (3%) is observed for the mixture with steel fibres of the length of 35 mm (SF35).

3.3 *Water absorption*

The slight decrease in water absorption of concretes with SF35 or SF60 steel fibres (Fig. 7) can result from the positive effect of fibres on the reduction of shrinkage strains and then crack formation. For other types of fibre reinforced concretes tested, water absorption is higher than for concrete without fibres. Since water absorption is highly dependent on workability of the concrete mixture, which considerably worsens after the addition of a large number of thin fibres (polypropylene fibres) or fibres long,complicated in their shape (e.g. steel fibres of the length of 60 mm with double hooks (SF60d)), the largest value of water absorption (6.1%) is observed in concrete with the combination of SF60d steel fibres and 19mm polypropylene fibrillated fibres (PF19).

3.4 *Compressive strength*

The influence of the addition of one type of steel fibres (SF35 or SF60 or SF60d) or hybrid steel fibres (SF60 + SF13) on 28-day compressive strength is insignificant (Fig. 8).

Polypropylene fibres decrease this property by about 10% in the case of the combination of polypropylene macrofibres (PF60) and microfibres (PF19), and by about 8% for polypropylene macrofibres. Also polypropylene microfibres (PF19) used with steel fibres of the length of 60 mm (SF60, SF60d) slightly reduce compressive strength.

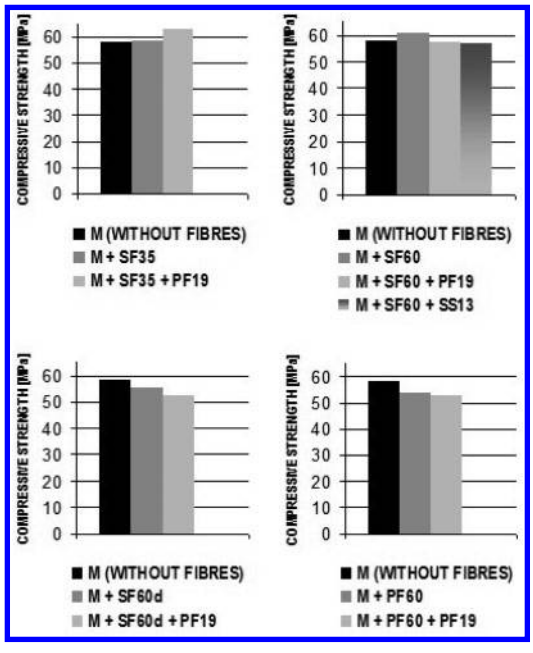

Figure 8. 28-day compressive strength of concretewith and without fibres.

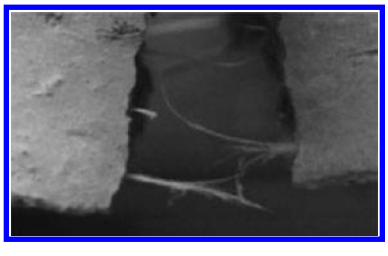

Figure 9. Bi-component polypropylene fibres, broken during the destruction of the beam.

3.5 *Flexural strength*

The behaviour at bending of 28-day concretes tested, recorded as the load-deflection curves is reported in Figure 10. The obtained curves show the synergistic effect of hybrid fibres. The deflection, accompanying the appearance of the first crack is greater for concrete containing the combination of SF35 steel fibres or SF60 steel fibres or PF60 polypropylene macrofibres with PF19 polypropylene microfibres than for concrete with the mono-fibre reinforcement and concrete without fibres. The positive influence of PF19 fibrillated polypropylene fibres, which reduce shrinkage strains and prevent the cement matrix from crack formation and propagation, is noticeable. The synergistic effect ofthree types of hybrid fibres,SF35 + PF19, SF60 + PF19, SF60 + SF13 is also observed in the behaviour of concrete after the peak load.The amount of energy, required for the deflection of 2 mm (the deflection, which is equal to the 1/150 beam span; $1/150 \times 300\,\text{mm} = 2\,\text{mm}$),

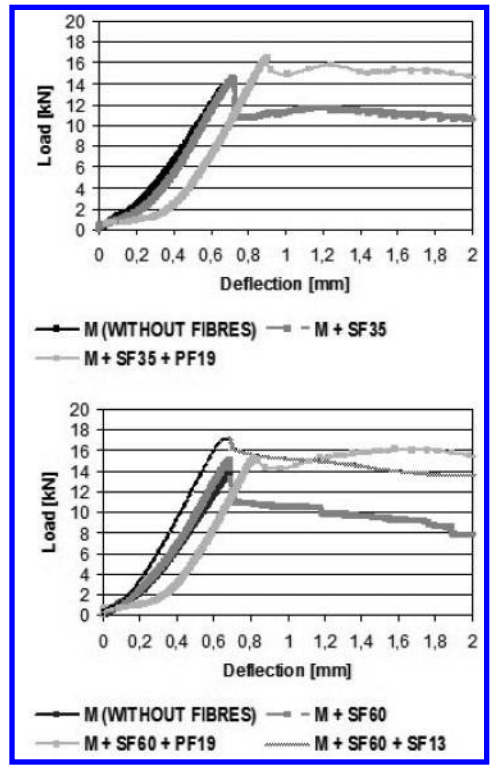

Figure 10. Load-deflection curves recorded for 28-day concretes with and without fibres.

calculated as the area under the load-deflection curve to the deflection of 2 mm, according to the Japanese standard JCI – SF4 (energy, which is used for the calculation of equivalent flexural strength)is higher for hybrid fibre reinforced concretes than for concretes with one type of steel fibres (SF35, SF60, respectively) (Table 5). The values of energy and equivalent flexural strength (calculated from the formula: $f_{eq} = T_b L/\delta_b bh^2$; where T_b = energy; L = beam span; L = 300 mm; δ_b = deflection; $\delta_b = 2$ mm, b = beam width; b = 100 mm; h = beam height; h = 100 mm) for concretes tested are given in Table 5. The analysis of calculated parameters has only comparative character because the dimensions of the tested specimens were not consistent with JCI – SF4.Steel fibres of length of 60 mm with double hooks (SF60d) are those which strongly enhance concrete after the peak load (Fig. 10). But SF60d steel fibres used together with polypropylene microfibres (PF19) as the hybrid reinforcement are not so effective (Fig.10).The values of flexural strength of tested concretes are illustrated in Figure 11. The largest flexural strength is observed for concrete with the combination of long (SF60) and short (SF13)steel fibres (with high quantity of fibres: 30 kg/m^3 of SF60 and 30 kg/m^3 of SF13).During the beam breaking, hooked steel fibres were pulled out from the cement matrix, but polypropylene fibres were broken (Figure 9).

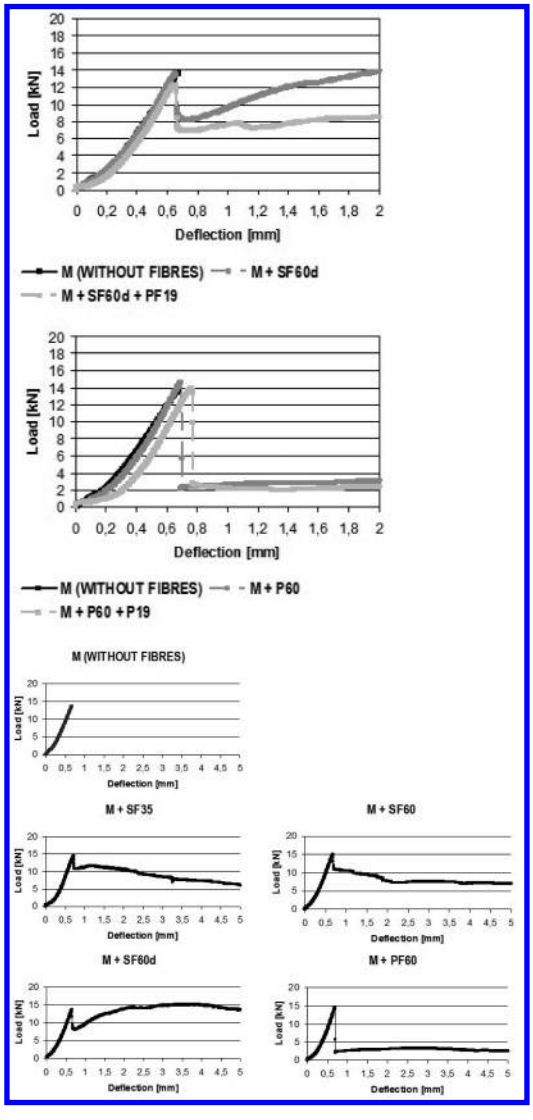

Figure 10. Continued.

Table 5. Toughness parameters for concretes with and without fibres (according to the Japanese standard JCI – SF4).

Name of concrete mixture	Energy required for the deflection of 2 mm, kNmm	Equivalent flexural strength, MPa
M (without fibres)	3.9	
M + SF35	18.3	0.6
M + SF60	17.1	2.8
M + SF60d	18.7	2.6
M + PF60	7.4	2.81
M + SF60 + SF13	28.0	4.2
M + SF35 + PF19	23.6	3.5
M + SF60 + PF19	24.6	3.7
M + SF60d + PF19	13.5	2.0
M + PF60 + PF19	6.4	1.0

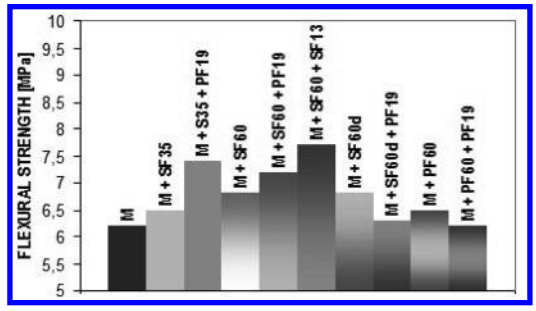

Figure 11. Flexural strength of 28-day concretes with and without fibres.

4 CONCLUSIONS

The presented research on cement concretes modified by hybrid fibres lead to the following general conclusions:

1. Hybrid fibres effect the physical properties. The huge quantity of fibresresults in lower liquidity and higher water absorption of hybrid fibre reinforced concretes compared to concretes with one type of fibres.
2. The influence of hybrid fibres on 28-day compressive strength is negligible. Polypropylene fibres in the mono-fibre and hybrid forms reduces this property by 10%.
3. The positive, synergistic effect of hybrid fibres on the flexural properties of concretes is noticeable in four of five types of hybrid fibres tested: SF60 + SF13, SF35 + PF19, SF60 + PF19, P60 + P19. The application of PF19 together with SF60d does not improve the properties of concrete with one type of fibres (SF60d).

A review of the shear behaviour of reinforced steel fibre concrete

S. Zeranka & G.P.A.G. van Zijl
Stellenbosch University, Stellenbosch, Western Cape, South Africa

ABSTRACT: The shear behaviour of Reinforced Steel Fibre Concrete (RSFC) has undergone extensive research over the past 40 years. A comprehensive review of the literature is therefore essential in order to extend on the existing research. This paper will convey the origin, development and current status of the research topic and field, identifying the key issues and developments. In order to define the role and objectives of this research, this state-of-the-art will introduce a summary of the main findings from the primary research contributors and will present and evaluate to a limited extent the prominent research methodologies employed, both from an experimental design and modelling perspective. In conclusion, a research proposal will be established, based on the findings contained herein.

1 INTRODUCTION

1.1 *The shear transfer problem*

A shear failure originates as a tensile failure of the concrete, in the shear span of a reinforced concrete (RC) beam, when the principal tensile stresses exceed the tensile strength of concrete. Diagonal cracks develop and propagate in the beam web and due to the brittle nature of plain concrete in tension, collapse occurs suddenly, shortly after the formation of the first crack. Shear failure is therefore characterised by small deflections and a lack of ductility and is an undesirable mode of failure.

The shear behaviour of RC is a complex phenomenon which may lead to a variety of possible shear failure modes, which are dependent on a several interacting shear transfer mechanisms that are difficult to quantify. The shear transfer mechanisms themselves are also influenced by many factors related to the material properties and the structural configuration of the member.

1.2 *Research significance*

Over the past four decades, many authors have motivated the partial or complete replacement of conventional shear reinforcement with steel fibres. The shear performance of fibrous RC beams has been shown to be similar to beams reinforced with conventional stirrup reinforcement (Mansur et al. 1986) and in some instances exhibit improved behaviour (Narayanan & Darwish 1987).The structural use of steel fibre-reinforced concrete has not yet been fully achieved in the concrete industry. This is attributed to the current high cost of fibres and a lack of rational guidelines (with regard to standardised codes) for design and production (Slater et al. 2012, Noghabai 2000).

2 LITERATURE REVIEW

2.1 *Material and structural enhancement*

The increase in the first shear crack strength due to steel fibre-reinforcement can be significant, and is attributed to the crack-arresting mechanism of steel fibres (Roberts & Ho 1982). Steel fibre reinforcement can also substantially increase the ultimate shear capacity, especially for members without conventional shear reinforcement (Parra-Montesinos 2006). The rate of increase in ultimate shear strength is however dependent on several conditions, which will be discussed in the sections that follow.

A substantial post-cracking or residual strength is observed for RSFC beams after the formation of diagonal cracks (Sharma 1986). The structural stiffness can be enhanced both pre- and post-cracking (Furlan Jr. & de Hanai 1997). Increased structural ductility, energy absorption and toughness were observed for members containing steel fibres (Adebar et al. 1997). Fibre-reinforcement significantly reduces and possibly eliminates the occurrence of concrete spalling in the post-cracking stage and at final collapse (Lim & Oh 1999).This can protect reinforcement from corrosion in adverse environments, and hence improves structural durability (Li et al. 1992).

Fibre-reinforcement delays the formation and restrains the opening and propagation of cracks (Watanabe et al. 2010). In addition a more distributed cracking pattern develops, with more closely spaced cracks, which delays the localisation of a major shear-critical crack (Minelli & Plizzari 2008).

This is attributed to a more uniform distribution of stresses in FRC beams, compared to conventional beams (Narayanan & Darwish 1987). The cracks are also more diffused i.e. the crack width is reduced, which improves the transmission of shear load and the redistribution of stresses (Juárez et al. 2007). The cracking pattern of FRC beams has been observed to be similar to corresponding RC beams with conventional stirrup reinforcement (Narayanan & Darwish 1987). It is has also been postulated that in members without stirrup reinforcement, the effect of beam depth on shear strength is reduced with fibre-reinforcement (Dinh et al. 2011).

The effective control of cracking in FRC beams, results in a reduction of deflections as well as an increase in the deformation capacity and ultimate deflection (Kwak et al. 2002).

Fibre-reinforcement reduces the bar reinforcement strains, especially in the post-cracking range and thereby delays and reduces the stresses in the bar reinforcement (Cho & Kim 2003). This is an indication that the fibre-concrete is contributing to the shear strength (Furlan Jr. & de Hanai 1997).

The inclusion of steel fibres can change the mode of failure from a brittle shear failure to a ductile flexural failure, even in the absence of stirrups, allowing the RC member to reach its full flexural capacity (Swamy & Bahia 1985).

2.2 *The shear transfer mechanisms*

The efficiency of fibre-reinforcement depends on the governing load-carrying mechanisms, which may vary (Noghabai 2000). Fibre-reinforcement is known to enhance many of the shear transfer mechanisms.

The shear resistance increases as the longitudinal reinforcement ratio increases. The longitudinal reinforcement serves to increase the cracking strength, delaying the formation and propagation of flexural and inclined cracks and increasing the total dowel capacity (Li et al. 1992). The longitudinal reinforcement ratio also influences the size of the compression zone and the overall structural ductility (Dinh et al. 2010). Steel fibre-reinforcement improves the effectiveness of dowel resistance due to its ability to enhance the tensile strength (greater resistance to the propagation and widening of dowel cracks in the dowel zone along reinforcement) of concrete in the splitting plane along the longitudinal reinforcement (Li et al. 1992).

An increased concrete compressive strength does increase the shear capacity of both RC and RSFC beams (Mansur et al. 1986). The degree to which steel fibre-reinforcement influences concrete compressive strength varies from a significant increase in compressive strength (Lim & Oh 1999), to a marginal or insignificant increase (Tan et al. 1993), especially in low volume fractions (Dinh et al. 2011). Even a reduction in compressive strength may be observed, which is attributed to the reduced consolidation of concrete due to the presence of fibres (Adebar et al. 1997). The most significant enhancement of steel fibre-reinforcement to the compressive properties of concrete is the substantially higher compressive strain at peak stress compared to ordinary concrete. This is attributed to the confinement provided by the fibres (Tan et al. 1993). An increase in residual compressive strength is observed due to the reduced damage in tension (Minelli & Vecchio2004). This may be beneficial in deeper beams where arch action is prominent and compression forces are transmitted to the supports through compression struts. The key property influencing the effectiveness of fibre-reinforcement is the fibre-matrix interfacial bond (Li et al. 1992).

The shear behaviour of RC beams is affected by the shear span-to-depth ratio to a large extent. In general, for a span-to-depth ratio greater than 2.5, flexural effects predominate, whereas shear predominates for lower values of the span-to-depth ratio (Ashour et al. 1992). The cracking and ultimate shear strength decrease with increasing span-to-depth ratio. Arching and dowel action become less effective as the span-to-depth ratio increases (Kwak et al. 2002).There does appear to be some controversy with regard to when fibre-reinforcement is more effective i.e. for slender or deep beams. According to some authors the rate of increase in shear strength is higher at low values of the span-to-depth ratio and consequently arch action is believed to benefit more from fibre-reinforcement (Mansur et al. 1986, Narayanan & Darwish 1987, Ashour et al. 1992). This is attributed to the greater cohesion of fibre concrete and the improved tensile capacity of the concrete in the transverse direction. Contrary to these findings other authors state that the efficiency of fibres as shear reinforcement increases as the span-to-depth ratio increases. The reasoning is that improvements due to fibre-reinforcement are related directly to the pull-out performance of fibre concrete and the beam action failure mechanism has a greater capacity to utilise the improved material performance due to fibre-reinforcement (Li et al. 1992, Cucchiara et al. 2004).

In conventional design, the contribution of aggregate interlock or interface shear to the shear capacity is conservatively ignored. This is mainly because the aggregate interlock contribution diminishes with increasing crack width and is therefore not reliable. Aggregate interlock is believed to become more effective due to the crack width limitation provided by the fibres, however to the authors' knowledge this has not been investigated in detail. The fibres therefore have a function which is similar to conventional shear reinforcement, but unlike conventional reinforcement are uniformly distributed throughout the member volume (Sharma 1986, Wight & MacGregror 2009). The contribution of aggregate interlock in shear transfer is mainly influential during shear sliding of diagonal cracks in beams with a span-to-depth ratio greater than 2.5 (i.e. slender beams). The aggregate interlock contribution disappears for deeper beams which fail in arch action, where crack face shearing is negligible (Li et al. 1992).

In beams without conventional transverse reinforcement, size-effects significantly influence the shear behaviour and fibre-reinforcement is less effective in large-scale beams (Adebar et al. 1997). There is a general trend of decreasing shear strength with increasing beam size or depth and this is consistent with results of plain concrete beams as well as theoretical work (Li et al. 1992). Few tests have been conducted on large FRC beams. Steel fibres have been shown to beineffective in preventing catastrophic shear failures in full-scale beams (Williamson & Knab(1975) cited by Adebar et al. 1997).The contribution of fibres is therefore size dependent, whereas the contribution provided by stirrups is expected to be size independent. In larger beams, conventional shear reinforcement is more effective than steel fibres in terms of bearing capacity and ductility. The scale effects can be mostly eliminated using minimum transverse reinforcement (Minelli & Plizzari 2008). A reduction in crack spacing due to fibre reinforcement could at least in some instances potentially reduce or eliminate shear-size effects in beams without conventional transverse reinforcement (Dinh et al. 2010).

2.3 *Fibre properties*

The following composite properties related to the fibres, influence the shear behaviour of RSFC beams: fibre -content, -aspect ratio, -length, -shape (profile and end anchorage), -strength, -stiffness, and the fibre-matrix interfacial bond. At lower fibre volumes, the increase in shear strength is proportional to the quantity of fibre; however, the rate of increase is reduced at higher fibre volumes (Adebar et al. 1997). An optimum fibre dosage therefore exists for every composite type. In the practical range of typical steel fibres used (0.25–2.0% by volume), an optimum fibre dosage appears to lie between 1.0% and 1.5%. Volume fractions of fibres smaller than or equal to 0.5% did not produce shear resistance at failure substantially greater than the required minimum (Parra-Montesinos 2006).

High-strength fibres may produce an increased residual strength compared to normal-strength fibres, this attributed to a greater plastic strength of fibre hooks (Dinh et al. 2010). The beneficial effect of high-strength fibres is dependent on the properties of the composite, especially the fibre-matrix bond and matrix strength.

Longer fibres exhibit a more ductile response compared to shorter fibres (Adebar et al. 1997). The stress transfer capability of shorter fibres reduces faster than longer fibres, resulting in a faster rate of force transfer to the other shear-resisting mechanisms (Li et al. 1992). The fibre factor is a combined fibre parameter consisting of the fibre aspect ratio, the fibre volume and a bond efficiency factor which is dependent on the fibre type. The fibre factor has a greater influence on the shear strength than any individual fibre parameter and is used in most semi-empirical models (Slater et al. 2012). In a study by Li et al.(1992), polyethylene and steel fibres were found to be the most effective in increasing shear strength. Synthetic fibres are however not as effective as steel fibres in increasing the shear strength of concrete beams, due to its low modulus of elasticity (Furlan Jr. & de Hanai1997). Steel fibres are better able to redistribute the strains among cracks compared to non-metallic fibres (Noghabai 2000).

2.4 *The synergetic effect of fibre and stirrup reinforcement*

There are design instances where fibre-reinforced beams cannot achieve the same performance as beams containing conventional shear reinforcement. In these cases steel fibres alone are not effective in preventing catastrophic shear failures (Williamson & Knab (1975) and Lafraugh & Moustafa (1975) cited by Swamy & Bahia 1985). There is a limited amount of experimental data in the literature on the shear behaviour of beams where a combination of fibres and conventional transverse reinforcement is used (Cucchiara et al. 2004). Tests have shown that such a combination can form an effective system of shear reinforcement in a structural member (Craig (1984) cited by Sharma 1986). Fibres and stirrups in small quantities can be effective to enhance the shear strength, as well as the crack and deformation control, providing a ductile post-peak behaviour. Such a reinforcement combination can change the mode of failure and preserve the ductility and integrity of the structural member (Swamy & Bahia 1985, Meda et al. 2005). The amount of stirrups required can be reduced with the introduction of fibre-reinforcement (Lim & Oh 1999). A combined use of fibres and stirrups is believed to be more suitable, because the stirrups allow greater deformation capacity beyond the elastic limit (Cucchiara et al. 2004). The conventional shear reinforcement also reduces the scatter in the data and assists in crack width control and consequently assists the bridging of fibres along the diagonal crack, increasing the shear-resistance carried by the steel fibres. Stirrups effectively prevent the rapid opening and propagation of the diagonal crack, which increases the efficiency of the fibres. In conclusion, there exists a synergetic interaction between the shear resistance mechanisms (Watanabe et al. 2010). Other authors have also observed a positive composite effect and efficiency for a combination of stirrups and steel fibres, on the mechanical behaviour (including ultimate load, ductility, post-peak behaviour, toughness and failure pattern). The shear strength has been shown to be approximately proportional to the steel fibre content; however this is dependent on the conventional shear reinforcement ratio (Ding et al. 2011). Fibre-reinforcement is less effective at higher conventional shear reinforcement ratios i.e. the rate of improvement with increasing fibre content decreases with increased conventional shear reinforcement (Ding et al. 2012). This is attributed to a greater proportion of the load being carried by the stirrups and less by the fibres in the ultimate stages when cracks widen and fibre pull-out occurs (Swamy & Bahia 1985).

3 RESEARCH METHODOLOGIES

3.1 *Experimental design*

Experimental investigations to date have been predominantly shear tests of simply supported RC structural beam members subjected to flexural loading. The parameters related to the specimen geometry, loading configuration and conventional reinforcement are: the shear span-to-effective depth ratio, longitudinal reinforcement ratio, transverse reinforcement ratio and beam depth (size effect). Structural tests are usually accompanied with fracture mechanics tests such as flexural or splitting tests, where the residual post-cracking strength is of primary importance. This is used as input to reconcile material models with the structural response. The material parameters typically include: the concrete compressive strength, fibre content and the fibre properties (length, aspect ratio, strength, mechanical anchorage and profile).

The data typically recorded for these types of tests are the load vs. beam deflection response (at mid-span), crack widths, development and patterns, the load at first visible diagonal/shear cracking and ultimate load, failure modes, reinforcement and concrete strains, rotation at supports and specimen curvature.

Far less work has been done on the direct shear response of fibre reinforced concretes (Soetens &Matthys 2012, Lee & Foster 2006). These types of tests are performed to evaluate the direct/pure shear response in terms of the relative shear interfacial slip and shear capacity i.e. crack sliding or Mode II fracture. Two test methods are typically employed, the shear push-off (or Z-type specimens) (Lee & Foster 2006, Tan & Mansur 1990) and the shear push-through specimens (JSCE 1990) modified by (Mirsayah & Banthia 2002, Soetens & Matthys 2012, Boulekbache et al. 2012, Malatesta & Contreras 2009). Even fewer investigations, attempt to link the pull-out behaviour of single fibres to SFRC under mode II fracture i.e. the transverse pull-out of steel fibres (Lee & Foster 2006, Soetens & Matthys 2012).

3.2 *Modelling*

A rational and generic model for shear design with fibre-reinforcement requires an understanding of the governing load-carrying mechanisms. Experimentation alone is insufficient to expose the underlying mechanisms. Analytical formulations which implement the theory are required in order to explain the structural behaviour in mechanical terms and to correctly interpret the experimental results.

3.2.1 *Empirical and semi-empirical models*

The majority of predictive equations for the shear strength of FRC beams, including those found in most design codes, are empirical or semi-empirical (Cho & Kim 2003), fitted by test data, and therefore are not comprehensive (Kim et al. 2012). These types of models can only predict the ultimate shear capacity and in some instances also the cracking shear strength. Typically some form of an existing shear design model for conventional RC (such as those currently implemented in most design codes) is utilised as a framework which is modified to account for the contribution of fibres. Models are typically sourced from the ACI Building Code (ACI 318-08) or Eurocode 2 (2003)and in some instances the theory of concrete plasticity or limit analysis is also used. These models are sometimes used in conjunction with linear or nonlinear regression analysis. Empirical formulas usually only evaluate a limited set of parameters that typically only include the shear span-depth ratio, beam depth, compressive strength, reinforcement ratio and concrete flexural or tensile strength.

Semi-empirical models place greater emphasis on the fibre contribution. These models differ in their level of consideration. Some models will evaluate the fibre contribution at a single fibre level and include such parameters as the fibre distribution, mean fibre pull-out length, average fibre-matrix interfacial bond stress, fibre aspect ratio, fibre volume and bond efficiency factor (Narayanan & Darwish 1987, Al-Ta'an & Al-Feel 1990). Whereas other models consider the fibre contribution at a composite level, which typically includes a residual post-cracking strength parameter obtained from standard fracture mechanics tests, such as flexural and splitting tensile strength tests (Mansur et al. 1986, Minelli & Plizzari 2008, Dinh et al. 2011).

3.2.2 *Analytical models*

Analytical models are capable of simulating the stress-strain history and in some instances, the load-deflection response of a member. The model parameters typically include the stress-strain relations for FRC in tension and compression or alternatively the fibres are modelled explicitly as mentioned in the previous section (Kim et al. 2012). The earliest work was first performed by Tan & Mansur (1990) and then later again by Tan et al. (1993). The theoretical background of these models is based on the softened truss model (Hsu et al. 1987) and the modified compression field theory (MCFT) (Vecchio & Collins 1986), which is essentially a smeared, rotating crack model for cracked RC elements. These models have three basic requirements: equilibrium, compatibility and material constitutive equations. The MCFT has been used extensively as the theoretical framework for such models. Nonlinear truss or lattice models which incorporate geometric and mechanical modelling, have also been investigated (Noghabai 2000).

3.2.3 *Numerical/Finite element (FE) models*

Few numerical studies are published concerning FRC structures (Minelli & Vecchio 2004). In order to allow for a redistribution of stresses in the model, a FE method must be used. These models are capable of simulating the strength, stiffness, ductility, crack pattern development, and failure modes, essentially the complete member response. These types of models

allow for a more detailed investigation into the development of shear resistant mechanisms and an accurate evaluation of the fibre contribution to shear resistance is possible (Minelli & Vecchio 2006). The fibre contribution to concrete tension softening and the material nonlinearities are incorporated into the models. In addition these models include crack limits, arch action mechanisms and concrete residual strength in the presence of fibres. Once again models differ in their consideration of fibre-reinforced concrete, which may be on a composite level or single fibre level (Lee et al. 2012). The MCFT is once again used as the theoretical framework for the finite element analysis and is adapted for FRC in terms of the post-cracking behaviour and local conditions at cracks (Minelli & Vecchio 2004). An extension of the MCFT is the disturbed stress field model (DSFM) which is capable of simulating the crack shear-slip deformation (Minelli & Vecchio 2006).

Recent approaches, including the MCFT or plasticity theory are rational and have physical significance (Cho & Kim 2003). However, a model which is based on FRC performance in terms of the residual post-cracking strength (which is considered to be a significant index for structural design and is obtained through simple fracture mechanics tests), can easily be applied and transferred to practice (Minelli & Plizzari 2008).

4 DESIGN CODES AND RECOMMENDATIONS

There are very few standards or recommendations that allow for the quantification of shear strength and shear ductility enhancement provided by fibre-reinforcement (ACI 544 Committee 2008b, cited by Malatesta & Contreras 2009). A design procedure that considers the randomly distributed discrete fibre behaviour across cracks in a rational manner is still rare (Ding et al. 2012).

The design codes which provide shear design provisions for RSFC beams include the ACI Code (ACI 318-08), fib Model Code 2010 and the RILEM TC 162-TDF recommendations. These design provisions are similar in that they all incorporate and specify minimum post-cracking residual strength criteria which are evaluated through flexural test methods.

5 CONCLUSIONS

Based on the findings contained in this state-of-the-art, some omissions and areas of limited research have been identified. Limited research has been placed on examining the fibre pull-out/dowel and aggregate interlock (shear interface roughness)interaction at different loading stages or crack widths. Limited research has been performed on the composite effect of a fibre and conventional stirrup reinforcement combination. Extending the knowledge of the shear transfer mechanisms through carefully designed characteristic testing and the development of a refined analytical model is proposed and postulated to clarify the dominant shear mechanisms and structural resistance of RSFC beams.

Time-dependent behaviour of pre-cracked polypropylene fibre reinforced concrete (PFRC) under sustained loading

A.J. Babafemi & W.P. Boshoff
Department of Civil Engineering, Stellenbosch University, South Africa

ABSTRACT: This study investigated the delayed deformation behaviour of pre-cracked Polypropylene Fibre Reinforced Concrete (PFRC) under sustained loading. Post-peak residual strength, loading-unloading-reloading response, shrinkage and uniaxial tensile creep are reported. Specimens for the creep test were pre-cracked and subjected to 30% and 50% stress levels of the post-peak residual strength of PFRC. All tests were done using $100 \times 100 \times 500$ mm prism specimens in a controlled climate room. It is shown that the shrinkage deformation of unloaded specimens' exhibit increased reduction after 45 days of testing up to 4 months when compared to predicted behaviour of normal concrete. Specimens loaded at 50% post-peak residual strength showed increased creep when compared to those loaded at 30%. While specimens subjected to 30% sustained loading showed an almost stable response at 4 months, those loaded at 50% experienced creep fracture at same period.

1 INRODUCTION

The use of steel and synthetic fibres in concrete has become an interesting subject in the past few decades in the construction industry. Fibres have generally become known to improve the residual tensile capacity of concrete in the cracked state (toughness) by bridging the cracked surfaces (Buratti, et al. 2011). Hence, they are usually referred to as crack arresters. Depending on the fibre type, geometry and volume, the behaviour could be strain hardening or strain softening. Other benefits of using fibres in concrete as reported by numerous researches include impact resistance, fatigue resistance, reduction in early plastic shrinkage cracking, etc. (Zhang 2003, Mackay & Trottier 2004, and Zile & Zile 2013).

Many studies have been undertaken on the quasi static mechanical behaviour of fibre reinforced concrete (FRC). It should be noted that the fibres used in concrete becomes engaged only after the initiation of cracks (Arango et al. 2011). Hence, the European Code (EN 14651, 2005) made provision for the residual strength of concrete tested under three-point bending at different crack openings. However, there is still a dearth of information in literature on the time-dependent behaviour of FRC under sustained loading. It is required to understand the creep behaviour of FRC before this time-dependent behavior can be included in design guidelines. Hence, this pre-cracked samples need to be tested at different levels of sustained loading. Of concern is the increase of the crack opening of tensile and flexural samples.

Little work have been reported in literature on the long term behaviour of FRC under sustained loadings. Zerbino & Barragán (2012) reported on the flexural creep behaviour of beams reinforced with steel fibres (0.5% fibre volume) over a period of 21 months. The pre-cracked beams were said to display a significant load-bearing capacity with maximum residual stress as high as 60% above the first peak stress.

Beams subjected to flexural creep with a pre-cracked crack width of 0.2 mm at a constant stress of 100% of the residual post-crack stress were said to show stable responses after 18 months. With less than 50% of the post-crack stress, slight displacement that later stabilized to almost zero crack rate openings was also reported in the same study. However, for beams showing softening post-crack behaviour, Zerbino & Barragán (2012) reported that failure occurred when applied stresses were almost as much as the residual post-crack stress.

There are still little work reported in literature on the uniaxial tensile time-dependent behaviour of pre-cracked steel fibre reinforced concrete (SFRC). More researches have been reported on flexural creep of SFRC than on the uniaxial tensile creep (Tan et al. 1994, Mackay & Trottier 2004, Tan & Saha, 2005, and Zerbino & Barragán 2012). The positive results reported for SFRC can be attributed to the high stiffness of steel fibres unlike polypropylene fibre (PF) which has a low stiffness.

Recently, the use of PF to replace steel fibres (SF) in concrete is being advocated as it is cheaper, lighter and does not corrode in concrete (Richardson 2004). However, much remains unknown about the time-dependent behaviour of PFRC. In one study, beams reinforced with macro synthetic PF and subjected to 50% of the residual load in bending after pre-cracking have been reported to creep between 10-30 times more than those with steel fibres after 2 years (BEKAERT, 2008).

2 RESEARCH SIGNIFICANCE

This study investigates the time-dependent behaviour of concrete prisms incorporating discrete monofilament macro synthetic fibres subjected to sustained loads over a period of 4 months. Specimens were loaded at 30% and 50% post-peak residual uniaxial tensile strength. The study provides an understanding of the delayed behaviour of concrete incorporating PF under varying levels of sustained loading.

3 EXPERIMENTAL PROGRAMME

The uniaxial tensile creep behaviour of cracked PFRC was investigated. All tests were performed using concrete prisms measuring $100 \times 100 \times 500$ mm. These tests included uniaxial tension, shrinkage and creep tests. All tests were done in a climate controlled room with a temperature of $23, \pm 1°C$ and an average relative humidity of 65 ± 5 %. Specimens were cast and demoulded after 24 hours and cured in water for a further 27 days before testing. Specimens for the creep and shrinkage tests were kept in the climate controlled room for about 12 hours before the test was started.

3.1 *Materials*

PF supplied by Fibsol (Fibre Reinforcing Solutions), South Africa, with a trade name Rocstay CXO 50/40 SS were used. Details of the fibres are shown in Figure 1 and Table 1.

The coarse aggregate (greywacke stone) used were those passing through the 6 mm sieve size while the fine aggregate was natural sand (Malmesbury) passing through 2.36 mm sieve with a fineness modulus (FM) of 2.34. CEM I 52.5 cement was used as the binder.

Table 2. Concrete mix design used.

Materials Type	kg/m^3
Cement	395
Stone	800
Sand	990
Water	190
Fibre	9.1
Super plasticizer (0.2%)	0.79

The requirement of the 6 mm stone size was justified by the relationship between maximum grain size and fibre volume in per cent given by Kobayashi & Cho in Markovic (2006). The maximum stone size can be calculated as follows

$$S = 5\sqrt{\frac{\pi}{0.002\,L/d + 0.4}}\frac{d}{\sqrt{V_f}} - d \qquad (1)$$

where S = maximum grain size in [mm]; L = fibre length in [mm]; d = diameter of fibre in [mm]; and V_f = volume ratio of fibre.

3.2 *Mix design*

A mix design was developed for the investigation as shown in Table 2.

Workability test was done using the slump test (SANS 5862-1:2006). Slump was measured before and after the additions of the fibres. The fibres were allowed to mix for 5 minutes after its addition to the concrete mix until a consistent mix was visible without any sign of segregation. Slump measurement was 160 mm and reduced to 100 mm after fibres were added. The average compressive strengths of the mix with and without PF were 40.19 MPa and 43.80 MPa respectively. Dynamon SP1 superplasticizer classified according to EN 934-2 (2009) and supplied by MAPEI South Africa was used.

3.3 *Preparation of test samples*

Uniaxial tensile strength, shrinkage and creep deformation tests were done using $100 \times 100 \times 500$ mm prisms. All specimens, except those for shrinkage test, were notched in the centre of the specimens on all four sides to a depth of 10 mm resulting in an effective area of 6400 mm^2. The notch thickness was 3 mm. The design of the sample preparation and test setup was based on the work of Mouton and Boshoff (2012). Specially designed steel hooks were used as anchors and embedded in the specimens during casting. The hooks protruded at both the ends of the beams and are shown in Figure 2(a). Hooks were welded to the ends of the anchors for the connections to the test setups. Apart from the prisms, cube samples of 100 mm were also cast to determine the compressive strength of the mixes with and without PF.

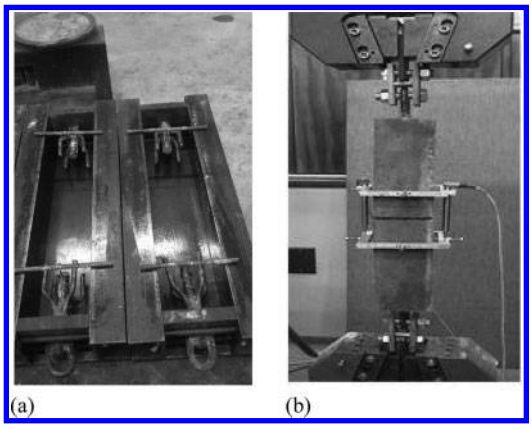

Figure 2. (a) Steel hooks positioned in moulds (b) Uniaxial tensile test.

3.4 *Uniaxial tensile test*

The benefit of FRC is only visible once the concrete is cracked. The uniaxial tensile tests were done in order to determine the ultimate and post-peak residual strength. Post-peak residual strength is required to determine the sustained load. The uniaxial tensile test was done in a Zwick Z250 Universal Testing Machine using the same setup as described by Babafemi and Boshoff (2013) and is shown in Figure 2(b). The tests were performed using a crack mouth opening rate of 0.8 mm/min and using two 10 mm linear variable displacement transducers (LVDT). The unloading specimens were unloaded at the same rate. The same setup was also used to pre-crack the tensile creep test specimens.

Three specimens were tested to study the post-peak uniaxial tensile response. Three other trial specimens were cracked and then unloaded at same rate to study their unloading response while one of the three specimens was reloaded again after unloading. The similarity in the post-peak strength after unloading was compared with the specimens that were tested to full post-peak strength without unloading.

3.5 *Shrinkage test*

Two specimens were used to study the shrinkage deformation of PFRC so as to distinguish it from the creep deformation of the unsealed specimens subjected to sustained loading. The specimens were unnotched and uncracked with a gauge length of 285 mm achieved by using an extender (Figure 3). The specimens were tested in an unrestrained condition by placing them on PVC rollers to minimise the restraint against shrinkage. The readings were measured electronically using a HBM Spider8 Electronic Measuring System.

3.6 *Creep of pre-cracked samples*

The frame used for the tensile creep test uses a lever arm system for load application. It is designed to

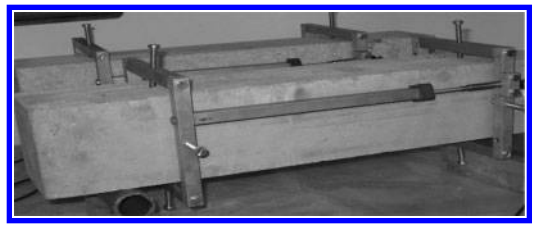

Figure 3. Shrinkage test.

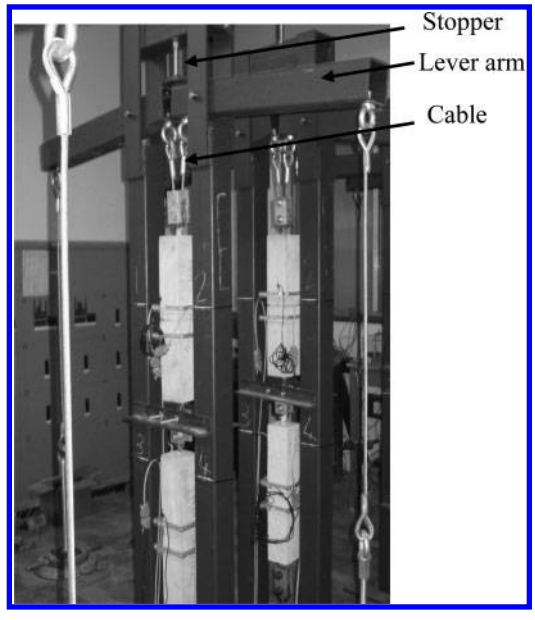

Figure 4. Creep frame with specimens under sustained loading.

accommodate two specimens in series, see Figure 4. A stopper was placed at the top of the specimens used to stabilise the setup should one of the specimens fails. The specimens were connected to the loading frame using cables fixed to the eyes welded on the anchors of the specimens. This ensures that no moments are induced in the specimens.

The deformation over the notched area was measured using two 10 mm LVDT fixed to the specimens using two aluminium frames. The gauge length between the aluminium frames was 70 mm. The measured creep consists of material creep and it also included the crack mouth opening displacement. As in the case of shrinkage reading, the displacement readings were acquired using the HBM Spider8 Electronic Measuring System. Data were saved at regular intervals for the full duration of the tests. The specimens were tested unsealed, therefore basic creep, drying creep, crack widening and drying shrinkage occurred at the same time. The drying shrinkage could be subtracted, but it was not possible to distinguish between the drying creep and basic creep.

The test frame was calibrated using a load cell in the specimen's position to find the relationship

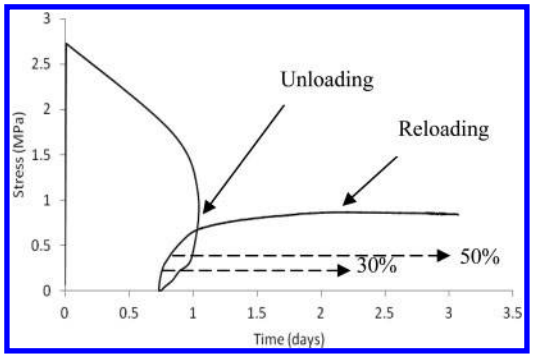

Figure 5. Pre-cracking, unloading and reloading of test specimens.

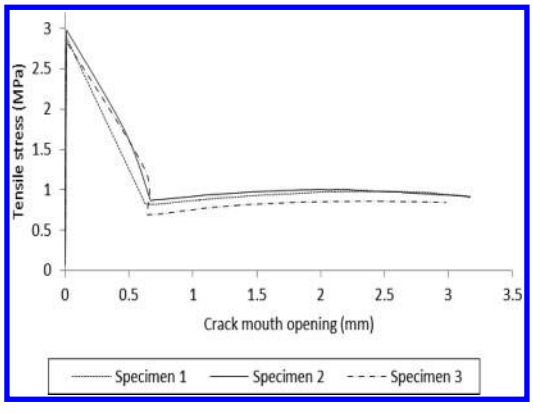

Figure 6. Ultimate and post-peak uniaxial tensile strength.

between the weights and the actual forced applied on the specimens. The load was applied on the set of specimens almost instantaneously while ensuring that no dynamic loading occurred. Two load levels were tested (30% and 50% of the post-peak residual strength) with four specimens each. Creep fracture was also observed for specimens loaded at 50% post-peak residual strength after 4 months under sustained loading. The two sustained load levels are shown in Figure 5.

4 EXPERIMENTAL RESULTS

4.1 *Uniaxial tensile strength results*

The results of the three specimens tested for uniaxial tensile strength are shown in Figure 6.

The main purpose of the test was to investigate the post-peak uniaxial tensile strength of the specimens.

Since the specimens to be tested for the time-dependent behaviour are to be subjected to sustained loads at fractions of the post-peak residual strength, this test was required in order to determine the post peak residual strength. Figure 6 shows an average post-peak residual strength of 0.78 MPa. When compared with the trial specimen shown in Figure 5 that

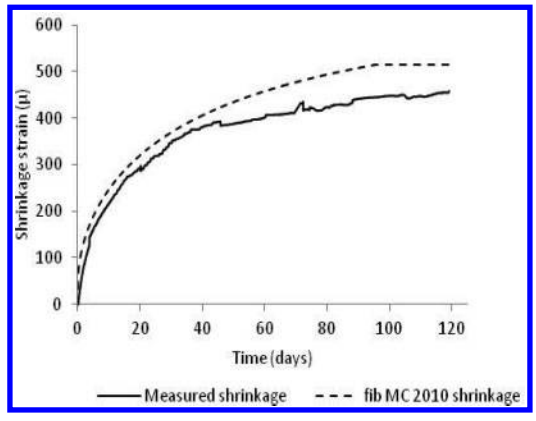

Figure 7. Shrinkage measured on unloaded, unsealed specimens.

was loaded, unloaded and reloaded again to maximum post-crack strength, the strain softening behaviour of both tests show the same pattern and specimens unloaded and reloaded attained the same stress with samples in the uniaxial tensile test.

4.2 *Shrinkage test results*

The average time-dependent shrinkage strain evolution of the two unloaded, unsealed specimens in the same climate controlled room where the creep specimens were also placed is shown in Figure 7.

The experimental shrinkage was compared with the predicted shrinkage using the final draft of the *fib* Model Code (2010). The experimental result showed close but slightly lower shrinkage when compared with the predicted shrinkage up to 45 days. This is in agreement with an earlier work by Babafemi and Boshoff (2013). Beyond this point, the experimental shrinkage became lower than the predicted. It should be noted that the *fib* Model Code prediction was for conventional concrete without fibres. The measured shrinkage strain as at 120 days is in the region of 482 μ while the predicted at same time is about 520 μ.

The reduction in the shrinkage of PFRC when compared to normal concrete is an indication that macro synthetic fibre such as polypropylene may not significantly reduced early age shrinkage, but with time, shrinkage is reduced when compared to normal concrete.

4.3 *Pre-cracked tensile creep results*

The time-dependent crack mouth opening from the time the specimens were loaded up to 120 days is shown in Figure 8. It should be noted that the average experimental time-dependent strain of the four specimens loaded in series (two apiece in the creep frame) and measured as crack mouth opening displacement (CMOD) is shown in Figure 8. An equivalent shrinkage strain had been deducted from the measured total creep strain.

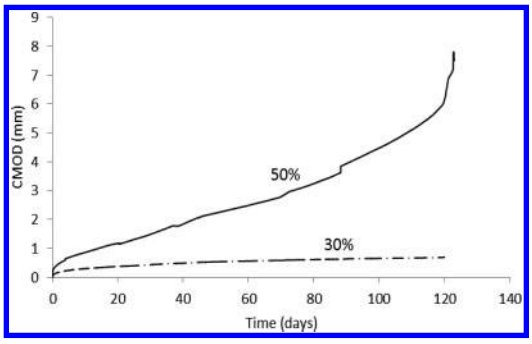

Figure 8. Average time-dependent strain for each loading level.

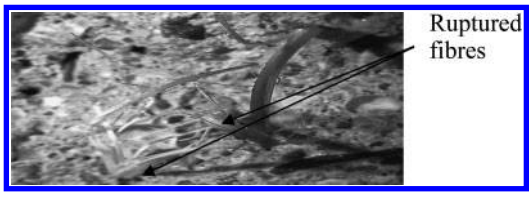

Figure 9. Damaged surface of PF after creep fracture.

Figure 8 shows significant creep for specimens loaded at 50% stress level when compared to those loaded at 30%. Specimens loaded at 50% stress level showed unstable response as the crack mouth continued to increase until creep fracture occurred. This behaviour showed a three-stage creep response of the specimens: primary, secondary and tertiary (Boshoff 2007). The specimens entered the third stage of creep failure after 80 days under sustained loading and eventually, creep fracture occurred after 4 months of testing. This is evident by the continued increase of the crack mouth until failure. However, specimens loaded at 30% stress level showed a decreasing rate of increase in creep at 4 months of testing with a CMOD of about 0.6 mm.

The time-dependent strain behaviour of specimens loaded at 50% stress level was alarmingly high and should be a cause of concern for potential users of synthetic fibre reinforced concrete when in the cracked state. The increased creep of the cracked PFRC may be attributed to the high creep rate of the macro synthetic fibres (BEKAERT, 2008). Figure 9 shows the deformed state of PF after the specimens tested at 50% stress level had failed.

It can be observed that one of the mechanisms that caused creep failure of the specimens was fibre rupture under sustained loading. However, it is intended that further studies will be done on single fibre pullout and fibre creep tests to understand the mechanism causing the time-dependent crack mouth opening of PFRC.

A comparison of the specific creep strain of specimens at both stress levels compared to the creep of normal concrete is shown in Figure 10.

The specific strain was obtained by subtracting the shrinkage strain from the total time-dependent strain,

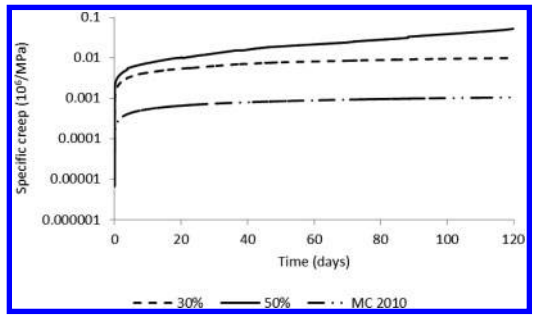

Figure 10. Specific creep of PFRC for each loading levels.

and normalizing by the creep stress levels. According to the *fib* Model Code 2010, the definition of stress-strain law for fibre reinforced concrete is based on the identification of the crack width and the corresponding structural characteristics length, l_{cs}, of the structural element when softening materials are considered. Hence, strain is assumed to be as below.

$\varepsilon = w/l_{cs}$, where w = crack mouth opening displacement and $l_{cs} = y$,where y = distance between the neutral axis and the tensile side of the cross section.

For sections without traditional reinforcement such FRC, the Code recommends that y = h be assumed. For a typical beam depth of 300 mm, $l_{cs} = 300$ mm. This was used to compute the specific creep of both specimens loaded at 30% and 50% stress level and a comparison made with the specific creep of a normal creep model using the Model Code. It is clear from Figure 10 that the cracked creep strain of specimens loaded at 30% and 50% were significantly more when compared to normal concrete. The specific creep was plotted on log scale because of the difference in specific creep value of cracked specimens when compared to normal concrete to an order of magnitude of two.

5 CONCLUSION

This study has investigated the time-dependent behaviour of PFRC under two different stress level; 30% and 50% of the post-peak residual uniaxial tensile strength. The tests performed were uniaxial tensile tests, shrinkage and creep test. The time-dependent tests were performed for 4 months in a climate controlled environment using concrete prisms measuring 100 × 100 × 500 mm. The investigation in this study indicted the following:

(a) Time-dependent deformation, i.e. shrinkage of unloaded PFRC specimens showed lower strain after the first 45 days when compared to the predicted deformation of conventional concrete as given in the Final Draft of the *fib* Model Code 2010. Measured shrinkage was 482 μ after 4 months as against the predicted 520 μ for conventional concrete at the same period.
(b) The creep response of pre-cracked PFRC was alarmingly high when subjected to 50% of the

post-peak residual uniaxial tensile strength. Creep fracture occurred after 4 months under sustained load. At 30% stress level, a decreasing rate of increase in the crack mouth opening was observed after 4 month.

(c) Fibre rupture is one of the mechanisms that caused the creep fracture of specimens subjected to sustained loading at 50% post-peak residual stress.

Effect of temperature on the behaviour of polymer reinforced concrete façade

J.O. Akinyele
Department of Civil Engineering, Federal University of Agriculture, Abeokuta, Nigeria.

ABSTRACT: Polymer reinforced concrete is gradually becoming popular; due mainly to the damage caused to steel elements by corrosion. But the effect of temperature on polymer reinforced slabs has not been critically looked into.

This paper described the construction of concrete façade reinforced with polymer (polyethylene) rod and steel reinforcements. Ten number model sized elements of area 0.15 m^2 and a depth of 40 mm were considered, some models were exposed to an elevated temperature of 50°C for six hours (average temperature for a desert area), all samples were subjected to incremental load of 1 kN until failure. Thermal expansion, deflections and crack width were measured for each element.

Deflection in steel reinforced façade exposed to elevated temperature was 11.20 mm while that of polymer was 12.72 mm. The study concluded that the low thermal effect on polymer reinforced concrete is a result of low thermal conductivity of polymer.

1 INTRODUCTION

The construction sector is one of the world's largest consumers of polymer composites. Unreinforced polymer composite materials have been used by the construction industry for many years in non-load bearing applications such as trimmings, kitchenware, vanities and cladding. Recently efforts are being made to include reinforced polymer composites as load bearing materials in the construction industry. However, to date the number of primary structural applications of reinforced polymer composites in construction remains relatively low and there appears to be a number of issues contributing to their slow uptake by the construction industry, such as cost of production, lack of standard design codes, and poor understanding of the material properties.

Civil or building construction are commonly claimed to also place these materials at a disadvantage when considered against traditional construction materials. However, this paper proposes that as issues of sustainability become increasingly important to material choice, some fibre composite materials could be at an advantage over traditional materials in façade structure.

A polymer is a large molecule (macromolecule) composed of repeating structural units typically connected by covalent chemical bonds. Whereas the term *polymer* is sometimes taken to refer to plastics, it actually encompasses a large class of natural and synthetic materials with a wide variety of properties.

Natural polymeric materials such as shellac, amber, and natural rubber have been used for centuries. A variety of other natural polymers exist, such as cellulose, which is the main constituent of wood and paper. The list of synthetic polymers includes synthetic rubber, Bakelite, neoprene, nylon, PVC, polystyrene, polyethylene and many more (Wikipedia, 2011).

The problem of corrosion in reinforced concrete structures has made some of the elements like concrete façade to become less attractive to clients who would have love to have it. Though many solutions have been proposed, the use of non metallic materials readily comes to mind. Many works have gone into the use of Fibre Reinforced Polymer (FRP) by Sivagamasundari and Kumaran (2008). Also Hegger *et al* (2010) investigated the advantages of textile reinforced concrete applied to a pedestrian bridge in Germany, and the results concluded that it is possible to design slender and light weight concrete members by using technical textiles instead of steel as reinforcement. A small number of new loads bearing civil engineering structures have been made predominantly from FRP materials over the last three decades. These include compound curved roofs (Hollaway, 2002), pedestrian and vehicle bridges and bridge decks, energy absorbing roadside guardrails (Bank and Gentry, 2000), building systems, modular rooftop cooling towers (Barbero and GangaRao, 1991), access platforms for industrial, chemical and offshore (Hale, 1997), electricity transmission towers, power poles, power pole cross-arms and light poles and marine structures such as seawalls and fenders (Weaver, 1999).

The potential benefits offered by fibre composites include high specific strength and specific stiffness, tolerable durability, good fatigue performance and the potential to reduce long-term costs. However, in many cases these potential benefits are difficult to

Table 1. Properties of reinforcement.

Reinforcement	f (N/mm^2)	E_s (N/mm^2)	D_f (mm)	Strain, ε
Polyethylene	30	1,110	6	0.0270
Steel rod	250	200,000	6	0.0012

f = Tensile strength of reinforcement, E_s = Modulus of elasticity of Reinforcement, D_f = diameter of reinforcement, ε = Strain of reinforcement at ultimate load.

realize and are sometimes based on specious fact and irrelevant data. In addition to this, the lack of bona-fide applications has caused many constructors to be skeptical of the material's ability to provide a viable alternative to traditional materials. Many of the existing applications are experimental in nature and are aimed at demonstrating the ability of fibre composite materials to perform in certain applications. To this end they may be successful in terms of structural performance, but offer little by way of meaningful financial performance data.

The use of non metallic materials may not be popular yet because most of the design codes are silent about it. But some codes like the ACI code and CAN/CSA code allow the use of Glass Fibre Reinforced Polymer (GFRP) bars as main reinforcement for concrete structures such as bridge decks, floor slabs and wall type structures. (ACI committee, 1996, CAN/CSA-S6-02, 2002).

The aim of this paper is to determine the response of both polymer and steel reinforced concrete façades to increase in temperature under load.

1.1 *Mechanical properties of polymer*

The tensile strength of a material quantifies how much stress the material will endure before suffering permanent deformation (Ashby and David, 1996, Meyers and Chawla, 1999). This is very important in applications that rely upon a polymer's physical strength or durability. For example, a rubber band with a higher tensile strength will hold a greater weight before snapping. In general, tensile strength increases with polymer chain length and cross-linking of polymer chains. A High Density Polyethylene HDPE has strength between 25–30 MPa and a Low Density Polyethylene LDPE has strength of between 10–20 MPa (omnexus.com, 2011). The melting temperature for this material is 137°C.

Young's Modulus quantifies the elasticity of the polymer. It is defined, for small strains, as the ratio of rate of change of stress to strain. Like tensile strength, this is highly relevant in polymer applications involving the physical properties of polymers, such as rubber bands. The modulus is strongly dependent on temperature (Ashby and David, 1996, Meyers and Chawla, 1999). Table 1 showed the mechanical properties of polyethylene and steel rods.

2 MATERIALS AND METHOD

2.1 *Polyethylene Rod Production*

The polyethylene rods were made from sachets water packs. The packs were gathered in large amount, washed and spread to drain the water from it. After the water had been drained, they were taken to a polyethylene bag manufacturing company in Lagos Nigeria.

The sachets were introduced into intake of the extrusion machine after the temperature and the pressure for the melting had been set on the control panel of the extrusion machine. As the sachets were introduced into the intake, the sachets start melting and then came out from the mould at the mouth of the extrusion machine in rod form of 6mm diameter (Adjusted diameter).

As the rods came out, a water bath was provided where the rods were made to go through so as to cool off the temperature and make it harden. Also, a fan was provided to give additional cooling to the process.

2.2 *Specimen details*

The façade were designed based on the tensile strength of the reinforcing materials, mild steel rod with strength of 250 N/mm^2 and polyethylene rod of 30 N/mm^2 were used for the design of the slab prototypes. Both the steel and the polyethylene rods were arranged based on the design specifications which gave the diameter of the material and the spacing, for the polyethylene rod, 18 number 6 mm rod was used at a spacing of 25 mm while for steel rod 4 number 6 mm rod at 125 mm spacing was applied, the distribution reinforcement is based on the same spacing obtained for the short span for each type of slab. The reinforcing materials were then placed into the wooden mould (i.e. form work). These formworks are 500 mm by 300 mm by 30 mm. There were a total of ten (10) number concrete façade produced from the experiment, five number each for the Steel and polyethylene rods respectively. The concrete mix used was 1:2:4 i.e. the proportion of 1 part of cement to 2 parts of fine aggregate and to 4 parts of coarse aggregate while the water-cement ratio (the w/c ratio) was 0.5 i.e. 1 part of water to 2 parts of cement by weight.

The concrete was well mixed, the cement, fine and coarse aggregate were measured through the use of weighing balance i.e. batching was by weigh. Ordinary Portland cement was used and the fine aggregate was the sharp sand. The size of the coarse aggregate used was half an inch (12 mm).

The moulds were lubricated with oil before concrete was poured into it to allow easy removal of the slab specimens after it is set. After the preparation of thoroughly mixed concrete, it was then poured into the moulds and then compacted or vibrated manually by shaking the moulds. The slab specimens were removed from the mould after it has been allowed to set for 24hrs. The slabs were then cured to gain full strength by pouring water on it everyday. After 28 days, the slab specimens were put into test.

2.2.1 *Thermal and load test*

It is possible for stresses to be induced by temperature changes in composite members which are additional to those produced by applied loads. These stresses arise when the components of a composite member have different rate of thermal expansion: Hence the need to carryout the effect of temperature on the two different façade types.

Six of the specimen were placed in an oven that was regulated to 50°C, which is the average temperature of a dessert area in Africa, this samples were left in the oven for six hours, while the remaining four were left at an ambient temperature of 25°C. The specimens were placed in an axial load testing machine immediately after removal from the oven in such a manner that the point load was applied at the top surface of the slabs and supported on all four sides. The axis of the specimen was carefully aligned with the axis of loading device. The digital dial gauge attached to the retort stand was placed on the slab close to loading point to measure the deflection due to the applied load and the mechanical loading was monotonically increased by the adjusting knob and the corresponding deflection was recorded. The specimen was loaded until the ultimate load capacity of the slabs was achieved, the ultimate failure load was recorded and the crack width was measured at failure load.

Theoretical deflections of the slabs were computed using equation 1 while thermal expansions for each slab were obtained using equation 2.

$$\Delta_c = \frac{\alpha_c \Delta T l^2}{4h} \tag{1}$$

$$\delta = L_0 \Delta T \left(\frac{\alpha_c A_c E_c + \alpha_s A_s E_s}{A_c E_c + A_s E_s} \right) \tag{2}$$

where h is the slab thickness (30 mm), l is the slab span (500 mm), ΔT is the thermal gradient, and α_c is the coefficient of expansion, E is the young modulus of the material; A is the area of reinforcement.

3 RESULTS AND DISCUSSIONS

From the results showed in Table 2, polyethylene reinforced façade have higher experimental and theoretical deflections than the steel reinforced specimen, but the thermal expansion of steel reinforced specimen is marginally higher than that of polymer by 0.001 mm. At higher temperature of 50°C after six hours, the crack width for steel reinforced facades was 0.70 mm, the deflection was 11.20 mm while the slab failed at 5.30 kN load. Figure 1 showed the graph of load against deflections. For the polymer reinforced slab, crack width was 1.30 mm, deflection was 12.72 mm and failure load was 3.00 kN. The graph is showed in Figure 2. The above results showed that increasing the temperature of slabs has effect on its properties.

The increment in temperature led to increase in deflections and crack widths; these can be traced to the reinforcement used in both type of slabs. The wide difference in the deflection between the two steel elements (elevated and ambient) showed the effect of high temperature, while the very marginal difference in that of the two polymer elements showed that the effect of temperature on polymer façade is very minimal. The experimental deflection in steel façade at ambient temperature of 25°C was over 100% higher

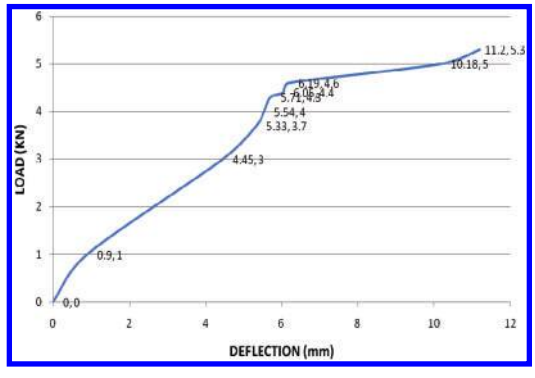

Figure 1. Deflection of Steel façade at 50°C.

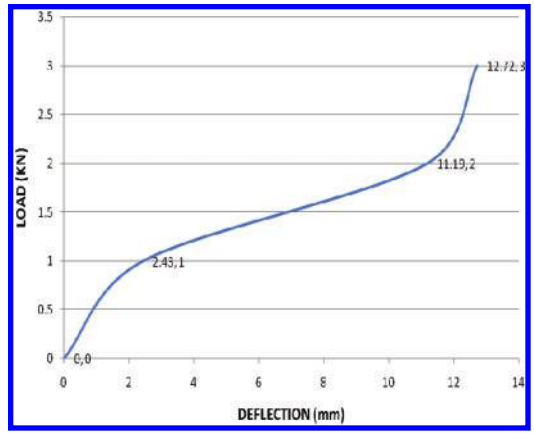

Figure 2. Deflection of Polymer rod façade at 50°C.

Table 2. Experimental and Theoretical Results.

Specimen	Experimental Δ_c(mm) 25°C	Experimental Δ_c (mm) 50°C	Theoretical Δ_c (mm) 25°C	Linear Expansion δ (mm)	Crack width (mm)
Steel	5.99	11.20	2.60	0.300	0.70
Polyethylene	12.25	12.72	12.50	0.299	1.30

than the theoretical results, the difference must have been due to many factors, since the theoretical results was based on ideal situations which may not be totally captured during the experiment. But for the polyethylene façade, the difference was about 5% which falls within an experimental error of ±10%, the consistency in the result of polymer reinforced façade deflections in the experimental and theoretical test and at both ambient and high temperature made the prediction for polyethylene deflection accurate, and this is a very good advantage when compared to the inconsistency observed in steel reinforced façade.

4 CONCLUSIONS

The present study have showed that steel is still the best reinforcing material, but it characteristics under certain conditions like temperature and corrosion which is not very consistent has prompt research in to looking for an alternative to it.

The use of polymer can be a good substitute especially with its low thermal conductivity which gave it advantage over steel reinforcement. Further research in nanotechnology can greatly improve the properties of polymer as alternative reinforcement materials in concrete in the nearest future.

Flexural behaviour of normal and high strength concrete beams reinforced with GFRP rods

N.F.O. Evbuomwan
Accenture Inc, Irving, Texas, USA.

ABSTRACT: This paper reports on research done involving the use of Glass Fibre Reinforced Plastic (GFRP) rods as reinforcements in lieu of steel within concrete. The parameters investigated include types of concrete (Normal density and Lightweight), Reinforcement Ratios, Concrete Strengths (including very high strength concrete) and two beam lengths (1 m and 2 m long). Results of static flexural tests carried out on these beams are discussed in detail. The flexural and Load-Deflection behavior of the beams are greatly influenced by the reinforcement ratio and beam size. The cracking results (width, height and spacing) were found to be controlled principally by reinforcement ratio, beam dimensions and concrete type.

1 INTRODUCTION

For structural engineering applications, particularly in concrete structures, efforts are now being made to explore the potential of using FRPs as an alternative material to steel. FRPs do exhibit certain properties that particularly make them attractive to engineers, such as : low weight, high static and fatigue strengths, high tensile strengths, resistance to chemicals and corrosion, high damping capabilities, and so on (Deskovic 1995). Most of the research in the use of FRP with concrete, has involved (i) strengthening and rehabilitation of concrete members with CFRP and/or GFRP plates, (ii) the use of FRP rods as reinforcements in concrete beams and (iii) the use of FRP rods as prestressing tendons in concrete beams (Taerwe 1995). Currently, efforts are being made to generate adequate data on the behaviour of such composite members and there is need for the development of a sound technical basis and design guidelines that can be incorporated into future design codes (Clarke & Waldron 1996). Previous work in the use of non-prestressed GFRP in concrete is that of (Nawy et al 1971) and (Nawy and Neuwerth 1977). Their results showed that beams reinforced with steel had fewer cracks than the corresponding beams reinforced with fibreglass. They observed that failure of the GFRP reinforced beams occurred on the compression side due to the compression failure of the concrete rather than the tensile failure of the GFRP rods. They found that at ultimate loads, the deflections of the fibre glass reinforced beams were approximately three times greater than those of the corresponding steel reinforced beams. In an early work by (Nanni 1993), he posited that the working stress method was most suitable in design FRP reinforced concrete. This is due to FRP beams behaving linearly-elastic up to failure, exhibiting reduced rigidity compared to steel reinforced beams. More recently, many other researchers have investigated the use of GFRP rods with roughened surfaces (Benmokrane, B. et al 1995) as well as in hybrid form with steel (Nanni et al 1994). In their work, Benmokrane et al [6] reported that cracking of the beams in the flexural span consisted predominantly of vertical cracks perpendicular to the direction of maximum principal stress induced by pure moment. They observed that after cracking, the reduction in stiffness was greater in GFRP reinforced beams compared to steel reinforced beams. (Nanni et al 1994) in their paper observed that the beams reinforced with hybrid rods, had fewer cracks and a greater spacing between cracks than beams reinforced with steel. (Theriault & Benmokrane 1998) observed in their research inter-alia that concrete strength and reinforcement ratio had minimal effect on crack spacing and higher reinforcement ratio reduced crack width and height, for the same applied moment.

This paper reports on research done involving the use of Glass Fibre Reinforced Plastic (GFRP) rods as reinforcements in lieu of steel within concrete. It discusses results of static flexural tests carried out on both 1 m and 2 m beams reinforced with two GFRP reinforcement ratios. This involved load versus deflection readings as well as crack measurements (crack number, width, height and spacing). Experimental results of ultimate strength capacities are compared with theoretical calculations based on the code provisions in BS 8110 Part 1 (Rahmat 1997).

2 MATERIALS AND SPECIMEN PREPARATION

In this series of tests, the high strength normal density concrete beams (HN1-HN4) were prepared using Ordinary Portland Cement, 5 mm fine sand, 10 mm

Table 1. Reinforcement Details of Beams.

Specimen Number	Beam Length	Reinforcement Type	Reinforcement
HN1	1 m	GFRP	3 – 4 mmϕ
HN2	1 m	GFRP	2 – 6 mmϕ
HN3	2 m	GFRP	3 – 6 mmϕ
HN4	2 m	GFRP	2 + 4 – 6 mmϕ
SHN2	1 m	STEEL	2 – 6 mmϕ
HL1	1 m	GFRP	3 – 4 mmϕ
HL2	1 m	GFRP	2 – 6 mmϕ
HL3	2 m	GFRP	3 – 6 mmϕ
HL4	2 m	GFRP	2 + 4 – 6 mmϕ

HN1-HN4 – High Strength Normal Density Concrete
HL1-HL4 – High Strength Lightweight Concrete

coarse (gravel) aggregate, micro-silica and superplasticizer in the proportions of 1:1:3:0.1:0.02 with a water cement ratio of 0.4. For the high strength lightweight concrete beams (HL1-HL4), the mix ratio used was 1:0.58:1.21:0.1:0.02 representing the proportions of Ordinary Portland Cement, 5 mm fine sand, lightweight aggregate, micro-silica and superplasticizer with a water cement ratio of 0.3. Cubes were cast as control specimens along with the beams and were tested for compressive strength. Four beams (2 of 1 m length + 2 of 2 m length) were each prepared for the HN and HL series and reinforced using GFRP rods. The reinforcement details for these beams including the 1 m control beam are shown in Table 1 and Figures 1 and 2. The ultimate strength of the GFRP rods was taken as 700 N/mm^2.

The steel bars had a yield strength of 460 N/mm^2. For the 1m beams, T2.6Ø bars were provided as links at 50 mm c/c spacing, while in the case of the 2 m beams, T6.0Ø bars were provided as links at 100 mm c/c spacing. The 1 m and 2 m beams had a cross-section of 50 × 100 and 100 × 200 respectively. All the beams were cast in steel moulds and the mix was adequately vibrated with an electric vibrator to ensure full compaction. They were demoulded 24 hours after casting and then left to cure in water until tested. Each beam was then tested at the age of 42 days. The elevation and cross-sectional details of the beams, showing the loading and support conditions are shown in Figures 1 and 2.

3 TESTING PROCEDURES

The rectangular beams were loaded in bending using a four point loading arrangement, with two concentrated loads placed symmetrically about their mid-spans. The loads were applied via a load cell using a hydraulic jack. The applied load readings were read in percentages from a digital readout, and were converted afterwards into kilonewtons, with the maximum load cell capacity set to 100%. Each beam was loaded in gradual increments of percentage load (1–4%) until

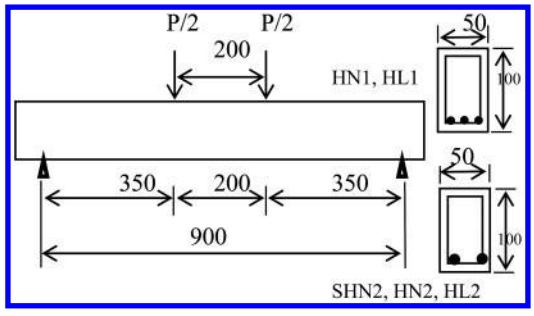

Figure 1. Loading Arrangement for 1 m Beams.

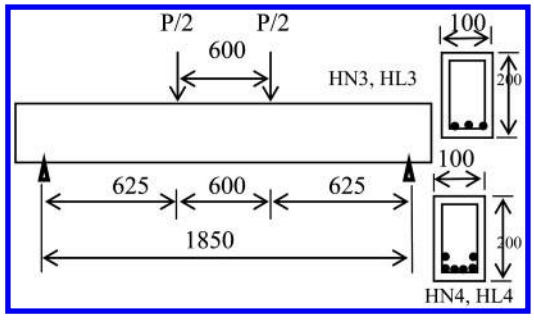

Figure 2. Loading Arrangement for 2 m Beams.

maximum (failure) load was reached. At each load increment, deflection readings were read from a dial gauge placed at the bottom of the mid-span position of the beam and strain readings were taken off demec discs placed on the 1 m and 2 m beams, using mechanical gauges of 100 mm and 200 mm gauge lengths respectively. During loading, when cracks occurred, readings of crack widths were taken using a crack microscope. In addition, crack number, heights and spacing were also recorded. Control cube specimens were tested after 42 days and the average compressive strengths are shown in Table 2.

4 RESULTS AND DISCUSSION

The Flexural and Cracking results of all the beams tested in this series are shown in Tables 2 to 6. It can be observed from Table 2 that Concrete strength had no major effect on cracking or ultimate failure loads for either the 1 m or 2 m beams. For both normal density and lightweight concrete 1 m beams, increase in reinforcement ratio generally resulted in slightly higher ultimate failure loads, but in the case of 2 m beams, this increase was much more significant.

Table 3 compares the theoretical moments and the experimental ultimate failure moments for all the beams. For the normal density beams with higher concrete strengths, the ratio of the experimental moments to the theoretical moments were generally about 60% irrespective of the reinforcement ratio or beam length. The lightweight concrete beams on the other hand showed closer correlation between the experimental

Table 2. Cracking and Ultimate Loads.

ultimate moments and theoretical values especially for the 1 m beams. These beams were more able to attain to the BS 8110 code predicted/expected moment capacity owing perhaps to higher extreme fibre compression strains in the HL series beams.In comparison however to the steel reinforced beam, the GFRP reinforced beams performed less effectively in attaining to ultimate moment capacity. The theoretical deflections and experimental deflections for all the beams are compared in Table 4. On the whole for all beams, the experimental deflections were significantly higher than their corresponding theoretical values irrespective of beam length, concrete strength or reinforcement ratio. With the exception of HL3, the HN series beams showed higher maximum deflection than the HL series. In Table 5, the cracking characteristics of the beams are shown for maximum and mean values of crack width, height and spacing. As expected the mean values were generally lower than the maximum values. For HN series, the maximum and mean crack widths with the exception of HN1, were generally similar in values did not seem to be affected by reinforcement ratio.

On the other hand for HL series, the maximum and mean crack widths generally decreased with increase in reinforcement ratios. The maximum and mean crack heights for both the HN and HL series showed very similar patterns. The maximum and mean crack heights in general, approximately doubled with increase in beam height from 100 mm to 200 mm. The exceptions were beams HN4 and HL4, where the mean crack heights were further affected and reduced by the increased number of cracks that occurred in both beams. In the case of maximum and mean crack spacing, the values observed for both the HN and HL series, approximately doubled when the beam lengths increased from 1 m to 2 m, with the exception of HN4 and HL4, where again the higher number of cracks played an additional factor in reducing the crack spacing.

It is interesting to observe the cracking behavior of beams HL2 and HL4 where HL4 had twice as many number of cracks (14) as HL2 (7) as shown in Table in 6. The maximum crack width, height and spacing of HL4 are about double those of HL2, whilst withthe exception of the mean crack height, the mean crack widths and spacing are approximately the same for both. The interplay here is both the height and length of the beams. This observed pattern shows that there is consistency in the bond between the GFRP rods and the

Table 6. Experimental vs Theoretical Crack Widths.

Beam ID	Total No. of Cracks	Experimental Max Crack Width, CW_E (mm)	Theoretical Max Crack Width, CW_T (mm)	Ratio CW_E/CW_T
HN1	3	0.80	0.78	1.03
HN2	3	1.88	0.57	3.30
HN3	3	1.86	0.77	2.42
HN4	10	1.94	0.83	2.34
SHN2	21	0.30	0.107	2.80
HL1	5	1.42	0.86	1.65
HL2	7	0.96	0.69	1.39
HL3	6	2.14	1.15	1.86
HL4	14	1.76	0.88	2.00

concrete irrespective of beam length and/or reinforcement ratio. In comparison with the GFRP reinforced 1 m beams, the steel reinforced beam showed much lower values for maximum and mean crack width, height and spacing.

Table 6 shows the comparison between the experimental maximum crack width for each beam and the theoretical values calculated based on BS 8110: Part 1, 1985. The total number of cracks observed for each beam is also shown. The number of cracks generally increased with increase in reinforcement ratio. All beams generally showed much higher maximum crack width than their theoretical counterparts and there is no significant observed pattern for concrete beam type/length, concrete strength or reinforcement ratio.

4.1 *Load Deflection Curves*

Figure 3 shows the applied load versus deflection curve for the HN series beams. It can be observed that up to about 2 kN, all the beams generally showed similar stiffness, but beyond there the 1 m GFRP reinforced beams showed much less stiffness and significantly increasing deflection with minimal increase in applied load up to failure.

The 2 m beams showed higher stiffness than the 1 m beams and slightly higher stiffness than the 1 m steel reinforced beam up to 10 kN beyond which they began to show increased deflection as applied load increased up to failure. For the 2 m beams, increasing the reinforcement ratio clearly showed improved ductility over the loading regime all the way to failure. Figure 4 shows the applied load versus deflection curve for the HL series beams.

The dominant observation is the improved stiffness for the 2 m beams with increased reinforcement ratio. The under-reinforced HL3 although showing a lower failure load compared to HL4 exhibited significantly higher ductility in comparison. In Figure 5, all the 1 m beams for both HN and HL series are compared. The GFRP reinforced beams all showed very similar deformational characteristics irrespective

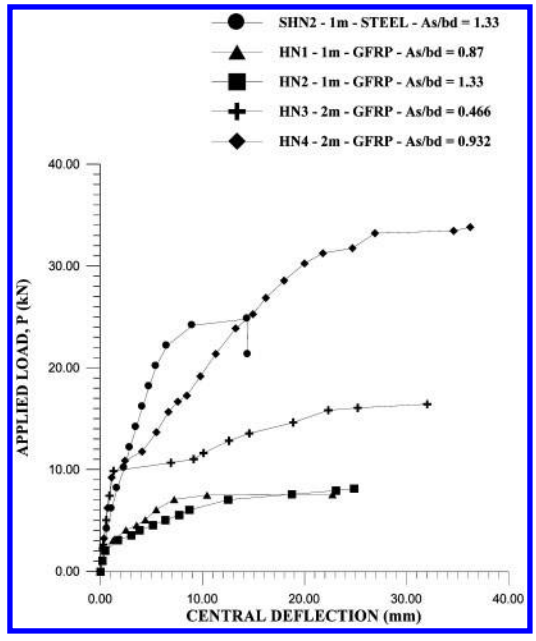

Figure 3. Applied Load vs Central Deflection for GFRP Reinforced High Strength Normal Density Beams.

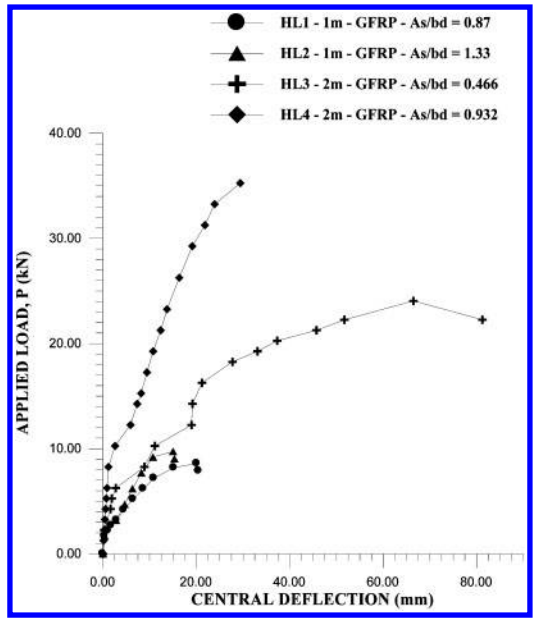

Figure 4. Applied Load vs Central Deflection for GFRP Reinforced High Strength Lightweight Beams.

of concrete strength and reinforcement ratio, but less stiffness compared to the steel reinforced beam. Similarly, the 2 m beams were compared in Figure 6. It can be seen that in this case, the beams with similar reinforcement ratio behaved similarly irrespective of the concrete type especially for HN4 and HL4 that showed very similar load-deflection behavior all the

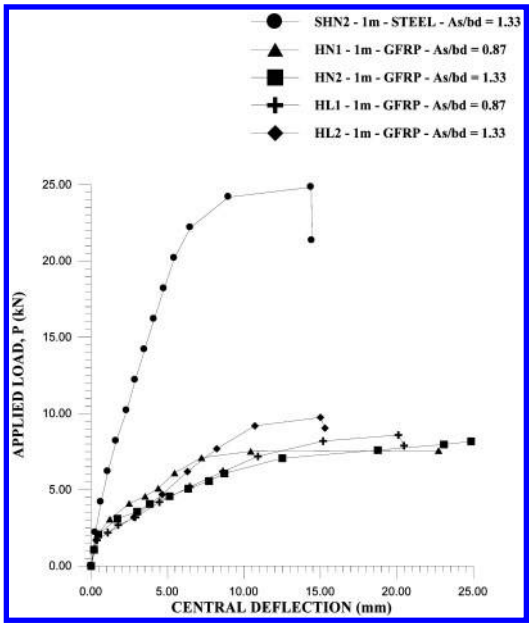

Figure 5. Applied Load vs Central Deflection for GFRP Reinforced 1 m Beams.

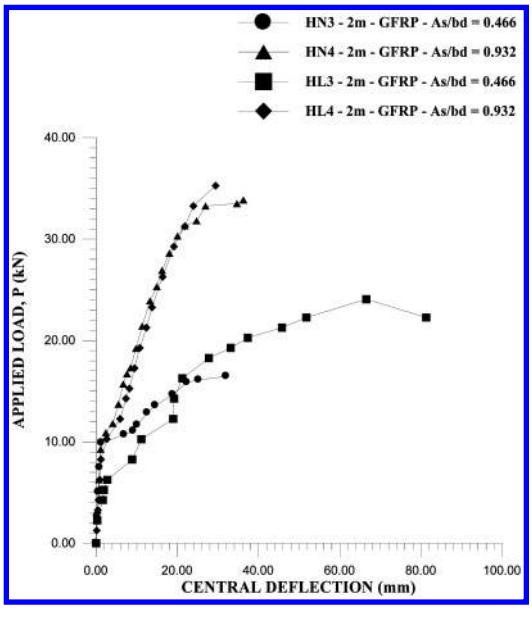

Figure 6. Applied Load vs Central Deflection for GFRP Reinforced 2 m Beams.

way to failure and much higher stiffness compared to HN3 and HL3 reinforced with half the reinforcement ratio.

4.2 *Cracking Behaviour*

In Tables 5 and 6, the cracking results of the beams were clearly elucidated. Figures 7 to 10 show in particular the Applied Load versus Maximum Crack Width

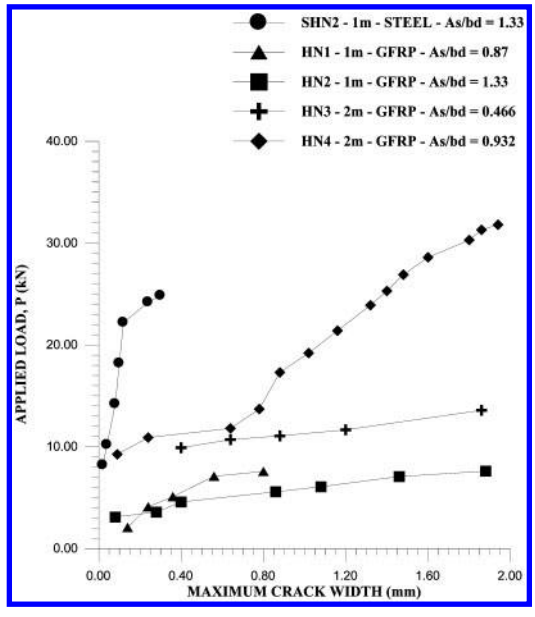

Figure 7. Applied Load vs Maximum Crack Width for GFRP Reinforced High Strength Normal Density Beams.

patterns throughout the loading regime of the beams. Figure 7 shows the results for the HN series, from which it can be observed that the GFRP reinforced beams showed higher maximum crack widths with slight increase in applied load compared to the steel reinforced beam.

This perhaps reflects poorer bonding performance of the GFRP beams compared to SHN2. Beam HN4 with higher reinforcement ratio showed higher applied load for the same crack width compared to the other beams.

The maximum crack width behaviour for the HL beams is shown in Figure 8. It can be observed that growth in crack width appear to be steadily increasing with increasing applied and that increasing the reinforcement ratio led to reduction in maximum crack width. This was more significant for the 2 m beams.

Figure 9 shows the maximum crack widths for all the 1 m beams irrespective of concrete strength and reinforcement ratio. It can be observed that the GFRP reinforced beams showed very similar patterns in their applied load versus maximum crack width curves, but higher values of maximum crack widths compared to the steel reinforced beam. Increase in reinforcement ratio resulted in moderate reduction in maximum crack widths.

In comparison the maximum crack width results for all the 2 m beams, we can observe in Figure 10 that increasing the reinforcement ratio resulted in significant reductions in crack width especially in the case of the lightweight concrete beams.

The lightweight beams HL3 and HL4 also showed reduced maximum crack widths compared to their normal density counterparts

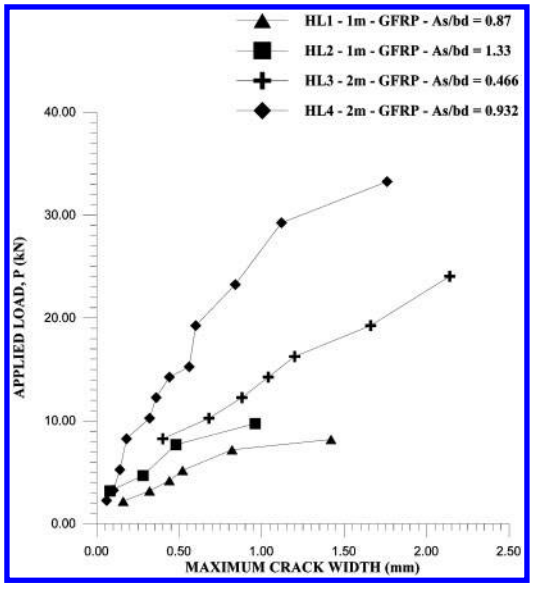

Figure 8. Applied Load vs Maximum Crack Width for GFRP Reinforced High Strength Lightweight Beams.

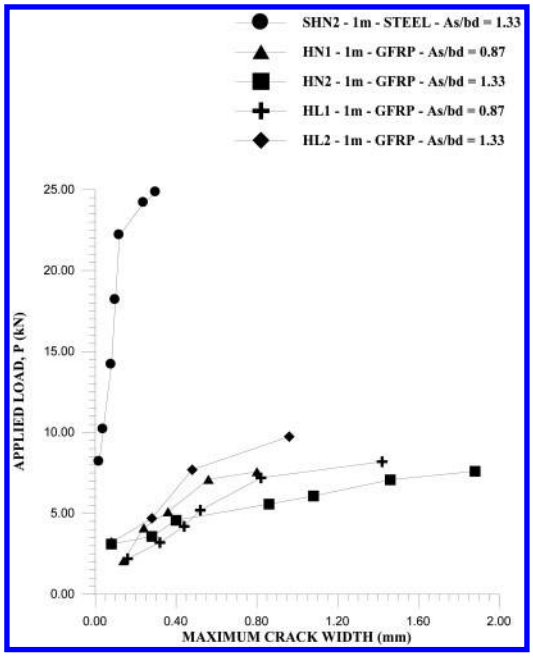

Figure 9. Applied Load vs Maximum Crack Width for GFRP Reinforced 1 m Beams.

5 CONCLUSIONS

Fundamental conclusions arrived at are as follows:

Reinforcement ratio, concrete type and compressive strength appear to have an effect on load deflection, stiffness and ductility of GFRP reinforced beams.

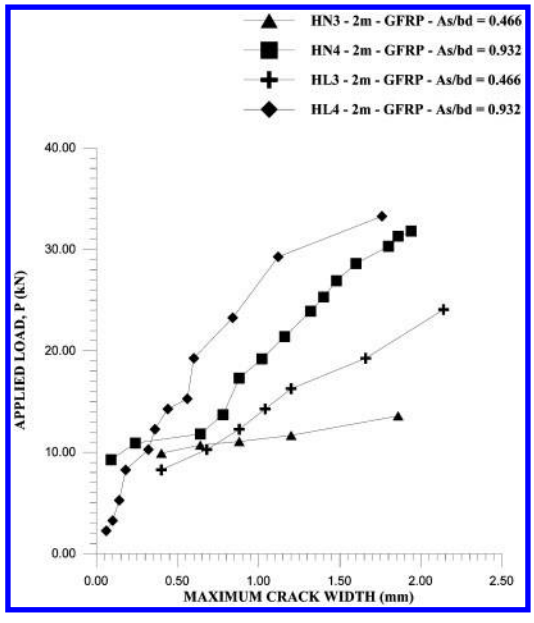

Figure 10. Applied Load vs Maximum Crack Width for GFRP Reinforced 2 m Beams.

Cracking characteristics are significantly influenced by reinforcement ratio and beam dimensions.

Using GFRP in High Strength concrete beams appear to show promise, but bond aspects as well as the challenge of the low modulus of the GFRP rods need to be addressed. Theoretical equations based on BS 8110 don't appear to be very suitable for estimating and/or predicting crack widths for GFRP beams and further research is needed to establish a more rational and suitable approach.

Flexural behaviour of GFRP prismatic beams in composite action with concrete

N.F.O. Evbuomwan
Accenture Inc, Irving, Texas, USA

ABSTRACT: This paper reports on a major research done that involved the use of various forms of FRP in composite action with concrete. The paper elucidates succinctly results of experimental investigations performed on the structural behavior of FRP prismatic beams/sections bonded at the top to concrete slabs. These composite beams which were 1.18 m long, were investigated for varying parameters including normal and lightweight concrete, concrete slab dimensions, bonding systems and FRP section type (rectangular and I-sections). The effects and implications of these parameters on structural behavior of these beams, including failure patterns are discussed comprehensively. The paper concludes with highlights about the importance of developing a technical basis for the efficient use of Concrete/FRP composite beams as well as experimental and parametric data that can be employed in the development of design guidelines and codes of practice for Concrete/FRP composite structures and applications.

1 INTRODUCTION

In the early years the use of FRP in engineering applications was predominantly restricted to aerospace and automobile industries. The significant achievements and advancements in engineering application of FRP eventually resulted in its use within the Architectural, Engineering and Construction industry. Structural application and use of Fibre Reinforced Plastics (FRP) is increasingly becoming more evident in many buildings and Structures. The application of FRP in the construction industry, especially for structural engineering applications has been driven by the beneficial properties that make them attractive to engineers. Such properties include: resistance to chemical and corrosion, high stiffness and rigidity, low weight, superior static and fatigue strengths, high damping capabilities (Deskovic et al 1995a). Within the last few decades, besides other popular and emerging use of FRP in concrete structures, there has been significant interest in the use of FRP prismatic sections in composite action with concrete. The structural behavior of these hybrid FRP/Concrete beams has been the subject of a number of researchers over the years, with the general intent of understanding the structural behavior of such hybrid/composite beams (Taerwe 1995, Sims et al 1987, Maji et al 1997, Nagaraj & GangaRao 1997, Deskovic et al 1995b, Saiidi 1994). Such understanding can then be employed to further improve the design and application of FRP in real life structures. (Li 2006) studied hybrid beams of concrete and GFRP and observed that failure of the beams occurred predominantly by FRP web shear fracture and that the beams with thicker concrete showed more stiffness and rigidity. (Canning et al. 1999) in their investigation of the composite action of FRP/Concrete beams studied shear transfer at the interface between the two components for six methods of connection. They observed that using an adhesive compatible with freshly made concrete gave the most adequate level of composite action. (Khennane & Heslehurst 2009) in their study of a new design of hybrid FRP-Concrete beams involving both wrapped and unwrapped beams, observed that the wrapped beams exhibited 100% increase in load carrying capacity and significantly improved ductility compared to the unwrapped beams. A previous paper by (Evbuomwan 1998) involving various bonding parameters and combinations of FRP-Concrete for 500mm and 750mm long beams showed that in general, composite beams demonstrated much higher ultimate failure loads and lower deflections than the plain GFRP beams, particularly for the beams bonded with Epoxy alone. Various forms of failure mechanisms were observed for these beams similar to those reported by (Hulatt et al. 2004, Nordin & Taljsten 2004, Kavlicoglu 2001, Branco et al. 2003).

2 MATERIALS AND SPECIMEN PREPARATION

The objective of the experimental set up was to explore and investigate the composite behavior of rectangular and I-beam prismatic sections acting compositely with concrete under varying parameters and combinations. The plain rectangular GFRP sections were 50.6×101.62 mm with a flange thickness of 5.2 mm

and a web thickness of 3.48 mm. The plain GFRP I-sections were 49.52 × 100.94 mm with a flange thickness of 6.37 mm and a web thickness of 6.28 mm. The design of experiments was based on the use of 1180 mm long GFRP prismatic sections along with other parameters such as concrete type, width and thickness of the concrete slab and the bond type used in combining the two materials (Abeyasinghe 1997).

Nominal high strength concrete mixes were chosen for these series of tests for both the normal density and lightweight concrete beams. All the slab specimens were prepared using a mix proportion (by weight) of 1:1:3:0.28:0.2:0.02 (normal density) and 1:0.58:1.21:0.23:0.2:0.032 (lightweight), representing the ratio of Cement : Sand : Coarse Aggregate or lightweight aggregate: Water : Microsilica : Superplasticizer. Concrete cubes (100 mm square) were cast as control specimens for compressive strength tests. After mixing, the fresh concrete was poured into plastic moulds (for the slabs) and three cube moulds. The concrete in the moulds was then compacted using an electric vibrator and a tamper, and then left to cure for 24 hours before demoulding. On demoulding, after 24 hours, the concrete specimens were left to cure in water for 28 days, after which they were removed and then bonded to the GFRP and then left to cure in air for another 14 days.

Bond between the concrete slab and GFRP was achieved using two types of proprietary epoxy adhesives referred to here as Epoxy A and Epoxy B (Flexural strength at room temperature = 35 MPa) and/or mechanical shear connectors (bolts). The epoxy adhesives were two components types, that is, hardener and resin. Mixing was carried out as specified until a uniform colour was achieved. Prior to bonding, both the concrete slab and GFRP surfaces were roughened using a sand paper, followed by the application of acetone solvent. After mixing, the adhesives were applied onto both surfaces and then joined together. The thickness of the adhesive bond was estimated to be about 2 mm. When the bonding was completed, the specimens were left to cure in air for 14 days before being tested.

For specimens that required the use of mechanical connectors, Grade 8.8 bolts (25 mm long, and 6 mm diameter) and Grade 8 nuts in accordance with BS 3692 were used (Yield Stress = 628 MPa). Necessary analysis was carried out to estimate the total number of bolts required in the shear spans as well as their spacing. Bolts were also provided in the middle span to prevent the two materials separating as a result of bending. Each bolt was screwed through a tapped hole in the top flange of the GFRP and tightened with a nut from underneath the top GFRP flange. The length of the bolt left outside was embedded in the slab halfway along its thickness. The bonding of all the GFRP specimens with bolts was carried out when the concrete slab was cast. The concrete was poured into the plastic moulds and levelled to the appropriate thickness, while the GFRP-bolt surface was then pushed into the fresh concrete at the middle, until the surface was in contact with the concrete top layer. The beam was then supported in-place using pre-designed supports and C-clamps. When used in combination with bolts, the epoxy adhesive was applied on the GFRP-bolt surface before placing into the fresh concrete.

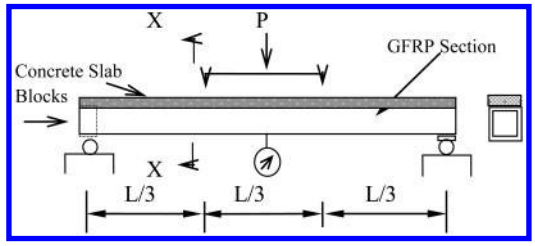

Figure 1. Details of the loading arrangement for a typical composite beam.

3 TESTING PROCEDURES

All the beam specimens were tested in Flexure 42 days after the concrete slabs were cast. Prior to testing, the GFRP box or I-sections were stiffened both from inside and outside the webs using wooden blocks and clamps. The beams were loaded in bending using a four point loading arrangement, with two concentrated loads placed symmetrically about their mid-span, as shown in Figure 1. The loads were applied via a load cell using a hydraulic jack. Readings of the applied load were taken from a digital meter, with each load increment applied gradually until maximum failure load was attained. Other necessary readings were taken at each load increment. These included deflection readings from a dial gauge placed at the bottom of the mid-span position of the beam, as well as strain readings taken off demec discs placed across the mid-span, using a mechanical gauge of 100 mm gauge length. After the test, cracks occurring in both the concrete and the GFRP, were identified. Control cube specimens were tested after 42 days and compressive strength values are shown in Table 1.

4 RESULTS AND DISCUSSION

The Flexural results of all the beams tested in this series are shown in Table 1.

It can be observed that for the composite beams involving the GFRP I-Sections, they generally exhibited higher failure loads than the plain GFRP I-Section by a factor of 37% (IB2) to 124% (IB3). For the composite beams involving the GFRP rectangular sections, only the beams with Normal density concrete exhibited much higher failure loads than the plain GFRP rectangular beam. The beams topped with Lightweight concrete exhibited lower failure loads than the plain GFRP beam. The type of bonding system used, concrete type and GFRP Section type had the most significant effect on maximum load attained as well

Table 1. Ultimate Load and Deflection Results.

Specimen No.	F_{cu} (MPa)	Slab width (mm)	Bond Type	Failure load P_{ult} (kN)	Mid-span deflection Δ_{ult} (mm)
IBP				21.85	9
IB1	76	200	Epoxy A	40.0	5.34
IB2	76	100	Epoxy A	30.0	4.56
IB3	72	200	Bolts	49.0	11.65

RB4(LW)	59	200	Epoxy A	20.0	9.70

Table 2. Group Definitions.

Group name	Beam length	Member specimens	Differing parameter(s)
I-1	1180 mm	IB1, IB2, IBP	Slab Width
I-2	1180 mm	IB1, IB3, IB4, IBP,	Bond Type
R-1	1180 mm	RB2, RB4, RBP	Bond Type
R-2	1180 mm	RB1, RB3, RBP	Slab Width
R-3	1180 mm	RB3, RB4, RBP	Concrete Type
IR	1180 mm	IB1, RB3, IBP, RBP	GFRP Type

as resulting deflection. Table 2 shows the groupings of the beams that are compared based on the main varying parameter(s) as well as in relation to the behavior of plain GFRP control beams.

Group I-1 represents composite beams with GFRP I-Sections bonded with the same Epoxy A agent, but with different slab width. The beam with a 200 mm slab width (IB1) exhibited higher failure load, deflection ductility (Figure 2) than the one with 100 mm slab width. For Group I-2, the varying parameter compared is the Bond type.

The composite beams with concrete bonded either with steel bolts (IB3) or Epoxy A + bolts (IB4) showed higher failure loads than that bonded with Epoxy A (IB1) alone. Beams IB3 and IB4 also demonstrated much more ductility compared to beam IB1 as shown in Figure 2. Overall, we can observe that all the composite beams showed very similar stiffness up to a load of 20 kN, but significantly higher stiffness than the Plain GFRP I-Section throughout the loading regime and until failure load. The much higher stiffness demonstrated by these beams is corroborated by the lower compressive and tensile extreme fibre strain compared to the plain GFRP I-Section for the same applied moment as shown in Figure 3. The composite beams however at higher applied moments eventually demonstrated similar or higher tensile extreme fibre

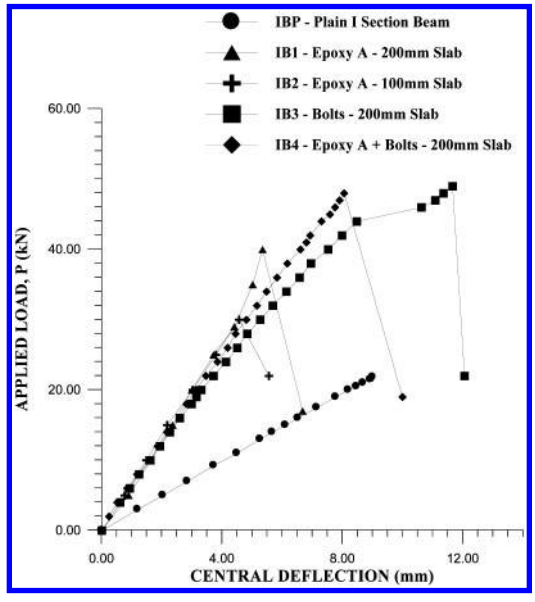

Figure 2. Applied Load vs Central Deflection for Composite GFRP I-Section Beams.

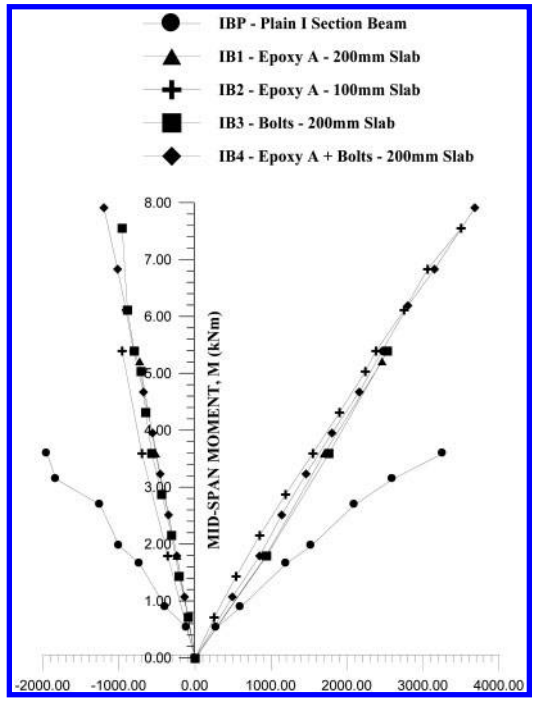

Figure 3. Mid-Span Moment vs Top & Bottom Extreme Fibre Strain of Composite I-Section Beams.

strain compared to the control beam. For the rectangular GFRP composite beams, their behaviour is discussed under the Groups R1, R2 and R3 representing the effect of Bond Type, Slab Width and Concrete Type (Table 2, Figures 4 & 5). The R1 group where the

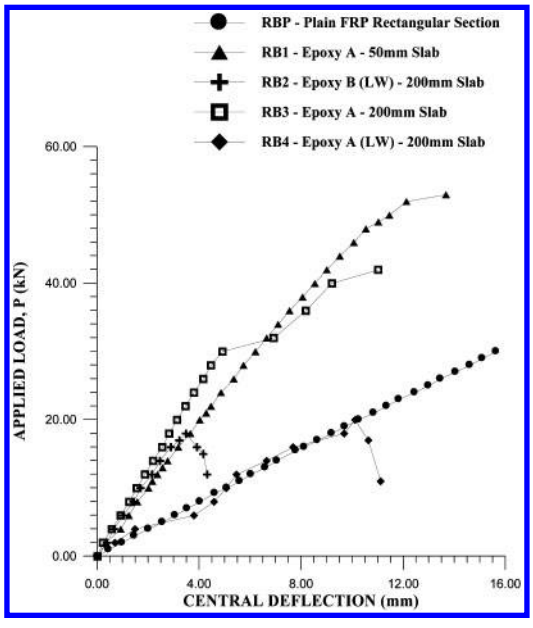

Figure 4. Applied Load vs Central Deflection for Composite GFRP R-Section Beams.

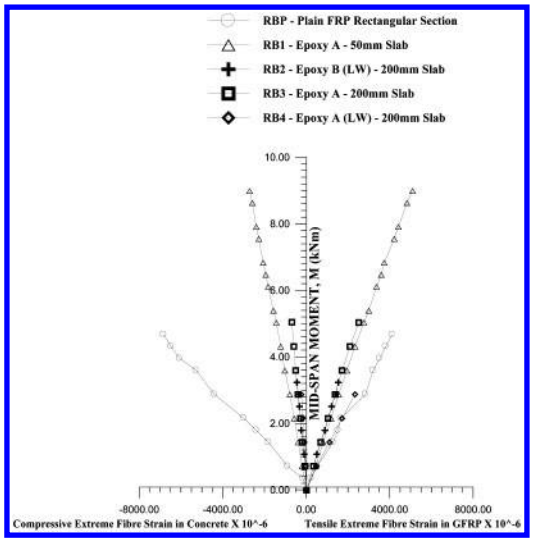

Figure 5. Mid-Span Moment vs Top & Bottom Extreme Fibre Strain of Composite R-Section Beams.

beams were topped with lightweight concrete showed no obvious difference in the ultimate failure load attained. The main differential is in the significantly higher deflection exhibited by beamRB4 bonded with Epoxy A compared with RB3 bonded with Epoxy B which showed much higher stiffness (Figure 4). For group R2, beam RB3 with 100 mm slab width showed higher stiffness in the early load regimes, but attained lower ultimate failure load than beam RB1 with 50 mm slab width.

Table 3. Failure Modes for the Composite Beams.

Specimen Number	Mode of Failure
Beam IBP	Fracture in top GFRP web-flange joint in symmetric mid-span region up to 200 mm long.
Beam IB1	Fracture/debonding of concrete + web shear fracture of GFRP in both midspan and shear span of the beam
Beam IB2	Fracture/debonding of concrete + web shear fracture of GFRP in both midspan and shear span of the beam
Beam IB3	Cracks in GFRP web-flange joint = concrete fracture along alignment of the bolts in one shear span
Beam IB4	Cracks in GFRP web-flange joint on both sides of beam
Beam RBP	Fracture in top GFRP web-flange joint near the point loads
Beam RB1	Fracture in top GFRP web-flange joint near the point loads followed by concrete crushing and buckling of webs in same region
Beam RB2	Concrete fracture followed by local bearing failure of bottom web
Beam RB3	Bearing failure and fracture of bottom web-flange joint.
Beam RB4	Concrete fracture followed by local bearing failure of bottom web

This is attributed to the fact that RB3 failed principally by bearing and the fracture of the GFRP web-flange compared to RB1 which was able to attain a higher failure load until it failed by crushing of the concrete in compression. For group R3 which for similar parameters compared effect of concrete type, beam RB3 topped with normal density concrete exhibited higher stiffness and ultimate failure loads than beam RB4 topped with lightweight concrete for about the same level of maximum deflection. In comparing the effect and significance of the GFRP type used, group IR (Table 2, Figures 6 & 7) is used.

We can observe that the plain GFRP I- section beam showed higher stiffness than the GFRP rectangular section beam, but attained lower ultimate failure load. The plain rectangular GFRP beamattained a much higher ultimate failure load, deflection and extreme fibre tensile strain. Both plain GFRP beams exhibited a linear elastic behaviour throughout the loading regime all the way until failure. The composite beams exhibited much higher stiffness than the plain beams all the way until failure, but similar.

Stiffness up to a load of about 30 kN, with RB3 showing more ductility beyond that until failure compared to IB1. Both composite beams however exhibited about the same ultimate failure load.

4.1 *Failure Modes*

Table 3 shows the various modes of failures for all the beams tested in this series. The plain beams were

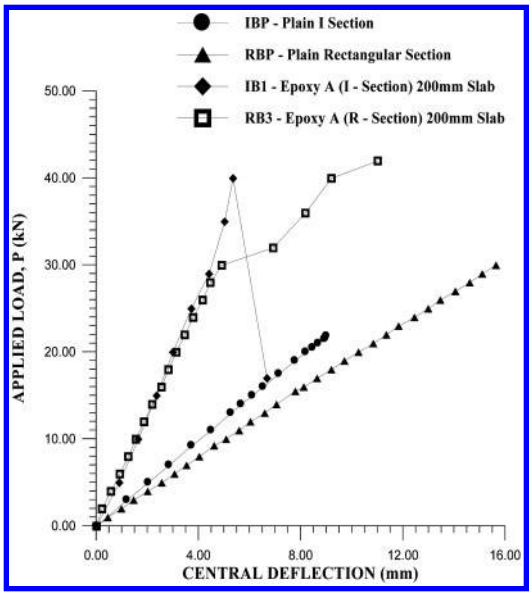

Figure 6. Applied Load vs Central Deflection for Composite GFRP I & R -Section Beams.

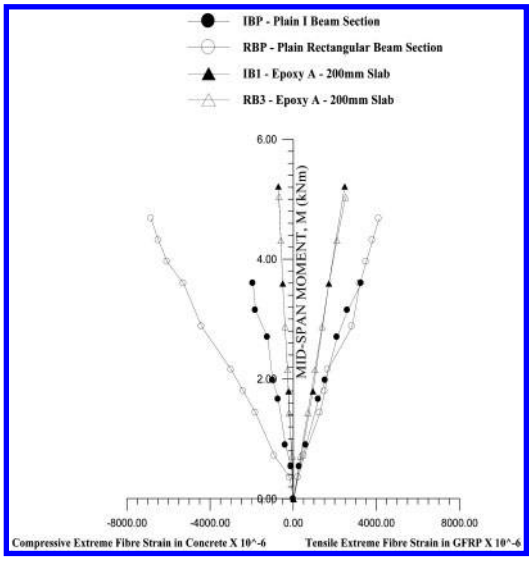

Figure 7. Mid-Span Moment vs Top & Bottom Extreme Fibre Strain of Composite I/R-Section Beams.

observed to fail by fracture of the top web-flange joint in symmetric mid-span region and close to the point loads. Virtually all the beams failed by fracture of either the top or bottom web-flange joint of the GFRP beam. For all the composite beams, with the

exception of IB4 and RB3, the GFRP failure occurred in combination with fracture/de-bonding and/or crushing of the concrete and in other cases some form of bearing failure of the GFRP at the supports. The Applied Load versus Central Deflection Curves shown in Figures 2, 4 and 6 were to some extent influenced by the modes of failure reported for all the beams. The kinks and departure from expected behavior in some cases, were undoubtedly due to how failures were initiated and up to ultimate failure of the beams.

5 CONCLUSIONS

In this paper, the results of tests performed on the behaviour of GFRP prismatic sections acting compositely with bonded concrete slabs have been reported. It was observed that in general, the use of epoxy adhesive and/or mechanical connectors (bolts) ensured adequate composite action. The composite beams exhibited much higher ultimate failure loads than the plain GFRP beams. The higher extreme fibre tensile strain exhibited by a number of the composite beams compared to the plain GFRP sections, clearly indicates that the use of concrete in composite action with GFRP can enable maximum utilization of FRP in tension and concrete in compression. Failure of the composite beams also appear to be governed principally by web shear and/or web-flange joint fracture in the GFRP, except in the beams bonded with bolts when re failure was initiated by longitudinal shear along the alignment of the bolts. Some of beams failed simultaneously with concrete fracture and web-flange fracture and in some cases in combination with bearing failure at the supports. In general, the use of FRP in composite action with concrete does show some promise that needs further investigation. To establish a more rational basis for the efficient use of concrete/FRP composites particularly with respect to the nature of the bond system/interface, controlling the mode of failure as well as numerical and analytical modeling, further work is needed.

UHPC – a challenging material for innovative structures

Ekkehard Fehling
Institute of Structural Engineering, University Kassel, Germany

ABSTRACT: UHPC offers superior characteristics with regard to strength, durability, and – when reinforced by fibers – also ductility. Thus, it enables architects and designers new possibilities with regard to filigree and lightweight structures as well as for long spans and high rises. Since reliable knowledge about the material itself as well as a good understanding of structural behavior are essential, remarkable research efforts have been expended. The paper highlights a number of actual research results and shows some outstanding structures that have been built recently at different places in the world.

1 INTRODUCTION

The capability of Ultra High Performance Concrete is not represented by its high compressive strength only but as well by superior resistance against chemical attack and durability. Furthermore, by addition of fibres UHPC can become very ductile in compression and tension and a tensile capacity can be ensured which is much more reliable due to the fibers acting as micro-reinforcement than the plain concrete matrix. This enables the designer to build slender and filigree structures with UHPFRC and gives the architects degrees of freedom beyond actual possibilities when building with steel and concrete. With regard to the ecological footprint, UHPC gives new chances to reduce primary energy consumption and carbon dioxide emission.

UHPC further extends the potential of prestressed concrete. The extremely high compressive stress allows for much higher prestressing forces so that high tensile stressed can be compensated which makes lightweight and long span structures possible.

However, current design rules do not cover the range of extremely high concrete strength classes. In addition, the way of thinking during design of structures may be different for UHPC and, hence, special regard has to be paid to exploit the advantages of UHPC and specific research is required. During the last decade, for this reason a lot of research has been conducted throughout the world and an increasing number of buildings, bridges and other structures have been built using UHPC. This development has been triggered by French and Canadian colleagues (e.g. Aitcin & Richard 1996) who started in the 1990's to transfer the principles developed 1966 by Walz and Bache (1981) in Denmark to engineering structures.

This paper shall give a short overview of actual research results and developments in research and practice. With regard to research, mainly questions with regard to structural design shall be addressed here. Actual developments with respect to the material development and research and code provisions will be described in other contributions to this conference by Schmidt and Walraven.

2 RESEARCH

In Germany the Author has started to do research in the field of UHPC in 1998. The Deutsche Forschungs-Gemeinschaft DFG (German Research Council) has started a coordinated research program (SPP 1182) on sustainable building with UHPC in 2005. It deals with material related topics as well as structural design, both in the light of the aspect of sustainability.

2.1 *Material Aspects*

Regarding research into composition, optimization and behavior of the material, the following fields shall be mentioned:

- Optimization of mixture,
- Technology of (super)plasticizers,
- Ecological assessment and optimization,

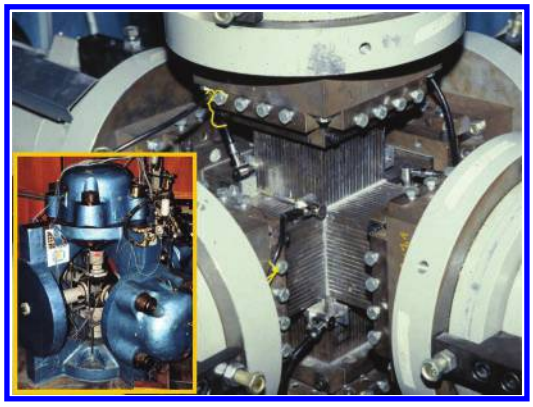

Figure 2. Experimental setup for triaxial tests at TU Dresden.

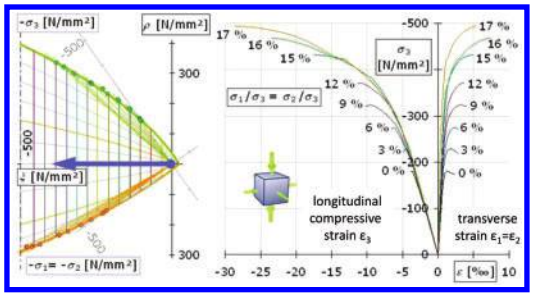

Figure 3. Strength curve in Rendulic-Plane and stress-strain relationshiip for compressive meridian.

- Nanotechnology for UHPC and "Smart Materials"
- Foam UHPC,
- Distribution and orientation of fibers in UHPFRC,
- Durability and resistance against chemical attack,
- Mechanical behavior of fresh concrete,
- Creep and shrinkage dependent behavior,
- Multiaxial strength and deformation behavior,
- Fatigue,
- Fire Resistance,
- Material testing for UHPC (destructive as well as nondestructive),
- Sustainable development using UHPC.

As examples, two topics shall be highlighted here.

2.1.1 *Multiaxial Strength of UHPC*

At the Technical University Dresden the two dimensional and three dimensional strength of HPC and UHPFRC has been investigated in a 3-axes testing setup, see e.g. Speck 2008. In order to minimize lateral restraint, metal brushes have been used to introduce the load into cubical specimens (see Fig. 2). For two dimensional compressive loading it could be shown that the strength increase is less pronounced than for normal strength concrete (NSC). As a consequence, the usual models and design equations cannot be transferred directly to UHPC.

For UHPC subject to triaxial compressive loading, the behavior changes from brittle to ductile starting at

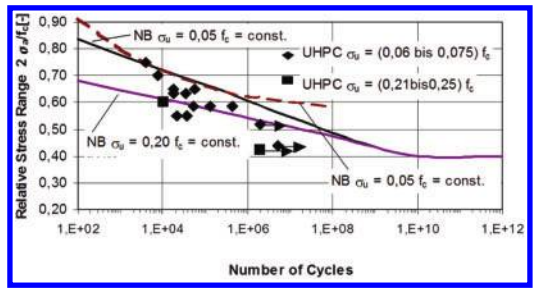

Figure 4. Fatigue in uniaxial compression.

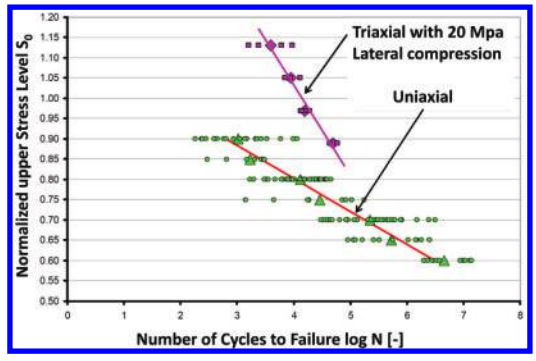

Figure 5. Uniaxial and triaxial fatigue loading.

6 to 9 % lateral compression stress. This can be seen in the right part of Fig. 2.

2.1.2 *Fatigue of UHPC*

First experimental investigations at the University of Kassel (Bunje 2002, see Fig. 4) have shown that fiber reinforced UHPC survived stress ranges of at least 0,4* fc for up to $5*10^6$ load cycles. Tests on UHPC without fibers showed a similar behavior, however with higher scatter. Within the DFG coordinated research program, investigations have been performed for uniaxial and multiaxial fatigue at different universities in Germany, see Fig. 5 from Grünberg & Ertel 2012.

2.2 *Structural Behavior*

With regard to design of structures, studies for many different topics may be mentioned:

- combination of fiber reinforcement with bar reinforcement,
- behavior and design for bending and normal force in SLS and ULS,
- design for shear, punching and torsion,
- application of strut and tie models,
- biaxial compressive/tensile strength of UHPC with fibres, rebars and combinations thereof,
- connection techniques and bond or rebars,
- use of UHPC for medium and long span bridges,
- Innovative connectors for composite structures using UHPC,
- modular construction techniques, implants for introduction of concentrated loads,

- columns using UHPC and high strength steel sections,
- prestressed/posttensioned UHPC girders with and without web openings,
- UHPC-coating and strengthening of reinforced concrete structural members,
- Structural gluing,
- behavior of UHPC for high strain rates and use of UHPC for impact resistance,
- fire safety of UHPC structures.

This listing can neither be complete nor is it possible to address all these projects in detail. However, some general remarks can be made.

2.2.1 *Preconditions for economic use of UHPC*

The cost for a cubic meter of UHPC is of course much higher than for ordinary normal strength concrete. In order to make the application of UHPC for structural applications interesting, it is important that specific advantages of UHPC such as superior durability or reduced overall volume, size, and weight of the structure can be exploited.

Due to the much higher durability of the very densely structured UHPC matrix there is a chance of a long life of the structure and low maintenance costs. Although that may be arguments for using UHPC, it is often necessary that further advantages, such e.g. regarding a simplified construction process come into play. This can be e.g. the elimination of scaffolding and/or formwork.

In many cases UHPC competes more with steel structures than with R/C or P/C structures. It can be stated, that the overall dimensions of UHPC elements do not differ so much from those of steel elements with the same bearing capacity, but the price and the weight can be significantly lower.

One possibility to reduce the cost is to minimize the use of expensive fibers, since normally the biggest cost factor is the addition of steel fibers. Following this observation, it becomes interesting to rely not only on fibers as reinforcement but to combine them with ordinary bar or mesh reinforcement or even prestressing This has been the starting point for several research projects (e.g. Leutbecher 2008) at the author's institute, where the interaction between fibers and bar reinforcement has been studied.

Another interesting line is structural gluing. Due to the dense structure of UHPC and the high surface tensile strength, it is much more promising to connect UHPC members by gluing than to do so with NSC members. In the consequence, gluing of large elements made of UHPC becomes interesting, especially when combined with prestressing across the joints, see contribution of Tue to this conference.

2.2.2 *Actual research projects*

Based on results of investigations for UHPC with combined fiber and bar reinforcement in Kassel, the behavior of structural UHPC members in bending has been studied experimentally and analytically. Different types or bar reinforcement (ordinary reinforcing steel and high strength reinforcing steel) as well as different amounts of fibers per volume have been investigated. Due to the fibers, very small crack widths are possible in SLS. Later on, however, a localization of deformation takes place and typically one crack may open extremely due to yielding of the bar reinforcement (ULS), see Figure 6.

Figure 6. Crack pattern of UHPC bending beam with combined bar and fiber reinforcement.

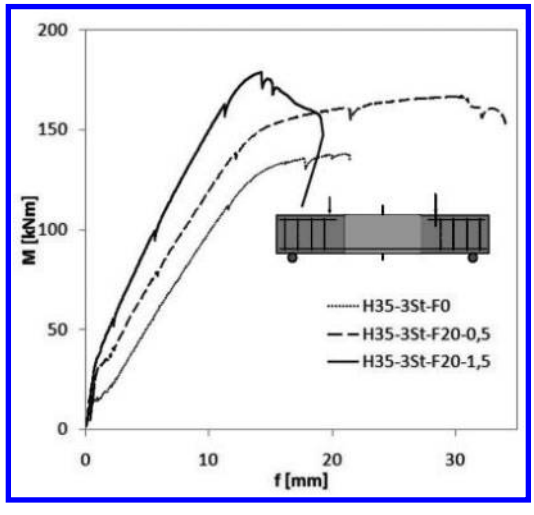

Figure 7. Force deflection relationships for UHPC beams with different amounts of fibers.

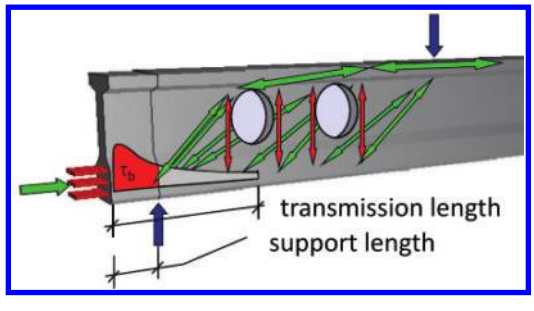

Figure 8. Investigations on end regions of prestressed UHPC girders.

At RWTH Aachen University, prestressed UHPC girders with openings have been investigated. Precast and prestressed girders are extremely important for hall structures both for industry and trade. UHPC with

fibers can help to eliminate stirrup type of reinforcement for shear forces as well against splitting tension, see Bertram & Hegger 2012.

To anchor prestressed strands in UHPC, it is possible to reduce the transmission length extremely due to the high possible bond stresses. This, in turn can lead to high local splitting tensile stresses, which has made research necessary to avoid problems in that respect. The investigations concerned different thickness of concrete cover as well as different prestressing degrees. A bond model for anchoring of prestressed reinforcement has been developed.

As a next step, 34 prestressed girders have been tested with regard to shear force capacity, influence of web openings and cyclic vs. static loading (see Fig. 6). Based on the results of the experimental tests as well as on nonlinear Finite-Element models, recommendations for design provisions have been deduced.

With regard to composite construction using thin UHPC slabs, innovative connectors have been proposed and investigated as alternative to usual shear connectors. Examples are the puzzle strip (see Fig. 9) or (plow-) shares (Schnell & Kurz, TU Kaiserslautern).

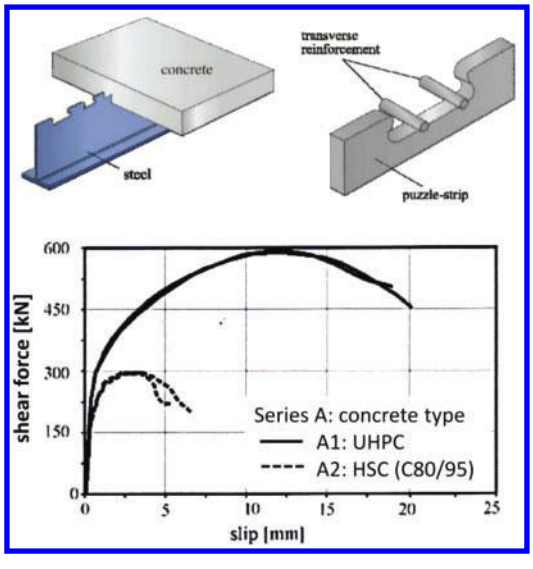

Figure 9. Puzzle strips and test results for UHPC and HSC.

The main advantages of the puzzle strip are its high initial stiffness and the high bearing capacity. Furthermore, two strips can be produced by one cutting process without loss of material. Fig. 9 depicts results of push out tests with puzzle strips. For UHPC with compressive strength of 180 MPa a much higher shear capacity and ductility has been achieved than for HSC with 90 MPa.

It should be noted, that in both cases transverse reinforcement (two bars with $d_s = 12$ mm diameter) were provided per puzzle opening.

3 PRACTICAL EXAMPLES

3.1 *Bridges*

As a high performance material, UHPC takes profit from well controlled fabrication conditions as can be found in precasting plants. Hence, most of the examples of built bridges were made from precast elements or segments. Some examples have been presented by the author at SEMC 2010.

A very elegant example is the Bridge of Peace in Seoul, Korea (Behloul et al. 2003), see Fig. 10. The structure consists of six precast segments, built using Ductal®. Each segment has a π-section with a transversely ribbed plate. In longitudinal direction the segments are posttensioned by 6 tendons, in transverse direction single strands are used in conjunction with small, specially produced anchors. Cross section and dimensions are depicted in Fig. 11.

Being also an arch bridge but suited for vehicle traffic, the WILD-Bridge in Austria near Völkermarkt shall be mentioned here (Sparowitz et al. 2012). It spans a romantic valley and leads to the production plant of the WILD company, a manufacturer of optical/mechatronical equipment.

The bridge has been built using the arch lowering method, for which the reduction of weight by the use of UHPC is a big advantage. Due to the small self weight forces, the hinges required at the abutments could became much cheaper. The construction principle is depicted in Figs. 12 to 14. The two arches consist of precast and externally posttensioned box segments. In order to facilitate the construction, flat dry joints have been used. In order to avoid stress concentrations due to unevenness, all contact surfaces have been milled with high precision using CNC-milling tech-

Figure 10. View of Seonyu footbridge in Seoul, Korea.

Figure 12. WILD-Bridge in Völkermarkt, Austria.

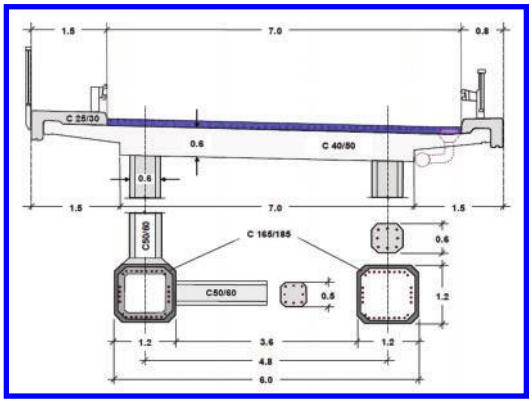

Figure 13. Cross section of Wild bridge.

nology. This technology has been developed by the Max Bögl company, Germany and was being used the first time for the production of slab tracks for railway lines.

Special knee elements have been inserted into the arch in order to accommodate the piers for carrying the superstructure which has been designed in a conventional way using C 40/50.

A comprehensive test program has been conducted in order to verify the design and to test the behavior of the posttensioned elements. Since the box segments are reinforced by fibers only, special attention has been paid to the distribution and orientation of the fibers as well as the optimization of the pouring process in that respect.

Another interesting Project is the GSE-Bridge at Tokyo Airport which connects the northern and southern airfields for the ground services (Watanabe et al. 2007), see Fig. 15. The client aimed at minimizing the volume of the ramp dam as well as ensuring the required clearance height below the bridge. Hence, the

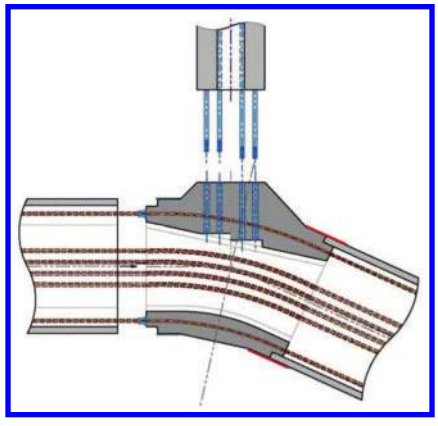

Figure 14. Knee Element of WILD-Bridge.

Figure 15. GSE-Bridge at Tokyo Airport.

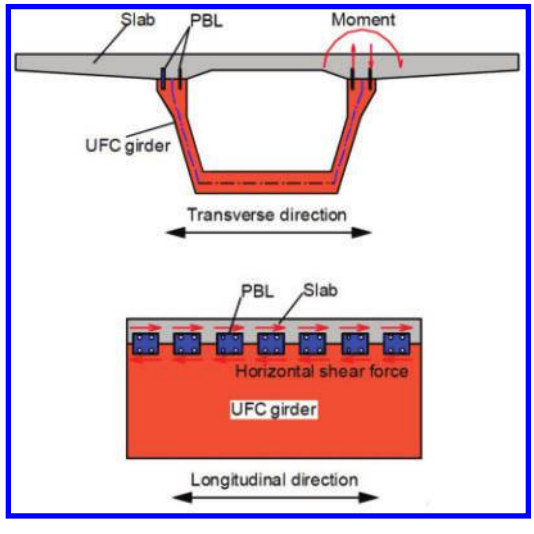

Figure 16. Position and load transfer by Perfobond shear connectors for GSE-Bridge at Tokyo Airport.

gradient should be positioned as low as possible and the construction height had to be minimized. These requirements could be fulfilled using UHPFRC for the bridge girders, in this case, UHPFRC with 2%

Figure 18. View / computer animation of MuCEM.

steel fibers (diameter 0,2 mm, length 15 mm). No conventional bar reinforcement has been necessary. The superstructure consists of three parallel segmental box girders with tendons inside the box girders. The shear connection between webs and the upper deck plate (made of conventional reinforced concrete) consists of Perfobond strips (PBL). These can also take tension forces arising due to the long cantilever deck plates.

3.2 *Buildings*

UHPC is also very interesting for building structures, as the following examples can show. In 2012/2013, the MuCEM museum in Marseille, France, is being built (Architect Rudy Ricciotti). It uses UHPC columns with tree-shaped columns and a very filigree UHPC façade (see Fig. 17). Further UHPC elements are the longitudinal edge girders carrying the slab and a slender UHPC bridge connecting the roof of the museum to the adjacent old Fort Saint Jean.

The columns are connected to the floor and to the foundation by tendons which increases the bending capacity of the columns significantly. Design checks have been performed with the aid of physically nonlinear Finite-Elements models and experimental investigations on three straight and one Y-shaped column configuration. Fig. 18 shows a 3-D computer view of the building.

Modular constructions made of UHPC

N.V. Tue
Graz University of Technology, Graz, Austria

M. Reichel
KHP Leipzig, Leipzig, Germany

ABSTRACT: UHPC (Ultra High Performance Concrete) is a high tech material with outstanding properties. Because of its need for special regard at production and casting an application in the precast industry is generally recommended. Furthermore, the costs of UHPC are nearly 10 times higher compared to ordinary concrete. For economic use of this new concrete material, new design philosophies in concrete construction have to be developed. Suitable construction types and building methods are filigree, flexible and modular constructions with precast elements. This effectively combines the high-performance material properties and the special features of this new material with the demands for sustainability, fast construction progress and wide application. This contribution presents general considerations on modular UHPC constructions by introducing four recent examples of UHPC application. Finally this illustrates the high potential of UHPC for sophisticated constructions in both aspects, architecture and structural engineering.

1 INTRODUCTION

UHPC with its inherent benefits of high compression strength and remarkable durability opens new possibilities in structural engineering. At the same time the increasing material and production costs of this innovative concrete material call for the development of suitable construction types and beneficial building methods.

Because of UHPC's high modulus of elasticity, compared with conventional concrete, very light and thin-walled cross sections with sufficient stiffness (light cross sections with high moments of inertia or arch and truss structures) are favorable. The modulus of elasticity-ratio between UHPC and structural steel of nearly a fourth indicates a classification of the construction concepts for UHPC structures between the construction concepts of conventional steel and concrete structures.

If such light cross sections were realized in conjunction with prefabricated segmental construction, external prestressing and dry joints, new or adapted erection methods, which speed up construction progress or allow erections in restricted areas, are imaginable.

Both, the material savings due to light cross sections and the benefits of fast and less environment effecting construction methods provide the way for an economic application of UHPC. Besides this, the remarkable durability of UHPC increases service life while costs for maintenance decrease. Finally this unburdens our public budgets for infrastructure.

The following four examples of recent UHPC projects, which are completed or in the last realization process, give an overview about efficient use of this innovative material and its economic application.

2 ROAD BRIDGE WILD

2.1 *Structure and construction sequence*

The first example is an arch road bridge in Austria (Reichel et al. 2010, Reichel et al. 2011). Due to the high stiffness of the arch structure a maximum utilization of the high compressive strength of UHPC was achieved. In contrast to this, beam structures for bridges with strict limits regarding deformation and vibration to achieve sufficient traffic safety never would reach such efficient utilization of compressive strength.

The road bridge, which consists of a main arch span with 69 m and two foreland bridges, has a total length of 157 m. At main span each of the two parallel arches is assembled of thin-walled (60 mm) precast hollow box UHPC-segments and seven connection segments, so called knee-segments. They are prestressed together by external tendons running inside the arches. Because of very low bending and shear force in the arches no further ordinary reinforcement was needed in all UHPC-segments. Only the tensile capacity provided by the steel fibres ensures a save load bearing behaviour. Furthermore, additional prestressing of the arch improves the stability. All further components of the bridge (columns, deck, foreland bridges) are made with cast in place normal strength concrete.

Figure 1. Road Bridge WILD - completed stage/summer 2010.

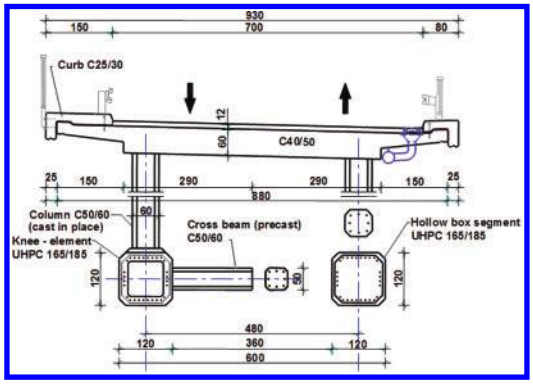

Figure 2. Standard cross section.

The road bridge, which consists of a main arch span with 69 m and two foreland bridges, has a total length of 157 m. At main span each of the two parallel arches is assembled of thin-walled (60 mm) precast hollow box UHPC-segments and seven connection segments, so called knee-segments. They are prestressed together by the use of external tendons running inside the arches. Because of very low bending and shear force in the arches no further ordinary reinforcement was needed in all UHPC-segments. Only the tensile capacity provided by the steel fibres ensures a save load bearing behaviour. Furthermore, additional prestressing of the arch improves the stability. All further components of the bridge (columns, deck, foreland bridges) are made with cast in place normal strength concrete.

Because the bridge is crossing a deep gorge, the most efficient construction method for the arch was to combine the swivel-in method of arch construction with the light precast UHPC-segments. After completion of the foreland bridges, the several arch-segments are assembled in a vertical position using external tendons. The effort for equipment is minimal: a mobile crane for the manipulation and temporary ties for fixing the arch's position. The very light arch halves can easily be swivelled in. The hinge for swivelling is a simple steel bolt with a diameter of merely 80 mm. The maximum tensile force in the temporary ties was about 2×450 kN and therefore 2×4 mono strands were sufficient. After joining the arch halves further tendons overlapping at the arch's crown were installed.

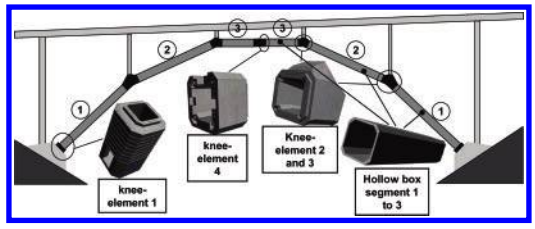

Figure 3. Assembly of the UHPC-precast segmental arch.

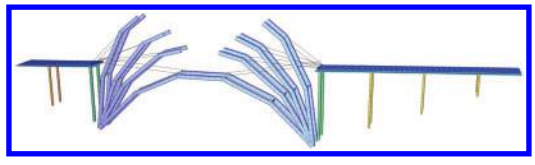

Figure 4. Principle of swivel-in method of arch construction.

Figure 5. Vertical assembling of the arch.

Due to pouring the space between the knee-segment 1 and the arch abutment, the arch gets a rigid restraint.

The connection of the segments is realized by dry joints without any shear keys due to the low shear force. The strict requirements on the evenness of those joint surfaces to reach the required final arch geometry and to transfer the high compressive stresses as well as due to durability reasons could only be met by milling with a CNC-machine.

Further investigation was needed to transfer the concentrated loads due to lifting devices or other anchorage elements during assembling into the thin walled UHPC-elements. Even the needed space for conventional lifting devices was often not available. Only the more massive knee-segments allowed a fixing of temporary lifting devices. Also special considerations regarding storage, transportation and handling during assembly were necessary in order to avoid damage or harmful cracking of the filigree thin walled segments. Specially developed lifting devices and a mobile crane with two independent winches provide simple and fast adjustment in all directions for a proper assembling.

2.2 *Design, Detailing and Tests*

In order to analyse and design the arch, the material laws, the associated partial safety factors for UHPC

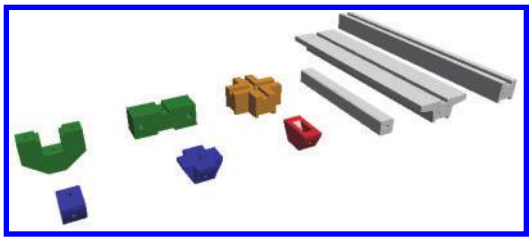

Figure 6. Elements of the truss structure.

and the design rules for ULS and SLS are gathered on the basis of (Schmidt et al. 2007, AFGC 2002, Reichel 2010). The buckling behavior of the segmental arch during the construction as well as in the final state was a special issue in the design and required the consideration of the stiffness change due to the gapping of the segmental joints. Therefore a special three-dimensional nonlinear calculation model based on beam elements was developed. This model was calibrated with the conducted full scale tests and other tests documented in literature.

The only steel fibre reinforced knee-segments with their complex shape at the bends of the segmental arch are sensitive discontinuity regions. Several actions such as anchoring and deviation of the prestressing tendons, bending moments induced by the columns as well as the shear and axial force in the compression zone of the segmental joint impact on those elements. Investigations by means of nonlinear and linear 3D-FE analysis delivered information about the expectable stress distribution.

Because present design codes and guidelines do not completely cover the use of UHPC in relation to the structure presented and the lack of experience, many experimental tests (including two full scale tests) gave answers to open questions for design and detailing (Freytag et al. 2009). The focus of the full-scale test was the load carrying behaviour in the region of the springing.

The used material models in the performed nonlinear 3D-FE analysis were calibrated and verified with the conducted tests. A recalculation of the full scale test confirmed the used material models.

3 MODULAR TRUSS CONSTRUCTION

3.1 *General description of the structure*

The second example is an UHPC truss construction according to Lego-system. Because of the prevention of monolithic nodes all components of the construction can be industrially produced in concrete plant.

The connection between node elements and other components of the construction is designed as dry joints. Precast elements and dry joints allow a high flexibility of the construction in span and in construction height. With the variation of the prestressing forces the bearing capacity can be adapted in any order. Due to strict requirements on surface evenness the

Figure 7. Elements of the truss structure.

grinding of the node elements with CNC machine is the precondition for the realisation with dry joints. External prestressing tendons satisfy the requirements of ULS and SLS. The construction weight is only about 20 % higher than comparable steel constructions and a non-destructive demounting of the construction is possible any time (Tue et al. 2010).

3.2 *Detailing, design and tests*

The most important detail of the construction is the node. In this element the transfer of compressive, tensile and shear forces is necessary. Due to the use of dry joints the friction coefficient between concrete surfaces is of high importance. Model tests considering different surface qualities are carried out in order to determinate the friction coefficient (Schoening et al. 2013) for the design of the shear bearing capacity. Additionally nonlinear calculations were conducted to analyse the stress state in the node element in ULS and SLS (Grube 2011). Furthermore, the influence of tolerances of the single components on the behavior of the whole construction was also analyzed in detail (Schwarz 2011).

4 UHPC FOOTBRIDGE MARKLEEBERG

4.1 *General description of the structure and of the construction process*

The third example is a hybrid construction for a pedestrian bridge in Markkleeberg near Leipzig to replace an about 10 years old wood arch bridge. An important design issue was to maintain the old arch shape, the clearance profile between bridge and river and the old abutments. Further demands on the design were aesthetic, a simple and fast erection, long service life and low effort for maintenance. These conditions can be perfectly matched by the proposed hybrid construction with UHPC.

The two parallel arches of the new bridge consist of conventional steel tubes and a flat UHPC-deck slab as a tie between the arch springing, which is suspended from the steel arch by inclined but non-intersecting hangers. The deck slab is assembled of 10 precast

Figure 8. Hybrid footbridge Markleeberg.

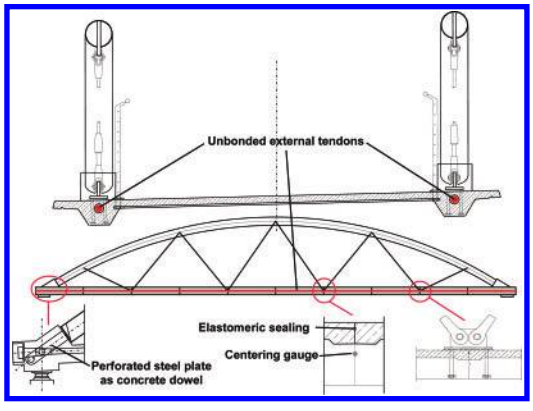

Figure 9. Standard cross section and details.

UHPC-segments and the tensile force is compensated at each arch by exchangeable external tendons, which are running inside of the deck slab. There is no waterproofing or other surface treatment for the deck slab due to the excellent durability properties of UHPC required.

The cross section has a width of 5.3 m. By a distance between the webs of 4.2 m the thickness of the slab is only 8 cm. In the line between the arch springing the slab is enlarged to so-called main girders which are 30 cm thick and inside of these main girders the tendons are positioned. Again, the joints between the precast segments are dry joints. A mechanical CNC-milling of the joint surface was not required, because the compressive stresses in longitudinal bridge direction are not so high. Therefore sufficient accuracy of the joint evenness could be reached be a highly precise steel formwork. To meet the durability requirement and a dense joint an additional elastomeric sealing between the precast segments was applied.

To reduce the construction time the new bridge will be assembled on one side of the river. After that the old bridge will be removed and the new bridge will be completely lifted into its final position by a mobile crane.

4.2 *Detailing, design and tests*

Because the load bearing behaviour of fibre reinforced structures depends on fibre orientation and distribution it is very difficult to guarantee the assumed

Figure 10. Full scale test in transverse direction.

design tensile strength in the produced segment. Furthermore the material costs increases significantly with increasing fibre content. Therefore in transverse direction a combination of fibres and ordinary reinforcement is used. Herewith a fiber content of only 1.0 Vol.-% is necessary for very small and not harmful crack widths, ensuring high durability adequate to the used UHPC. For bending design under ULS conditions only the ordinary reinforcement is sufficient and therefore the contribution of fibers negligible.

Because of the minor experience and missing codes for the design of UHPC structures, a full scale test in transverse direction was performed. A second issue of the test, was to investigate the deformation behaviour of the very slender deck slab at SLS, which was decisive for the design. This investigation was carried out under quasi permanent and rare loads and the development of the deformation was observed for 10 load cycles. After that the load was increased until load and finally failure. The load deformation behaviour in the test indicates a brittle failure due to localisation of the fracture process in one crack. However the ultimate bearing capacity is many times higher than required and the deformations at point of failure amounts more than 30 cm. According to this, the failure will be indicated due to large deformations and therefore sufficient ductility can be assumed.

Because of the less space in the thin-walled segments the dimensions of the load bearing plates of the prestressing anchors must be reduced comparing to the technical approval for ordinary concrete. Therefore additional tests according ETAG 013 for the span anchors with reduced dimensions were performed.

5 FLEXIBLE MODULAR TEMPORARY RAILWAY BRIDGE

5.1 *General description of the structure*

The fourth example is a modular temporary railway bridge made of UHPC (Reichel et al. 2009). Since a continuous ballast bed and ample working space under the structure are required, only a U-shaped cross section meets the preconditions by providing sufficient stiffness as well as low constructional depth. Due to assembling of single equal prefabricated segments

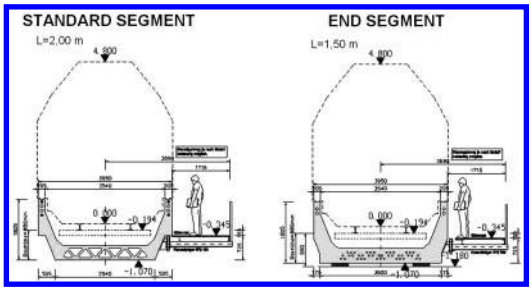

Figure 11. Cross sections with clearance diagrams.

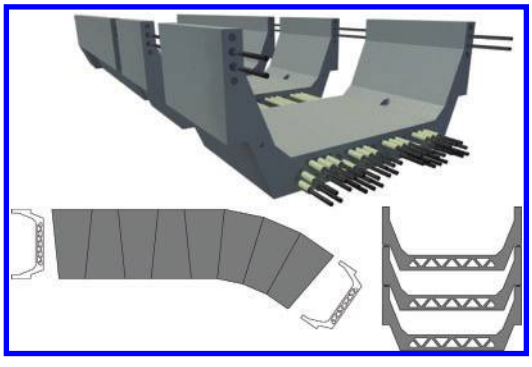

Figure 12. Basic principle and idea.

variable span lengths become possible and a trapezoidal shape of the segments in plan view enables a variable alignment of the rail. In addition assembling and dismantling is fast and simple by using re-usable Dywidag Steel Threadbars as external tendons. Further benefits of the U-shaped segments are the noise insulation, the segments ability to stack with minimum space for storage and the possibility to substitute single segments if they are damaged.

The width of the bridge is 3.95 m, the overall depth is 1.80 m and the possible span length ranges from 3 m to 26 m. Two different types of segments are used: 2 end-segments, which are 1.5 m long and more massive, to provide space for the elastomer bearings, the expansion joint and the anchorage for the prestressing bars. Further the end-segment supplies torsional resistance against lateral instability of the slender compression flange by activating a frame effect between the bottom plate and the webs. The more filigree standard segments, whose number depends on the aimed span length, have a hollow bottom plate which has a trussed framework in transverse direction to gain sufficient stiffness and load carrying capacity.

The prestressing bars running through the openings of the bottom plate are protected against deterioration by plastic ducts and by an additional spray coating. In transverse direction the upper and lower flange are pretensioned with strands and the diagonal ties are reinforced too. This results from high fatigue loadings as Austrian Railways demands a fatigue life of 50 years per segment. Furthermore the high railway loadings

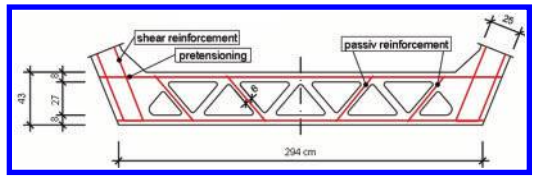

Figure 13. Cross section with reinforcement.

Figure 14. Full scale test in transverse direction.

and fatigue loadings require the arrangement of shear reinforcement in the webs. The segmental joints are dry joints and no additional shear keys were required because of the high amount of prestressing.

5.2 *Detailing, design and tests*

To achieve sufficient traffic safety at a maximum speed range of 200 km/h the deformation of the deck and the dynamic response due to train crossing were decisive for global design. The resistance of the steel fibres was disregarded because of too little experience and experimental results about the load carrying behaviour of fibres under cyclic loading in tension.

As Austrian Railways OBB demanded, one full scale test was performed in transverse direction and one test in longitudinal direction is currently under preparation with the maximum span length of 26 m. Furthermore tests according ETAG 013 for the smaller anchoring plates of the prestressing bars were already performed.

6 CONCLUSIONS AND OUTLOOK

The previously illustrated examples show, that an efficient and economical use of UHPC is possible. Especially the combination with filigree, flexible and modular segmental construction methods and the consequent involvement of all drawbacks and benefits regarding the special properties and features of this new building material offers a wide range of very promising solutions. Meanwhile a lot of experience could be gained with many completed pilot projects

all over the world, which showing the wide variety of new possibilities. But the next big step is to cast all the experience and the results from research in recommendations or codes to implement UHPC as a building material in practice and furthermore to enhance the acceptance of clients and authorities.

Development of ultra-high performance concrete and applications to bridges in Korea

C. Joh, S.Y. Park, K.T. Koh, S.W. Kim, Y.J. Kim & B.S. Kim
Korea Institute of Construction Technology, Goyang, Korea

ABSTRACT: This paper presents the features of K-UHPC, the ultra-high performance concrete that has been developed by the Korea Institute of Construction Technology since 2002 in terms of the total amount of shrinkage, improved tensile strength and toughness, and cost reduction compared to ordinary concrete. This presentation is followed by the description of the design guidelines of K-UHPC for the extensive exploitation of its tensile performance and deformed bars. Moreover, the future of K-UHPC cable-stayed bridge is forecast through the analysis of its economic efficiency and some examples of the application of the developed technologies to bridge structures.

1 INTRODUCTION

The application of ultra-high performance concrete (UHPC) featured by its ultra-high strength, high toughness and remarkable durability to structures will contribute to substantial weight reduction by realizing slender structures. Since a durable lifespan of 200 years will be secured, it can be forecast that the future concrete structures will evolve into cost efficient structures exhibiting innovative design by adopting UHPC. France, the first country to develop commercial UHPC products, Japan and Germany recognized the potential of UHPC since 1990s and initiated active R&Ds. Today, these countries have reached a stage aiming to apply UHPC to large civil structures from pedestrian bridges and construction materials to road and railway bridges (Schmidt 2012, Resplendino 2012). In Korea also, the Korea Institute of Construction Technology (KICT) started dedicated R&D in 2002 and developed its own UHPC called as to K-UHPC. KICT is now conducting research in various fields for further exploitation of K-UHPC in bridges like cable-stayed bridges (KICT 2012). This paper examines the features of K-UHPC and related design guidelines. The future of K-UHPC cable-stayed bridge is forecast through the analysis of its economic efficiency and some applications to bridge structures.

2 PERFORMANCE IMPROVEMENT OF UHPC: K-UHPC

Apart from its ultra-high strength and high durability K-UHPC developed by KICT presents three characteristics that distinguish it from other UHPCs (KICT 2012). Tables 1 and 2 arrange the mix proportions and mechanical properties of K-UHPC.

Table 1. Mix proportions of K-UHPC (in weight ratio, volume fraction for steel fiber).

W/B	Cement	Silica fume	Sand	Filling powder	Super-plasticizer	Steel fiber
0.2	1	0.25	1.1	0.3	0.016	$V_f = 2\%$

Table 2. Mechanical properties of K-UHPC*.

Design strength		Elastic	Poisson's	Total	Creep
Compr.	Tension	modulus	ratio	shrinkage	coefficient
180 MPa	9.5 MPa	45 GPa	0.2	600×10^{-6}	0.45

*Steel fiber: diameter 0.2 mm, 16 mm-length 1%, 20 mm-length 1%.

The first distinctive feature of K-UHPC is the total amount of shrinkage (autogeneous and drying), which with a value of about 600 με is comparable to that of ordinary concrete (Table 2). This enables to use deformed reinforcing bar as in ordinary concrete, which was difficult in UHPC due to the risk of cracking. The use of deformed bars in addition to the prestressing tendon usually applied in UHPC opens ways to achieve more efficient design for K-UHPC structures.

The second feature is the improved tensile strength and toughness developed by K-UHPC by using a combination of short and long steel fibers with a volume fraction of 2% similar to that adopted for previous UHPCs. Traditional UHPC developed a tensile strength of about 12 MPa by including 2% of steel

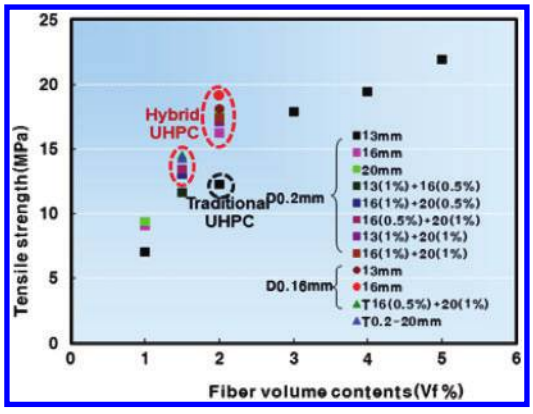

Figure 1. Comparison of the tensile strength of various UHPCs.

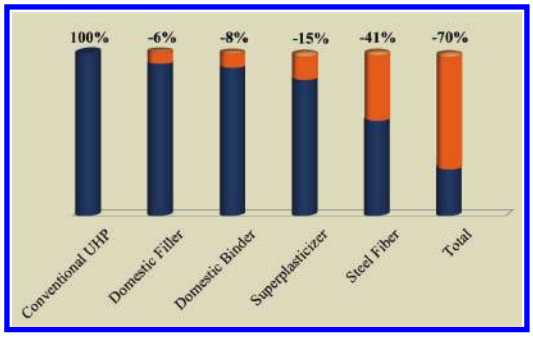

Figure 2. Cost reduction contribution per material of K-UHPC.

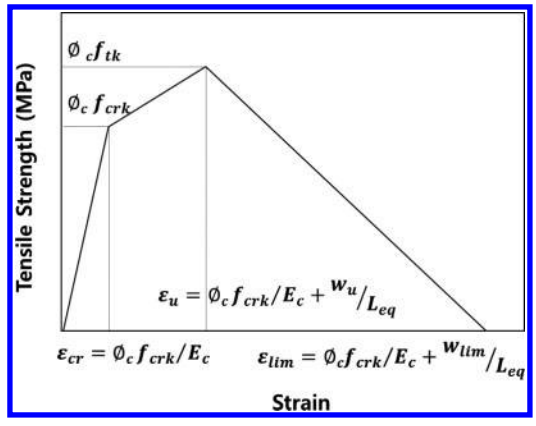

Figure 3. Tensile stress-strain diagram of K-UHPC.

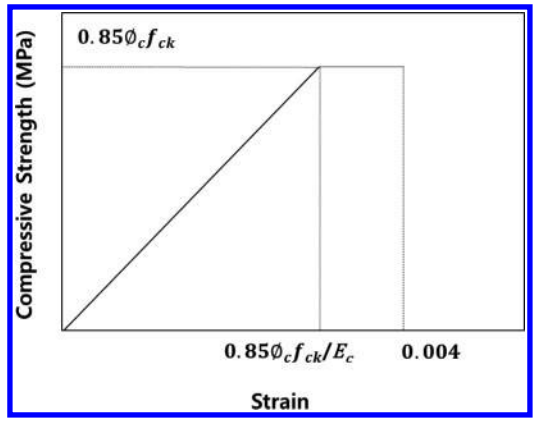

Figure 4. Compressive stress-strain diagram of K-UHPC.

fibers with diameter of 0.2 mm and length of 13 mm. Besides, K-UHPC develops a tensile strength of about 16 MPa by using steel fibers with diameter of 0.2 mm but lengths of 16 mm and 20 mm at respective volume fractions of 1% (Figure 1).

The third distinctive feature of K-UHPC is its fabrication cost, which is reduced by about 70% compared to previous products. This cost reduction was obtained by shifting the supply of the materials from import to regional areas and by replacing the costly water reducing agent and steel fibers by cheaper materials exhibiting equivalent performances (Figure 2).

3 DESIGN GUIDELINES OF K-UHPC

In 2012, KICT prepared design guidelines for K-UHPC (KCI 2012) by synthetizing the results of SUPER Bridge 200, a research project dedicated to K-UHPC (KICT 2012) and under the supervision of the Korea Concrete Institute. These guidelines deal with the material characteristics of K-UHPC and suggest structural design reflecting these characteristics. The latest research conducted in Korea and overseas like the French guidelines (SETRA-AFGC 2002), Japanese guidelines (JSCE 2004) and German research reports (DAfStb 2008) are reviewed and analyzed. The proposed guidelines are based on the results of more than 2500 material tests and 300 structural tests.

The guidelines present also material models enabling to exploit the improved performances of K-UHPC. Differently from the Japanese guidelines, the tensile stress-strain diagram selects a model with different values for the cracking strength (f_{crk}) and the tensile strength (f_{ck}) in order to consider the properties of K-UHPC exhibiting strain hardening and softening characteristics (Figure 3). For the compressive stress-strain diagram, the model is subdivided into the linearly elastic part and the perfect plastic part similarly to the Japanese guidelines. The difference is the ultimate compressive strain, which is set to 0.004 based upon test results (Figure 4). The strength reduction factor (ϕ) is used instead of the material factor (Figure 3 & 4). Apart from these contents, the guidelines specify also provisions relative to the elastic modulus, Poisson's ratio, shrinkage and creep, thermal properties, durability, water tightness and fatigue strength.

Figure 5. Torsional behavior of K-UHPC girder (no stirrups).

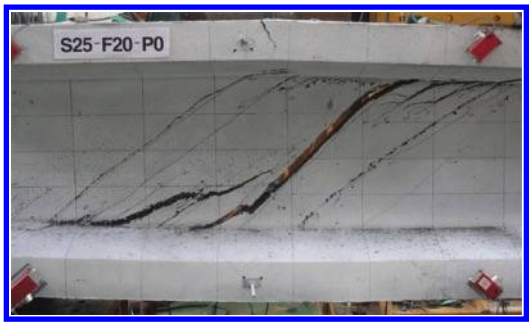

Figure 6. Shear behavior of K-UHPC girder (no stirrups).

Figure 7. Flexural test of K-UHPC girder prestressed with tendons.

In the provisions for the structural design, regulations related to torsion, prestress anchorage zone, connection of precast members, and deformed bars are proposed to allow the designer to exploit extensively the tensile behavior of K-UHPC and deformed bars considering the structural characteristics of UHPC structures that are mostly slender precast prestressed structures. Especially, for torsion, the guidelines adopt a novel design method taking into account the tensile behavior of K-UHPC. This is different from the French and Japanese guidelines referring to the specifications of ordinary concrete, which neglect the tensile force of concrete. For example, based on test results (Figure 5), the torsional rigidity (T_d) of the K-UHPC girder is assumed to be the sum of T_s provided by the transversal stirrups and T_{K-UHPC} provided by the tensile strength of K-UHPC (Joh et al. 2012). For the flexural, compressive and shear design, the guidelines propose provisions similar to those of the French and Japanese guidelines (Figures 6 and 7).

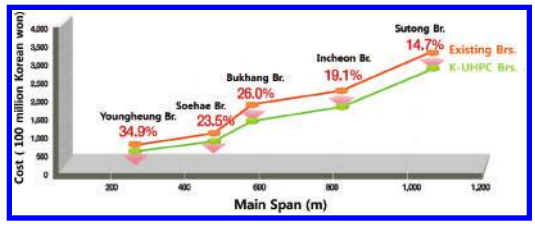

Figure 8. Cost analysis of cable stayed bridges.

4 ECONOMIC EFFICIENCY OF K-UHPC CABLE-STAYED BRIDGE

Detailed designs were carried out to compare the cost necessary for the erection of K-UHPC cable-stayed bridges to that of previously constructed cable-stayed bridges. The results revealed that the K-UHPC cable-stayed bridge offers economic efficiency for main spans ranging between 200 m and 1000 m (KICT 2012) (Figure 8). Especially, the cost analysis for Incheon Bridge, known to be the 5^{th} longest cable-stayed bridge in the world with its central span of 800 m, showed that the K-UHPC cable-stayed bridge of similar dimensions was cheaper by 19.1%. This significant cost-reduction is realized by the adoption of the K-UHPC girder which, despite of the slight increase of the weight of the superstructure, enables to diminish drastically the quantities of costly steel since steel composite or steel-box bridges are usually adopted for cable-stayed bridge longer than 400 m. Besides, in the case of cable-stayed bridges with main span ranging between 200 m and 400 m for which concrete bridges are known to be cost efficient, the replacement of the bulky and heavy concrete girder by the K-UHPC girder achieves significant lightening of the weight, which in turn enables to reduce the demand in cables and the size of the foundations, and thus contributes also to the cost efficiency.

5 DESIGN AND CONSTRUCTION OF K-UHPC BRIDGES

In 2009, KICT realized the design and erection of a K-UHPC pedestrian cable-stayed bridge for the first time in the world (KICT 2012) (Figure 9).

This bridge is composed of a single pylon with 3 planes of cables arranged in fan type. Four K-UHPC segments were fabricated with width of 2.5 m, length of 7.0 m, girder depth of 0.3 m and slab thickness of 70 mm. Then, two segments per span were assembled in the cast-in-place part of the pylon to realize a span length of 18 m. The design and erection of the bridge enabled to test and validate the core technologies necessary to the K-UHPC cable-stayed bridge.

In 2011, based on the cost analysis and research results related to the cable-stayed bridges using K-UHPC, the Korean construction company Daelim contracted technology transfer with KICT and bid for

Figure 9. View of the K-UHPC pedestrian cable-stayed bridge at KICT.

Figure 10. Rendering of Jobal Bridge.

Figure 11. Construction of K-UHPC road bridge (2012).

the turnkey of Jobal Bridge on National Road 77 linking Jobal Island and Dunbyung Island in the southern coast as the first tender of a K-UHPC cable-stayed road bridge in the world (KICT 2012) (Figure 10). This bridge is a 3-span cable-stayed bridge with main span of 200 m and pylon's height of 90 m. For a width of 15.4 m, the depth of the edge girder reaches only 1.2 m achieving a slender structure. Cost analysis showed that this proposal was cheaper by about 14% than the PSC cable-stayed bridge envisaged as an alternative.

In 2012, the first trial construction of a K-UHPC road bridge in Korea was conducted by exploiting the

Figure 12. Fabrication of ribbed K-UHPC deck.

fabrication and bridge design technologies developed by KICT (KICT 2012) (Figure 11). This structure is a single span bridge with span length of 11 m, width of 5 m and π-shape cross section of 0.6 m height. The weight is only 112 kN per segment. Even if the bridge is relatively small, its construction applied all the major technologies necessary for the construction of a K-UHPC bridge like the prestressed precast fabrication and connection technologies.

In late 2012, a bridge applying the ribbed K-UHPC deck developed by KICT was erected (KICT 2012) (Figure 12). This lightweight deck is lighter by 50% than the conventional precast concrete deck. The results of the cost analysis revealed that the construction cost of the superstructure can be reduced by about 10% only by replacing the deck of the traditional steel composite cable-stayed bridge.

6 CONCLUSIONS

KICT developed the K-UHPC, an ultra-high performance concrete exhibiting reduced amount of shrinkage, improved tensile behavior and substantial reduction of the fabrication cost. Corresponding design guidelines for K-UHPC were prepared to exploit its remarkable characteristics. Based on these results, cost analysis was conducted for the K-UHPC cable-stayed bridge and step-by-step field applications were realized. The analysis showed that the K-UHPC cable-stayed bridge could secure economic efficiency by 20% on the mean over the whole applicable portion of the cable-stayed bridge. It can be predicted that, based on its cost efficiency and innovative design, the K-UHPC cable-stayed bridge will take place as a strong alternative enabling to surmount the limitations faced by traditional bridges like concrete, steel composite and steel box cable-stayed bridges.

Behaviour of hybrid PVA-steel fibre reinforced ultra high performance concrete at high temperature

S. Sanchayan & S.J. Foster
Centre for Infrastructure Engineering and Safety, School of Civil and Environmental Engineering, The University of New South Wales, Australia

ABSTRACT: Reactive powder concrete is an ultra-high performance concrete that exhibits superior strength, durability and ductility compared to normal concretes; this is due to its homogeneity, dense microstructure and the presence of steel fibres. To best utilize the benefits of this material in construction, it is essential to understand its behaviour under different loading conditions, with high temperature exposure being one of such conditions. Reactive powder concrete containing only steel fibres or no fibres has been found to perform poorly under extreme temperatures due to explosive spalling caused by a build-up of pore water pressure within its dense micro-structure; this may be alleviated with partial replacement of steel fibres with PVA fibres. This paper presents the behaviour of reactive powder concrete containing equal amounts of PVA and steel fibres, occupying a total volume fraction of 2% and tested at high temperatures. The behaviour is characterized by measuring the stiffness and axial deformation at various temperatures and at stress levels of 30 per cent of the cylinder compressive strength determined at room temperature. The elastic modulus at high temperature was found to decrease gradually with temperature. Transient creep was observed to develop between 200°C and 300°C, increasing gradually with temperature thereafter.

1 INTRODUCTION

Concrete technology is constantly evolving, pushing the limits of concrete compressive strengths. In these series of developments, reactive powder concrete (RPC) is a relatively recent innovation that can have compressive strengths up to 200 MPa, and greater (Richard and Cheyrezy 1995). Much of its improved mechanical properties are due to its dense micro structure, homogeneity and the presence of steel fibres. The dense micro-structure is achieved by optimizing the packing density of the mix by incorporating fine particles such as silica fume and/or silica flour. Such optimization requires the use of third generation superplasticisers that are effective in dispersing particles. Homogeneity is improved by eliminating coarse aggregates completely and improving the mechanical properties of the paste. The addition of steel fibres helps to improve both the strength and ductility.

For new materials, it is essential to understand their behaviour under different loading conditions before adopting into full scale applications. High temperature exposure is one of such loading condition. However, limited experiments have been reported on the behaviour of RPC under such conditions (Tai et al. 2011; Peng et al. 2012).

Concrete, in general, is perceived as a good material under high temperature environments as compared with steel and timber. However, some concretes show explosive spalling during heating to elevated temperatures that can lead to loss of cross section and, therefore, affect the structural performance of the member. Such spalling is caused mainly by the build-up of pore pressures and thermal stresses (Khoury 2000).

In a previous study by the authors, it was found that plain RPC and steel fibre reinforced RPC is susceptible for explosive spalling when heated to high temperatures (Sanchayan et al. 2012). This explosive spalling was reported to occur when the surface temperature of the RPC was between 350°C and 450°C. The standard practice of mitigating spalling risk in high-strength concrete structures is to add synthetic fibres with a melting point that is sufficiently low that the fibres melt and vaporize before the vapour pressures build to a level that cause stresses that cannot be sustained by the concrete. Once vaporised, mezzo-sized channels are left in the structure that provide passage of the vapour to the surface, reducing the build-up of pore pressures. It was found that adding 1% by volume of PVA fibres with a melting point of 220°C, with 1% by volume of steel fibres, improves the behaviour under high temperature and also to result in good mechanical properties at the ambient temperature.

This study investigates the behaviour of hybrid PVA-steel fibre RPC under high temperature. The deformation characteristics, as defined by the modulus of elasticity and transient creep, are found using a specially designed furnace in a universal testing machine for loading under high temperatures.

Table 1. Mix design data (mass ratios).

Component	Mass Ratio
Cement	1.0
Silica fume	0.25
Sydney sand	1.1
Superplasticizer	0.062
Steel fibres	0.087
PVA fibres	0.014
Water	0.17

The residual strengths of the hybrid RPC mix after exposure to high temperatures, and followed by a period of cooling, are also studied. The results are presented below.

2 EXPERIMENTAL PROGRAMME

2.1 *Materials and Mix design*

The materials used to make the RPC mix were Type 1 general purpose cement complying with AS3972, undensified silica fume manufactured by SIMCOA, Western Australia, Sydney sand with maximum particle size of 600 μ m and dried at 105°C and Glenium 51 superplasticizer. The mix contained equal volumes of 13 mm long by 0.2 mm diameter steel fibres and 12 mm long by 0.2 mm diameter PVA fibres. The fibres occupied a total volume fraction of 2%. The steel fibres were manufactured by Dramix, Belgium, and had a reported minimum strength of 1800 MPa and an elastic modulus of 200 GPa. The PVA fibres were manufactured by Kuraray, Japan, and had a reported minimum strength of 1000 MPa, an elastic modulus of 29 GPa and a melting point of 220°C. The detailed mix data is presented in Table 1 with the quantities expressed as mass ratios relative to the mass of cement.

2.2 *Mixing and fabrication*

The materials were batched using an electronic balance and mixed using a horizontal pan type mixer. The dry constituents were mixed for 10 minutes and then the water and superplasticizer were added together. Mixing was continued until the mix had an even plastic consistency. The fibres were then sprinkled into the mix and mixing was continued for another 5 minutes.

Cylinders of 100 mm diameter and 200 mm high were cast in steel moulds and were stored in a controlled environment room at 50% relative humidity (RH) and 26°C for a period of 24 hours. After 24 hours, the cylinders were de-moulded and cured for a further 72 hours at 85°C in a hot water bath. At the end of the curing period, the cylinders were removed from the hot water bath and stored in the controlled environment room at 50% RH and 26°C until the time of testing.

The mean compressive strength obtained for the batch was 158 MPa. The elastic modulus was 43 GPa.

Figure 1. Arrangement of the furnace with extensometer.

2.3 *Testing Apparatus*

Testing was carried out in a specially designed furnace loading frame arrangement which allows for simultaneous loading and heating of the specimen. The apparatus consisted of a vertical single zone split type furnace, and can be used to heat up to a maximum temperature of 1220°C, and a stiff 1 MN Instron servo-hydraulic controlled testing frame. The load was transferred from the frame to the specimens using Nickel Alloy 625 loading rods, which can tolerate high temperatures. There were also platens of the same material placed on top and bellow the cylinders. Ultra high strength concrete blocks were used between the loading rods and the frame to safeguard the frame from heat and the loading rods were also insulated using thermal blankets. A spherical seat was placed between the upper loading plate and the upper insulation block. A high temperature extensometer was used to measure the strain and the load and strain data were captured using a TMR 211 data logger. Figures 1 and 2 show, respectively, the testing frame and a schematic of the testing arrangement.

2.4 *Heating Procedure*

Two sets of experiments were conducted. In the first set four temperature points were selected, 150°C, 300°C, 450°C and 600°C and three specimens were tested for each temperature. To minimise the potential for explosive spalling at the higher temperatures, the cylinders to be tested at temperatures of 450°C and 600°C were first oven dried at 105°C. Explosive spalling had been

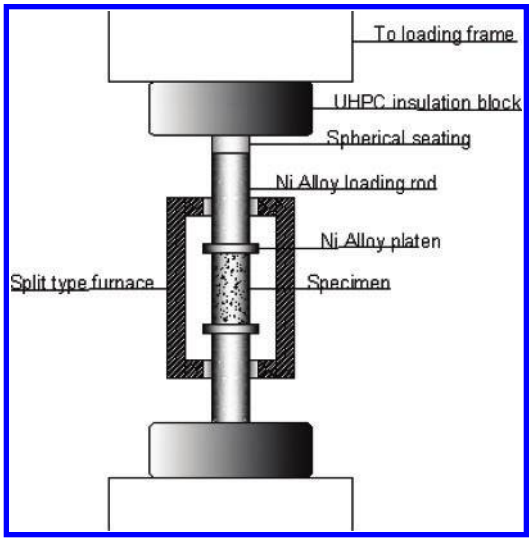

Figure 2. Schematic diagram of the furnace and the loading frame.

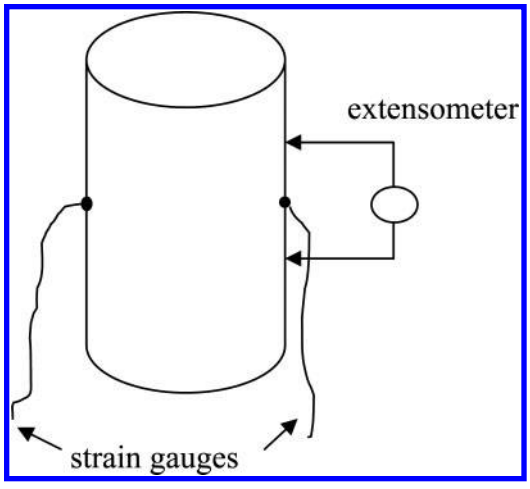

Figure 3. Position of strain gauges and the extensometer.

encountered during previous studies by the authors with significant potential for damage to the testing apparatus (Sanchayan et al. 2012).

Each specimen in the first series of tests was heated in the split type furnace frame arrangement at a rate of 5°C/min until the target temperature was reached. Thereafter, the specimen was maintained at the desired temperature for at least two hours to obtain a uniform temperature distribution through the specimen. The cylinder was then tested to obtain its modulus of elasticity in the hot state. Next, the specimen was allowed to naturally cool and was then again tested to determine its residual modulus of elasticity. Lastly, each specimen was tested to destruction to obtain its residual compressive strength in a different frame.

In the second set of experiments, a constant axial load was applied to the specimens and axial strains were measured as the heat was applied, up to temperatures of 600°C. The heat was applied at a rate of 2°C/min. The temperatures were measured using a thermocouple attached at the mid-height of the cylinder. The loading levels adopted in the tests were zero and 30% of the strength measured under ambient conditions. Two cylinders were used for each loading level. To eliminate shrinkage strains induced through drying at high temperatures, all cylinders used in this test series were pre dried at 105°C in an oven until a constant mass was attained. Thus, the resulting strains are due to heating and loading alone.

2.5 *Testing procedure*

Two strain gauges were attached at the mid-height of each cylinder in diametrically opposite positions. The cylinder was then placed in the loading frame and the extensometer was attached to the cylinder, aligned with one of the strain gauges. Figure 3 shows the position of strain gauges and extensometer. Next, the cylinder was loaded at the ambient temperature in 3 cycles to obtain a relationship between extensometer reading and average of the strain gauge readings. This data was used to obtain a calibration curve to correct the extensometer measurements taken under high temperature, which were taken from one side of the specimen only. This is required to adjust for the effect of small loading eccentricities on the cylinder induced from the ends not being perfectly square with the cylinder edges. The strain gauges were removed before heating of the specimen.

After the relationship between the average strain and the extensometers was obtained, the specimens were heated to the target temperature at the rate of 5°C/min; the target temperature was maintained for a period of 2 hours to stabilise the temperature through the specimen before testing for the elastic modulus. After the temperature stabilisation period, loading was applied to the cylinders to obtain their elastic modulus, with the strains measured using the extensometer and corrected using the previously obtained calibration curve for the given cylinder.

In the second series of tests for measurement of strain changes under constant axial load, the axial strains were measured using the extensometer only. In this case, loading eccentricity is not of concern as the load, and hence stress, is constant; any additional strain after the load is applied is due to the effect of heating alone. The load was applied, and maintained, while the temperature was increased from ambient (room) conditions to 600°C at a rate of 2°C/min.

3 RESULTS AND DISCUSSION

3.1 *Hot and Residual Elastic Modulus*

The change in the elastic modulus measured both at (i) the hot state and (ii) after cooling to room temperature is presented in Figure 4. The graph is plotted as a ratio of the elastic modulus resulting from high temperature

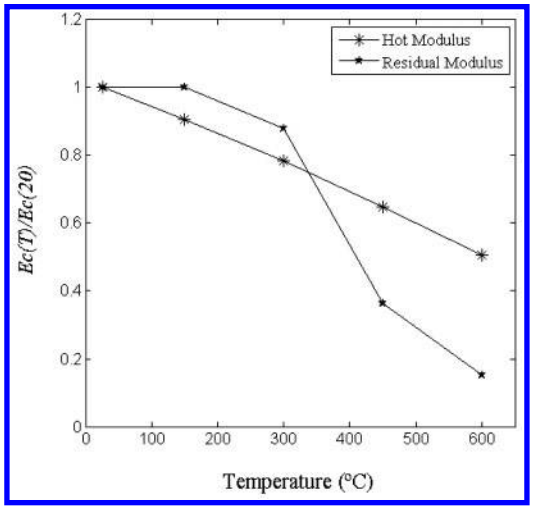

Figure 4. Hot and residual state elastic modulus.

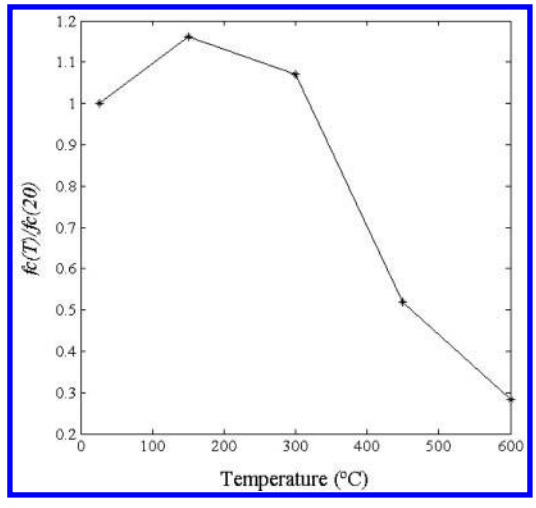

Figure 5. Residual compressive strength.

exposure, E_c(T), to that at the ambient temperature, E_c(20). The hot state elastic modulus shows a steady decrease with rising temperature. It reaches a value of 80% of that measured under ambient conditions between the temperature points of 200°C and 300°C, and 50% at 600°C.

The residual modulus of elasticity, which was measured after the specimens were cooled to the ambient temperature, shows a very different behaviour to that measured at the hot state. There is no appreciable change in the modulus up to the temperature of 300°C, thereafter it drops considerably reaching about 40% and 15% of the original modulus at temperatures of 400°C and 600°C, respectively.

It is interesting to note that there is an increase in the elastic modulus when cooled to room temperatures when the exposure temperature is lower than 300°C, while there is a significant drop in the elastic modulus for the temperatures greater than 300°C. Generally, the residual modulus is found to be higher than the hot state value reported in the literature for normal concretes (Bazant 1996). The hot state elastic modulus values produced in this study are in good agreement with that for steel fibre reinforced RPC containing Polypropylene fibres reported by Piementa et al. (2011). However, the residual elastic modulus produced by them was higher than the hot modulus, regardless of the temperature.

3.2 *Residual Compressive Strength*

Figure 5 presents the residual compressive strength as a ratio of compressive strength measured under heat, f_c(T), to the mean strength measured at ambient temperature, f_c(20). An increase in strength was observed up to the temperature of 300°C, reaching about 20% higher than the original strength. After 300°C, the residual strength drops significantly, reaching about 25% of the original strength at a temperature of 600°C. The initial increase in the strength is probably due to removal of adsorbed water, which leads to higher Van der Waal's forces.

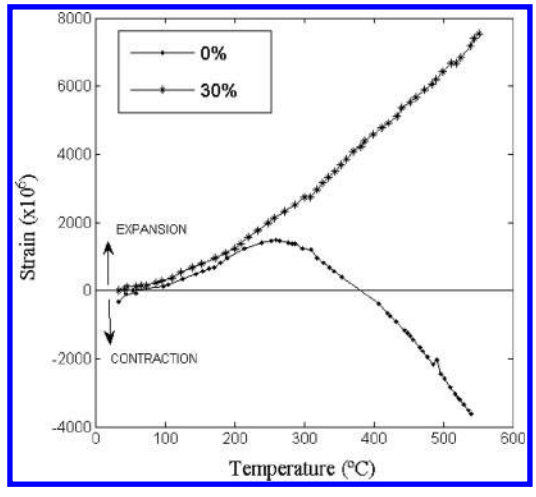

Figure 6. Thermal strains under heating with constant loading.

3.3 *Axial Thermal Strain Measurements*

Figure 6 shows the evolution of axial thermal strain of RPC cylinders when subjected to heating to 600°C under constant loading. The strains are presented as a function of the surface temperature of the cylinder. Positive strains indicate expansion; negative strains indicate contraction. Two constant loading levels were considered; 0% and 30% of the ambient mean average compressive strength. Under no loading, the specimen expands freely due to heat. When the specimen is heated under constant load, initially it undergoes free thermal expansion. Subsequently the matrix undergoes deterioration as result of dehydration that causes contraction in the specimen.

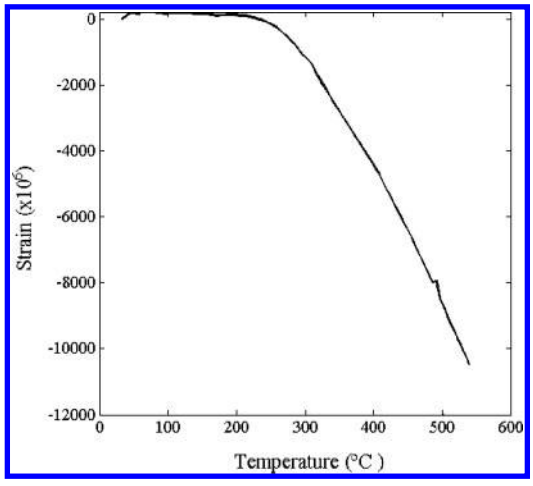

Figure 7. Load induced thermal strains for PVA-steel fibre reinforced RPC under load of 30% of the mean compressive strength at the ambient temperature.

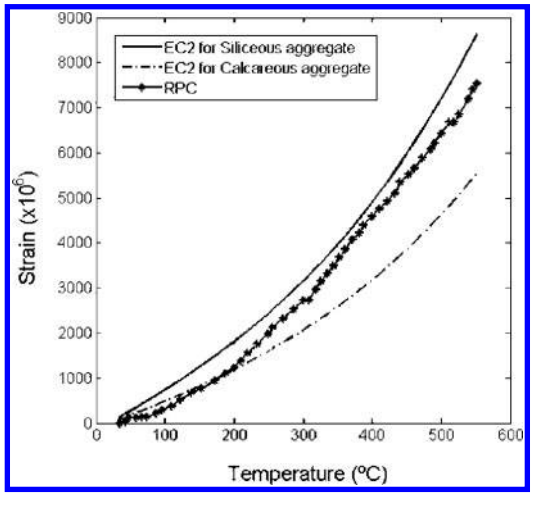

Figure 8. Comparison of thermal strains of hybrid fibre RPC with given values for siliceous and calcareous aggregate concretes in Eurocode 2(BS EN 1992-1-2:2004).

The contraction under load, i.e. difference in strain between 0% loading level and 30% loading level, is referred to as 'load induced thermal strains' (LITS) or transient creep, whereas the former is called 'free thermal strains' (FTS) (Khoury 1985). LITS depends on temperature and applied level of stress, whereas FTS depends only on temperature for a particular material. The LITS is calculated and presented in Figure 7. The transient creep for RPC used in this study is quite similar to that reported for other cementious materials. It becomes significant above temperatures of 250°C and continues to increase with increases in temperature. The co-efficient of thermal contraction due to transient creep is calculated as 40×10^{-6} per °C.

Figure 8 compares the thermal strain of RPC with the thermal strains for siliceous and calcareous aggregate concretes as given in the model in Eurocode 2 (BS EN 1992-1-2, 2004). From the figure it is observed that the behaviour of RPC is similar to that of the siliceous aggregated concrete.

4 CONCLUSIONS

This research studied the transient and steady state behaviour of PVA-steel fibre reinforced RPC subjected to high temperatures. In the first part of the study, variations in the elastic modulus were investigated for cylinders, while the temperature was held constant. The specimens were gradually heated to the target temperature, the temperature was then held constant for a period of two hours, after which the hot elastic modulus was determined. The specimens were then cooled to room temperature to find the residual elastic modulus and residual strength. Target temperatures from zero to 600°C were investigated.

In the second part of the study, transient creep and thermal strains were measured for RPC cylinders held under a constant load while the temperature was increased from zero to 600°C at the rate of 2°C/min.

The following observations are made and conclusions drawn:

1. The elastic modulus of hybrid fibre RPC drops gradually and approximately linearly with increasing temperature;
2. The residual elastic modulus shows no appreciable variation up to the temperature of 300°C. At higher temperatures, the residual modulus of elasticity reduces significantly;
3. The residual elastic modulus was found to be higher than the hot elastic modulus when the temperature was 300°C and lower;
4. An increase in residual compressive strength was observed when temperature was below 300°C. This increase is caused by removal adsorbed water, which increases the surface forces and, thus, strength;
5. At temperatures greater than 300°C, the residual compressive strength was significantly less than the compressive strength at room temperature;
6. Free thermal strains were found to be similar to that of a siliceous aggregate concrete; and
7. Load induced thermal strains (LITS), or transient creep, is significant when the temperature rises above 250°C.

Sustainable building with ultra-high performance concrete (UHPC) – coordinated research program in Germany

M. Schmidt
Institute of Structural Engineering, University of Kassel, Germany

ABSTRACT: In Germany, a 12 Mio. € Research Program on UHPC was performed since 2005, covering a wide range of topics related to UHPC. The program was funded by the German Research Foundation (DFG) and coordinated by the University of Kassel. More than 20 research institutes were involved. Its purpose was to elaborate the basic knowledge necessary to draft reliable technical standards covering materials, material-adequate design principles and innovative construction and fitting technologies to make UHPC a reliable, commonly available, economically favorable, regularly applied material. This paper describes the intention and the background of the program, and it gives an overview over the topics being dealt with and the results recently available. As one result material adequate limits for the composition of durable UHPC are presented.

1 INTRODUCTION

In Germany, a comprehensive 12 Mio. € Research Program on UHPC has recently reached its end. The program was funded by the German Research Foundation (DFG) and coordinated by the University of Kassel. More than 20 research institutes were involved, striving to elaborate the basic knowledge necessary to draft reliable technical standards covering both materials and design principles to make UHPC a reliable, commonly available, economically favorable, and regularly applied material. The fields of interest that the individual research projects concerned themselves with include the suitability and performance of raw materials including cements, inert or reactive mineral fillers, artificial nanoparticles, and improved plasticizers. Basic research on appropriate mix designs for different applications, the rheological specifics of the fresh concrete and its hydration are evaluated as well as the time dependent strength and deformation behavior of hardened UHPC with and without fibers. Also covered were material-adequate design and construction procedures including new appropriate technologies to build high performance light and slender and therefore sustainable structures.

2 OBJECTIVES AND TECHNICAL BACKGROUND

The most notable characteristic of Ultra-High Performance Concrete (UHPC) is its extremely dense microstructure, resulting in a steel-like compressive strength of about 180 to 250 MPa, combined with a significantly improved durability. The structural density is primarily due to the high packing density accomplished with an optimum grading curve comprising fine and ultra-fine particles $\leq 125\,\mu m$ in the cement matrix, and a comparatively low w/c-ratio of about just 0.20.

Undoubtedly, UHPC represents a milestone in concrete technology due to the new challenges for both civil engineering and architecture and the opportunity to develop material and energy conserving slim and slender concrete structures significantly reducing the energy and material related impact on the environment by up to 40% (Schmidt & Jerebic, 2008) Nevertheless apart from a small number of pilot projects, the application of UHPC has been restricted due to the fact that neither the material itself nor the material-specific design of the structures had already been sufficiently explored to draft technical standards as a basis for a common application.

To support the idea of promoting UHPC as a commonly available and standardized material based on individual regionally available raw materials, the German Research Foundation initiated an extensive research program in 2005. It would break the mold by far to report on all the theoretical and experimental research and the information that has already been gathered. A more extensive survey covering most of the findings already gathered is given in the Proceedings of the Second and the Third International Symposiums on UHPC, held in Kassel in 2008 and 2012, both available online (Fehling et al. 2008; Schmidt et al. 2012). Reports on all projects assorted in Table 1 will be presented in a comprehensive report to be finalized and published in 2013.

Table 1. Working groups inside the priority program and their individual research topics.

Working group	# of projects 2005–2013	Topics of the individual projects
Raw materials, rheology, processing, sustainability	4	– Influence of shape and texture of fine grains and of interparticle forces on packing density and rheology – Life cycle inventory on UHPC – UHPC with low-energy binders – Optimization of the mixing process
Hydration and microstructure	2	– Characterization of the microstructure – Micro- and nanostructure of UHPC with nanotubes and pyrogenous SiO_2
Time-dependent behavior (shrinkage, creep, cracking)	6	– Early age behavior of UHPC – Reduction of crack formation by internal curing – Shrinkage-reducing chemical admixtures – Time-dependent stress-strain behavior – Early age cracking and durability – Autogenous shrinkage and microstructure
Fiber efficiency and interaction with conventional reinforcement	3	– Load-bearing capacity of elements reinforced with fibers and bars under tension and bending – Ductility of UHPC with fibers and nanoparticles – Self-compacting UHPC with fiber meshes
Strength and deformation	2	– Fatigue under uni- or multiaxial loads – Modeling of multiaxial strength
Durability	4	– Resistance to freezing and deicing agents – Resistance to chemical attacks (acid, sulfates) – Fire safety of UHPC under load – Corrosion of steel fibers and influence on the microstructure
Design, construction, and application	11	– Prestressed beams – Performance of steel fitting elements for hybrid structures (UHPC/steel) – Loadbearing of extensively loaded columns – Fitting of elements by gluing – Thin fiber-reinforced UHPC layers on conventional concrete structures – UHPC under transverse (biaxial) forces – Anchorage and overlapping joints of reinforcing – UHPC/steel pipes for truss structures – Thin-walled pipes – Structural connection of precast elements – Miniaturized fitting devices for slender slabs
Testing	2	– Adjusted test procedures for rheology and strength – Fiber distribution and orientation

3 MICROSTRUCTURE

The most notable characteristic of Ultra-High Performance Concrete (UHPC) is its extremely dense microstructure of the matrix based on the high amount of fines with an optimum packing density and a low w/c-Ratio (Geisenhanslüke & Schmidt, 2004; Teichmann & Schmidt, 2004) Depending on the application and especially on the amount and the maximum grain size of the aggregates, UHPC contains between 450 and 1000 kg cement per m^3, between 50 and 250 kg/m^3 of microsilica and a significant amount of other mineral fillers (primarily fine ground quartz or basalt). Table 2 shows some quite different mixture compositions with different fresh concrete consistencies developed at the University of Kassel and already practically realized: Self compacting UHPC for precast elements and floor layers (M2Q, B5Q in Table 2), plastic consistency for concrete pavement layers to be placed by slipform pavers (UHPC-PV) or even no-slump consistency for sewer system pipes with an increased mechanical and chemical resistance (UHPC-NS) (Schmidt, 2012). The w/c-ratio ranges from 0.22 to 0.29, and the w/(c + m) ratio considering microsilica as part of the reactive binder is between 0.19 and 0.25. Independent of the w/c-ratio, the average 28-days compressive strength of all mixtures in table 1 was about 150–165 MPa when the concrete specimen were stored at 20°C under water. It was about 190 MPa when the concrete was heat treated at 90°C for app. 48 h.

The dense microstructure is the key factor that is determining the outstanding performance of UHPC. Electron microscopy investigations e.g. by Möser (Möser & Pfeiffer, 2008) using a NanoSEM microscope confirm that the hydrate phases in UHPC are significantly shorter as a result of the high packing density, the low w/c ratio of about 0.20 only Figure 1

(Fehling et al., 2005) shows a SEM micrograph of unhydrated microsilica particles surrounded by dense C-S-H phases in UHPC (left) compared to the long and instable phases and the rather porous structure of ordinary concrete.

The ability of concrete to withstand physical and chemical attacks is usually attributed to the amount of capillary pores in the cementitious matrix.

Capillary pores arise during the hardening period when excess water evaporates, which is the part of the total amount of water that is not chemically or physically bound in hydration phases or in the pores of the microstructure (gel pores). Thus, the amount of capillary pores is a quite reliable benchmark to classify the durability of a specific concrete. E.g., Figure 2 shows the characteristic pore size distributions of an ordinary concrete C45/55 with a w/c-ratio of about 0.48, a High Performance concrete C105 with a w/c-ration of 0.35, and UHPC M2Q acc. to Table 2 with a w/c-ratio of only 0.22 the latter being virtually free of capillary pores with diameters between 0.01 and 1 μ m. This accounts for its extremely high resistance to the ingress of harmful liquid or gaseous agents, e.g. chloride and alkaline ions or to frost attacks with and without deicing agents. As an example, Figure 3 shows the results of chloride diffusion tests on the three concretes already mentioned in Figure 2. When tested in an accelerated test, (Tang & Nilsson, 1992) both the depths of the chloride intrusion and the transmitted charge fairly correlated with the amount of capillary pores shown in Figure 2 and thus with the w/c-ratio of the concretes. The UHPC M2Q was practically impermeable to chloride ions.

Another indicator for the resistance of the microstructure is the relative absorption of water or other liquids in relation to the total pore volume.

Table 2. Application oriented UHPC compositions.

	UHPC fine M2Q (0/0,5)	UHPC coarse B5Q (0/8)	UHPC-PV Pavements	UHPC-NS Pipes

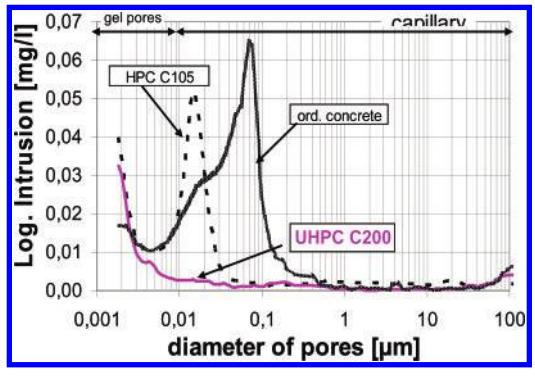

Figure 2. Typical pore size distributions of Ordinary Concrete C 45/55, High Performance Concrete and UHPC M2Q acc. to Table 2 (mercury intrusion) (Fehling et al., 2005).

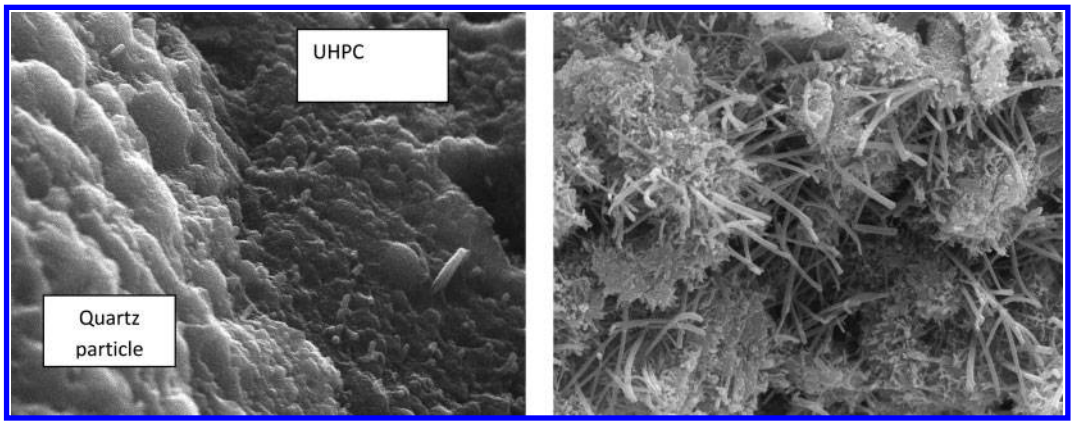

Figure 1. Matrix of UHPC, (left) compared to ordinary concrete (right).

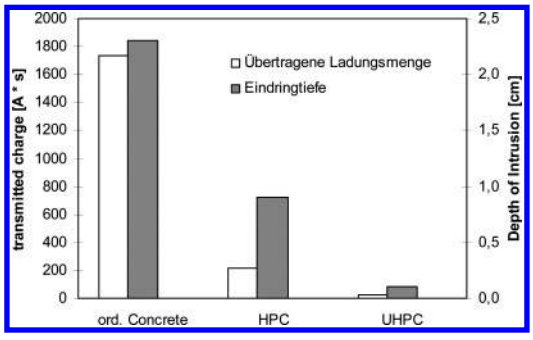

Figure 3. Resistance to chloride diffusion of heat treated UHPC M2Q (table 2), HPC C105 and OPC C45/55. Porosity as shown in Figure 2.

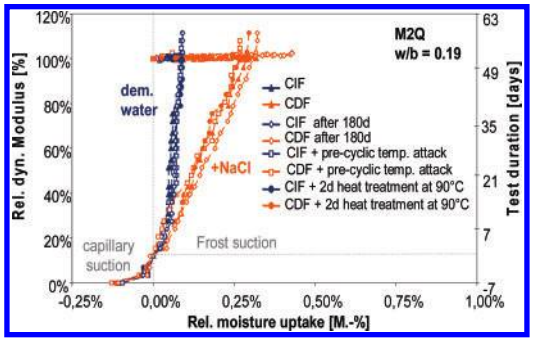

Figure 4. Absorption of water/NaCl-solution during freezing and sawing cycles. UHPC M2Q acc. to Table 2 (Setzer & Palecky, 2007).

Figure 4 shows the relative amount of water or of 3%-NaCl-solution respectively being absorbed by capillary suction and during freeze-thaw-cycles of UHPC when tested acc. to the CIF(water)- or the CDF (NaCl)-procedure respectively (Setzer & Palecky, 2007). The maximum uptake of water of about 0.25 % b.m. is significantly smaller than for ordinary concrete indicating an extremely high resistance to both frost attacks as well as to harmful liquids. Due to the low w/(c + m)-ratio of only 0.19 (w/c-ratio 0.22 acc. to table 2), the heat treatment seems to be of minor influence on the porosity of the matrix.

4 MATERIAL-ADEQUATE LIMITS WITH REGARD TO STRENGTH AND DURABILITY

Based on the strength classification system of the European Standard EN 206, the design strength of UHPC is commonly characterized by a minimum characteristic strength of 150 MPa after 28 days when tested on cylinders d/h = 150/300 mm. As can be seen from Table 2, this minimum strength can be achieved even at a w/c-ratio of up to 0.30. This is due to the increase in strength gained by the physical optimization of the packing density of the fine particles of the matrix.

But as for ordinary concrete, the compressive strength does not comprehensively describe the durability properties. A general boundary value for the appropriate w/c-ratio assuring an optimum impermeability of the microstructure can be derived from the shrinkage behavior of the two compositions M2Q and B5Q consistently used in all research projects given in Table 1. The amount of drying shrinkage fairly corresponds to the amount of free water evaporated during hydration and thus to the w/c-ratio. No drying shrinkage means that the water added to the fresh concrete is fully bound in the cement hydrates and/or in the gel pores. Figure 5a (left) shows the shrinkage-related contraction of the UHPC mixture M2Q with a w/c-ratio of 0.22 when stored at 20°C/65% r.h., measured in a shrinkage rim with and without waterproof plastic sealing (Scheidt & Müller, 2012). In both cases, the same contraction could be measured. This leads to the conclusion that the total deformation was caused by autogenous shrinkage only. As no free water evaporated, capillary pores were not formed as can be seen from the pore size distribution of the M2Q mixture presented in Figure 4. The w/c-ratio of the UHPC mix B5Q in Figure 5b (right) was 0.26. In this case, the unsealed specimen showed a small but significant amount of drying shrinkage due to evaporation of unbound water and thus capillary pores arose weakening the microstructure..

Based on these and also on further research results gained in other projects of the Coordinated Research Program dealing with the durability of UHPC (see table 1), a boundary value for a w/c-ratio assuring both high strength and a virtually negligible permeability and thus optimum durability is proposed to be 0.22 if the concrete hardens under ambient conditions and is not heat treated If one will consider the silica fume to be part of the rective binder content one must not forget that, primarily due to the low water content, without an intensive heat treatment only a small share of silica fume will react with the cement components to form additional C-S-H phases. (Heinz, 2012). In this case, silica fume primarily acts as a physical filler improving the packing density and thus partly contributing to the higher strength of UHPC. But it is not a reliable factor with regard to durability.

If the hydration is accelerated and improved by heating the young concrete e.g. for 24 to 48 h at 80 to 90°C a maximum value of 0.26 may be acceptable to assure a sufficient impermeability

5 CONCLUSIONS

In a comprehensive Coordinated Research Project performed in Germany a wide range of open scientific and technical questions of UHPC were clarified. The research results provide a safe foundation to develop technical regulations for UHPC based on regionally available raw material. One of the outcomes was that an appropriate compressive strength of at least 150 MPa can be achieved even at a w/c-ratio of up to 0.30 if the

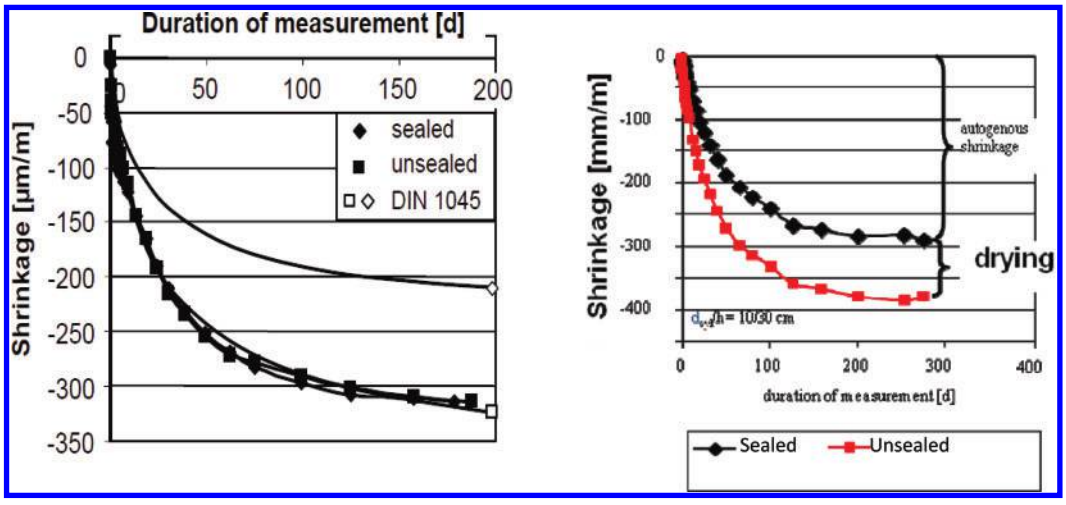

Figure 5. Shrinkage of UHPC with an w/c-ratio of 0.22 (left) and 0.26 (right) both tested at 20°C/65% r.h. sealed and unsealed respectively (Scheydt, Müller, 2012).

packing density of the matrix is sufficiently improved by means of calculated amounts of various micro-fine fillers of different fineness. This could be a sufficient definition for "Ultra-High Strength Concrete" aiming at a high design strength only. To make the microstructure of UHPC practically impermeable to harmful gases and liquids and thus to achieve its significantly improved resistance to concrete corrosion and its high ability to protect the steel reinforcement from corrosion as well UHPC must be practically free of capillary pores. Thus in addition to the optimized packing density the w/c ratio of UHPC hardening under ambient conditions shall be limited to no more than 0.22 if the kind of application calls for an improved durability ("Ultra-High Performance Concrete"). Without heat treatment, Silica fume should not be considered to be part of the binder. If the concrete is heat treated at temperatures of 80–90°C, a maximum w/c-ratio of 0.26 seems to be adequate.

Composite structures of steel and filigree UHPC-elements – Experimental and numerical investigations

Thomas Lechner & Oliver Fischer
Chair of Concrete and Masonry Structures, Technische Universität München, Germany

Günter Seidl
SSF Ingenieure AG, Berlin, Germany

ABSTRACT: Composite structures of steel and filigree concrete elements can be realized utilizing the innovative material Ultra-High Performance Concrete (UHPC). This high-tech construction material allows the production of extreme thin but high-strength elements. Thus, using UHPC the dimensions and the dead weight of composite structures with a given load-bearing capacity can be minimized. Shear connectors with high shear strength and a ductile load-deformation behavior are necessary to connect the UHPC-member with the structural steel. Continuous shear connectors with a clothoidal shape, the so-called modified chlothoid strip (MCL-strip), were chosen for this research. These shear connectors are arranged parallel to the concrete surface and have only a minimum of concrete cover on each side. A series of push-out tests has been conducted to figure out the load bearing capacity and the failure mechanisms for this configuration. Furthermore, preliminary numerical simulations showed good results in comparison with the physical tests.

1 INTRODUCTION

The outstanding mechanical properties of Ultra-High Performance Concrete (UHPC) offer the opportunity to create filigree structures. In composite structures the steel carries the tensile forces and the concrete is arranged in the compression zone. This kind of task sharing led to structural elements made of normal or high strength concrete with conventional bar reinforcement and high load bearing capacities. If the normal or high strength concrete is replaced by UHPC for which the compressive strength and the durability are considerably better, a significant reduction of the outer dimensions and the dead-weight of the composite structures are possible. A modern type of continuous shear connector, the composite dowel, is investigated to connect thin UHPC-members with structural steel. The composite dowel consists of a steel-strip with a special cut, which is referred to as steel dowel in the following, and the concrete that fills the spaces between the steel dowel and which is called concrete dowel. From the existing different shapes of composite dowels the so-called modified chlothoid strip (MCL-strip) was chosen for this research. MCL-strips offer a high shear strength and a very ductile load-deformation behavior (Berthellemy et al. 2011) which is necessary to fully take advantage of the high concrete strength.

The load-bearing capacity and also the failure mechanism of shear connectors that are positioned parallel to the concrete surface (e.g. in thin concrete beams or wall panels) with only a few centimeters of concrete cover differ from the usual application in plates. Whereas the concrete failure in plates is mainly governed by concrete pry-out, the failure in panels or thin beams is mostly caused by splitting failure due to the small concrete cover and splitting tensile forces resulting from the concentrated load introduction of the steel dowel. Furthermore, concrete shearing or a combination of both might occur, if the thickness of the wall-panel is very small.

Experimental investigations with push-out tests have been designed to check the ductility behavior and steel failure loads for small MCL-strips in thin UHPC-elements with and without conventional bar reinforcement. Additionally, a main objective of this research was to determine the concrete failure mechanisms that can occur when such filigree UHPC-member are used. During these test series the influence of the yield strength and the thickness of the MCL-strip as well as the thickness of the UHPC-element were studied.

Numerical studies of the push-out tests accompanied the experimental investigations. Preliminary analyses show good results compared to the experimental tests and help to understand the different influence factors and also to examine the complex stress states in the steel and concrete.

2 ULTRA-HIGH PERFORMANCE CONCRETE

Ultra-High Performance Concrete is an extremely dense concrete with a compressive strength of more than 150 MPa. The composition of UHPC differs

Table 1. Composition of UHPC.

Raw materials	Amount in kg/m^3
CEM I 52,5 R HS-NA	650
Silica Fume	177
Quartz I	325
Quartz II	131
Sand 0,125/0.5	354
Basalt 2/8	597
Superplasticizer	30.4
Steel fibers	2.5 [vol. %]
Water	158
w/c-ratio	0.24 [–]

strongly from normal or high strength concrete since the matrix porosity is minimized with the help of a very low w/c-ratio and a very dense packing of fine particles due to the use of different mineral additions like silica fume and quartz.

For this research the mixture B5Q with a maximum grain size of 8 mm and a regular fiber volume content of 2.5 vol. % was used. It was developed during the priority program 1182 of the German Research Foundation. The chosen steel fibers had a length h of 9 mm and a diameter d of 0.15 mm which gives an h/d-ratio of 60. A certain amount of steel fibers assures a ductile behavior and enhances the tensile as well as the bending strength of UHPC.

3 CONTINUOUS SHEAR CONNECTORS

In composite constructions headed studs are the predominant shear connectors until today. The design follows DIN EN 1994-1-1 (EC 4, 2012) for concretes up to C60/75. Experiments on the behavior of headed studs in high strength concrete showed that the failure was becoming more brittle when the concrete strength was increased and the diameter of the headed studs decreased (Jähring 2008). Hence, an application of small studs in filigree elements of high strength concrete leads to a very low ductility even if steel failure occurs.

Composite dowels have been used in normal strength concrete since the development of the perfobond strip in 1985 (Andrä 1985). During the last two decades research mainly focused on the optimization of the geometry of this shear connector in order to achieve an economically advantageous connector, a higher shear-bearing capacity and a better behavior under cyclic loading. A few shapes of composite dowels that have been tested lately are displayed in Figure 1.

The puzzle-strip shear connector (PZ) offers the main advantage that the geometry is symmetrical and therefore with one cut two shear connector strips can be manufactured (Gallwoszus et al. 2012). An improvement of the CL-shape (clothoid-shape) in terms of fatigue behavior led to the modified CL-shape (MCL-shape) which is used for this research.

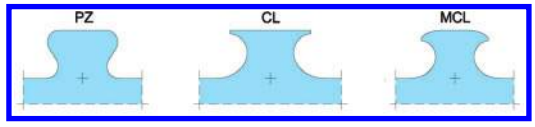

Figure 1. Shapes of composite dowels (Berthellemy et al. 2011).

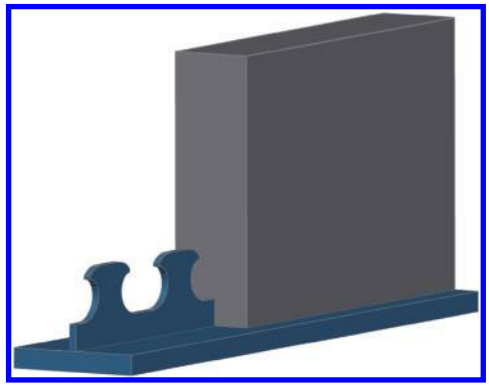

Figure 2. Application of MCL-strip in filigree UHPC-element.

Recent investigations with UHPC composite beams and puzzle-strips prove that composite dowels can carry high loads and show a good ductility in combination with UHPC (Gallwoszus et al. 2012). However, experiences concerning the structural behavior of MCL-strips in filigree UHPC-elements with a thickness of 4–6 cm, as displayed in Figure 2, are missing.

4 EXPERIMENTAL INVESTIGATIONS

4.1 *Test set-up*

To analyze the shear-carrying behavior of MCL-strips in thin UHPC a series of push-out tests (PO-tests) has been carried out. The geometries of the steel-element (left) and the push-out specimen (right) are shown in Figure 3. The right part of the UHPC-member is cut in the middle plane and because of this the steel-dowels and the screening made of polystyrene beneath the last dowel are visible.

The relatively small MCL-strips have a height of 40 mm and a longitudinal distance between the dowels of 100 mm. Deformation controlled loading allowed to measure the post-fracture behavior even if a brittle failure occurred. The slip δ between the shear connectors and UHPC-members was measured with two displacement transducers.

Testing of the specimen was usually after 28 days of concrete hardening. At this time the compression strength of the used UHPC was up to 183 MPa for a cube with 150 mm side length.

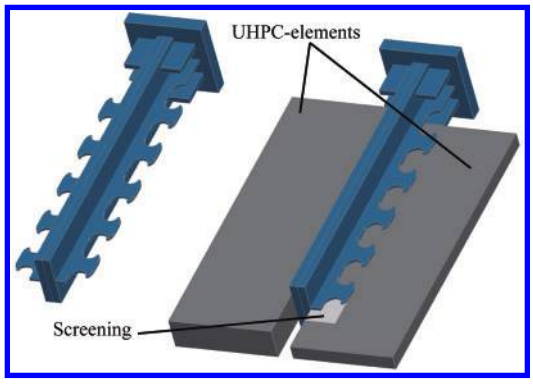

Figure 3. Steel-element (left) and push-out specimen with partly visible steel (right).

Table 2. Test program in extracts.

		Parameter			
Lable	No.	$f_{y,MCL}$ [MPa]	t_{MCL} [mm]	t_{UHPC} [mm]	stirrups/ bars
PO-1	2	438	5	60	w
PO-2	2	438	5	60	w/o
PO-3	2	438	5	50	w/o
PO-5	2	384	10	60	w
PO-6	2	384	10	60	w/o
PO-7	2	384	10	50	w/o
PO-8	2	384	10	40	w/o
PO-15	2	326	5	60	w/o

4.2 *Test program*

Especially parameters that influence the concrete failure mechanisms, e.g. splitting failure or shear failure, were investigated in the first test series, since these were expected to become the most critical for filigree UHPC-elements with only a few centimeters of concrete cover. Table 2 shows the test program in extracts and the most important research parameters.

Besides the yield strength of the MCL-strip ($f_{y,MCL}$), the thickness of the steel (t_{MCL}) and UHPC-Panel (t_{UHPC}) were studied. Furthermore, some specimens were equipped with stirrups (Ø 6 mm between each steel-dowel) and longitudinal bars (Ø 6 mm) and the others were plain fiber reinforced concrete without conventional bar reinforcement. For the specimens PO-1 to PO-8 the steel grade S355 was used, whereas the continuous shear connector of PO-15 was made of S235.

4.3 *Results*

Conclusions from the experimental push-out tests are that certain combinations of steel- and concrete-thickness guarantee a high load bearing capacity but a low ductility whereas with other combinations a good ductility with a reduced load-bearing capacity is reached.

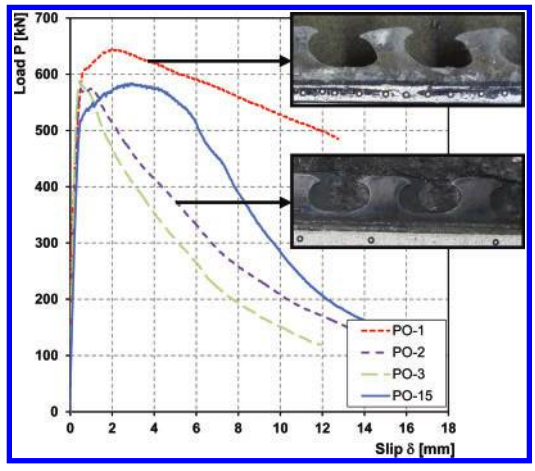

Figure 4. Load-slip diagram of push-out tests with $t_{MCL} = 5$ mm and exemplary deformation of steel after testing.

As the load-deformation behavior for the two specimens with the same test set-up is almost identical, it is possible to calculate mean load-slip-curves, which are presented in Figure 4.

The specimens with a 5 mm thick MCL-strip either showed a combined steel and concrete failure (PO-1 and PO-15) which was quite ductile or they failed more brittle by pure splitting (PO-2 and PO-3). A combined failure (first steel failure and later concrete-splitting) occurred for specimens with conventional bar reinforcement or if the steel grade S235 was used. In general, the thinner the UHPC-element and the higher the yield strength of the steel was, the more brittle was also the load-deformation behavior. The comparison between PO-1 and PO-2 shows that reinforcement can be used to increase the maximum load and ductility. However, it should be noted that reinforcement is not necessary to achieve a ductile behavior as can be found from PO-15. For this specimen the maximum load is only 10 % lower than for PO-1 and the reached ductility is nearly the same.

If steel failure occurs the steel-dowel deformation looks in principle as shown in the upper picture of Figure 4. It is obvious that the slip measured during the tests with a good ductility results at least partly from the steel deformation. In contrast the lower picture shows that the measured displacement for PO-2 results only from concrete failure since no steel deformation is visible.

Specimens with a steel thickness of 10 mm (see Fig. 5) reach a significant higher maximum load than specimens with only 5 mm MCL-strips. However, the main failure mechanism is a brittle splitting failure. Even the specimens PO-5 with reinforcement, for which a combined failure was observed, failed rather brittle in comparison to PO-1 because only small deformations of the steel dowel occurred before the concrete failed. Specimens without reinforcement (PO-6) behave clearly brittle. The difference

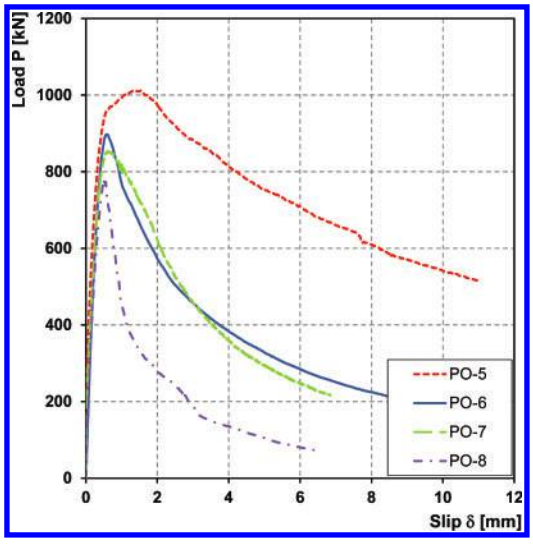

Figure 5. Load-slip diagram of PO-tests with $t_{MCL} = 10$ mm.

between UHPC with a thickness of 60 (PO-6) and 50 mm (PO-7) is small. For the push-out tests PO-8 with a UHPC-thickness of only 40 mm pure concrete shear failure occurred. This test resulted in the lowest ductility of all specimens.

In summary it was found that MCL-strips can be used as shear connectors in filigree UHPC-elements. Depending on the strength and thickness of the materials chosen it is possible to transfer very high shear forces up to 1250 kN/m (PO-5) or to achieve a composite element with a good load-deformation behavior and a load-bearing capacity of about 800 kN/m (PO-1).

5 NUMERICAL SIMULATIONS

5.1 *General overview*

A numerical model of the push-out test was developed using the finite element software ABAQUS and preliminary results are presented in the following paragraphs. Finite element calculations can be used as a tool to help understand the force flow and the three dimensional stress-state in the concrete dowel. Furthermore, it is possible to investigate the influence of different parameters that could not be tested in the lab if the results from the FE-program are verified by experimental data.

5.2 *Geometry and boundary conditions*

In all FE-models the twofold symmetry of the push-out test is taken into account so that only a quarter of the specimen has to be analyzed. Appropriate boundary conditions were applied at the symmetry planes for this reason. It was possible to reduce the number of elements and thus also the calculation time using a quarter-model as displayed in Figure 6.

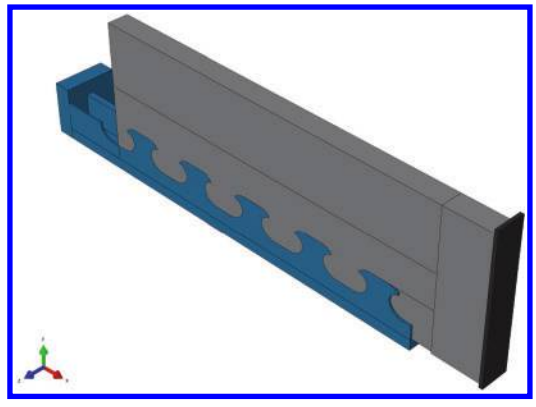

Figure 6. Geometry of quarter-model for numerical simulations.

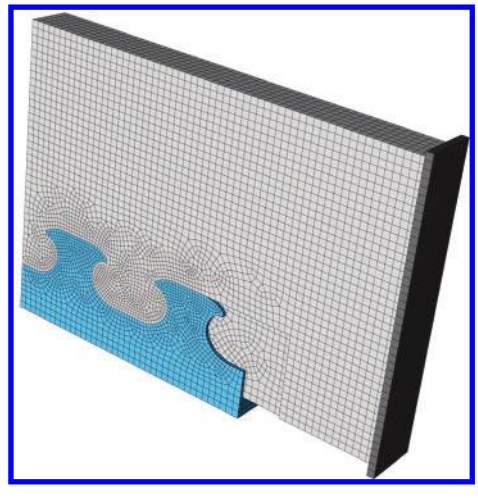

Figure 7. Geometry and mesh of OD-model with right dowel screened.

It seemed advantageous to further reduce the size of the FE-model since it is sufficient to know the behavior of one dowel for basic investigations. Thus, the quarter-model with four active steel dowels was reduced and simplified so that only one steel dowel transfers shear forces to the concrete. This model will be referred to as One-Dowel model (OD-model, see Fig. 7). In both models there is always one dowel which is screened so that there are five dowels visible in Figure 6 and two dowels in Figure 7. The connection between steel and concrete was established with the help of interactions for both models. Interaction properties were defined to allow compression and friction to be transferred between neighboring elements of steel and concrete whereas a separation occurs for tension.

5.3 *Materials*

All parts made of steel had the same material model. The stress-strain curve for the steel was found by direct tension tests. For the concrete the basic properties

such as compression and tension strength or Young's Modulus were taken from the material testing. FE-simulations were made with the assumption that the concrete behaves linear-elastic (e.g. for pure steel failure) and in addition simulations with consideration of nonlinear concrete behavior under tension and pressure (i.e. cracks and compression failure) were carried out. Material parameters that could not be determined in our lab were chosen as ABAQUS default values.

5.4 *Elements*

In general the steel and also the UHPC were modeled with continuum elements C3D8R. These are three-dimensional hexahedral (brick) elements with linear approximation of displacements, 8 nodes and reduced integration. The influence of mesh density was studied for the quarter-model and also for the OD-model and as a result a refined mesh was used along the steel dowel for all calculations. In Figure 7 the geometry and the mesh for a One-Dowel model is displayed.

5.5 *Solution procedures*

There are two methods for solving numerical problems with ABAQUS. The first one is an implicit method (ABAQUS/Standard) and the second one is an explicit method (ABAQUS/Explicit). Both techniques were tested and the results and efficiency of the calculations were compared. Finally, the explicit approach was chosen for the most simulations because this integration method very efficiently solves extremely discontinuous events, such as concrete cracking or contact. The explicit dynamic integration method is also known as the forward Euler or central difference algorithm. Especially advantageous is this solution technique because the elements use a lumped mass matrix which allows the program to calculate the nodal accelerations rather easily. However, since out-of-balance forces are propagated as stress waves between neighboring elements, oscillations may occur if the stability time limit of the central difference operator is not met. Therefore the time increments are calculated and chosen by ABAQUS to be sufficiently small. It is possible to identify if dynamic effects had impacts on the behavior of the model by checking the ratio between kinetic and internal energy.

5.6 *Results of the preliminary calculations*

The first calculations were designed to study the influence of some basic parameters such as the mesh density, the element formulation and interaction properties. Furthermore, the solution procedures of ABAQUS/Standard (imp) and ABAQUS/Explicit (exp) were compared to verify that the results are independent on the procedures used. All these parametric studies were done using the One-Dowel model. The results from the OD-model with different solution procedures are displayed exemplarily in Figure 8.

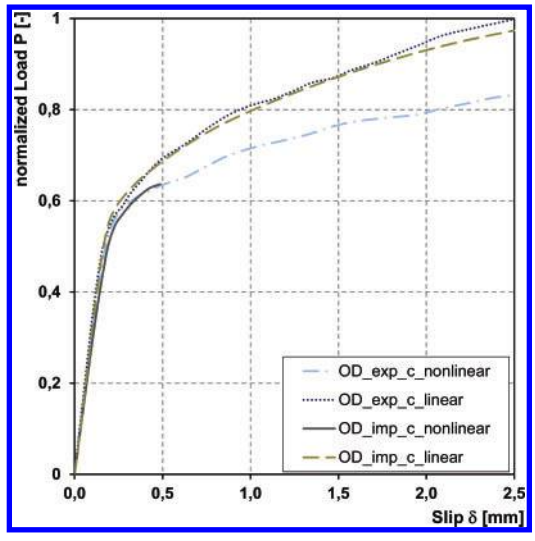

Figure 8. Normalized load-slip diagram of OD-results for different solution procedures.

In addition, for both solution procedures one FE-simulation was made with a linear-elastic concrete behavior (c_linear) and the other one with a nonlinear behavior under consideration of concrete failure effects (c_nonlinear). It could be confirmed that the load-slip curves for explicit and implicit procedures are quite similar if linear concrete behavior is assumed. However, the consideration of plasticity and damage effects for other concrete material model led to a premature termination of the ABAQUS/Standard calculation due to numerical problems. Still it is possible to see that the paths of both nonlinear curves are very close to each other. From these results it is possible to conclude that ABAQUS/Explicit can be used for static calculations if the kinetic energy is small compared to the internal energy, which was checked for all models.

In Figure 9 the first results of the numerical simulation with the quarter-model are compared to the load-slip curve of PO-15. The initial stiffness of the FE-model is quite close to the stiffness from the experiments. The small difference might be due to cohesion effects which were not considered in the numerical analyses. Nevertheless, the failure, which starts with yielding of the first dowel, appears at nearly the same load. After yielding of the first dowel a combined steel and concrete failure occurs in the quarter-model as well as in the real tests. The FE-curve is jagged because of sudden concrete failure. It might be possible to enhance this behavior with an even more refined mesh but an exact prediction or calculation of a combined failure is difficult since the concrete failure is strongly dependent on the distribution and orientation of steel fibers. Further numerical simulations have to verify these first results and it is intended to create models for sole concrete and sole steel failure.

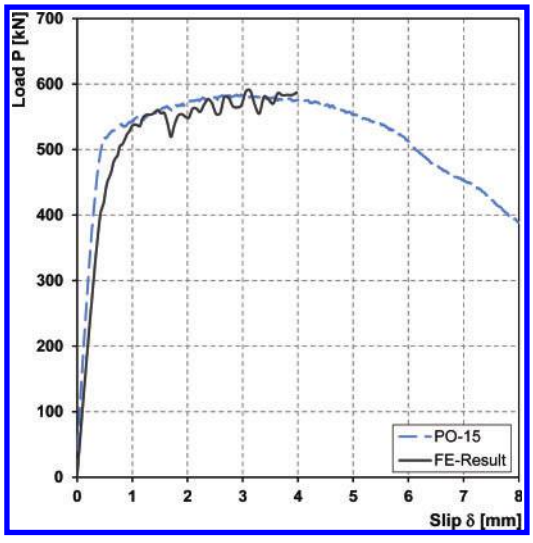

Figure 9. Comparison of real tests results with FE-simulation for quarter-model.

6 SUMMARY AND OUTLOOK

Steel and filigree Ultra-High Performance Concrete can be used to reduce the outer dimensions of composite structures because of the extraordinary load bearing capacity of UHPC under compression. A ductile behavior and a high bending strength of this innovative concrete are achieved by adding steel fibers. Push-out tests with miniaturized shear connectors and thin UHPC-members were conducted and it was found that a maximum shear force of 1250 kN/m could be transferred. However, the failure for PO-specimens with a 10 mm thick shear connector occurred rather brittle by concrete shearing or splitting. A ductile load-deformation behavior and shear forces up to 800 kN/m were achieved for specimens with a 5 mm thick MCL-strip. If the ratio of steel yield strength and tensile strength of the UHPC-panel is chosen well, there is no need for a conventional bar reinforcement since the ductility is sufficiently high.

Preliminary numerical simulations were realized to verify the parameters that influence such nonlinear Finite Element Analyses and to check how sensitive the results react if input parameters are changed. FE-analyses with the One-Dowel model were used to study the influence of different material models, mesh densities, interaction properties and solution procedures. The first simulations with the quartermodel showed that the load-slip curve fits well to the results from the experiments.

The conducted experimental and numerical researches confirm that continuous shear connectors offer an excellent method to transfer shear forces to filigree UHPC-elements. It is intended to carry out additional push-out tests and numerical simulations to verify the results obtained until now and to investigate the load-deformation behavior for specimens with changed parameters (e.g. fiber content, steel strength or thickness).

Optimization process for thin-walled high performance concrete sandwich panels

K. Hodicky, T. Hulin, J.W. Schmidt & H. Stang
Danmarks Tekniske Universitet, Kongens Lyngby, Denmark

ABSTRACT: A Nearly zero energy buildings are to become a requirement as part of the European energy policy. There are many ways of designing nearly zero energy buildings, but there is a lack of knowledge on optimization processes in the sense of structurally and thermally efficient design with an optimal economical solution. The present paper aims to provide multi-objective optimisation procedure addressed to structural precast thin-walled High Performance Concrete Sandwich Panels (HPCSP). The research aim is concerned with developing a tool that considers the cost of HPCSP materials along with the specifications of the design constrains and variables. The tool integrates the processes of HPCSP design, quantity take-off and cost estimation into a single system that would provide different costs for different HPCSP designs. The proposed multi-objective optimisation scheme results into derivation of basic design recommendations, regarding the material's strength and HPCSP's geometrical parameters that fulfil the objective of minimum cost.

1 INTRODUCTION

According to EU (2010) residential and commercial buildings are responsible for about 40% of the total energy consumption and CO2 emissions in Europe. Therefore, ambitious targets for energy consumption of new buildings are being implemented, and by the year 2020 nearly zero energy buildings will become a requirement in the European Union. In consequence of this the building sector has faced a growing demand for development and manufacturing of modular, light and strong building elements having a high degree of insulation, a long life time, a low CO2 emission, a low consumption of raw material, and an attractive surface with minimum maintenance. Moreover, architects and engineers will face the challenge of designing these new buildings with only limited extra cost compared to new buildings today. Thus finding the balance between structural performances and economically optimal solution in building design is needed. The thin-walled High Performance Concrete Sandwich Panels (HPCSPs) are an interesting option for future low or plus energy building constructions.

The main objective of the research summarized in this paper is to present a general optimization procedure of HPCSPs in the sense of structurally and thermally efficient design with an optimal economical solution. A quick and accurate systematic optimization approach is based on material cost function in HPCSP design. The research aims at developing a tool that considers the cost of HPCSP materials along with the specifications of the design constrains and variables. The tool integrates the processes of HPCSP design, quantity take-off and cost estimation; thus a change of any parameter or design constrain in one process would have its effect on the other processes. The suggested optimization procedure could set the ground for further research in predicting optimal design dimensions, mixture proportions and structural designs and systems.

2 BACKGROUND AND DESCRIPTION OF THIN-WALLED HPCSP

The thin-walled HPCSPs are structurally, thermally and environmentally efficient elements for exterior walls in multi-stories residential, commercial and warehouse buildings. The HPCSPs have several beneficial features such as high quality, proven durability, fast erection, and attractive architectural appearance (Einea et al. 1994). A typical HPCSP consists of two precast High Performance Concrete (HPC) plates and layer of insulation separates the two HPC plates. The connectors penetrate the insulation layer and join the two HPC plates.

The HPCSPs may be designed as: non-composite, partially composite or fully composite (Rizkalla et al. 2009). The degree of composite action depends on the nature of the connection between two HPC plates. The connections between the plates have been traditionally made by using bent reinforcing bars or various specially-designed steel or non-metallic connectors (Frankl et al. 2008). Increasing degree of composite action between two HPC plates using any type of these connectors increases the structural capacity of the HPCSP making it more efficient. However, increasing degree of composite action leads to significant thermal efficiency reduction of the panel through thermal bridges (Wade et al. 1998). Recently,

the sandwich panel design concept has leaped forward by introducing fiber reinforced polymer, or FRP, shear reinforcement grids allowing for benefits that make the use of these panels even more desirable than ever before as they have a relatively low thermal conductivity compared to steel (Soriano & Rizkalla, unpubl.). Furthermore, undesirable thermal bowing may occur due to different temperatures between interior and exterior surfaces. The thermal deflections in long HPCSPs can be significant and may cause cracking due to southern exposure especially at building corners. Recent research and development work indicates that load-bearing thin-walled HPCSPs are prone to structural cracking due to the combined effect of shrinkage and high temperature load. The stiffness of the connectors is proportional to the thermal deflection and thus has significant role in the design of HPCSPs. The connector design represents tradeoff between development of fully composite action for resisting lateral loads, and reduction of composite action to limit thermal deflections. Two main categories of connectors exist: non-shear connectors and shear connectors. Non-shear connectors are used in non-composite HPCSPs to resist insignificant shear forces. These connectors primarily resist the tensile forces required to maintain integrity of the panel by keeping two HPC plates attached. Shear connectors must provide adequate stiffness and strength to create significant composite behaviour in the panel and resist the ultimate and service loads of the panel. Bond between the insulation and HPC plates provides some shear transfer, but this bond diminishes over time and will not provide full strength over the life time of the panel (Salmon et al. 1997). The insulation layer mainly provides thermal efficiency of the panel. This efficiency depends on the thickness of the insulation material, amount and type of penetrations through this layer. The insulation should have low absorption to minimize the loss of water from the fresh concrete during manufacturing the panel.

Several authors have attempted to optimize concrete sandwich elements. Their work focused mostly on standard thick walled concrete sandwich element where they attempted to reach full composite action and fulfil the requirements for thermal properties and material reduction. The literature review revealed that there is a lack of optimization studies in the design of HPCSPs. This fact is probably caused due to designers protect their optimization strategies as a result of competition among other producers. For thin plates, the work of Papanicolaou & Triantafillou (2002) should be mentioned. They performed the procedure on minimum cost design of concrete sandwich panels made of HPC faces and PAC core for the case of in-plane and out-plane loading.

3 OBJECTIVE FUNCTION

The objective of HPCSP development is to establish the elements with the best structural and thermal performances and minimum cost. The present paper includes the material costs and ignores others such a transportation and assembly costs. In the case of HPCSPs the cost of mold is not taken into consideration as the cost is included in fix production plant investment costs. The cost function can be described as the sum of material cost functions that already include other costs, such as labour cost per unit volume. The total cost of HPCSP, C per unit volume is shown beneath:

$$C = \frac{t_b}{t} C_{HPC} + \frac{t_f}{t} C_{HPC} + \frac{t_{ins}}{t} C_{ins} + \rho_s \rho_{sh} C_{sh} \qquad (1)$$

where t_b, t_f and t_{ins} are the thicknesses of the back, front plate and insulation layer, respectively; t is total thickness of the HPCSP. C_{HPC} and C_{ins} stand for the cost per unit volume of the HPC layer and insulation layer, respectively, C_{sh} is the cost of shear connectors/reinforcement per unit weight. ρ_{sh} is shear connectors/reinforcement ratio along HPCSP height and length; ρ_s stands for shear connectors/reinforcement density (density of steel/FRP).

4 CONSTRAINTS

The producers and designers can set certain constraints to the design of the HPCSPs, e.g. maximum wall thickness, composition of the wall, choice of materials etc. Above all, material strength constrains should be applied to resist flexural, shear and face local buckling behaviour problem (ULS). The SLS constrain in sense of maximum horizontal/vertical deformations should be prescribed by national codes and standards or by structural requirements for openings. Furthermore, thermal resistance requirement has to be set as design constrain. The HPCSPs can be used as load carrying members as well as fill-in non-bearing members. Hence, the composite/non-composite action of HPCSPs or particular degree of composite action has to be constrained prior to its optimization procedure. In the case of composite and partially composite load carrying HPCSPs the type of shear connectors/reinforcement ratio may be selected. Finally, the set of boundary conditions must be specified taking into account subgrade friction, temperature gradients over the thickness and connections between HPCSPs.

5 MATERIAL COST FUNCTION

Conduct a study of the HPCSP's cost for the past two years, and establish change indicator for these costs. This requires cost data collection from current and previous projects and HPCSP materials suppliers. The collected data will be developed in a database to be used for cost references. Although the economic data of raw materials vary across regions and countries and are influenced by local costs of energy, labour and material resources, attention should not be focused on single cost values. The present cost study is used in

order to draw useful conclusions on relative influences of design variables and variations on the HPCSPs cost and consequently to propose the optimum design solution.

5.1 *HPC plates*

Rougeron et al. (1994) and Ozbay et al. (2001) performed the studies on multi-objective mix proportioning optimization of HPC. Their studies may be implemented to find the optimum mix design for special performance characteristics. These characteristics should take into account structural requirements and production induced constraints, such as:

1. HPC mix must be designed to minimize autogenous shrinkage
2. Provide adequate strength to design load
3. High early age strength (time- related production cycles)
4. Durability (life time up to 100 years)
5. Improved crack control (avoiding damage risks during lifting, transport and assembly)

The total unit cost of HPC plates is equal to the sum of material and labour costs for all stages of production. The HPC cost is generally expressed as a non-linear function of its compressive strength for high-strength concretes (Papanicolaou & Triantafillou 2002).

5.2 *Insulation layer*

Bond between the insulation layer and HPC plates provides in the case of thin walled HPCSPs significant shear transfer, the shear stiffness depending on the insulation thickness. Hansen (2012) performed the optimization of the insulation thickness based on the energy performance requirement in European Union for 2020. The thickness was constrained to a maximum of 400 mm. Optimizing without this constrain would result in unrealistic insulation thickness. The cost function for insulation layers can be described by linear function with an increasing cost/thickness gradient.

5.3 *Shear connecting system/Reinforcement*

The number and position of shear connectors and degree of reinforcement is dependent on required structural systems. The steel provides relatively cheap solution but it can negatively influence thermal efficiency of HPCSPs. An interesting option is using different kind of FRP materials which do not affect thermal efficiency. However, the cost may be relatively high in comparison with steel solution. The choice of material should be chosen prior to optimization procedure. Hence, the cost function of shear connecting system/reinforcement is equal to individual costs of used materials.

6 OPTIMIZATION PROCEDURE

The design of full scale HPCSP usually requires a building block approach to testing and design. This approach involves increasing the testing complexity and size from small scale tests to full scale tests. The chemical and material tests in the first stages are generally well defined tests. As we move from the laminate level to sub-element component and sub-structure level the tests become more application dependent. Neither standard test methods nor databases exist for these large scale tests. Thus there is a need to reduce cost and increase the efficiency of structural design and structural failure prediction by a global local testing and analysis approach. The global local approach involves supporting the global tests and analyses used in traditional design approaches by critical local sub-element tests. These tests are intended to be in between a material and sub-structure test. They are cheaper to manufacture and test, and most importantly they are fully representative of structural configurations undergoing the same manufacturing processes and may even be cut from the real structure (Petras 1998). The testing procedure is used for verification and validation of numerical modelling performed in Abaqus FE software. The model has to take into account that improving some parameters can negatively influence other parameters. For instance significant thickness reduction of HPC plate may cause structural cracking. The numerical model with estimated geometrical proportions is a starting point for its design and optimization procedure. Multi-objective optimization is essential in the real design of HPCSP structures. The single objective simulated annealing was developed by Kirkpatrick et al. (1983). It is considered as the basis of the multi-objective optimization (Paya et al. 2008). The single objective optimization gives an optimum set of design variables with respect to single objective, while the same variables give an unacceptable design for other objectives. A reasonable design solution could be reached by using a combination of more than single objective by using multi-objective design optimization (Konak et al. 2006). The optimal set procedure is preferred in the multi-objective design optimization. In the movement from one solution to another solution, there is always an amount of loses in one objective to achieve some gain in the other objective.

The multi-objective optimization method gives a set of solutions and the best solution measured regarding to all objective functions. Engineers always like to get only one value from the set of solutions. Therefore, solving multi-objective optimization problems can be conducted by both searching and decision making (Awad et al. 2010).

Optimization process is closely related with environmental aspects, material reduction and cost reduction at the same time. Finding the optimum solution involves extended iterative calculations and, thus, need of powerful calculation tools. Optimization of all design parameters at the same time would lead to high

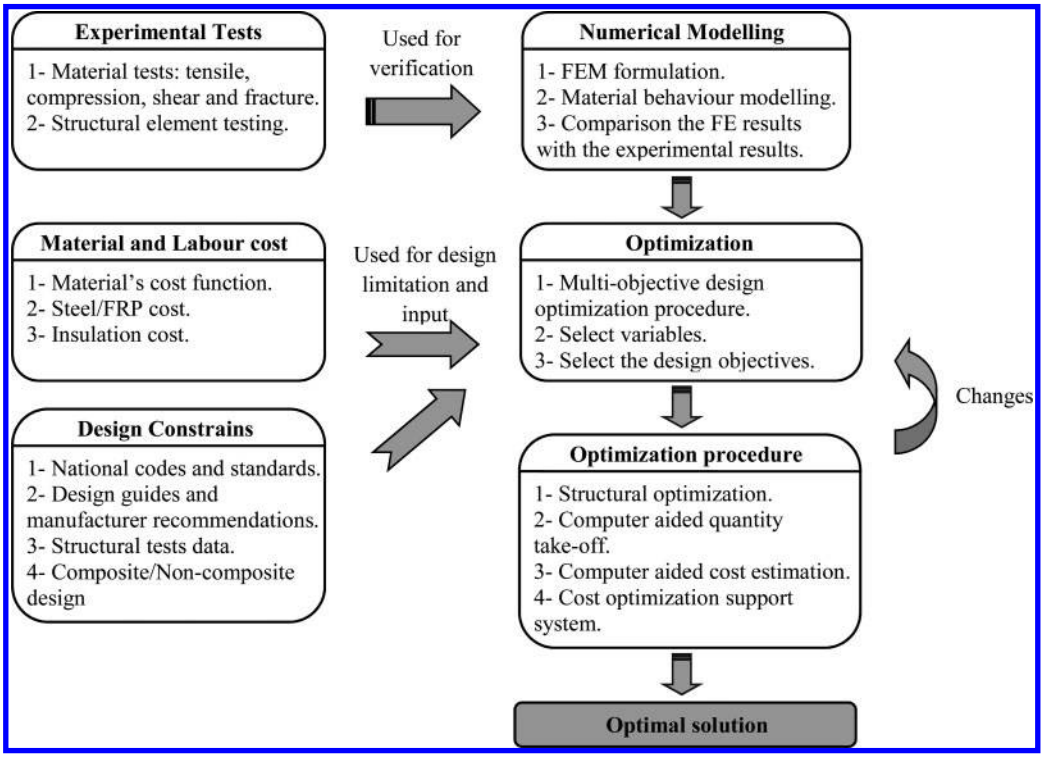

Figure 1. Proposed design optimization methodology of HPCSPs.

number of iteration and to very complicated ways to find the convergence in the sense of the best economically and structurally efficient solution. Therefore, all the design constrains should be carefully set before its optimization process. The proper selection of constrains leads to the faster convergence solution and significant reduction of computation time. Figure 1 shows the proposed design optimization methodology of HPCSPs.

Optimization procedure for which the cost is minimum and all bearing capacity values exceeded the respective design values is needed solution. Its optimization procedure is consists of the four phases as follows:

a) The structural FE software Abaqus is used to perform structural optimization. It automates the design process for accuracy and speed purposes.
b) The quantity take-off computer program. This program measures the total quantities of HPCSPs on basis of measured units trough given set of dimensions and number of elements.
c) Computer aided cost estimation. The program uses the cost data functions from material cost database and the quantity take off procedure to calculate total cost of materials.
d) Cost optimization support system. The three programs of HPCSP design, quantity take-off and cost estimating, are integrated into a single system that would provide different costs for different HPCSP designs.

The minimum cost is achieved when design performance demands exceed the panel's capacity. It is clear that thicknesses of the HPC plates have to be the lowest possible. The functionality of the cost optimization system requires additional testing in an iterative mode to ensure reliability prior to final implementation. As a result of successful testing, parametric cost studies are conducted to determine the relationship between the HPCSP's dimensions and its cost.

7 AUTHOR'S REMARKS

Two of the HPC layers of the HPCSP are made in the fabrication process and their performance is a result of how that process is carried out. Therefore, an assessment of the HPCSP concept must be closely linked to a clearly specified manufacturing process including the quality system in operation to control manufacturing and any inspection and checks to confirm quality. Qualification of the HPCSP technology would have to address these novel aspects carefully in relation to the intended use of the technology over the service life and foreseeable accident scenarios. Above all, the producers and designers attempting to develop and optimize novel thin-walled HPCSPs should keep in mind the subsequent steps:

1) HPC mix must be designed to minimize autogenous shrinkage and provide adequate strength to design load. (risk of cracking in HPCSPs)

2) The bond between layers of thermal insulation, HPC plates and insulation must be carefully evaluated.
3) Number and position of the shear connectors must be specified to eliminate the structural cracking of HPC plates.
4) Shear connectors must provide adequate strength and stiffness for optimum composite/non-composite action between the exterior HPC plates.
5) Shear connectors must be designed to eliminate thermal reduction of the panel through the thermal bridges.
6) No concrete penetrations through the insulation layer should exist.
7) The panels should be designed to withstand the applied loads.

8 CONCLUSION

The advantages of the HPCSPs make them attractive to be used in the building and construction industries recently. The challenge is to optimize the HPCSPs to achieve a high structural efficiency at minimum cost. Considering the limitations of the existing optimization methods, the authors proposed a design optimization procedure for HPCSPs. The multi-objective optimization method found to be the most suitable for HPCSPs allows considering different kind of variables and constraints. The method has several advantages but also some limitations. As costs of building materials vary across regions and countries and are influenced by local costs of energy, labour and material resources. The cost database requires regular updates and new inputs for different regions and countries. Nevertheless, further investigation is needed on the proposed methodology applied to different case studies to investigate its validity and limitations.

Quality control of UHPC by using non-destructive ultrasonic testing methods

Bernhard Middendorf
University Kassel, Department of Construction Materials and Building Chemistry, Germany

André Glaubitt
TU Dortmund University, Department of Building Materials, Germany

ABSTRACT: UHPC has a very dense micro structure, which possesses high compressive strength and deformation resistance. It has an excellent load capacity, as well as a high resistance to the penetration of liquids and gases. Such high performance building materials inevitably require efficient and reliable test and quality control procedures, because the high loaded cross sections are not suitable for destructive investigation. The non-destructive ultrasonic testing method is very well suited to the investigation of UHPC, because of its fine grained components and its homogeneous structure. Due to this, ultrasonic frequency ranges >1 MHz can be used. Using highly frequent probes results in a much higher resolution, and therefore a higher reliability of examinations and quality control of UHPC. On different UHPC samples it could be shown that the ultrasonic inspection can be used efficiently to detect structural changes within the framework of quality control or material research.

1 INTRODUCTION

The method of high-frequency ultrasonic testing of homogeneous materials such as steel or ceramics is nationally and internationally acknowledged and specified in various standards.

Meanwhile, ultrasonic testing has become standard in quality control of conventional concrete. However, testing frequencies (kHz-range) are by far lower than for example for steel or ceramics (MHz-range). Due to the small aggregate used for UHPC (1/5 to 1/20 of the grain diameter of normal concrete), it can be scanned with high frequencies in the MHz-range, this increases the resolution of the received signals which then causes a high reliability of the tests.

2 ULTRASONIC INSPECTION OF UHPC SAMPLES

In the following, results from measurements on UHPC samples-beams in bending, cylinders and laboratory prisms- are presented, in order to show the possibilities for a qualitative evaluation of UHPC by ultrasonic inspections which can be carried out quickly and non-destructively.

2.1 *Ultrasonic inspection for quality control of a UHPC beam in bending*

For these inspections, two differently composed and fabricated steel fiber reinforced UHPC beams in bending ($15 \times 15 \times 70\,cm^3$) were inspected with regards to their structural formation using non-destructive ultrasonic measurements. One of the beams in bending was made of a UHPC laboratory mixture (referred as LAB), the other was made of an industrially created mixture from a UHPC producing company, which will be referred as IND.

An ultrasonic procedure was used, in which transmitting and receiving probes are located at opposite positions of the scanned beam in bending. The beams in bending were fitted with a 2 cm spacing grid for the measurements and scanned with longitudinal wave probes (rated frequency 2.25 MHz). The measurement results were processed with the Hilbert transformation (Poularikas 1999) and generating the envelopes. The determination of the run time of the ultrasonic impulses is then done using the difference of the maximal peaks of the sending and receiving impulse under the consideration of the preliminary leadtimes of the probes. From the run time and the known thickness of the beams in bending, the longitudinal wave velocity was calculated and graphed (Fig. 1 and 2). Additionally, the beams in bending were scanned over their entire length (0.7 m) with the above mentioned probes. Based on the broad frequency bandwidth of the selected probes, receiving impulses up to 1 MHz with a significant onset could be detected on a measurement of this size.

A significantly lower longitudinal wave velocity v_p (by 4600 m/s) can be seen in the results from the LAB beam in bending in the margin than in the rest of the beam (4800–4900 m/s) (Fig. 1). These differences are

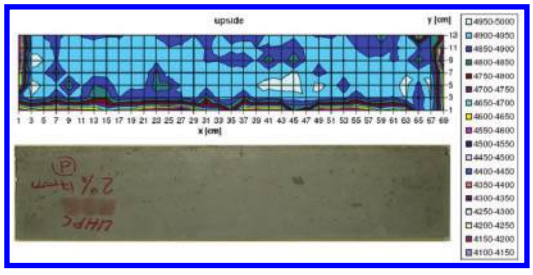

Figure 1. Longitudinal wave velocity v_p [m/s]; UHPC beam in bending LAB.

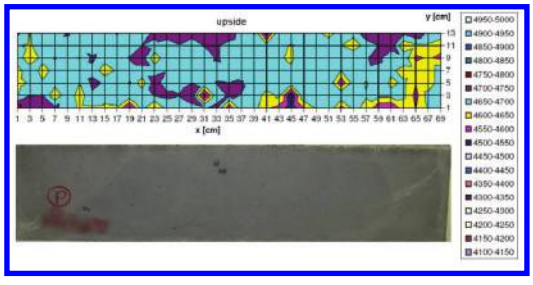

Figure 2. Longitudinal wave velocity v_p [m/s]; UHPC beam in bending IND.

Table 1. Wave velocity v_p and standard deviation of the inspected beams in bending LAB and IND.

Longitudinal wave velocity		LAB	IND
Median	m/s	4847	4668
Standard Deviation	m/s	130	42

a result of the structural inhomogeneities of UHPC, which can be traced back to non-uniform compaction of the beam in bending. Geometry effects, which sometimes can influence the measured ultrasonic signal, are not the cause of the deviations in the wave velocity in the margin, because then similar measurements would have to have been made on the IND beam in bending (Fig. 2).

The IND beam in bending showed a more homogenous structure than the LAB beam in bending with respect to the wave velocity (Fig. 2), though fluctuations of v_p were also present.

Looking at the obtained measurements (Table 1), one can clearly see based on the given standard deviation, that the LAB beam in bending shows a significantly higher structural inhomogeneity (see also Fig. 1 and Fig. 2).

Due to the high inhomogeneity of the LAB beam's UHPC, it was sawn at different positions, in order to inspect the apparent structure. Figures 3 and 4 show regions from the center of the beam (vertical section at $l = 35$ cm). The partial range in figure 3 shows the middle region with a comparably low porosity. In figure 4 a higher porosity can be detected, here the lower corner region of the beam is displayed at $l = 35$ cm.

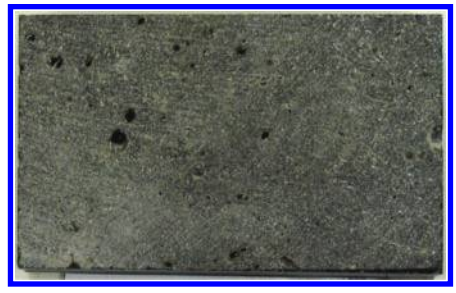

Figure 3. sample middle region (beam in bending LAB at $l = 35$ cm); picture width approx. 4 cm.

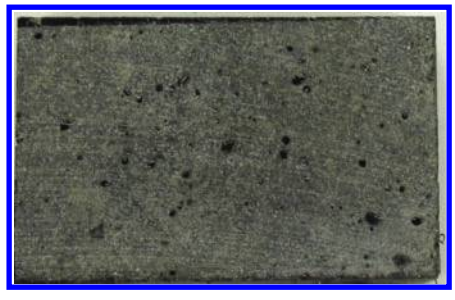

Figure 4. sample corner region (beam in bending LAB at $l = 35$ cm); picture width approx. 4 cm.

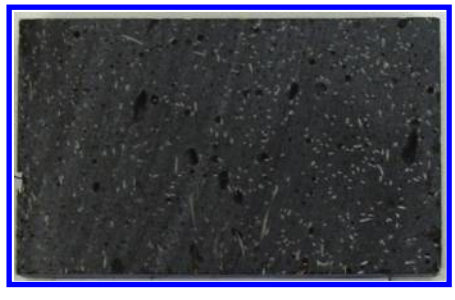

Figure 5. sample middle region (beam in bending LAB at $l = 0$ cm to 3 cm); picture width approx. 4 cm.

Observing the ultrasonic run time at this vertical section ($l = 35$ cm) in figure 1, it can be recognized that the deviation of the running time in the lower region is not as high as in the other boundary areas of the beam. Therefore, samples from the regions $l = 0$ to 3 cm and $l = 67$ to 70 cm were taken, which show significantly higher deviations in the ultrasonic run time. These samples are presented in figures 5 and 6 and hold a considerably higher amount of larger pores.

2.2 *Ultrasonic Inspection for Quality Control in Materials Research on Two Constricted Cylinders*

The ultrasonic run time measurement is well suited for, among other things, determining the dynamic elastic constants E_{dyn} and μ_{dyn} (see Eq. (1) and (2)). The elastic constants determined in this manner can be

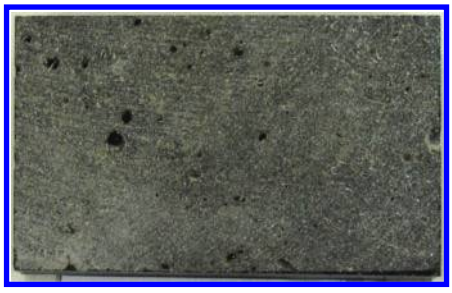

Figure 6. sample middle region (beam in bending LAB at l = 67 cm to 70 cm); picture width approx. 4 cm.

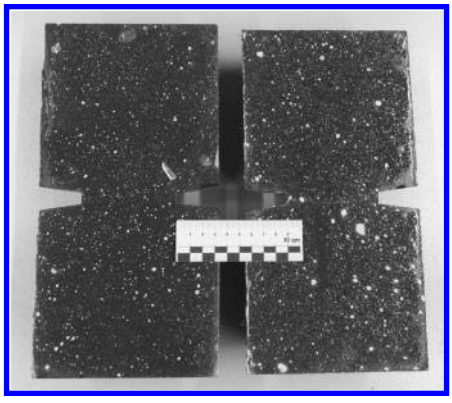

Figure 7. Photographic documentation of the structure of the inspected cylinders; left: without fibers, right: with fibers. The light specks in the UHPC are pores.

used both in quality assurance as well as in materials research and development, in order to, for example, show chronological (strength development) or local (workmanship) material changes (Facaoaru & Stamate 1968, Hennike & Leers 1965, Jones 1950, Kaplan 1959, Manns 1969, Morscichin 1969, Neisecke 1974, Rentsch & Krompholz 1963). By determining v_p, v_s and the bulk density, it is also possible to calculate the dynamic elastic constants E_{dyn} and μ_{dyn} for a material (Glaubitt et al. 2003, Lacouture et al. 2003). Therefore, not only the wave velocity, but also the physical properties of a material are taken into account for an evaluation (Beutel et al. 2008, Glaubitt et al. 2007).

Two constricted UHPC cylinders (Ø 15, 8, 15 cm, l approx. 30 cm, CYL1 und CYL2) were available for inspection (Fig. 7). Their recipes were identical, but one probe was additionally reinforced with 1.5 mass % steel fibers (lf/df = 9 mm / 0.15 mm). The cylinders were scanned with longitudinal wave probes (rated frequency 2.25 MHz) and transversal wave probe arrays (rated frequency 55 kHz) and the corresponding wave velocity v_p und v_s was calculated using the run times.

In the cylinder without steel fiber reinforcement (CYL1) $v_p = 4890$ m/s ($\sigma = 4$ m/s) and transversal wave velocity $v_s = 3183$ m/s ($\sigma = 2$ m/s) were measured. By adding steel fibers, the overall velocity of the longitudinal wave impulses in the cylinder with steel fibers should have increased, due to the higher wave velocity in steel ($v_p = 5900$ m/s, $v_s = 3230$ m/s) (Washer et al. 2003, Washer et al. 2004). However, this is not the case in the inspected cylinder (CYL2) ($v_p = 4870$ m/s ($\sigma = 26$ m/s) and $v_s = 3193$ m/s ($\sigma = 3$ m/s)). Because the median of v_p for the steel reinforced cylinder lies below the median of v_p for the non-reinforced cylinder, this indicates different material properties of the concrete used.

Table 2. Wave velocity and material figures, cylinder 1 without fibers and cylinder 2 with fibers.

Velocity and Material Figures		CYL1	CYL2
Longitudinal wave velocity	m/s	4890	4668
Transversal wave velocity	m/s	3183	3193
Bulk density	g/cm^3	2.26	2.31
Dyn. modulus of elasticity	N/mm^2	51,860	52,900
Dyn. Poisson's ratio	-	0.13	0.12

For the purpose of ocular assessment of the inspected UHPCs, the cylinders were sawed through along the ultrasonic measurement range (Fig. 7). The cylinder with steel fibers shows a significantly higher porosity – mostly air and compaction pores – than the non-reinforced cylinder. A direct comparison of the mechanical properties with respect to the influence of the steel fibers is not possible at this point, because the cylinders, despite having the same composition, could not be compared on the same terms.

$$v_s = \sqrt{\frac{E}{\rho} \cdot \frac{1}{2(1+\mu)}} \tag{1}$$

$$v_p = \sqrt{\frac{E}{\rho} \cdot \frac{(1-\mu)}{(1+\mu)(1-2\mu)}} \tag{2}$$

The material figures calculated in this manner for both cylinders are presented in Table 2.

The density of cylinder 2 is, due to the steel fibers (1.5 mass %) – despite a higher porosity (see Fig. 7) – larger than in cylinder 1. As expected, the dynamic modulus of elasticity of the steel fiber reinforced cylinder is higher than of the non-reinforced cylinder. Based on the porosity, CYL2 has a lower dynamic Poisson's ratio than CYL1. The dynamic elastic constants are in the range of statically determined values for UHPC ($E \approx 50{,}000$ N/mm^2, $\mu \approx 0.16$–0.24 (Fehling et al. 2005). Dynamically determined constants are larger than the statically determined constants (secant model) due to determining them in the purely elastic state of stress of the material (tangents in the coordinate origin). Therefore, E_{dyn} and μ_{dyn} of these two cylinders are rated as being low.

2.3 *Ultrasonic Inspection for Determination of Steel fiber Distribution*

Another possibility to use high frequency ultrasonic measurements on UHPC test samples, is

Figure 8. Photographic documentation of the inspected part of the steel fiber reinforced UHPC prism with scan areas for ultrasonic measurements.

an approximated determination of the fiber distribution in the UHPC matrix. For this, a part of a steel reinforced prism (see Fig. 8) with the dimensions $4.0 \times 4.0 \times 5.7\,cm^3$ was ultrasonically scanned laminary in different directions. This UHPC prism was reinforced with 1.5 mass % steel fibers (lf/df = 13.0 mm/0.19 mm). The same ultrasonic procedure as for the beams in bending was used. Therefore transmitting and receiving probes are located at opposite positions of the scanned part of the prism. The opposite sites (here areas of $4.0 \times 4.0\,cm^2$) were fitted with a 1 cm spacing grid for the measurements and scanned with longitudinal wave probes (rated frequency 2.25 MHz).

The measurements were taken in the longitudinal direction of the prism (l = 5.7 cm) and in lateral direction (l = 4.0 cm), from one side to another as well as from the bottom to the top side. The calculated longitudinal wave velocity was graphed (Fig. 9) and compared to a Microtomography (μ-CT) picture of the prism. In the μ-CT picture the cement matrix was removed by using image analyzing software so the only visible parts are the steel fibers. The here presented scan was taken of 2000 measurements with a voxel resolution of 32.4 μ m.

The first direction of the ultrasonic measurements was parallel to the direct-axis of the prism. In figure 9 it is obvious that the ultrasonic velocities determined correspond to the density of the steel fibers. In the boundary regions higher velocities than in the core of the prism were measured (see upper part of figure 9). This can be explained by the higher content of steel fibers in the boundary regions which can also be seen in the μ-CT picture.

Furthermore, the prism was scanned along the cross axis. Figure 10 graphically presents the ultrasonic scan from the formed side wall to the opposite formed side wall (cross axis 1). Here also, the higher ultrasonic

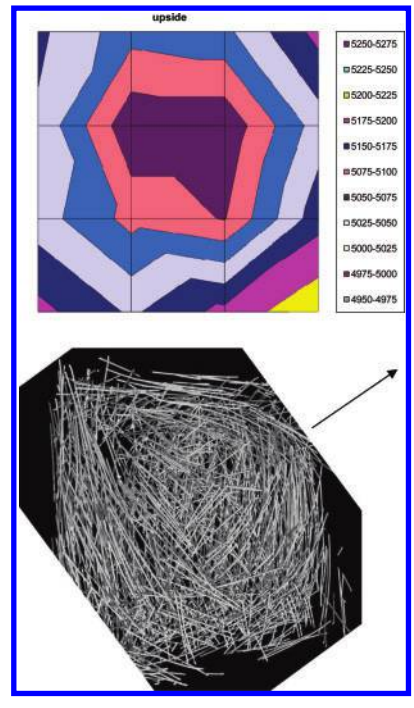

Figure 9. top: Longitudinal wave velocity v_p [m/s] of prism (direct-axis); bottom: μ-CT picture of the steel fibers of prism (arrow: measuring direction).

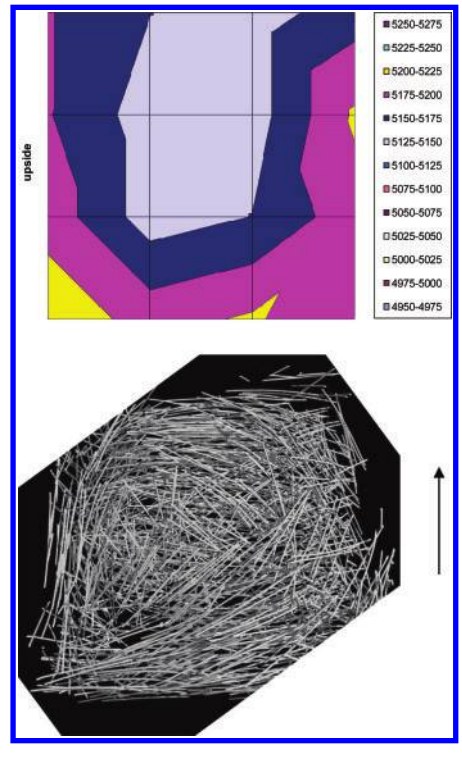

Figure 10. top: Longitudinal wave velocity v_p [m/s] of prism (cross axis 1); bottom: μ-CT picture of the steel fibers of prism (arrow: measuring direction).

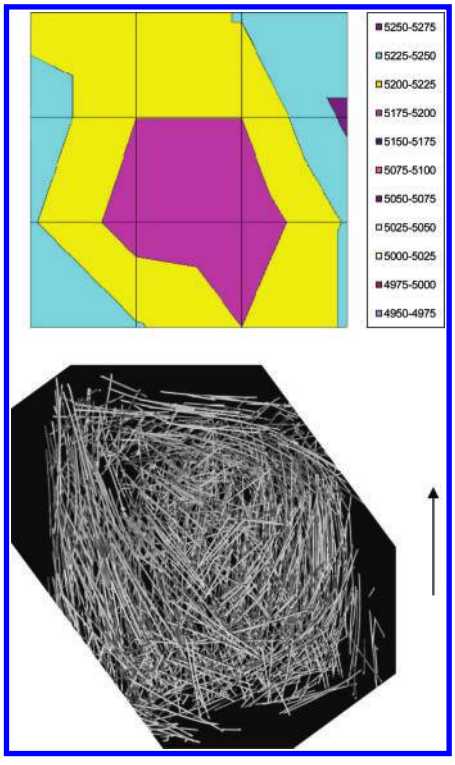

Figure 11. top: Longitudinal wave velocity v_p [m/s] of prism (cross axis 2); bottom: μ-CT picture of the steel fibers of prism (arrow: measuring direction).

velocities in the boundaries due to the higher content of steel fibers become significantly obvious.

A further ultrasonic scan was conducted along the axis from the formed bottom side to the top side (cross axis 2). These results can also be seen in figure 11. Again, the higher fiber content in the boundary regions reflects in higher sonic velocities. These are higher (Ø $v_p = 5217$ m/s) than those of the cross axis 1 scan (Ø $v_p = 5171$ m/s). This can be traced back to the alignment of the steel fibers, which increasingly adjust in the direction of the sound propagation (cf. figure 11 below, right and left area). This is being confirmed by the fact that the sonic velocities in the direction of the longitudinal axis are lower (Ø $v_p = 5135$ m/s), because there are less fibers existing parallel to the sound propagation.

In figure 12 a 2D scan taken by μ-CT is presented. It could be easily seen that the fibers are orientated parallel the sectional plane.

3 ASSESSING THE INSPECTIONS

The results presented here show, on the one hand, that the quality of UHPCs can be quantified using ultrasonic measurements. On the other hand, the results show the need for a qualitative assessment of UHPC samples using quickly executable, non-destructive

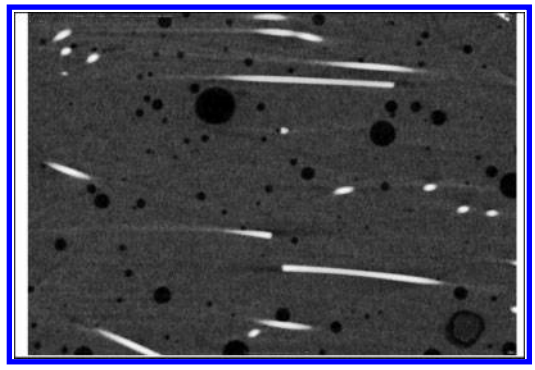

Figure 12. μ-CT picture of a part of prism (voxel resolution 55 μm), picture width approx. 15 mm.

ultrasonic measurements. It is apparent, that quality assurance of UHPC components is absolutely necessary. Both in material research of UHPC as well as in the later production of prefabricated UHPC parts, this quality assurance using ultrasonic inspection can be performed, but in its current state, it does not have the standard to be the only method of inspection for UHPC.

Statistical model for compressive strength prediction of high-performance concrete

A. Kapelko
Wrocĺaw University of Technology, Institute of Building Engineering, Wrocław, Poland

M. Kapelko
Wrocław University of Economics, Institute of Applied Mathematics, Department of Logistics, Wrocław, Poland

R. Kapelko
Wrocław University of Technology, Institute of Mathematics and Computer Science, Wrocław, Poland

ABSTRACT: Compressive strength is one of the most important mechanical properties of hardened concrete. In this paper we address the issue of compressive strength for high-performance concrete. High-performance concrete is a specially designed concrete with one or more characteristics, which are enhanced through the selection of component materials and mix proportions. This study proposes a statistical model to predict the compressive strength of high-performance concrete using the experimental data which control for the type of cement applied. The compressive strength of concrete is modelled as a function of water-to-cement ratio (W/C), compressive strength of cement, quantity of superplasticizer, grit basalt, silica fume and sand, and age of concrete. The coefficients of models are found with the use of Mathematica 5.0 program. The obtained explicit formulas are of great importance in building practice.

1 INTRODUCTION

High-performance concrete can be defined as a low water/cement concrete which receives an adequate water curing (Aïtcin, 2003). High-performance concrete was initially known as high-strength concrete to emphasize its high strength characteristic. Lately, however, it was coined as high-performance concrete because it was found to be much more than just stronger (Aïtcin, 2003, 2000). Compared to ordinary concrete, high-performance concrete has extraordinary rheological properties, especially its superworkability and flowability, which makes it superior to other concrete mixes (Zain et al., 1999). Other desirable properties of high performance concrete include: a high modulus of elasticity, high density, low permeability and resistance to some forms of attack (Neville & Aïtcin, 1998). The European Standard EN 206-1:2000 classifies the high-performance concrete as concrete with compressive strength greater than 60 MPa at 28 days. American Concrete Institute (ACI) defines the high-performance concrete as a specially designed concrete with one or more characteristics which are enhanced through the selection of component materials and mix proportions. These properties include high workability, very-high early compressive strength, high toughness and high durability to exposure conditions. High-performance concrete can be made with cement alone as a binder or any combination of cement and mineral components, such as blast furnace slag, fly ash, silica fume, metakaolin, rice husk ash, and fillers, such as limestone powder (Aïtcin, 2003).

High-performance concrete is nowadays more frequently applied in the building practice and it has become an active area of research. A number of studies analyzed its development, properties, compressive and tensile strength, durability and other characteristics. Despite the growing interest in high-performance concrete in research and practice, additional information is still needed in order to exploit in full its unique characteristics.

In particular, modelling the compressive strength of high-performance concrete is an important issue in the building practice as strength is a primary factor in selecting a concrete for a particular application. The compressive strength is regarded as one of the most important properties in concrete mixture design and quality control. In the case of high-performance concrete the development of compressive strength is especially complex in nature, which makes the prediction difficult to undertake. The compressive strength of high performance concrete has been modelled in some research papers. Some recent studies in the subject indicated that compressive strength of high-performance concrete is determined not only by the water-to-cement ratio (W/C), but is also influenced by the content of other concrete ingredients (Kapelko et al. 2010; Zain & Abd, 2009; Popovics & Ujhelyi, 2008). With many different factors used to explain

compressive strength of high performance concrete, however, no previous study has accounted for the impact of compressive strength of cement. In addition, most of attempts for compressive strength prediction are undertaken using neural networks.

Against this background, this paper extends previous research that was predicting the compressive strength of high performance concrete, in particular we extend the work of Kapelko et al. (2010). Our objective is to establish a statistical model for the prediction of compressive strength of high-performance concrete based on the experimental data. To attain this aim, the compressive strength of cement, W/C ratio, age and some variables which represent components' structure of concrete mixtures are included in the modified multiple lineal regressions. In order to disentangle the impact of type of cement used in concrete mixtures, our regressions control for this variable.

The rest of this paper is organized as follows. The factors explaining compressive strength of concrete are presented in the next section. This is followed by the description of experimental procedure. The next section summarizes and discusses the results of compressive strength tests and statistical modelling. Final section offers concluding comments and some potential future extension of present work.

2 FACTORS AFFECTING COMPRESSIVE STRENGTH OF HIGH PERFORMANCE CONCRETE

Abrams' exponential mathematical model is an equation relating compressive strength of concrete with water-to-cement ratio at a particular age of concrete testing (Abrams, 1918). The generally accepted rule is that an increase in the W/C decreases the concrete strength, whereas a decrease in the W/C ratio increases the strength. The implication, therefore, is that the compressive strengths of various concretes are identical as long as their W/C ratios remain the same, regardless of other variables.

In subsequent studies the Abrams' model was generalized for any age of concrete and applied for the prediction of concrete strength. In particular, De Tango (2000) confirms the validity of such models to high-performance concrete with silica fume. Popovics & Ujhelyi (2008) in the context of ordinary concrete propose to improve this formula with the second independent variable, such as the cement content or water content or paste content, etc. Following, the models were extended to include more variables, analyzed by multiple regression or neural networks (Kapelko et al. 2010; Peng et al., 2010; Zain & Abd, 2009; Öztas et al., 2006; Ni & Wang, 2000; Yeh, 1998).

The basic concept of model proposed in this paper is to produce a reliable relationship between compressive strength of high performance concrete, and compressive strength of cement, W/C ratio, age and some variables which define concrete's components. To differentiate from previous studies, we include compressive strength of cement as explanatory variable and we use a modified multiple lineal regression, where age is modelled as a natural logarithm. Some authors found that compressive strength of concrete versus time increases very slowly and it is well represented by a logarithmic function of time (Kapelko, 2004; Kearsley & Wainwright, 2001; Yeh, 1998). In particular, Kapelko (2004) analyzes the relationship between compressive strength and hardening time of high-performance concrete observed during a very long time (from 3 days until 5 years) and he founds that logarithmic curves are a good approximation of this relation (correlation coefficient ranging from 0.92 to 0.98).

The explanatory factors (independent variables) that we use in this study to predict the compressive strength of high performance concrete (dependent variable) are important from the point of view of technology and previous research. The variables which form a part of our model are following:

1. Water/Cement ratio (W/C)
2. Quantity of silica fume (SF)
3. Quantity of superplasticizer (PC)
4. Quantity of grit basalt 8–16 mm (CA_1)
5. Quantity of grit basalt 5–8 mm (CA_2)
6. Quantity of grit basalt 2–5 mm (CA_3)
7. Quantity of sand 0–2 mm (SA)
8. Age of concrete (t)
9. Compressive strength of cement (RC)

Therefore, the general formula for the model can be written as below:

$$f_c = [a \cdot \ln(t) + b] \cdot (c \cdot \frac{W}{C} + d \cdot PC + e \cdot SF + f \cdot CA_1 + g \cdot CA_2 + h \cdot CA_3 + i \cdot SA + j \cdot RC) \quad (1)$$

where: a, b, c, d, e, f, g, h, i and j are coefficients of explanatory variables.

3 EXPERIMENTAL PROCEDURE

3.1 *Materials and mixture proportions*

Following materials were applied in the experimental work: locally available coarse aggregate, sand, two types of cement: either CEM I 52.5R or CEM III/A 42.5N, silica fume, and polycarboxylate ether based superplasticizer. Tap water was used as mixing water. Superplasticizer was compatible with the cement utilized. Coarse aggregate and sand were experimentally combined in order to obtain an optimum aggregate composition, characterized by maximum compactness and minimum amount of water adsorbed by the aggregate (Kapelko & Kapelko, 2005). Twenty mixtures were cast from the aforementioned components: ten with cement CEM I 52.5R (indicated as concretes C1-C10) and ten with the application of cement CEM III/A 42.5N (concretes C11-C20). The consistency of concrete mixtures according to the slump test (Abrams' cone) was within the range of 30 and 220 mm.

Table 1. Content of concrete mixtures' components (per m^3).

Component	Content, in kg/m^3
CEM I 52.5R (C) or CEM III/A 42.5N (C)	450– 550
Tap water (W)	143–162
Coarse aggregate:	
Grit basalt 8–16 mm (CA_1)	535–570
Grit basalt 5–8 mm (CA_2)	468–652
Grit basalt 2–5 mm (CA_3)	201–659
Sand 0–2 mm (SA)	550–627
Silica fume (SF)	19.9–41.2
Superplasticizer (PC)	4.1–22.0

Table 2. Weight compositions of concrete mixtures.

Concrete mixture code	Cement (C)	Water (W)	Silica fume (SF)	Super-plasticizer (PC)
C1, C11	0.90	0.36	0.000	0.009
C2, C12	1.00	0.32	0.000	0.025

3.2 *Strength testing*

The compressive strength of cement was determined after 2, 7, 28, 56 and 365 days of curing following the European standard EN 196-1:2005.

The compressive strength of high-performance concrete was determined from 150 mm cube specimens

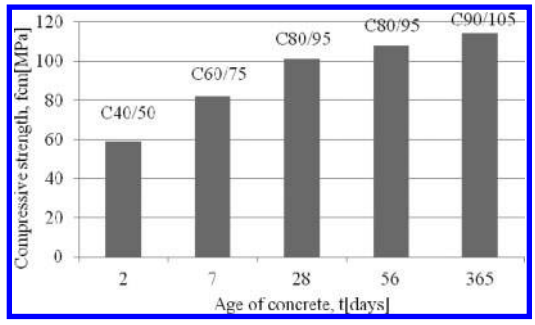

Figure 1. Compressive strength and classes of concrete C2.

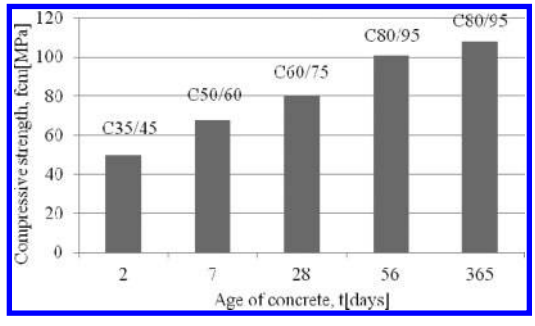

Figure 2. Compressive strength and classes of concrete C3.

and testing was performed after 2, 7, 28, 56 and 365 days of curing. For each of twenty concrete mixtures and time of testing, six specimens were made (hence, in total 600 specimens were prepared). They were cured in a climatic room at a constant temperature of 20° and a relative air humidity of 95% up to the due day of testing.

4 RESULTS AND DISCUSSION

The tests of compressive strength show seven different classes of compressive strength after 2 days of hardening according to the European Standard EN 206-1:2000: C25/30, C30/37, C35/45, C40/50, C45/55, C50/60 and C55/67 and six different classes of concretes after 28 days of hardening: C60/75, C70/85, C80/90, C8/95, C90/105 and C100/115.

The compressive strength results for some examples of concretes (C2, C3, C12 and C13) are illustrated on Figures 1–4.

The figures show that in the initial period of hardening of concretes the compressive strength is higher for concretes prepared with CEM I 52.5R (concretes C2 and C3) as compared to concretes with CEM III/A 42.5N (C12 and C13). On the contrary, for older age of concrete, compressive strength is higher for mixtures prepared with CEM III/A 42.5N. The explanation for this finding is directly connected with the differences in heat releases between these cements (heat release kinetics).

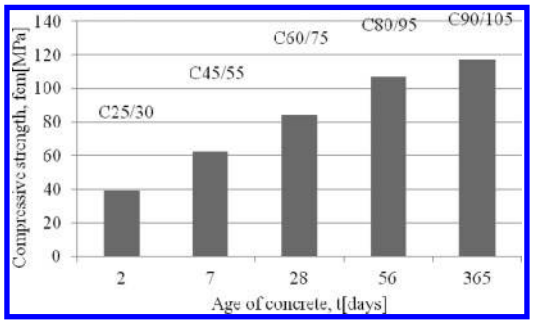

Figure 3. Compressive strength and classes of concrete C12.

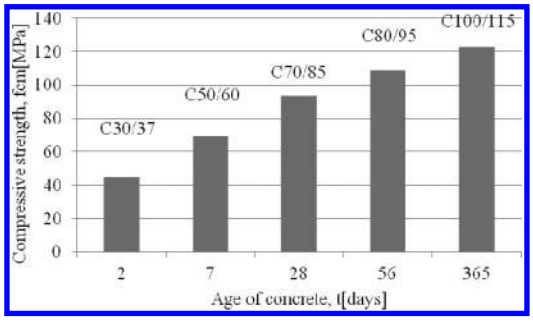

Figure 4. Compressive strength and classes of concrete C13.

Regression models of compressive strength on age, W/C, concrete mixtures' components and compressive strength of cement were developed from the results of tests. These analyses were conducted using the Mathematica 5.0 program. The equations below show the relationship between the compressive strength and all independent variables for the entire sample of concretes and separately for concretes casted with particular types of cements:

a) For all concretes:

$$f_c = [0.42 \cdot \ln(t) + 5.33] \cdot (-21.01 \cdot \frac{W}{C} - 0.18 \cdot PC + 0.05 \cdot SF - 0.80 \cdot CA_1 - 0.36 \cdot CA_2 - 0.80 \cdot CA_3 + 1.31 \cdot SA + 0.12 \cdot RC) \quad (2)$$

b) For concretes prepared with CEM I 52.5R:

$$f_c = [0.06 \cdot \ln(t) + 0.81] \cdot (-128.90 \cdot \frac{W}{C} - 0.89 \cdot PC + 0.35 \cdot SF - 1.59 \cdot CA_1 - 0.65 \cdot CA_2 - 1.60 \cdot CA_3 + 2.65 \cdot SA + 1.04 \cdot RC) \quad (3)$$

c) For concretes prepared with CEM III/A 42.5N:

$$f_c = [0.79 \cdot \ln(t) + 0.58] \cdot (-42.74 \cdot \frac{W}{C} - 0.28 \cdot PC + 0.13 \cdot SF - 2.04 \cdot CA_1 - 0.02 \cdot CA_2 - 2.39 \cdot CA_3 + 2.78 \cdot SA - 0.28 \cdot RC) \quad (4)$$

Table 3. Relationship between compressive strength (f_c) as the function of time (t) and compressive strength of cement (RC).

Concrete code	Equation
C1	$f_c = (0.08 \cdot \ln(t) + 2.34) \cdot (4.04 + 0.61 \cdot RC)$
C11	$f_c = (2.79 \cdot \ln(t) + 0.92) \cdot (14.96 - 0.1 \cdot RC)$
C8	$f_c = (0.31 \cdot \ln(t) + 3.22) \cdot (18.39 - 0.16 \cdot RC)$
C18	$f_c = (0.83 \cdot \ln(t) + 0.66) \cdot (51.68 - 0.32 \cdot RC)$

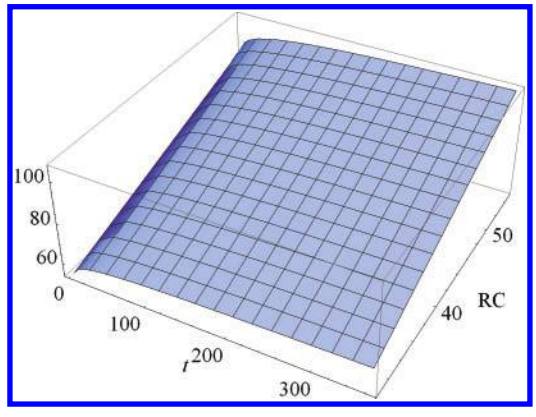

Figure 5. Relationship between compressive strength (f_c) as the function of time (t) and compressive strength of cement (RC) for concrete C1.

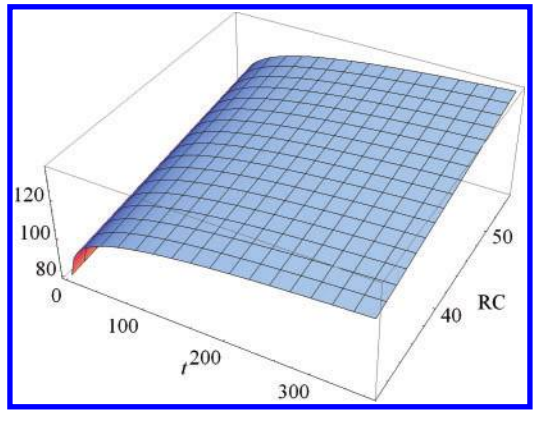

Figure 6. Relationship between compressive strength (f_c) as the function of time (t) and compressive strength of cement (RC) for concrete C11.

All equations confirm the Abrams' law that is the negative influence of W/C on the compressive strength of concrete. Also, W/C has the biggest impact as compared to other variables as shown by the coefficient that ranges between −128.90 and −21.01. Also, W/C has the biggest negative influence for concretes prepared with CEM I 52.5R. Interestingly, we find the differences in the impact of compressive strength of

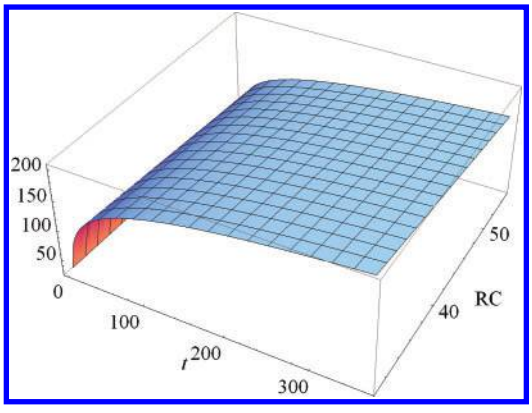

Figure 7. Relationship between compressive strength (f_c) as the function of time (t) and compressive strength of cement (RC) for concrete C8.

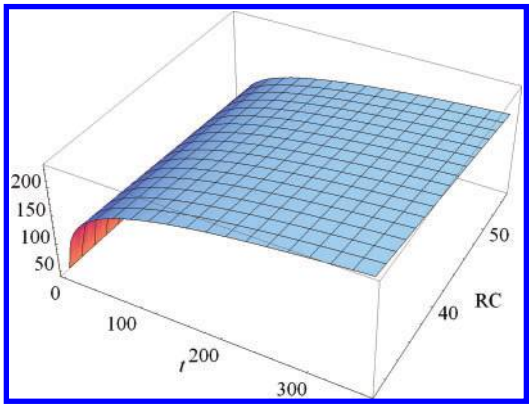

Figure 8. Relationship between compressive strength (f_c) as the function of time (t) and compressive strength of cement (RC) for concrete C18.

cement on compressive strength of concrete as positive association is found for concretes prepared with addition of CEM I 52.5R and negative, although not very substantial, for concretes with CEM III/A 42.5N.

For four exemplary concretes we obtained also the relationship between compressive strength as a function of time and compressive strength of cement (RC). The obtained formula is expressed in a form ($f_c = (\mathrm{A}\ln(t) + \mathrm{B}) \cdot (\mathrm{C} + \mathrm{D} \cdot RC)$), where: A, B, C and D are coefficients of explanatory variables (Table 3).

The figures below illustrate mathematical formulas relating compressive strength as the function of time with compressive strength of cement.

5 CONCLUSIONS

The objective of this study was to develop a statistical model to predict the compressive strength of high-performance concrete, based on the data obtained in experiments. Our model extended the Abram's law by including not only W/C ratio, but also other factors and components of concrete which influence compressive strength of concrete. To differentiate from previous research we applied a modified multiple lineal regression model, where the relationship between compressive strength and time is modelled as a natural logarithm. Also, we included the compressive strength of cement as an explanatory variable, while controlling for the type of cement used to cast concrete mixtures.

In this study we obtained several formulas which can explain the essence of strength models, linking compressive strength of concrete with compressive strength of cement, W/C ratio, age of concrete and several concrete's component characteristics. These explicit formulas are of great importance in building practice. The proposed models provide the practical opportunity to predict the compressive strength as the function of time under existing concrete's components conditions and compressive strength of cement. The models will be of value when one designs the high-performance concrete where specific compressive strength under technological demands must be achieved at certain ages.

As a future research we could consider other methods for compressive strength prediction of high performance concrete such as neural networks.

Experimental tests and analytical modeling of UHPC beams subjected to torsion

E. Fehling, M. Ismail & T. Leutbecher
Institute of Structural Engineering, University of Kassel, Germany

ABSTRACT: Twelve UHPC beams with different combinations of steel fibers, longitudinal and transverse reinforcement were investigated experimentally under pure torsion. Steel fibers having 17 mm length and 0.15 mm diameter with volumetric ratios of 0.5 % and 0.9 % were used. The average compressive strength of the reference UHPC standard cylinders was about 205 MPa. The UHPC beams with steel fibers only showed a ductile behavior. It was found that the addition of either longitudinal or transverse reinforcement to the steel-fiber UHPC beams added much to the ductility and very little to the ultimate capacity. The steel fibers having a volumetric ratio of 0.9 % together with the longitudinal or transverse reinforcement accomplished an effective load carrying mechanism after cracking. Only the case of both longitudinal and transverse reinforcement in addition to steel fibers provided a very high increase both in ultimate torsion capacity and ductility. An analytical model based on the well known ”thin-walled tube” analogy was developed. The comparison between the experimental and analytical results shows very good agreement.

1 INTRODUCTION

Torsion appears in structural elements when the line of action of the shearing force does not coincide with the shear center of the cross section. It appears, for example, in bridges, curved structural elements and spandrel beams in buildings.

Ultra High Performance Concrete (UHPC) is characterized by a very high compressive strength which may reach more than 200 MPa. The behavior of 0 plain UHPC under tension and compression has been established to be very brittle. Discontinuous fibers (normally steel fibers) are usually added to UHPC mix to introduce ductility. Little information is found in the literature about the behavior of this material under torsion.

2 EXPERIMENTAL PROGRAM

The test beam had a square cross section with extra enlarged reinforced ends in order to withstand the concentrated stresses due to load application at these areas and to gradually transfer the stresses to the main tested part of the specimen, see Figure 1.

The cross-sectional dimensions, the length of the test region and the reinforcement details for section A-A are shown in Table 1 for different beams. The parameters studied during the experimental program were: steel fiber volume, the capability of the steel fibers to replace the longitudinal or transverse reinforcement, the effect of combining both traditional

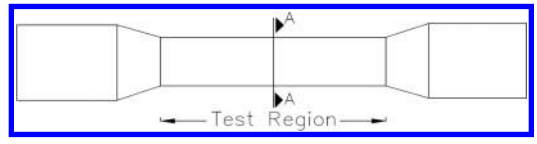

Figure 1. Shape of the test beam.

reinforcement and steel fibers and the wall thickness of the ”thin-walled tube”. The varied steel fiber volumetric ratios were 0.5 % and 0.9 %. The varied wall thickness were 45 and 90 mm. The test setup, the instrumentation and the test procedure can be found in details in (Fehling & Ismail 2012).

3 MATERIALS

A fine-grained (maximum grain size of 0.5 mm) UHPC mix (M3Q) was used. This mix was developed at the University of Kassel and was used as the reference mix in the priority program (Sustainable construction with UHPC, SPP 1182) of the German Research Foundation (Deutsche Forschungsgemeinschaft DFG). It is considered as a further development of the (M2Q) UHPC mix which is described in detail in (Fehling et al. 2005). For all the test beams, the average cylinder compressive strength was about 205 MPa and the average modulus of elasticity was about 49,000 MPa.

BSt 500 reinforcing steel with a yield strength of 550 MPa and an ultimate strength of 630 MPa was used. The steel fibers (F1) had a tensile strength of

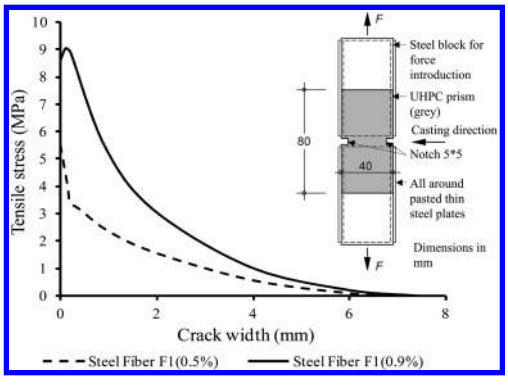

Figure 2. Average axial tensile tests of notched prisms.

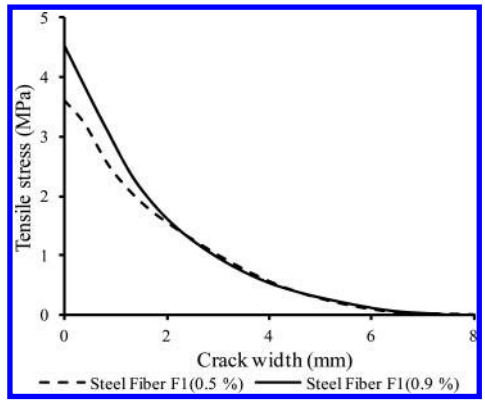

Figure 3. Average axial tensile tests after fiber analysis.

2500 MPa and dimensions of 17 mm in length and 0.15 mm in diameter. To study the behavior of the steel fibers in the hardened UHPC, axial tensile tests of notched UHPC prisms according to (Leutbecher 2008), having steel fiber volumetric ratios of 0.5 % and 0.9 % have been conducted. Figure 2 shows the average stress-crack width diagrams for these tests. However, the distribution and orientation of the steel fibers in the small size prisms may not agree with that in the actual test beams. In order to capture the actual distribution of the steel fibers in the test beams, an optical steel fiber analysis of the tested beams at the failure surfaces according to (Lange 2009) and also tensile tests on prisms cut from the test beams was conducted. According to this analysis, the UHPC with 0.5 % and 0.9 % steel fiber by volume show a softening behavior after cracking as shown (Fig. 3).

4 CASTING AND TREATMENT

The beams were cast in pairs together with the reference test specimens for the compression and tension tests. A mixer with 400 litres capacity was used, where the coarser materials were added first followed by the finer materials. Steel fibers were added to the mix through a sieve to insure that the fibers will not accumulate in bundles in the mix.

The beams were compacted using a vibrating table in order to keep the normal distribution of the fibers within the mix. After casting, the beams were left in the formwork for two days to harden. The forms were then removed and the specimens were heat treated under 90°C for two days.

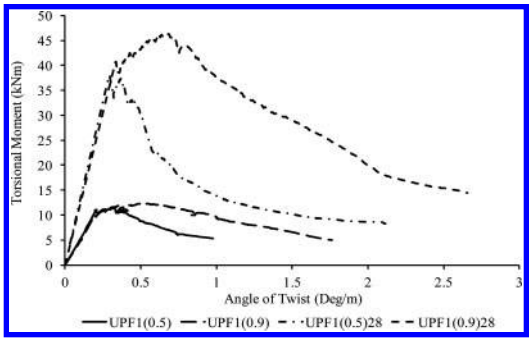

Figure 4. Torsion test results for UHPC beams with steel fibers only.

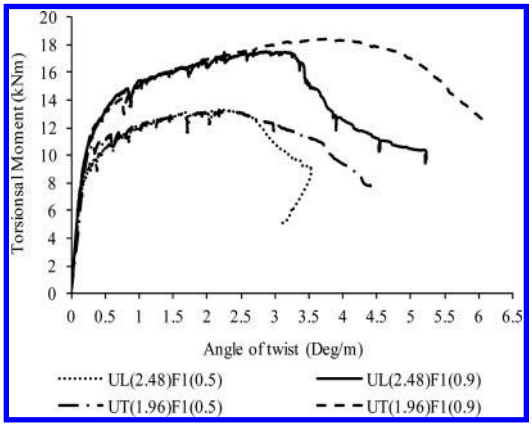

Figure 5. Torsion test results for UHPC beams with steel fibers and either longitudinal or transverse reinforcement.

5 TEST RESULTS

5.1 *UHPC with steel fibers only*

Figure 4 shows the load-deflection diagrams of these beams. After reaching the UHPC tensile strength, few cracks were developed before a localized failure at one crack occurred due to fiber pull-out from the UHPC matrix. As for all the tested beams, the cracks were initiated at the middle of the cross-sectional walls, then propagated inclined to the longitudinal axis of the beam to circulate around the beam walls. The initial cracks were very narrow in widths, where they begun at widths of about 0.03 to 0.05 mm.

Figure 4 shows also that the higher the steel fiber volumetric ratio in the mix, the higher the cracking torsion, the ultimate torsion, the stiffness after cracking and the ductility.

5.2 *UHPC beams with steel fibers and either longitudinal or transverse reinforcement*

This group of beams shows much more ductile behavior than the UHPC beams with steel fibers only (Fig. 5).

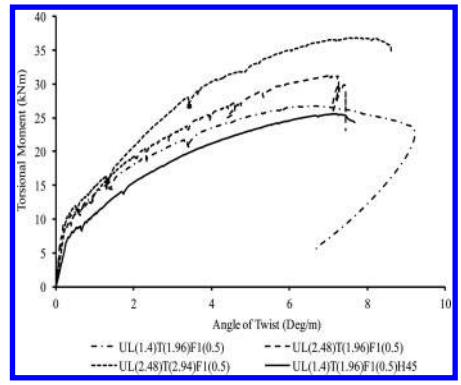

Figure 6. Torsion test results for UHPC beams with steel fibers and both longitudinal and transverse reinforcement.

These beams showed in general intensive cracking before failure. The number of cracks was directly proportional to the volumetric ratios of the steel fibers and the longitudinal reinforcement. The cracks were uniformly distributed along the length of the beams and closely spaced, while those of the UHPC beams with steel fibers only were non-uniformly distributed but rather congested in a cracking zone. This may be attributed to the different load resistance mechanisms of the two types of reinforcements: the pull-out of the steel fibers and the yielding of the reinforcement.

Failure of these beams was initiated by continuous widening of more than one crack, where the final failure was due to yielding of the reinforcement and pull-out of the steel fibers from the UHPC matrix at one crack location.

In comparison with the UHPC beams with steel fibers only, the combination of either longitudinal or transverse reinforcement with low steel fiber content (0.5%) added much to the torsional ductility and very little to the ultimate torsional capacity, however, the steel fiber content of (0.9%) increases the ultimate torsional capacity significantly.

Figure 5 shows also that the beams with the same fiber content but different type and a little bit different volumetric ratio of bar reinforcement have almost the same torsional capacity. Moreover, despite having a little bit less reinforcement ratio, the beams with steel fibers and transverse reinforcement show enhanced ductility in comparison with the other pair of beams. This reveals that the steel fibers have a better ability to perform as a longitudinal reinforcement than as a transverse reinforcement. It could also be argued that the transverse reinforcement in the test beams provides better confinement to the concrete core and hence better ductility. If this is the case, then the steel fibers have the same ability to perform as longitudinal or transverse reinforcement.

5.3 *UHPC beams with steel fibers and both longitudinal and transverse reinforcement*

The increase in the torsional capacity and ductility for the beams in this group was significant (Fig. 6). The

Figure 7. Deformation parallel to the crack direction.

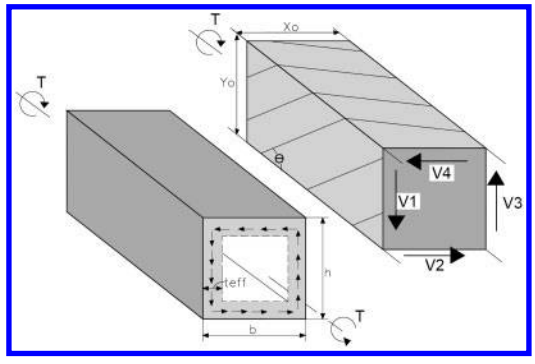

Figure 8. Thin walled tube (left) and Shear forces in the tube walls (right).

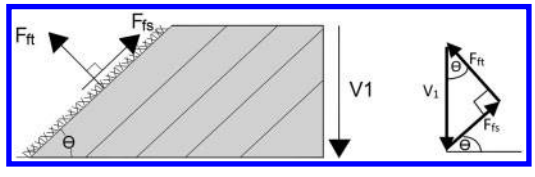

Figure 9. Resolution of the shear force V_1 (left) and Force equilibrium triangle (right).

failure occurred after very intensive cracking. Increasing the steel reinforcement ratio of any type, whether longitudinal or transverse, increases the ductility and post cracking stiffness, but the maximum increase of these factors happened when both the longitudinal and transverse reinforcement were increased.

The torsional capacity of the beam UL(1.4)T(1.96)F1(0.5)H45 is about 96% of that of the beam UL(1.4)T(1.96)F1(0.5), which reveals that the "thin-walled tube" thickness of the reinforced UHPC beams with steel fibers is a little bit larger than the cross sectional area divided by the circumference (in our case 45 mm).

6 ANALYTICAL MODELLING

An analytical model based on the well known thin-walled tube analogy is developed to estimate the torsional moment capacity of reinforced UHPC beams with steel fibers. This analogy considers that after cracking, the torsional resistance exists mainly at the outer shell of the cross section with a specific wall thickness (t_{eff}). Before describing the model and its resistance mechanism, an important aspect about the development of shear cracks will be reviewed.

At the onset of cracking, the shear cracks develop perpendicular to the principal tensile stress direction. Afterwards, the cracks generally do not open perpendicular to their direction (Fig. 7). This is because the reinforced concrete is considered as isotropic material before cracking as the reinforcement practically does not take part in torsion resistance before cracking. After cracking, the matter is different. The reinforced concrete is no longer isotropic and the influence of the reinforcement increases gradually which affects the load bearing behavior of the reinforced concrete. This induces shear stresses parallel to the crack direction. As a result the cracks can transmit shear forces parallel to their direction (Walraven 1980). In reinforced concrete, the resisting components are the dowel action and the aggregate interlock. In the fine aggregate UHPC with steel fibers only, the aggregate interlock can be assumed to be of minor influence, so that we are left with the shearing resistance of the steel fibers.

6.1 *The model resistance mechanism*

An UHPC beam with steel fibers only subjected to torsion is idealized as a thin-walled tube of dimensions b × h with a constant shear stress τ along the perimeter of the cross section (Fig. 8).

In Figure 8, the line of action of the shear flow encloses a gross area of A_k:

$$A_k = X_o \times Y_o = (b - t_{eff}) \times (h - t_{eff}) \quad (1)$$

where $X_o = b - t_{eff}$ and $Y_o = h - t_{eff}$

Figure 8 shows the shear forces V_1 to V_4 induced in the walls of the tube due to torsion. Once the beam has cracked in torsion, its torsional resistance is provided primarily by the tensile and shear stresses in the steel fibers along the cracked walls of the tube. Figure 9 shows the resolution of the shear force V_1 into tensile (F_{ft}) and shear (F_{fs}) forces perpendicular and parallel to the crack direction.

6.2 *Derivation of torsional strength formula*

According to Bredt's Theory, the torsional moment can be given as:

$$T = \frac{V_1}{Y_0} \times 2A_k \quad (2)$$

Table 2. Comparison between the model and the test results (steel fibers only).

Beam	σ_{cf0} (MPa)	Inclination of cracks θ (deg)	T_{ut} (test) (kNm)	T_{n1} (Eq5) (kNm)	T_{n2} (Eq6) (kNm)	T_{n1}/T_{ut}	T_{n2}/T_{ut}
UPF1(0.5)	3.60	47	11.36	11.84	10.42	1.04	0.92
UPF1(0.9)	4.60	47	12.24	15.13	13.32	1.24	1.09
UPF1(0.5)28	3.60	52	38.00	45.80	40.32	1.21	1.06
UPF1(0.9)28	4.60	47	46.32	55.64	48.97	1.20	1.06

From the force equilibrium diagram in Figure 9, V_1 can be given as:

$$V_1 = \frac{\sigma_{cf0} \times A_w}{\cos\theta} \tag{3}$$

where $F_{ft} = \sigma_{cf0} \times A_w$ is the tensile force corresponding to the fiber efficiency σ_{cf0}, σ_{cf0} is the value of the tensile strength of the test prisms after cracking according to Figure 3 and $A_w = t_{eff} \times (h - t_{eff})/\sin\theta$ is the inclined area to which both the tensile and shearing forces are acting.

Substituting Equation (3) into (2), the nominal torsional strength T_n can be written as:

$$T_n = \frac{\sigma_{cf0} \times A_w}{\cos\theta \times (h - t_{eff})} \times 2A_k \tag{4}$$

6.3 *UHPC with steel fibers only*

The Eurocode EC2 (2004) as well as the Model Code 90 (1991) define the "thin-walled tube" wall thickness for reinforced concrete beams as not less than twice the distance between the external face and the line joining the axes of the longitudinal reinforcement. As a first approximation, the two codes allow t_{eff} to be calculated as:

$$t_{eff} = \frac{A_{cp}}{P_{cp}} \tag{5}$$

For the calculation of the cracking torsion T_{cr}, the ACI Building Code (ACI 318-08) defines the effective wall thickness of the tube as:

$$t_{eff} = \frac{0.75 \times A_{cp}}{P_{cp}} \tag{6}$$

where A_{cp} and P_{cp} are the total area and perimeter of the cross section. A comparison between the estimations of the ultimate torsion of the steel fiber UHPC beams using Equations (5) and (6) and the test results is shown in Table 2. Using the definition of the wall thickness in equation (5) results in overestimation of the ultimate torsional capacity in all cases, whereas Equation (6) results in better agreement between the model and test results. It should be noted that the average angle of inclination of the cracks θ was taken from the test results found in (Fehling & Ismail 2012).

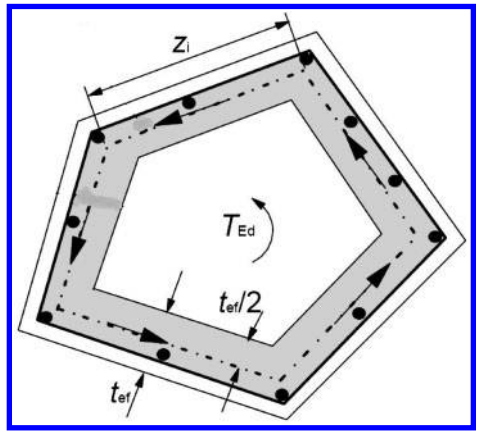

Figure 10. Definition of the centerline of the shear according to the Eurocode 2.

6.4 *UHPC beams with steel fibers and either longitudinal or transverse reinforcement*

To calculate the torsional capacity of UHPC beams with steel fibers and either longitudinal or transverse reinforcement, the only change that is made here is to use the definition of the Eurocode regarding the effective thickness of the tube wall t_{eff} for reinforced concrete elements (Fig. 10), where:

$$t_{eff} = 2\left(S_c + d_t + \frac{d_s}{2}\right) \tag{7}$$

where S_c = concrete cover, d_t = diameter of transverse reinforcement and d_s = diameter of longitudinal reinforcement.

It should be noted that for the beams with steel fibers and transverse reinforcement only, it was strictly adhered to the Eurocode 2 definition of the wall thickness (t_{eff}), such that only for the purpose of calculating t_{eff}, it was assumed as if at every corner of the cross section a longitudinal steel bar of 12 mm diameter exists. For this group of beams, the angle of inclination of the cracks θ was documented at three deformation stages (angles of twist) during the tests, but unfortunately not at failure.

The angle θ at failure was calculated assuming linear extrapolation between the last two documented angles. Table 3 shows good agreement between the model and the test results.

Table 3. Comparison between model and test results (steel fiber, in addition to either longitudinal or transverse reinforcement).

Beam	σ_{cf0} (MPa)	Inclination of cracks θ (deg)	T_{ut} (test) (kNm)	T_n (model) (kNm)	T_n/T_{ut}
UL(2.48)F1(0.5)	3.6	44	13.40	12.44	0.93

6.5 *UHPC Beams with steel fibers and both longitudinal and transverse reinforcement*

The assumption here is that the nominal torsional capacity of the beam is composed of two parts, the first is the contribution of the steel fiber (T_f) as calculated in paragraph 6.3 using the ACI code formula for t_{eff}, and the second is the contribution of the space truss model (T_t) as found in the Eurocode 2.

$$T_n = T_f + T_t \tag{8}$$

Table 4 shows very good agreement between the model and test results.

7 CONCLUSIONS

Addition of steel fibers to the plain UHPC beams increased both the cracking and ultimate torsional capacity and provided torsional ductility.

As the steel fiber volumetric ratio in the mix increases, the torsional capacity enhances and the number of cracks increases as well.

The addition of traditional reinforcement (whether longitudinal, transverse or both) to the steel-fiber UHPC results in almost uniformly distributed cracks along the beam, while the UHPC beams with steel fibers only show non-uniform distribution of cracks, such that the cracks were congested in a cracking zone.

The combination of either longitudinal or transverse reinforcement with low steel fiber volume enhanced very much the stiffness after cracking and the ductility but the resulted increase in the ultimate torsion was marginal. The most significant increase of these factors happens only when both the longitudinal and transverse reinforcement increased together.

The steel fibers show almost the same capability to behave as longitudinal or as transverse reinforcement.

The result of the traditionally reinforced hollow UHPC beam with steel fibers reveals that the thickness of the tube wall is a little bit larger than the cross sectional area divides by the circumference.

The developed analytical model shows very good agreement with the test results.

Compressive strength of high-performance concrete with absorption capacity of Super-Absorbing-Polymers (SAP)

B.J. Olawuyi & W.P. Boshoff
Department of Civil Engineering, Stellenbosch University, Stellenbosch, South Africa

ABSTRACT: This paper reports the absorption capacity of super-absorbent-polymer (SAP) in water and cement pore solution. This was considered for the free water requirement for high-performance concrete containing SAP. The rheology and compressive strength properties of this low water/binder (w/b) concrete are reported. A $2 \times 5 \times 4 \times 3$ factorial experimental arrangement was used for the study. Two sizes of SAP (03/08 μm and 06/12 μm) monomers acrylic acid were tested at different SAP contents (0%; 0.2%; 0,3%; 0.4%; and 0.6% by weight of cement) for concrete mix proportion of 0.25 w/b ratio ($F_{cu28} \geq 80$ MPa target strength).Specimens were also tested at different curing ages namely 3, 7, 21 and 28 days. The results are presented in this paper with a discussion on the influence of water absorbed by SAP at the mixing stage on the compressive strength of the high-performance concrete.

1 INTRODUCTION

1.1 *High performance concrete*

High performance concrete (HPC) is a generic term for all concrete exhibiting properties and constructability which exceeds that of normal strength concrete (Kosmatka et al., 2002). They are specially designed to meet combination of performance and requirements which specifically includes high workability, high strength, high early strength, durability and high modulus of elasticity amongst other properties (Kosmatka et al., 2002; Malhotra, 1994; Neville, 2006).

A recent definition by Mehta & Monterio (2012) presents HPC as concrete that has been designed to be more durable and if required, stronger than conventional concrete. The mixtures are essentially composed of the same materials as conventional concrete mixtures, but the proportions are designed or engineered to provide the strength and durability needed for structural and environmental requirements of the project. HPC application in building structure according to A_itcin (1998) was first recorded in the Water Tower Place, built in 1970 in Chicago, Illinois, USA (adopting 60 MPa concrete with lingosulfonate based water reducers). The use is now adopted extensively for the fabrication of precast pylons, piers and girders of many long span bridges in the world with variety of HPC classes available (Mehta & Monterio, 2012).

The growing trend in the utilisation of high-performance and ultra-high-performance concrete (HPC and UHPC) in the construction industry and the susceptibility of this concrete types to self-desiccation and autogenous shrinkagenecessitated research into materials for internal curing of concrete (IC-agents). The real site situation can hardly offer effective curing by complete immersion in water to prevent drying in concrete elements. An intensive study of the IC-agents being introduced in concrete is of essence. Any material for use as an IC-agent should be of appropriate type and optimum proportion while its addition should not result in any detrimental effect on the requisite properties of the concrete. This paper thereby presents a study of the influence of super-absorbent polymers (SAP) as IC-agent on the compressive strength of HPC of low w/b ratio (0.25) having 28 day cube strength specification of 90 MPa (C90/C105 strength class of the Eurode2 – BS EN 1992: 2008).

1.2 *Super Absorbent Polymers*

Super absorbent polymer (SAP) is defined by Siriwatwechakul et al.(2010) as a general term referring to polymers that are able to retain large amount of water. The two main categories mentioned are thermoplastic polymers (linear polymers) and thermoset polymers (cross-linked polymers). The thermoplastic polymers are noted to be of high molecular weight, having overlapping polymer chains with the junction acting as physical cross-links which form pseudo-three dimensional structures. The thermoset polymers on other hand are three dimensional polymer networks with chemical cross-links which hold polymer chains together, thus preventing it being dissolved when soaked in solvents (Siriwatwechakul et al., 2010). This study focuses on thermoset polymers specifically the covalently cross-linked polymers of acrylic acid and accrylamide, neutralised by alkali hydroxide, which according to Schrofl et al. (2012) have been proven efficient as internal curing agents in concrete.

This SAP types according to Siriwatwechakul et al. (2010) absorbs water when it comes in contact with water thereby causing water molecules to diffuse into the void space inside the polymer network to the hydrate polymer chain resulting in swollen polymer gel. This process can be reversed by removing water and the SAP returned to the collapsed state. This water absorbing ability is called the swelling rate i.e. the ratio of the weight of swollen SAP (swollen state) to the dried SAP (collapsed state). This is adjudged to be about 500 g/g in distilled water but only about 12 g/g in cement pore solution as argued by Hasholt, et al. (2012) while Craeye, et al. (2011) used an assumed value of 45 g/g in his work. Schrofl, et al. (2012) however made a proposal that the SAP swelling rate should be determined with the "tea-bag method". The swelling ratio may vary for the variants of SAP. The effectiveness of internal curing of SAP according to Siramanont, et al. (2010) is influenced by the swelling rate of SAP and the inter-particle spacing of the SAP. This work thereby examines the effect of SAP addition on the compressive strength of HPC when the mixture has additional water equivalent to water absorbed by SAP based on the SAP absorption capacity in cement pore solution.

2 MATERIALS AND METHODS

2.1 *Super absorbent polymer (SAP)*

SAP is the admixture introduced in the HPC as IC-agent. Two sizes of SAP (03/08 μm and 06/12 μm) were used at different SAP contents (0%, 0.2%, 0.3%, 0.4% and 0.6% by weight of cement (b_{woc})).

2.2 *Absorption capacity of SAP*

Absorption capacity of the SAP in distilled water and cement pore solution was determined using the so-called "tea bag method" cited in Schrofl et al. (2012). The cement pore solution was obtained from the ordinary Portland cement type – CEM I 52.5 N (conforming to SANS 50197-1 and BS EN 197 – 1:2000) available in the Western Cape, South Africa.

The cement pore solution was made with a mixture of 5.2 water/cement (w/c) ratio. The measuring scale used in this study was however of two decimal digits in grams (g) based on availability as against the four digit analytical scale specified. The result of the "tea bag test" is presented in Table 1. The SAP absorption capacity of 10 mins was chosen as the basis of additional water for the concrete mixes.

2.3 *Mix composition and testing procedure*

A natural sand with minimum particle size 300 μm having physical property values (FM (2.79), Cu (2.43), Cc (1.02) and dust content (0.3%)) of medium sand classification (Shetty, 2004) as observed in the preliminary sieve analysis reported in Olawuyi & Boshoff, (2013) was used as fine aggregate. 13mm crushed greywacke stone serve as coarse aggregate. OPC CEM I 52.5 N was the binder with silica fume (5% b_{woc}) added as cement extender while Premia 310 at 2.75% b_{woc} was added as super-plasticiser.

A concrete mix design for HPC with water/binder (w/b) ratio of 0.25 and 28 day target strength of C90/C105 using British Method was adopted as reference (CM) with the other mixes having varied SAP contents (0.2%, 0.3%, 0.4% and 0.6%) for the two SAP sizes. The concrete was cast in 100 mm cube moulds and tested in the Contest material testing machine after curing in water for 3, 7, 21 and 28 days in accordance with BS EN standards (BS EN 12350-1 & 5, 2000; 12390-1 & 2, 2000; 12390-3, 2002) for compressive strength. Slump flow test was conducted immediately after mixing to assess the consistency of concrete while the density (demoulded and at 28 day) of the cube specimens was also determined.

Table 1. Absorption capacity of SAP.

Time (min)	SAP1(g/g) Water	CPS*	SAP2(g/g) Water	CPS*
0.5	72.34	20.11	65.80	26.61
2	170.29	20.84	180.63	31.49

*CPS = cement pore solution.

3 RESULTS AND DISCUSSION

3.1 *Absorption capacity of SAP*

The result of the tea-bag test shows that (Table 1) absorption capacity (also known as swelling rate) of SAP in both water and cement pore solution increases as the time of immersion increases. This however increased at a decreasing rate after the first 10 mins of immersion. The swelling rate was also observed to be higher for the SAP2 having larger grain sizes (06/12 μm) than the SAP1 (03/08 μm size). The value at the 10 mins time in cement pore solution was however noted to be 24.30 g/g and 33.93 g/g for SAP1 and SAP2 respectively which is about 10% of the swelling rate in water for both SAP sizes. The value at 10 mins time of immersion (taken as the time required for complete concrete mix and casting after water addition to mix constituents) was thereby taken as 25 g/g (SAP1) and 30 g/g (SAP2) for the HPC mixes with SAP adopted for this study. This was kept at this value to avoid wide variation between the swelling rates of the two SAP sizes as they were known to be made from same material and production process. The two SAP sizes were expected to have the same swelling rate on

Table 2. Mix constituents for HPC.

Constituents (kg/m^3)	SAP Content (%)				
	0.0	0.2	0.3	0.4	0.6
Water	130	130	130	130	130

Total w/b**					
SAP1- Mix	–	0.31	0.34	0.36	0.41
SAP2- Mix	–	0.32	0.35	0.38	0.44

*b_{woc} = by weight of cement.
**Total w/b = (initial water + water added for SAP absorption + super-plasticiser weight)/total binder weight.

basis of their supposed chemical composition but a small variation was found.

The swelling rate determine in this study is however below the value assumed by Craeye et al. (2011) in their study (45 g/g) but above the value used by Hasholt et al. (2012) as the swelling rate of SAP (12 g/g).

The observed swelling rate in the cement pore solution for the respective SAP sizes was thereby adopted for calculation of additional water required in the HPC mixes containing SAP in this study. This was done to make allowance for water to be absorbed by SAP in the concrete mixture before casting as shown in Table 2. The total w/b ratios for the SAP mixes are thereby determined as 0.31, 0.34, 0.36, 0.41 for HPC containing SAP1 (03/08 μm) and 0.32, 0.35, 0.38, 0.44 SAP2 (06/12 μm) HPC mixes. The preference mix(CM) however has a total w/b ratio of 0.25.

3.2 *Consistency and Density of HPC*

Table 3 presents the observed values of the slump flow (i.e. consistency) and densities (demoulded and at 28 days) of the HPC mixes. All the slump flow values were noted to be within the acceptable values for a good and workable HPC with low w/b ratio (450 mm–550 mm) as specified in literature (Kosmatka et al., 2002; Neville, 2006). The trend shows that the slump flow value decreased as the SAP contents increases with a deviation from this trend at 0.6% SAP content for both SAP sizes. The slump flow value at this SAP content was however still within the acceptable value of between 450 mm and 550 mm. A physical observation indicated that none of the HPC mixes experienced any segregation.

The densities (both demoulded and at 28 days) of the HPC also decreased as the content of SAP increased, hence the porosity as calculated increased. Beyond

Table 3. Workability and Density of HPC with SAP.

S/No*	Slump Flow (mm)	Demoulded		28 Days

MS_2^D	42.79 (40.32)	51.79 (48.80)	63.44 (59.78)	65.74 (61.95)

*values in parentheses () shows percentage of the 28 day strength of the control mixture (CM).

0.2% SAP content for both sizes of SAP, the porosity value fell out of the acceptable value of 2% for HPC. The situation is worsefor the larger SAP size which is believed to require additional water based on its observed swelling rate.

3.3 *Compressive strength of HPC with SAP*

The 28 day compressive strength of the HPC with varying SAP content is shown in Table 4. Figure 1 shows that the compressive strength decreases as SAP contents increases at a linear rate up to 0.4% SAP content (i.e. strength loss $\leq$ 25%) but with a strong deviation from the trend occurring at 0.6% SAP content (strength loss of about 40%) for both SAP sizes. All the

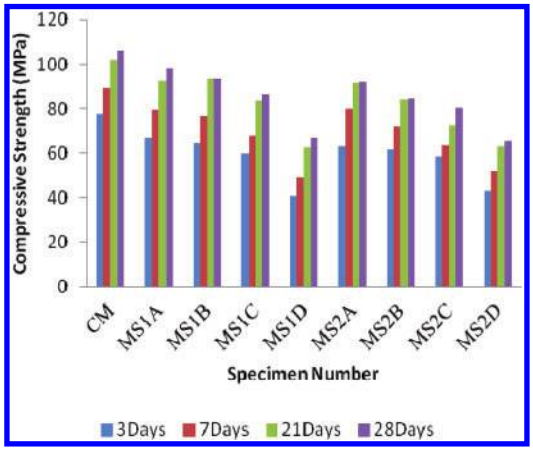

Figure 1. Compressive strength of HPC with SAP.

HPC specimens were observed to experience steady increase in strength development as the age of hydration increases. The 28 day cube strength (Fcu_{28}) of the mixes containing SAP1 at 0.2% (MS_1^A) and 0.3% (MS_1^B), 97.81 MPa and 93.41 MPa respectively both met the target 28 day cube strength of 90 MPa for the C90/C105 HPC classification. The Fcu_{28} for the 0.4% SAP content (MS_1^C) in this mix type is also close to the target strength with the possibility that it will develop a strength more than the target strength at later curing age since it contains silica fume (a pozzolanic material).

For the SAP2 HPC on the other hand only the mix with 0.2% SAP content (MS_2^A) with $Fcu_{28} = 92.00$ MPa met the target strength of 90 MPa. The 0.3% SAP content mix (MS_2^B) $Fcu_{28} = 84.65$ MPa has the possibility of achieving the design strength at later curing age. The excess water added to the mixes with SAP2 can be adjudged to be responsible for their low 28 day strength as the literatures affirms that the optimum actual water required for cement hydration is a total w/b ratio of 0.36. This is the point at which hydration stops ($\alpha_{max} = 1$) according to the Powers' model concept (Hasholt et al, 2012).

It can therefore be inferred that HPC with or without SAP having total w/b ratio below 0.36 (CM, MS_1^A, MS_1^B, MS_2^A) gave compressive strength values adequate for the design strength. The HPC mixes with SAP on the other hand with total w/b ratios around 0.36 (MS_1^C and MS_2^B) also has the possibility of achieving the design strength at later curing ages. The total w/b ratio of 0.36 should thereby be taken as the limit of SAP addition in HPC for no detrimental effect on the strength of the concrete.

4 CONCLUSION AND RECOMMENDATIONS

4.1 *Conclusion*

The following conclusions can be drawn from the results of this study.

The absorption capacity of SAP in both water and cement pore solution increases as the time of immersion increases. The swelling rate of SAP in cement pore solution is about 10% of the swelling rate in water. After 10 minutes of immersion, SAP1- 03/08 μm has a swelling rate of 25 g/g but 230 g/g in water while SAP2 – 06/12 μm has a value of 30 g/g in cement pore solution and 260 g/g in water. The "tea-bag" test involves dabbing the swollen SAP in your palm after been rolled in towel for removal of excess water. This might be the reason for the varied swelling rate of the two SAP sizes studied, both samples been from same chemical materials and production process should be of same nature and hence have the same swelling rate.

The higher the SAP contents in HPC, the lower the densities (both demoulded and at the hydrated stated) and hence the higher the porosity.

HPC of low w/b (0.25) with SAP as admixture gives compressive strengths that is commensurate to the expectations of the design mix up to the limits of SAP addition (0.3% for SAP1 and 0.2% for SAP2). This is the limit to which the total water addition is within the w/b value of 0.36 at which the optimum water required for complete hydration is provided. Beyond this limit the additional water provided in the mix to account for the requisite absorption by SAP in HPC with high SAP contents led to detrimental effect in the compressive strength. This work thereby concludes that the limit of SAP addition in HPC of low free w/b ratio (e.g. 0.25) is 0.3% by weight of cement based on the outcome of the tests in this study.

4.2 *Recommendations for further studies*

Towards advancement in the utilisation of SAP as IC-agent in HPC with low w/b ratio, attention thereby ought to be given to the followings in future studies.

Developing improved test method (i.e. modified tea-bag test) for determination of SAP absorption capacity. Effort should be geared towards elimination of inherent variations in measurement due to human error.

The size, structure, and intermolecular interaction of the material constituents of HPC containing SAP as IC-agent over a long hydration period should be studied.

A model for spalling of HPC thin plates exposed to fire

T. Hulin, K. Hodicky, J.W. Schmidt, J.H. Nielsen & H. Stang
Department of Civil Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark

ABSTRACT: An experimental program was carried out to investigate the behaviour of high performance concrete (HPC) thin plates in fire for use in sandwich panels. To reveal the influence of moisture two initial moisture contents for wet and dry samples were examined. In addition, two thicknesses were used to disclose the temperature distributions during the test. A non-linear coupled model for time dependent heat and mass transfer in concrete thin plates was used for temperature and pore pressure computations. Results from modelling and tests are compared and discussed. Moisture content was found to be a critical parameter in the spalling process. The calculated pore pressure induced too low tensile stresses in the matrix to trigger failure, suggesting a major role played by thermal stresses.

1 INTRODUCTION

High performance concrete (HPC) allows making thin flanges (20 to 30 mm thick) suitable for structural purpose. Used in sandwich elements where the concrete layers frame a thick insulation material, they provide a construction system addressing some of the growing environmental challenges of the building industry.

The reduction of material use due to HPC makes the profiles lighter, which reduces production- and transportation-induced emissions. Furthermore the industrial manufacturing optimizes on-site building time. Those advantages coupled with a thick insulation result in an end-user friendly solution.

However, a major issue of this system lies in the explosive spalling tendency of HPC when exposed to fire (Hertz 2003, Majorana et al. 1998, Phan & Davis 2001), which has been seen in previous certification attempts within the scope of this research. The low permeability of HPC leads to high pore pressures when temperature rises, triggering a fracture process followed by explosion due to thermal stresses. This principle has been extensively studied analytically (Bažant & Thonguthai 1978, England & Khoylou 1995, Ahmed & Hurst 1997a,b, Tenchev et al. 2001) in the case of thick walls used in nuclear power plants, and is here addressed to thin HPC profiles.

This paper presents a preliminary study of spalling behaviour in HPC used for thin plates. Numerical modelling of temperature and pressure distributions as well as the hydrostatic stresses due to those pressures is investigated. The influence of thickness and moisture content on the spalling behaviour of those thin flanges have been investigated experimentally and compared to the analytical study.

2 METHODS

2.1 *Experimental work*

The experimental work presented in this paper intends to give preliminary test data on thin HPC plates exposed to fire. Only temperature was measured since the small thickness does not allow implementing pressure sensors that would significantly disturb the concrete behaviour.

The HPC mix used in those experiments has a compressive strength of 80 MPa and a tensile strength of 5 MPa. The precise composition is kept secret by the producer, only tested material characteristics are known.

The square profiles ($540 \times 540\,mm^2$) come in thicknesses of 20 mm and 30 mm and two different conditionings. The wet conditioning was achieved by keeping the samples in an ambient temperature water basin for the whole duration of hardening. The dry conditioning was achieved by keeping the samples in water for a week to develop a similar microstructure as the others, and placed in an oven at 35°C for the rest of the hardening period. Two samples of each configuration were tested for repeatability, the concrete coming from two different batches. The precise sample labelling is given in Table 1.

The samples are tested horizontally, exposed to fire on the bottom side and to the ambient air temperature on the other as shown in Figure 1. To record the temperature through the thickness, three sets of three thermocouples were embedded at 1/4th, 1/2nd and 3/4th of the thickness. An extra four thermocouples were glued on the outer surface of each plate. The plates are exposed to the environment on the sides but insulated from the furnace by mineral wool to avoid

Table 1. Sample labelling for fire test. W and D respectively stand for wet and dry conditioning. 1 and 2 stand for the two concrete batches.

Name	Thickness mm	Conditioning	Moisture sample
W20.1	20	wet	mW20.1
W20.2	20	wet	mW20.2
W30.1	30	wet	mW30.1
W30.2	30	wet	mW30.2
D20.1	20	dry	mD20.1
D20.2	20	dry	mD20.2
D30.1	30	dry	mD30.1
D30.2	30	dry	mD30.2

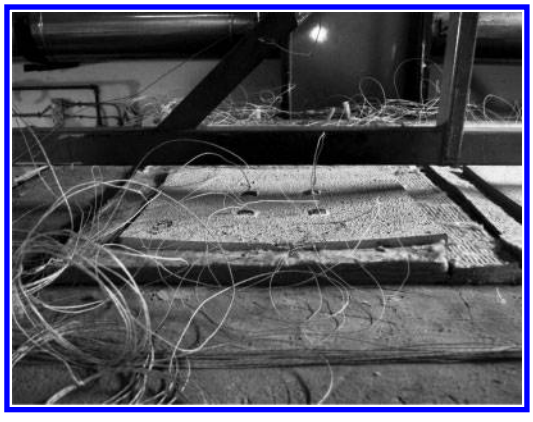

Figure 1. Sample laid on the top of the furnace. Thermocouples are visible on the cold surface exposed to the air, and going out of the sample sides.

heat conduction. The furnace provides only radiant and convective heating. Thermocouples are placed in the furnace to monitor the temperature which follows the ISO 834 (EN 1363-1) curve. The pressure in the furnace is kept at 20Pa. The specimens are heated up to 40 min or thermal equilibrium.

Along with each of those large plates a smaller plate ($300 \times 300\,mm^2$) was cast for moisture content measurement. Their central parts were crushed and placed in an oven, weighed at regular intervals until reaching equilibrium. The result is used as input data for the numerical model. Table 1 shows the moisture samples identification and link with the fire tested tiles.

2.2 *Numerical analysis*

The numerical analysis is carried out using a finite element program, as it enables modelling a coupled system of two non-linear differential equations for temperature and pressure. This is important since the temperature dependency of many material parameters used as coefficients in the coupled system makes the formulation highly non-linear.

The one-dimensional numerical model calculates temperature and pressure distributions over time through the thickness of the thin plates using Comsol Multiphysics. Both thicknesses (20 mm and 30 mm) are accounted for. To reproduce the experimental set-up, heating takes place on one side only, the other exchanges heat with the environment.

The equations for heat and mass transfer in porous bodies in general have been described by Luikov (1966) and extended specifically for concrete by various researchers (Bažant & Thonguthai 1979, Tenchev et al. 2001, Dwaikat & Kodur 2009). Under the assumption of local thermodynamic equilibrium of all phases of water between adjacent pores and considering concrete as a matrix of undistinguished mortar and aggregates including pores, a two-equation formulation for both heat and pressure describes accurately the problem (Bažant & Thonguthai 1978).

Fourier's law (Equation 1) governs temperature and Darcy's law (Equation 2) governs pressure.

$$q = -k\nabla T \quad ; \quad J = -\frac{a}{g}\nabla p \tag{1,2}$$

where $\boldsymbol{q}$ = heat flux; k = thermal conductivity; T = temperature of the sample; $\boldsymbol{J}$ = moisture flux in concrete; a = permeability; g = gravity acceleration; and p = pore pressure.

The cross-effects of Dufour and Soret fluxes are disregarded, found to be of negligible impact (Bažant & Thonguthai 1978). Additionally, Fick's law describes moisture diffusion but the high heating rate which follows the standard ISO 834 heating curve makes it unnecessary in the present model as Darcy's law predominates.

The balance equations are presented by Equation 3 and 4 for heat and pressure.

$$\left[\rho_S C_S - \left(C_a + \lambda_D\right)\frac{\partial w_d}{\partial T} - C_a\frac{\partial w}{\partial T}\right]\frac{\partial T}{\partial t} - \nabla.\left(q\right) = C_a\frac{\partial w}{\partial p}\frac{\partial p}{\partial t} \tag{3}$$

$$\frac{\partial w}{\partial p}\frac{\partial p}{\partial t} + \nabla.J = \left(\frac{\partial w_d}{\partial T} - \frac{\partial w}{\partial T}\right)\frac{\partial T}{\partial t} \tag{4}$$

where w = free water content; w_d = amount of chemically bound water released by heat increase ρ_s and C_s = density and isobaric heat capacity of the solid structure; C_a = heat of vaporisation of water; and λ_D = heat of dehydration of chemically bound water.

The temperature evolution of permeability is not easily described experimentally, thus curves from Bažant & Thonguthai (1978, 1979) are used. The sorption equations needed to characterise the free water content and the water released by dehydration have been described in Bažant & Thonguthai (1979) and Dwaikat & Kodur (2009). Those equations were implemented in Matlab to calculate the free water content and the water produced by dehydration and their derivatives according to temperature and pressure for various conditions of temperature and pressure. Other temperature-dependent material parameters were computed using Matlab. The result

of those computations was loaded in Comsol as interpolation functions, allowing reduced computation time.

The initial moisture content w_0 and initial permeability a_0 are of primary importance, governing the amount of free water in the concrete and its evolution through the pore system thereby affecting pressure. The former comes from the experimental work and the latter is estimated at $1{\cdot}10^{-13}$m/s regarding the compressive strength.

The boundary condition for heat takes into account both convection and radiation, as shown in Equation 5.

$$n.q = h\left(T_{amb} - T\right) + \varepsilon\sigma\left(T_{amb}^4 - T^4\right) \tag{5}$$

where h = heat transfer coefficient of concrete; ε = surface emissivity; σ = Stefan-Boltzmann constant; T = temperature just under the surface of concrete exposed to the environment; and T_{amb} = furnace temperature on the heated side and environment temperature on the other.

The boundary condition for pressure is set by ISO 834 to be 20 Pa inside the furnace for the duration of the test, and atmospheric pressure on the side of the sample exposed to the ambient air.

The time step for the simulations was chosen to be 1s, and the mesh contained 100 elements over the thickness.

From the computed pore pressure seen as hydrostatic stress in a spherical pore system, a preliminary tensile stress can be calculated to assess the spalling probability as described in a simple model by Ichikawa & England (2004). Considering the one-dimensional model as the heat and mass transfer through the thickness of a unit area plate, and the concrete as a new system of single-pore material surrounded by a solid matrix, allows calculating the pressure-induced tensile stress with the following Equation 6 (Ichikawa & England 2004)

$$\sigma_t = \frac{\left(1 + 2V_p\right)}{2\left(1 - V_p\right)} p \tag{6}$$

where σ_t = tensile stress; V_p = relative pore volume; and p = computed pore pressure.

The relative pore volume is calculated from the weight loss measurements on wet samples. Considered as initially fully saturated, they give a value of porosity of $V_p = 0.18$.

The values of pressure-induced tensile stress are computed and compared with the tensile strength found in wedge splitting test using inverse analysis performed within the scope of this research.

3 RESULTS

3.1 *Experimental results*

The results of the moisture content measurement in each tile are presented in Table 2.

Table 2. Moisture content of the fire tested tiles.

	Moisture content	
Tile ID	mass %	kg/m^3 of concrete
mW20.1	7,2	172
mW20.2	8,5	204
mW30.1	6,9	166
mW30.2	8,2	197
mD20.1	5,0	119
mD20.2	4,3	102
mD30.1	5,3	126
mD30.2	5,1	123

The two batches of the wet conditioning show different moisture content when the samples from the dry conditioning show consistent values.

The temperature distributions from the fire test are presented in Figure 2 where the plates are grouped by thickness. For each plate, the values from the three thermocouples embedded at the same depth are averaged. Thermocouples connection problems in the early phase of the recording of sample D30.1 caused measuring errors, making the results unreliable. The temperature distributions are very similar for both wet and dry conditioning, in the tendency of the curves as well as the values. A temperature plateau around 200°C is to be noticed on many curves, more pronounced for the samples with wet conditioning but still visible on some of the samples with dry conditioning. The temperature of this plateau occurred to be slightly lower for the 30 mm thick plates than for the 20 mm thick plates.

From the wet conditioning, the two plates with the highest moisture content (W20.2 in Figure 4b and W30.2) showed minor surface spalling (3 mm deep) between 7 and 10 min whereas the others did not spall as shown on Figure 4a. The spalling was distributed over the entire surface of the plates without specific location. W30.2 exhibited the most severe damage with respect to lost area when W20.2 showed slightly deeper cracks.

No plates stored according to the dry conditioning showed spalling.

3.2 *Numerical results*

Figure 3c shows numerical results when modelling sample W20.1. The other simulations are not shown but similar correlation between test and simulation is found in these.

The results from the temperature and pore pressure calculations are presented in Figure 3. The temperature curve (Figure 3a) shows a slope break at 200°C that corresponds to the release of chemically bound water. The temperature curves at given locations (Figure 3c) present this tendency as well, particularly closer to the outer surface. The pressure curves (Figure 3b) display a fast build up in the early time steps, reaching a maximum of 3.3 MPa at 1/2nd of the thickness at 13 min.

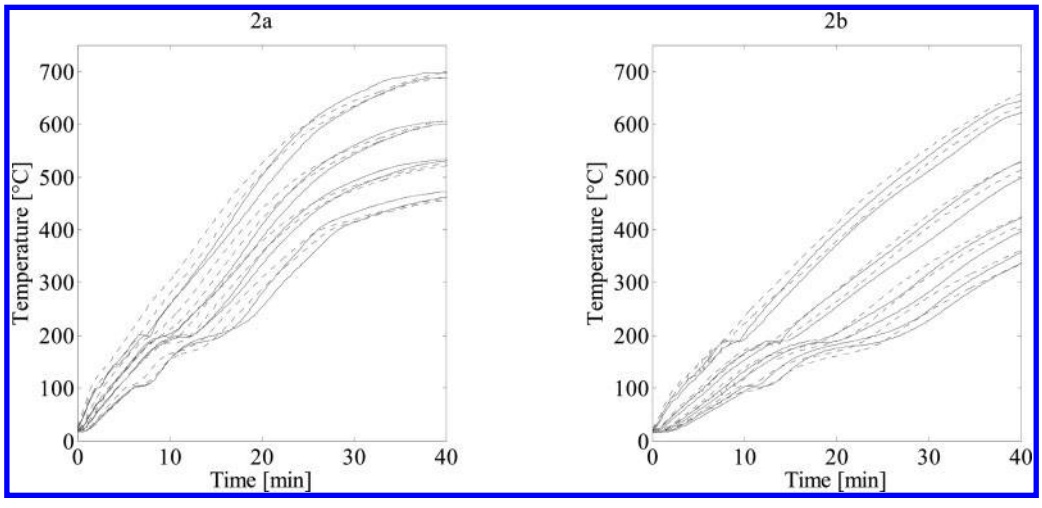

Figure 2. Temperature distributions from experiments for thickness 20 mm (1a) and 30 mm (1b) at 1/4th, 1/2nd, 3/4th of the thickness and on the surface (curves from top to bottom). Plain lines: wet conditioning. Dashed lines: dry conditioning.

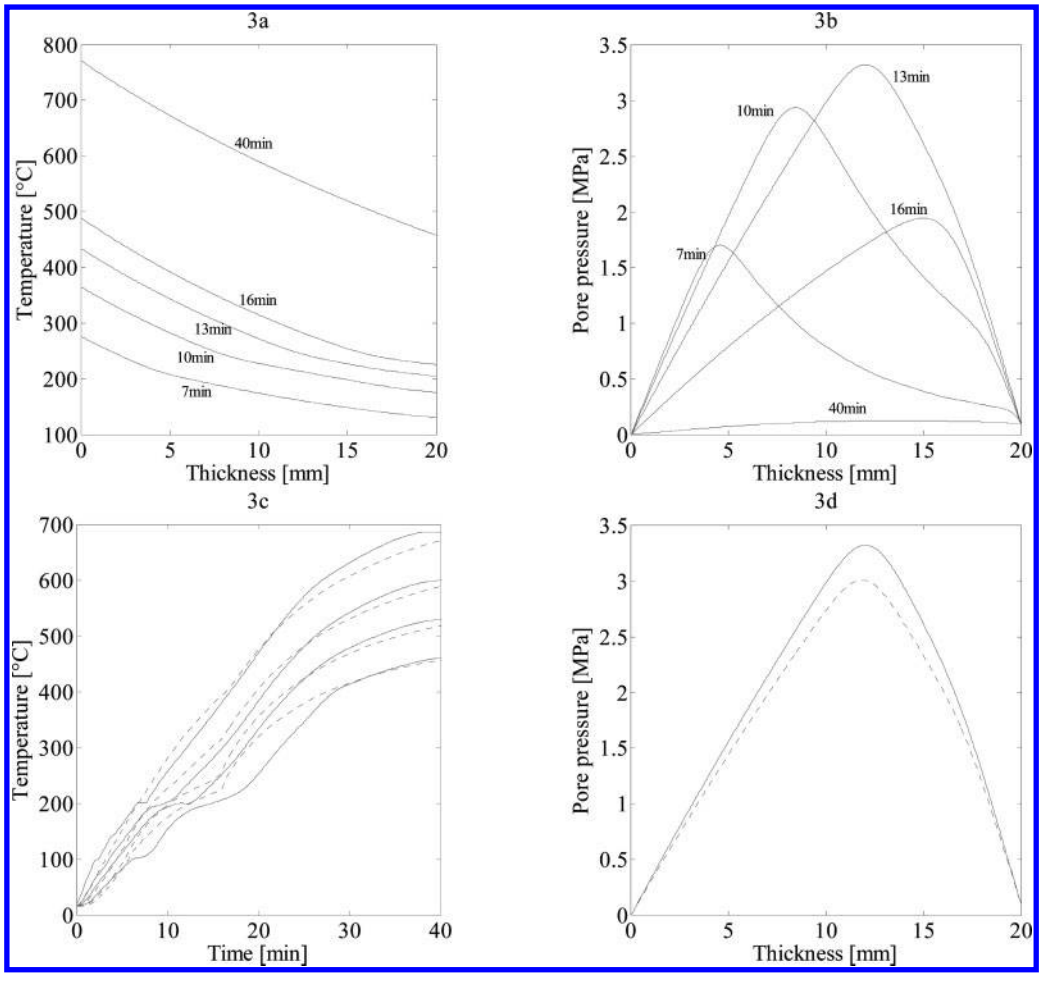

Figure 3. Numerical results for W20.1. Temperature over the thickness (3a).Pressure over the thickness (3b).Temperature over time (3c) with experimental results (plain lines) and numerical results (dashed lines). Max pressure for wet and dry sample W20.1 and D20.1 respectively plain and dashed line (3d).

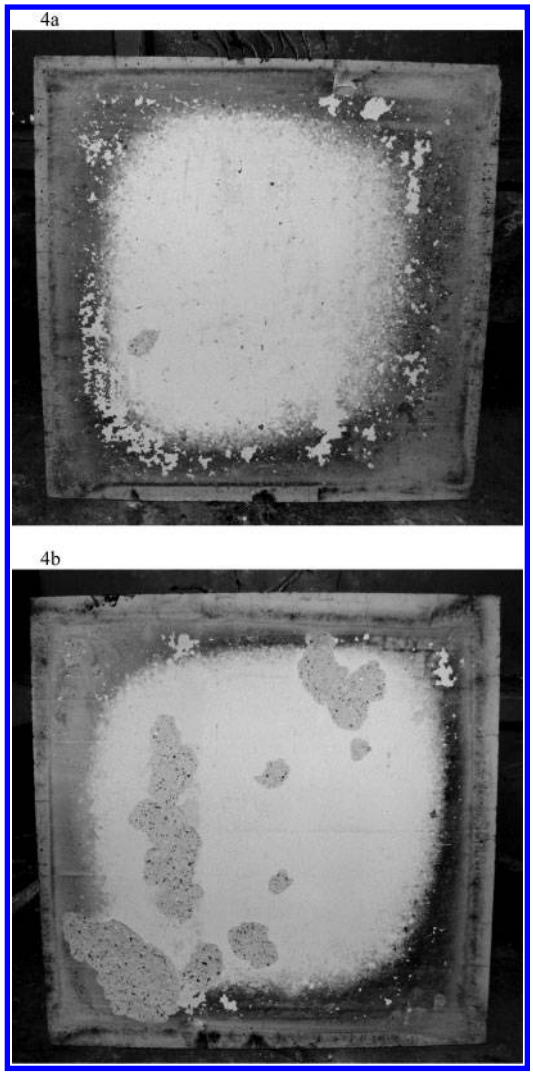

Figure 4. Results of the fire test on specimen W20.1 (4a) and W20.2 (4b)

A gradual decrease follows until pressure equilibrium at the end of the 40 minutes of testing.

Figure 2d presents a comparison of maximum pressures for W20.1 and D20.1. The dry sample experiences a lower maximum pressure at similar to the wet sample. The pressure difference remains small.

For the maximum pressure of 3.3 MPa and the pore volume calculated in Section 2.2, the pressure-induced tensile stress is found to be 2.7 MPa which remains below the allowable 5 MPa tensile strength.

4 DISCUSSION

The experimental data and behaviour of the test specimens tend to confirm that initial moisture content plays a critical role in the spalling phenomenon. The slight 30 kg (1.3%) difference in moisture content (Table 2) between the wet specimens and the fact that no dry specimens spalled suggest the existence of a moisture threshold for a given concrete type. Special care should be given to respect mix proportions during casting. No significant difference was noticed between the behaviours of 20 mm and 30 mm plates.

However, the output of the modelling work shows that pore pressure in this particular case does not suffice to trigger any cracks or spalling in the thin plates for any moisture content. According to the tendency of the pressure curves in Figure 3b, the sample dries out fast, explaining the pressure decay and moisture moves inwards to build a maximum pressure past half the thickness. Previous experiments carried out on thicker samples showed spalling at depths of 20 mm or more (Kalifa et al. 2000) which corresponds to the thickness of the plates considered here. In the case of thin plates, even for high initial water contents, the absolute amount of water is too low and cannot gather sufficiently to build up in high pressure. Hence the result of computed tensile stress from pore pressure of only 2.7 MPa. The time of spalling between 7 min and 10 min confirms this hypothesis since the maximum pressure is reached at 13 min. If this mechanism only were to lead to material failure, the pore pressure would have to be of 6 MPa which is reached in thicker profiles according to Ichikawa & England (2004).

Since the specimens spalled only on 3 mm, thermal stresses play a major role in the behaviour of the plates. It is then assumed that thermal stresses use a fair part of the tensile strength and a slight moisture content increase would create a sufficient pressure to induce total stresses comparable to the tensile resistance. Thermal stresses caused by thermal gradients have to be investigated further, considering that the geometry of the plate carrying the samples above the furnace might introduce large radiation differences on the edge of the specimens.

The pressure predictions of previously proposed models vary widely from 1 MPa up to 16 MPa (Tenchev et al. 2001) and few measurements were successfully performed. The pressures predicted by the present model enter this range and show likely tendency when compared to the output of early time steps in Tenchev et al. (2001).

To fit the test data, only the concrete thermal properties have been adapted since they were not recorded experimentally. The thermal conductivity equation from the standard prEN 1992-1-2 and a heat transfer coefficient of 40 W/(m^2.K) are used. With those parameters, the proposed model shows a good agreement with the temperature curves within concrete for wet and dry samples in both thicknesses as shown in Figure 3c. The temperature plateaus seen at 200°C correspond to the release of water by dehydration. At the interface with ambient air, experimental and numerical results differ largely (Figure 3c). The temperature plateaus at 100°C and 200°C on the experimental curves at the boundary (Figure 1a) describe the presence of large amounts of liquid water changing phase.

This water was not taken into account in the boundary conditions. Moreover, the glue fixing the thermocouples on the surface of the plates may influence the recording. Those two parameters explain the observed differences.

Despite the good agreement with test data, the model requires comparison with another kind of concrete with different composition, compactness, compressive strength and a known composition for final validation. The thermal properties of the concrete should be investigated as well. An experimental program in that sense is currently developed.

5 CONCLUSION

Preliminary test data from an experimental program on the fire resistance of HPC thin plates are presented, as a first step in the assessment of the possibility to use such profiles in sandwich elements. The influence of the initial water content on the spalling behaviour of HPC thin plates showed the existence of a threshold inviting to a careful respect of mix proportions when casting. Samples with thicknesses of 20 mm and 30 mm behaved similarly.

A coupled model for the time dependent distributions of temperature and pressure for HPC thin plates was presented and compared to the experimental data. The temperature profiles proved in good agreement and the predicted pressure within the range of published literature. The computed pressure was too low to be the only trigger to the spalling seen on some of the plates. Thermal stresses are assumed to use a significant amount of the tensile resistance which would not hold the extra pressure created by an increase in moisture content.

For further investigations concerning sandwich elements, the size effect should be considered with larger profiles. The delicate issue of loaded bearing structure should be carefully examined as external solicitations can significantly raise the inner stresses leading to complete material failure.

ACKNOWLEDGEMENTS

The authors are grateful for the support of Connovate, who provided the test specimens and the Dansk Brand ogsikringstekniskInstitue (DBI) for performing the fire tests.

Micro structural optimization of high strength performance air hardened foam concrete

Bernhard Middendorf
University Kassel, Department of Construction Materials and Building Chemistry, Germany

Armin Just
EBZ Business School, University of Applied Science, Department of Building Technology, Bochum, Germany

ABSTRACT: In present-day constructions any building material fulfils its specific task. Concrete is mainly used for load transfer but it does not achieve thermal insulation properties. For heat insulation, highly porous materials with low density is necessary. Mixed constructions have energetic disadvantages because different composed building materials must be produced, assembled and also, finally, have to be recycled. An advantage of multifunctional building materials is that one building material can fulfil different tasks. A new type of foam concrete was developed by combination of chemical foaming with aluminium powder and air hardening. Compared to autoclaved aerated foam concretes the manufacturing of this new type of foam concrete consumes less energy and the production is not stationary. The new foam concrete combines high thermal insulating properties with high strength. The micro structural optimization of this foam matrix is based on the same approaches which were already developed for HPC and UHPC.

1 INTRODUCTION

Buildings require energy during any period of their life cycle. The energy consumption starts with the production of the building materials and the construction of the buildings. After that the use and operation of buildings need energy as well. Finally there is also energy required for the deconstruction of a building.

The paper deals with the benefits of multifunctional building materials. With present-day construction, any building material fulfils its specific task. Steel and concrete are used for load transfer but they do not achieve thermal insulation properties. For heat insulation, highly porous materials like foams are necessary. Such complex constructions have energetic disadvantages because different building materials and components must be produced, assembled and also, finally, have to be disposed of or recycled. One advantage of multifunctional building materials is that one component and of course one material can fulfil different tasks in a modern building.

High strength mineral bound foam is such a multifunctional building material. These fine grained foam concretes have a density ≤ 2.0 g/cm^3 and are classified as lightweight concretes. Some of them are applicable for load bearing constructions with thermal insulation properties at the same time. Thereby the use of this class of building materials requires less energy and supports the establishment of sustainable construction.

The process of forming air voids in the fresh foam concrete paste is significant. The methods of chemical expansion, as well as physical or mechanical foaming are well known and state of the art. Autoclaved aerated concrete can be based on a paste with finely grounded, quartzitic sand, cement and lime and water where a foaming agent, commonly aluminium powder, is added. The set material is cured after being removed from its mould in a saturated steam atmosphere in autoclaves at high pressure within a few hours and thereby receives its final properties (Homan, 2008).

Foam concretes are given their structure by using foam generators or stirring up the cement paste using foaming agents and fast rotating pug mill mixers. The paste consists of the binder, usually cement, finely grounded quartzitic sand, water and foam generating admixtures. After moulding the foam, the concrete hardens under normal atmospheric conditions. During the mechanical foaming procedure, a foam agent is added to the mortar. Numerous voids are mechanically introduced by high speed mixers. A relatively unstable foam develops with an irregular structure and undefined void structures. In practice, a more usual manufacturing method is physical foaming. A premanufactured foam consisting of water and chemical admixture is mixed with the additional components. Under these conditions, a more stable mortar with a fine pore structure can be created (Readymix 1978).

In addition to the two established representatives of mineral bound foams, the possibility to produce chemically expanded, air cured, mineral bound foams, with mechanical properties which allow their use as construction material has been established recently

Table 1. Basic materials used for the production of chemical expanded and air hardened foam concretes.

binder	
cement	CEM I 42.5 R
additives	
aluminium powder	I (average. Ø 60–70 µm)
	II (average. Ø 20–30 µm)
	III (average. Ø 15–20 µm)
	IV(average .Ø 15 µm)
plasticizer	PCE
admixtures	
microsilica	suspension

(Just, 2008, Just & Middendorf 2009, 2010, 2011). The physical mechanical properties of these air cured foams – like density, compressive strength and thermal conductivity – are partially superior to the conventional cellular concretes hardened in autoclaves. This type of foam concrete hardens without using an autoclave and therefore without the need of additional production energy. Thus it makes the further development of this innovative foam concrete ecologically worthwhile.

2 MATERIALS AND METHODS

The studies on chemical expanded and air hardened foam concretes were made by using a cement paste without aggregates. In part, admixtures and additives were added. In table 1 the used raw materials for the production of paste mixtures are listed.

CEM I 42.5 R according to EN 197-1 (2004) was used as binder. By using different grain sizes of the aluminum powder, the air void distribution in the hardened material was controllable, whereas the air void volume was adjusted by the total quantity of the aluminum powder.

The water/cement ratio (w/c) has a crucial influence on the increase of volume of the cement paste during expansion. In order to ensure an expansion in cement pastes with a low water volume, the introduction of superplasticizers on the basis of polycarboxylatether was necessary.

The structure of the hardened cement paste matrix was also optimized by using microsilica suspension.

The samples were examined by means of light microscopy with an associated digital image analysis, scanning electron microscopy as well as by mercury intrusion porosity.

For example figure 1 shows a chemical expanded air hardened foam concrete sample with a density of 0.85 kg/dm^3 and a compressive strength of approx. 10 MPa.

2.1 *Digital image analysis*

For structural examination of foam concrete digital image analysis were used for the investigation of air voids in cross sections. In the first step the sample were saturated with coloured epoxy resin. After hardening of the epoxy resin polished cross section were prepared. The digital image analysis detects air voids by means of differences of contrast between the cement paste matrix and the air voids which are filled with the coloured epoxy resin. The properties of the air voids are determined by analysing polished cross sections by means of light microscopy for each individual air void.

Figure 1. Chemical expanded and air hardened foam concrete sample.

For the investigations the digital image analysing software Omnimet by Buehler GmbH and a light microscope by Zeiss were used.

2.2 *Scanning electron microscopy (SEM)*

SEM images were acquired using a Philips XL30i scanning electron microscope. Imaging was performed in high vacuum with the application of a conductive coating based on carbon and/or gold.

2.3 *Mercury intrusion porosimetry (MIP)*

For the determination of the porosity and the pore size distribution a mercury intrusion porosimeter was used. Therefore the samples were first dried. After this the samples were put into a dilatometer which was afterwards filled with mercury up to a pressure of 200 MPa. Therewith pore radii to 4 nm could be determined. A mercury intrusion porosimeter type Pascal 140–240 by Porotec was used for the investigations.

3 RESULTS AND DISCUSSION

3.1 *Microstructure*

The structure of the hardened cement paste implies the spatial arrangement of the reaction products and the partly unfilled or filled areas with an aqueous solution: the pores. The pore area is composed in its entirety by the gel pores, the capillary pores and the air voids. The existing gel and capillary porosity are primarily responsible for the characteristics of the microstructure. Regarding the optimization of this structure of air hardened foam concretes, the same basic approaches maintain their validity for mineral bound foams, as they were already developed for high performance concrete (HPC) or even for ultra high performance

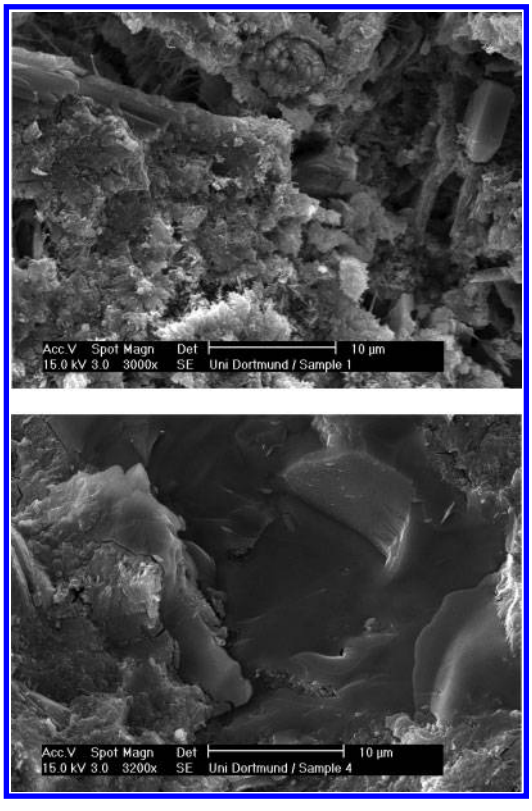

Figure 2. Microstructure of two foam concretes; top: w/c ratio = 0.60, without microsilica; down: w/c ratio = 0.35, 0.85 wt.% PCE, 10 wt.% microsilica.

concrete (UHPC) (Bornemann et al. 2001, de Larrad & Sedran 2002, de Larrad 1989, Richter 1999, Cwirzen et al. 2008).

The influence of the reduction of the w/c ratio and the simultaneous use of microsilica solidify and consolidate the microstructure of the hardened cement paste matrix. In figure 2a hardened cement paste is represented (top), which was manufactured without additives and admixtures and with a w/c ratio of 0.60. Figure 2 (down) illustrates a foam concrete, which is manufactured with a w/c ratio of 0.35 and the use of superplasticizers as well as microsilica. A clearly more consolidated and thus firmer structure is identifiable. This structure of the foam concretes' cement paste matrix is comparable with the dense structure of a HPC or UHPC. Usual for the production of UHPCs w/c ratios less than 0.20 are typical. This low w/c ratio is not applicable for mineral-bound foams. The approach taken by UHPC technology for improving the hardened cement paste structure often make the generation of an arranged air void area more difficult even by using superplasticizers. The lower limit for w/c ratio of chemically expanded, air hardened, mineral bound foams is 0.28 (Just 2008). Of course this sets limits to the properties of the structural optimized foams.

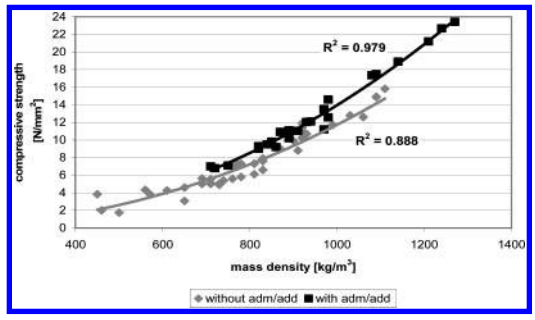

Figure 3. Compressive strengths as a function of the density with and without the usage of admixtures (adm) and additives (add).

Figure 3 clearly shows the influence of the selected structure optimizing methods by comparing more than 100 foam concretes which differ in their compositions. The trend line of the foam concretes, which were prepared by using additives and admixtures, is clearly above the trend line of the foam concrete mixtures which were produced only with cement, water and aluminum. The increase in compressive strength depends on the mass density which is illustrated in figure 3. The use of admixtures and additives increase the compressive strength by approximately 20%. The same methods for the improvement of the structure have a significantly larger influence on the properties of pure hardened cement pastes, which were manufactured without foaming agents.

3.2 *Structure of air voids*

The content and the distribution of air voids are responsible for the increase of compressive strength on air hardened foam concretes. By optimization of the microstructure a higher strength increase should be accessible.

Getting a detailed view of the structure of the porosity of the air voids, the results of three selected sample mixtures are examined and compared to each other. Sample A does solely consist of water, cement and aluminium powder. This three-substance-system is extended by a superplasticizer in sample B. In sample C the mineral-bound foam represents a five-substance-system consisting of water, cement, aluminium powder, superplasticizer and microsilica. Thereby the microstructure of the hardened cement paste of specimen C is comparable with the microstructure of HPC.

Although the composition of the single samples differentiate extremely, density and compressive strength are very similar. The compressive strength has values between 10.9 and 12.0 MPa with densities of 0.92 and 0.93 kg/dm^3. The compositions and the properties of the selected mixtures are shown in table 2.

The shape and the size distribution of the air voids are responsible for the properties of the hardened foam concrete. The structural differences within the air voids become clear when examining the roundness of the

Table 2. Recipes and properties of selected sample mixtures.

sample	w/c ratio	Al powder [wt.%]	micro-silica [wt.%]	super-plasticizer [wt.%]	density [kg/dm^3]	comp. strength [MPa]
A	0.60	0.05	0	0	0.92	11.9
B	0.40	0.08	0	0.04	0.92	10.9
C	0.40	0.10	10	0.85	0.93	12.0

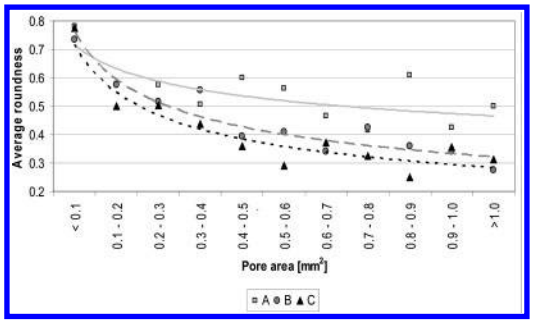

Figure 4. Average roundness of different air void classes of the three selected specimens.

pores. The roundness of all examined samples tends to decrease with rising pore sizes (Figure 4).

For all samples the roundness of the pores with a surface $<0.1\,mm^2$ is very similar. The roundness has values from 0.74 to 0.78 and has the least deviation from the cross section of all classes. Since these pores develop in all cases similarly, their influence on compressive strength must take place via the pores with an area larger than $1.0\,mm^2$. The roundness of the air voids of the class $>1.0\,mm^2$ ranges between 0.50 for sample A to 0.27 for sample B. These differences are justified in the consistency of the fresh paste. The high water content of the sample A permits the production of a foam with the dry bulk density of $0.92\,kg/dm^3$ when using an aluminium powder content of 0.05 wt.%. The remaining samples represented here reach this dry bulk density only with an accordingly higher aluminium ratio of 0.08 and 0.10 wt.%. This means that the roundness of the air voids decreases when the generation of gas bubbles is obstructed by stiffer fresh paste consistency. This change to the air voids finally results in a reduction of the compressive strength when comparing the samples A with B and C because the hardened cement paste matrix solidified due to the reduced w/c ratio and due to the use of admixtures and additives, as shown in (Just & Middendorf 2008).

The most important results can also be derived qualitatively from figure 5. With a high performance microstructure, that means with decreasing w/c ratios and simultaneous use of microsilica and superplasticizer, the average diameter of the air voids decreases and the number of inconsistently formed

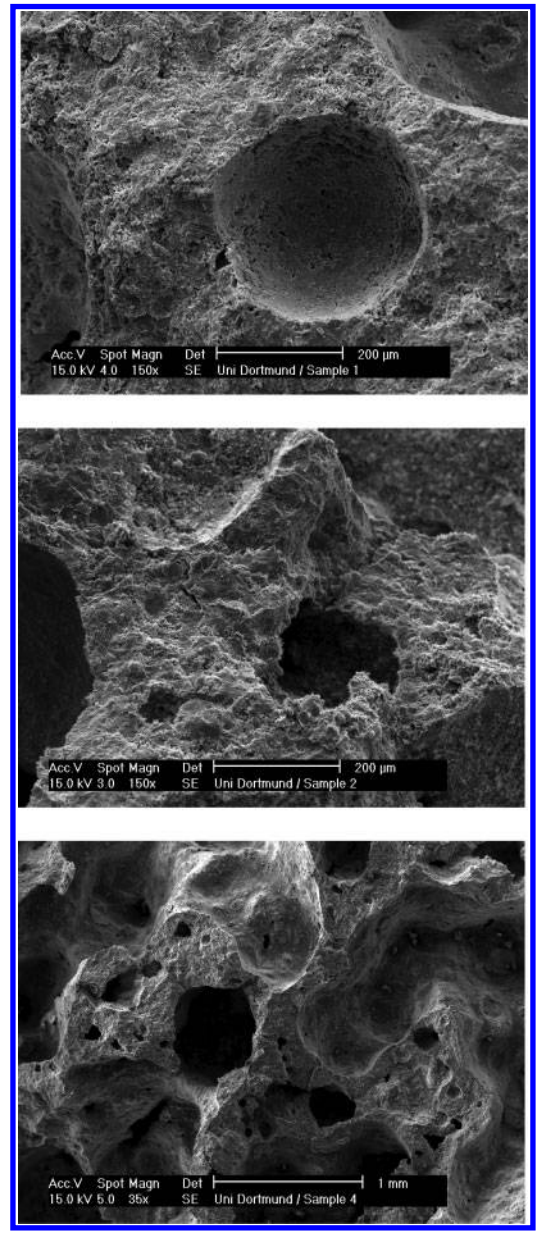

Figure 5. SEM pictures (different magnifications) of air voids in foam concretes: top: w/c ratio = 0.60, no microsilica, no superplasticizer; middle: w/c ratio = 0.40, no microsilica, 0.04 wt.% superplasticizer; down: w/c ratio = 0.40, 10 wt.% microsilica, 0.85 wt.% superplasticizer.

pores increases. This is because a stiffer fresh paste consistence requires a higher amount of aluminium for the same densities compared with less stiff consistences. Furthermore, the quantity of irregularly formed pores increases considerably. The smaller the diameter of the pores are, the more regularly they are formed. Regularly formed air voids, however, increase the compressive strength with comparable densities.

4 CONCLUSIONS

It is technically possible to manufacture chemically expanded, air cured, high performance mineral bound foams, which can be used for load bearing structures. These foams are sustainable and multifunctional because of the combination of high strength and high thermal insulating properties.

The properties of HPC and UHPC mineral bound foams can be improved by the specific use of microsilica as well as superplasticizer. The reduction of the w/c ratio and the simultaneous use of microsilica lead to a optimized cement paste matrix and a stiffer consistency. To get a processible consistency the use of a PCE superplasticizer is necessary. The microstructure of high performance foam concretes is largely comparable with the microstructure of HPCs or UHPCs. Furthermore the consistency of the stiff paste is influenced by the use of superplasticizer in such a way, that the growing of unequally shaped air voids, which occur during the chemical expansion, is encouraged. These unequally shaped air voids negatively affect the properties (e.g. compressive strength) of the hardened foam concrete, because the load transmission within the cement paste matrix is disturbed. The more superplasticizer is used the more irregularly formed air voids occur. It was observed that the size of the air voids plays a decisive role. The bigger the air voids the more irregularities occur.

It can be stated that optimized air hardened foam concretes, which should have increased compressive strengths, must be adjusted in such a way that they preferably possess as few air voids as possible, with a cross section area of $>1.0\,mm^2$. Independent of the paste composition, air voids with a cross section area $<0.1\,mm^2$ are consistently formed.

The anchorage of rebars in UHPC

P. Lorenz & E. Fehling
University of Kassel, Kassel, Germany

ABSTRACT: Test-series were conducted to determine the influence of the main parameters for the bond-behavior of rebars in UHPC with small concrete covers and small bond lengths. To get basic information for the development of design rules for anchorage of rebars in UHPC, test results from specimens with parameter combinations of concrete cover and bond lengths were used which lead to splitting failure. By comparing test results and results from analytical back analysis as well as from back analysis using a non linear finite element model, bond stress-slip relations could be derived covering both ULS as well as SLS (slip s < 0.4 mm) situations.

1 INTRODUCTION

Ultra high performance concrete (UHPC) exhibits values of compressive strengths over or near to 200 MPa, which enables reducing cross sections and the use of less material and energy resources. In terms of reinforcement corrosion, the high packing density and the high resistance against ingress of fluids and gases allows markedly smaller concrete covers. At the same time, minimum concrete cover requirements must be observed in order to ensure adequate bond behavior and anchorage.

Therefore, systematic studies of the bond behavior of non-prestressed steel reinforcement in UHP(FR)C are necessary, regarding the relationship between anchorage length and concrete cover.

For normal strength and high strength concrete, the bond behavior of non-prestressed reinforcement is well described in fib (2000) or in fib (2012) regarding the different types of bond failure like splitting or pull-out. However, for ultra high performance concrete, there is currently no comparable publication. Considering this, different test series were carried out.

2 PULL-OUT TESTS

RILEM test specimens were used to study the pull out failure. Due to the high bond strength of UHPC, the ratio between bond length and rebar diameter was reduced to $l_b/d_s = 1.5$ (see Fig. 1). The bond strength was calculated by dividing the force through the bond length and perimeter of the rebar. The slip was measured at the unloaded side. After the test the specimens were split to check the bond length.

The results in Figure 1 show that the bond strength corresponds to a steel stress near to the yield strength. Due to the high concrete cover of 4.5 d_s all three tests had a pull out bonding failure. Splitting did not occur. These results cannot be applied universally to all anchorage types. The bond behavior, particularly the bond strength, depends on the confining action of the concrete surrounding the rebar. Hence, the failure mechanism is decisive.

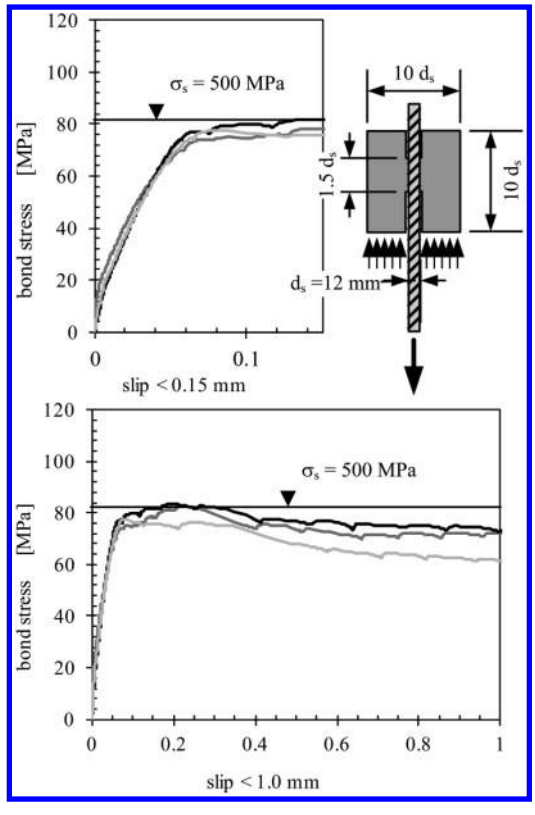

Figure 1. Pull out test results.

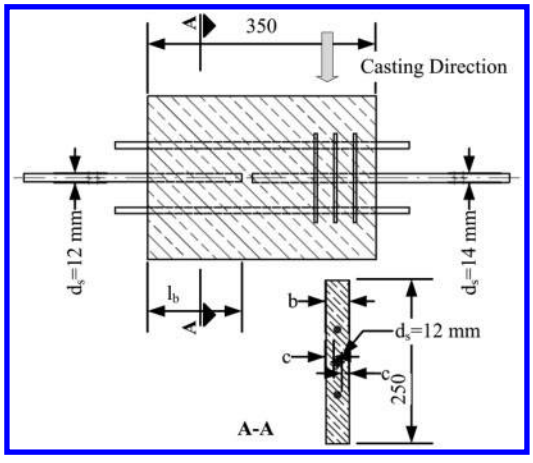

Figure 2. Test specimens regarding different bond length l_b and concrete cover c.

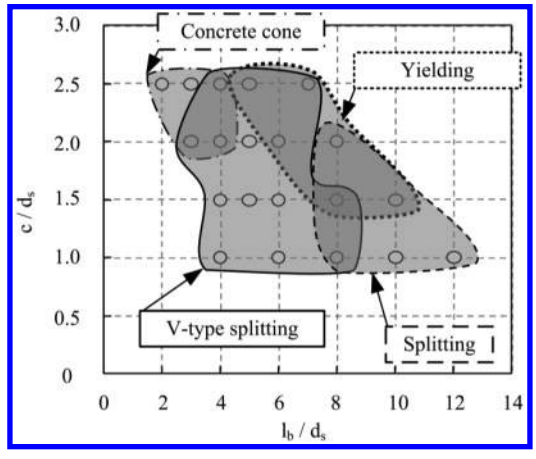

Figure 3. Examined parameters l_b and c with observed failure modes (for details see (Lorenz & Fehling 2012a)).

3 ANCHORAGE TESTS WITH SPLITTING

To consider different failure types, further test series were performed using a panel with constant length and width (see Fig. 2). Each panel contained a ribbed bar with $f_y = 500$ MPa, a diameter of $d_s = 12$ mm, an embedded length l_b, and a concrete cover c. Varying the concrete cover and bond length specimens were fabricated.

A steel fiber reinforced, fine grained UHPC M3Q from DFG (2013) with a fiber content of 1.5% by vol. ($l_f/d_f = 13$ mm/0.19 mm = 68.4) and a compressive strength of 170 MN/m^2 was used for all specimens. Details can be seen in (Lorenz & Fehling 2012a). Figure 3 shows the different observed failure modes for the examined combinations of c and l_b.

In cases of concrete cone failure (see Fig. 3) for the concrete cover $c = 2.5d_s$ and $c = 2.0d_s$ the maximum bond stress (see Fig. 5) shall be regarded with caution, since there was no bonding failure between the ribs of the rebar and the concrete. Instead, tensile failure occurred between the concrete cone and the remaining concrete.

In cases of v-type splitting, splitting and yielding, bond failure occurred, but it was strongly influenced by the degree of confinement by the surrounded concrete i.e. of the concrete cover and the post cracking behavior of UHPFRC.

4 ANALYTICAL BACK ANALYSIS

In (Lorenz & Fehling 2012b) an analytical model was described and a back analysis was presented. To verify the model, the test specimens were used which were presented in the section above. Only tests were considered where no plastic strains were measured and no concrete cone failure occurred. For the the local bond stress-slip law, a linear approach (see Fig. 6) was chosen. Using the known values of slip on both sides and of strain on the loaded side as well as the equilibrium

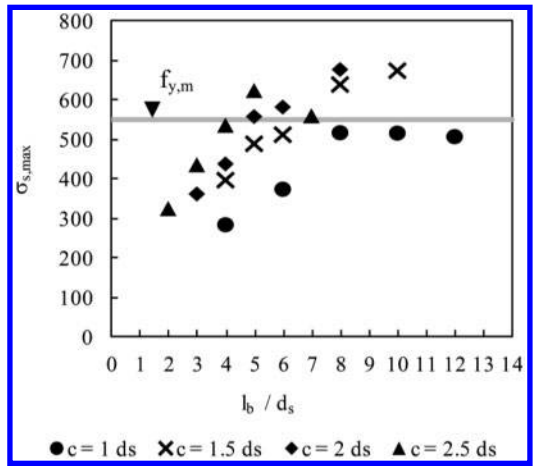

Figure 4. Maximum steel stresses ($\sigma_{s,max} = F_{max}/A_s$) in a relationship to concrete cover c and bond length l_b.

condition that stress and strain at the end of the bond length l_b should be zero, the unknown values $\tau_{u,BA}$ and $s_{u,BA}$ for the linear bond stress-slip law could be determined iteratively using data of all loading steps. This procedure was performed for all above mentioned tests, i.e. parameter combinations of c and l_b.

In Figure 7 the determined local bond stress-slip relations are shown for parameter combinations of $c \leq 1.5\ d_s$ and $l_b \leq 8\ d_s$.

For $c = 2.0d_s$ no bond slip relations were established due to the concrete cone failure mode. Here a large portion of the measured loaded end slip resulted from the crack opening behind the concrete cone.

These bond stress-slip laws are valid for large slips i.e. for slips much higher than 0.4 mm. For smaller values of slip, not only the bond stress-slip relation obtained by using the results from pull-out test (see Fig. 1) can be used. Additional considerations are necessary.

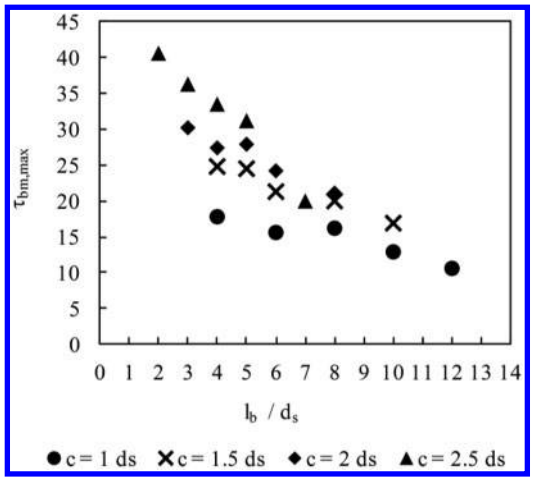

Figure 5. Maximum bond stresses ($\tau_{bm,max} = F_{max}/A_{lb}$) in a relationship to concrete cover c and bond length l_b ($A_{lb} = d_s \pi l_b$).

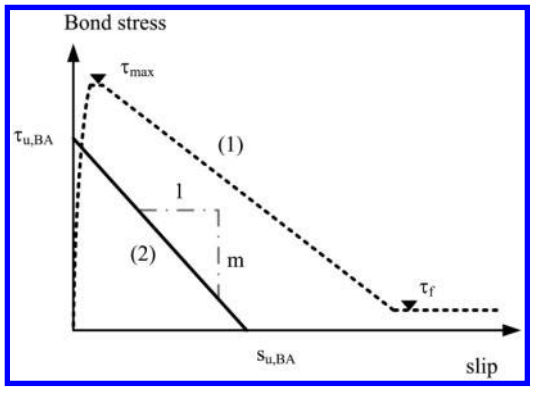

Figure 6. Linear approach (2) for the local bond stress slip-law in case of splitting failure and the approach for pull out failure (1) according to fib (2012).

5 BACK ANALYSIS USING NON LINEAR FINITE ELEMENT METHOD

Based on a non linear finite element model using ATENA 2D software, as described in (Červenka & Červenka 2012), it was possible to perform a back analysis based on the test results which were mentioned in the third section.

Due to symmetry, only a quarter of the specimen was modeled in ATENA 2D. For relevant combinations of concrete cover and bond length an FE-model was used for the calculations. The following mechanical values were used for the materials steel reinforcement and concrete.

5.1 *Iterative process to find a sufficient law*

The loading was applied in a displacement-controlled way. The slip was measured in the same way as during the real tests. For the back analysis, an iterative procedure was necessary. To start the iteration, an assumption for the bond relation was chosen based on the pull out tests in section 2 and the results as presented in section 4.

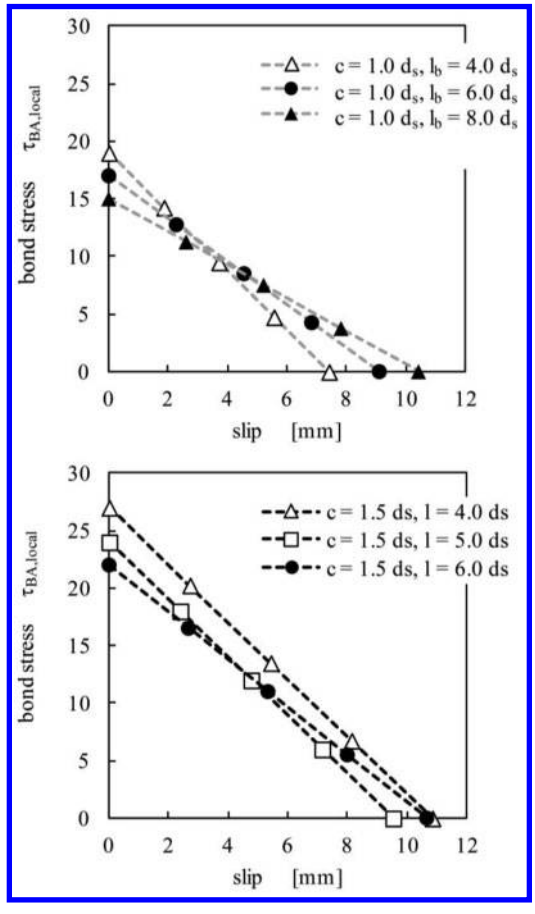

Figure 7. Determined linear bond stress slip laws for a rebar with $f_y = 500$ MPa and $d_s = 12$ mm embedded in UHPFRC M3Q from (DFG 2013) with 1.5% by vol. $l_f/d_f = 68.4$.

strain mm/m	compressive stress –
0.0	1.0 f_c
−0.178	0.0 f_c

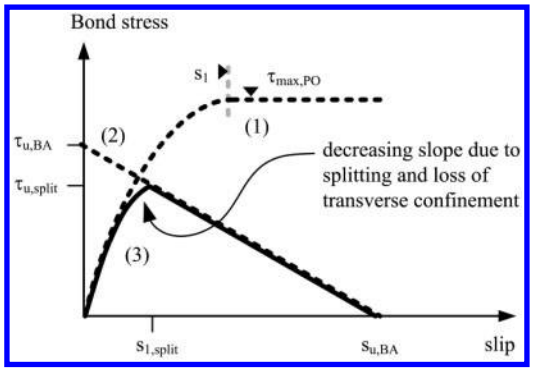

Figure 8. Proceeding in defining the bond stress-slip law for the finite element analysis. (1) represents the approximation for pull out test. (2) represents the analytical back analysis results and (3) represents the chosen bond stress-slip relation for the first iteration.

After a first calculation the output values i.e. the slip and the stress at the loaded side were compared to the values of the test results for different load steps. If there was no sufficient match, the assumed bond relation was changed. Then a new calculation was started and the results were compared again to decide if another change of the bond model was necessary. This procedure was repeated until there was a sufficient match between the FEM results and the test results (see Fig. 9).

For NSC and HSC in (fib 2000) it is shown that after the chemical adhesion is lost, a reduced slope in the ascending branch of the bond stress-slip relationship appears, depending on the presence of a transverse confinement (see Fig. 8). This transverse confinement can be the transverse reinforcement or the tensile UHPFRC ring which balances the compression struts around the rips of the rebar.

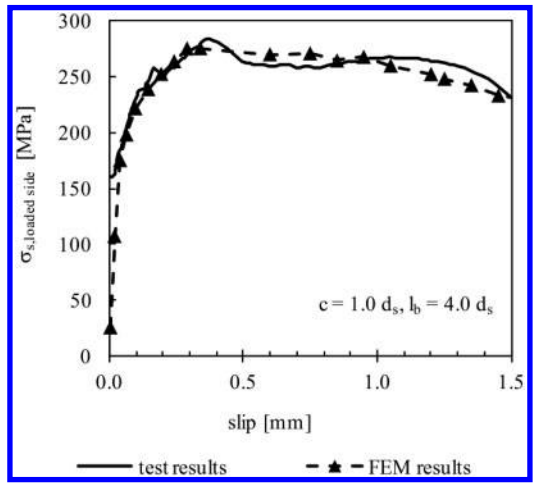

Figure 9. Sufficient match between test results and FEM results after iterative searching of the bond stress-slip law for a test specimen with $c = 1.0\ d_s$ and $l_b = 4.0\ d_s$.

This phenomenon could be confirmed with the FEM back analysis. During the process of the iterative solution, it was necessary to change the slope after loss of chemical adhesion. In Figs. 10 to 12, the results of the analytical back analysis are shown together with the approximation for the pull out tests results. In addition, the derived bond stress slip relationships are plotted.

One can see that for small bond stresses there is a very stiff bond behavior due to adhesion. After the chemical adhesion breaks down, the "bond – law" leaves the path of the approximation for the pull out tests. The gradient of the path goes down but the bond stress grows with growing slip until the path reaches the line of the analytical solution.

5.2 *Discussion of the results*

From the Figures 10 and 11 one can see that the chemical adhesion in the derived bond stress-slip relationships is between 3 MPa and 12 MPa. The slip $s_{1,split}$ where the path of the derived bond law reaches the line of the analytical solution is between 0.05 mm and 0.35 mm. To describe this path, an equation according to (fib 2012) may be used.

$$\tau_b = \tau_{u,split} \cdot \left(\frac{s}{s_{1,split}} \right)^{\alpha} \tag{1}$$

Here, $\tau_{u,split}$ is the maximum bond stress and $s_{1,split}$ the slip where the derived bond law path reaches the line of the analytical solution, i.e. where the maximum bond stress $\tau_{u,split}$ occurs (see also Fig. 8). For the exponential behavior in Eq. 1 a good approximation can be achieved with a value of $\alpha = 0.2$.

For larger slip values than $s_{1,split}$, the solution from the analytical back analysis remains valid. The slip at the end of the descending branch, i.e. where the bond stress becomes zero, can be seen in Figure 7. For

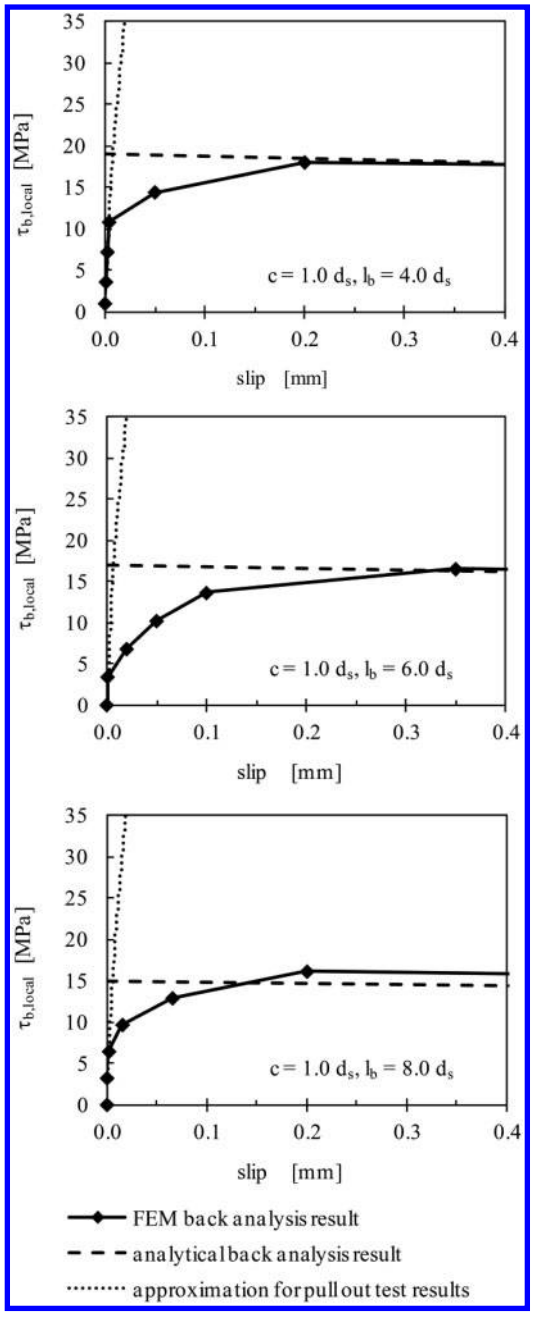

Figure 10. Derived bond stress slip-law for the test specimen with $c = 1.0\ d_s$ and $l_b = 4.0$, 6.0 and 8.0 d_s for $s \leq 0.4$ mm.

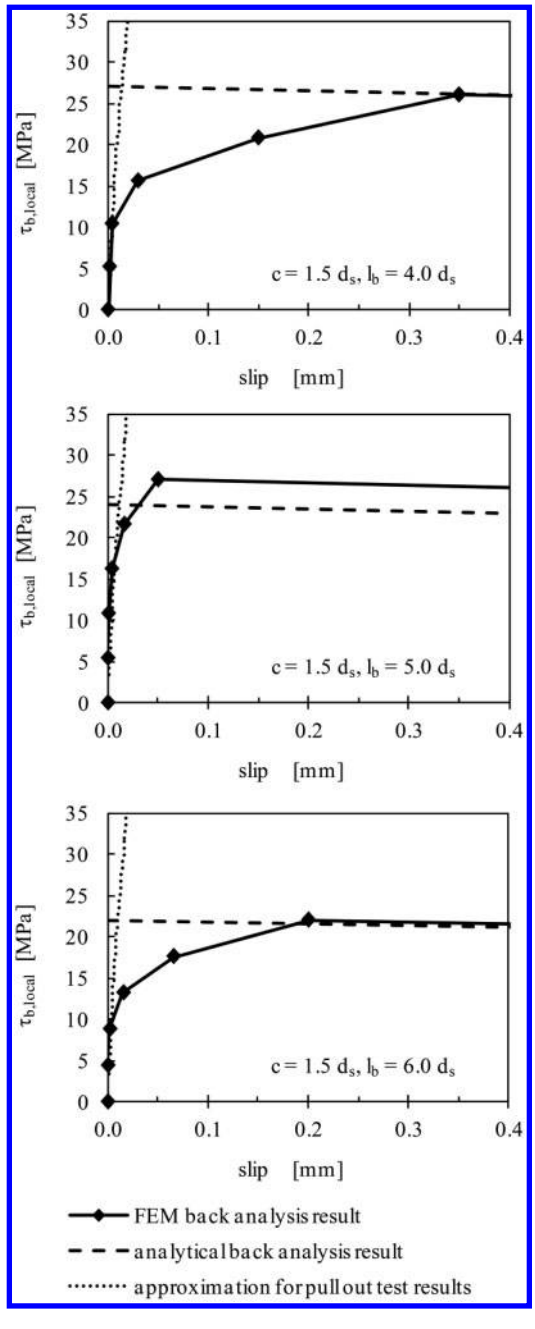

Figure 11. Derived bond stress slip-law for the test specimen with $c = 1.5\ d_s$ and $l_b = 4.0$, 5.0 and 6.0 d_s for $s \leq 0.4$ mm.

concrete cover $c \leq 1.5\ d_s$ the slip appeared between 8 mm and 11 mm.

6 CONCLUSIONS

The bond and anchorage behavior of rebars in UHPC has been studied experimentally. The combination of the described analytical and numerical back-analysis approaches enabled to derive bond stress-slip relationships.

It is well known that the bond behavior is affected by many parameters. Most important, however, it is to delineate between the different failure types.

Prior to pull out failure, the concrete around the ribs can resist high bond stresses. The pull out failure can

only be achieved, if due to transverse confinement the tensile ring which balances the struts around the ribs does not fail. If it fails and the splitting cracks propagate through the concrete over to the surface, the bond strength decreases linearly as described in fib (2012). If the splitting cracks do not propagate to concrete surface, the path of the bond-slip relation leaves the curve valid for pull out failure and approaches the curve valid for splitting failure.

In the consequence, the bond stress-slip law for concrete failure types v-type splitting and splitting and for concrete covers less than $c = 1.5\ d_s$ can be described by two parts. In the first part an exponential function (see Eq. 1) can be used for slip values $s \leq s_{1,slip}$. In the second part a linear decrease can be assumed for slips $s > s_{1,slip}$.

To find out the path of the second part, the first part may be ignored as has been done by using the analytical back analysis which was introduced in (Lorenz & Fehling 2012b).

To identify the path of the first part for small slip values, the back analysis using non linear finite element models can be used. The value $\tau_{u,split}$ can be calculated by dividing the maximum measured force through the rebar perimeter and the embedded length.

ABSTRACT: The focus of present research investigation was on exploring the use of nanotechnology-based nano-filament, such as carbon nanotubes (CNTs), the most promising nano material because of its unique physical and mechanical properties as excellent reinforcements in enhancing high ultra strength, stiffness, resilience and fracture toughness when integrated with conventional concrete. The main aim is to bridge the gap between Nano-technology and Construction industry. The present investigation is to study the behavior of CNT based carbon concrete in hardened state. The variables studied include dosage of CNTs with design Mix of M60 grade of concrete. CNTs specifically designed for use with concrete composites as admixture. Six different concentrations such as 0.025%, 0.050%, 0.075%, 0.1%, 0.125% and 0.15% of CNTs by weight of cement were used. Carbon Nanotubes were first dispersed in water and surfactant using an ultrasonic Mixer, then combined with concrete as per state-of-the-art techniques. The various mechanical properties like Compressive, Flexural and Split tensile strength can be improved with the addition of low concentrations of CNT in carbon concrete.

Keywords: carbon nanotubes, surfactant, SEM, carbon concrete

1 INTRODUCTION

Concrete is the second most used material on earth (after water), and is the most common and widely used construction material in the world. However, over the past several years, structural deterioration has become a critical issue the loss of structural capacity over time is caused mainly by the nucleation and growth of micro-cracks and their evolution into macro-cracks, which degrades the structural strength and stiffness of concrete structures. The control of concrete damage requires implementing inspection, maintenance, and rehabilitation programs, resulting in high costs. On the other hand, addition of nano-scale materials into concrete could improve its performance. Carbon nano-tubes (CNTs) have unique mechanical properties where their stiffness, strength, and resilience exceed any current material such that they offer tremendous opportunities for the development of fundamentally new material systems. The potential use of CNTs in concrete provides extraordinary specific stiffness and strength, which represents tremendous opportunity for its application in the 21st century.

1.1 *Carbon nanotubes*

Carbon nanotubes (CNTs) discovered in 1991, (Grigorij. 2006) are a unique form of carbon that has desirable mechanical, thermal and electronic properties. They can be easily visualized by considering a single graphene sheet, a lattice of carbon atoms distributed in a hexagonal pattern. A single walled CNT looks like a single sheet rolled up into a tube, while multi-walled CNT look like multiple sheets rolled into a series of tubes, one inside the other. A single walled CNT is typically 1–3 nm in diameter and a micrometer or more long. Multi-walled CNT typically range in diameter from 10 to 40 nm. Mechanically, CNT show elastic behaviour, with a Young's Modulus of approx, 1 TPa. Single walled CNT have measured yield stresses of between 20 and 60 GPa, with measured yield strains of up to 10%. Theoretical considerations suggest that the yield stress for single walled CNT may be as high as 100 GPa.

1.2 *Carbon nanotubes as reinforcing materials in cement composites*

CNTs are expected to have several distinct advantages as a reinforcing material for cements as compared to more traditional fibers. Firstly, they have significantly greater strengths than other fibres, which should improve overall mechanical behaviour. Secondly, CNT have much higher aspect ratios, requiring significantly higher energies for crack propagation around a tube as compared to across it than would be the case for a

lower aspect ratio fibre. Thirdly, the smaller diameters of CNT means both that they can be more widely distributed in the cement matrix with reduced fibre spacing and that their interaction with the matrix may be different from that of the larger fibres.

2 LITERATURE REVIEW

In the erstwhile high performance concrete is a concrete in which certain characteristics are developed for a particular application and environment, so that it will give excellent performance in the structure in which it will be placed, in the environment to which it will be exposed, and with the loads to which it will be subjected during its design life. The use of nanotechnology-based nano-filaments such as carbon nanotubes (CNTs) and nanofibers (CNFs) as reinforcement in improving the mechanical properties of cement paste as a construction material. This was achieved by testing (Jeongwoo Lee 2007, Perumalswamy Balaguru 2006) the integration of CNTs and CNFs in OPC paste through state-of-the-art techniques. Different Mixes in fixed proportions (e.g. water-to cement ratio, air content, admixtures) along with varying concentrations of CNTs or CNFs were prepared (Rashid K 2010). Small-scale specimens for mechanical testing in order to measure the modified mechanical properties as a function of nano-filaments concentration, type, and distribution. The results state that with 0.1%–0.4% CNTs (Roohallah 2011) showed by using nanofiber a new material which exhibits enhanced the ultimate strain capacity, flexural strength, fracture toughness, young's modulus and early age strain capacity can be improved with the addition of low concentrations of either CNTs or CNFs. Further Super plasticizer, which is a high range polycarboxylate-based water reducing admixture works well to disperse (Saez de Ibara Y. 2006) the CNTs without affecting the hydration of the cement paste, with use proper techniques involved in dispersing CNTs into an aqueous solution that would not adversely affect the cured cement such as use effective anionic surfactant, caused the cement paste to entrap 5 times more air than is typical in plain cement paste. But improper dispersion of CNTs will adversely affect the cementatious composites of carbon concrete.

Based on the existing literature, an attempt has been made in the present study to produce crack free carbon concrete made with nanofiber reinforcement with optimising the dispersion techniques and dosage of CNTs. Prior to their addition to cement matrix, the nanofiber were dispersed in water using a surfactant. The major drawback however, associated with the incorporation of CNTs in cement based materials is poor dispersion. Research conducted has shown that by applying ultrasonic energy and use of a surfactant, CNTs can be effectively dispersed in the cementatious matrix.

2.1 *Aim and scope of present investigation*

The objective of the research is to investigate the potential use of nano-filament such as CNTs as nano-reinforcement to improve the mechanical properties of High Performance Concrete. Due to their high surface area, they can act as excellent reinforcements in carrying internal stresses. To investigate the potential use of CNTs as nano-reinforcement in concrete, the main obstacle has to be overcome which lies in the difficulty of dispersing the nano-filaments.

The main tasks can be broken down into two major areas in following order:

i PRIMARY PHASE: Dispersion of nano-filaments in water.
ii SECONDARY PHASE: The compressive strength, tensile strength and flexural strength characteristics of Carbon concrete were evaluated.

Table 1. Properties of Materials used.

Parameter	Specification
Cement Specific Gravity	3.15

Average diameter of MWCNTs	20 nm

3 MATERIALS AND TEST PROGRAMME

In the present work Ordinary Portland cement 53 grade, crushed granite with a maximum nominal size of 12.5 mm down size, fine aggregates satisfying the requirements of Zone II, Silica Fume, Ground Granulated Blast Slag (GGBS), MWCNTs having average diameter 25 nm with length of 30 to 60 μm, Glenium ACE 30 a High-range water reducing polycarboxylate-based admixture as super-plasticizer were used. Detailed mechanical properties of materials are shown in table 1.

3.1 *Dispersion of nano-filaments in water*

In Primary Phase, the entire dispersion of CNTs has been done, first the CNTs are dispersed in water as shown in figure 1. For carbon nano-filaments to be fully utilized within materials, they must first be properly dispersed.

The following chemicals are used for dispersion of CNTs

(a) ACETONE: Acetone is an organic compound with formula $(CH_3)_2CO$ is colourless, flammable liquid and is the simplest ketone. It is mainly used as a solvent and is a product of methyl methaacrylate and bisphenol A.

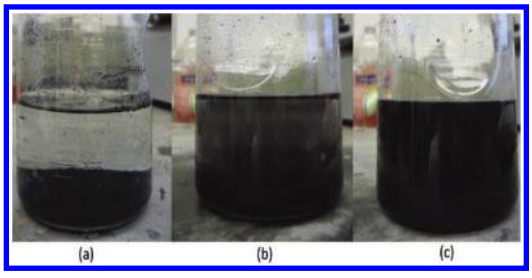

Figure 1. Effect of CNTs dispersion when mixed with water and Surfactant by (a) Hand Stirring (b) Hand Shaking (c) Ultrasonic Mixing.

(b) HDF (SODIUM DODCYL SULPHATE): HDF is an organic compound with formula $CH_3(CH_2)_{11}$ SO_4Na. This salt is an organo-sulfate consisting of 12-Carbon tail attached to a sulphate group giving the material the amphiphilic properties required of a detergent.
(c) TWEEN 20: This is a type of Polysorbate surfactant whose stability and relative non toxicity allows it to be used as a detergent and emulsifier in pharmacological applications.

To prepare each mixture, water, surfactant, and either CNTs are first measured, and then mixed with water and chemicals. In order to ensure a well-dispersed solution, an ultrasonic mixer is used, which can deliver up to 500 watts at 20 kHz. The energy in the shock waves is extremely high and significantly accelerates chemical reactions and breaks the lumps and agglomerations of particles. CNTs are mixed for 20 minutes.

3.2 *Test specimens*

In secondary Phase, weigh batching for materials was used for the experimental study. Cement, Silica fume, GGBS, Fine aggregate, coarse aggregate, water mixed with Super plasticizer and dispersed CNTs of known volume. Care should be taken when using CNTs. The dispersed solution of CNTs is added to the mix & the mixing is continued until the lump free homogeneous mix is obtained. A series of test specimens are chosen for the investigation and all are having a unique nominal sectional dimensions for cubes 150 mm, cylinders 150 mm dia. and 300 mm height and prisms 100 × 100 × 500 mm. The test programme consists of four different trail mixes of designed grade of M60 with varying percentage of silica fumes and GGBS as cementatious replacements. The four different trial mixes are.

Mix 1 M60 (Cement 79% + SF 06% + GGBS 15%)
Mix 2 M60 (Cement 71% + SF 09% + GGBS 20%)
Mix 3 M60 (Cement 63% + SF 12% + GGBS 25%)
Mix 4 M60 (Cement 55% + SF 15% + GGBS 30%)

From the above mentioned trail Mixes, Mix 2 M60 (Cement 71% + SF 9% + GGBS 20%) was found to satisfy sustainable point of view and optimized to obtain maximum compressive strength to which a Nano material i.e., carbon nanotubes (CNTs) are added. The integration of CNTs in Mix 2 M60 (Cement 71% + SF 9% + GGBS 20%) was added from 0.025% to 0.15% with regard to the cement content.

Table 2. Slump Values for M60 trial Mixes

Concrete Type	Slump mm
Mix 1 = M60 (SF6% + GGBS15%)	78
Mix 2 = M60 (SF9% + GGBS20%)	78
Mix 3 = M60 (SF12% + GGBS25%)	79
Mix 4 = M60 (SF15% + GGBS30%)	79

Table 3. Slump values for various Mix with CNTs.

Concrete Type	Slump (mm)
Mix 2 N1 = Mix 2 + 0.025% CNTs	76
Mix 2 N2 = Mix 2 + 0.050% CNTs	76
Mix 2 N3 = Mix 2 + 0.075% CNTs	74
Mix 2 N4 = Mix 2 + 0.100% CNTs	74
Mix 2 N5 = Mix 2 + 0.125% CNTs	75
Mix 2 N6 = Mix 2 + 0.150% CNTs	74

Mix N1 = Mix 2 + 0.025% CNTs
Mix N2 = Mix 2 + 0.050% CNTs
Mix N3 = Mix 2 + 0.075% CNTs
Mix N4 = Mix 2 + 0.100% CNTs
Mix N5 = Mix 2 + 0.125% CNTs
Mix N6 = Mix 2 + 0.150% CNTs

4 TESTS AND RESULTS

Most concrete structures designed under all assumption that the concrete develops compressive strength but not tensile stresses. The compressive strength is the main criteria for the purpose of structural design. The compression tests are relatively easy to carry out. The compressive strength is generally considered as most important property of concrete and gives overall picture of quality of concrete. The required slump values of various mixes with and without CNTs are shown in table 2 and 3. In the present study Compressive strength, Split tensile strength & Flexural strength are taken into account.

Figure 2–7 shows results obtained for compressive strength, split tensile strength and flexural strength for 3,7 and 28 days for the concrete matrix for the Mix 1 to Mix 4 and Mix N1toN5. It is seen that Mix2 N4 shows the significant increase in the load carrying capacity.

4.1 *SEM (scanning electronic microscope)*

SEM is an instrument used to investigate the structural morphology of any material to its nano scale level. Figure 8 and 9 shows the comparison between the Mix 2

and the fracture surface of Mix 2 N4 having 0.10% CNT reinforced with concrete composites.

5 CONCLUSIONS

1. Among the four design Mixes of M60 grade with varying amount of cementatious materials such as Silica Fumes and GGBS viz. Mix 1; Mix 2; Mix 3

and Mix 4; compressive strength obtained at 28 days for Mix 2 was found to be increased by 106 % of the designed strength. The same has been optimised to add the Nano carbon to Mix N2.

2. The results showed that there is a significant improvement in the load carrying capacity of the CNTs composite material Nano concrete, when compared to the designed Mix without Nano carbon.
3. The Compressive strength results indicates that all six (Mix N1 to Mix N6) different percentage Mixes of CNTs with M60 grade showed an increased in strength of about 120% tested at 28 days. Carbon Nano tubes increase the compressive strength at early age in concrete.
4. The split tensile strength results of all six different percentage Mixes of CNTs with M60 grade exhibited an increased amount in strength of about 110% with respect to 28 days.
5. The flexural strength results indicate that all six different Mixes of CNTs with M60 grade exhibited an increase in strength of about 130% with respect to 28 days.
6. SEM observations of the fractured surface on the hardened concrete containing CNTs showed good dispersion within the cement matrix. Large areas observed under the SEM showed evidence of CNTs. A well dispersed aqueous Mixture with cement resulted in a relatively good dispersion and leading to production of dense concrete matrix with improved form of durability.

ABSTRACT: In the field of concrete technology the conventional ingredients were slowly and safely replaced by new and more efficient materials, which have opened a wide scope for research on their specific uses. Strength and ductility are the main important factors to be considered in the design of structures subjected to seismic and other dynamic forces. Hence many attempts have been made in the recent past to develop a new material which exhibits a higher strength and ductility than the conventional concrete so that they could be used in the case of structures subjected to seismic loading and impact or blast loading. The present study is aimed at the evaluation of behaviour of Polymer Modified Steel Fiber Reinforced High Performance Concrete at predefined plastic hinge location in beams for strengthening and improving seismic performance. A three point bending test is carried out on six concrete beams with dimension 150 mm × 230 mm and an effective length of 2000 mm to obtain load deflection response, as well as frequencies. The ultimate moment capacity, energy absorption, ductility index and toughness index have been evaluated. The results of the study indicates that modification at the central portion of the test beam specimens is replaced with a highly ductile composite such as Polymer Modified Steel Fiber Reinforced High Performance concrete ensures structural integrity with increase in natural frequency, resulting in enhancement of ductility and energy absorption capabilities.

Keywords: natural frequency, free vibration test, plastic hinge, SBR-Latex, ductility index, energy absorption, toughness index

1 INTRODUCTION

High Strength Concrete is a material often used in construction of high rise buildings, large span bridges where strength, durability and service behaviour are particularly important. Using high strength concrete it is possible to reduce size and weight of reinforced concrete structural members. But concrete with high strength can result in less ductility response of structural members under seismic loads. Use of admixtures such as Silica Fume, GGBS and Polymer (SBR-Latex) in a concrete matrix with inclusion of steel fibre in production of polymer modified high performance steel fibre reinforced concrete will increase the strain level corresponding to the value of peak stress. This enhances the resistance against deterioration as a result of high ductile, high fatigue, high impact strength and also reduces carbonation related shrinkage and controls the crack formation. Because of this property the member can absorb and dissipate large amount of energy compared to conventional concrete so that this could be used in structures subjected to seismic loads.

Ductility is important in the design of reinforced concrete structures subjected to seismic loads. The structural ductility and structural performance factor depends on both the structural form selected and the material used (M. Sudhakar 2009). Ductility of reinforced concrete structure is a desirable property where the resistance to brittle failure is required during flexure to ensure structural integrity. Ductile behavior in a structure can be achieved through the use of plastic hinges positioned at appropriate locations throughout the structural frame (J.M. Park 2009). In seismic design of reinforced concrete members it

is desirable to allow large ductility so that seismic energy is absorbed to avoid shear failure or significant flexural degradation of strength (S.M.R Lopes 2003). The design of ductile structures involves identifying a ductile failure mechanism for the structure and locating the position of associated plastic hinges (Monita Olivia 2005) these are referred as primary plastic hinges and are likely to develop in regions of maximum moment at the centre with shear free zone of the beam for a length which is twice the depth of the beam (Rajesh P 2008, Sreekala 2009) due to the design actions and these are the main source of inelastic response and the ductile behavior of a structure which is associated with energy dissipation. Hence beams should be required to have sufficient flexural ductility such that the potential plastic hinges in the beams are able to maintain their moment resisting capacities for seismic resistance (Young Jang 2008). For evaluation of stiffness due to low energy impact blow applied on reinforced and prestressed concrete beams natural frequency has been used (Muthumani et al. 1995, Zai 2008) thus variation in natural frequency is related to the stiffness characteristics and the ductile behaviour of system. In the present investigation ductile behavior of test beam specimens under three point bending involves formation of plastic hinges in the beam at the location where a modified concrete matrix with Polymer Modified Steel Fiber Reinforced High Performance Concrete has been incorporated only at the plastic hinge location where higher ductility is needed and also determination of natural frequencies to evaluate the ductile behaviour and energy absorption capacity.

2 EXPERIMENTAL INVESTIGATIONS

2.1 *Materials and mix proportions*

Ordinary Portland Cement (OPC) of 53 grade conforming to IS 12269:1987, locally available river sand and crushed stone coarse aggregate of 12.5mm passing, crimped round steel fibres having aspect ratio of 80, SBR-Latex, Ground Granulated Blast Furnace Slag (GGBS), Silica Fume and a high range water reducer (Glenium ACE 30) as admixtures were used. High yield strength deformed bars having characteristics strength of 415 N/mm^2 was used as longitudinal and transverse reinforcement in the entire test beam specimens. The mix ratio adopted is 1:1.03:2.03 with water binder ratio of 0.33, steel fibre 0.65% by volume, Glenium ACE 30 was added at the ratio of 0.8liter per 100 kg of binder, 9% of Silica Fume and 20% of GGBS were added as a cement replacement to the mix. The test beam specimens are Polymer modified steel fibre reinforced high performance concrete (SBR-Latex Polymer and steel fibres combined with design mix of M60 grade of concrete). Table 1 shows the hardened properties of concrete matrix of High Performance Concrete (HPC), polymer modified high performance concrete (PMHPC) and polymer modified steel fibre reinforced high performance concrete (PMSFRHPC). Figure 1 shows the reinforcement details adopted.

Table 1. Properties of Hardened Concrete.

Properties	Age	HPC	PMHPC	PMSFRHPC
Compressive strength (N/mm^2)	3 Days	32.00	26.66	32.33
	7 Days	48.00	45.33	42.00
	28 Days	64.01	55.11	66.00
Split tensile strength (N/mm^2)	3 Days	1.86	1.63	1.94
	7 Days	2.17	2.24	2.60
	28 Days	2.80	3.30	4.80
Flexural strength (N/mm^2)	3 Days	2.00	1.69	2.45
	7 Days	2.97	2.50	2.93
	28 Days	4.43	3.13	4.70

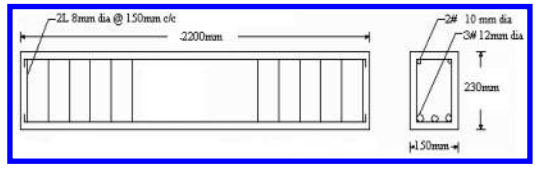

Figure 1. Reinforcement Details.

Figure 2. Concreting the Plastic hinge length.

3 PREPARATION OF TEST SPECIMENSS

The test beam specimens, for the condition of simply supported reinforced concrete under single point loading at the centre of span, the plastic hinge length was calculated as twice the depth of beam. The modified concrete matrix (PMHPC and PMSFRHPC) was first poured at plastic hinge at a length of 460 mm and remaining length on either side of beam high performance concrete (HPC) was poured as shown in figure 2.

4 TEST PROGRAMME

i. Flexural Behaviour of Test beam specimens.

The experimental programme consists of testing three series of test beam specimens under flexural loading. Loading arrangement and instrumentation are shown in figure 3. Test beam specimens consist of HPC, PMHPC and PMSFRHPC designated as A1, A2, B1, B2, C1, and C2 respectively.

Figure 3. Test Setup.

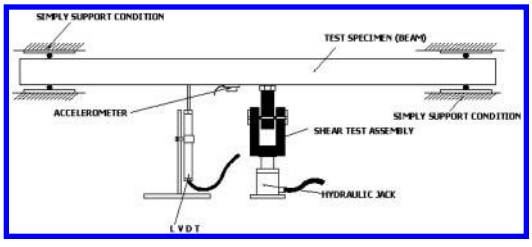

Figure 4. Free Vibration Test Setup.

ii Natural Frequency of test beam specimens.

A free vibration test is conducted to determine the natural frequencies as shown in figure 4. The test beam specimens were held rigidly between two supports depth wise and is given an initial lift within the elastic limit using loading jack so that the inertial effect will not come into picture. Then the test beam is let free with the failure of shear rods used to give the initial disturbance from the static equilibrium condition. The instruments used to record the natural frequencies are Linear Variable Differential Transducers (LVDT) and piezo electric accelerometers. The post processing of recorded data was carried out using data acquisition system which is equipped with MS Visual Basic 6.0 software. The natural frequencies were recorded during the free vibration test for three series of test beam specimens A1,B1 and C1 for un cracked condition respectively.

5 ANALYSIS OF TEST RESULTS

5.1 *Load-deflection curves*

Typical load-deflection curves for A1,A2, B1,B2 and C1,C2 test beam specimens are shown in figure 5. Major stages observed on load deflection curves are first cracking load (Pcr), Service Load (Psl), Yield point load (Pyl) and ultimate load (Pul).

5.1.1 *First crack load, yield load and ultimate load and deflection characteristics*

The first crack load P_{cr} in the entire test beam specimens was observed in the mid span of beam by visual inspection from the initial stages of loading. It is noted that B1,B2 cracked much before A1,A2 at lesser loads.

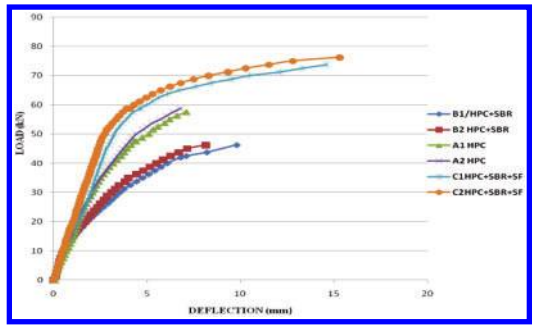

Figure 5. Load Deflection Curves.

Table 2. Load carried at various stages by the beams.

Beam	First Crack Load (P_{ct} kN)	Service Load (P_{sl} kN)	Yield Load (P_{yl} kN)	Ultimate Load (P_{ul} kN)
A1	10.00	39.12	45.00	58.75
A2	11.25	39.12	45.00	58.75
B1	8.75	30.84	35.00	46.25
B2	7.50	32.50	37.50	48.75
C1	12.50	49.12	55.00	73.75
C2	13.75	50.84	57.50	76.25

First crack in B1,B2 occurred at 24% lesser load. Similarly 18.7% decrease in service load, 19.5% decrease in yield load and 19.15% decrease in ultimate load was observed compared with A1,A2. The load-deflection pattern was similar to A1,A2 and C1,C2 but the beams sustained large deflection than A1,A2 but lesser than C1,C2. The large deflections at near maximum load of the B1,B2 beams exhibit high ductile behavior. On the other hand, A1,A2 carried higher loads than B1,B2 but did not undergo large deflection. This is mainly because of the brittle nature of beams. C1,C2 beams sustained higher loads than A1,A2 and B1,B2 beams. In C1,C2 the first crack was seen at 19% higher load, 21.8% increase in service load, 20% increase in yield load and 37% increase in Ultimate load capacities compared with A1,A2. This indicates that beams with steel fibres can carry higher loads and undergo large deformation. From table 2 and figure 5 shows a linear pattern for load-deflection values up to first crack then afterwards the rate of increase in deflection increases with load and this may be because of the cracking of concrete. After the yielding of steel C1, C2 beams continue to show ductility by undergoing higher deflections with non linearity without much increase in the ultimate load. This indicates that modification of HPC with polymer and steel fibre resulted in enhanced load carrying capacities.

5.1.2 *Prediction of cracking moment*

The cracking load depends on the tensile strength of the concrete and the geometry of the specimens. From

Table 3. Experimental and predicted cracking moment.

Test Beam	Experimental M_{CR} (kN-m)	Theoretical M_{CR} (kN-m)	Ratio of M_{CR} Exp./Theo.
A1	5.00	7.41	0.67
A2	5.63	7.41	0.76
B1	4.38	6.88	0.64
B2	3.75	6.88	0.55
C1	6.25	7.53	0.83
C2	6.88	7.53	0.92

Table 4. Experimental and predicted ultimate moment.

Test Beam	Experimental M_u (kN-m)	Theoretical M_u (kN-m)	Ratio of M_{CR} Exp./Theo.
A1	29.38	23.32	1.26
A2	29.38	23.32	1.26
B1	23.13	23.03	1.00
B2	24.40	23.03	1.06
C1	36.88	23.09	1.60
C2	38.13	23.09	1.65

the table 3 it can be observed that there is a significant increase in cracking moment when the HPC is modified with steel fibres. The experimental cracking moment (Mcr,exp) are compared with the corresponding moments calculated as per IS:456-2000.

5.1.3 *Prediction of ultimate moment*

The theoretical and experimental ultimate moments were calculated. The results show that the C1,C2 beams have higher moment capacities than A1,A2 and B1,B2 beams and the same has been tabulated in table 4.

5.2 *Natural frequency of test beam at virgin and cracked stage*

The natural frequencies are recorded during the free vibration test and are determined by evaluating the time taken for a given number of cycles. The natural frequency in Hz is obtained as n/T, where 'n' is the number of cycles and 'T' is the total time taken and is tabulated in table 5. Figures 6 to 8 show the variation displacement with respect to the time for virgin test beam specimens. It is observed that the frequencies increases in test beam specimens C1 as compared to A1 and B1.

5.3 *Evaluation of beam ductility*

The term ductility is defined as the ability of the material or member to sustain deformation beyond the elastic limit, while maintaining a reasonable load-carrying capacity before total collapse. Ductility is measured by the ratio called ductility index (μ). In this study, the member's ductility index was evaluated by

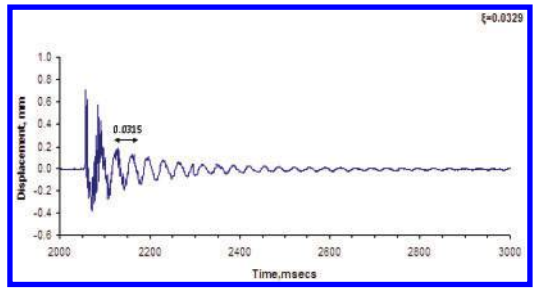

Figure 6. Variation of displacement with time for beam A1.

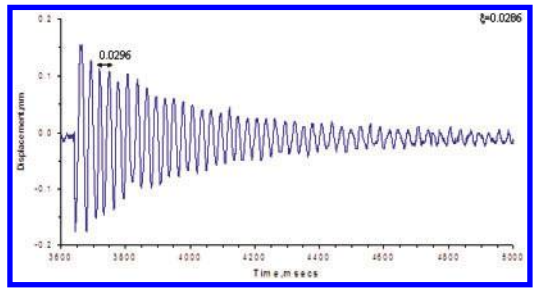

Figure 7. Variation of displacement with time for beam B1.

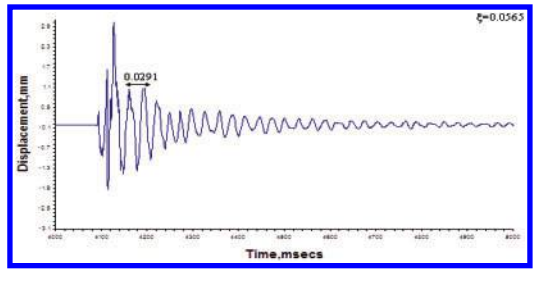

Figure 8. Variation of displacement with time for beam C1.

Table 5. Details of natural frequency.

Beam	Natural Frequency (Hz)
A1	31.74
B1	33.78
C1	34.36

displacement expressed by the ratio of the deflection at yield and the deflection at ultimate load. The specimen's ductility index is shown in table 6. The ductility for B1,B2 and C1,C2 beam type ranged between 2.05 to 2.40 and 3.77 and 4.14 respectively.

5.4 *Energy absorption capacity*

Energy absorption capacity of the entire test specimens was calculated as area under load deflection curve. Table 7 shows the results and it was found that C1,C2 have 43% increase in energy absorption capacity compared to A1,A2. This can be attributed to the effect

Table 6. Ductility Index.

Beam	δ_y,mm	δ_u,mm	$\delta_d = \delta_u/\delta_y$	Avg μ_d
A1	3.8	7.10	1.87	1.83
A2	3.8	6.80	1.80	
B1	4.77	9.80	2.05	2.23
B2	4.79	11.50	2.40	
C1	3.87	14.60	3.77	3.96
C2	3.70	15.30	4.14	

Table 7. Energy Absorption Capacity.

Beam	Energy absorption capacity (kN-mm)	Avg. Energy absorption capacity (kN-mm)
A1	136.23	133.40
A2	130.55	
B1	142.32	141.00
B2	139.46	
C1	236.93	232.50
C2	228.04	

Table 8. Toughness Index.

Beam	Toughness Index	Avg. Toughness Index
A1	41.42	42.54
A2	43.66

B2	46.52	
C1	74.62	72.31
C2	70.00	

of fibres and latex in bridging the crack and hence enhancement in energy absorption capacity. It is seen that the addition of both fibers and SBR does not have much influence on the behavior of a hardened concrete before peak load. However, a significant improvement in energy absorption is observed after peak load.

5.5 *Toughness index*

It is defined as the ratio of area under the curve up to ultimate load to area under the curve up to first crack load. The values of Toughness index for different concrete mix under investigation are given in table 8.

5.6 *Strain charactersitics*

The tensile and compressive strains of reinforcement and concrete respectively were measured at every 5 kN load increment as shown in table 9. The higher strains in C1,C2 beams may be attributed to higher deflection.

5.7 *Crack pattern and number of cracks*

The flexural cracks were the first to initiatein the plastic hinge length during the course of test as shown in figure 9. The number of cracks in A1,A2 beams was

Table 9. Strain Characteristics.

	Strain at ultimate load	
Beam	Compressive	Tensile
A1	1.35×10^{-3}	2.08×10^{-3}
A2	1.45×10^{-3}	2.40×10^{-3}
B1	1.85×10^{-3}	6.20×10^{-3}
B2	2.60×10^{-3}	6.35×10^{-3}
C1	3.43×10^{-3}	7.68×10^{-3}
C2	3.63×10^{-3}	7.89×10^{-3}

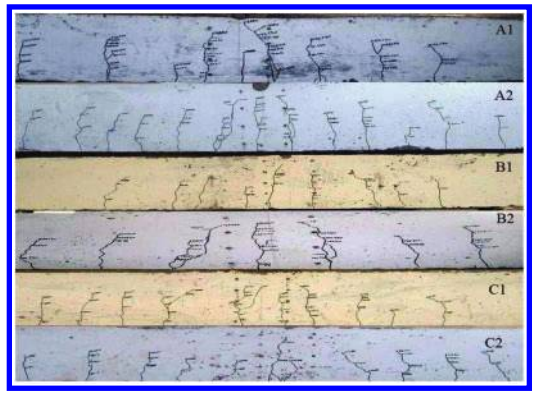

Figure 9. Crack Pattern and Number of Cracks.

more ranging about 10 to 13 with cracks propagating to the top surface of the beams. In case of B1,B2 cracks were ranging about 7 to10. C1 and C2 has about 9 cracks with the cracks not reaching up to the top this indicates the polymer modified steel fibre reinforced high performance concrete which is used in plastic hinge zone is more ductile and has significant energy absorption capacity.

6 CONCLUDING REMARKS

1. From the experimental investigation it is found that there is an increase in the natural frequency of modified concrete in test beams C1and C2. This has resulted in increase in the stiffness and thus corresponding increase in effective modulus of elasticity of modified test beams C1 and C2.
2. In general the longitudinal steel provides monotonic ductility at low reinforcement ratio and transverse steel are needed to maintain ductility through reverse cycles and at very high strain (plastic hinge development). Similarly, in the present experimental investigation the polymer modified steel fibre reinforced high performance concrete at the plastic hinge zone will enhance the ductility through reverse cycles at very high strain at these modified locations.

3. Further, from the load deflection curve it is observed that test beams C1 and C2 shows improvement in the maximum load carrying capacity as compared to test beams A1, A2, B1, and B2. Also it is evident from the experimental result that there is enhancement in ductility index, toughness index and energy absorption capacity of modified beams C1 and C2.

Structural behavior of high performance fiber-reinforced flowable concrete beams and plates

Samaan G. Ladkany & Abebe T. Berhe
Department of Civil and Environmental Engineering, University of Nevada, Las Vegas, USA

ABSTRACT: Some aspects concerning the characterization and potential applications of high strength (>10,000 psi) Steel Fiber Self Consolidating Concrete (SFRSCC) and flowable concrete, with fiber content ranging from 0%-to-2% in volume fraction, are presented. Research in the area of fiber concrete has been conducted at the University of Nevada, Las Vegas (UNLV) for several years with the latest emphasis placed on high strength and high steel fiber content. Such characteristics place this fiber-reinforced concrete amongst the new high performance materials. The high tensile and shear strength of this fiber concrete would allow its use in structures with little or no longitudinal reinforcement.

This paper discusses the behavior, under structural testing of beams 102 mm × 102 mm × 305 mm (4 in. × 4 in. × 12 in.) and very thin plates, 32 mm (1.25 in.) thick. The structural behavior and performance that were studied include: 3-point loading of beams, rectangular plates 305 mm (12 in.) wide by 1219 mm (48 in) long loaded in the transverse and longitudinal directions. The study encompasses the mechanical properties of the fiber-reinforced concrete, such as compressive and tensile strength, modulus of rupture and modulus of elasticity. Observation of the failure mode of the specimens will also be discussed.

Keywords: Flowable, High-Strength, Self Consolidating Concrete, SCC, Steel Fiber, beams, plates

1 INTRODUCTION

This research is the continuation of previous studies conducted at the Civil Engineering Department at University of Nevada, Las Vegas since 1997 (Ahmed 2001; Ahmed and Ladkany 2003, Ladkany and et al 2005). In this research 1% by volume fraction of one inch long steel-fiber and Styrene-Butadiene, rubber based polymer, were added to normal 27.6 MPa (4 ksi) concrete mixture to study the ductility behavior of steel-fiber and polymer concrete mixtures (Ahmed 2001). High strength steel-fiber mixtures, with 0.3% of steel by volume, were studied for compressive and tensile strength with different combinations of admixtures and cement substitutes (Doli 2007).

The desirability of high strength concrete is in the overall reduction in the weight of structures, the volume of concrete used in the construction, and the resulting beneficial environmental effects associated with reduction in weight and materials and to reduce the overall structural weight of the concrete especially in areas such as beam-column joint, two way slab-column joints and heavily loaded columns reinforcing steel are normally present triggered the launch of this particular research. Normal strength fiber SCC with 1% fiber volume fraction in Europe is being effectively used for slabs and flat plates with longitudinal reinforcement placed only between adjacent columns (Destree 2004). Other researchers have investigated SFSCC columns (Aoude 2009) and the shear behavior of beams (Greenough 2008). Longitudinal reinforcing steel can be reduced greatly and in some cases eliminated if steel-fiber reinforcements coupled with high concrete strength are used. Kearns (Kearns 1989), tested ultra thin straight and curved plates using normal 1% SFC, which prompted our research group to study the mechanical properties of HSSFSCC in thin plates and shells.

This paper discusses the behavior, under structural testing of beams 102 mm × 102 mm × 305 mm (4 in × 4 in × 12 in) and very thin plates, 32 mm (1.25 in.) thick. The structural behavior and performance that were studied include: 3-point loading of beams, rectangular plates 305 mm (12 in.) wide by 1219 mm (48 in.) long loaded in the transverse and longitudinal directions.

2 PURPOSE OF RESEARCH

The purpose of this phase of our research is to study the behavior of beams and very thin plates, 32 mm (1.25 in.) thick, under structural testing. The structural behavior and performance that were studied include: 3-point loading of beams, rectangular plates 305 mm (12 in.) wide by 1219 mm (48 in.) long line- loaded in the transverse and in the longitudinal directions. The next phase of this research, which will not be presented in this paper, will concentrate on the behavior of thin square, thick circular plates and thin pipes and shells.

The mechanical and fresh properties of the high strength SCC/flowable concrete were presented in previous publications by our research group for 0%, 1% and 2% steel fiber by volume fraction (Ladkany 2013, 2011 and 2005), however some of these properties will also be discussed in this paper.

3 STEEL FIBER CONCRETE PROPERTIES

3.1 *Raw material*

Coarse and fine aggregates were obtained from a local quarry in Las Vegas, Nevada. Since the application of the concrete mixtures were ultimately to be used for thin plates and shells (about 25.4 mm thick), the size of the coarse aggregate was limited to nominal sizes of 9.53 mm (3/8″) and #4. The oven-dry specific gravity and absorption of the coarse aggregate (ASTM C 128-07a) are 2.777 and 0.60%, respectively. Fine aggregate grading, with fineness modulus of 3.03, met the requirements of ASTM C33 grading limitations. The oven-dry specific gravity and absorption of the fine aggregate (ASTM C 128-07a) are 2.785 and 0.64%, respectively. Deleterious substances are substantially below the maximum allowable limits for both coarse and fine aggregates.

ASTM C 150 Type V Portland cement 404 kg/m^3 (25.2 lb/ft^3), which is widely used in the local area due to its resistance to sulfate and Class F fly ash, at 42.5% by weight of cement, meeting the requirements of ASTM C 618 were used. Silica fume, 7.5% by weight of cement, was also used.

The admixture used was High Range Water Reducers (HRWR).

ASTM 820-90 Type II Deformed cut sheet carbon steel fibers with equivalent diameter of 0.584 mm (0.023 in) and aspect ratio, l/D, of 47:1 were used. The steel fibers have rectangular cross section of 0.406 × 0.838 × 19.05 mm (0.016 × 0.033 × 3/4 in) and specific gravity of 7.85. The tensile strength of steel-fibers ranges between 379 to 763 MPa (55,000 to 111,000 psi).

The amount of water-to-cement ratio and coarse-to-fine aggregate ratio were adjusted to suite the concrete mixture under consideration. Optimum coarse-to-fine aggregate ratio for FRC was found to be 44% to 56% (724:920 kg/m^3), respectively. The water-to-cement ratio was set at about 0.435 to meet both self consolidating properties and high strength concrete requirements.

3.2 *Fresh properties of steel fiber reinforced SCC*

Concrete mixtures were subjected to the following fresh property SCC tests.

1. Slump flow Test (>482 mm (19 in.))
2. J-Ring Flow Test (≥50 mm (2 in.))
3. V-Funnel Test (flow time ≥5 sec)
4. U-Box Test (filling height ≥305 mm (12 in.))

Even though some of the V-Funnel and U-Box requirements for regular SCC were not fully met, the mixtures were highly flowable and the specimens were fully consolidated. The full results are shown in tabular format in SEI 2011 (Ladkany & Berhe 2011) and SCC Congress 2013 (Ladkany and Berhe to be published).

3.3 *Mechanical (hardened) properties SFRSCC*

From the current experimental study, it can be concluded that, with the increase of steel-fiber volume fraction the required HRWRA increases. Ultimately, VMA and water- to-cement ratio need to be adjusted to get the SCC properties for 1% and 2% steel fiber mixtures while maintaining the high strength concrete characteristics.

The test results show that mechanical characteristics, modulus of elasticity, compressive and tensile strength of high strength 69 MPa (10 ksi) concrete can be substantially enhanced by the addition of steel fibers in the neighborhood of 2%. The 7-Day compressive strength of HSSCC was in the range of 65% to 70% of the 28-Day strength, which may be favorable for construction methods that require high early strength concrete.

4 EXPERIMENTAL PROCEDURES

Two types of structural specimens were tested using concrete mixtures having 0%, 1% and 2% steel fiber by volume fraction. The structural specimens tested are Beams, rectangular plates loaded in transverse direction and longitudinal direction under line loads. The testing procures are described in section 4.1 through 4.3 below.

4.1 *Beams*

Beam specimens were prepared and tested per ASTM C78 standard for the computation of modulus of rupture and flexural capacity. The beam sizes were 102 mm (4 in.) wide × 102 mm (4 in.) deep × 356 mm (14 in.) long and supported at 305 mm (12 in.) on center. Line loads were applied at third points 102 mm (4 in.) apart from the support, as shown Figure 1. For beam experiments which were performed at the onset of this research, the amount of HRWR used in kg/m^3 (lb/ft^3) was: 6.279 (0.392), 6.023 (0.376) and 6.664 (0.416). Whereas, the amount of HRWR used for rectangular plates was constant for all steel fiber volume fractions as shown in section 4.2.

4.2 *Rectangular plates: Supported and line-loaded in the longitudinal direction*

Plate specimen sizes were 1219 mm (48 in.) long × 356 mm (14 in.) wide × 32 mm (1.25 in) deep. The plates were loaded in the longitudinal direction with a line load placed at the mid width of the plate. The supports were spaced at the 305 mm (12 in.) on center,

Figure 1. Beam under flexural load.

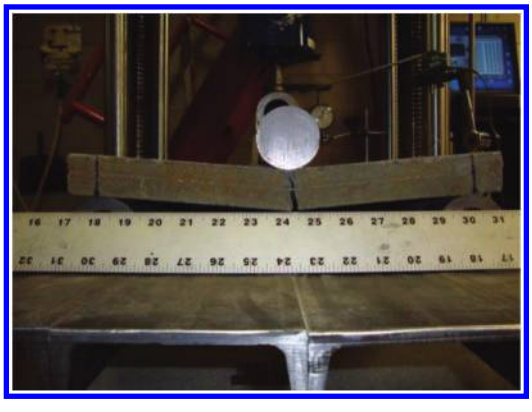

Figure 2. Rectangular plate under longitudinal load.

as shown in Figure 2. The HRWR used for both rectangular plates (section 4.2 and 4.3) were 6.279 kg/m^3 (0.392 lb/ft^3) for all steel fiber volume fractions.

4.3 *Rectangular plates: Supported and line-loaded in transverse direction*

Plate specimen sizes were 1270 mm (50 in.) long × 305 mm (12 in.) wide × 32 mm (1.25 in) deep. The plates were loaded in transverse direction with a line load placed at the mid length of the plate. The supports were spaced at the 1219 mm (48 in.) on center, as shown Figures 3 & 4.

5 RESULTS AND DISCUSSION

5.1 *Beams*

The average 28 day compressive (ASTM C 39) and splitting tensile strength (ASTM C 496) of four cylinders each for 0%, 1% and 2% steel fiber by volume fraction are given in Table 1.

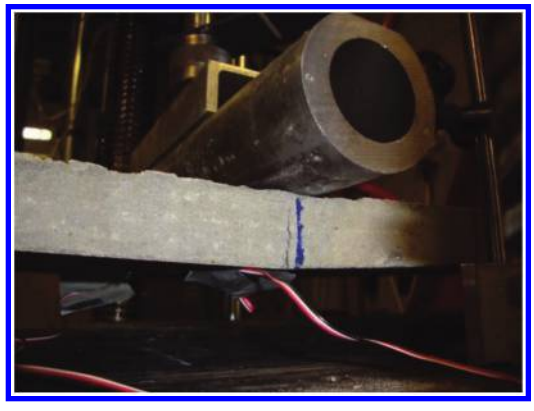

Figure 3. Rectangular plate under transverse load.

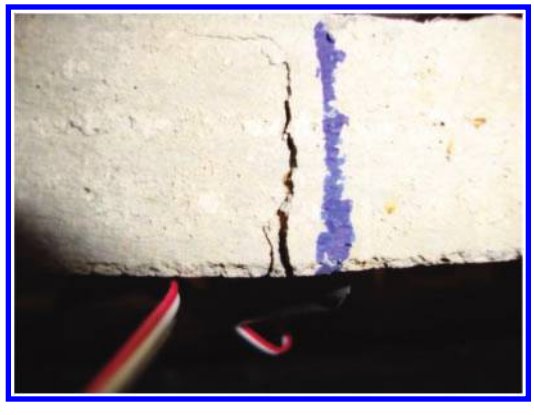

Figure 4. Rectangular plate under transverse load.

Table 1. 28 Day compressive and splitting tensile strength of cylinders used for beam tests and beam modulus of rupture.

Steel fiber	f'_c MPa/(ksi)	f_t MPa/(ksi)	f_r MPa/(ksi)
0%	68.0/(9.86)	6.69/(0.97)	9.7/(1.41)
1%	75.3/(10.9)	8.90/(1.29)	9.5/(1.38)
2%	80.7/(11.7)	10.35/(1.5)	11.5/(1.66)

As mentioned in section 4.1 the amount of HRWR used in the fresh mixture for the 1% SFRSCC was lower than the amount used for 0% and 2%, which affected the bonding between steel fiber and matrix. While the compressive and tensile strengths of the SFRSCC cylinders increased steadily with the increase of steel fibers, the short beam test for modulus of rupture, f_r for 1% fiber decreased slightly from the 0%. The cylinder tests were run at a load controlled rate, the beam tests were displacement controlled. Thus, it is difficult to make valid comparison. The short and stubby beams are too rigid and brittle to allow for any other study except for the modulus of rupture, shown in Table 1.

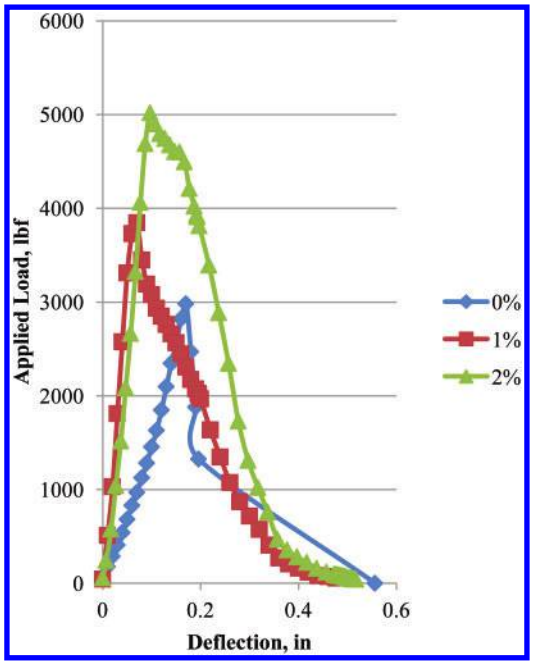

Figure 5. Applied load Vs deflection for 0%, 1% & 2% SFRSCC rectangular plates line-loaded in the longitudinal direction.

Table 2. 28 Day compressive and splitting tensile strength of cylinders used for rectangular plates.

Steel fiber	f'_c MPa/(ksi)	f_t MPa/(ksi)
0%	85.6/(12.4)	5.9/(0.85)
1%	84.2/(12.2)	7.5/(1.09)
2%	84.9/(12.3)	10.7/(1.56)

5.2 *Rectangular plates: Supported and line-loaded in the longitudinal direction*

Load-deflection curves for 0%, 1% and 2% steel fiber SFRSCC rectangular plates line-loaded and supported in the longitudinal direction are shown in Figure 5. While the compressive and splitting tensile strength of the cylinders associated with these plates tested are shown in Table 2.

The results taken from 6 cyliders for each test show a substatial increase, of 6.9, 8.9 and 12.6%, respectively in tensile to compressive strength ratios with increasing fiber percent. Similarily, the tensile strength increases by 28% and 184% for 1% and 2% over 0% respectively. The load- deflection curves for the plates shown in Figure 5, diplay similar behavior.

5.2.1 *Energy absorption*

The increase in ductility is impressive for steel fiber concrete compared to 0% high strength SCC.The load-deflection curves of longitudinally loaded SFRSCC are shown in Figure 5. The energy absorption of the plates within the elastic range were 223, 146 and 243 in-lb for 0%, 1% and 2%, respectivley. These results indicate that the energy absorption is not affected by the fiber content. The post-crack energy absorption were 59, 528 and 782 in-lb, showing substantial increase for the 1% and 2% SFRSCC over 0%.

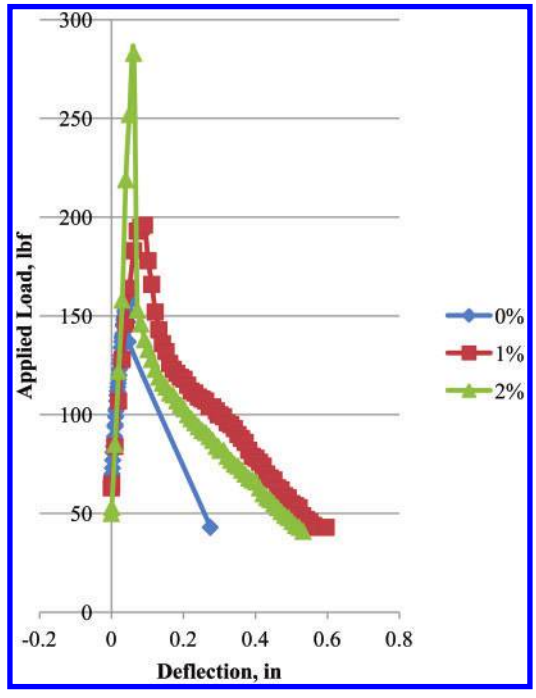

Figure 6. Applied load Vs deflection for 0%, 1% & 2% SFRSCC rectangular plates line-loaded in the transverse direction.

5.3 *Rectangular plates: Supported and line-loaded in the transverse direction*

The compressive and splitting tensile strengths of the cylinders associated with the plates tested, are shown in Table 2.

The load-deflection curves for the plates shown in Figure 6, diplay similar behavior to the plates loaded in the longitudinal direction shown in Figure 5.

5.3.1 *Energy absorption*

The increase in ductility is also impressive for steel fiber concrete compared to 0% high strength SCC for this case. The energy absorption of the plates within the elastic range were 5.1, 12.5 and 11.1 in-lb for 0%, 1% and 2%, respectivley. The post-crack energy absorption were 0.7, 47 and 41 in-lb, substantial over 0% as in the previous case.

6 CONCLUSION

Experiments with high strength 83 MPa (12 ksi) concrete with 1% and 2% steel fiber SCC indicate that

this material, due to its high compressive strength and ductile failure mode, is highly promising for use in a variety of engineering applications that require reduction in concrete volume, longitudinal and transverse steel reinforcement and labor cost. The thin plates tested show an impressive ductile failure mode and ability for energy absorption, which indicates much improved overall structural toughness over plain high strength concrete.

Influence of fiber orientation on the properties of strain hardening ultra-high performance fiber reinforced concrete (UHPFRC) under direct tensile loading

C. Hollmann & K. Wille
University of Connecticut, USA

ABSTRACT: Research was conducted to investigate and analyze the uniaxial tensile behavior of strain hardening ultra-high performance fiber reinforced concrete (UHPFRC) in dependency of fiber orientation of the test specimen. Enhanced mix design, casting, and specimen preparation methods allow for an artificial alignment of fibers at different angles. Several research investigations have been carried out on the effect of single fiber pullout as well as the effect of fiber orientation on bending and tensile strength, however, the amount of research on UHPFRC tensile behavior in dependence on fiber orientation is still lacking. The paper will review a variety of casting methods and tensile test setups used by other researchers and will present a revised and tailored casting method and tensile setup herein. The experimental investigation will quantify, analyze, and link steel fiber orientation in UHPFRC to properties such as strain hardening and maximum strength. The results of the paper support the prediction of the tensile behavior of UHPFRC and should motivate carrying out further research of this composite material.

1 INRODUCTION

1.1 *Motivation and background*

Ultra-High Performance Fiber-Reinforced Concrete (UHPFRC) is shown to have a pronounced strain hardening effect depending on the mix proportions, fiber dosage, fiber distribution, fiber orientation, and casting methods used. The quantity of fibers bridging crack planes and the fiber orientation relative to the direction of applied tensile stresses can drastically influence mechanical properties under tensile loading. Casting method has a very influential effect on fiber orientation and therefore has the ability to negatively or positively affect the maximum strength and strain hardening properties after initial cracking. Casting methods can be designed to optimize fiber orientation longitudinally to the applied load direction which has been shown to produce the best results.

In this paper an optimized casting method is used to provide insight on how the angle of fiber orientation with respect to the direction of applied tensile load can affect the mechanical properties UHPFRC of a structural element. This is done by optimizing the casting method for a thin plate slab in order to align fibers in one direction as perfectly as possible. Tensile specimens were then cut out of the thin plate slab at angles of 0, 30, 45, 60, and 90 degrees with respect to initial direction and were subjected to uniaxial tension loading.

1.2 *Literature review*

Casting along the direction of applied load has a large effect on mechanical properties of UHPFRC. Wille et al. (2010) show that casting with a scoop in layers back and forth along the length of a dog-bone tensile specimen will lead to a preferable alignment of fibers in the direction of axis of the specimen and hence the direction of the applied load. The relatively constant flow and the casting motion have a pulling effect on the fibers which coaxes them to align along the casting direction. Kim & Kang (2011) poured tensile dog-bone specimens with a scoop along the direction of the applied load as well as across the direction of the applied load. The specimens poured across the direction of the applied load had an over 40 percent reduction in average maximum stress. In regards to flexural stress, Kang, Kim, Kim, & Lee (2010), found that flexural specimens cut longitudinally to the back and forth casting direction had a 61% greater flexural strength than those cut transverse to the pouring direction.

UHPFRC flow, such as channel flow or radial flow can also effect fiber alignment. Kang, Kim, Kwon, and Lee (2012) showed that when concrete is poured in the center of a plate and allowed to flow radially the fibers will increasingly orient more perpendicular to radial flow with increasing distance from the center of the flow. However, for a confined flow, the fibers orient parallel to the direction of the flow. Joh, Kim, & Yang (2011) cast one flexural beam

Table 1. Proportions for mix UHPFRC Mix.

Material	Proportions by weight	
	UHPC	UHPFRC
Cement	1.00	1.00
Silica fume	0.25	0.25
Powder	0.25	0.25
Water	0.24	0.24
HRWR	0.036	0.036
Steel fibers	0.00	0.25
F110 sand	0.3	0.3
F75 sand	0.70	0.70

specimen by pouring from the center of the beam and cast another beam specimen by pouring from the end of the beam. The beam poured from the end behaved better because the fibers aligned with the flow so that in the middle of the beam, where stresses were highest, the fibers were oriented longitudinally to the applied tensile stresses. Matinie & Roussel (2011) analyze simple channel flow. Along the length of the channel the shear effect of flow is highest near the faces of the mold and the fibers are very well aligned within 10 degrees in these areas. The shear flow orientation effect happens within a matter of seconds after flow begins. The walls do play a small role in forcing fibers to align through a mechanism known as the wall effect. This wall effect might be greater for smaller channel widths and smaller fibers. The experimental method of casting in this research paper utilizes shear flow, wall effect, and the pulling effect.

Fiber pullout tests have also been done with regard to fiber orientation angle. Kang, Kim, and Lee (2010) observed the largest peak fiber pullout load at an angle of 30 to 45 degrees due to the combined effect of snubbing and matrix spalling. However, research also suggests that inclined orientation in UHPFRC tension specimens does not lead to better strain hardening performance compared to longitudinal orientations due to the fiber group effect.

In regards to tensile test setup, many research uses dog-bone shapes, however this is impractical for specimens cut from a structural element. Bruehwiler et al. (2009) cut rectangular prism tensile specimens from a slab and placed aluminum plates on the tops and bottoms of the specimens. A regular servo-hydraulic machine was used with hydraulic clamping jaws to test the specimens. The aluminum plates prevented failure cracks from happening in the clamps and allowed for better LVDT readings within the zone not covered by the aluminum plates. Their method of specimen preparation and test method is a model for the preparation and experimental method used within this research paper.

2 MATERIALS AND CASTING

2.1 *Pouring device*

A pouring device was constructed from chemical resistant type-1 PVC U-channels that glued together along

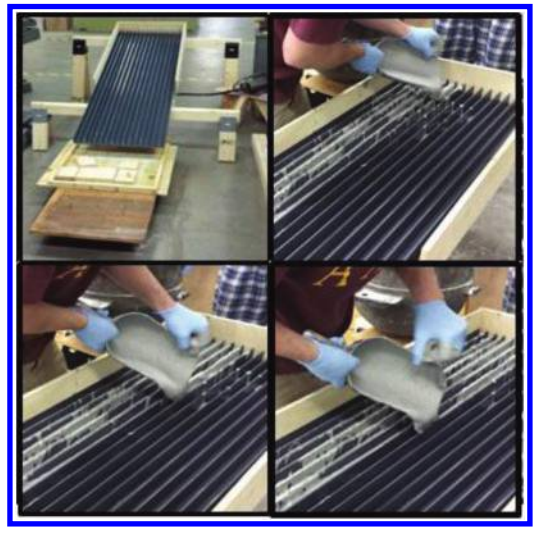

Figure 1. UHPFRC pouring device (top left). Placing UHPFRC into the pouring device (top right to bottom right).

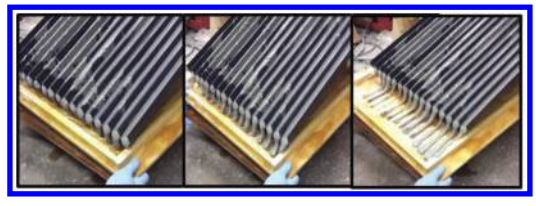

Figure 2. The beginning of the pouring device casting process.

their length (Figures 1, 2 & 3). A total of 16 channels were used, each with dimensions of $5' \times 1.14''$ base $\times$ $1.650''$ leg height $\times$ $0.080''$ wall thickness. Plywood backing and sides were added to increase structural stability. Two saw horses were made so that the pouring device can rest on them at a pouring angle of 20 degrees. On the back of the pouring device a concrete vibrator is latched using metal brackets. It is wrapped in cloth to dampen its force and is used to aid the UHPFRC to flow. Directly below the pouring device is a skateboard on which the final formwork will lie. The skateboard is fashioned out of two skateboard axles mounted onto a $5' \times 2'$ sheet of plywood.

2.2 *Mixture design*

Smooth brass coated high strength steel fibers of $0.5''$ length and of 2.5% volume fraction were used. Three $3'' \times 6''$ cylinder compression specimens were cast with this UHPFRC mix design and the average maximum compressive stress for the specimens is 32.9 ksi. A spread test was performed with both UHPC and UHPFRC in accordance with ASTM C 230/ C 230M. The UHPFRC had a spread of 250 mm whereas the UHPC had a spread of 265 mm.

Figure 3. Midway through the pouring device casting process.

2.3 *Mixing procedure*

The mixing procedure is modeled after that proposed by Wille et al. (2011). The process is designed to ensure that any agglomerations of UHPC particles are broken up properly and that everything is homogenously dispersed. In order to achieve homogeneity, materials are first mixed dry according to the mix proportions previously given. The mixer used is a 3/4 horsepower floor mounted rotary mixer.

At a low speed the full amount of sand was mixed with the silica fume for 8 minutes. The silica powder and cement were then added to the same bowl to mix for an additional 8 minutes at a low speed. A third of the HRWR was added to the water. Still on low speed, the HRWR and water mix was added to the mix within one minute of first pouring it. The remaining two thirds of the HRWR were added within the next minute. The mixing speed was turned from low to medium once all the liquids were added. The mix became fluid in about 3 to 8 minutes and immediately after this the mixing speed was put on high for 1 minute. The mixing speed was put on low and the fibers were added within 1 minute. Mixing at low speed continued for another minute so that the fibers could mix homogenously.

2.4 *Casting*

2.4.1 *Oriented using pouring device*

The pouring device is initially set in a horizontal position. The skateboard is set underneath the pouring device on top of which sets a plywood formwork roughly $18.5'' \times 24'' \times 1''$ height. The formwork is coated in mineral oil. Plastic shrink-wrap is used to line the formwork and the mineral oil helps it adhere to the plywood. This is done because previous trials without shrink-wrap resulted in shrinkage cracking along the fiber alignment due to the high surface area, high plastic shrinkage and the lack of crack bridging fibers.

After the mixing procedure is done the mixing bowl full of concrete is brought to the pouring device. The concrete vibrator is flipped on. A large scoop is filled with UHPFRC and its entire content distributed uniformly along one 5' length U-channel section at a time in one sweeping motion with the scoop (Figure 1). This helps jumpstart the fiber alignment process but most importantly it spreads out the material for an even flow during the casting process. The remaining 16 U-channels were filled in this fashion. Immediately the trough is lowered into its 20 degree position and the concrete begins to flow. Previous trials showed that due to the high surface area the UHPFRC can begin to set in the channels, if the filling procedure takes too long. This can create clumping and can negatively affect fiber orientation and the uniformity of the matrix.

Figure 4. Randomly oriented casting using a scoop.

Once the device is in the 20 degree position the UHPFRC is given 10-20 seconds to flow out of the device in order for the flow to reach a constant rate such as the flow shown in Figures 2 & 3. This flow is contained outside the formwork and is not used for the specimen. After the constant flow is reached, the roller supported slab specimen is pushed forward at a rate of about 0.2ft/s so that the formwork comes in contact with the flow from the pouring device. When the formwork reaches the end then the specimen direction is reversed and the process is repeated so as to cast in lifts. The flow from the pouring device is never broken which allows the UHPFRC to be dragged by the movement of the specimen. This dragging movement helps align the fibers. This process is repeated until the majority of the UHPFRC is in the mold and the flow from the pouring device becomes too weak to continue. A total of 5 separate slabs were poured with this method.

2.4.2 *Random oriented*

The same plywood formwork lined with plastic shrink-wrap is used for this method. However, instead of using the pouring device to orient the fibers, a large scoop is filled with UHPFRC and poured into the mold as randomly as possibly (Figure 4). Only one slab was poured with this method.

2.4.3 *Oriented in tensile mold with scoop*

This procedure is done much like the procedure of laying the UHPFRC into the U-channels (Figure 1). However, instead of filling U-channels, tensile molds are filled. The tensile molds are $16'' \times 1'' \times 2''$ height (not shown in figure) and are poured with the $2''$ side vertical and the $16 \times 1''$ sides horizontal. This size is roughly the same size as the specimens that will be cut at different angles from the plywood molds. Before starting, the tensile molds were coated with mineral oil as a release agent. This process was also repeated using a UHPC mix with the same proportions as the UHPFRC except without the fibers. In both cases the

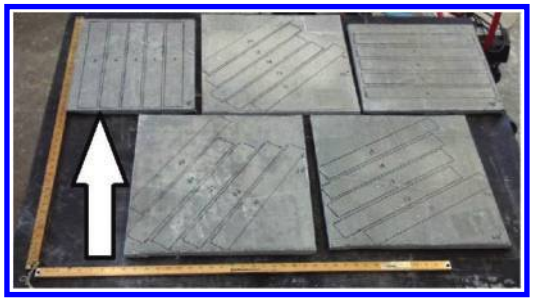

Figure 5. Proposed saw cut lines for 0, 45, 90, 30, 60 degree angles are drawn into the slabs (top left to bottom right respectively). The white arrow shows pouring direction.

Table 2. Description of test specimens.

Specimen #	Casting method	Series name
1–5	slab w/pouring device	0
6–10	slab w/pouring device	90
11–15	slab w/pouring device	60
16–20	slab w/pouring device	45
21–25	slab w/pouring device	30
26–30	slab w/scoop	random
31–35	tensile mold w/scoop	0 (scoop)
36–40	tensile mold w/UHPC	UHPC

molds were placed on a vibration table on the lowest possible setting so as not to induce fiber settling. Five specimens were cast with the UHPFRC and five specimens were cast with the UHPC.

2.5 *Preparation*

All specimens were covered with a plastic sheet immediately after casting. Special care was taken not to let the sheets touch the top of the slabs. All specimens were left covered and in their formwork for 36 hours. After 36 hours the specimens were de-molded and placed in a steam curer at a temperature of 90 Celsius degrees for 48 hours.

The proposed cut lines were drawn, using a permanent marker and a yardstick, on the slabs taken from the plywood formworks (Figure 5). A protractor was used to find angles of 0, 30, 45, 60, and 90 degrees. Five specimens were taken from each slab with dimensions of $2'' \times 16''$. A wet saw was used to cut the slabs along the lines drawn onto the slabs.

All of the tension specimens were lightly ground to help reduce the impact of irregularities such as surface air bubbles. $5'' \times 2'' \times 0.32''$ thick aluminum plates were adhered to the specimens using a two part epoxy. All of the specimens were labeled 1 through 40 and their exact dimensions were measured and recorded. The description to match the numbering of each specimen is shown in Table 2.

3 TESTING PROCEDURE

The $2'' \times 1'' \times 16''$ length specimens were placed in the wedge grips of a 60 kip serve-hydraulic testing machine. Tests were conducted in displacement controlled mode at a rate of .17 mm/min. The central part of the specimen, about $6''$ to $6.5''$ in length, was instrumented with two LVDTs to measure the displacement.

Table 3. Stress and strain comparisons.

Series	$\sigma\, m_{avg}$	εm_{avg}	$\%\sigma m_0$	$\%\varepsilon m_0$
0	1.8	.23	100	100
30	1.28	.059	71	26
45	1.03	.068	57	30
60	0.56	.12	31	51
90	0.41	.10	23	44

4 RESULTS

Specimen #'s 3 & 5 (0 series), 15 (60 series), 19 (45 series), 35 (0 scoop series), & 38 (UHPC series) were disregarded from analysis due to not representative stress strain curves. Several reasons for this include improper handling during saw cutting and preparation, improper assembly in the tensile grips system, LVDT alignment difficulties, specimen slip within the tensile grips during tests. All other specimens are included in analysis. The complete softening effects are not shown in every stress strain curve because failure crack opening were not always limited to within the zone of the LVDTs which leads to invalid strain results after maximum stress is reached.

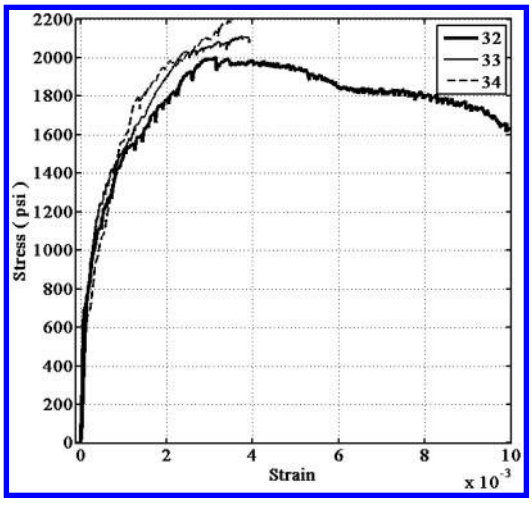

Figure 7. Stress strain curve for 0 degree (scoop) series.

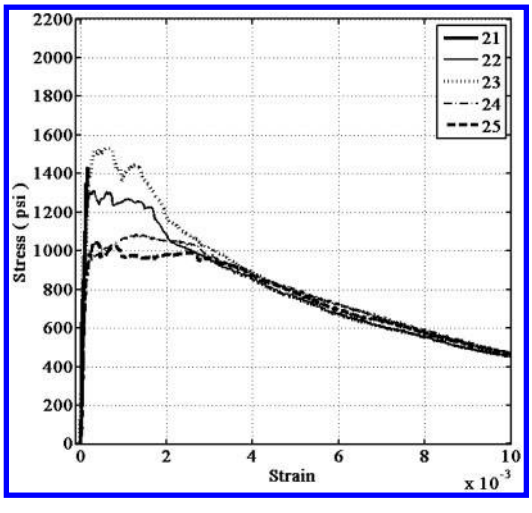

Figure 8. Stress strain curve for 30 degree series.

Figure 6 and Table 3 summarizes the test results of tensile strength and strain at maximum stress, whereas Figure 7 to 11 show the stress versus strain curves in dependency of fiber orientation and casting method. The UHPFRC specimens casted with a scoop directly in the prism shape mold achieved the highest values in average strength of 2.15 ksi and in strain at maximum stress of 0.47%. The higher values in comparison to the cut out slab specimens are attributed to the following effects: The shrink-wrap lining of the plywood molds resulted in wrinkle indents into these specimens. The slabs had roughly twice as much surface area subjected air bubble concentrations than that of the tensile mold specimens. The saw cut specimens were subject to fibers and matrix ripping out during the preparation process and the distribution of fiber quantity throughout the thickness of the tensile mold specimens was more uniform than the specimens cut from the slabs

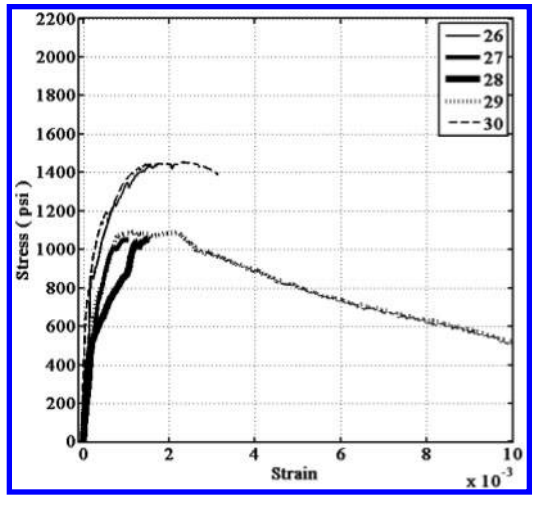

Figure 9. Stress strain curve for random degree series.

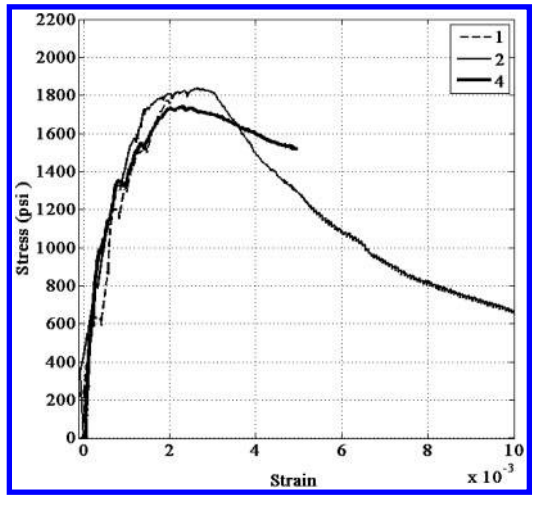

Figure 10. Stress strain curve for 0 degree series.

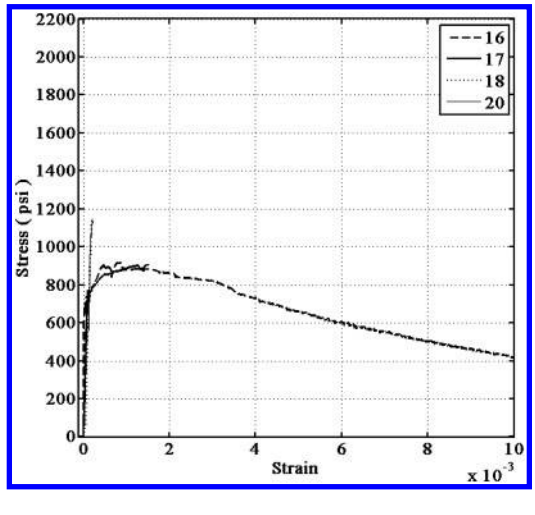

Figure 11. Stress strain curve for 45 degree series.

where the fibers tended to settle towards the middle and bottom the plywood mold.

The randomly poured slab specimens are comparable to the specimens with fiber alignment of 30 degrees to the applied load. The more the fibers were aligned perpendicular to the load direction the less strength and the more brittle behavior was achieved. It is worth noticing that the failure crack changed from a horizontal crack to an inclined crack along the fiber orientation the more the fibers were aligned perpendicular to the applied load. This was observed for some specimens of 45 and 60 degree fiber orientation. If the failure crack forms along the fiber orientation, which was the case for some specimens of 45 degrees, most of 60 degrees and all of 90 degrees fiber orientation, a sudden and brittle failure is observed, comparable to plain matrix (UHPC). This is in contradiction with single fiber pull out test results, in which the fiber pull out load at 45 or 60 degrees still provides significant strength and energy dissipation through fiber pull out. This mechanism and energy dissipation is not valid, if the crack in the composite is formed with an incline to the applied load along the fiber orientation. This crack formation is based on the path of least amount of energy.

5 CONCLUSIONS

The casting method used in this research was able to provide a uniform and repeatable way of casting fibers in one direction so that specimens could be cut out at angles and then uniaxial tension tested.

The results of this experiment support that fiber orientation has a significant impact on strain hardening effects of UHPFRC. The influence of the fiber group effect as well as the influence of failure crack development could be experimentally taken into account. The results do stress that in order to accurately predict the design strength of UHPFRC fiber orientation needs to be accounted for. Existing research shows that analytical models have promise in being able to predict UHPFRC behavior in tension when fiber distribution and orientation are known. However all models consider crack development perpendicular to the applied load. Alignment of fibers could change the failure crack development based on least amount of global energy dissipation. This can be of concern of the applied load acts at and larger 45 degrees to the aligned fiber orientation.

Future research will include validating of the research results, analyzing of the fiber group effect and extending the test matrix by including different types and lengths of fibers.

The origin of plastic settlement cracking and the effect of re-vibration

R. Combrinck & W.P. Boshoff
Department of Civil Engineering, Stellenbosch University, South Africa

ABSTRACT: Plastic settlement cracking is one of the earliest forms of cracking in concrete structures as it occurs within the first few hours after the concrete has been cast. The mechanism responsible for plastic settlement cracking is differential settlement of the concrete due to rigid inclusions in the concrete element. Although the mechanism and general location of these cracks are known, not enough attention has been given to the basic behaviour and origin of pure plastic settlement cracks. This is mainly due to the difficulty of observing purely plastic settlement cracks without observing some influence of plastic shrinkage cracking caused by evaporation. This study experimentally showed that the origin or start location of pure plastic settlement cracks are from the bottom upwards and not from the surface downward as would be expected. This indicates that plastic settlement cracks may be present in concrete elements even if the cracks are not visible on the surface. This observation was confirmed through a numerical analysis of the plastic settlement cracking using a visco-elastic approach combined with a total strain smeared crack model. The experiments also showed that these cracks can form even if curing is applied. Finally, since these cracks can form below the concrete surface, workers and engineers may not be aware of their presence. Robust mitigation methods are therefore of utmost importance to ensure concrete durability and prolong the service-life of the structure. Experiments were performed to determine if one such mitigation method, the re-vibration of concrete, adversely affects the concrete strength. The results showed that if re-vibration is to be used as mitigation method for plastic settlement cracking, it should preferable be completed well before the final setting time of the concrete is reached.

1 INTRODUCTION

The phenomena of plastic settlement cracking has been well documented in literature for the past 50 years (Powers 1968, Weyers et al. 1982 & Kwak et al. 2010). It is arguably the earliest form of cracking in concrete structures as it occurs within the first few hours after the concrete has been cast. The mechanism responsible for plastic settlement cracking is differential settlement of the concrete due to rigid inclusions in the concrete element, for example: reinforcing steel or a non-uniform concrete depth (Weyers et al. 1982). T-beam type elements and reinforced ground floors or decks are examples of structural elements prone to differential settlement and therefore plastic settlement cracking.

Although the mechanism and general location of these cracks are known, not enough attention has been given to the basic behaviour and origin of pure plastic settlement cracks. This is mainly due to the difficulty of observing pure plastic settlement cracks without observing some influence of plastic shrinkage cracking which is caused by evaporation (Kwak et al. 2010 & Combrinck et al. 2012).

The most common method to mitigate these cracks is through the re-vibration of the concrete while it is still in the plastic state (Owens 2009). The initial setting time of concrete serves as a good indication of the end of the plastic state as well as the point in time where the potential for plastic settlement cracking stops since settlement also typically ceases at this time. Re-vibration of the concrete before or at the initial setting time effectively removes all plastic settlement cracks and increases the concrete compaction and therefore also strength (Owens 2009 & Rao et al. 2008). In practise, re-vibration is seldom applied at the correct time and the question remains whether poor timing can negatively influence the concrete. Furthermore, if these cracks are not mitigated they act as potential weak spots where prospective crack widening due to plastic-, thermal- and drying shrinkage will originate. Cracks acts as access for aggressive and corrosive agents to penetrate the concrete surface. This accelerates concrete degradation and decreases the overall durability and the corresponding service life of the structure (Weyers et al. 1982 & Qi 2003).

With all of this in mind, this paper aims to determine the origin or start location of pure plastic settlement cracks. This is believed to be vital information if plastic settlement cracking is to be understood and prevented. In addition, the location of the cracks is also verified with a numerical analysis of the settlement and the cracking by combining a visco-elastic material approach with total strain smeared cracking behaviour. Finally, concrete was subjected to re-vibration at both the initial and final setting times to determine if

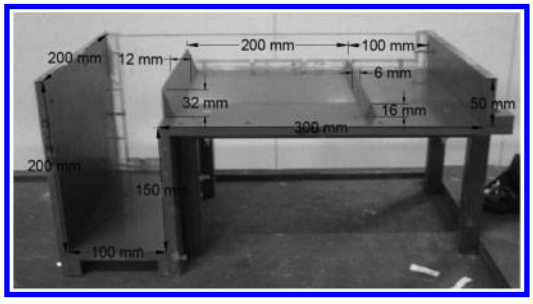

Figure 1. L-Shaped mould with transparent sides used to observe plastic settlement cracks in concrete.

re-vibration can be applied confidently as a robust mitigation method for plastic settlement cracking without adversely affecting the concrete.

2 PLASTIC SETTLEMENT CRACKING

The pattern of plastic settlement cracks generally coincide with the reinforcing steel layout or positions with significant changes in section height. In practice these cracks are only visible at the concrete surface and may in several cases be widened by plastic shrinkage. Plastic shrinkage is caused by the evaporation of concrete water which causes capillary pressure buildup within the concrete. This capillary pressure causes the concrete body to contract horizontally which causes cracking (Wittmann 1976 & Uno 1998). Although plastic shrinkage cracking normally occurs just after plastic settlement cracking, they may interact under conditions with high evaporation rates (Combrinck et al. 2012). This makes it difficult to distinguish between the two cracking types. The following experiment was conducted to determine pure plastic settlement cracking behaviour and origin. This is also confirmed with a numerical analysis.

2.1 *Experimental setup*

The aim of the experiment was to observe the formation of a pure plastic settlement crack without the influence of evaporation and therefore plastic shrinkage cracking. Two L-shaped moulds as shown in Figure 1 were used to ensure cracking. The mould has a deep and a swallow section that give pronounced differential settlement and therefore cracking at the boundary between the sections. The left triangular insert creates a clear boundary between the sections, while the right triangular insert plays no role in these experiments and can be ignored. The mould has transparent sides which allow cracks to be observed below the concrete surface.

The proportions and constituents of the mixture used are shown in Table 1. A 13 mm stone was chosen as the maximum size appropriate for use in a mould which is 50 mm deep. A coarse natural sand was used to give adequate bleeding/settlement to ensure cracking.

Table 1. Mix proportions and material constituents.

Content	(kg/m^3)
Water	215
CEM I 52.5 N	538
Greywacke stone (13 mm)	1050
Coarse natural sand	572

Bleeding and settlement is nearly identical if chemical shrinkage is negligible (Kwak et al. 2010). The mix showed good workability with no segregation and achieved a 28 day compression strength of more than 40 MPa.

The experiments were carried out in a controlled environmental room with a temperature of 23°C and relative humidity of 65%. The surface of the mould was continuously kept wet to ensure no capillary pressure buildup in the concrete due to the evaporation of concrete water. This ensured that no plastic shrinkage cracking could occur and that only the pure plastic settlement cracking is observed. During the experiments the moulds were continuously checked for cracks at the sides and on the surface.

2.2 *Experimental results*

Both L-shaped concrete specimens showed hairline cracks at the tip of the triangle at the boundary between the deep and swallow sections of the mould. One of the specimens also showed a clear crack just below the surface of the concrete. This crack was not visible at the surface of the concrete, but only from the side. All the cracks appeared around 80 minutes after the concrete was cast, which is long before the initial setting time was reached at 330 minutes. The crack widths were between 30 and 90 μm.

Figure 2 shows images of the specimen that had a crack just below the surface and at the tip of the triangle. The photo in Figure 2a was taken through the transparent side panel just after its first appearance. This photo also shows the water layer present on the concrete surface to prevent evaporation. The photo in Figure 2b was taken after 360 minutes with the transparent side panel removed.

Both images show that the dominate crack start forming from within the concrete at the triangle tip, while the top crack only occurred for one of the specimens and was not visible on the concrete surface. Plastic settlement cracks therefore form from the bottom upwards and not from the surface down as would be expected. This behaviour of plastic settlement cracks has important practical implications. It indicates that plastic settlement cracks may be present in concrete elements even if the cracks are not visible at the surface. In addition, these cracks may be present even if all evaporation was prevented through curing practices. These cracks may also be further widened due to drying shrinkage or structural loading and possibly expose reinforcing steel to the environment.

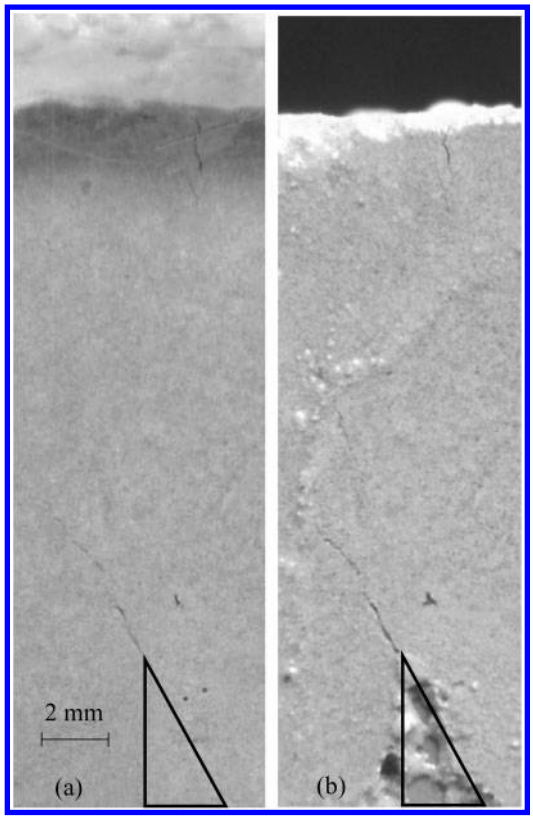

Figure 2. Observed cracks for the L-shaped specimen at the tip of the triangular insert as well as just below the concrete surface. Both images are of the same specimen but taken at different times. (a) Taken 80 minutes after casting through the transparent side panel. (b) Taken 330 minutes after casting with the transparent side panel removed.

2.3 *Visco-elastic approach to settlement*

The settlement of concrete is best described by the process of self-weight consolidation (Josserand et al. 2006 & Kwak et al. 2010). This analogy uses the concept of effective stress which is often used in soil mechanics. It means that if a load is applied to a saturated soil, the load is initially resisted by the solid soil skeleton as well as the pressure in the water (pore pressure). As time elapses the pore pressure dissipates and the full load is gradually transferred to the soil skeleton. This is similar to the settlement or bleeding of concrete and for both systems the soil/concrete skeleton can be seen as a spring element while the pore pressure can be seen as a dashpot. This makes it possible to model concrete settlement using time dependent visco-elastic material behaviour. Visco-elastic materials are commonly used to describe materials that exhibits behaviour that is part liquid and part solid such as fresh concrete. For settlement, a constant stress is applied through the self weight which gradually increases the cumulative settlement. The Kelvin chain visco-elastic model is best suited to represent constant stress and cumulative strain increase or simply creep (Illston et al. 2001). The

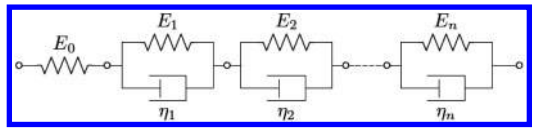

Figure 3. Kelvin chain visco-elastic model (DIANA 9.4.3, User's Manual 2010).

basic Kelvin chain model with springs and dashpots is shown in Figure 3.

In order to assign values to all the springs and dashpots of the entire Kelvin chain model, it is first necessary to consider only one chain element which consists of one spring and one dashpot in parallel. The viscosity η of the dashpot can be calculated by multiplying the relaxation time λ with the spring stiffness E as follows:

$$\eta = \lambda E \tag{1}$$

The stress in the spring (s) and the dashpot (d) can be calculated with the following equations respectively.

$$\sigma_S = E\varepsilon_S \tag{2}$$

$$\sigma_D = \lambda E\dot{\varepsilon}_D \tag{3}$$

where σ_S = stress in spring; ε_S = strain in spring; σ_D = stress in dashpot and $\dot{\varepsilon}_D$ = strain rate of the dashpot. The sum of the stress in the spring and the dashpot gives the stress in the chain element and can be expressed as follows:

$$\sigma = E(\varepsilon_0 + d\varepsilon) + \lambda E\frac{d\varepsilon}{dt} \tag{4}$$

where ε_O = strain at the beginning of the time step; d ε = change in strain during the time step and dt = duration of the time step. Rearranging Equation 4 and integrating over time and strain leads to the following equation which expresses the change in strain $\delta\varepsilon$ for each time step $\delta t = t - t_o$:

$$\delta\varepsilon = \varepsilon - \varepsilon_0 = \frac{\sigma - E\varepsilon_o}{\frac{\lambda E}{(t - t_o)} + E} \tag{5}$$

Now consider the entire Kelvin chain model as shown in Figure 3, where the stress in each chain element is constant and the total stain is equal to the sum of the strains in each chain element. Given this, the total strain in the Kelvin chain model at any time can be calculated as follows:

$$\varepsilon_{tot,m} = \varepsilon_{tot,m-1} + \delta\varepsilon_{0,m} + \delta\varepsilon_{1,m} + \ldots + \delta\varepsilon_{n,m} \tag{6}$$

where $\varepsilon_{tot,m}$ = total strain at time m; $\varepsilon_{tot,m-1}$ = total strain at time m less one time step and finally $\delta\varepsilon_{n,m}$ = change in strain for each Kelvin chain element

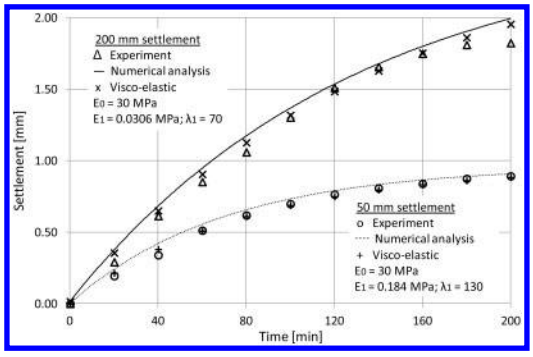

Figure 4. Experimental, Kelvin chain visco-elastic material approach and numerical results of concrete settlement with 50 mm and 200 mm depth.

n (from element 0 to n) over time step δt. $\delta\varepsilon_{n,m}$ can be calculated as follows:

$$\delta\varepsilon_{n,m} = \frac{\sigma - E_n \varepsilon_{2,m-1}}{\lambda_n E_n / \delta t + E_n} \quad (7)$$

Using Equations 6 and 7 any settlement behaviour can be represented by the equivalent visco-elastic Kelvin model though curve fitting using the method of least squares. This method minimizes the error between the experimental results and the equivalent visco-elastic material. The experimental results for the settlement were determined by measuring the bleeding of a 50 mm and 200 mm deep concrete specimen. The bleeding was considered to be equal to the settlement (Kwak et al. 2010). A more detailed description of the measuring procedure can be found elsewhere (Josserand et al. 2004). A time step of 20 minutes was chosen as this conforms to the experimentally measured time intervals. Figure 4 compares the measured settlement with the estimated settlement using a visco-elastic approach. The figure also shows the results of a numerical analysis which will be discussed in the next section.

Two Kelvin chain elements were found to adequately represent the measured settlement and Figure 4 also indicates the calculated visco-elastic parameters. The parameters were determined by choosing the spring stiffness of the first chain element and the relaxation time of the second chain element while the spring stiffness of the second chain element was iteratively solved to satisfy the least square method. This also simplified the numerical analysis described later in this paper. Figure 4 shows favourable agreement between the experimental results and the equivalent visco-elastic material behaviour. A visco-elastic approach using the Kelvin chain model can therefore be used to represent concrete settlement.

2.4 *Numerical analysis of settlement*

Figure 4 also shows the results of the numerical analysis which used the visco-elastic material parameters as input values. A two dimensional numerical analysis was performed with the commercially available finite element analysis program DIANA 9.4.3 (DIANA 9.4.3, User's Manual 2010). Both the 50 mm and 200 mm bleeding moulds were modeled separately using four-node quadrilateral isoparametric plane stress elements. The element size was 5x5 mm. Only self weight was applied where after the time dependent visco-elastic material behaviour influenced the settlement. A time step of 0.5 minutes was chosen. The specimens were fixed at the base against vertical translation. The results in Figure 4 show that the numerical analysis results, obtained using the calculated visco-elastic parameters, give an acceptable representation of the measured settlement.

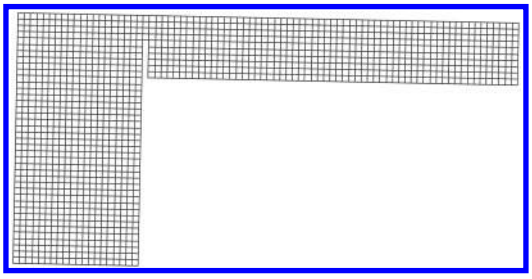

Figure 5. Model geometry and mesh.

2.5 *Numerical analysis of plastic settlement cracking*

A numerical analysis of the concrete settlement and possible concrete cracking in the plastic settlement mould was also performed. The same element types, applied loads and visco-elastic material behaviour were used as in the previous sections. Figure 5 shows the model geometry and mesh. The boundary conditions were as follows: all the base edges were fixed against vertical translation, while all vertical edges were fixed against horizontal translation. Figure 5 also shows that the triangular insert was modeled by removing a column of elements equal to the height of the triangle.

Cracking is taken into account by using a total strain smeared crack model which can be combined with direct input for Kelvin chain visco-elasticity (DIANA 9.4.3, User's Manual 2010). The analysis also requires the tensile behaviour of the fresh concrete. The experimental determination of the tensile behaviour of fresh concrete has proven to be troublesome, especially at very early ages (Hannant et al. 1978 & Doa et al. 2009). The post cracking behaviour is also unknown and as with the tensile strength will vary with time. The goal of this analysis is only to verify the experimental crack locations as observed in Figure 2 and therefore it is deemed sufficient to assume the post peak behaviour. The simple linear tension softening curve was chosen to represent the tensile behaviour. The tensile strength was chosen as 3000 Pa and the ultimate strain as 0.00011 as shown in Figure 6. This is

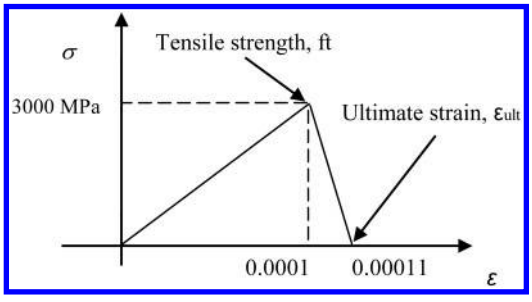

Figure 6. Predefined linear tension softening curve for total strain crack model (DIANA 9.4.3, User's Manual 2010).

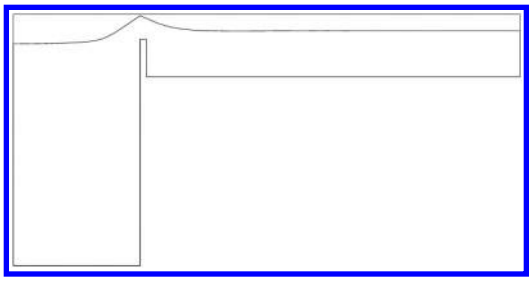

Figure 7. Deformed shape obtained from numerical analysis of concrete in the plastic settlement mould after 80 minutes.

Figure 8. Cracking as function of maximum principal strain as obtained from the numerical analysis of concrete in the plastic settlement mould after 80 minutes.

qausi-brittle crack behaviour since the ultimate strain is only 10% more than the strain at the tensile strength.

It is acknowledged that the chosen behaviour might not be correct. However, it is believed that it can still be used to verify the cracking positions. Furthermore, the characterization of the tensile behaviour of fresh concrete requires more investigation and is currently part of an ongoing project at Stellenbosch University.

The results of the analysis at 80 minutes are shown in Figures 7 and 8. Figure 7 shows the deformed shape and Figure 8 shows the maximum principal strain. Figure 7 clearly shows the difference in settlement between the deep and shallow sections as well as the influence of the triangular restraint.

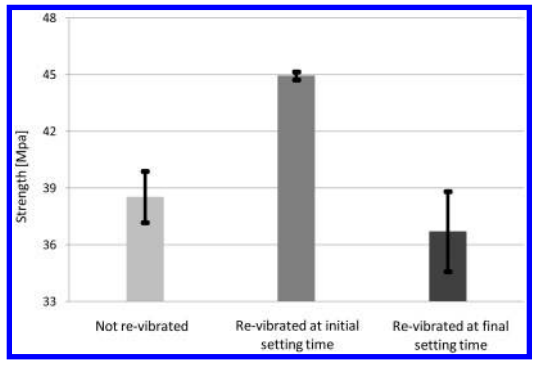

Figure 9. Compression strength results at 7 days of the re-vibration tests.

3 EFFECT OF RE-VIBRATION

The previous section discussed the behaviour of pure plastic settlement cracking. It showed that these cracks can be present below the concrete surface even if curing was applied successfully. Workers and engineers may therefore not be aware of the presence of these cracks. This observation highlights the importance of applying mitigations methods for plastic settlement cracks even when no cracks are visible on the concrete surface. The re-vibration of concrete just before it loses it plasticity is the most common mitigation method that has been shown to close plastic settlement cracks (Roa et al. 2008 & Owens 2009).

However, if this method is to serve as a practical solution, it should not adversely affect the concrete if applied at the wrong time. The aim of the following experiments is to determine whether the re-vibration of concrete at both the initial and final setting times respectively negatively influences the concrete's strength.

3.1 *Experimental setup*

The mixture given in Table 1 was also used for these experiments. After mixing the concrete, 100x100x100 mm specimens were filled and compacted. A number of the specimens were left undisturbed while the rest were either re-vibrated at the initial setting time or at the final setting time. The setting times were determined with the Vicat needle apparatus (Combrinck et al. 2012). The re-vibration lasted for 3 minutes on a standard vibrating table. Finally, the specimens were water cured and tested at 7 days.

3.2 *Results and discussion*

Figure 9 shows the 7 day compression strength results of the re-vibration tests. The figure indicates a noticeable increase in strength if re-vibrated at the initial setting time. One possible reason for this result was observed during the experiment where a significant amount of extra bleeding water was transferred to the concrete surface due to the re-vibration. This lowered

the water-cement ratio and is believed to be the reason for the increase in strength.

Figure 9 also shows that the re-vibration of the concrete at the final setting time reduced the strength. The reasons for this are possibly due to the disturbance of the initially formed hydration products as well as observation that no additional bleeding water was transferred to the surface when re-vibrated at the final setting time.

Although this requires further investigation, it can be concluded that if re-vibration is to be used as mitigation method for plastic settlement cracking, it should preferable be completed well before the final setting time to avoid a possible decrease in concrete strength.

4 CONCLUSIONS

In this study the origin of pure plastic settlement cracking was investigated experimentally. A numerical analysis of plastic settlement and plastic settlement cracking were also performed. Lastly, the effect of re-vibration on concrete strength was investigated. The following significant conclusion can be drawn:

- The most likely starting location or origin of plastic settlement cracking is from the bottom upward and not from the surface downwards.
- Due to its origin, plastic settlement cracks may be present in concrete elements even if not visible on the surface and even if curing prevented all possible plastic shrinkage cracking.
- The Kelvin chain visco-elastic approach can be used to represent the settlement of concrete.
- Kelvin chain visco-elastic material behaviour can be combined with a total strain smeared cracking model to predict the location of cracks.
- If re-vibration is to be used as mitigation method for plastic settlement cracking, it should preferable be completed well before the final setting time to avoid a possible decrease in concrete strength.

Composite material under influence of moisture

Jan Skramlik, Miloslav Novotny & Karel Suhajda
Brno University of Technology, Faculty of Civil Engneering, Czech Republic

ABSTRACT: One of the properties of porous composite materials, which may be decisive for their utilization in a building structure, is their ability to absorb and release water. It is a case of moisture that flows through a material, saturates it, or drains it. The moisture content varies both in space and in time. Many properties of a material (insulating value, strength, etc.) depend on its moisture content and therefore material moisture must be taken into account.

Water penetrates a porous material from the environment and the equilibrium between the material moisture and the ambient air moisture is reached under steady temperature and moisture conditions. If the partial pressure of water vapor in a building material is lower than that in the ambient air, then the material absorbs water vapor from the air. Conversely, the material releases water vapor. Equilibrium moisture is characterized by zero increment of weight and temperature in time. An impact of moisture on coefficients of thermal conductivity varies according to the concrete temperature and moisture content of a material.

The research deals with the application of nondestructive measurement of moisture parameters of composite materials being developed for application in practice, using the experimentally assembled measuring apparatus on the principle of using electromagnetic microwave radiation.

Keywords: capillary conductivity, continuity equation, electromagnetic microwave radiation

1 INTRODUCTION

The publication introduces the results of experimental measurements carried out for the transport of humidity in porous steady masses in non-stationary conditions to express the moisture distribution by the help of measuring apparatus working on the non-destructive principle of electromagnetic microwave radiation. The aim is verify the mentioned method of measurement for the description of moisture parameters of the composite materials.

2 TESTING MATERIALS SAMPLES

We deal with the samples of materials, produced based on the waste products usage. The used samples are marked "R" concrete samples. See the Fig. 1. The development of these building materials is based on the recycling of waste materials.

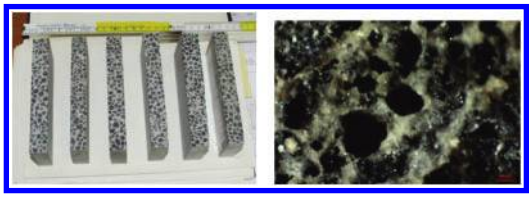

Figure 1. Material samples developed at Department of Building Materials at Brno University of Technology.

Material characteristic is porous structure as well as inert homogenous material. The homogenous material includes gradation in range 0 up to 8 mm or in range 4 up to 8 mm when used porous gravel. The composite material represents isolation with filling of light components. The usage of the mentioned materials in building activities is based on the material characteristics. These items are subject for the following examinations. The experimental measurement of the moisture parameters is based on the observation of the moisture transport. It allows describe distribution of moisture, needed for the calculation of the capillary conductivity coefficient using the nondestructive method.

The test results were acquired from the basic samples, see the following graphs.

Primary aim was to observe the transport of the moisture in order to find out the capillary conductivity coefficient. We used microwave method based on the set methodology and by the help the measuring instrument which was developed at the Department of Building Structures at the University of Technology by Brno.

3 MOISTURE BEHAVIOR

We tested time of intake of water through the material. The sample dimension was $60 \times 20 \times 200$ mm. The process was done by the close contact of lower sample surface with the liquid area. This behavior was

Table 1. Basic parameters of material sample labeled “R” concrete.

„R“ concrete material

Sample no.	Weight [g]	Size [mm]	Bulk [m^3]	Bulk weight [$kg.m^3$]
01	356	190x58x149	0,0001642	2168
02	353,2	190x58x149	0,0001642	2151

06	358,7	190x59x149	0,0001670	2147
Average	366,56	195x59x14	0,0001714	2150

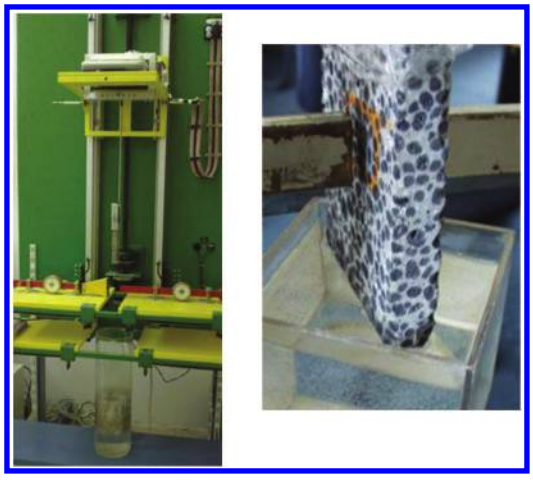

Figure 2. Position of the “R” concrete materials samples during moisture behavior measurement.

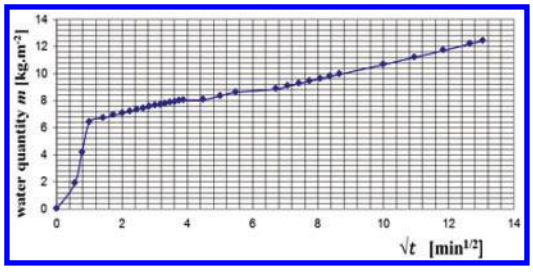

Figure 3. Process of dampness in time t.

tested in the time line (see the Fig. 2). For the measurement was used objective sample of the new developed material on the basis using of composites, marked as “R” concrete.

Graphical expression of the time line for the moisture can find on the Fig. 3. This is base to set right time period to calculate profile of the moisture front coordinates.

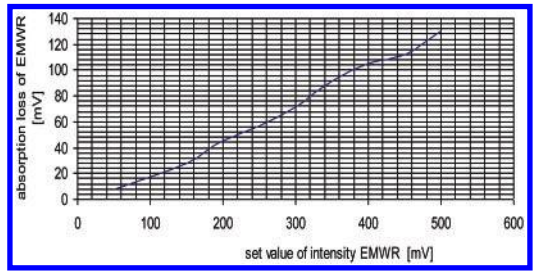

Figure 4. Dependency of the intensity change detection according the level of electromagnetic MW radiation (dry state material).

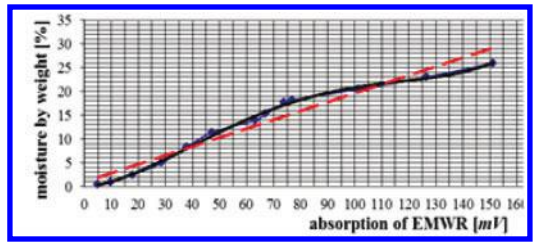

Figure 5. Dependence of change of the intensity of electromagnetic radiation on the moisture by weight of sample “R” concrete.

4 DEPENDENCY OF EMWZ PERMEABILITY BASED ON THE SET INTENSITY

Dependency of intensity changes of material permeability on electromagnetic MW radiation and its graphical expression is base to set intensity of the radiation. Dependency intensity of microwave radiation changes according to the specific moisture as well for detect of the moisture profile. Fig. 4 includes results of the measurement of the MW radiation.

Functional dependency of the tested sample materials has linear course. This confirms presumption for calculation of the capillary conductivity coefficient.

5 FUNCTION OF INTENSITY CHANGES DEPENDENCY EMWR ACCORDING TO THE MOISTURE BY WEIGHT

Using gravimetric method there were measured level of the radiation based on the moisture by weight of the samples’. The aim of the experiment was determination the function dependency of intensity changes on electromagnetic MW radiation on the moisture by weight (Fig. 5).

6 MOISTURE DISTRIBUTION IN SAMPLE

Fig. 6 shows a sample of the material in the apparatus during the measurement.

At the Fig. 7 is the output measurement of moisture distribution during wetting of the sample of the material in 3D.

Figure 6. "R" concrete and "H" material samples during recording of the moisture front profile position.

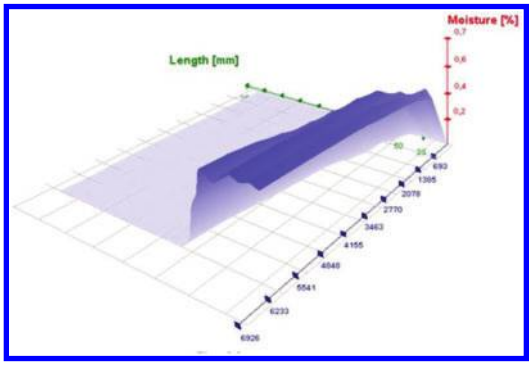

Figure 7. Distributions of moisture in the reference sample material.

Fig. 8 shows the change of EMWR intensity depending on the moisture by weight in the length of measured sample at time intervals in the course of its moistening and consequently determines functional dependence on moisture for calculation of capillary conductivity coefficient.

The values of coordinates determining location of the wetting front profile are obtained from measurements using the microwave measuring apparatus. Detection of moisture quantity diffusing in the material is carried out at certain time intervals from the start of moistening of sample material.

7 CAPILLARY CONDUCTIVITY COEFFICIENT

By using of mathematical method is possible to continue processing the results of measurement for expressing of capillary conductivity coefficient depending on the moisture by weight for expression the thermal insulation properties of materials depending on the moisture.

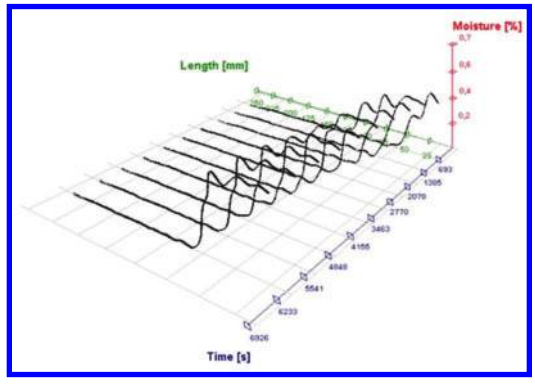

Figure 8. Graphical output - "R" concrete samples during non-stationary state for recording of the moisture front profile position.

The result of the derivation and application of boundary and the initial conditions is the basic equation:

$$\kappa(u(x,t)) = -\frac{1}{2.t.\frac{\partial u}{\partial x}} . \int_{x}^{\infty} x . \frac{\partial u}{\partial x} . dx \qquad (1)$$

where:
$\kappa(u(x))$ coefficient of capillary conductivity $[m^2.s^{-1}]$
t time interval $[s]$
ς substitution of the distance measured $[-]$
η Boltzmann transformation $[m.s^{-1/2}]$
x coordinate in the length of sample $[m]$
u_1 maximal value of humidity by weight $[-]$
u_2 humidity by weight of material $[-]$

Relationship between weight and the amount of moisture microwave radiation that passes through the sample can be approximated by a polynomial by a polynomial using least squares.:

$$y = \sum_{j=0}^{3} k_j . x^j \qquad (2)$$

Calculation of capillary conductivity coefficient can be solved numerically for each percent of moisture (eg from 15 to 80 percent) and gradually applied in equation (1). This yields a specific capillary conductivity coefficient values depending on the weight of moisture. The result can again be approximated to obtain a mathematical formula for this dependence:

$$\kappa(u) = f(u) \qquad (3)$$

$$\kappa(u) = \sum_{j=0}^{n} k_j . u^j \qquad (4)$$

Individual curve can be approximated using appropriate mathematical methods

$$^{1}u_m(\tau) = \frac{m(\tau) - m_s}{m_s} \qquad (5)$$

$^1u_m(\tau)$ moisture by weigh from measurements [%]
τ time [s]
$m(\tau)$ weight of sample in time τ [kg]
m_s– weight of sample in dry state [kg]

Moisture by weight of sample over time τ can also be expressed by integrating of the curve (see figure 8) according to the spatial coordinates x:

$$^2u_m(\tau) = \int_0^\infty v_m(\tau, x).dx \tag{6}$$

$^1u_m(\tau)$ moisture by weight by integrating [%]
τ time [s]
$v_m(\tau,x)$ wetting curve in time τ [m^{-1}]
x– dimensional coordinate [m]

Coefficient to expressing the relative systematic error:

$$k = \frac{^1u_m(\tau)}{^2u_m(\tau)} \tag{7}$$

After substitung (3) in (4):

$$k = \frac{m(\tau) - m_s}{m_s . \int_0^\infty v_m(\tau, x).dx} \tag{8}$$

The results of moisturizing curve corrected in time τ will be in the form:

$$v_{m,k}(\tau, x) = k.v_m(\tau, x) \tag{9}$$

Based on the above mentioned measurements, it is possible to express moisture curves (according to the methodology) as a base to calculate capillary conductivity coefficient.

8 CONCLUSION

Capillary conductivity of liquid moisture in the porous structure of the building materials for the needs of construction practice is still insufficiently explored. The standards on this issue mention only and refers to the experimental measurement using magnetic resonance imaging In fact there does not exist practically usable methodology for the integration of its impact on the thermal-technical characteristics of building materials. Experimentally prepared apparatus and proposed methodology allows continuing in the mathematical processing of the obtained data to calculate the capillary conductivity κ and to determine the functional dependence on moisture. It is the incorporation of the impact of liquid moisture in building materials in assessing the thermal insulation properties.

On samples of composite material has been tested the possibility of obtaining the description of distribution of moisture using non-destructive method by help of microwaves for verification of the mathematical solution for the outputs of the moisture measurement during non-stationary state and for the utilization of the integral method is considered in the current time. The integral method allows giving precision for the figures measured through the EMWR.

Chimney cracked reinforced concrete walls as a problem of durability exploitation

M. Kaminski, M. Maj & A. Ubysz
Institute of Building Engineering, Technical University of Wrocław, Poland

ABSTRACT: Some reasons of appearance of horizontal and vertical cracks as temperature, influence of construction joints, thermal insulation etc. are presented in this paper. There are presented some problems connected with reinforced concrete chimney operation in the aggressive environment. Chimney exhaust fumes have big influence on durability and longevity of chimney wall. Specially there are big difficulties in the case when it is impossible to disconnect chimney from constant work. The repair works are not effective and very expensive.

1 INTRODUCTION

In designing chimney walls there are no place for cracks. Horizontal and vertical cracks can caused corrosion of concrete and steel bars. Cracks decreases stiffness of reinforced concrete chimney shell construction. Local and global mperfactions of chimney walls are increasing according to greater number of cracks. Taking into account these facts, cracks reduce the service life of chimneys. Horizontal and vertical cracks allow condensate water infiltrates into wall. It causes corrosion and dank of concrete wall and during winter time cracks become bigger because if glaciations water in cracks.

Problems with a large number of cracks on chimneys walls occurred in last years in Poland. It was connected with changing chimney codes and in particularly introduction requirement of double reinforcement of concrete walls. Until the end of XX centaury reinforcement bars were located in one row, near the external surface. After receiving in Poland European Standards two rows of reinforcement are demanded. It caused several difficulties in building chimneys because of little space of reinforcement bars.

Additional problem of increasing number and widths of cracks is chimney insulation. Badly placed insulation results in an increase bending moments and on the creaks are wider.

2 ERRORS IN CONSTRUCTING CHIMNEYS WALLS

There are many mistakes which were made during building chimneys:

- too small distance between vertical and horizontal steel bars in concrete wall
- insufficient concrete care during building
- too rapid drying wall

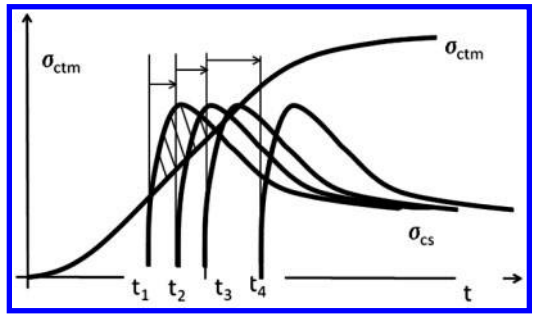

Figure 1. Increasing strength concrete σ_{ctm} versus stresses of shrinkage in concrete σ_{cs}.

- using adjustable formwork in building chimneys
- using joints in chimneys during building
- non proper joint design
- too long pause between subsequent concrete filling
- using vibrators inappropriate for steel bars diameter and for distances between them
- touching by vibrator steel bars (PN-63 B-06251)
- too small or destroyed thermal insulation
- destroyed moisture protecting coating
- too much condensate inside chimney
- too few steel bars calculated shrinkage for chimneys wall
- adding loads on chimney as satellite dishes

Figure 1 shows increasing strength concrete σ_{ctm} versus stresses of shrinkage in concrete σ_{cs} in the beginning of concrete bonding (Flaga 2002). Time t_i can be delayed from t_1 to t_4 through maintenance moisture in concrete wall or by using special plasticizers. Between time t_1 and time t_3 stresses caused by shrinkage are bigger than strength of concrete and cracks can occur in the time of strengthening concrete itself. In this case, when shrinkage stresses are bigger than concrete strength, special reinforcement steel bars should

Figure 2. Horizontal cracks in the place of joints.

Figure 3. Horizontal joints with condensate flowing from internal chimney space.

Figure 4. New chimney without any faults.

be used. But after this initiation time shrinkage stresses decrease.

Vertical and horizontal cracks on chimneys walls are shown on Figure 2 to Figure 10.

3 THE REASONS FOR APPEARANCE OF CRACKS IN THE PLACE OF JOINTS

After changes of chimney codes and particularly after acceptance condition of reinforcement in two rows near outside and inside surface of wall appeared many cracked in joint places. There were made many samples cut form chimney wall. On one of them it is shown that cracks were caused by vibration reinforcement bars (Figure 9 and 10). Joint as a place is between rather mature concrete and fresh concrete. Vibrated bars move on a their considerable length. Vibration of bars can initiate craks in place of high stresses which are in the joint places. High stresses are caused by process of shrinkage as is shown on Figure 7 to 8.

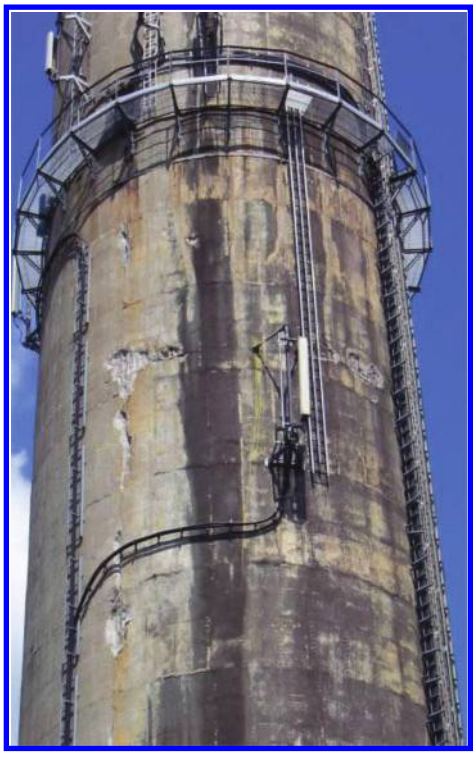

Figure 5. Chimney after many years of exploitation with many horizontal and vertical cracks and many surface defects.

Figure 6. Vertical and horizontal cracks on chimney wall with condensate flowing form horizontal cracked joints.

Figure 8 shows different consistency of concrete above and below joint.

4 THE THERMAL CHIMNEYS PROTECTION

Thermal insulation protects chimney wall against high temperature and high temperature gradient resulting in an increase of the tension force and of the bending moment. Additional non uniform distribution of temperature on chimney wall causes increasing of

Figure 7. Place of joint where the sample was picked up.

Figure 8. The sample with different consistencies of concrete above and below the joint.

Figure 9. The sample picked up from the place with joint.

Figure 10. The sample picked up from the place with joint.

Figure 11. The condensate flowing form horizontal cracked joints.

Figure 12. Chimney with demaged thermal protection.

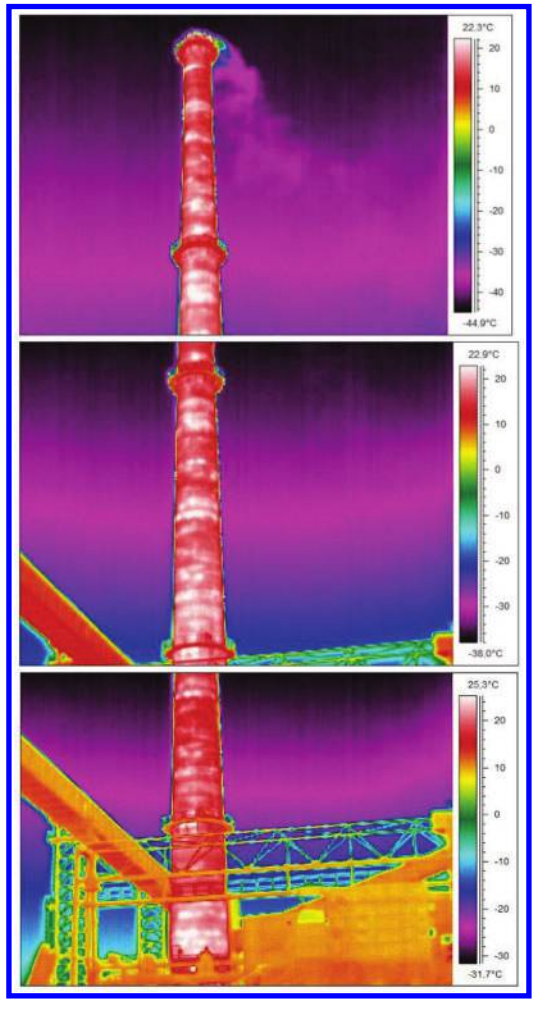

Figure 13. Destroyed thermal protection seen in the thermographic camera.

deflection of chimney and increasing vertical inner forces. This is the reason that vertical and horizontal cracks appear additionally.

Thermal insulation can be destroyed or may fall down because of excessive number of condensate penetrate to surface of chimney wall. Thermographic photographs were made (Maj&Ubysz 2012) on new built chimney (Figure 12). It is shown on Figure 13 where bright fields are places of high temperature i.e. spaces without insulation or with insulation weakened.

5 METHODS OF REPAIR CRACKED CHIMNEY WALLS

Methodology of repair of chimney wall can be presented in the following points:

a. Checking the current strength of concrete and reinforcement steel bars,

b. remove the cause of fracture design if possible i.e. repair of thermal insulation, repair of internal and external moisture insulation coatings,
c. cleaning and drying of damaged sites if it is possible,
d. filling under pressure the vertical and horizontal cracks using specialized mortar,
e. the annual chimney check the technical condition

6 CONCLUSIONS

During designing chimney constriction it is very important to provide a method of building, type of vibration of concrete, appropriate reinforcement spacing, choose the good technology of joints.

Suggests the use of sliding formwork which ensures no joints. During building chimney wall vibrators can not touch any reinforcement and any formwork. With a heavy an accuracy and under constant control building inspectors should be put thermal insulation.

Water transport in surface layer of fair-face concrete

Pavel Reiterman, Filip Vogel, Ondřej Holčapek, Karel Kolář & Petr Konvalinka
Experimental Centre, Faculty of Civil Engineering, Czech Technical University in Prague Technical University, Prague, Czech Republic

Martin Keppert, Monika Čáchová & Eva Vejmelková
Department of Material Engineering and Chemistry, Faculty of Civil Engineering, Czech Technical University, Prague, Czech Republic

ABSTRACT: In the production of fair-face elements is very popular, but aesthetic quality needs to withstand its lifespan. In the case of non-protected concrete surface, any failure is much more pronounced. An important parameter determining the durability of concrete is the quality of the surface layer, as it is directly exposed to the environment. In terms of durability properties, it is worth to monitor the parameters of the surface layers, particularly the transport processes. The paper presents the selected experimental methods for evaluation the quality of the surface layer of concrete aimed at monitoring the permeability of concrete, since concrete permeability is a property uniquely affecting durability of concrete. These methods are complemented by experimental results and other traditional tests. These findings will serve to further optimization of the structure being created, thus ensuring its better aesthetic and functional characteristics.

1 INTRODUCTION

The origin and character of the concrete surface layer is given by the technology of production of concrete elements; during vibration compaction is going on initiation and rising of air bubbles upward. This eliminates air content in concrete, but also the concentration of fine particles takes place close the walls of the formwork. Coarse aggregate – due to its geometry – cannot get its entire plane to formwork or to the corners (Reiterman). Hence the concrete surface exhibits completely different properties compared to bulk – it is called wall effect. The characteristic properties of the surface layer are low content of coarse aggregates and an increased amount of cement stone which consists of fine fractions of aggregate and cement hydration products. A very important feature is especially high content of pores in comparison with the inner layer (Reiterman). Such a surface layer having a thickness of 20–50 mm has highly very different, usually worse properties than the surrounding material. Therefore attention is drawn to quality of concrete surface layer. Each void and crack decreases a steel covering concrete layer and thus accelerates the process of its corrosion which is associated with visual degradation of the building (Kolář). Degradation processes are closely related to the quality of the surface layer and the pore system of concrete (Konvalinka).

2 EXPERIMENTAL PROGRAM

Permeability of porous materials is one of the principal parameter influencing their transport properties and durability. The intrinsic permeability of material K [m^2] is defined in terms of Darcy's law describing flow of a liquid through a porous material saturated by the liquid under the action of pressure gradient across the material. It is material property and thus does not depend on the kind of permeating liquid. One of possible definitions of K is given by equation (1) (Ěerný).

$$j = -K \cdot \frac{\rho_l}{\eta} \cdot \frac{\partial p}{\partial x} \tag{1}$$

There j is mass flux [$kg\,m^{-2}\,s^{-1}$], ρ_l is density of the liquid [$kg\,m^{-3}$], η is dynamic viscosity of the liquid [Pa s] and driving force is pressure gradient through the material. Intrinsic permeability is extremely dependent on properties of porous system of hardened concrete. That is one of the reasons of very different result of published experimental works.

Permeability was measured by means of high pressure permeameter made by CNE Technology. The design is based on work (Green). The method is based on definition equation (1). This method is not standardized in Europe, but there is an American standard (RILEM). Altogether were measured four concrete mixtures (tab. 1).

Experiment based on Darcy's law provides coefficient of permeability K valid for saturated state of material. The dependence of K upon volumetric moisture content w can be derived by help of pore size distribution of the material. Mualem [8] proposed equation (2) which uses experimentally determined pore size distribution function f(r); other input parameters are

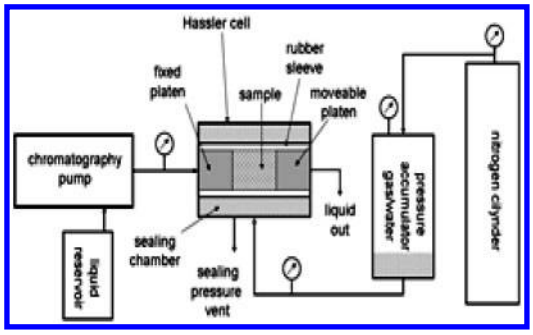

Figure 1. High pressure permeameter scheme.

Table 1. Composition of used concrete mixtures.

Mixture Components	I [kg/m^3]	II [kg/m^3]	III [kg/m^3]	IV [kg/m^3]
Cement CEM I 42,5 R	350	350	400	400
Aggregate: sand 0–4 mm	785	830	930	930
crushed 4–8 mm	350	350	315	315
crushed 8–16 mm	650	580	600	600
Plastisizer (Sika 1035)	0	0	3	2
Water	186	208	180	180
Water-cement ratio	0.53	0.59	0.46	0.46

saturated moisture content w_{sat} and parameter n. For computing was used software HydraPor developed at Department of Material Engineering and Chemistry Czech Technical University in Prague. Final composition and properties of the studied mixtures are at (tab.1 and tab. 2).

$$K(w) = K\left(\frac{w}{w_{sat}}\right)^n \cdot \left(\frac{\int_{R_{min}}^{R} r\,f(r)dr}{\int_{R_{min}}^{R_{max}} r\,f(r)dr}\right)^2 \quad (2)$$

Pore size distribution was determined by means of mercury intrusion porosimetry (MIP). The method is based on intrusion of mercury – non wetting liquid – to pores of studied sample. The penetrated pore's diameter is inversely proportional to applied pressure (Washburn equation). The applied pressure is gradually increasing during the experiment and thus mercury penetrates narrower pores. The result of experiment is dependence of pore volume (it corresponds to measurable volume of intruded mercury) upon pore diameter (corresponds to applied pressure). The experiment was carried out by means of Pascal 140 and 440 devices (Thermo).

The water vacuum saturation method was used for the measurements of bulk density, matrix density and open porosity (Vejmelková). Each sample was dried in a drier to remove majority of the physically bound water. After that the samples were placed into the desiccator with deaired water. During three hours air was evacuated with vacuum pump from the desiccator. The specimen was then kept under water not less than 24 hours.

Table 2. Properties of concrete mixtures.

Mixture	I	II	III	IV
Bulk density [kg/m^3]	2325	2330	2310	2320
ρ_{mat} [kg/m^3]	2614	2612	2598	2600
ψ_0 [−]	11.97	12.68	10.18	11.48
Compressive strength [MPa]	46.7	43.8	67.8	60.5
Hydraulic conductivity [m/s]	$0.8 \cdot 10^{-11}$	$1.2 \cdot 10^{-11}$	$1.2 \cdot 10^{-11}$	$1.2 \cdot 10^{-11}$
Depth of pressure [mm] water penetration	100	80	38	48
Equilibrium volume moisture [−]	4.8	4.0	6.2	5.8

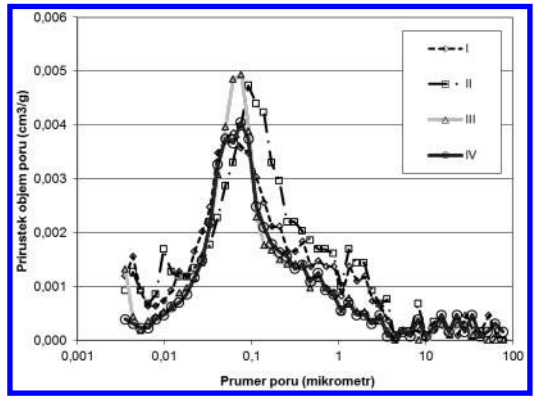

Figure 2. Pore distribution.

From the mass of the dry sample m_d, the mass of water saturated sample m_w, and the mass of the immersed water saturated sample m_a, the volume V of the sample was determined from the equation (3), (Vejmelková).

$$V = \frac{m_w - m_d}{\rho_w} \quad (3)$$

Where ρ_w is the density of water. The open porosity ψ_0, the bulk density ρ and the matrix density ρ_{mat} were calculated according to the equations (4), (5), (6).

$$\psi_0 = \frac{m_w - m_d}{\rho_w} \quad (4)$$

$$\rho = \frac{m_d}{V} \quad (5)$$

$$\rho_{mat} = \frac{m_d}{V(1-\psi_0)} \quad (6)$$

Sufficient concrete surface resistance depends not only on the quality of the surface layer, but also on the character of the pore system. It directly affects the

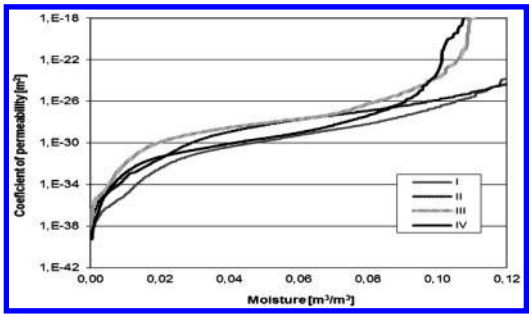

Figure 3. Coefficient of permeability as function of moisture content.

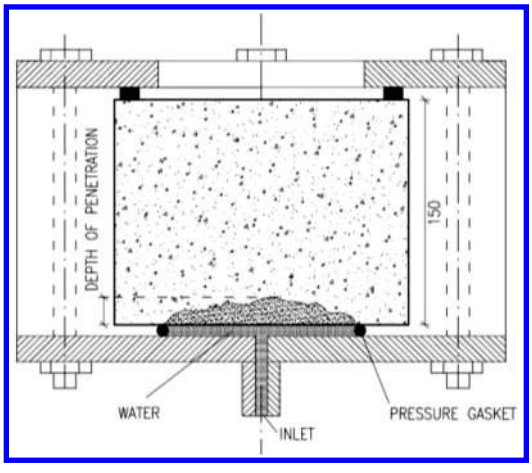

Figure 4. Water penetration test scheme.

rate of penetration of aggressive substances from the external environment to the internal structure of the concrete and thus the degradation rate of the material. It is very important therefore to reduce transport of liquid water solutions and water vapor as a primary protection against corrosion of reinforcement. Determination of depth of penetration was performed according standard ČSN EN 12390-8; water has a pressure of 0.5 MPa for 72 hours.

3 CONCLUSION

Durability of concrete depends not only on the quality of the surface layer, but also on the nature of the pore system that is truly defining parameter because it affects the rate at which aggressive substances, gaseous or liquid, penetrate from the external environment into the internal structure of concrete, and thus the rate of degradation of the material and its durability. Very important is the limitation of water and moisture transport of having a role in reinforcement protecting against corrosion. Results of these tests will become the basis for a correlation dependence permeability of concrete and concrete methodologies for evaluation in terms of its durability. At this point it should be noted that the in construction practice and research, the term of permeability is used quite freely (for different tests), it is always necessary to present the results along with the method and conditions of the experiment. It is obvious that a material will have a dramatically (ASTM C 1202-97) different permeability for air, for water or "permeability" of the chloride ions, reported in the Coulombs.

In connection with the introduction of the new standard system came into issues of concrete durability on importance. Action of aggressive media concentrated in the external environment is to develop a wide range of corrosion mechanisms (CRD C 163-92), (RILEM). Most buildings are protected from the effects of adverse conditions by other types of structures. In case of the fair-face concrete, however, this protective layer is formed by the material itself. Due to the fact that concrete degradation processes are going on a long-term, and aggressive substances act at low concentrations, it is very difficult to describe such effects and to quantify the resulting degradation phenomenon under test in the laboratory. In the case of porous building materials is intrinsic permeability one of the parameters that affect their behavior in structures; depend on it water resistance and indirectly resistance to action of frost, salts and other degradation processes, that is durability.

Creep influence on concrete slabs, pre-stressed in both directions

G. Sossou
Kwame Nkrumah University of Science and Technology, Kumasi, Ghana

ABSTRACT: This report relates to pre-stressed concrete slabs, subjected to static long-term service loads.

For structural predictions, the well-known finite elements and multi-scale/multi-grid methods have been used to estimate (a) transient bi-directional forces and strains due to the concrete creep and shrinkage, (b) the resulting bi-directional stress redistribution, as well as (c) bi-directional displacement variations and (d) bi-directional pre-stressing losses in the pre-stressed high yield tendons.

A series of laboratory experiments with once evaluated strength parameters are planned to be used to provide encouraging support for the numerical evaluations said at above points (a) – (d) in addition to (e) calibrating the parameters likely to enable the estimations of the pre-stressing losses, (f) predicting the slabs sections' stiffness and strength by determining their long-term flexural and nonlinear creep capacity and hence, (g) devising a definition for structural durability and reliability, with regards to the concrete stress-strain relationship under prolonged service loads.

Keywords: concrete matrix creep, shrinkage, concrete slabs, strength, reliability, durability, pre-stressing tendons, pre-stressing losses

1 INTRODUCTION

During these last two decades many theoretical and experimental studies have shown that the use of pre-stressed concrete for precast concrete members, especially for slabs pre-stressed in both directions is effective comparable to our conventional monolithic in-situ cast slabs.

But many negative factors like ageing, time-dependent increased loads, exposure to aggressive environmental factors have resulted in the progressive deterioration of many potentially functional building structures like higher flat apartment house buildings, industrial buildings, office buildings, post-harvest structures, …, etc. This paper describes the present ongoing numerical and experimental analysis model used to evaluate the structural long duration flexural characteristics of reinforced concrete slabs, pre-stressed in both directions. This present study has been based on nonlinear differential equations of the concrete matrix creep theory which reflects the correlation between the matrix stress and strain by its modulus of elasticity and on the well-known geometrical preconditions of the theory of elasticity concerning thin plates with small flexural deformations.

Many Authors carried out a lot of research experiments to improve the strength of the structural material, predicting the eventual cracking characteristics of the structural members. Design formulas for stress-strain limit states of the structures have been previously proposed based on the well-known concepts. However this present ongoing study is of higher importance, as it is recognized that little information is available on the time dependent factors like the concrete matrix creep, shrinkage and loss of pre-stresses, in relation to bi-directional pre-stressing of reinforced concrete slabs, with high yield tendons, subjected to long-term service loads.

It may be of grate importance to allow for factors influencing on the structural performance characteristics of the slabs by averaging maximum, and minimum estimated effects, and provided that this is done and there are a number of calculation methods available which will give reasonable results. The methods adopted developed by the Code of Practice are comprehensive, and are based on calculation of curvatures of the slabs sections subjected to the appropriate forces and moments, with allowances for concrete creep and shrinkage effects.

2 THEORETICAL ANALYSIS – MAIN CONCEPTUAL DESIGN PARAMETERS

The numerical part of this study is based on the well-known concepts by Yasinskiy, Timoshenko, Barashikov, Yatsenko, Baykov, Vlasov, Drozdov, Juravskiy, … etc and many other Authors, on the problem of quality, stiffness, strength, reliability, durability, fatigue, life safety and stability of the precast concrete slabs, pre-stressed in both directions.

The main conceptual design of the slabs has been based also on the orthotropic plate theory with grillage analogy in a suitable finite element model. The

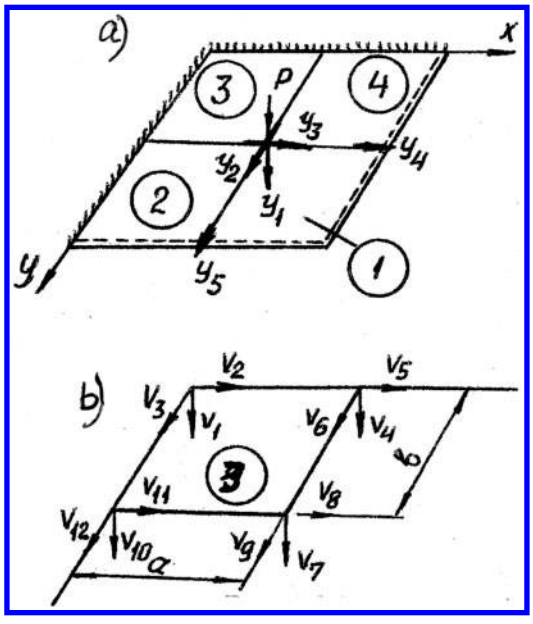

Figure 1. The concrete slab's design model.

Table 1. Each finite element's subscripts.

y_k 0	y_1	y_2	y_3	y_4	y_5
1	1	2	3	5	12
2	4	5	6	0	9
3	7	8	9	0	0
4	10	11	12	8	0

slab's model as shown in Figure 1- a) includes 4 finite elements having 5 nodal displacements y_1, y_2, y_3, y_4, and y_5. The finite elements are of the same dimensions a×b as shown in Figure 1- b) and each of them has 12 nodal displacement parameters: v_1, v_2, v_3, ..., v_{12}. Thus, the finite element method based on the displacement matrix formulations has been successfully used to solve the systems of matrix equations. Force equilibrium and deformation compatibility protocols have been observed at all stages of calculations.

Then the finite element's stiffness matrix has 12 columns and 12 rows, and its elements C_{ik} have subscripts i – the column's number and k – the row's number.

Now let us fill below the subscripts' table in which columns designate the finite element's number, and rows – the parameter's number y_k:

To fill the first column's subscripts, we need to bring the element from Figure 1 – b) to the place of element 1 in Figure 1 – a) and find out which parameters v_ℓ coincide with parameters y_k. Subscripts of coinciding parameters should be placed into corresponding boxes of first column.

For example, v_{12} coincides with y_5; consequently under y_5 we should place subscript 12. Similarly we need to fill the second column, bringing finite element from Figure 1 – b) to the place of element 2 in Figure 1 – a). For example, parameter v_9 coincides with parametery_5, consequently under y_5 we should place subscript 9. With parameter y_4 no coincidence, that is why under y_4 we should place zero. The procedure is similar for other columns.

Table 2. Stiffness matrix subscripts.

y_1	y_2	y_3	y_4	y_5	
r_{11}	r_{12}	r_{13}	r_{14}	r_{15}	y_1
	r_{22}	r_{23}	r_{24}	r_{25}	y_2
		r_{33}	r_{34}	r_{35}	y_3
			r_{44}	r_{45}	y_4
	Sym.			r_{55}	y_5

Now the complete subscripts' table could give us the opportunity for the stiffness matrix of the whole slab's model to choose from the original stiffness matrix those of its elements which coincide with a given node. For the slab's model shown in Figure 1 – a), the stiffness matrix is discussed using the subscripts' table.

More, this very subscripts' table gives us the opportunity to bring the global displacements y_k into the local Cartesian coordinate system according to the formula $\vec{v}_\ell = a_\ell \vec{y}$, where a_ℓ is coordinates transformation matrix.

$$
\begin{aligned}
&r_{11} = c_{11} + c_{44} + c_{77} + c_{10,10};\\
&r_{12} = c_{12} + c_{45} + c_{78} + c_{10,11};\\
&r_{13} = c_{13} + c_{46} + c_{79} + c_{10,12};\\
&r_{14} = c_{15} + c_{8,10};\ r_{15} = c_{1,12} + c_{49};\\
&r_{22} = c_{22} + c_{55} + c_{88} + c_{11,11};\\
&r_{23} = c_{23} + c_{56} + c_{89} + c_{11,12};\\
&r_{24} = c_{25} + c_{8,11};\ r_{25} = c_{2,12} + c_{59};\\
&r_{33} = c_{33} + c_{66} + c_{99} + c_{12,12};\ r_{34} = c_{35} + c_{8,12};\\
&r_{35} = c_{3,12} + c_{69};\ r_{44} = c_{55} + c_{88};\ r_{45} = c_{5,12};\\
&r_{55} = c_{12,12} + c_{99}.
\end{aligned}
$$

For example, concerning elements 1, 2, 3, 4 in Fig.1- a we have (according to the subscripts' table)

$$
\begin{aligned}
&v_1 = \{y_1\ \ y_2\ \ y_3\ \ 0\ \ y_4\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ y_5\}^T;\\
&v_2 = \{0\ \ 0\ \ 0\ \ y_1\ \ y_2\ \ y_3\ \ 0\ \ 0\ \ y_4\ \ 0\ \ 0\ \ 0\ \}^T\\
&v_3 = \{0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ y_1\ \ y_2\ \ y_3\ \ 0\ \ 0\ \ 0\}^T\\
&v_4 = \{0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ y_1\ \ y_2\ \ y_3\ \ 0\ \ 0\}^T
\end{aligned}
$$

Now the slab's rectangular finite element shown in Fig. 1-b with dimensions a×b has 12 nodal displacement parameters v_j (j = 1, 2, …, 12) and corresponding 12 nodal reactions ς_j (j = 1, 2, …, 12). If the directions of these displacements coincide with the directions

of local coordinate axes x and y, then these displacements together with their corresponding reactions will be positive.

According to the number of the finite element's nodal displacements the function of its vertical displacements is defined in form of poly-nom with 12 coefficients, that is: $w(x,y) = W(x,y)\,\vec{\alpha}$, where $\vec{\alpha}$ is the 12 coefficients vector, and W(x, y) – the linear displacements' functional matrix having this following form:

$$W(x,y) = \{\, 1 \;\; x \;\; y \;\; x^2 \;\; y^2 \;\; xy \;\; x^2y \;\; xy^2 \;\; x^3 \;\; y^3 \;\; x^3y \;\; xy^3 \,\} \qquad (1)$$

Let us analyze the correlations between the components of the bending moments' units $M_x(x,y)$, $M_y(x,y)$, $mboxM_{x,y}(x,y)$ and their co-responding strains' components representing their flexural curvatures $\Re_x(x,y), \Re_y(x,y), \Re_{x,y}(x,y)$:

$$M_x = D(\Re_x + \mu\,\Re_y);\; M_y = D(\Re_y + \mu\,\Re_x);\; M_{x,y} = 2D(1-\mu)\Re_{xy}, \qquad (2)$$

where subscripts 'x' and 'y' indicate the directions of forces and strains, parallel to their corresponding Cartesian coordinates axes x and y;

μ – Poisson's coefficient; D – cylindrical stiffness:

$$D = \frac{E\,h^3}{12(1-\mu^2)}, \qquad (3)$$

with h – the thickness of the finite element.

Let us denote

$$\vec{M}(x,y) = \begin{Bmatrix} M_x(x,y) \\ M_y(x,y) \\ M_{xy}(x,y) \end{Bmatrix};\; \vec{\Re}(x,y) = \begin{Bmatrix} \Re_x(x,y) \\ \Re_y(x,y) \\ \Re_{xy}(x,y) \end{Bmatrix};\; \Im = \begin{Bmatrix} 1 & \mu & 0 \\ \mu & 1 & 0 \\ 0 & 0 & 2(1-\mu) \end{Bmatrix}.$$

Now Equations (2) should be re-written into single matrix equation as follows:

$$\vec{M}(x,y) = \Im\,\vec{\Re}(x,y). \qquad (4)$$

From the theory of elasticity concerning thin concrete matrix membranes with small flexural deformations these next Equations are true:

$$\Re_x(x,y) = -\frac{\partial^2 w(x,y)}{\partial x^2};\;\; \Re_y(x,y) = -\frac{\partial^2 w(x,y)}{\partial y^2};\;\; \Re_{xy}(x,y) = -\frac{\partial^2 w(x,y)}{\partial x \partial y}.$$

Now taking into consideration Equation (1) we obtain the stiffness matrix:

$$C = D\begin{Bmatrix}
c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} & c_{17} & c_{18} & c_{19} & c_{1,10} & c_{1,11} & c_{1,12} \\
 & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} & c_{27} & c_{28} & c_{29} & c_{2,10} & c_{2,11} & c_{2,12} \\

$$c_{26} = c_{29} = c_{2,12} = c_{35} = c_{38} = c_{3,11} = c_{59} = c_{5,12} = c_{68} = c_{6,11} = c_{8,12} = c_{9,11} = 0.$$

From past theoretical results, before the transfer of the pre-stressing forces P to the slab, in the eth steel reinforcement tendons' row were acting the initial controlled stresses $\sigma_{e,contr.}$, without first losses, independently on properties of the concrete. At the moment of the transfer, taken like the beginning of

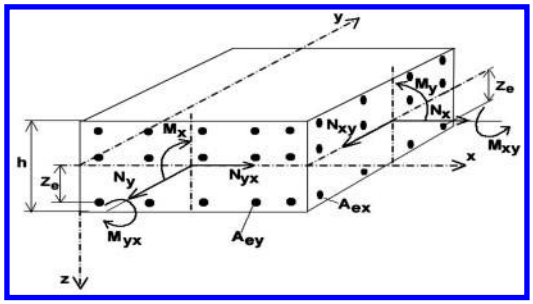

Figure 2. Slab element with acting forces and moments.

time-dependent counting out, in the steel tendons and in the concrete matrix were actively acting elasto-instantaneous increases of stresses respectively σ_{e0} and $\sigma_0(y_e)$, where $y_e = z_e$ is the distance from the slab's neutral axis to the axis of the eth tendons' row (Figure 2). At a certain maturity of concrete matrix t these above said elasto-instantaneous increases of stresses were changing and their values became equal to $\sigma_e(t)$ and $\sigma\ (y_e,t)$ respectively, with the fact that stresses in steel tendons were increasing, but in concrete matrix stresses were reducing. After the transfer the above said initial controlled stresses $\sigma_{e,contr.}$ have become equal to $\sigma_{e,contr.} - \sigma_e(t)$.

According to the Codes of Reinforced Concrete Structures, stress losses due to concrete matrix creep and shrinkage in a certain eth steel tendons' row have been calculated, taking into consideration that part of stresses, which cannot comply with the action of the initial pre-stressing forces P, applied with an eccentricity e_{0P} can nullify the stresses formed in the concrete matrix $\sigma\ (y_e, t)$ at the level of the same steel tendons' row. In that way, the stresses $\sigma\ (y_e, t)$ have been provoked by the pre-stressing forces P in the tendons, by the concrete matrix creep and shrinkage, by the slab's self weight and by the intensity and duration of the long-term service loads acting on the slab.

At the loading duration τ, as the long-term service loads were acting on the slab, the long duration of these actual loads can contribute to the fact that, stresses in the steel reinforcement tendons have been increased, but in the concrete matrix theses stresses have been reduced, and just this positive effect can contribute to the efficiency of the slabs. By applying to the slab the initial pre-stressing force P with an eccentricity e_{0P} at a certain concrete maturity t for the purpose to reduce the developed stresses $\sigma\ (y_e,\tau)$ to zero, we have changed the stresses in steel tendons to their actual value $\alpha_e(\tau)$ $\sigma\ (y_e,\tau)$, where $\alpha_e(\tau) = E_e/E(\tau)$ – elasticity modulus ratio of the eth steel tendons' row and the concrete matrix, at the concrete maturity t. In that way, proper stresses in steel tendons will become equal to:

$$\sigma_{eP} = \sigma_{e,\ contr.} - \sigma_e(t) + \alpha_e(\tau)\ \sigma(y_e,\tau). \tag{5}$$

These same stresses can be presented in the following way:

$$\sigma_{eP} = \sigma_{e,\ contr.} - \sigma_{loss2e}(t) \tag{6}$$

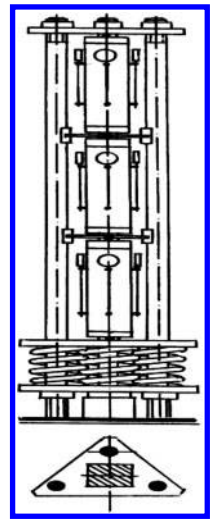

Figure 3. Loading frame for creep test.

where $\sigma_{loss2e}(t)$ – pre-stressing losses in the eth steel tendons' row at the application moment of the force P. By equating expressions (5) and (6) we have obtained the formula for the evaluation of the generalized losses, in the eth steel tendons' row:

$$\sigma_{loss2e}(t) = \sigma_e(t) - \alpha_e(\tau)\ \sigma(y_e,\tau) \tag{7}$$

Thus, for the determination of pre-stressing losses in any eth steel tendons' row of the slab, it is necessary just to know the current initial stresses in the tendons' row and in the adjacent concrete matrix at the level of the same row, provoked by all of the long-term influences on the slabs. These said current initial stresses can be evaluated by creep computation of the slabs. The pre-stressing forces P which can generalize the effect of proper stresses and the eccentricity of its application e_{0P} can be evaluated by following formulas:

$$\begin{aligned} P &= \sum_{e=1}^{s} (\sigma_{e,contr} - \sigma_{loss2e})A_e\ ; \\ e_{0P} &= [\sum_{e=1}^{s} (\sigma_{e,contr} - \sigma_{loss2e})A_e y_e]/P, \end{aligned} \tag{8}$$

where A_e is the cross-sectional area of eth steel tendons' row.

The displacements in the slab Δ have been determined on the basis of

$$\Delta = \sum_{i=1}^{n} \int_0^{\ell_i} (M_1 \Re + N_1\ \varepsilon)_i\ dx, \tag{9}$$

where $i = 1, 2,..., n$ – quantity of homogeneous elements with a length wise of λ_i;

M_1 and N_1 – forces from generalized force unity, applied in the place and to the direction of the unknown displacements;

$\Re$ and ε – components of deformations in the slab.

3 EXPERIMENTAL PROGRAM AND SOME TEST RESULTS

The experimental program consisted of casting twelve $180 \times 180 \times 5$ cm pre-tensioned concrete slabs with material properties of 40 MPa for the concrete matrix and $E_{SP} = 195$ GPa for the high-yield steel tendons with nominal diameter of 10 mm which will be contained in frames made of 6 mm bent mild steel mesh with $E_S = 200$ GPa. At the concrete age of 9 days with natural curing, all of the slabs, after the transfer of stresses from the steel tendons to the concrete matrix, will be compressed out by the initial pre-stressing forces and then will be taken away from the pre-stressing beds together with their deflection indicators, after cutting the steel tendons. Two of the slabs, marked S-1, will be maintained in the laboratory without loads. From them will be calibrated the variations of the deformations in the steel tendons and in the concrete matrix, due to pre-stressing forces and due to the shrinkage of the concrete matrix. Further, at the concrete matrix age of 36 days, 10 other slabs will be tested under long-term uniformly distributed static loads, with different force intensities. For the evaluation of concrete matrix physical-mechanical properties, specific subgroups of $300 \times 150\text{Ø}$ mm cylinders and 150 mm cubes will be tested periodically, using British Standards through Euro Codes. The variations in lateral deflections influenced by concrete matrix creep and shrinkage will be monitored continuously. At the concrete matrix age of 300 days, all of the members will be tested quasi-statically and after, under cyclic quasi-dynamic vertical loads up to their failure state.

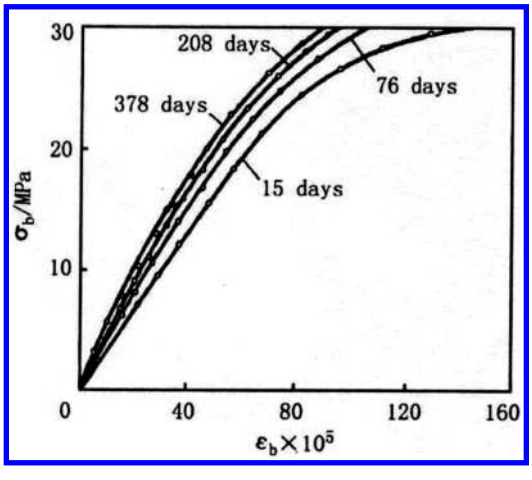

Figure 4. Compression diagrams of concrete prisms tested with static loads.

Parallel to all of these tests, as above said, will be also tested at specific different following concrete matrix ages of 9, 12, 15, 28, 36, 76, 118, 136, 200 and 300 days, concrete matrix cylinders and cubes (3 cylinders and 3 cubes at each concrete matrix age) for the determination of the concrete matrix physical and mechanical properties, and for the evaluation of the creep and shrinkage characteristics of the concrete matrix. During these creep tests, the cylinders will be mounted on the loading frame (Figure 3) which consisted of a hydraulic jack, a load cell, and a system of coil springs held in compression by a set of roads and plates.

Similarly to these experiments, for the determination of concrete physical-mechanical properties (Figure 4) and for the evaluation of creep and shrinkage behavior of the concrete (Figure 5), have been tested at different concrete ages of 9, 12, 15, 24, 36, 76, 118, 192, 208 and 378 days, concrete prisms and concrete cubes (3 prisms and 3 cubes at each above concrete age).

The concrete matrix prisms tested for creep were marked $P_{12}^{7,5}$; $P_{36}^{7,5}$; $P_{76}^{7,5}$ and P_{76}^{15}; where the superscripts of the prisms' series show the static stresses' values in MPa, and their subscripts show the different concrete ages.

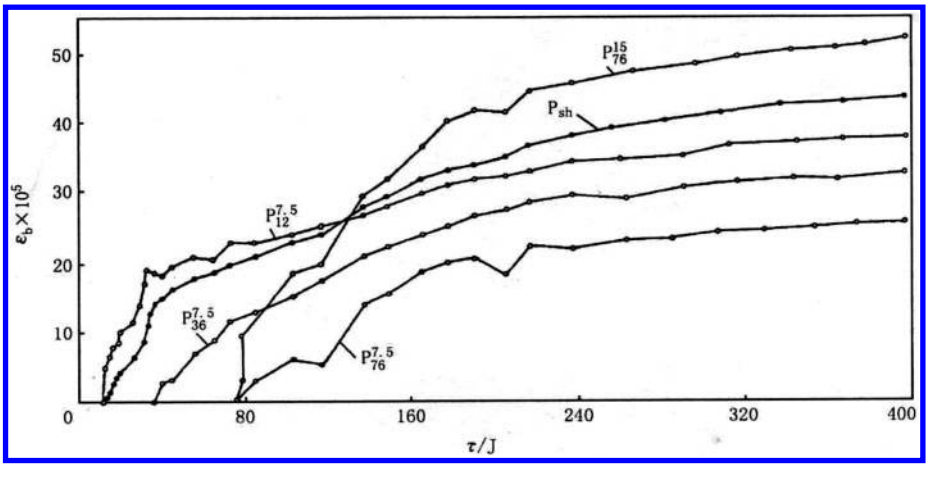

Figure 5. Experimental graphics of time-dependent strains due to shrinkage (index "sh") and to the creep of the concrete, obtained by the tests of concrete matrix prisms: $1 - P_{sh}$; $2\text{-}P_{12}^{7,5}$; $3 - P_{36}^{7,5}$; $4 - P_{36}^{7.5}$; and $5 - P_{76}^{15}$.

4 CONCLUSIONS

1. It is hoped to confirm at the end of the study that nonlinear concrete creep is capable to contribute to the redistribution of stresses between the concrete and the steel tendons with long-term loading influences on the slabs. This said redistribution is capable to provoke the accumulation of natural initial stresses in the steel tendons and in the concrete, which are equivalent to the artificial initial stresses due to the pre-stressing forces in the steel tendons, and this fact could reduce losses and, consequently, capable to increase the durability, the reliability and the exponents of the slabs' limit states.
2. The proposed slabs will help widely and reliably reveal the positive effects and generalize them to more complicated type of structural elements. These positive effects could be capable to predict the quality, the reliability, the durability, the life safety and the stability of the slabs and could be able to contribute for steel tendons' economies up to 15%.

Frost resistance property of concrete doped with scrap rubber powder

B.M. Wang, Y. Han & S. Liu
School of Civil Engineering, Dalian University of Technology, Dalian, China

ABSTRACT: The quick frost method was used to measure the mass loss rate and relative dynamic elastic modulus of rubberized concrete and ordinary concrete. The frost resistance property of the rubberized concrete in seawater environment was studied by comparing the difference of mass loss rate and relative dynamic elastic modulus between rubberized concrete and ordinary concrete. Results show that, the frost resistance property of rubberized concrete is superior to ordinary concrete in seawater environment, when the water-cement ratio was 0.40 the rubberized concrete could undertake 150 times freeze-thaw cycles, which is 2 times higher than ordinary concrete. The enhancement on frost resistance property is obvious by adding rubber power into concrete under the effect of freeze-thaw cycle and media corrosion, and this enhancement decreases with the water-cement ratio increasing.

1 INTRODUCTION

Concrete is the most widely used construction material in modern engineering structure[1]. Compared with other common building materials, its energy consumption is low, the sources of the raw materials are wide and the craft is simple. So it has some advantages such as low production cost, strong adaptability and easy application, etc. [2,3]. But concrete is one kind of brittle materials. Nearly years the strength of the concrete has been constantly improved, and the increasingly prominent contradiction between its high strength and brittleness has limited the development and application of concrete [4]. How to alleviate the contradictions through the concrete material modification gradually become people's research focus [5]. Rubberized concrete which through scrap tire rubber powder blending into the concrete can effectively improve the concrete brittleness [6–8]. It's a new type of "elastic concrete" and it gradually gets more and more attention of scholars both around the world [9]. The research shows that adding rubber powder to concrete can effectively improve the concrete toughness and impact resistance. In addition, its resistance to contraction and damping performance is also better, and the durable performance is improved [10–12].

The number of waste tyre is huge in our world, The powder can be used as a new type of material blended into concrete, and the application prospect of rubberized concrete is well. Through the rubber concrete characteristics, we can expect it can be widely used in road, square, high seismic area, basic engineering and railway station for vibration damping high places, retaining wall of highway and bunkers for impact resistance and blast resistance place, It also can be used in building decoration materials and self-leveling packing [13].

As a new type of concrete, rubberized concrete has owned widely attention in the industry. The existing researches mainly focus on the mechanical properties, anti-permeability, shrinkage, etc., there is no study on its anti-freezing endurance performance based on the sea water erosion medium.

2 EXPERIMENTAL

2.1 *Materials*

(1) Cement: This test used PO 42.5 R type cement produced by Dalian Onoda cement co., LTD. Table 1 and 2 show the concrete index.
(2) Fine aggregate: river sand. Its fineness modulus is 2.73. It's II area velvet. Apparent density is 2520 kg/m^3 and bulk density is 1540 kg/m^3.

Table 1. Cement component and physical parameters.

Chemical composition (%)		Specific Ignition loss (%)	surface area	Setting time (min)		Stability
MgO	SO_3	3.14	330	Initial set	Final set	Boiling
1.88	2.53			196	248	qualified

Table 2. Properties of cement.

rubber powder	Black Powder	120	120	95	1.0	10	15	0.5	0.08

(3) Coarse aggregate: size for 5 ~ 25 mm uniform gradation. Apparent density is 2800 kg/m^3 and bulk density is 1590 kg/m^3.Faller gill degree is 4%. Crushing value is 2.65%.
(4) Mixing water: ordinary tap water.
(5) Admixture: SW – 4 type high efficiency water reducing agent, Dalian Shenwei building materials co., LTD., production.
(6) Rubber powder: Sichuan lvyuan technology co., LTD., production. It's 120 mesh waste tire rubber powder. Density is 1.116 g/cm^3. Mean grain size is 119 μm. Bulk density is 284 kg/m^3. The shape is shown in figure 1 and the specific technical data is shown in table 3.

2.2 *Mix proportion*

2.3 *Specimen preparation*

Because the rubber powder particle size is small, it's easy to occur reunion phenomenon when they are mixed in concrete. In order to make the rubber powder in cement mortar scattered as uniformly as possible, we adopt the method which put water reducing agent, rubber powder into cement mixing uniform in advance. In mixing concrete, put sand, stones into a blender firstly, dry mixing 60 s, then add in the mixture consist of cement powder and additive to mix 30 s, and then add water to mix 120 s.

Put the new concrete into the mold, vibrate dense on vibrostand immediately. Then take apart a die and numbers after 24 hours. Put the test-piece in 20 ± 2°, relative humidity 95% standard curing chamber, maintain to the standard required age, then test the performance [14].

2.4 *Testing procedures*

Put the test-piece into seawater for four days after 24 days age, then take them out according to GB/T 50082-2009 method, and injection seawater into specimen bucket to conduct quick freezing and thawing test. The seawater should be changed once every 25 times freeze-thaw cycle. The test index are mass loss rate and dynamic elastic modulus. The seawater is taken from seaside of HeiShiJiao in Dalian. Its composition is shown in table 5 below.

3 RESULTS

The mass loss rate and the relative dynamic elastic modulus of rubberized concrete and the corresponding normal concrete in seawater freeze-thaw environment see below table 6–9.

The destroyed appearance of rubberized concrete and ordinary concrete in seawater is shown in figure 2 and 3.

4 DISCUSSION

The mass loss of rubber concrete with the increasing of freeze-thaw cycle times in seawater are shown below.

From the test results and the figure above we can reach that:

1 At early stage of the freeze-thaw cycle, qualities of ordinary concrete and rubber concrete are slightly increased in seawater, rubber concrete increase slowly than ordinary concrete; Along with the

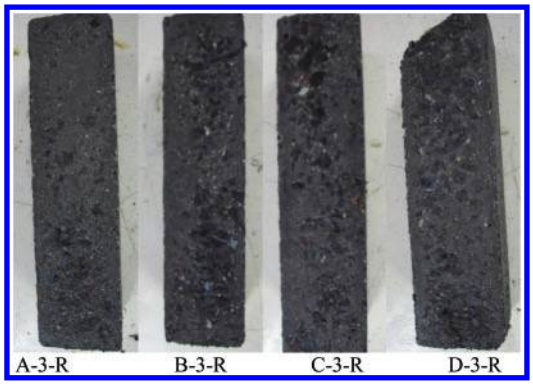

Figure 3. The destroyed appearance of rubberized concrete in seawater.

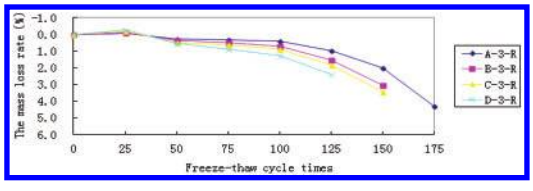

Figure 4. The mass loss rate of rubberized concrete with the increasing of freeze-thaw cycle times in seawater.

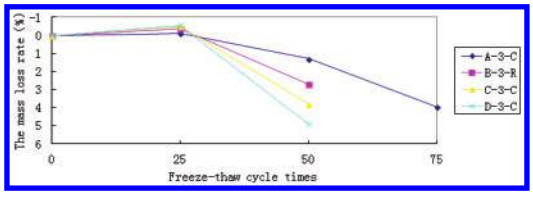

Figure 5. The mass loss of ordinary concrete with the increasing of freeze-thaw cycle times in seawater.

freezing and thawing cycle, mass loss rate ordinary concrete begin to increase sharply, rubber concrete is moderate relatively; Ordinary concrete of 0.40 water cement ratio failure in 75 times freezing and thawing cycles, rubber concrete of the same water cement ratio failure in 175 times cycles.

2 The failure characteristics caused by seawater: damage on the surface, the surface mortar peel seriously, aggregate exposure, failure at a very fast rate. From the final failure pattern we can see, the common concrete show collapse form with water cement ratio increasing, but rubberized concrete is only surface mortar peeling off and the coarse aggregate revealing.

The relative dynamic elastic modulus of rubberized concrete and common concrete with the increasing of freeze-thaw cycle times in seawater below figure 6 and 7.

From the test results and figure above we can reach that ordinary concrete and rubberized concrete in seawater are destroyed mainly in relative dynamic elastic modulus reducing to less than 60%. Rubber concrete

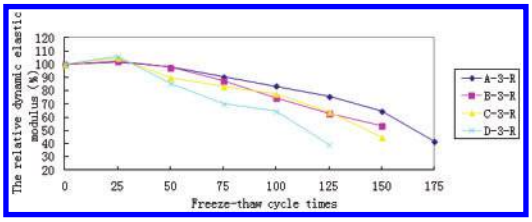

Figure 6. The relative dynamic elastic modulus of rubber concrete with the increasing of freeze-thaw cycle times in seawater.

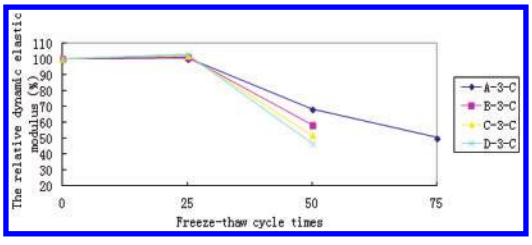

Figure 7. The relative dynamic elastic modulus of ordinary concrete with the increasing of freeze-thaw cycle times in seawater.

with water cement ratio 0.40, 0.45, 0.50, 0.55 reach freeze-thaw damage after 175, 175, 175, 150 times respectively, the relative dynamic elastic modulus are 64.5%, 53.9%, 44.9%, 39.7% when are destroyed; Common concrete with the same water cement ratio reach freeze-thaw damage after 75, 75, 75, 50 times respectively, the relative dynamic elastic modulus are 50.6%, 58.4%, 52.2%, 46.9% when are destroyed.

The anti-freeze mechanism analysis in the sea: the chlorine salt solution in seawater focus on the concrete surface pore firstly, so that the water saturation degree in the concrete surface pore increase. With the freezing and thawing, friction increases, unfrozen water in the surface pore flow to the interior, compared with unfrozen water internal, unfrozen water on surface is under more high hydrostatic pressure, the speed of producing and expanding micro-fracture is faster. The presence of salt causes that hole liquid produce concentration difference, the difference is bigger than that in the water, so that the freeze-thaw cycle times in seawater is less than that in fresh water [15]. In addition when concrete structure long-term exposure chlorine salt solution, NaCI can leach hydration products of cement paste [16], resulting in accelerated destruction of concrete structure.

5 CONCLUSIONS

In the seawater, freeze-thaw damage of rubberized concrete is mainly for obvious surface spalling, from the dropping speed of relative dynamic elastic modulus, the internal damage is more serious than external peeling, and ordinary concrete in seawater is more heavy damage, relative elastic modulus decline more rapidly, the whole test-piece is destroyed collapse form

block which water cement ratio is above 0.45. Ordinary concrete show the same failure trend as rubber concrete, but destroy faster than rubber concrete, and at the later stage of freezing and thawing damage, test-piece will fracture suddenly and then fail.

Determination of the relation between the content of used reclaimed asphalt material and deformation characteristics of asphalt concretes

K. Milčèková, P. Mondschein & J. Valentin
Department of Road Structures, Faculty of Civil Engineering, Czech Technical University, Prague, Czech Republic

ABSTRACT: The objective of this paper is to summarize experimental findings of functionalities between the content of added reclaimed asphalt material (RAP) in asphalt mixtures of the AC (asphalt concrete) and HMAC (high modulus asphalt concrete) type, selected suitable bituminous binders (including the applicability of chemical additives) and performance characteristics describing the behavior of asphalt mixes in the range of high and low temperatures. The results of dynamic non-destructive stiffness measured in a temperature interval of 0–30°C, creep behavior at 40°C with the assessment of resistance to permanent deformation as well as the regular rutting test are presented here. Further, master curves for the complex dynamic modulus of the asphalt mixtures are determined and assessed. Finally, recommendations about acceptable contents of reclaimed asphalt material securing the minimum technical requirements of technical standards and sufficient asphalt mixture durability are formulated. The influence of combined use of reclaimed material and selected bituminous binders is described as well.

1 INTRODUCTION

Asphalt mixtures represent a kind of composite material which is traditionally based on natural aggregates and bituminous binders. With respect to the extent of infrastructural structures, the consumption of natural resources is enormous. In connection with the increasing necessity of gradual rehabilitation of the existing road infrastructure, the general trend is to reduce the material demand of pavement structures by the enforcement of maximized recyclability and re-use of existing structures and materials in use. By utilizing reclaimed asphalt material from existing pavements, efficient limitation in the consumption of natural aggregates is supported. The substitution of aggregates by reclaimed material can theoretically reach a level of up to 100%. It is, nevertheless, essential to assess and to consider the impact of reclaimed material on the performance behavior of the resulting asphalt mix and/or the pavement structural layer. The reasons are, in particular, degrading processes, which occur in the asphalt pavement during the road use and operation. The degradation usually leads to irreversible alterations of the functional characteristics of the asphalt mixture.

The issues of asphalt pavement recycling, taking, in particular, the form of cold asphalt mix technologies using asphalt emulsions, foamed bitumen or hydraulic binders, or combinations of the above binders have been the subject of growing interest in the last 5–10 years, both among numerous road construction companies and in applied research at technical universities. The main activity in the Europe-wide scale may be the European SCORE – Superior Cold Recycling (Potti, 2004) project which involved the performance of a series of laboratory tests of binders and mixes. In 2004–5, test sections were laid in France, Spain and the Czech Republic. The objective was to verify and further specify investigated key characteristics (both strength and performance-based ones). Laboratory tests within the SCORE project were done using the same methodology for both mixes with emulsions and cement and mixes with foamed bitumen.

In hot-in-place recycling, there is a common practice which, nevertheless, still limits the use of reclaimed asphalt material (RAP) in new asphalt mixes in the Czech Republic to only some types and only to amounts of max. 20%-wt. when used in existing mixing plants. This fact may be compared with the knowledge in some west European countries where technologies applying RAP in quantities exceeding 30%-wt. have been developed on a long-term basis because of a limited availability of natural resources or for the reason of active support for the principles of sustainable construction. In this context, the trends and experience from the Netherlands or from Germany are worth mentioning; in the latter case a comprehensive methodology, "Wieder-verwenden von Asphalt" (DAV 2009) must be pointed out, which delimits the links to the legislation on waste currently in force in Germany and, at the same time, describes in a relatively clear and detailed way how to handle RAP and what procedures to apply for it in the asphalt mix. Analogically, since 2007, these issues have been addressed by the LCPC French laboratories for roads and bridges with the aim of gaining a better understanding of the processes and

qualitative parameters in the application of more than 50%-wt. of RAP in asphalt mixes. In this context, the focus in France is both on the requirements for the production machinery and for the application of suitable additives which due to chemical reactions allow the application of RAP at higher rates observing the limit criteria for the quality of the new asphalt mix.

2 MIX DESIGN SPECIFICATION

Two types of asphalt mixes were selected for the experimental verification. In the first case, it was a mix with a high stiffness modulus (HMAC), which had originally been developed in France and is presently used in some countries mainly for constructions of highly loaded pavements. Its principle consists in a modified design of the aggregate matrix and a choice of harder or polymer modified bitumen thanks to which the reaching of higher stiffness of the mix is allowed, or its resistance to the permanent deformations is significantly improved. The mix should simultaneously allow reaching longer durability. HMAC mixes are used in binder and base courses; therefore, they are not immediately exposed to climatic effects. The second selected representative is the asphalt concrete mix for wearing courses (ACO). The key feature in this case is the compactness of the layer, which guarantees smooth and safe road traffic. The problems of the appearance of permanent deformations, however, play a minor role here as well, even though not so essential. Of greater significance is the durability of the asphalt mix expressed as a rule by the characteristic of the indirect tensile strength ratio (ITSR) considering the negative impacts of water.

The mixes designed for testing contained aggregates coming from the same locality characterized by a not quite perfect shape index in coarse fractions. As a standard for individual variants (except for the reference HMAC mix) the initial binder was chosen to be 50/70 as bitumen suitable for both applications. In contrast to the 30/45 binder applied in the reference HMAC mix which generally results in stiffer characteristics, the choice of the 50/70 binder is also supported by the fact that one half of the mixes designed use RAP where partly degraded binder of the original asphalt mix is already present and, therefore, the overall stiffness of the mix and, primarily, the increased brittleness of the binder from the reclaimed material must be limited and sufficiently regulated. Besides Storflux which is used as a rejuvenator based on special oils, another two additives were applied which are known mostly from the field of warm asphalt mix technologies, namely synthetic Fischer-Tropsch paraffin with the potential of lowering the manufacturing temperature of the mix preparation and paving by 15–20°C, and a surfactant based on tensides under the name IterLow T. For the ACO 11 mix, the Storbit additive was selected which combines the effect of a rejuvenator and an additive improving viscosity. The second additive is based on a different principle in comparison to FT paraffin; however, it allows reducing the working temperatures by a similar range. The content of Storflux and Storbit is related to the bitumen. The reason for the application of the additives is the possibility of reducing the necessary heating of the RAP while maintaining the workability needed, thus minimizing further degradation of the bituminous binder contained in the asphalt material.

Table 1. Experimentally assessed HMAC mixes.

A: HMAC with 4.5% 50/70 + 10% Storflux + RAP (0/11)
B: HMAC with 4.5% 50/70 + 0.5% Iterlow T + RAP (0/11)
C: HMAC with 4.5% 50/70 + RAP (0/11)
D: HMAC with 5.8% 50/70 + 0.5% Iterlow T
E: HMAC with 5.8% 50/70
F: HMAC with 5.8% 50/70 + 3% FTP
G: HMAC with 4.5% 50/70 + 3% FTP + RAP (0/11)
REF: HMAC with 5.8% 30/45

Table 2. Experimentally assessed ACO mixes.

I: ACO with 5,9% 50/70 + 10% Storflux + 40% RAP (0/11)
II: ACO with 59% 50/70 + 10% Storbit + 40% RAP (0/11)
III: ACO with 6.0% 50/70 + 10% Storflux + 20% RAP (0/11)
IV: ACO with 6.0% 50/70 + 10% Storbit + 20% RAP (0/11)

The effects of various bituminous binders and, particularly, the effect of applying 30%-wt. of RAP for HMAC 16 and 20%-wt. or 40%-wt. for the ACO 11 mix were examined. The design and optimisation of mixes as such were carried out based on the standard procedures applied for traditional asphalt concretes according to the ČSN EN 13108-1 standard. Test cylinders were usually compacted by 2 × 75 blows by the Marshall compactor for HMAC and 2 × 50 blows for the ACO mix.

In the case of HMAC mixes, RAP demonstrated a better aggregate shape index which led to improved compactability and satisfactory void contents. The average void content in mixes with no reclaimed material amounted to 5.3%-vol., while mixes with reclaimed material reached a lower void content of about 4.2%-vol. In both cases, the values correspond with the limits restricted by 6%-vol. for control testing (Tab. 3). The addition of RAP does not have a crucial negative effect on water susceptibility of the mix. In most cases, only a very small drop was identified. A similar situation is in the case of the water susceptibility test with one frost cycle (ITSR_frost cycle).

While analyzing ACO mixes with 40%-wt. or 20%-wt. of RAP material, then it is visible, that the Storbit additive leads to slightly lower bulk densities. With respect to the voids content, it was interesting to find out that better values are reached for mixes with higher RAP contents. A similar result can be obtained by comparing the ITS ratio. Generally, all mixes reached

very high values but higher RAP contents lead to no changes in the indirect tensile strength performance.

3 EXPERIMENTAL ASSESSMENT OF DEFORMATION BEHAVIOR

3.1 *Stiffness modulus*

The stiffness modulus is generally identified as the absolute value of a complex modulus where it simultaneously holds true that its value equals the creep modulus for the loading time $t = \omega^{-1}$. This value is sometimes also denoted as a dynamic modulus.

The above-described fact stated by (Luxemburk, 1977) is of essential importance for the mutual comparison of the results of measurement obtained by static and dynamic tests. The definition of the stiffness modulus, at the same time, determines the conditions of its identification where for short-term loading it is expedient to identify the value of the modulus on the basis of tests in which a test specimen is loaded by a harmoniously variable force.

There are more potentially usable alternative methods suitable for the identification and analysis of the stiffness modulus characteristics; the EN 12697-26 standard does not strictly prescribe any specific device and its choice is at one's own discretion depending on traditional approaches used in a respective country. In any case, however, the prescribed test conditions must be observed. The procedure described in the relevant European standard is suitable for the classification of an asphalt mix based on its stiffness being also applicable for the specification of the pavement performance in terms of its bearing capacity.

For the purposes of comparisons in our study, a non-destructive test by repetitive indirect tensile stress under the EN 12697-26 standard (IT-CY method) was selected. The test principle is repetitive loading of a test specimen by force during which horizontal deformations in the range of 5-10 microns are exerted. To achieve this maximum required deformation 10 preparatory load impulses are applied before the test itself during which the experimental tester exerts the loading necessary for reaching the deformation.

Temperatures of 5°C, 15°C, 20°C and 30°C were selected for the stiffness measurement. The choice of these temperatures corresponds to the knowledge in mainly the temperature domain of 40°C where very low values are usually obtained and measurements at these elevated temperatures lose their credibility. The results reach a domain with very high measurement inaccuracies where deviations may dramatically distort the resultant values. To enhance the interpretation of the results, the minimum temperature selected for HMAC mixes was 5°C and the maximum temperature selected was 30°C. The value of 15°C is subsequently the essential one for gaining the characteristics which are considered in the pavement multilayer structure dimensioning. Additional calculation using linear regression, which best interprets the stiffness modulus to temperature relationship, was made for the temperature of 0°C as is displayed in Table 5. At the same time, the thermal susceptibility value which corresponds to the ratio of the stiffness modulus at the lowest and the highest test temperature was identified. The measurements were performed only for HMAC mix variants.

The results presented in Table 5 clearly manifest the following findings. The reference mix (REF) with a harder 30/45 bituminous binder manifested a very high stiffness modulus at 15°C, and complied with the requirement for its minimum value prescribed in TP 151. Comparing the reference mix with mix (E) the effect of the used binder was prominently manifested in this case. The mix with the 50/70 binder failed to reach the prescribed values. The result is not very surprising confirming the necessity of using harder binders or modified binders in HMAC mixes.

It may be stated that the use of RAP increases the stiffness modulus (C-E) thanks to the content of hard bitumen in the reclaimed asphalt. This result is not very surprising being in line with the experience of how binder gradation affects the mix behavior. The application of rejuvenators may lead to the reduction of the stiffness modulus below the minimum value required (C-A, C-B). The highest values of the stiffness modulus were achieved with the use of additives allowing the reduction of the manufacturing temperature in the whole production cycle of the mix and during its paving (F, G) where the measured values were higher even for the reference mix. This experience implies

Table 5. Results of stiffness modulus by IT-CY.

Mix	Temperature (°C)			
	5	15	20	30
A	8 100	4 500	2 800	1 100
B	17 200	9 079	6 300	2 000
C	16 650	11 450	6 900	2 450
D	16 500	9 350	6 250	2 300
E	12 250	7 400	5 200	2 400
F	18 550	14 750	9 400	4 250
G	18 950	14 400	8 750	3 350
REF	21 300	13 850	9 300	3 500

Mix	Calculated value at 0°C	Thermal susceptibility t_s
A	9 050	7.36
B	19 200	8.60
C	19 500	6.80
D	18 550	7.17
E	13 700	5.10
F	22 050	4.36
G	22 600	5.66
REF	24 550	6.09

that the application of RAP in the HMAC mix will not lead to the reduction in the stiffness modulus, but quite the contrary. The mix behavior at low temperatures, however, must be monitored; aged bitumen from the RAP might cause impaired mix qualities at low temperatures.

In terms of thermal susceptibility it is evident that the combination of bituminous binder with the Iter-Low T additive is the least suitable one in this respect, in this case both with RAP and without it. The variant containing only road asphalt or the variants with the Fischer-Tropsch paraffin (FTP) additive, on the contrary, lead to the most favorable results. It is even apparent that, apart from the significantly stiffening effect, FTP also has a favorable impact on a lower drop in stiffness at different temperatures of the stiffness modulus verification. This finding may be of importance for the operational behavior of mixes in the pavement structure where it will raise the mix resistance to temperature changes during the day and in different seasons.

3.2 *Stiffness with additional calculation of the master curve*

Another testing method suitable for the identification of the asphalt mix stiffness, including the possibility of a subsequent plotting of the so-called master curve is the procedure described in Annex F (CIT-CY method) to the EN 12697-26 standard. The principle of loading a cylindrical test specimen is based on its exposure to the effect of horizontal load which exerts compressive and tensile stresses on the vertical axis of the test specimens. The stiffness test is performed using the sinusoidal loading principle with the effect of indirect

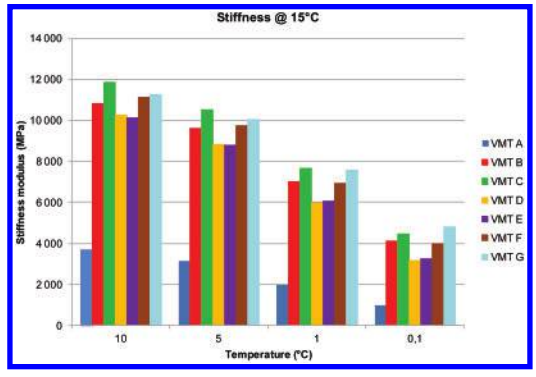

Figure 1. Stiffness modulus at 15°C for selected test frequencies.

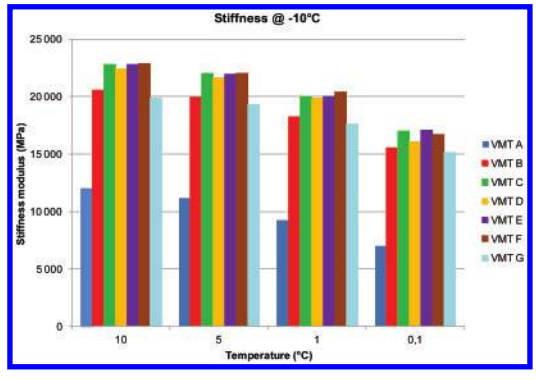

Figure 2. Stiffness modulus at −10°C for selected test frequencies

cyclic compressive loading. To assess the results the test must be performed at different temperatures to be able to assess the asphalt mix by means of the master curve whose main benefit is the option of the superposition of the results obtained at different temperatures and frequencies to one reference temperature. The test temperatures chosen for the analyses included values of −410, ±0, +15 and 25°C. Further the loading range of 50 kN with an accuracy of ±50 N is specified.

With respect to the selected mix designs and materials used, it is necessary to assess the effect of RAP for comparative purposes. The comparison always involved mixes with the application of RAP and without it for one selected additive. Assessing the effect of the used binder it may be seen in Figures 1 and 2 that a significant drop in the stiffness values may be registered in the mix with the Storflux rejuvenating additive.

In terms of the results achieved the following can be stated:

- The assessment of mixes without additives shows that the stiffness modulus master curve of the mix applying RAP is steeper at lower frequencies, which changes at a frequency around 10^4 Hz and starting from that point it is, on the contrary, more gentle. In the high frequency domain of around 10^5 Hz, the

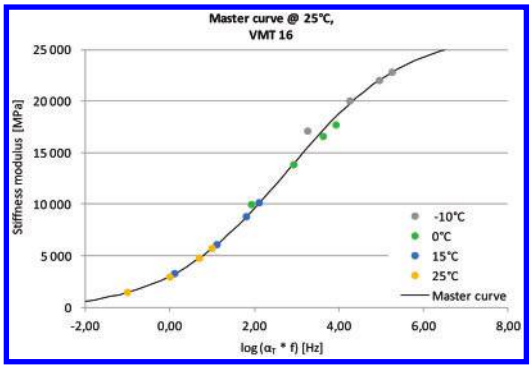

Figure 3. Typical stiffness modulus master curve, example for mix (E).

difference between the patterns of both curves is nearly constant.

- A trend similar to the master curve pattern for the mix without any additives is also manifested by the mix using the IterFlow additive. There is only one difference: the curve of the mix with RAP is steeper up to a frequency of 10^3 Hz, while its further growth is less steep for higher frequency.
- The last comparison by the effect of the used additive involves mixes with the addition of FTP. Here, the development trend differs from the comparisons above. In the low frequency domain, the stiffness master curve of the mix with RAP grows more slowly, which changes after reaching the frequency of 10^2 Hz; starting from that point, the curve is, on the contrary, steeper up to the high frequency domain (from 10^8 Hz) where another change occurs and their mutual difference gets smaller again.
- Another finding is the fact that, unlike the patterns of the other curves mixes (C), (F) and (G) show a difference from the very initial point. The results clearly show that at the initial low frequency they manifest higher stiffness (around 2 300 MPa). Comparing the values obtained by using stiffness master curves it was discovered that the highest values of the stiffness modulus had been reached by the mix (C) which simultaneously also has the steepest growth of the curve in the investigated medium frequency domain. The lowest values and the least steep growth in the curve, on the contrary, had been reached by the mix (A), which is most likely due to the very effect of the additive which plasticizes the bituminous binder.

3.3 *Resistance to permanent deformations*

The results of resistance to the formation of permanent deformations are presented in Table 6. The test was performed on a small testing device according to the European ÈSN EN 12697-22 standard currently in force. The testing has been dan at 50°C in a air bath. The measured values complied with the requirements for HMAC mixes as well as ACO mixes. The results are generally comparable. In the case of the HMAC mix,

Table 6. Results of rutting test in small test device.

Mix	Increment in rut depth WTS_{AIR} in mm	Relative rut depth PRD_{AIR} in%
A	0.023	1.9
B	0.026	1.6
C	0.043	2.9
D	0.032	2.7
E	0.024	1.6
F	0.012	1.5
G	0.016	1.6
I	0.046	5.0
II	0.042	3.9
III	0.072	3.0
IV	0.076	5.2

it was also manifested in this test that the application of 30%-wt. of RAP does not have a negative effect on the mix behavior. While comparing ACO mixes it even appears that in terms of the increment in the rut depth there is even an improvement in the value of this parameter. In the case of the PRD_{AIR} parameter, no straightforward conclusions may be drawn as the behavior of the mixes was quite opposite depending on the asphalt binder or the chemical additive used.

3.4 *Cyclic compression test*

European testing methods for asphalt mixes allow applying two testing methods to determine resistance to permanent deformations through dynamic creep. It is the test in an un-axial device and in a tri-axial device under EN 12697-25. The performed measurements focused on testing dynamic creep in an un-axial device. Its principle is based on the exposure of a cylindrical specimen to the effect of axial compression. At this point, it must be added that it is not a test which allows predicting the rut depth, but a test suitable for the assessment of a given mix.

The method is based on cyclic loading of cylindrical test specimens which are simultaneously exposed to elevated temperature whose standard value is 40°C. This test does not involve vertical loading. The output is the shift in the upper load plate measured always after a certain number of load cycles. Pursuant to the standard, deformation must always be measured after the following load cycles: 2, 4, 6, 8, 10, 20, 40, 60, 80, 100, 200, 300, etc. Permanent horizontal deformation is expressed as the function of the number of load cycles, i.e. as a creep curve. The test is terminated if the relative creep exceeds 4% or if the test reaches the final number of 10.000 load cycles; for this reason it is also necessary to record the number of load cycles at the moment of the test specimen failure.

The cyclic compression test may be assessed using several options of the expression of the relationships and characteristics. First, the relative strain relationship to the number of cycles reached in the inflexion point is expressed. The inflexion point denotes the moment during the test when a change in the creep

Table 7. Results of cyclic compression test for HMAC mixes.

Mix	No. of cycles [−]	Strain [‰]	Creep [‰*10^{-4}/n]	Creep modulus [MPa]
A	559	7.9	74.5	44.30
B	2.662	16.4	28.3	21.41
C	2.409	10.5	20.9	33.23
D	965	8.6	37.1	40.86
E	1.246	9.9	33.8	35.35
F	8.914	7.3	0.4	48.17
G	9,458	6.0	0.2	58.01

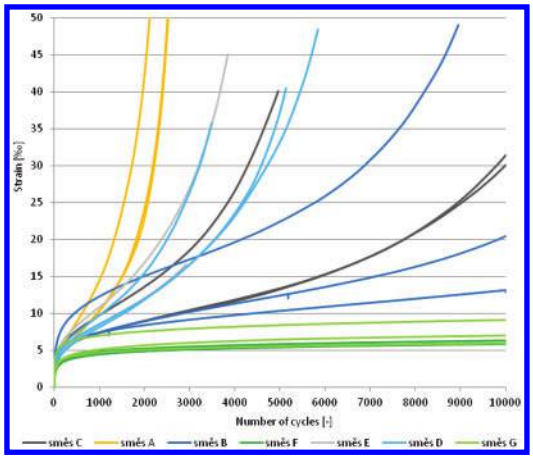

Figure 4. Creep curves of assessed HMAC mixes.

curve development occurs, it is usually situated at the end of the second phase, and then, due to deformation, a change in the structure of the specimen and thus also a change in its properties occurs lasting until the moment of its complete failure which may or need not occur during the test.

The trend of the inflexion point characteristics may be well derived from Figure 4 where it is evident that the lower the number of load cycles, the higher the relative deformations reached. On the contrary, in the case that a higher number of cycles has been reached, the lower the relative deformation of the specimen was. This figure allows us to draw a conclusion that the mixes reaching lower relative deformations in the inflexion point and simultaneously a relatively higher number of load impulses show better resistance to permanent deformations. At the same time, however, the total creep curve pattern is also important. Individual time patterns of the creep test for investigated mixes clearly show the scatter reached for individual mixes. The greatest deviations were reached for the mix (B), while much lower deviations were reached by mixes (C) and (F). Overall, it may be stated that by far the best results in terms of creep were reached by the mix variants where bitumen with FTP has been applied. In this very case, it was even mix with RAP that reached better results.

Feasibility of lightweight aggregate concrete for structural and non-structural works in Tanzania

A.L. Mrema
College of Engineering and Technology, University of Dar es Salaam, Tanzania

H.A. Mboya
Department of Civil Engineering, Mbeya University of Science and Technology, Tanzania

ABSTRACT: There has been serious land degradation in Tanzania due to extensive exploitation of granite aggregates even in areas where there is plenty of natural lightweight aggregates. Many Engineers have resorted to using normal weight aggregates in construction not only due to the feeling that lightweight aggregates (LWA) are too weak for structural purposes but also due to lack of knowledge of the design procedures for lightweight aggregate concrete (LWAC). Structures made of normal weight aggregates have higher dead loads which demand reduced span lengths, deeper structural members, more reinforcement and increased foundation area when compared to those made of LWAC. In Tanzania there are major deposits of LWA in areas of previous volcanic eruptions namely Kilimanjaro, Mbeya and Arusha and these remain largely un-exploited. Research was done to investigate the feasibility of using scoria and pumice aggregates in structural lightweight concrete. The aggregates were obtained from Kilimanjaro and Mbeya respectively. A mix design for grade 20 concrete was performed for both aggregates. It was found out that it was possible to use the scoria aggregates for structural concrete but not the pumice. Using pumice aggregates, the strengths obtained were less than 17 MPa which is the minimum strength acceptable for structural LWAC. It was concluded that the use of scoria aggregates for structural LWAC was feasible and that the pumice aggregates could be used for non-structural LWAC. Further research is required to characterize the lightweight aggregates present in Tanzania for better utilization in construction. Engineers in Tanzania are now in a position to design and use LWAC as the design procedures have now been elaborated. The use of light weight aggregates in areas where these deposits are present will reduce the costs of transport of normal weight aggregates from long distances and this will also protect the environment.

1 INTRODUCTION

Lightweight concrete (LWC) is defined as the concrete of substantially lower unit weight than that made of gravel or normal weight crushed aggregates. The dry densities are normally in the range of 800 to 2000 kg/m^3 (Schlaich & Zareef, 2008). In practice, designation of lightweight concrete is according to standardized strength and density classes (Chandra et al., 2002). Lightweight concretes having dry densities below 800 kg/m^3 are defined as Infra-lightweight concretes. Lightweight concrete is produced by either using lightweight aggregates or by formation of voids in concrete by omitting sand or by formation of voids in cement by addition of substances causing foam. There are three categories of LWC, namely structural LWC, low density LWC and moderate strength LWC (Neville & Brooke, 2005). According to NRMCA (2003), structural LWC has an in place density of between 1440 kg/m^3 and 1840 kg/m^3. Clarke (2005) defines structural LWC as having densities in the range of 1200 kg/m^3 to 2000 kg/m^3. Normal density concretes range from 2200 kg/m^3 to 2600 kg/m^3 depending on the type of aggregates used (Neville & Brooke, 2005). According to the above literature, structural LWC should have a minimum compressive strength of 17 MPa. LWC is manufactured by combination of fine and course lightweight aggregates or course lightweight aggregates with normal weight fine aggregates. Complete replacement of normal weight aggregates with lightweight aggregates reduces the air dry density to about a half that of normal weight concrete (Clarke, 2005 & NRMCA, 2003). Neville & Brooke (2005) defines three classes of LWC which can be made available according to their method of production: (i) No fines concrete obtained by omitting the finer fraction of normal weight or lightweight aggregates to create air filled voids, (ii) Aerated concrete produced by inclusion of air bubbles in cement paste or cement mortar matrix to form a cellular structure. This contains 30 – 50 % voids and (iii) Lightweight aggregate concrete obtained by replacing either wholly or

Figure 1. Scoria (L) and Pumice (R) aggregates used.

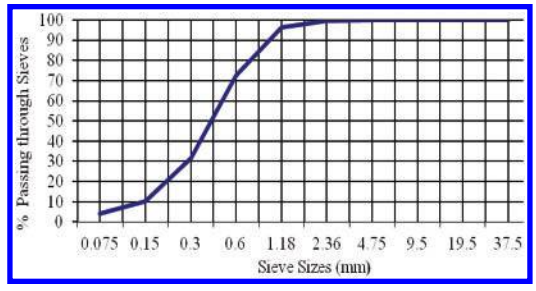

Figure 2. Sieve analysis of natural sand.

partially normal weight aggregates in a concrete mix with lightweight aggregates of low apparent specific gravity (porous aggregates containing large proportion of voids). This last type is the subject of the present investigation where all course aggregates were replaced with lightweight aggregates of pumice or scoria to obtain what we refer to as light weight aggregate concrete (LWAC). LWC does not provide only lighter structures but also structures with better insulation against heat and sound and such structures are more resistant to earthquakes.

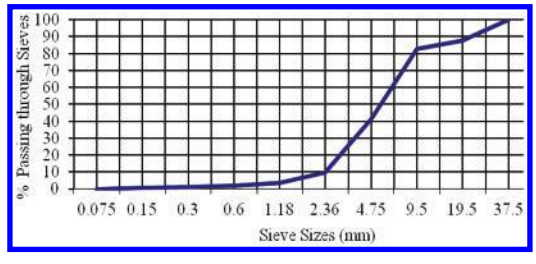

Figure 3. Volumetric analysis of scoria aggregates.

2 OBJECTIVES OF THE INVESTIGATIONS

The objective of the investigations was to find out whether pumice and scoria aggregates found in vast quantities in SW (Mbeya) and NE (Kilimanjaro) of Tanzania respectively were suitable for producing structural light weight concrete. Engineers in Tanzania prescribe the use of normal weight aggregates in these areas despite the fact that normal weight aggregates are very expensive as they have to be hauled from very long distances. One of the reasons why many engineers do not use these LWC aggregates is due to lack of knowledge of the mix design procedures for LWAC.

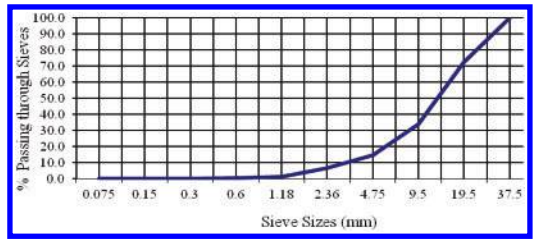

Figure 4. Volumetric analysis of pumice aggregates.

3 MATERIALS AND METHODS

Pumice and scoria aggregates were sampled from Mbeya and Kilimanjaro respectively (Fig. 1).

The cement used was Portland limestone cement CEM II/A-L/32.5R and was tested to conform to BS EN 197-1-2000. Natural sand was tested for its gradation (Figure 2) according to BS 812-103.1:1985. Volumetric sieve analysis according to TxDOT (2008) was performed on the scoria and pumice aggregates (Figures 3 and 4). The results show that about 60% and 70% of the scoria and pumice aggregates respectively lie between 4.75 mm and 37.5 mm.

The ten percent fines value test was done for scoria and pumice aggregates according to BS 812 part 111:1990 and the values obtained were 89 kN and 52 kN respectively. Table 1 shows the properties of the aggregates used.

Table 1. Properties of LWA used.

10% Fines Value	(kN)	89	52	–

4 MIX DESIGN PROCEDURE FOR LIGHT WEIGHT AGGREGATE CONCRETE (LWAC)

The main emphasis in the design of LWAC is that the density and the strength of the LWA are related to the density and strength of the concrete.

4.1 *Determination of the mean compressive strength of concrete*

The compressive strength should satisfy the following conditions:

$$f_m = f_{cu} + \lambda S_n \tag{1}$$

where f_m = mean compressive strength; f_{cu} = specified characteristic strength; λ = statistical factor dependent of the acceptable probability of failure; and S_n = standard deviation of the distribution. The coefficient of variation is approximately 5 – 10% for the strength and 3 – 5% for the density (Chandra & Brooke, 2002)

4.2 *The strength of the LWA particles*

The recommendation is to design the concrete mortar with a compressive strength double that of the strength of the lightweight aggregate. The mean compressive strength of the lightweight aggregate is calculated using the formula:

$$f_{la} = a \cdot 10^{b\rho/1000} \tag{2}$$

where a and b are coefficients according to Table 2 and ρ is the particle density in kg/m^3. For all types of LWA, natural or factory produced, there are different relationships between the strength of the LWA and the particle density. There are special methods to measure the particle strength of the aggregate. Because the particles interact with the surrounding matrix, the cement paste or mortar, the method is based on estimating the strength of the concrete. The results are then used to evaluate coefficients a and b in equation (2).

The relationships among the strength of mortar, the strength of the LWA, the strength of the concrete, and the volume of the mortar or volume of the LWA are calculated using:

$$\log f_{con} = v_{la} \cdot \log f_{la} + v_M \cdot \log f_M \tag{3a}$$

or

$$\log f_M = \frac{\log f_{con} - v_{la} \cdot \log f_{la}}{1 - v_{la}} \tag{3b}$$

where f_{con} = strength of concrete; f_M = strength of mortar; f_{la} = strength of LWA; v_{la} = volume of the LWA particles; and v_M = volume of mortar.

4.3 *The compressive strength of mortar*

The compressive strength of mortar can be calculated from equation (4). Here natural sand and ordinary Portland cement are assumed to be used, and the specimens for mortar testing are the same type and size as used for the testing of concrete.

$$f_M = A \cdot 10^{-B(W/C)} \tag{4}$$

Table 2. Coefficients a and b in Equation (2) (Chandra & Leif, 2002).

Aggregate No.	a	b
1	1.52	1.14 (1.08, 1.03)
2	1.12	1.22 (1.16, 1.11)
3	1.00	1.25 (1.15, 1.14)
4	0.89	1.28 (1.22, 1.17)

In parenthesis the value of b is for 5 and 10% water content in the aggregate. The value of b is not or is marginally influenced by the water content. Aggregate no. 3 is for the bulk density of 300 kg/m^3. The LWA is some type of high quality sintered clay. Other LWA may have other values and shall be provided after the test.

where A and B are experimentally evaluated coefficients. With A = 140 and B = 0.87 (ordinary Portland cement after 28 days and W/C or W/binder > 0.30), the compressive strength is:

$$f_M = 140 \cdot 10^{-0.87(W/C)} \quad \text{or}$$

$$W/C = \log\left(\frac{140}{f_M}\right) / 0.87 \tag{5a}$$

When $W/C > 0.20$ and <0.25, the following formula is is used:

$$f_M = 160 \cdot 10^{-0.87(W/C)} \tag{5b}$$

When W/C is between 0.25 and 0.30, A is to be interpolated. According to accepted definition, the water/cement ratio is: $W/C = W \cdot 10^3/C$ where W is the water content in m^3/m^3 and C is the cement content in kg/m^3. The formulae are valid for natural sand, not lightweight sand, and for water/cement ratio less than 0.8. (Chandra & Leif, 2002).

4.4 *The volume of cement paste*

The volume of cement paste or binder in concrete should adhere to the principle of a constant paste-aggregate volume and should be about 30% of the volume of concrete. The volume of cement paste depends on many factors, for example, the type and shape of aggregate, consistency, stability of the concrete mixture, the strength of the mortar or concrete and water absorption of the LWA. According to experience even from normal weight concretes, the volume of the cement paste or binder may be in the range of 30 ± 2%. (Chandra & Leif, 2002).

4.5 *Cement content*

The cement content is calculated using the formula:

$$C = \frac{1000 \times v_p}{0.31 + W/C} \text{ kg/m}^3 \tag{6}$$

where v_p = volume of cement paste in concrete.

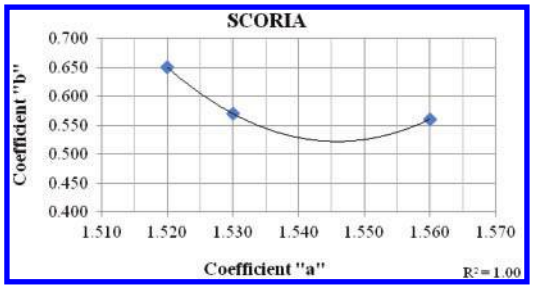

Figure 5. Strength coefficients for scoria aggregates.

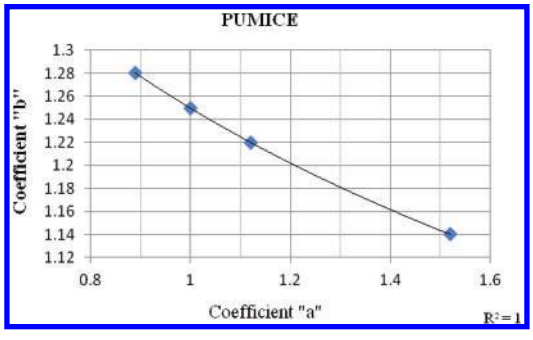

Figure 6. Strength coefficients for pumice aggregates.

4.6 *Volume of sand*

The volume of sand is calculated from the formula

$$v_s = 1 - \left(v_p + v_{la} + v_{air}\right) \tag{7}$$

where v_{la} = volume of LWA; and v_{air} = volume of air in the concrete. Normally, the air volume is 1.5–2% of the volume of concrete.

4.7 *The bulk density of the concrete*

The density of the concrete can be obtained by adding all the amounts of the ingredients in 1 m^3 of compacted concrete.

5 MIX DESIGN CALCULATIONS

The mix proportioning of the LWAC using the scoria and pumice aggregates was based on estimating first the coefficients a and b in equation (2) by interpolating the values shown on Table 2. The coefficients were then recalculated from trial mix design strength test results using Equation (3a). The re-calculated coefficients are plotted on Figures 5 and 6. Three trial mixes (Trial 1, Trial 2 & Trial 3) were then prepared each with the pumice and the scoria aggregates. Table 3 & Table 4 show the design parameters and the calculations respectively.

Confidence factor, $\lambda = 1.64$. Standard deviation, $S_n = 8.5$. Characteristic strength, $f_{cu} = 20$ MPa.

Mean Compressive strength, $f_m = f_{cu} + \lambda S_n =$ 33.94 MPa.

6 TEST RESULTS

6.1 *Tests on fresh concrete*

The workability and density of the LWAC were measured according to BS 206-1:2000 and the air content was according to BE 96-3942/R4 (1999). The results are shown on Table 5.

6.2 *Tests on hardened concrete*

The test results on densities and compressive strength of the hardened concrete is shown on Table 6. Figure 7 shows the failure modes of the concrete cubes after the compressive strength tests and they clearly show that failure was initiated by failure of the aggregates which were weaker than the mortar. The development of strength of the concretes with age is shown on Figure 8.

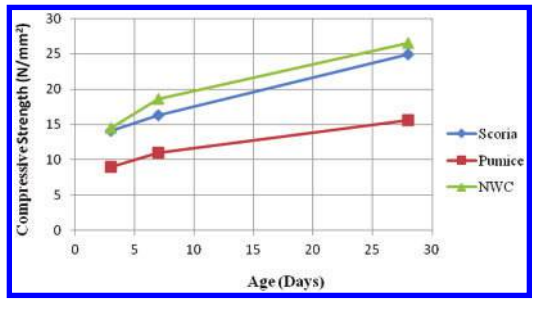

Figure 8. Relationship between compressive strength and age.

7 DISCUSSION OF RESULTS

The tests on fresh concrete for both the scoria and pumice concretes gave slump values between 25 mm and 100 mm as expected indicating medium workability. The air content was, however, higher than the 2% assumed in the design. The densities of the fresh concretes were also a bit lower than the design values (Tables 4 & 5). This might have partly been due to insufficient compaction of the concrete but it has to be mentioned here that some of the formulae used in the design are empirical in nature and these variations are not unexpected. Tests on the hardened

concrete (Table 6) showed that the dry densities of the LWAC produced were actually in the range of 1200 to 2000kg/m^3 as defined by Clarke (2005). The design characteristic strength of 20 MPa at 28days was reached with the scoria aggregates but not with the pumice. The average strength reached with pumice aggregates was 15.6 MPa which was lower than the 17 MPa recommended for structural LWC. Developing a concrete of grade 20 with pumice went beyond the capability of the pumice aggregate which was weaker than the scoria. This was actually observed in the modes of failure of the tested concrete cubes (Fig. 7) where it was found out that in both cases it was the aggregates that actually failed first in tension. The mortar was designed to be of strength greater than that of the lightweight aggregate as recommended (Table 4). Table 6 shows that using LWAC the demand for cement/m^3 is higher than with normal concrete using normal aggregates. This additional cost is offset by the additional costs which would be incurred by transporting normal aggregates from longer distances to these locations.

8 CONCLUSIONS AND RECOMMENDATIONS

It can be concluded from these investigations that the scoria aggregates are suitable for structural concrete and the pumice aggregates for non-structural purposes. Non-structural concrete is employed in the construction of non-load bearing elements, roof, floor and wall insulation and production of self curing concrete. In a separate study by Mboya et al, (2011), it was established that the pumice used in this study could also be used in the production of suitable concrete building blocks. It was noted from literature survey that mineral additives and chemical admixtures such as silica fume, ground blast furnace slag, fly ash, superplasticizers etc. are used in LWA concrete mixes to improve LWC strengths. This can also be applied with these aggregates to get better concrete strengths. There is a need of characterization of the lightweight aggregates that are present in vast amounts in Tanzania so that they can be better utilized. There is also a need to disseminate the knowledge of the use of lightweight aggregate concrete to engineers in Tanzania so that they can start utilizing this material in construction.

ABSTRACT: The hydrated Portland cement doesn't resist to high temperature very well. In the course of heating Portland cement loses its strength and also chemical changes take place in its mineral composition. For these reason we use composites based on aluminous cement at high temperature applications which shows much better characteristics. Experimental studies were conducted to examine mechanical properties of cement paste made from aluminous cement and reinforced by various types of fibers. During the experimental program was measured compressive strength and three-point bending strength. Specimen size of 160 × 40 × 40 mm were made from aluminous cement and used in experimental program. One series of specimen was deposited in laboratory condition and the second one was exposed to high temperature and all mechanical properties were compared. The effect of amount of water was also investigated, because the values of water ration has an influence to mechanical and also rheological properties of final product.

1 INTRODUCTION

Significant advances in the field of building materials leads to increasingly frequent enforcement these high performance materials in real constructions. Efforts to maximize the efficient use of non-renewable resources and especially energy-intensive materials lead to efforts to maximum efficiency and usability. For this reason new buildings design started gradually using high quality entrance raw materials to create super-construction while reducing the overall emission of carbon dioxide. The increasing the cost of input materials will significantly reduce the total volume and weight of structures. This leads to cost reduction of other part of construction.

However, a common problem of new types of structures, made from high performance materials, is their inferior properties in some very specific areas of their proposal. Typical example of these properties is a lack of fire resistance, especially in case of very subtle structures. The behaviour of concrete surface layer of High-performance concrete with special consideration to spalling was described in (Sicáková). This deficiency is necessary to be solved by other additional measures in the form of fire tiling or other kind of measures. Development of fire barriers, which are based on aluminous cement, has become an integral part of building industry, especially with regard to the current global political and security situation. Compared to traditional Portland cement the aluminous has excellent characteristics in relation to the high temperatures. There were many research focused on studying behaviour of concrete or high-performance concrete after exposure to temperatures up to 1000°C. There were researches on Young's modulus in his experimental investigations (Huo). Research of dynamic behaviour of concrete after exposure to high temperatures was also investigated (Bahr). All these researches and other one show the negative influence temperature to mechanical properties.

2 EXPERIMENTAL PROGRAM

The experimental program was focused on studying mechanical properties like tensile strength in bending and compressive strength of composite made from aluminous cement, various type and amount of basalt fibers, plasticizer and water. All these properties were examined on specimens with dimension 160 × 40 × 40 mm.

2.1 *Aluminous cement*

The original aluminous cement was developed as a mixture of limestone and bauxite in French company Lafarge. However there is still a place for application of aluminous cement especially in the form of composite materials for high temperature applications.

For the purposes of the experimental program was used aluminous cement manufactured by the French company Lafarge Aluminates SECAR ®71. The main component of the hydraulic binder is aluminium oxide in this case monocalcium-aluminate $CaO{\cdot}Al_2O_3$

Table 1. Chemical composition of aluminous cement.

CII-c (8)	426.05	1704.20	17.04	3.30
CIII-c (9)	426.05	1704.20	25.56	3.30

(Collepardi). This cement isn't made from natural sources of bauxite but from chemical clean artificial aluminium oxide. The manufacture of the aluminous cement takes place in electric arc furnace. The chemical composition of aluminous cement SECAR®71 is shown at (tab. 1).

2.2 *Basalt fibers*

Historical use of the asbestos fibers for high-temperature applications concrete composites is already overcome due to the health risk, especially laugh cancer. Fortunately the asbestos is not the only usable material with the required properties. We can use basalt fibers because they resist with success the temperatures up to 1000°C. In experimental program were used basalt fibers of two lengths. There were used fiber with length 6,35 mm (1/4″) and diameter 13 μm and length 12.7 mm (1/2″) with the same diameter. The density of used fibers is 2900 kg·m^{-3} and it's tension strength is 2000 MPa (Artemenko). Using two kinds of fibers with different amount leads to investigation their influence to the final properties.

2.3 *Treatment and manufacture*

All used mixtures and their designation are presented at (tab. 2). The first experiences with aluminous cement paste show that due to high hydration heat there were many cracks on the fresh samples which were kept in laboratory condition. This negative phenomenon was eliminate by leaving the fresh cement composite in forms in a humid environment with relive humidity over 90% while avoiding the water evaporation from the surface (Behnood). The specimens in steel forms were after 72 hours removed from steel forms and till its age 28 days were left in the humidity environment. After 28 days all samples were dried at 105°C for

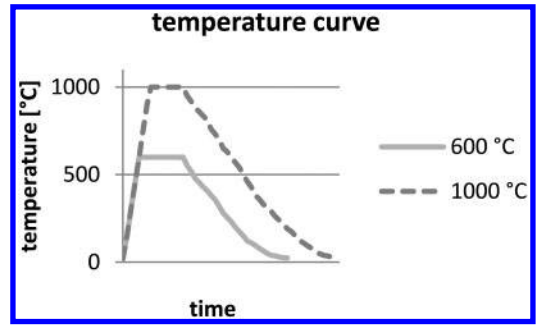

Figure 1. Temperature profile during loading.

Table 3. Compressive strength of composite.

	Compressive strength		
	f_c [MPa]	f_c [MPa] 600°C	f_c [MPa] 1000°C

24 hours and then the influence of high temperature started being examining. The group of three samples was examined after dried at 105°C, second group of three samples was examined after exposure to 600°C and the last on group of three samples was examined after exposure to temperature 1000°C. The time process of temperature is show at (fig. 1).

3 RESULTS

There were designed nine mixtures of composites of aluminous cement, water, different length of basalt fibers and plasticizer. The amount of each components and the water-cement ration is shown at (tab. 1). From each mixture were made nine samples, three reference three for temperature load 600°C and the last three for temperature 1000°C. The water-cement ration was designed according to suitable workability, therefore it's lower while using plasticizer. Using the same values of water-cement ratio for mixtures with and without plasticizer leads to segregation of water during compaction because of high efficiency of plasticizer. The fibers were added in amount of 0.5; 1.0 and 1.5 of weight percent. Using of two different lengths of fibers was chosen to investigate their influence to the mechanical properties especially tensile strength in bending.

The results of tests of mechanical properties are presented at (tab. 3 and tab. 4). Tensile bending strength

Table 4. Tensile strength of composite.

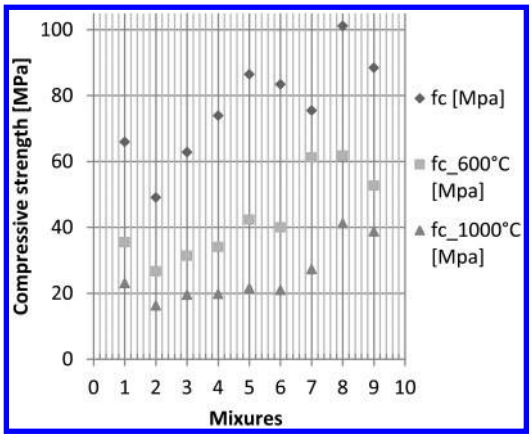

Figure 2. Compressive strength of composite.

and compression strength were measured on all specimens. The mechanical properties are very important parameter for fire resistance materials. For design is necessary to know changes of these properties caused by high temperature.

4 CONCLUSIONS

The exposure to high temperatures for silicate composites based on Portland cement has completely destructive consequences especially on hydrated cement paste. The primary phenomenon at high temperature load is the evaporation of free water, following losing of the gel water and crystalline water at 150°C. The disruption of cement binder's inner structure is indicated at 500°C, when the Portlandit is starting disintegrating. The complete disintegration of the cement binder takes place at temperatures higher than 800°C. By the temperature over 600°C the α-silica is converted to β-silica, which is accompanied by the volume expansion and increasing the tension in inner structure (Venkatesh).

Using aluminous cement appropriately supplemented by fibers and plasticizer leads to the creation

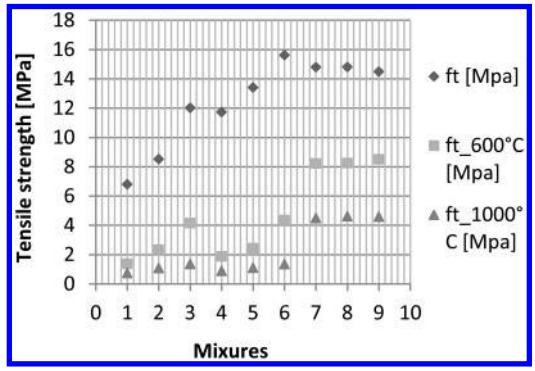

Figure 3. Tensile strength of composite.

of composite that resists the effect of high temperatures without volume changes and disintegration of inner structure. This is very important for design fire-resistance facing or other materials for high temperatures applications. The volume stability of presented composite prevents unwanted consequences like explosive spalling. The strength of aluminate cement also decreases by the influence of high temperature, but the residual strength still ensures cohesiveness and sufficient mechanical properties. The relationship between compressive strength of each mixture is determined at (fig. 2) and between tensile strength at (fig. 3). The tensile strength was very positively influenced by the value of water-cement ration and the amount of basalt fibers. Using of plasticizer while reducing the water-cement ration leads to an increase of compressive and tensile strength of the cement matrix, that results in higher properties. The length of basalt fibers was also investigated in this research. It showed the positive effect of length of fibers on tensile strength in bending, when the specimens with fibers 12.7 mm long (mixtures CI-b, CII-b, CIII-B) had higher values of tensile strength. With the growing amount of fibers in the total volume of the mixture decreases the workability and the mixing of all components. This negative effect leads to the formation of clusters of fibers. In these weaknesses starts the beginning of the development of cracks during testing mechanical properties. From this reason we can find lower values of tensile strength in bending in mixtures with the highest content of basalt fibers.

The influence of percentage replacement from coarse recycled concrete aggregate

D.W. Immelman & W. de Villiers
University of Stellenbosch, Stellenbosch, South Africa

ABSTRACT: The aim of this study was to investigate the potential use of coarse recycled concrete aggregate (RCA) as a material in structural concrete. The lack of knowledge and specifications surrounding RCA in South Africa were the main reasons for this research. The reduction of accumulating construction and demolition (C&D) waste at landfills and mining of depleting virgin materials are subsequent aims from this investigation. By increasing the database of research of RCA in South Africa the possibility of specifications for this alternative building material can be initiated. The implications of such specifications would lead to RCA acceptance in concrete design. The objectives that were achieved through this research project are; what is the percentage replacement of RCA to a concrete mixture that will produce a material that achieves similar or the same results as a concrete mixture containing natural aggregates and what aggregate properties and limits should be defined in the specification of RCA for it to be accepted as material in a concrete mixture. The objectives were assessed through examining the physical, mechanical and chemical properties of the aggregate as a material and the fresh and hardened concrete properties of RCA as a constituent in structural concrete.

1 INTRODUCTION

Concrete is the most widely used construction material globally and is contributing to the extraction of natural resources and energy usage, thus responsible for large quantities of CO_2 emissions (Lui & Chern, 2008). The construction and civil works industries account for 60% of worldwide consumption of raw natural resources (Bribian et al, 2011). The amount of C&D waste generated each year is estimated by different sources to be in the region of 1-3 billion tonnes (Lui & Chern, 2008, Mohammend, 2007 and Van Zijl, 2010). This C&D waste is mainly sent to landfill sites or reused in low grade applications such as backfill and unbound road base.

The use of processed C&D waste or recycled concrete aggregate (RCA) in high grade applications has been limited due to the hesitance to utilise a secondary material in structural concrete because of uncertain characteristics. Countries such as Germany, Switzerland, Netherlands, Denmark, Great Britain, USA and Russia all have established standards or specifications for the use of RCA in concrete (Dehn, 2007), therefore providing the relevant stakeholders with the assurance that the material conforms to the necessary specifications.

Currently, South Africa does not have similar standards or specifications. The South African Bureau of Standards (SABS) is currently revising the standards and test methods related to aggregates in concrete to coincide with the European standards (Perrie, 2011). There are South African companies such as Cape Brick which produce concrete masonry products from recycled C&D waste using percentages of RCA. There is a perception that products such as these cannot meet the standards that natural aggregate (NA) can deliver.

2 METHODOLOGY

The research conducted consisted of an extensive literature review of both local and international research related to RCA. Included in this review was overview of the current South African standard for aggregates in concrete, SANS 1083:2006, as well as the international standards and specifications listed below:

- BS EN 12620:2008 Aggregates for concrete
- RILEM TC 121 – DRG 1994 Specifications for concrete with recycled aggregates
- JIS A 5021 Class H Recycled aggregate for concrete-class H
- BS 8500-2:2006 Complementary British Standard to BS EN 206-1 Part 2: Specification for constituent materials and concrete
- ACI 555R – 01 Removal and Reuse of Hardened Concrete
- ACI E1 – 07 Aggregates for Concrete

The shortcomings of the South African standard were identified and investigated through an experimental programme and recommendations were made based on the outcomes of the experimental research.

2.1 *Materials*

Greywacke stone (19 mm), which is commonly found in the Western Cape region of South Africa, was

used. The aggregate is also well known for demonstrating alkali-silica reactivity (ASR). For consistency the same coarse NA from a single batch was utilised throughout the experimental programme. Sand known as "Malmesbury" sand was utilised. Three different Malmesbury sand batches were used in this study. A single batch of CEM I 52.5 N Ordinary Portland cement (OPC) and ground granulated Corex® slag (GGCS) was used as binder.

The coarse RCA was obtained from Cape Brick. C&D waste is primary crushed by a mobile crusher. This material is pre-screened to remove large contaminant items such as steel, bricks and other foreign materials. Topsoil and clay are removed, while light weight material is removed by air-sifting. Magnets are placed over conveyor belts to remove ferrous metals. The secondary crushing process includes a jaw crusher and a gyro-crusher after which the material is about 15 mm in size. A vertical impact crusher concludes the crushing process with material below 9 mm in size. Potable water is sprayed throughout the factory to control dust and is localized over certain conveyor belts. The recycled material was collected from a point in the production process before the vertical impact crusher.

The collected material was relatively dirty, damp and not graded, hence it was decided that the material should be further processed. This would allow for consistency between the different batches of RCA and could still be considered a practical recycling method. This would result in a superior secondary material compared to an unwashed material. The material was cleaned by hosing batches of the material for 30 seconds under water. Once dry, the material was sieved so that the individual stone sizes could be obtained and later combined to produce a nominal size of 19 mm. SANS 1083:2006 specifies the limits for the combination of stone sizes for a nominally graded coarse aggregate (Table 1).

A total of three batches were collected from Cape Brick at 6–8 week intervals. The preparation process described above was employed to prepare each of the experimental batches of RCA. However, due to an error, the percentages for the March sample were incorrectly batched. The 9.5 mm stone amounted to 6.25 kg per 50 kg batch instead of the intended 5 kg.

Table 1. Grading of RCA according to SANS 1083:2006.

Sieve size (mm)	% passing*	% passing**	% retained	Mass/50 kg (kg)

2.2 *Tests*

SANS 1083:2006 requires that certain properties are required for verification, but to correctly assess RCA additional tests are necessary to further define the sample material's properties (Table 2). The aggregate properties were examined for the percentage replacements: 0, 15, 30, 50 and 100%. Mass was taken as the measure of the percentage replacement for the aggregates tests. The aggregate properties are categorised according to the geometrical, physical and chemical properties. The chemical analyses for this study were done by the Central Analytical Facilities (CAF) at the University of Stellenbosch.

The fresh concrete was tested for workability and consistency through various tests which include: slump, slump loss with time, air content, and fresh concrete density. The hardened concrete was tested according to the properties of: mechanical, durability and dimensional stability (Table 3). The durability tests were conducted at the University of Cape Town.

2.3 *Mix design*

South Africa makes use of the C&CI method for guidelines to designing concrete mixtures. Most researchers pre-saturate the RCA to a surface saturated dry (SSD)

Table 4. Mix design examples.

condition to reduce the effects that the material may have on the concrete properties. The practical implications of following this method were not viable, not only for this investigation, but even more so in concrete production industry. Consequently, all the materials used were kept in an air dry condition. The concrete for this study was assumed to be a general structural concrete of 30 to 40 MPa for a coastal region and a W:C of 0.6 was chosen.

The percentage replacement was based on the volume and the sand amount was initially chosen and kept constant. Eight mixtures were prepared for comparison in the experimental programme. These mixtures are labeled according to the month the RCA concrete batch was produced (Mar, Jun or Aug), the percentage replacement (0–100%) and whether cement and/or cement extender (C or S) was used (Table 4).

Prior to mixing, items "X" and "FL" (Table 5) were removed. The inclusion of these contaminants may lead to results which are not representative of the larger sample of RCA due to the test specimen size. The screening process involved using a strong magnet to remove magnetic items and visual inspection to remove other items. All concrete specimens were mixed and compacted/vibrated in a similar manner for consistency.

3 RESULTS

3.1 *Aggregate properties*

The aggregate properties are summarised in Table 5. The increase in RCA percentage resulted in an improved continuous grading with higher proportions of smaller particles. The improved grading would result in a better packing ability. The dust content increased with increasing percentage replacement and although the dust content was higher in the RCA, it was still within the limits defined by SANS 1083:2006, RILEM TC 121 and JIS A 5021.

The RCA particles had an irregular, sub-angular and cubical shape with a lower Flakiness Index (FI). The NA was angular, elongated and flaky with a high FI value. The NA particles were rough in texture, while the RCA particles had a rough and porous surface texture associated to the adhered mortar and masonry particles. A higher FI value would improve the tensile strength by restricting the formation of continuous cracks through the concrete.

The RCA composition typically had a higher percentage of stone/mortar combination particles. The constituent composition is dependent on the source of the original material and the recycling process. A larger sample of RCA should be assessed to accurately determine the amount of foreign items found within an RCA batch. The floating items consisting generally of wood and plastics were below the 2 cm^3/kg limit defined in BS EN 12620. The amount of foreign items, especially larger items, should be limited to avoid localised corrosion and spalling.

The relative density (RD) decreased with increasing replacement percentage due to the higher presence of lower density materials such as brick and adhered mortar. The lowest RD measured was 2.59. RD could be used to reject a RCA batch due to the higher water absorption associated with a lower RD. The LBD and CBD increased with increasing RCA percentage due to the improving packing capacity. The LBD and CBD were lower when RCA with a lower relative density was assessed.

The water absorption increased with increasing RCA replacement. The highest water absorption was due to the presence of clay masonry items and adhered mortar particles. The water absorption percentage was below the 3.5% limit defined by JIS A 5021 and 3% in the RILEM recommendation for recycled aggregates.

The ACV was similar for all RCA combinations, except marginally higher for RCA with higher percentages of lower ensity particles. The lower density particles are fragile and crush at a lower force compared to the stone particles. The highest ACV was lower than the 30% limit defined in the SANS 1083:2006.

The water-soluble cations and anions analysis showed that the RCA combinations increased the amounts of the six ions analysed. The individual amounts from the various ions were not significantly high, with the highest total combination of all six ions amounting to 150 mg/l. The RCA samples which originated from C&D waste from a demolition project in the Cape Town harbour had higher amounts of chloride ions, but not considerably high with the highest amount of 9 mg/l.

The mineralogical composition of the RCA samples was similar to that of the reference material. The difference between the mineral oxides percentages for the various RCA combinations was not significant (below 5%). The CaO mineral increased with increasing RCA replacement, indicating the increasing presence of cement paste. The LOI also increased with increasing RCA percentage signifying the presence of water bound substances in materials such as brick and

cement paste. The mineralogical analysis also showed that although the RCA batches originated from different C&D waste sources, the compositions were similar. Assessing the RCA batches for potential ASR showed that the samples had compositions almost identical to that of greywacke, granite and grandoirite which are aggregates which have displayed ASR potential when used in concrete.

3.2 *Fresh concrete properties*

The influence of percentage replacement on the initial slump value was negligible (Table 6). The slag mixtures displayed more workability (i.e. higher slump) than the OPC mixtures. The influence which the fine aggregate has on the fresh concrete workability was evident in this investigation. The one batch of concrete was produced with sand which was coarser (higher FM) than the other sand used in the concrete mixtures. The sand thus required less mixing water to produce the target slump and in this case the concrete was highly workable (slump > 150 mm) and less cohesive.

Although the RCA had higher water absorption than the NA, the RCA grading which was more continuous improved the loss of workability. The surface texture

Table 6. Fresh concrete property results.

Batch	March		June		August	
Mixture	Slump (minutes)					
Time	0	60	0	60	0	60

R30S	3.6		3.9		5	
R100S	4		4.6		5.2	

and particle shape also contributed to the slump loss rate.

The increase in RCA replacement percentage resulted in an increase in air content (Table 6). The slag mixtures had the lowest air content. The lower air content in the slag mixtures can be attributed to the "fine-filler effect" of cement extender particles. Aggregates with a better grading should have lower air content due to improved packing ability. The higher air content in the RCA mixtures was attributed to the porous particles which entrapped air during mixing. The effect of less cohesive mixtures resulted in a higher air content than in mixtures which were cohesive. The higher percentages of RCA negatively influenced the fresh concrete properties, although not significantly.

3.3 *Hardened concrete properties*

The compressive strength displayed no clear trend with increasing percentage replacement of RCA (Table 7). The mixtures containing RCA produced strengths similar to and better than the control mixtures for both binder contents and curing periods. The slag mixtures produced low early age strength, but resulted in the highest overall strength with the mixtures containing 100% RCA. The water absorption and packing ability of the RCA were the reasons for the improved compressive strength results. The compressive strength tests also showed that mixture consistency is important in a fresh state. The RCA mixtures which had excess mixing water absorbed this water to produce higher strengths due to the W:C ratio being adjusted.

The RCA generally reduced the tensile splitting strength of hardened concrete due to the lower FI value with RCA (Immelman, 2013). The more angular and flaky the aggregate particles resulted in a better aggregate interlocking. The tensile strength was between 10

to 11% of the compressive strength. The weaker aggregate particles such as brick and old mortar had failure planes which passed through these particles.

The modulus of elasticity results were varied for the different mixtures (Table 8). There was no clear difference in RCA percentage replacement or binder content. The concrete mixtures generally had elastic moduli which were similar.

The durability of the concrete containing RCA was not significantly affected (Table 7). The durability

Table 9. Performance indexes durability index tests (Alexander et al, 1999).

Durability class	OPI (log scale)	Sorptivity (mm/$\sqrt{h}$)	Conductivity (mS/cm)
Excellent	>10	<6	<0.75
Good	9.5–10	6 – 10	0.75–1.5
Poor	9.0–9.5	10 – 15	1.5–2.5
Very Poor	<9.0	>15	>2.5

was assessed according to the performance indices in Table 9. The possible hydration of old cement in the adhered mortar could be the reason for the better performance in the RCA mixtures (Immelman, 2013). The difference between the results for the June concrete mixtures is due to the fact that the 7 and 28 day mixtures were cast from two separate concrete batches.

The hardened concrete properties were not significantly affected by the inclusion of RCA. The results from most of the hardened concrete tests produced no clear trend with the increase of percentage replacement (Immelman, 2013). Replacing NA with 100% RCA is possible based on the data presented in this investigation. This is based on concrete which utilises RCA with similar or better properties established in this investigation.

4 RECOMMENDATIONS

The incoming material should be visually inspected for any indications of large scale contamination. To assess the amount of foreign items or contaminants, a constituent composition analysis should be completed. The amount of constituents prescribed by the BS EN 12620:2008 and BS 8500-2:2006 should be used as limiting factors.

The material should meet the requirements for coarse natural aggregate as specified by SANS 1083:2006. The material should be graded in such a way that higher percentages of smaller particles are included in the material to improve packing capacity. Reducing the amount of foreign or weaker materials such as mortar or brick will improve the overall aggregate strength. It is recommended that RCA should be washed and graded. The RD will give a good indication of the amount of lower density materials in a sample of RCA. The RD according to this investigation should be limited to 2.6, but standards have allowed for lower RD values. The water absorption according to RILEM TC 121-DRG (1994) and JIS A 5021 Class H for high strength concrete should be limited to 3%. It is recommended that this limit be specified, as RCA with higher water absorption will possibly reduce the properties of fresh concrete and hardened concrete.

Finally, based on the current standard for aggregates in concrete for South Africa, RCA cannot be correctly specified. It is therefore recommended that the international standards and specifications should be consulted to accurately designate a particular RCA batch for the intended concrete class. According to the aggregate and concrete properties examined in this investigation, the full replacement of NA in structural concrete is possible and will improve the sustainable development of the construction industry.

Full-scale model of road structure

M. Varaus, P. Hyzl & D. Stehlik
Brno University of Technology, Institute of Road Structures, Czech Republic

ABSTRACT: The objective of the paper is to make the road technology specialists familiar with the programme and goals of the research project "Advanced reliable and durable civil engineering structures" that is solved by the Institute of Road Structures – Brno University of Technology in parallel with other departments of the Faculty of Civil Engineering. The programme is oriented on the development of full-scale model of flexible pavement structures. The full-scale model is constructed for the accelerated evaluation of the bearing capacity of road structures and the life time of the materials used for them. It can be used also for the testing of railway structures. The described model should help to shorten both the development and testing of new and recycled materials used for the above mentioned structures, and prove their long-term behaviour.

1 INTRODUCTION

The test equipment, also simply called the "stand", is being built on the premises of the Road Laboratory of the Institute of Road Structures – Brno University of Technology. It is intended for accelerated assessment of the bearing capacity and life of new materials and courses in the road structure or railway substructure. There is an assumption of shortened cycle of research and development of these materials in laboratory conditions, including assessment of their long-term behaviour in the structure of the road, possibly proving the benefits of the tested courses. At the first stage, the stand will be used primarily as a test mould for modelling and testing assemblies of non-rigid pavements, including simulations of different humidity levels in subgrades occurring under pavements in reality. As part of the prepared project of the Czech Technology Agency – CESTI Competence Centre, the test stand will be used primarily to determine the deformation characteristics of:

- Recycled bitumen without and with binders, both hydraulic and asphalt binders, including combinations of both binders;
- Recycled materials from pavements;
- Recycled building materials;
- Other secondary raw materials such as foundry sands and waste materials from quarries, etc.;
- Waste rubber materials.

The aim is to use the results to create a real database of design characteristics of materials for road building to be used in the design method.

2 SEQUENCE OF PREVIOUS WORKS

The works were divided into several partial stages outlined below:

2.1 *Preparing the study with test stand calculations and sizing, including the design*

This first stage involved the search for a suitable shape and optimum dimensions of the test stand in collaboration with the Institute of Structural Mechanics of Brno University of Technology using the ANSYS computer program. Following entering input parameters such as estimated load parameters (max. traffic load, dynamic traffic load action, estimated number of passes etc.) or properties of building materials to be used for construction, the above-mentioned computer program designed a stand from steel elements forming a cube with an edge length of 1.5 m and a damping lining around the vertical walls 15 mm thick.

2.2 *Preparing the project documentation*

The project documentation was prepared in collaboration with the Institute of Metal and Timber Structures, and the documentation was also used to prepare quotations for the tender.

First thoughts assumed embedding the test equipment under the ground floor level, but this plan was abandoned due to the high density of utility lines. It was decided in following discussion that the ultimate full-scale test equipment prototype would consist of two independent, separate stands (with shape described above). At the first stage, the test stands were

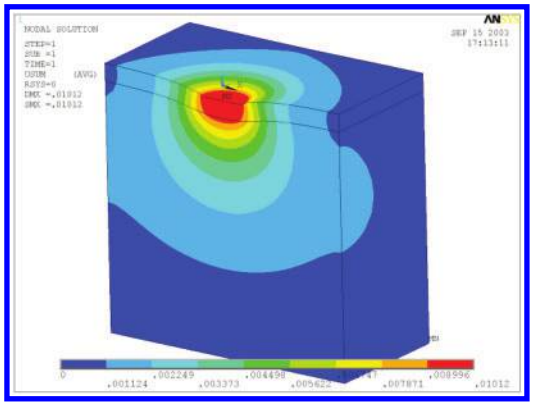

Figure 1. Computer simulation of the full-scale road model in the ANSYS environment.

supposed to be placed on the concrete floor 130 mm thick with aggregate bedding. Following computing the required loads with a maximum estimated load of up to 6000 kg, this method of foundation was abandoned, and a rigid steel damping grate was designed for the foundation of the dynamic full-scale test equipment. A stainless steel basin will always be located between the grate and the stand to simulate humidity modes in the model subgrade.

2.3 *Load unit acquisition*

In parallel with the manufacture of the test stand, a hydraulic dynamic load unit was purchased from the University Development Fund Project 2503/2008 in 2008. The load unit had the following configuration:

Linear drive AH 120-100
Control electronics EU 2000D-1
Hydraulic supply HU 40

2.4 *Manufacture of the stand*

Figure 2 below shows the 3D model of one assembled load stand (without lateral stepping grates) before surface treatment by hot-dip galvanizing.

2.5 *Transport and assembly*

A small 3-ton travelling crane and other handling equipment were used to handle the test samples and fixtures.

2.6 *Transport of soil for the subgrade*

Soil classified according to ČSN 73 6133 as clay with medium plasticity (F6 CI) was chosen for the subgrade of the pavement model being built. According to ČSN 73 6133, this soil is conditionally suitable for embankments and unsuitable for pavement subgrades. Large quantities of this soil can be taken from the Únanov u Znojma borrow pit. A total of 4 tons of soil were brought. The classification tests were performed in 2010. The test results are shown in Table 1.

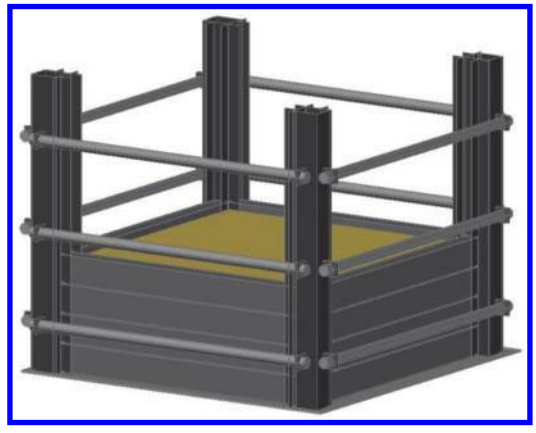

Figure 2. Computer 3D model of one load stand (without surface treatment).

Table 1. Classification tests of soil used for the subgrade under the test stand.

Grain size as per ČSN CEN ISO/TS 17892/4	
f (fine-grained particles)	82.4%
s (sand component)	17.2%
g (aggregate component)	0.4%

a) Plasticity as per ČSN CEN ISO/TS 17892/12: $w_L = 36\%$, $w_P = 20\%$, $I_P = 16$.
b) Compaction (standard Proctor test) as per ČSN EN 13286-2: $\rho_{d,max} = 1816\ kg/m^3$, $w_{opt} = 15\%$.
c) Immediate Bearing Index IBI as per ČSN EN 13286-47: 16%.
d) California Bearing Ratio CBR as per ČSN EN 13286-47: 10%.

Each compacted process layer of soil had 80 mm, and 2.0 kW, 60 kg Lumag vibrating plate was used for compaction. Compaction of the process layers compacted in the stand was tested by the direct method – by comparing the volume mass determined using cutting rings and a diaphragm stereometer and the maximum volume mass determined by the standard Proctor compaction test according to CSN EN 13286-2.

2.7 *Testing the performance and calibration of humidity sensors*

VIRRIB sensors are used to measure soil moisture by volume at any depth. The measuring sensor system is connected to the automatic measuring system capable of monitoring humidity with an accuracy of 0.1% at specific depth levels and specific intervals of time.

3 CONCLUSION

The pavement subgrade described in the paper is finished now, including the installation of measuring

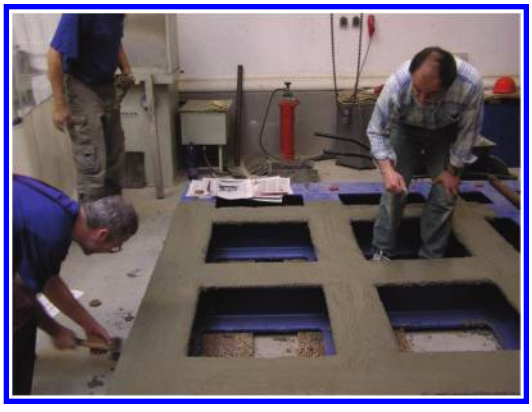

Figure 3. Preparatory work before placing the stainless steel basin on the grate.

Figure 4. Placing the stainless basin.

Figure 5. The layout after the first process layer compaction.

Figure 6. VIRRIB humidity sensors and their calibration.

Figure 8. Real location in the third process layer.

sensors. The building material for the pavement structure is being prepared. Also the design of layers for the test stand follows the system of pavement structures most frequently designed in the CR. Crushed-run rock ($ŠD_B$) of 0/31.5 fraction, 150 mm thick will be used

for the bottom base course. During measurements, this layer will be regularly replaced with unbound recycled concrete layer of the same thickness. The upper base course is designed to be from mechanically bound aggregate (MZK) 150 mm thick. The following materials were designed for the upper courses:

a) Asphalt concrete AC 16; and
b) Wearing course will probably contain SMA 11 with Crumb Rubber-modified Bitumen (CRmB).

The first real measurement on the finished full-scale model of the designed pavement is expected to take place in 2013. The series of verification measurements of the road structure will be followed by the design and assessment of pavements with bound and unbound recycled materials.

ACKNOWLEDGEMENTS

This paper has been prepared with the support of Research Projects MSM 0021630519 "Progressive reliable and durable load bearing structures", TA02030639 "Durable acoustic asphalt pavement courses with utilization of bituminous binders modified by rubber microfiller including innovative technology of rubber milling" and TA02030549 "The most effective utilization of reclaimed asphalt pavement layers for production of new asphalt mixes".

Monitoring of experimental sections with recycled waste materials

D. Stehlik, M. Varaus & P. Hyzl
Brno University of Technology, Faculty of Civil Engineering, Institute of Roads Structures, Czech Republic

ABSTRACT: The full-scale test polygon is constructed as a classical road structure with the length of 225 m. There are seven test subsections with different road structures. The base courses are constructed from hydraulically bound recycled construction materials. The test polygon will be loaded by approximately 100–200 heavy lorries in 24 hours. The bearing capacity of the test sections is periodically controlled by the falling weight deflectometer. The values of the moduli of deformation are compared in one year period. This full-scale testing is the main part of the research project for intensive use of the recycled construction materials for road structures.

1 INTRODUCTION

Base courses are an important part of the road structure, and their design and construction should not be underestimated. Correct functioning of the bound layer depends primarily on the adequate design of type and quantity of hydraulic binder as well as compliance with the technological process during placing, compaction and treating these courses. In terms of placement technology, it is very important to perform a sort of fragmenting the bound layer using vibrating rollers in the transition period between setting and hardening of the compacted bound mixtures (1 to 3 days after placement) in order to eliminate contracting forces that occur during hydration. In terms of the mixture design, also materials that do not have standard grain size of normal unbound mixtures can be used in these mixture types for base courses. Such mixtures can be produced from materials, the non-processed form of which can be classified as soil with a significant content of aggregate or sand particles. These properties are typical of recycled waste prepared from demolition waste or old road material. The current trend of monitoring recycled construction material properties while reducing input investments in construction engineering shows that the use of recycled waste in bound mixtures for base courses is one option of application in semi-rigid and rigid pavement construction. Of course, properties of these bound mixtures with recycled waste have to be verified. A major part of preliminary tests of these mixtures were done in the first year of the Czech Technology Agency's research project titled TA 01020333 Recyklované stavební materiály v konstrukcích dopravních staveb (Recycled Waste Building Materials in Road Construction). An experimental section of road with different bound base course types is currently under real traffic load. This applied research included the design of 7 road structures for the test polygon constructed as an access road to the recycling line of DUFONEV, R.C., a.s.

2 DESIGNS OF MIXTURES BOUND WITH HYDRAULIC BINDER USING RECYCLED WASTE

The design of bound mixtures using recycled waste was based on the assumption that the most frequently used components will be used to make the use of satisfactory mixtures in practice as simple as possible. All of the 6 designed bound mixtures are based on 0/31.5 fraction. This maximum grain size was chosen as it is most frequently used for base courses. Recycled waste type is another input parameter. Following preliminary laboratory tests and based on foreign experience, recycled concrete was chosen for this mixture type. Some bound mixtures are an experiment, for which a mix of recycled waste from pavements and demolition waste is considered due to the local lack of recycled waste from bitumen pavements. In this research task, this is tested on one experimental subsection with bound mixture of recycled concrete and recycled bitumen in the ratio of 3:1.

The performance test of modulus of elasticity Er as described in ČSN EN 13286-7 was performed on each designed mixture in addition to regular preliminary grading test, compaction test, simple compressive strength test, splitting tensile strength test, freeze-thaw test and wet-dry test (see Table 1 and 2). This European standard is not intended for regular testing of bound mixtures. Among other things, this is due to the "bouncing" of the dynamically loaded thrust during deformation testing and measurement, in particular for bound mixtures with design strengths over 10 MPa, which results in about 15% bias of cyclic deformation readings. This fact forces to average the measured

3 DESIGNS OF ROAD STRUCTURES USING RECYCLED WASTE

Seven road structures were designed for the test polygon based on preliminary tests of bound mixtures with recycled waste. These structures were designed using the LAYEPS computer design program. The main objective of the design involved specific applications of the designed and proven structures in practical use. That is why hydraulically bound structural base courses were designed for some subsections; one base course comprised grouted cement macadam and the other base courses were unbound. Table 3 shows an overview of road structures designed for the Cernovice test polygon. The same bituminous concrete pavement placed in two layers was used for the entire test polygon road section.

4 BUILDING THE TEST POLYGON

The old unpaved access road, the subgrade of which consists of different recycled waste types,

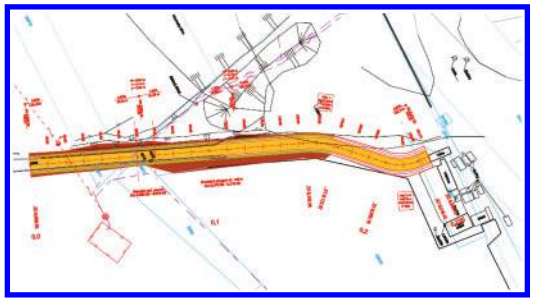

Figure 2. Layout of the test polygon with pavement using recycled waste for bound base courses.

Figure 3. Roadbed preparation before base course placement.

Figure 4. On-site preparation of bound mixtures with recycled material placement .

paradoxically had to be ripped due to its high bearing capacity, and mixed recycled material had to be added to reach a resulting compaction rate under $E_{def,2} = 100$ MPa as determined indirectly by static loading test.

5 MONITORING THE TEST POLYGON

Continuous monitoring of the bearing capacity is part of the test polygon construction where recycled waste is used for unbound base courses of the road. The monitoring benefits from the accurately known quantity

Figure 5. Compaction of bound mixtures with recycled material placement using vibratory rollers.

Figure 6. Subsequently two bituminous concrete layers were placed.

and structure of traffic load by heavy goods vehicles (HGVs) going on the test profile directly to the recycling line scales taking an accurate record of each vehicle's load and character. A daily average of 130 HGVs goes on the monitored road at present with up to 200 HGVs at peak hours and in high season. Bearing capacity will be measured continually by FWD impact test twice a year in the same climatic conditions. The first measurement was made in mid October 2012 and further measurements will be at six-month intervals.

5.1 *Road bearing capacity measurement*

Pavement load bearing capacity is the ability of a road's structure and subgrade to transfer traffic load. Each structural layer's bearing capacity can be measured using static or dynamic test equipment. Falling Weight Deflectometers (FWDs) are regularly used for load bearing capacity testing at present.

The principle of the non-destructive method consists in measuring and evaluating the response (deflection) of the pavement to the impact of a weight with a known mass on a round plate through a damping system from such height that the dynamic impact corresponds approximately to the effect of a crossing of a design HGV wheel axle. This dynamic impact is recorded by a force sensor and a set of deflection

Figure 7. The first load bearing capacity measurement on Brno-Cernovice experimental polygon sections.

sensors located at specific distances from the load centre on the pavement surface. The response of the pavement to the load is expressed by the measured deflection line determined as a pavement surface sag (deflection values) under the defined load depending on physical and mechanical properties of the environment, impulse magnitude and distance from the test point (load centre). The measurement is made using precision geophones (deflection acceleration sensors). Measurement evaluation is based on deflection line calculation along the laminated linear elastic half-space. The comparison of the computed and measured deflection line is used to determine the moduli of elasticity of each pavement layer by reverse calculation at each test point to compute bearing capacity, residual life and/or required pavement reinforcement. The impact load test using the FWD (Figure 7) was performed by PavEx Consulting, s. r. o. on the wearing course consisting of bituminous concrete (ACO 11).

The measurement was performed in the middle of each lane, in each of the seven sections in four measurements. Air temperature and pavement surface temperature were recorded during the research. The test was performed at a standard load of 50 kN and a load of 80 kN. The selected load was transmitted to the 300-mm diameter load plate through a damping system. Contact pressure was 0.707 MPa. Deflection sensors Y1 to Y9 were placed in recommended standard positions for non-rigid pavement testing as stated in Czech standard CSN 73 6192.

Distances of the sensors from the centre of the load plate were 0, 200, 300, 600, 900, 1200, 1500, 1800 to 2100 mm.

5.2 *Results of the first bearing capacity measurement using the FWD method*

Given the climatic conditions, the first measurement was made in autumn, when pavements and pavement subgrades in particular are subject to marked changes such as changes of bearing capacity. There is no risk of big changes to the pavement subgrade's water content and temperature in the test polygon. Therefore, the monitoring using the described FWD method focuses primarily on the test polygon pavement courses. The diagram in Figure 8 shows how the computed moduli of elasticity change depending on the spacing on each experimental subsection of the test polygon.

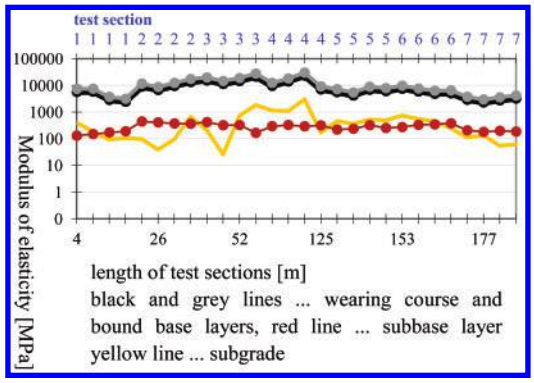

Figure 8. The result of the FWD dynamic impact test is the calculation of moduli of elasticity from measured deflection lines.

Following the evaluation of measured and computed deflections and moduli of elasticity determined by the FWD, the condition of each experimental subsection of the polygon pavement at the beginning of life was assessed (Table 4). There is a comparison of initial results of the non-destructive dynamic impact FWD test (Table 4) with design moduli of elasticity specified in technical conditions for the design of TP 170 road structures (Table 5).

Statistical evaluation of the monitored development of the modulus of elasticity of each structural course of the polygon is important to assess the designed road structures using recycled waste. As mentioned above, regular monitoring will be performed at six-month intervals, in spring and autumn.

Test cores will be made in 2013 to monitor additional properties of each compacted pavement course in the test subsections of the polygon. The time lag for the test cores was approved by all project investigators at one team meeting to discuss the project work progress in 2012.

Individual course segments will be separated from these cores. Properties characterizing materials used for the compacted bound mixtures will be consequently found by empirical and performance tests according to the plan for Project Stage 003 subgoal.

5.3 *Results of the first bearing capacity measurement using the FWD method*

Given the climatic conditions, the first measurement was made in autumn, when pavements and pavement subgrades in particular are subject to marked changes such as changes of bearing capacity. There is no risk of big changes to the pavement subgrade's water content and temperature in the test polygon. Therefore, the monitoring using the described FWD method focuses primarily on the test polygon pavement courses. The diagram in Figure 11 shows how the computed moduli of elasticity change depending on the spacing on each experimental subsection of the test polygon. Following the evaluation of measured and computed deflections and moduli of elasticity determined by the FWD, the

6 CONCLUSION

In the Czech Republic, a small country in the middle of Europe, regular and effective use of recycled waste for road pavement structures is very difficult to enforce. The quality of manufactured recycled materials has seen a marked improvement over the last 5 years, especially in established and known recycling lines. However, a more extensive use of recycled concrete in particular still faces legislative issues dictated by the state-owned investor of road construction. The aim of this paper was to present the potential of recycled waste used for bound course technologies, including the long awaited experimental section of pavement where these mixtures are used for base courses. The use of recycled waste in bound mixtures for base courses in the CR appears to be very advantageous in terms of required parameters of the final designed mixture of recycled material and binder. Properties of the final bound mixture are assessed according to EN standards applicable in the CR, which greatly facilitates the use of recycled materials, which have, in some cases, problems with grain size homogeneity and absorption capacity.

There is considerable potential for the use of recycled materials in the CR, particularly in the following areas:

- Homogeneous recycled aggregate production, primarily from recycled concrete;
- Use of bound mixture technology, primarily for road structures or other traffic areas with stationary traffic load or slow traffic;
- Use of dumps of old waste products for recycled material production;
- More specifically, setting realistic criteria of frost resistance for bound mixtures from recycled concrete.

Experience with experimental designs and performance assessment of cold asphalt mixtures – New type of pavement structure in the Czech Republic

J. Suda, J. Valentin, J. Žák, J. Šedina & K. Miláčková
Czech Technical University in Prague, Faculty of Civil Engineering, Department of Road Structures

ABSTRACT: Presently there is a definite focus in road construction on technologies, which allow reducing energy demand during manufacturing and realization of pavement structures and equally minimizing cost severity of new structures within the development of road infrastructure. Stated presumptions try to make provision for techniques of cold asphalt mixtures based on bituminous emulsion applications. Generally cold asphalt mix is a composite material containing crushed natural aggregates and sand with corresponding grading and slow-setting cationic emulsion, which is produced and can be applied in normal atmospheric temperature. In comparison with traditional hot mix asphalts there is no requirement for heating some of the mix components. In the Czech Republic the technology of cold asphalt mixes laid by normal pavers is not presently used, therefore insufficient laboratory and practical experience and data are available. As a starting point experience and vast sets of data about cold recycling mixes can be used. Because of the absence of valid technical specifications and so far not approved preliminary specification prepared within the tasks of Ministry of Transportation French experience, valid standards and validated procedures have been used. Within the experimental activity done at the Czech Technical University selected physical and mechanical properties as well as performance-based characteristics (stiffness, resistance against permanent deformations or fatigue) are presented. At the same time the most suitable compaction method for test specimen preparation was assessed as well. So far gained results and experience are presented in this paper. The objective is to extend and specify more precisely technical parameters and their requirements in the national technical specifications.

1 INTRODUCTION

There is currently no "generally accepted" design method for cold asphalt mixes. Findings of the American approach formulated in the so-called Cold Mix Design Manual or national technical regulations used in France can be used. Besides, with respect to the lack of unified laboratory methods and assessment thereof, particularly in the early curing stage, it is difficult to find reliable correlations between the results of experiments described in the sources by various specialists and expert teams. This paper focuses on defining the composition of a cold asphalt mix produced under laboratory conditions and on the relationships between physical and mechanical properties, workability and functional characteristics of experimental design mixes and test specimens prepared in the laboratory.

2 MATERIALS USED

The preparation of CMAC 11 (Cold Mix Asphalt Concrete) used aggregate from the Libodrice quarry. This is a basic rock (amphibolite) which was formed by metamorphosis of igneous rocks, primarily basalt and andesite. The main elements are amphiboles and plagioclase. The most appropriate use is primarily in road construction; the site is a traditional quarry producing good-quality crushed aggregate with the characteristics as indicated below (Table 1). Cationactive, medium-setting bituminous emulsion, Katebit C60B6, which is used in cold recycling mixes as a standard, was used as the bituminous binder. The reason behind the choice of this emulsion was the fact that in CR, it is currently impossible to prepare a suitable bituminous emulsion adjusted to this type of mixes flexibly for laboratory purposes. The same type of bituminous emulsion prepared in France using a suitable emulsifier (0.7% wt. Indulin GE7) and bituminous binder AZALT 70/100 were used. Hydraulic binder used in cold asphalt mixes is Portland slag cement CEM II/B – S 32.5R and an active micro-filler know as Dastit®. Dastit is a mechanically activated fluid ash characterized by pozzolan properties which is modified by high-speed grinding in a disintegrator; the grinding increases the specific surface and significantly increases reactiveness of the material (Valentin 2012).

Table 1. Characteristics of the Amfibolit aggregate- 0/11.

3 COLD ASPHALT MIX – LAB DESIGN

In connection to the current non-existence of technical specifications for the design, implementation and control of cold asphalt mixes the mix design per se was carried out based on the French experience and methods with a modification of applying the existing national technical regulations for hot asphalt mixes as much as possible. At the same time, repetitive consultations with the MeadWestVaco European research centre took place.

The design of a suitable aggregate skeleton was made according to the methodology for asphalt concrete (ČSN EN 13108-1) which corresponds with the French methodology indicated in the technical national standard (NF P98-139). Using another grading curve does not achieve optimum results; the mixes primarily demonstrate higher void contents. The density of the aggregate and absorbing capacity for individual fractions are given in Table 1. However, it must be pointed out that not every aggregate is suitable for cold mixes; primarily the shape index and grading of the finer fractions must be watched since in this type of mixes, these are rather critical parameters. The proposed mix grading curve is given below (Figure 1). The aforementioned grain sizes are intentionally more stringent, the grading curve may vary from the aforementioned grading limits.

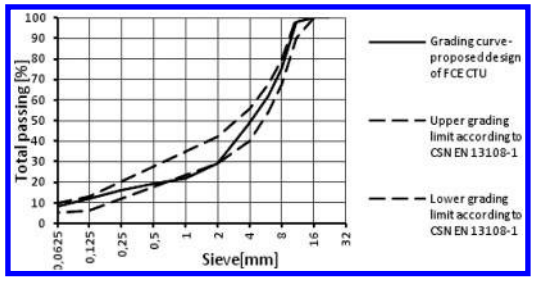

Figure 1. Grading curve of the proposed aggregate.

Table 2. Developed cold asphalt mix design.

Mix	Saturation coefficient K [−]	Emulsion content [%]	Residual bitumen content [kg/100 kg]	Cement [%]	Dastit [%]
1. E_{CZ} a/b	3.4	8.51	5.08	–	–
2. E_{CZ}	3.67	9.46	5.47	–	–
3. E_{Fr}	3.67	9.46	5.47	–	–
4. E_{CZ} DAS	3.67	9.46	5.47	–	5.0
5. E_{CZ} CEM	3.67	9.46	5.47	2.0	–

The theoretical optimal quantity of bituminous emulsion was determined using the calculation methodology according to the saturation coefficient which is applied in the French regulations, too (NF P 98-139). Hot asphalt mixes for wearing courses apply the saturation coefficient of 3.4 while other layers use the coefficient of 3.1. In the case of cold mixes, the calculation of the theoretical quantity of bituminous emulsion increases to a value exceeding 3.6 (for all layers). The saturation coefficient corresponds with the results according to (Suda 2012); however, contradictory trends affecting the optimum quantity of residual bitumen in the mix must be mentioned, particularly from the point of view of permanent deformation and thermal susceptibility against strength and deformation parameters along with the water susceptibility of cold asphalt mixes; the parameters must be in balance.

The ability of the emulsion to coat aggregate usually depends on the moisture of the aggregate during coating. Inappropriate (low) moisture causes the bitumen emulsion and fine aggregate particles to start forming clumps and the aggregate fraction is not coated sufficiently. In general, the minimum coating of the aggregate surface by the binder is stated at 50%. However, the value should be raised to 90% surface coating, particularly due to the susceptibility of the mix to water (Suda 2012). From the point of view of suitable moisture of a cold asphalt mix, two methods can be applied: determination of optimum moisture by the modified Proctor standard test according to (ČSN EN 13286-2). This method should be chosen if the emulsion and aggregate are not significantly affected by changes in the moisture. If the aggregate coating by bituminous emulsion is affected by moisture, the method of determining binder adhesion to the aggregate, the so-called "coating test" will be used. Within the framework of verifying the properties of cold asphalt mixes, five cold asphalt mixes have been designed with the compositions as indicated below (Table 2).

The individual experimentally designed mixes differ by the quantity and origins of the bituminous emulsion used. The effect of cement and mechanically

activated fluid ash, considering the full or partial filler substitution, on the cold asphalt mix properties constitute another option of extending the use of cold mixes in road construction practice.

4 EXPERIMENTAL VERIFICATION OF COLD ASPHALT MIXES

Different compaction method can be used. Some reports mention use of impact compactor (Thanaya 2009) or a hydraulic press. However, according to (Suda 2012) these methods cannot meet the requirements for cold mix void content as listed below. With respect to the lacking uniformity of the design and test methods the compaction was performed by a gyrator (SUPERPAVE Gyratory Compactor Troxler 4140), which, according to the French methods, better simulates the compaction achieved during paving. The method is preferred despite the fact that there is only one such apparatus available in CR at present. From the methods used in France, the void content reached during paving corresponds with the compaction reached by the gyrator under 60 revolutions and 600 kPa pressure. The French methodology also prescribes the number of revolutions of the gyrator depending on layer thickness and mix type regardless of the traffic load. The 60 revolutions applied on the gyrator correspond with the layer thickness of 5–10 cm (Burán 2007). Within the framework of laboratory design of cold asphalt mixes, void content under 60 revolutions on the gyrator must range within 5–12 %-vol. and, at the same time, under 10 revolutions the void content must be >12% in accordance with the requirements of the French standard (XP P98-121); the value represents the qualitative parameter of compactability during paving. Compacting by gyrator using 200 revolutions and axial pressure of 600 kPa corresponds with the value of maximum compaction of a cold asphalt mix for layers under traffic operation. It is generally assumed that a cold mix reaches full consolidation in 2–24 months from paving (Thanaya 2009). The void contents of individual mixes are indicated below in Table 3.

The determination of the basic strength parameters of a mix involves the indirect tensile strength test (ITS test) depending on different conditions (air-water) and curing time, 7, 14, 28 days (Table 4). The curing itself could range from 2 to 24 months depending on the weather conditions (Thanaya 2007). The specimens examined cured under 18°C and under 30°C in the laboratory conditions. This paper examines cold asphalt mixes primarily at the early stages of curing.

Table 4. Determination of the ITS and water susceptibility.

	Indirect tensile strength @ 15°C – curing under 18°C/30°C					
	7 air	14 air	7 air + 7w.	28 air	ITSR	Decrease of ITS
Mix	[MPa]				[–]	[–]
1. a/b E_{CZ}	0.61	1.00	0.52	1.18 / 2.34	51.5	85.2
2. E_{CZ}	0.72	1.09	0.67	1.43	61.5	93.1
3. E_{Fr}	0.75	1.07	0.62	1.23	57.9	82.7
4. E_{CZ} DAS	0.92	1.11	0.78	1.32	70.3	84.8
5. E_{CZ} CEM	0.87	0.96	0.54	1.04	56.3	62.1

Table 5. Basic deformation parameters of the mix.

	Stiffness modulus @ 15°C (MPa) – curing under 18°C/30°C					
Mix	7 air [MPa]	14 air [MPa]	7 air + 7 water [MPa]	28 air [MPa]	Decrease of stiffness (ITMR) [–]	Thermal susceptibility [–]
1a/b. E_{CZ}	2100/ 3800	3200/ 5700	1400	3100/ 7800	44.3	13.1/8.3
2. E_{CZ}	1900	3200	2500	4300	78.1	7.5
3. E_{Fr}	2000	3200	2700	4100	84.3	8.1
4. E_{CZ} DAS	5500	7100	6700	8700	94.4	2.6
5. E_{CZ} CEM	4100	4400	3400	4200	77.4	5.1

The basic deformation parameters (Table 5) are characterized by the stiffness modulus which was defined depending on the different conditions and curing times. Also the indicators of modulus decrease after immersion in water and thermal susceptibility were determined. The stiffness moduli were determined for cylindrical specimens by cyclic tensile stress (IT-CY) according to (EN 12697-26) applying the method of controlled deformation of 3 μm and load impact of 125 ms under 5, 15, 27°C.

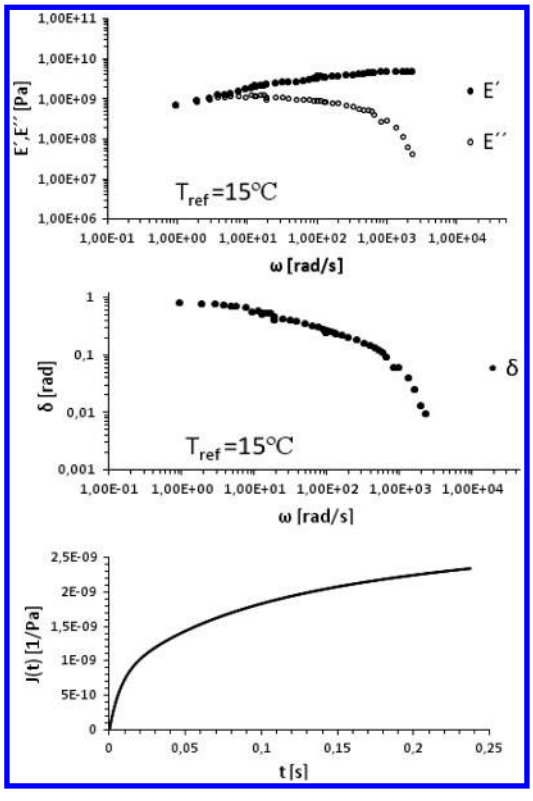

Figure 2. Linear viscoelastic parameters of the cold asphalt mix 2.ECZ examined.

As can be concluded from the results above, the difference between mixes with different bituminous emulsions is not too obvious. A higher quantity of residual bitumen in the mix improves the strength and deformation parameters of the mixes researched. Also from the point of view of using loose binders in cold mixes, the strength and deformation parameters improved in all regards, particularly in the case of Dastit. Another important property with respect to the viability of cold mixes in the wearing course of a pavement is water resistance which is determined by three methods, or ITS ratio under (TP 208), modified method under (ČSN EN 12697-12) and the stiffness modulus decrease coefficient respectively. In cold asphalt mixes, the thermal sensitivity is a rather essential quality parameter which is affected by the type of emulsion and bitumen used.

Cold asphalt mixes are a multi-stage system with many components some of which have a complicated inner structure with a high thermal sensitivity. They are basically components of irregular aggregate grains with a slightly higher binder content and small proportion of volume taken by air voids. Despite the complex structure, the material behaviour can be described by applying the viscoelasticity theory (Collop 1995; Ferry 1980; Tschoegl 1989; Underwood 2011; Zou 2010). One of the linear viscoelastic parameters is the complex modulus. Dynamic complex moduli were

Table 6. Permanent deformation parameters.

Mix	1a. E_{CZ}	2. E_{CZ}	3. E_{Fr}

PRD $_{AIR}$ [%]	21.2	Ndef	Ndef

measured by the 4PB-PR method according to (ČSN EN 12697-26) within the temperature range of −20 to +27°C and frequency of 0.1 to 40 Hz. Master curves were generated by means of the time and temperature superposition method by a shift in both the horizontal and vertical plane to obtain the thermal dependencies of rheological behaviour of the material and extend the time frequency scope under the relevant temperature. The Wiliams-Landel-Ferry equation with parameters $C_1 = 100.00$, $C_2 = 2156.44$ K was used to describe the shift in the horizontal plane; a polynomial with parameters $a_0 = 1.524$, $a_1 = 1.302$E-01, $a_2 = 2.928$E-03 was used to describe the shift in the vertical plane (Ferry 1980; Dealy and Wissbrun 1999).

If we look at the master curves from right to left it is obvious that under the lowest temperatures and highest frequencies tested, the material tends to behave as almost elastic. The conversion from viscoelastic to elastic behaviour is visible in the last six values measured on the decreasing imaginary part of the master curve. With the increasing frequency the real part of the master curve grows gradually; its derivation gradually falls and the last values almost reach 0. The phenomenon correlates with the conversion of the material properties to the elastic part and with reaching the module equilibrium. (Ferry 1980; Kim 2008). The phase angle increases very fast and reaches temperatures from 0.5°C to 45°C within three values measured. Therefore, the phase angle change shows that cold asphalt mixes are highly thermally and mechanically sensitive materials (Tschoegl 1989) in comparison to hot asphalt mixes. The malleability function shown (Figure 2) is calculated by non-linear regression of the master curves with a Maxwell model of four elements (Žák 2012; Baumgaertel 1989). With respect to the reference temperature of 15°C and the narrow range of temperatures measured, it is only represented up to 0.25 s.

From the point of view of permanent deformations, the test of wheel tracking on a small test device at 50°C in air bath under (ČSN EN 2697-22 + A1) was taken. The test specimen was loaded by 10,000 wheel cycles with the frequency of 0.44 Hz. Test boards using different quantities and types of bituminous emulsion were used. The results achieved are not too reproducible (Table 6), because there were significant deformations and damage to the test specimens. The next stage should be a discussion on whether the test conditions reflect the actual conditions of use within the life of the pavement construction if cold asphalt mixes are applied, or whether there is any other factor at play. This fact is not restrict the use of such mixes in road

construction as, according to the findings from France where e.g. testing for mix resistance to permanent deformation which usually yielded poor laboratory results never corresponded with the reality in the road. Cold mixes have always behaved better in-situ during the entire life.

5 CONCLUSION

This paper deals with experimental design and examination of selected parameters of cold asphalt mixes. Cold asphalt mixes (coated under the temperature of the ambient environment, at least 10°C though) are mixes of wet fractions of aggregate and bituminous emulsion which demonstrate changes in their properties during bituminous emulsion breakdown (Choudhary 2011). Based on the results achieved, we can conclude that under the assumption of correct mix design and subsequent processing, albeit with respect to their negative properties, cold asphalt mixes are appropriate primarily for roads with lower level of traffic or pedestrian/cyclist tracks. Negative properties are understood as considerable thermal susceptibility which might result in higher risk of defects in the pavement; however, it must be mentioned that the monitoring of defects in roads in France verify the sufficient performance quality and low rate of defects in the roads monitored after the application of the technology. In the mix design stage, attention should be paid to the choice of materials. The aggregate must meet the requirements of grading and durability. The right choice of bituminous emulsion type is determining for the life of the entire layer. Another important factor in processing is the moisture of the aggregate which allows good-quality coating of the individual grains by bituminous binder and the necessary compaction. The properties of cold asphalt mixes can be further adjusted by adding appropriate additives like cement or mechanically activated fluid ash.

Knowledge sharing and constructability in structural design

V. Kuo & J. Wium
Stellenbosch University, Stellenbosch, South Africa

ABSTRACT: It is well known that close collaboration between structural designers and contractors may lead to more effective construction processes, economic structural solutions and improved safety. However, traditional procurement standards, do not allow sufficient collaboration between these parties at early stages of design. For these reasons it is imperative that the structural designer has sufficient experience and knowledge of construction processes to produce suitably constructible designs. This paper aims to address the topic of constructability in structural design and demonstrates how structural knowledge sharing between contractors and designers is a pertinent approach to reducing constructability problems. The principle conclusions are that designers do not always understand what constitutes a constructible design. Furthermore, although there is a vast field of knowledge required, some guiding principles can be formulated. In addition, considering the unique characteristics of each project, these guiding principles should be supported by initiatives to facilitate structured forums of knowledge sharing between different parties to develop and transfer constructability knowledge that would also assist to accelerate the process towards becoming an accomplished designer.

1 INTRODUCTION

In the 1980s, the term "constructability" evolved in the USA. The proponents of this concept believe that constructability, which embraces both design and management functions, is comprehensive in facilitating construction operations and solving problems on site. In particular, the Construction Industry Institute (CII) was instrumental in providing guidelines for implementing constructability at various project stages (CII, 1986; 1987a, b; 1993). Constructability can be defined by "the optimum use of construction knowledge and experience in planning, design, procurement, and field operations to achieve overall project objectives" (CII, 1986), or simply "the extent to which the design of a building facilitates ease of construction", as is intuitively interpreted.

Constructability problems cause dire repercussions in the construction industry, and mainly arise due to poor embodiment of construction know-how in the design of the project. Gambatese et al. (2007) described the barriers to addressing constructability as the lack of construction experience in the design team and the absence of tools to assist designers in addressing constructability. The prevalent procurement methods of building construction projects, such as design-bid-build, hinder the application of constructability concepts in design. This is problematic mainly during early project phases, in which constructability application is particularly desirable (Pocock et al., 2006; Song et al., 2009).

The scope of this research is within the South African building industry, as most civil engineering organizations would have had substantial experience in building projects, where constructability issues are prevalent. Needless to say, constructability expertise and knowledge is primarily retained by contractors with substantial experience in the project execution phase. However, this know-how remains in a tacit, non-codified form within the minds of the professionals. The extraction of constructability expertise and related problems from the minds of the industry thus forms the basis of this study. The primary methodology employed is a combination of questionnaire surveys and personal correspondences.

To address the constructability issues, while accepting the conventional procurement standards, this paper investigates the nature of constructability knowledge (in both tacit and explicit forms) and how it can be captured and shared, especially between design and construction disciplines. The way knowledge is shared in the industry forms the basis by which constructability expertise can be disseminated, which is investigated in detail in this study. Furthermore, examples of real constructability problems in the industry are obtained and analyzed to reach accurate and realistic principal deductions.

2 BACKGROUND

2.1 *Constructability knowledge*

Despite various definitions and classifications of knowledge, work by Polanyi (1958), Nonaka and Takeuchi (1995) divided knowledge into tacit and explicit. Tacit knowledge represents knowledge based on the experience of individuals, expressed in human actions in the form of evaluation, attitudes, points of

view, commitments and motivation (Nonaka et al., 2000). Explicit knowledge, in contrast, is codified knowledge inherent in non-human storehouses including organizational manuals, documents and databases.

Naturally, the greater part of constructability knowledge exists in a non-codified, tacit form, as opposed to deterministic design knowledge, which is arguably much easier to articulate and document, hence enabling the compilation of numerous design codes and guidelines. Yet, there is no comprehensive code, as design aid for consultants, to ensure good constructability.

Explicit constructability knowledge may exist in project archives, where constructability related problems would have been extracted during and after the project. Project archiving is a common method to capture project lessons learnt and thus pertinent for the capturing of constructability knowledge. Whether or not project archives offer serviceable constructability knowledge is investigated in detail in this study. This would indicate if enough usable knowledge from existing project archives can be used to derive constructability guidelines.

2.2 *Knowledge sharing*

Foy (1999) defines the concept as "facilitating learning, through sharing, into usable ideas, products and processes." This definition implies that there is a specific purpose behind knowledge sharing, and "learning" is an artifact from the knowledge sharing process. According to Hickins (2000) knowledge sharing is about capturing the tacit knowledge locked in people's heads.

McDermott and O'Dell (2001) find that organizational culture is more important to knowledge sharing than the approach or commitment to knowledge management. They highlight the importance of using tools and structures for knowledge sharing that are consistent with the overall style of the organization, and building reward and recognition systems that support knowledge sharing.

Irrespective of whether or not constructability knowledge can be codified, sharing of the knowledge still remains a great challenge not only due to the technical, but also the social aspects of organizational culture. Constructability knowledge, be it in tacit or explicit form, needs to be shared to yield some perceivable positive effect.

To find a knowledge sharing approach fit for improving constructability, it is important to understand the extent and modes of knowledge sharing in consulting and contracting companies. The sharing of not only explicit knowledge, but also the sharing of tacit knowledge is investigated in this paper.

3 METHODOLOGY

3.1 *Questionnaire surveys and investigations*

For this research, the questionnaire survey was primarily used to extract tacit knowledge on constructability from experienced South African industry practitioners. The investigations were done in three parts, which are discussed in detail in the following sections: 1) Explicit constructability knowledge; 2) Knowledge sharing; and 3) Tacit constructability issues in practice. The rationale, results and analyses for each part is presented accordingly.

It is worthy to note that the interpretation of all the results, arising from qualitative and quantitative analyses in the investigations, was done with reasonable degree of tolerance. It is appreciated that the groups of respondents involved in the study may or may not be representative of the industry at large. The research takes care to consider all the limitations implicit in the research principles and questionnaire processes. Furthermore, it has not been the intention to focus particularly on a large scale statistical or quantitative analysis of survey results. Rather, it was of greater significance to reach insightful practitioners to provide relevant and meaningful responses; hence the seemingly small number of respondents that participated. However, the opinions of the practitioners offer valuable experience, the credibility of which should not be ignored.

4 PART I SURVEY: EXPLICIT CONSTRUCTABILITY KNOWLEDGE

This *preliminary investigation* was done to establish the extent that documentable, explicit information in typical project archives can be used to derive constructability guidelines. Survey respondents of this investigation consist of 11 South African industry professionals with an average of 15 years of experience. They hold positions as: project manager, engineer, site agent and director; in the buildings, bridges, roads and civil disciplines. The investigation on project archives is generic and is not limited to a specific discipline. Thus, respondents from a few disciplines are involved here, not exclusive to Buildings. The main questions posed in the Part I Survey are:

- What are the typical contents/documentations of a project archive?
- Are project archive contents seen to be insufficient or lacking in some way?
- If so, what are current project archives lacking?

4.1 *Contents of project archives*

The respondents were first asked to provide a list of currently available items in their project archives at his/her organization. All the responses were combined and rudimentarily categorized, to compile a list of typical items of project archives as shown in Table 1. The items shown are not analyzed in terms of frequency of occurrence between all the respondents, as it would not be sensible to make such deductions from the small group of respondents. However, a good idea of the constituents of a project archive – or what information

Table 1. Categories and items of project archives.

Categories	Items in project archives

Site Records	Site instructions Health and safety records Accident records Training records
Correspondences	Contractual information flow Letters and emails Minutes of meetings Variation orders All project related correspondences between key project participants

a good project archive should include – is generated here.

4.2 *Need for additional items to be captured*

The respondents were then asked whether the capturing of more items, additional to what is currently available, is desirable and why. Out of 11 respondents, 9 desired additional items to be captured. Due to the small number of respondents, this number is not of particular importance; rather, the reasons/motivations provided are worthy of note.

Some conclusions can be made from the motivations given. There is an evident need for the capture of items in addition to what is currently available in the archives. The responses show a problem with the knowledge capturing itself. Moreover, the incentive for personnel to access the knowledge also poses a challenge. Lack of motivation by user to extract knowledge is attributed to the fact that the documented material is not properly organized into sensible packages to be stored. This results in excessive effort and time required by the user, to obtain the relevant applicable knowledge. Information available is regarded more as raw "historical data" rather than synthesized knowledge or lessons. Furthermore, lots of information gets lost before it gets captured. This indicates that information waste is still common and that there is no adequate system to record usable, accessible project lessons or knowledge efficiently.

4.3 *Additional items to capture*

Respondents who wanted additional items to be captured were asked to list these items and explain what benefits they can pose to the organization or future projects. All the responses were combined and briefly categorized to compile a list of additional items to capture. Due to the excessive number of items obtained, the list will not be presented here. Only the broader categories are shown, which gives an idea of the type of desirable items that are currently lacking in project archives.

- Risk related information and reports
- Planned vs. actual information
- Change related information and reports
- Lessons learnt information

The additional items listed are not mere data, but are rather meaningful project lessons, which require some synthesis to obtain. Processes must thus be introduced to promote the capturing and synthesis of such knowledge/lessons, which can be structurally stored and thus accessed/shared efficiently in future.

5 PART II SURVEY: KNOWLEDGE SHARING

The respondents for the *Part II Survey* consist of 11 consultants and 17 contractors, with an average of 22 years of experience and expertise in: civil structures, project management, buildings, precast structures, earthworks, mining, and roads. Respondents hold senior positions in technical and/or managerial functions, as directors, engineers and managers in South Africa.

For the survey, a list of knowledge sharing modes was identified and respondents were asked to qualify each of them in terms of "popularity of use", to share knowledge within their organizations. Popularity is rated on the following scale: 0.00 – never used; 1.00 – unpopular; 2.00 – neutral; 3.00 – popular; and 4.00 – very popular. The results can be roughly divided into three groups and listed in increasing popularity as shown in Table 2. These results offer strategic direction regarding how constructability knowledge may best be disseminated.

Results show the prevalence of human interaction and tacit knowledge sharing for both consultants and contractors. Knowledge sharing modes employed are mostly people-orientated methods requiring socialization, such as informal chatting and storytelling,

Table 2. Popularity of Knowledge Sharing Modes.

	Knowledge sharing modes and their respective popularity ratings* in brackets	
	Consultant	Contractors
Unpopular	(0.82) Knowledge sharing boards (1.18) Internal newsletters and circulars (1.18) Newsgroup and web-based discussions (1.6) Memoranda and letters	(1.06) Newsgroup and web based discussions
Neutral	(1.64) Phone calls (2.27) Internal databases (2.27) Emails	(1.65) Knowledge sharing boards (1.94) Internal databases (2.06) Memoranda and letters (2.12) Talks and seminars (2.18) Internal newsletters and circulars
Popular	(2.55) Training and mentorship program (2.91) Talks and seminars (2.91) Informal chatting and storytelling (3.00) Project briefing and review sessions (3.36) Meetings	(2.53) Phone calls (2.65) Project briefing and review sessions (2.76) Training and mentorship program (2.82) Meetings (3.12) Emails (3.24) Informal chatting and storytelling

*Popularity rating is done according to the scale described in Section 5

meetings, project briefing and review sessions, and mentorship and training programs. Social knowledge sharing is much more popular than modes that contain written, explicit knowledge, such as databases, memoranda, internal newsletters and circulars etc. This suggests that if a new knowledge management initiative is to be introduced and implemented, it is likely to gain the most effect if it embodies a human-orientated nature.

6 PART III: TACIT CONSTRUCTABILITY ISSUES IN PRACTICE

Respondents for the *Part III Survey* are the same as that of Part II. To gain further insight to constructability issues and the nature of constructability knowledge in practice, respondents were asked to provide descriptions of specific constructability issues or problems from their past experience. The synthesis of these constructability cases in practice gives deeper insight to the relationship between consultant and contractor during a real project.

6.1 *Preventability by "better design"*

A total of 61 constructability issues with descriptions were obtained from the contractors. Out of the 61 constructability issues, 58 of them were indicated to be preventable by "better design". On the other hand, 41 constructability issues were obtained from consultants, of which only 15 were indicated to be preventable by "better design". Irrespective of which side is correct, this shows a contrast or misalignment in opinions regarding the nature and causes of constructability issues mentioned. Much fewer consultants believe that a better design can improve/solve constructability problems. Discussions between consultants and contractors on specific issues are thus necessary, to reach understanding.

6.2 *Categories of constructability cases*

Since it is accepted that contractors embody more knowledge regarding the execution phase and the practical details of the construction environment, the cases provided by contractors were primarily regarded and analyzed. The cases were condensed and analyzed individually; similar cases were consolidated together, and can be roughly categorized into the following areas:

1) Design problem; 2) Timing of design issuance; 3) Alternative construction from contractors' input; 4) Simplicity and standardization; 5) Site related issues; 6) Aesthetics

Note that these categories are not mutually exclusive. Many constructability issues may well be associated with a few different categories. Irrespective, these myriad cases hold many valuable lessons to be learnt concerning the nature of specific constructability problems. Only a condensed summary is set out in the sections below, under each of the categories mentioned above.

6.2.1 *Design problem*

– Inherent incompetence of the design results in problems such as: excessive deflections during construction, structural failures due to poor design, lack of provision for certain components (e.g. services, water/electricity reticulation, ceiling voids etc.) and neglect of inherent distortion of building materials during the fabrication or construction (e.g. distortion of flat plate galvanized box gutters).

6.2.2 *Timing of design issuance*

- Drawings are issued late or just in time, stifling the motivation for change/optimizing of design.
- Designers often wait for vendors or clients themselves for information, who are late in issuing.

6.2.3 *Alternative construction methods by contractors' input*

- Contractors' input often involves changes to the design that lead to a better project solution. e.g. re-sequencing of work, changing configurations of building components.
- Changes that lead to alternative (better) construction are often instrumental for the completion of the project on time.
- Alternatives are often simply not considered – resulting in a much more expensive and difficult construction process.
- If contractors propose alternative designs or construction details, they must often also supply guarantees for the life of the proposed structure; contractors are thus discouraged to do so.
- The pressures involved in the project schedule are a great barrier to the adoption of alternative design and construction. Many potentially beneficial alternatives are not pursued further due to time constraints.
- Self compacting concrete saves time as no vibration is needed; however, it is more expensive and need stronger shuttering.
- In situ slabs with down-stand beams are best avoided; precast alternative or permanent formwork is preferable in most cases. Back propping of in situ slabs also cause delays.
- Mass and density of structural steel implies the assembly process – e.g. put together in position or first assembled aside and then lift into position with a crane. This must be discussed between consultant and contractor to clarify the circumstantial preference.
- Very slender columns are difficult to construct. Together with dense rebar specifications, causes limitations to the construction procedure and delays. It would be better to make the column thicker with less dense rebar details.
- The in situ ring beam is unsuitable for fast-track projects; rather box-steel beam or precast beam.
- Precast beams are used for better finish, consistent colouration and standard dimensions of moulds.
- Chasing of masonry walls causes numerous potential problems, such as compromising the stability of the wall, material waste, dust and health & safety issues. Less chasing is better in principle.
- Excessively dense rebar cages or long rebar are difficult to lift with the crane and difficult to handle on site.

6.2.4 *Simplicity and standardization*

- Formwork standardization is typically not considered in most projects, but makes a great difference for improving construction processes.
- Specification of products that are new to the market or not within familiarity of the contractor causes delays and inherent uncertainty risks, and may also require additional training of personnel carrying out installation or construction.
- It is better to use a simple concrete wall over a brick skin wall with concrete cavity, which makes construction more difficult.
- Coordination of services is typically problematic. Clashes in components and procedures occur often, causing delays and additional costs.

6.2.5 *Site related issues*

- Safety issues of working at high altitudes need to be considered during the design.
- Access to site may be a problem if in situ material is poor, which makes the supply of equipment very difficult. The material is also more vulnerable to rain, resulting in much rework and delays.
- Site congestion may prevent the use of the mobile cranes if there is not enough space to allow access for mobile cranes.
- Excavations must be provided with proper drainage to prevent flooding.

6.2.6 *Aesthetics*

- Aesthetics requirements are sometimes absolute, and take priority over practicality, resulting in poor constructability. Contractors are often in a position to suggest alternative/better construction approaches, while still maintaining the aesthetic requirements. This should be made possible.

7 CONCLUSIONS AND RECOMMENDATIONS

This study sets out to determine the nature of constructability and related problems, and how better collaboration between consultant and contractor can be a holistic way to address such issues.

Firstly, this study investigates project archives – a primary source of explicit constructability knowledge from projects. It is revealed that existing archives and documentation are inadequate in providing constructability lessons. The problem is not only the capturing activity per se, but also the lack of willingness from employees to use such a system – which may have been cause by the inadequacy of the system in the first place. This indicates that there is insufficient explicit constructability knowledge, as well as a lack of accessibility within organizations, let alone on an inter-disciplinary level.

Constructability knowledge is predominantly in tacit form – in the minds of expert professionals in the field. Tacit knowledge sharing thus proves significant in disseminating constructability knowledge, amongst consultants and contractors, themselves and/or each other. Indeed, this study shows that current popular knowledge sharing modes are informal and involves social, people-orientated methods. This seems apt for the dissemination of constructability knowledge.

However these modes also suggest that knowledge sharing is unstructured and ad hoc; and thus poses additional challenges for documenting and managing constructability knowledge.

To gain accurate insight into the problem, this study obtained and analyzed numerous constructability cases from the field, then categorized into 6 basic areas. However, one should bear in mind that one constructability issue is seldom mutually exclusive to another. This emphasizes the uniqueness and complex nature of constructability cases. Nevertheless, this simple exercise demonstrates that substantial amounts of constructability experience can be extracted and explicated for sharing. It is thus pertinent for such activities to take place on a larger and more systematic scale within organizations.

From this study some broad constructability guidelines may be inferred – such as: consideration for precast methods; allow more contractor input; promote standardization and/or simplicity etc. However, due to the variety of circumstances and uniqueness of these issues, the holistic approach is rather to promote collaboration and more knowledge sharing, where issues can be addressed in the context of the project, by the participants involved.

In principal, constructability problems arise from a "poor design" due to inadequate constructability knowledge. As this study shows, it is rather attributed to a misalignment between perceptions of consultants and contractors, regarding what constitutes good vs. poor constructability. These misaligned perceptions often has anecdotal reasons, and can thus only be properly addressed through open channel of communication, where the most relevant knowledge can be shared consistently, to achieve a more integrated project delivery process. The recommendations arising from this study are as follows:

- Improve project archives so that more useful knowledge can be captured, organized and stored to be easily accessible by future personnel.
- Promote more structured implementation of existing, human-orientated knowledge sharing modes (be it meetings, seminars, word-of-mouth etc.)
- Increase research to further explicate constructability, especially industries involving substantial repetition (such as housing, precast fabrication), where standardization is common, and thus construction processes easily expressed explicitly.
- The 6 categories of constructability issues produced in this study may well be used as a reference or checklist for constructability discussions between consultant and contractors.
- Closer collaboration and better knowledge sharing may be achieved through a variety of knowledge management initiatives (e.g. lessons learnt programs and discussion forums).
- Social knowledge sharing should be integrated with IT systems (such as Building Information Models) to harness full operational potential.

Processes of ID-based linking of structural relevant construction phase data to planning phase data using auto-ID techniques

L. Laußat, A. Kelm, A. Meins-Becker & M. Helmus
Bergische Universität Wuppertal, Civil Engineering Faculty, Chair of Construction Management & Economics, Wuppertal, Germany

ABSTRACT: Today, architects' planning and modeling should be done object orientated. A unique ID number can be given to every object planned in the architects' model as the first step in the building information modeling (BIM) process. When in the next steps of this BIM process structural engineers are doing their work of detailing, e.g. for reinforcement, it is possible to link the ID of every part planned in detail to the ID of the architects' model – even if the work of detailing is done using traditional, but digital 2D methods, e.g. such resulting in lists of reinforcement. But a lot of questions dealing with the level of detail and data requirements have to be solved. In logistic processes a set of ID of single items can be aggregated to one delivery ID. If parts or sets are marked with automatic readable labels or tags (e.g. barcode or RFID), once the ITC environment is integrated, they can easily be tracked. Each part can be linked during logistic and construction processes to the BIM databases. The qualified staff on the construction site can be identified, e.g. using an identity card with barcode, RFID or biometric data, perhaps on an anonymous basis. The database entries for different processes on construction sites could then link material ID, personal ID, location ID and type of process ID to the virtual object ID. This would result in new status for the objects linked to the 'xD multi model data' usable for the BIM processes of the different participants. This new way of data generation, enabled by object orientated, digital planning and modern forms of ITC technology could be used as a basic step in processes of controlling and monitoring structural work. In the paper the authors give some impressions for the interdependence of BIM based data structures, auto-ID usage and process design requirements and possibilities reflecting their ongoing research.

1 INTRODUCTION

In past research projects the authors showed how auto-identification (ID) techniques could be used to support construction logistic processes (see e.g. Helmus et al. 2009 and 2011). They raise expectations, that real life ID Numbers (ID) used in the construction phase, such as product serial numbers or personal numbers, can be linked automatically to the object ID which are generated and used in building integrated modeling (BIM) processes in the planning phase using modern ITC technologies. They proposed e.g. using systems like article catalogs and classification systems for the building components and standardized ID for the real world processes (e.g. GS1/EPCglobal concepts). The detailed analysis of the multiplicity of processes needed to link the real life ID and the corresponding data to the virtual ID in the BIM database structure has not been focus in their past research.

This paper wants to describe the task of finding processes allowing these linking using two examples. These examples are able to illustrate the relevance of these issues for control and documentation of structural relevant construction work. The first example should be prefabricated reinforcement, the second example ready-mix concrete, both for a structural relevant concrete column.

2 IDENTIFYING AND DETAILING PLANNING PHASE DATA USING BIM METHODS

2.1 *BIM methods: The way for object based planning and building*

The BIM based, that means object orientated method of doing construction planning and work, usually is traced back to Eastman et al. 1974. Today due to software developments it has become very popular issue in different fields of research. The method allows the combination of geometrical data of objects with additional data in the objects' attributes and parametrical data bringing the objects in relations to each other. It is the logical enhancement of computer aided design (CAD) and engineering (CAE) systems.

Parts of the method will be described in the following sections looking at the above mentioned examples and a usual constellation of project participants. Here the authors make the assumption, that every participant uses his own model in a compatible multi

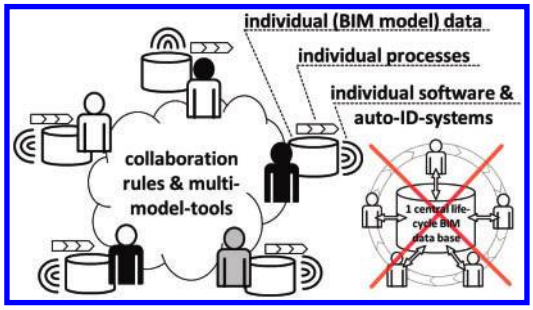

Figure 1. Auto-ID usage in decentralized (multi model) data structure: Collaboration rules for data interchange processes.

model landscape with data interchange possibilities. The early assumption that can be found in the literature, that all data of all participants should be put in one single central model respectively data base, is not part of the authors' concept. They want to reflect real world aspects such as decentralized database structures combined with collaboration rules for getting results relevant for the practice. The concept is drafted in figure 1.

One possibility of a multi model approach, that means a link-model-approach with several domain models, is shown e.g. in the reports to a German research project called Mefisto (see e.g. Mefisto 2013). This seems to be a good base for further developments.

2.2 *State of the art in using BIM methods in architectural planning*

Using an architectural BIM software, the architect today will begin his design work for a concrete column by defining the object as a simple geometrical volume that is parametrically integrated in the building structure. By doing this, the first virtual object ID for a part of the building is given to the column.

The object of the column will be further defined by the architect using attributes. E.g. he will attribute this object as a structural relevant, reinforced concrete column build as exposed architectural concrete class 'xy' with different other defined properties.

At this point the level of detail (LoD) of the planning phase model data is not very high. For further detailing the architect will submit his model to e.g. the structural engineer.

2.3 *State of the art in using BIM methods for structural detailing*

The structural engineer will import the architecture's BIM in his structural orientated BIM software linking the virtual ID of the column in the architect's model to the virtual object ID in his own structural model. (The processes of iteration between architect and structural engineer e.g. relating the column dimensions should be neglected at this point.)

Now the structural engineer will do his work of detailing, that means he will add structural relevant attributes such like e.g. specified concrete and exposition classes and he will plan or model the reinforcement. Using BIM methods or not, every single item of the reinforcement will get a position number, which is shown in the paper based position plans, the structural analysis and which is used for the lists of steel requirement. In the world of object orientated modeling every item could be modeled and made part of the structural model as a single object. In this case it can get its own virtual single item object ID which could be linked to the virtual column object ID of the structural model and so indirectly to the virtual column object ID of the architectural model.

So a new LoD of the structural model reflects the work of detailing by structural engineers in form of new attributes (e.g. ready-mix concrete quality requirements) and in form of assigned and linked single item (sub-)object ID (e.g. for the reinforcement).

2.4 *State of the art in using BIM methods during contracting*

Based on information at this LoD usually the contracting phase will start. In the world of using BIM methods the architect can use the data of both, the architectural as well as the structural model, for defining a work breakdown structure (WBS) and for getting quantity take offs (QTO) when working out the tender documents. For doing this, today special software is already available.

Using this software will change the LoD and generate a WBS with transparent QTO and directly linked properties (attributes and their values) of the building parts. This information is directly usable for contractors for defining construction processes and doing their calculation work. In their offers the contractors can also make their specification remarks (e.g. about the concrete supplier and recipe or about formwork systems incl. in the offer), which are automatically linked to the relevant virtual object ID.

2.5 *State of the art in using BIM methods for construction work scheduling*

When contractors are calculating their offers, they usually will make decisions about the chosen construction methods and therefore they will predesign construction processes and link them with resource requirements for answering resource leveling and allocation aspects resulting in scheduling assumptions.

In a BIM based world contractors can define their construction processes linking the object ID of BIM models to new process ID and adding construction relevant data to these processes, e.g. data about resource requirements. So virtual object ID and attributes as well as assigned virtual single item object ID will be linked to process ID and more, to resource requirements. When calculating the offer the LoD of process and resource linking will usually be very low. But

after getting the contract this will be the starting point of doing the resource and scheduling detailing work. This will be part of detailed examination about resource based scheduling in an ongoing research project mentioned in Laußat 2013.

2.6 *State of the art in using BIM methods for construction site logistics*

As shown in many research projects (see e.g. Günthner & Borrmann 2011 and Mefisto 2013 2013), using BIM methods can be very helpful also for planning the temporary construction site layout and for construction logistic and safety aspects. In a multi model approach temporary construction site models give information e.g. about crane availability, storage areas, working or safety place requirements etc. Also form- and framework as well as scaffold could be modeled in detail. These models and their data can be used and combined with the other models for different purposes. Hereby new virtual objects with own virtual object ID are designed which can be used e.g. for linking data of different systems. One example is a virtual location ID for a temporary storage area as a virtual zone in the 3D structure.

2.7 *State of the art in using BIM methods for manufacturing building products*

If the BIM-based planning is done in a suitable LoD and the relevant aspects are considered, BIM-data can be imported by computer aided production systems of the industry, which will produce and deliver the construction products or elements. E.g. computer aided production of reinforcement could be done using the detailed data of the structural BIM for every single reinforcement object. This can be seen as a logical enhancement of computer numerical control (CNC) machine tools' use of CAD data.

Using BIM methods in construction planning this way can open the door for the ongoing industrial revolution (in Germany called *"Industrie 4.0",* the 4th industrial revolution) for the construction sector, in which the gap between real and virtual reality will be closed allowing individualized production.

After getting the contract another possible process could be, as it is e.g. not unusual in the German construction industry, that the contractor changes the construction method and so switches from cast-in-place to precast columns. Then he or his precast element supplier can use the detailed data of the existing BIM models for making his own, new structural model. In this case, special additional processes of linking relevant data are required, e.g. for dividing one big cast in place concrete wall and its referenced reinforcement in several precast elements including reinforcement and connectors.

When prefabricated components shall be used production planning has to be done and the data from the production planning could be linked to the former planning phase data in the different models. So the produced element and its production data now can be virtually linked to all relevant planning phase data. To conserve this possibility of data linking outgoing from an object, it is necessary to make the real life objects identifiable.

3 CONCRETE CONTROL, MONITORING AND INSPECTION REQUIREMENTS

3.1 *German rules for building with concrete*

In Germany different rules have to be considered when building with concrete. Depending on concrete and building classes there can be inspection and documentation requirements by the suppliers, contractors and additional extern inspecting institutions (see e.g. BetonMarketing 2011). At different points of the construction phase the accordance of produced objects and chosen processes with the requirements set in the planning phase have to be inspected and documented. So the concrete, reinforcement and formwork have to be inspected as well from an object as from a process perspective. Thereby process-durations and whether conditions as well as confirmation paperwork and testing procedures, e.g. taking of test cubes, have to be checked and documented. Not at least the qualification of the staff as well as the machinery has to be reviewed and documented.

Next to these structural relevant inspections there are also inspecting requirements from an architectural point of view as e.g. the quality of formwork surfaces regarding exposed concrete quality aspects.

In a BIM based data environment it should be possible to use digital data from model databases when inspecting and testing as well as to document the results linked to this databases. Auto-ID techniques could be able to make these linking based or link producing procedures more efficient.

4 USING AUTO-ID TECHNIQUES FOR REAL LIFE CONSTRUCTION PHASE DATA

4.1 *Auto-ID techniques*

Today a lot of processes in different businesses are supported by the use of auto-ID techniques such as barcode, biometrics or radio frequency identification (RFID). Barcode techniques and biometric systems should be well known. Detailed information about RFID techniques could be found e.g. in Finkenzeller 2008. These techniques allow generating and processing data belonging to identifiable objects in real time, because no manual identification is necessary.

4.2 *AutoID techniques in context of construction*

The use of RFID techniques in construction context was first mentioned by Jaselskis 1995. It has been one focus of the authors' research in the last seven years (for results see e.g. Helmus et al. 2009

and 2011). Today already some RFID based systems supporting construction logistic processes exist (see e.g. AdNovum 2011 for planning and tracking transports in the ready-mix concrete industry).

In ongoing projects (see www.RFIDimBau.de & www.baubetrieb.de), the authors will focus on the combination of BIM methods and auto-ID usage. Figure 1 visualizes the authors' approach of decentralized systems usage when combining usage of auto-ID technique with BIM data structures.

A lot of interesting papers handling with the issue of RFID usage in BIM data structures already exists but cannot be reviewed at this point (e.g. Chin et al. 2008, Hajian & Becerik-Gerber 2009, Cho et al. 2009, Motamedi & Hammad 2009, Xie et al. 2010, Cheng & Chang 2011, Shiau et al. 2011). First systems using the new possibilities are already prospected by ICT companies (see e.g. Vela Systems 2008a, b).

4.3 *Using ID for construction resources*

One possibility of auto-ID usage, especially when looking at construction logistic tasks, is making resources identifiable and using this new possibility in new designed logistic, construction and control processes. So not only material, but also machinery and temporary frame- and formwork or scaffold as well as staff or locations etc. could be handled in a new way on construction sites, when the single objects are identifiable and when they as well as building model objects have virtual representations in the multi model context data bases.

5 LINKING REAL LIFE CONSTRUCTION TO BIM BASED PLANNING PHASE DATA USING AUTO-ID TECHNIQUES

5.1 *The challenge: Linking of real world resources' ID to virtual objects' ID in model data bases*

As shown e.g. in Helmus et al. 2009 and 2011 or Günthner & Borrmann 2011, in different research projects methods are searched for linking real life product and process data to BIM based, object orientated data structures. While some of these linking processes are possible today with existing software, for others linking processes concepts are still missing. This can be shown by using case examples.

A simple and trivial case example is to link an ID of a BIM object which is representing a prefabricated building element, e.g. a precast concrete column, to the real world product ID during production.

A more complicated, not trivial case example is to link the production phase data of a charge of ready-mix concrete to the different columns for which the concrete of one truck delivery was used and parallel to add more relevant process information (e.g. about the staff involved in the construction process, reinforcement control data consisting e.g. of the single item object ID of the mounted reinforcement, object ID of concrete test cubes, testing results, whether conditions, construction time).

Up to today, detailed descriptions of most processes in which construction phase data (real life object ID and corresponding data) is linked to planning phase data (virtual object ID of the BIM data-structure and corresponding data) are missing. Only a few basic approaches for some examples could be found in the literature mentioned above.

5.2 *Ongoing research: Requirements for the extension of the object orientated multi model data structure due to auto-ID technique usage*

In their ongoing research, the authors will define processes in which under the use of auto-ID techniques the linking of real life construction phase data to BIM multi model world , that means planning phase data structures will be essential. Therefore the usage of data generated from BIM models as well as the extension or reorganization of this data in processes of logistic, production, construction and control will be the focus of their ongoing research. The possibility to use the resulting data base for the rest of the building's life cycle will be a great add-on. The data requirements in the different processes will be used to overthink attributing systems for virtual objects as well as to overthink the requirement of new virtual object types. This will lead to the answer of the question: How must the BIM multi model data structures be designed for efficient usage in the processes of construction logistic, production of building elements, on-site construction work and control as well as process documentation when the use of auto-ID techniques should be possible? That means which model and which object types are needed and what has to be part of their attributes, when data using and adding through auto-ID systems should be possible?

Standardization of these data organization, data using and data generating processes will probably lead to new LoD and attribute requirements in the different models of a multi model approach. Perhaps new special model types or new virtual object types are needed for special tasks. These new attributes, model or object types shall on the one hand allow for new process designs not only for the whole construction phase, but also for the preconstruction phase and for the rest of the building's life cycle. On the other hand they will result from these new process designs.

5.3 *The context: Restrictions resulting from real life collaboration and software structures*

To answer these questions, the construction context has to be taken in account. This means, that the functions of the different software in use have to be considered when changing the data and software structures – at least when the development of new data-structures should be successful. For a better understanding some of the concerned systems should be named using examples: the individual BIM-software (e.g. Autodesk

Revit or Tekla Structures), the affordable multi model tools (e.g. model checker for collision control), the collaborative communication software systems (e.g. Groupwise), the computer aided production systems of the delivering industry (e.g. CNC software), the project management and scheduling software (e.g. Oracle Primavera or Asta Power Project), the calculation and contracting software (e.g. RIB iTwo), the enterprise resource planning (ERP) systems (e.g. SAP) and a lot more.

5.4 *Examples of linking or link using processes*

At the end of the planning phase (see lit. 2.2 to 2.7) there will be detailed planning phase data for the concrete column's reinforcement and attributes.

The architect now has added all his own special requirements in form of attributes. He exactly knows about the requirements of the structural engineer. The reinforcement is modeled and all items of the column's reinforcement are linked to the virtual column ID. The contractor's additional data has been made part of the contractor's planning phase data.

Looking at the start of the realization phase, the contractor now designs e.g. one or more separate processes with own process ID for the construction of the regarded column (cast-in-place method). He specifies the resource requirements and does his scheduling. Then he plans his processes of making the resources available at the right point of time. Due to flexibility reasons he will do this on a lower LoD. The processes of making resources available will get their own logistic process ID.

The logistic processes are now pre-planned on a low LoD, but the structure reflecting the chosen construction method and participants is fixed. Linkages between virtual object ID, construction process ID and logistic process ID now exist.

But yet no linking of the real life resource's object ID has been made. These linking procedures will be the focus of the authors' ongoing research. They will be done in the steps of detailing the construction work and logistic planning by the contractor and the production planning by the suppliers. Thereby new kinds of virtual objects like identifiable deliveries (delivery ID) or identifiable personal missions (mission ID) can be used.

The following resources will be needed for the cast-in-place concrete column: information, own staff for doing formwork and casting, sub-contractor's staff for reinforcing incl. their tools and material (e.g. tie wire), formwork (several elements, perhaps reused after finishing other cast-in-place columns at the same construction site), reinforcement (a set of several parts), tools and material from magazine container (e.g. vibration units for concrete compaction or formwork oil), crane capacity (for formwork, reinforcement and perhaps concrete hoppers), concrete-pump or concrete hopper, ready-mix concrete (part of one truck load, that means one delivery), sample taking equipment for concrete, electricity, water, gasoil etc. Every resource must fulfill different criteria like qualification of the personal, quality of the formwork surfaces, maximum age of the ready-mix concrete etc. Some of these criteria have to be proofed during the construction processes. Therefore control and monitoring processes are combined with the construction processes which probably could be supported by quick data delivering possibilities enabled by modern ITC technology combined with auto-ID techniques.

Some information about resource-requirement and allocation as well as about resource properties usually can be found explicit in the calculation software linked with resource planning data in project management and ERP software. Other information usually is taken into account implicitly when planning the construction work and during scheduling. But for high construction productivity it is necessary, to plan all resource requirements on a high LoD. The real life object ID for identifiable resources usually can be found in the companies' ERP and production software systems (e.g. personal ID, inventory ID of machines, serial numbers of produced material).

With a model based planning it should be possible to link the individual, identifiable real life resources to the different construction process ID and then to link the information belonging to logistic processes of making resources available after they are planned on a higher LoD. So all relevant data would be linked to the multi model ID. The detailed description of these backgrounds and the resource based linking from construction to logistic processes is part of an ongoing project (see Laußat 2013).

6 FUTURE PROSPECTS

The paper shows aspects of the authors' actual research focus. The task is to bring data structures of the planning and the construction phase to a level that allows linking virtual object ID from the planning phase to real life object ID of the construction phase by using defined processes during planning, preconstruction, fabrication, logistics, construction, monitoring, control and documentation. These process based data linking procedures could not be seen as solved from a scientific point of view, when real life constellations of participants and their rolls and challenges as well as their software structures and e.g. ERP environments are seen as restrictions that have to be considered in the system and process design.

The authors believe that combining BIM methods with process efficiency resulting from auto-ID usage can lead to a new quality in construction project execution coming along with cost reduction and shorter construction phases. Their general approach is visualized figure 1.

For the special point of controlling structural relevant work during the monitoring, control and acceptance procedures, e.g. before beginning the casting processes, a new quality of data transparence will be available. Process, product and resource property

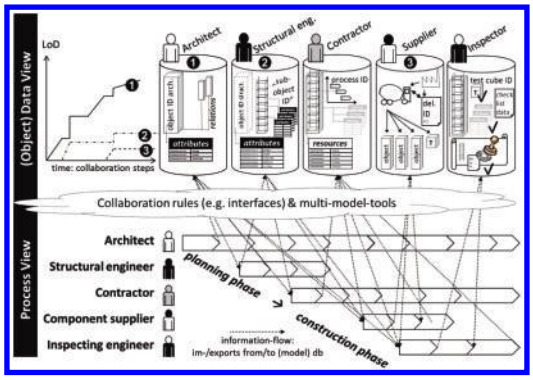

Figure 2. Principle of information flow resulting in a data set for usage in the inspection procedure of a concrete column.

information can be directly linked to virtual objects in the multi model data bases. They can be browsed by using virtual ID and links in one of the models or by using the real life ID fixed to the real life objects. Figure 2 shows an example visualizing the principal of information flow through collaboration rules.

This data can be held available over the lifespan of a building easily by using conventional methods of data aggregation, storage and backup. Usually in Germany it is the architect's challenge to aggregate a part of the decentralized and fragmented data generated during the planning and construction phase for giving it to the owner (HOAI Lph. 8-9). Once BIM methods are in use, this work package should be realized in a much more efficient way than today. Some of the auto-ID generated data which will be part of this data aggregation will lead to a much higher LoD of information also about structural relevant building parts.

Verification of MZELWE module in ESP-r programme with experimental confrontation

M. Čekon & M. Kalousek
Institute of Building Structures, Brno University of Technology, Faculty of Civil Engineering, Brno, Czech Republic
J. Hraška
Department of Building Structures, Slovak University of Technology, Faculty of Civil Engineering, Bratislava, Slovakia

ABSTRACT: The paper deals with the verification of the simulation module MZELWE using Esp-r programme and its confrontation with experimental measurements. This module focuses upon the calculation of longwave radiation heat exchange between non-transparent external surfaces of a building and its environment. Basic mathematical operations are defined by default sky radiation models. This study analyzes the precision of thermodynamic methods applied by the given simulating module in ESP-r with the aim to highlight the weak points of the sky radiation model that play an important role in the radiation heat exchange during night-time. The experimental measurements in dynamic outdoor conditions were used for this study. The Clarke model appears to be the most convenient among them, having well interpreted the measured course under all circumstances.

1 INTRODUCTION

Computer simulation is a modern tool of the present day design and planning of structural engineering and building construction. It is broadly applied in all sorts of scientific disciplines as well as in practical technology. In various fields of science it supports the implementation of findings ensuing from the solved case studies. This approach of design and planning is ever more current in all stages of project preparation, of the actual implementation of building constructions and during the whole life time of structures. The energies within the buildings and the creation of the indoor environment offer considerable opportunities for simulation. This area tends to depend upon very complex and dynamic links due to the interactions between the indoor and outdoor environment, the design itself, the technology in question and the users of the building. However, the outcome of simulations may show problems when confronted with the reality (Hopfe, 2009). Such problems can be handled by various assessment mechanisms combining empirical and analytical verification methods. They can often help to solve complex tasks that have not been scientifically monitored and experimentally confirmed, either. Yet also further uncertainties due to the involvement of the human factor are often reflected in the final result. All sorts of scientific symposia are regularly organized for discussing problems in connection with the utilization of these new methods in science and technology.

The basic problems related to simulations of energy flow and the indoor environment within the buildings can be addressed by way of thermodynamic simulations that are well suited for the analysis of both the energetic and the mass flow in the interior of the buildings. The well known ones (especially in the scientific sphere) include the calculation oriented simulation programme ESP-r (2010) that has been gradually developed and complemented, and also various modules have been added within the scope of scientific and research activities all over the world. It has been expanded by numerous innovations, but new options can be discovered by further exploration and improvements. Being outside the group of commercially distributed software, its development practically depends upon the present need in the field of research.

Although the ESP-r programme serves mainly to support research purposes, it finds ever more frequent applications for addressing practical tasks. Its setups offer options requiring very thorough studying before the user can apply them, but there are also some "prefab" models which, in turn, need not always comply with the given situation and place.

2 SIMULATION MODULE MZELWE AND THE SKY MODELS IN THE ESP-R SYSTEM

In general the basic theory of the thermal sky radiation suggests two relatively approximate methods for the determination of the volume of atmospheric radiation. The first is the assumption that the atmospheric

radiation equals that of a black body ($\varepsilon_{sky} = 1$) with variable effective temperature of the sky (T_{sky}).

$$q_{0\downarrow} = \sigma . T_{sky}^4 \qquad [\mathrm{W/m^2}] \qquad (1)$$

The next is the assumption that the sky radiates as a grey body having the same temperature as the ambient air close to the Earth surface (T_{ae}) and variable effective emissivity of the atmosphere ($\varepsilon_{sky} < 1$).

$$q_{0\downarrow} = \varepsilon_{sky} . \sigma . T_{ae}^4 \qquad [\mathrm{W/m^2}] \qquad (2)$$

$$\varepsilon_{sky} = q_{0\downarrow} / (\sigma . T_{ae}^4) \qquad [-] \qquad (3)$$

This generalizing approach may be sufficient for fundamental balance analyses, however, uncertainties appear in the respective calculation methods, in particular relating to the subjective determination of some marginal conditions, such as the degree of cloudiness of the atmosphere. In addition to that these models have been specified for sites with certain concrete climatic and weather conditions, and the latter tend to be used in a general way. This approach, accordingly, bears predominantly informative character for the reflection of the dynamics of the outdoor environment. There are analogies also in the application of calculation models like MODTRAN, LOWTRAN and others in the calculation system SBDART (Ricchiazzi et al.). These are approximate and simplified methods, frequently banning the reflection of a specific site, which is a required and indispensable issue for the investigation of real values of atmospheric radiation. They are both generalized and simplified for certain regions, such as the North-Atlantic Continent, for deserts and semi-deserts or some European regions, however, depending upon various subjectively defined parameters of the environment as well as generalized models of the climate.

The MZELWE programme module is intended for the calculation of the balance of longwave radiation between an external non-transparent surface and its environment. MZELWE operates predominantly with pre-defined sky models. The basic algorithm calculates the radiant exchange between the surface and the environment taking up the semi hemisphere above its plane.

$$q_{\downarrow\uparrow} = A_s . \varepsilon . \sigma . \left(\theta_e^4 - \theta_s^4\right) \qquad [\mathrm{W/m^2}] \qquad (4)$$

where q = balance of radiant flow [W/m^2]; A_s = surface area [m^2]; θ_e = equivalent temperature in function of the temperature of the sky, the terrain and the surrounding structures [K]; θ_s = surface temperature [K].

The calculation formula is entered by the un-known equivalent temperature of the environment allowing to express the net balance of longwave radiation. The unknown equivalent temperature is corrected by weight factors depending upon the position and place of the surface. In a standard situation it consists of a part of the sky, of the terrain and the ambient structures. Actually, the programme offers both a specific and a standard setup of weight factors (Table 1).

Table 1. Standard setup of weight factors.

Location:	f_s	f_g	f_u
City centers: surrounding structures of same height, vertical planes	0.36	0.36	0.28
City centers: higher surrounding structures, vertical planes	0.15	0.33	0.52
Urban parts: vertical planes	0.41	0.41	0.18
Agglomerations and villages: vertical planes	0.45	0.45	0.10
City centers: skew roofs	0.50	0.20	0.30
Urban parts: skew roofs	0.50	0.30	0.20
Agglomerations and villages: detached houses	0.50	0.50	0.00

$$\theta_e^4 = f_s . \theta_{sky}^4 + f_g . \theta_{grd}^4 + f_u . \theta_{sur}^4 \qquad [\mathrm{K}] \qquad (5)$$

From the viewpoint of calculation the decisive value is the sky temperature. The simulation module makes use of the assumption that the atmosphere radiates like a black body ($\varepsilon_{sky} = 1$) with variableeffective sky temperature (T_{sky}). As based upon the climatic conditions, the first step of the algorithm is the evaluation of the cloudiness that is applied separately according to the possibilities of each model. The simulation module with its setups and algorithms disposes of six physical models for the purpose of the unknown sky temperature expression (Table 2). When calculating the sky emissivity, the pre-set model Berdhal a Martin (1984) takes into account also the situation of cloudiness and atmospheric pressure conditions. Further models use, as a rule, the basic clear sky model of Swinbank (1963). Whereas the Swinbank models leave out the effect of cloudiness, using a uniform formulation, Clarke (2001), Cole (1976) and Czeplak Kasten (1980) follow in the footsteps of Swinbank, while expanding the applicability of his models. They consider the effect of cloudiness in their computation of the resulting sky temperature. Swinbank, however, differentiates between the input values of outdoor air temperature in his models, using the so-called dry or wet thermometer. In spite of that Stanzel (1994) recommends his basic model for the northern regions of Europe.

3 DESIGN, ASSEMBLY, DESCRIPTION AND TESTING OF THE MODEL

Based upon the actual dimensions and concepts of casing structures a double-zone model called Twin-box was developed for the purpose of simulation at the Faculty of Civil Engineering in Bratislava (Čekon, 2011; Čekon, 2012b). The separate zones are the measuring part (box_zone) and the adjacent zone (hc_zone)

Table 2. Physical models list and their basic formulas in ESP-r simulation module.

author - model:	abbreviation / setup in programme		Basic formulas
Berdhal a Martin (1984)	berdh&mar	0	$T_{sky,bam} = \left(q_{sky,bam} / \sigma\right)^{0,25}$ $q_{sky,bam} = \varepsilon_{sky} . \sigma . T_{ae}^{4}$ $\varepsilon_{sky} = 0,711 + 0,56 . \left(T_{dp}/100\right) + 0,73 . \left(T_{dp}/100\right)^{2} + 0,013 . \cos\left(\frac{2\pi t}{24}\right)$
Clarke (2001)	clarke	1	$T_{sky,clarke} = \left(9,36.10^{-6} . (1 - CC) . T_{ae}^{6} + T_{ae}^{4} . CC . \varepsilon_{cloud}\right)^{0,25}$ $\varepsilon_{cloud} = \left(1 - 0,84 . CC\right) . \left(0,527 + 0,161 . e^{[8,45.(1-273/T_{ae})]} + 0,84 . CC\right)$
Cole (1976)	cole	2	$T_{sky,cole} = \left((1 - CC) . T_{sky,swinbank}^{4} + CC . \varepsilon_{cloud} . T_{cloud}^{4}\right)^{0,25}$ $\varepsilon_{cloud} = 0,16 . \varepsilon_{air} + 0,84$ $\varepsilon_{air} = 0,527 + 0,161 . e^{[8,45.(1-273/T_{ae})]}$, $T_{cloud} = T_{ae} + 273$
Czeplak a Kasten (1980)	cz&kasten	3	$\varepsilon_{sky,zenith} = 9,36.10^{-6} . T_{ae}^{2}$ $q_{sky,wolke} = \varepsilon_{sky,cz} + \left(1 - \varepsilon_{sky,cz}\right) . \left(0,9 - 0,065 . C_{hh}\right) . \sigma . \left(T_{ae} + 273\right)^{4}$ $q_{sky,klar} = \left(1,174 . \varepsilon_{sky,cz} . \left(T_{ae} + 273\right)^{4}\right) - 33,0$ $q_{sky,cz} = \left(1 - CC\right) . q_{sky,klar} + CC . q_{sky,wolke}$ $T_{sky,cz} = \left(q_{sky,cz} / \sigma\right)^{0,25}$
Swinbank clear (1963)	swcl	4	$T_{sky,swinbank} = 0,05532 . T_{ae}^{1,5}$ dry air temperature
Swinbank bld	swbld	5	$T_{sky,swinbank} = 0,05532 . T_{ae}^{1,5}$ wet air temperature

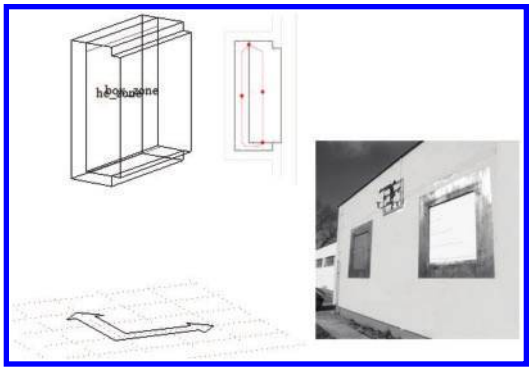

Figure 1. 3D model of Twin-box, zone model of air flow, external view on measured samples.

ensuring the preparation of heat and chilling down (Fig. 1). Thefigure shows a diagram of a network model of air streaming into the measuring part of the box. The model was derived from the existing dimensions and layout of casing structures. All surfaces were defined as non-transparent ones.

The box being surrounded from all sides by a compensation room ensuring air temperature at the level of air within the box, the external surfaces were chosen as adiabatic ones. As to the lateral sides of the box that are well insulated and contact the envelope of the compensation room, a certain simplification of the adiabatic condition has been considered. Physically the model was controlled so as to achieve constant temperature of air without any influence of internal temperature gain. The advantage consists in that the simulation serves to verify a simple model without large and changing numbers of variables, which allows concentrating exclusively upon the submitted objective.

The total of five measurements performed in three periods of time was subject to the verification. At the same time the effects of standard as well as low-emission surfaces were monitored in the field of thermodynamic behaviour of the simulation programme. Basic parameters of the tested models are represented in a table (Table 3). Radiative properties from different sources were applied to the internal and the external side of the simulated specimens (Chmúrny, 2003; Hagentoft, 2001; Halahyja et al., 1998) as well as calibrated with spectral measurements (Čekon, 2012a). The testing of each model was repeated with alternatives differing only as to the choice of the sky radiation computing model. The auxiliary database of the simulation comprised all climatic data registered by experimental measurements: outdoor temperature and humidity of air, velocity and speed of wind, horizontal, global and diffuse radiation and total solar radiation. Also the utilization of the measured ambient temperature was considered for the purpose of confrontation with the equivalent value of ambient temperature of the programme. The auxiliary database of measured data offers such option, but the present day setup of the algorithms did not support it. However, the 2-minute-step of the simulation was well in line with the interval of recording the measured values. The weight factors of model irradiation were set in the ratio 0.5 (f_s) : 0.5 (f_g) : 0.0 (f_u). We did not handle the calculation models of terrain temperature, having adopted the standard calculation used by the simulator with view to the combined effect of sun radiation and outdoor air temperature. The standard Perez model (Perez et al., 1990) was used in the model setup of solar radiation for all tested variants. Also the air flow models offered by the programme in broad scope play an important role for this verification.

Table 3. Basic parameters of the tested models.

Test/sim:	Measured period	composition:	interior		exterior	
			ε	α	ε	α
I.	12. 3. – 17. 3. 11	Zinc coated sheet 2 mm + Standard paint	0,23	0,35	0,90	0,25

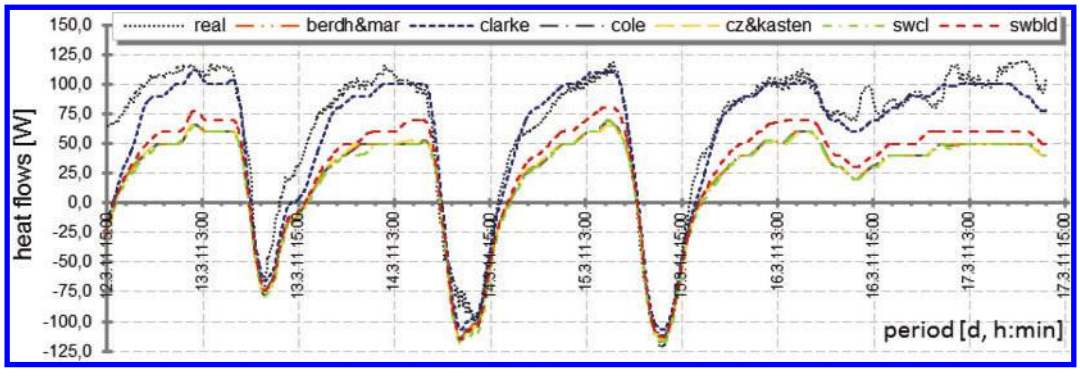

Figure 2. Simlulated heat flowsprogesses, "real" – measured heat flow; simulated heat flows form pre-defined models (Table 3).

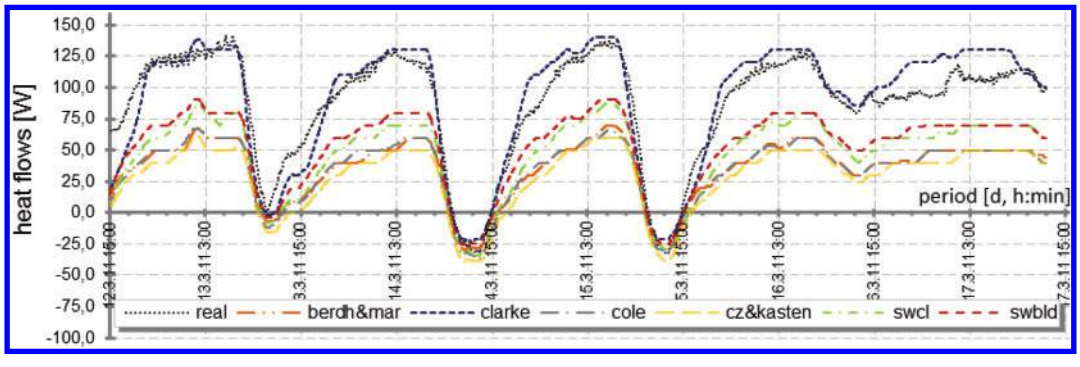

Figure 3. Simlulated heat flows progesses, "real" – measured heat flow; simulated heat flows form pre-defined models (Table 3).

4 ANALYSIS AND PROCESSING OF THE RESULTS

The simulation results are interpreted by way of diagrams showing the referential measured wave-forms of heat flow during the whole registered period as well as simulated ones. Simulations (Figs. 2–4) analyze compositions with close to zero thermal resistance where the essential part of the resulting heat flow is represented by the radiant flow and the transition phenomenon between the external surface of the composition and its environment. In this respect the sky models and temperature calculations play key roles. The compositions analyzed in further simulations (Figs. 5–6) were characterized by better thermal insulation capacity where, on the one hand, the effects of the sky radiation models compensate one another, and on the other hand their influence upon the resulting heat flows has been optically reduced. The mechanism of heat propagation by conduction takes over the decisive role. This enables the statement that along with the increasing influence of the thermal insulation properties of a structure the effect of the choice of model in the sky temperature calculation is seen to drop.

Yet another objective consisted in studying the effect of emissivity upon the non-stationary course of heat flow in the simulation programme under consideration. Since the simulator in its basic algorithm works in a clearly defined relation (4), reflecting the emissivity

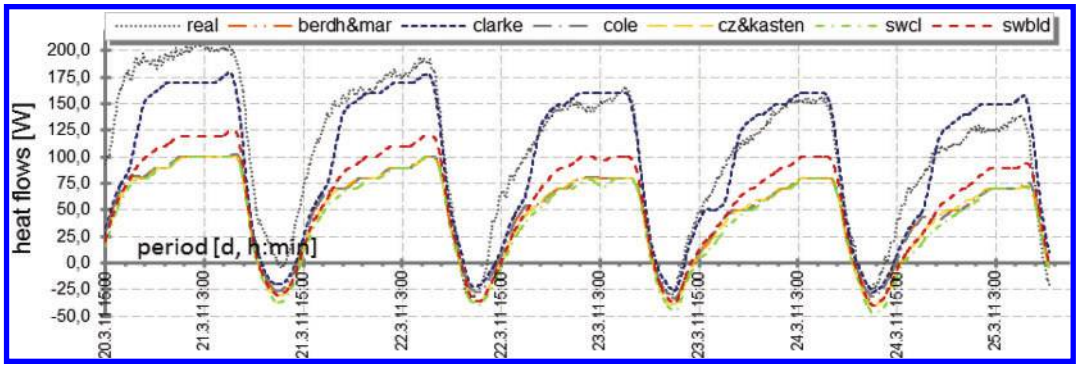

Figure 4. Simlulated heat flows progesses, "real" – measured heat flow; simulated heat flows form pre-defined models (Table 3).

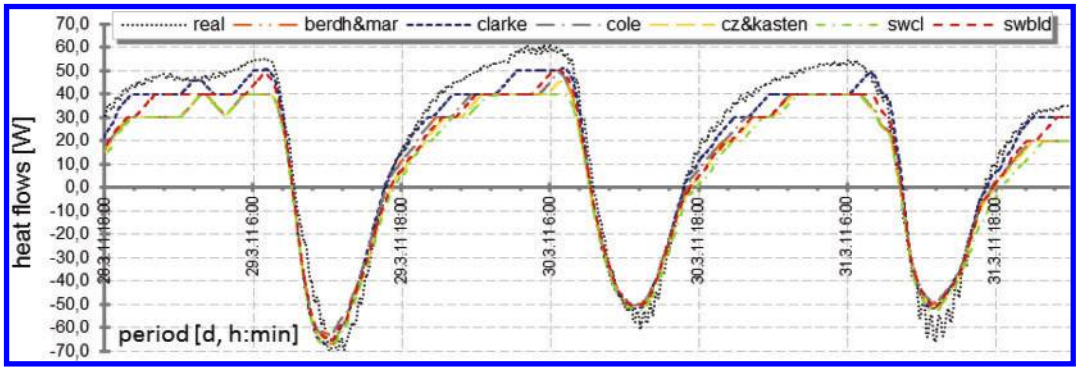

Figure 5. Simlulated heat flows progesses, "real" – measured heat flow; simulated heat flows form pre-defined models (Table 3).

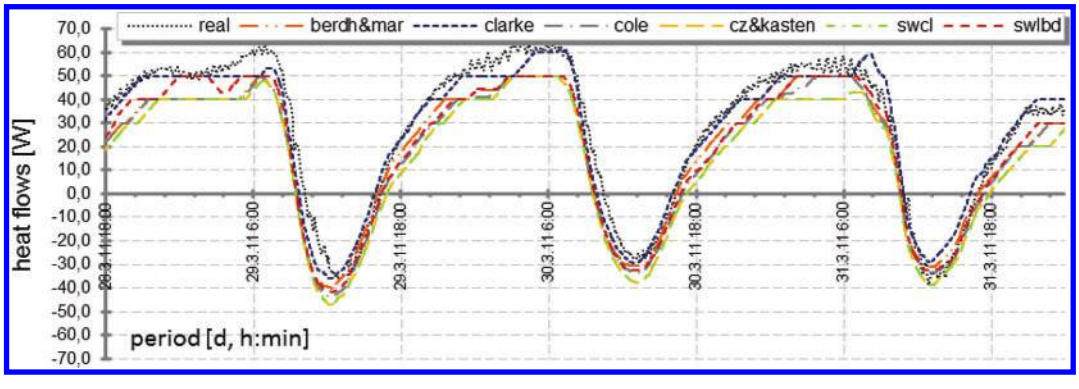

Figure 6. Simlulated heat flows progesses, "real" – measured heat flow; simulated heat flows form pre-defined models (Table 3).

of the external surface, the effects of different emissivity upon the results appear in this sense to have been proven.

5 CONCLUSION

The paper presents results of a study analyzing the programme module MZELWE in the ESP-r system, pointing to certain deficiencies of available sky radiation models that are of key importance for the radiation heat exchange during night-time conditions. The Clarke model appears to be the most convenient among them, having well interpreted the measured course under all circumstances. Detailed observations lead to the finding that Clarke operates with considerably lower sky temperature, which results in favourable heat flow. The other models operate with sky temperature calculations that do not comply with the actually measured heat flow course. This can be due to the

fact that these generalized models have been developed for certain specific circumstances of climate and need not reflect the conditions of some areas. It is also interesting that all of them show almost identical effects, doubtlessly in connection with the application of almost identical mathematical formulae. The mentioned analyses, accordingly, allow to recommend the Clarke model for the regions of central Europe (Slovakia and the Czech Republic) for the given task, i.e. for the calculation of radiation heat exchange between the external surface and the ambient environment, applying the MZELVE module in the ESP-r programme.

Thermal comfort of the rooms in the designing of commercial buildings

K. Nowak, K. Nowak-Dzieszko & M. Rojewska-Warchal
Cracow University of Technology, Division of Building and Building Physics, Cracow, Poland

ABSTRACT: The paper presents the results of the annual computational simulations in the designing of commercial buildings. The calculations were carried out in the Design Builder program which allows preparing the simulation of the building envelope as well as building interior. The simulations conducted for the polish climatic conditions allowed the assessment of the thermal comfort of the entire building and of the particular rooms. Based on those simulations authors determined the influence of different materials, structural solutions, glazing, sunshades on the thermal comfort of the separate rooms. The article emphasizes the individual attitude to the designing of different rooms taking into account the orientation, location, and room usage.

1 INTRODUCTION

It is very rare in the design process to take into consideration the requirements connected with the overheating effect. This issue is closely related to the thermal comfort of the building, especially during the summer months. The microclimate of the interior space is the combined effect of the design process, erection and the utilization of particular rooms. Thermal comfort is affected by human activity, clothing insulation and the environmental parameters such as air temperature, average radiation temperature, air flow speed and relative humidity. The evaluation of thermal comfort is based on the PMV (Predicted Mean Vote) and PPD (Predicted Percentage of Dissatisfied) indexes.

Based on the simulations, the authors determined the influence of different materials, structural solutions, glazing, and sunshades on the thermal comfort of separate rooms during the summer season. The article emphasizes the need to consider thermal comfort in the design process of individual rooms taking into account the orientation, location, and room usage as well as different materials, structural solutions, glazing, and sunshades.

2 MICROCLIMATE OF THE ROOMS

The national regulations regarding building design process draw attention to the expected energy consumption, heat losses and heat gains. In order to increase the solar gains and reduce the heating need, large window areas are located in the southern rooms. The thermal conditions in those specific rooms often become critical due to focusing only on energy needs. In order to avoid those critical conditions the thermal comfort in such south facing rooms should be analyzed to determine the risk of overheating.

Both designing and thermal modernization of the buildings are very interdisciplinary issues. From the building physics point of view those are requirements regarding energy savings, thermal comfort and acoustic insulation of the constructions.

The requirements regarding energy savings become the most significant while the thermal comfort issues are often omitted.

According to the newest Polish regulations from 2009, the building should be designed to avoid risk of overheating during the summer months. This aspect is especially important in the designing of commercial buildings with the significant glazing areas. In those buildings usually the air-conditioning systems are used to ensure the thermal comfort of the users.

3 THERMAL COMFORT

Thermal comfort by ASHRAE 55 is “the condition of mind in which satisfaction is expressed with the thermal environment”.

It is related to the thermal balance of the body which is affected by different parameters: personal (activity level or metabolic rate, thermal resistance of clothing) and environmental (air temperature, mean radiant temperature, relative air velocity, relative humidity).

There are several different methods used for estimation of thermal comfort. International standard PN-EN ISO 7730 „Ergonomics of the thermal environment. Analytical determination and interpretation of thermal comfort using calculation of the PMV and PPD indices and local thermal comfort criteria” and ASHRAE 55 use Fanger’s method.

The PMV (Predicted Mean Vote) method combines the following environmental features: air temperature, air velocity, mean radiant temperature and relative humidity and two personal variables: clothing insulation and activity level into the index that can be used to predict the average thermal sensation of a large group of people. The ASHRAE thermal sensation 7

level scale with values between -3 and 3 describes the thermal sensation between "hot" and "cold".

The PPD (Predicted Percentage of Dissatisfied) index establishes a quantitative prediction of the percentage of thermally dissatisfied people who feel too cold or too warm.

The most well known two-node thermal model is Pierce's model based on two energy balance equations, one for core node and one for skin node. It takes into account the effects of heat accumulation, physical work done, conductive and convective heat transfer by blood, flow between the core and shell, heat loss caused by respiration, metabolic heat generated during physical activities and the heat exchange processes between the skin and its surroundings by means of convection, radiation and evaporation of moisture.

The KSU (Kansas State University) two-node model is based on the changes that occur in the thermal conductance between the core and the skin temperature in cold environments, and in warm environments, it is based on changes in the skin wettedness. In this model, metabolic heat production is generated in the core which exchanges energy with the environment by respiration and the skin exchanges energy by convection and radiation. In addition, body heat is dissipated through evaporation of sweat and/or water vapor diffusion through the skin.

The control signals, based on set point temperatures in the skin and core, are introduced into passive system equations and these equations are integrated numerically for small time increments or small increments in core and skin temperature. The control signals modulate the thermoregulatory mechanism and regulate the peripheral blood flow, the sweat rate, and the increase of metabolic heat by active muscle shivering. The development of the controlling functions of skin conductance, sweat rate, and shivering is based on their correlation with the deviations in skin and core temperatures from their set points.

4 BUILDING SIMULATION

The aim of the building simulations was to assess the importance of different factors influencing the thermal comfort of the entire building, of separate rooms and possible overheating during summer months.

The numerical building simulations were conducted for the academic building, plan area 72.9 m × 21.7 m; 10.5 m high with three levels.

In the chosen building there are many south facing windows. Visualization of the south building elevation is presented in Figure 1.

Percentage share of glazing areas at the elevations is as follows:

N – 69%
S – 44%
E – 46%
W – 46%

Exterior walls made of solid brick, 20 cm of insulation with plaster at both sides: $U = 0.18$ [W/m^{2}K] (the value meets the polish standard requirements for external walls in this kind of building which should not exceed $U = 0.3$ [W/m^{2}K]), concrete flat roof, insulated with 5 cm of styrofoam: $U = 0.59$ [W/m^{2}K], slab on ground insulated with 5 cm of styrofoam: $U = 0.50$ [W/m^{2}K], double glazing windows: $U = 1.7$ [W/m^{2}K].

Figure 1. Model view of the building, south elevation.

Building with the natural ventilation, gas heating system with convection heaters.

Communication area located in the center part of each building story, office rooms located at the south side of building (similar at each level). The area of office rooms is relatively small but the ratio of the window area to the single room area is significant.

Lecture classes located on the south, north-east and north-west sides of the building.

The calculations were carried out in the Design Builder v.3 program which provides a simulation of the building envelope and the Energy Plus program for simulations of building interiors. The simulations conducted for the Polish climatic conditions (building located in Cracow) allowed the evaluation of the thermal comfort of the entire building and of the particular rooms.

The main aim of simulations was to determine the temperature of the building interior space and of the particular rooms during summer months.

In the first phase of simulations the building was modelled in the service conditions.

The assumptions for the first phase of simulations (base case):

1. Heating system on from September to March (22°C), 7 days per week, 24 hours a day.
2. Occupancy density:
   – Office rooms – 0.1 person per m^2
   – Lecture classes – 0.85 person per m^2
3. Operating Schedule:
   – Office rooms – July thru August 8:00 – 16:00, 5 days a week; September thru June 8:00 – 21:00, 7 days a week
   – Lecture classes – September thru June 7:30 – 21:00, 7 days a week, July thru August 7:30 – 21:00, 5 days a week
4. Metabolic activity: factor 0.9, winter clothing – clo = 1.0, summer clothing clo = 0.5.
5. Ventilation
   – Office rooms – one ac per hour
   – Lecture classes – five ac per hour

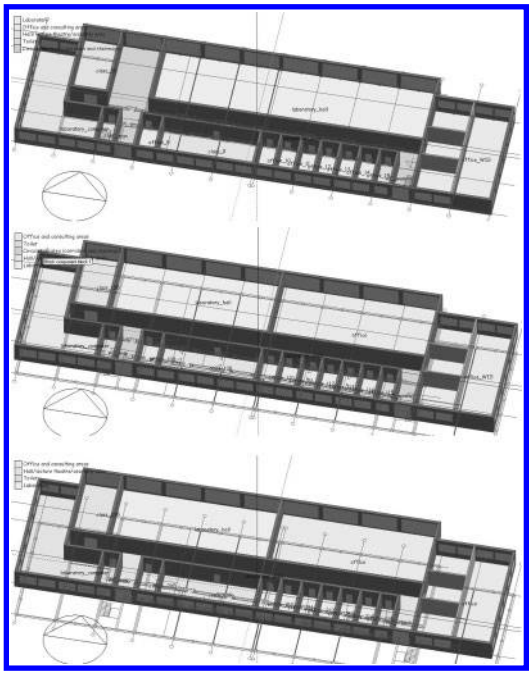

Figure 2. Building zones visualization – ground floor, first floor, second floor.

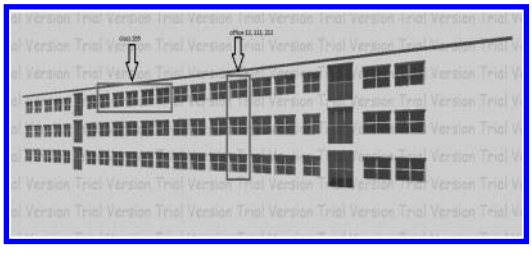

Figure 3. Visualization of south building elevation. Windows in rooms 13, 113, 213.

5 TESTS RESULTS

The thermal comfort of the entire building as well as microclimate conditions of three different office rooms, 13 at ground level, 113 at the first floor and 213 at the second floor, were separately analyzed, Figure 4.

The thermal comfort conditions of the entire building were not met. The simulation results, Figure 4, have shown that on a few days between 15th of May and 15th of September the average interior air temperatures of the different rooms exceed 30°C and the PMV factor is higher than 1.5. Those microclimate building conditions exceed the optimal internal summer temperature of 25°C and recommended value $-0.5 < \mathrm{PMV} < +0.5$.

In the lecture class located at the south building side, on the second floor, the operative temperature for most of time is significantly higher than 25°C. The daily maximum interior temperature is 34,41°C and

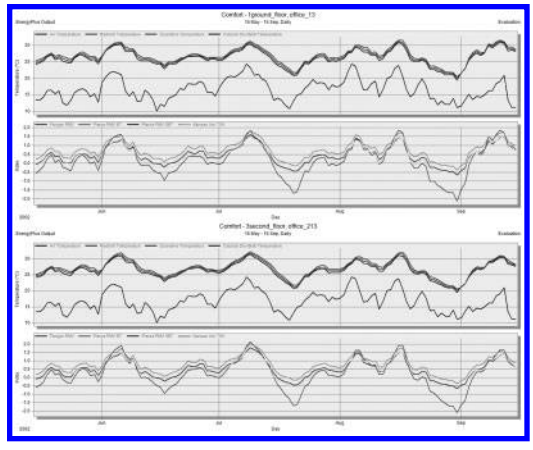

Figure 4. Simulation results for office rooms: 13,113 and 213. a – temperature – air temperature inside, radiant temperature, operative temperature, outside dry bulb temperature; b – PMV comfort factor (Fanger, Pierce, TSV Model).

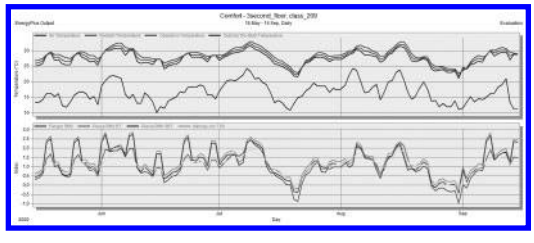

Figure 5. Simulation for lecture class 209. a – temperature – air temperature inside, radiant temperature, operative temperature, outside dry bulb temperature; b – PMV comfort factor (Fanger, Pierce, TSV Model).

the PMV value is above 2, Figure 5. The number of discomfort hours in the assumed period of time is 1127. Those negative room conditions continue almost for the entire day and do not change significantly during the night. Due to the safety conditions rooms cannot be cooled during the night through the open windows.

The primary factor affecting thermal comfort is the percentage share of glazing at the south elevation in those particular rooms.

The significant internal gains are affected by the high occupancy density especially in the lecture classes – 0.85 person per m^2. In practice the number of students in the lecture class (209) is usually smaller than assumed in the analysis.

The second phase of the modelling focused around the impact of internal shadings on the thermal comfort. To lessen the unfavorable influence of glazing during summer months with the same occupancy density, the internal gains were reduced by internal solar shadings (blinds with medium reflexivity slats).

Comparing Figure 4 with the findings shown in Figure 6 (for the same rooms) reduction of hours with the high operative temperature can be observed. The usage of internal shadings eliminated the temperature higher than 30^{o}C.

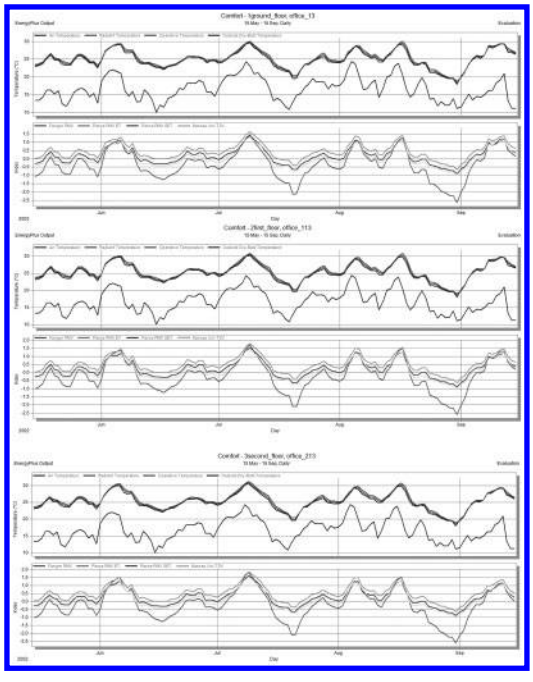

Figure 6. Simulation results for office rooms: 13,113 and 213 with the internal shadings. a – temperature – air temperature inside, radiant temperature, operative temperature, outside dry bulb temperature; b – PMV comfort factor (Fanger, Pierce, TSV Model).

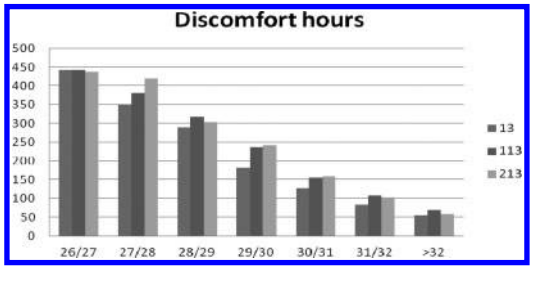

Figure 7. Number of overheating (discomfort) degree hours for separate office rooms (13, 113, 213) with the internal shadings.

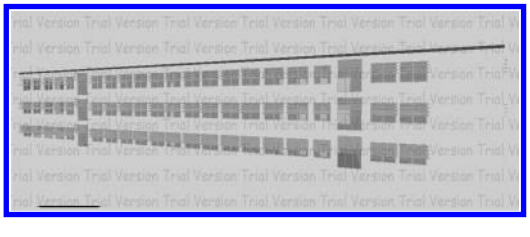

Figure 8. Visualization of the external louvers.

Much more significant results could be observed after applying the internal shadings together with the external shading panels. Four panels (louvers blade), were assumed, Figure 8.

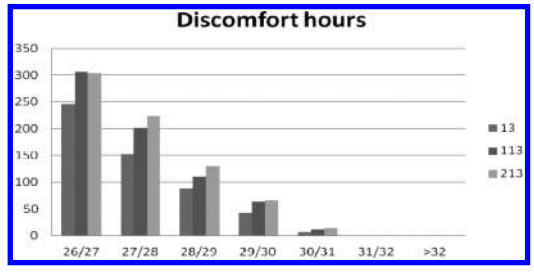

Figure 9. Number of overheating (discomfort) degree hours for separate office rooms (13, 113, 213) with the internal shadings and external louvers.

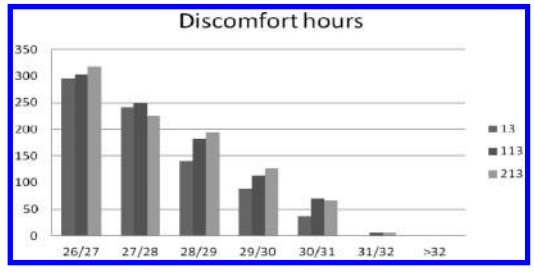

Figure 10. Number of overheating (discomfort) degree hours for separate office rooms (13, 113, 213) with the internal shadings and reduced window areas.

Both in the lecture class and office rooms with the extensive windows area at south elevation the combination of internal shadings and external louvers improved the thermal comfort significantly.

The number of discomfort hours during the summer months in the analyzed rooms was significantly lessened up to 65%. The usage of external shadings almost entirely eliminated the operative temperatures above 30^{o}C. It can be noticed that the number of discomfort hours is connected with the location of rooms at different levels.

The surface of the glazing at the south elevation of the building is 44%. In the single office room the window area is 4.72 m^2 which is the 23% of the floor area. Due to the lighting requirements the window area cannot be smaller than 2.5 m^2.

Such reduction of the window area should reduce solar gains in the summer months and reduce the heat need during winter months. The results of such simulations are presented in Figure 10 and Figure 11.

Comparing Figure 10 with the findings shown in Figure 7 (for the same rooms), for the external shadings combined with the reduced area of windows, the significant reduction of hours with the high operative temperature can be observed.

As it is the existing building structure, from the economical point of view, the more advantageous solution is the one presented in Figure 9 (glazing area 4.72 m^2, together with the combined external and internal shadings).

Another factor affecting the thermal conditions inside the building are the external shading objects

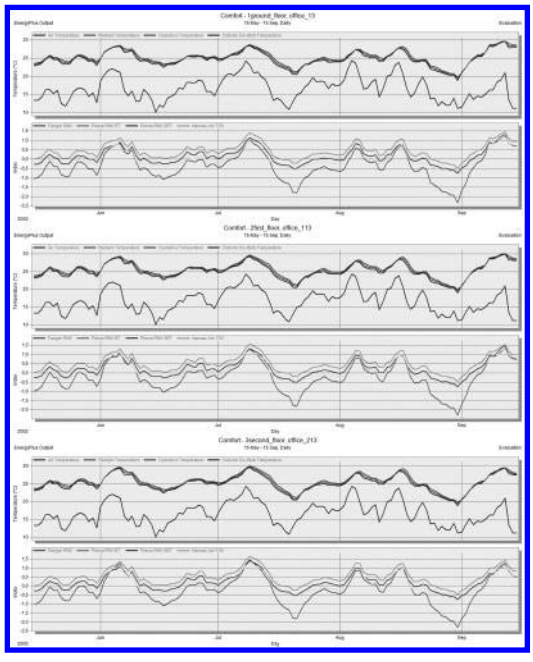

Figure 11. Simulation results for office rooms: 13,113 and 213 with the internal shadings and reduced window areas. a – temperature – air temperature inside, radiant temperature, operative temperature, outside dry bulb temperature; b – PMV comfort factor (Fanger, Pierce, TSV Model).

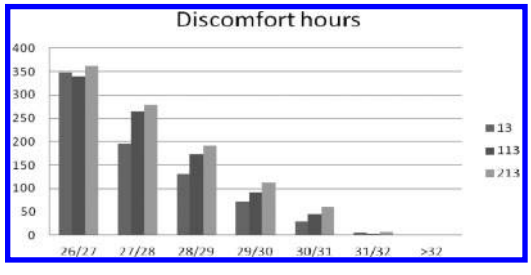

Figure 12. Number of overheating (discomfort) degree hours for separate office rooms (13, 113, 213) with the internal shadings including tree growing at the front of the building.

next to the building, such as different building structures or trees.

As the next modelling stage, a set of simulation runs was conducted for the actual window areas and including the tree growing in front of the south elevation of the building, opposite the windows in rooms 13, 113 and 213. Assumed diameter of trunk is 50 cm and branches 3.0 m.

The simulation results, Figure 12, are much better than for the ones for the same window area but without external shading object, Figure 7. The number of discomfort hours in the analyzed rooms was significantly lessened from 42% up to 48,8%. The significant reduction of the temperatures above 30°C may be observed. The tree does not allowed for the rooms overheating.

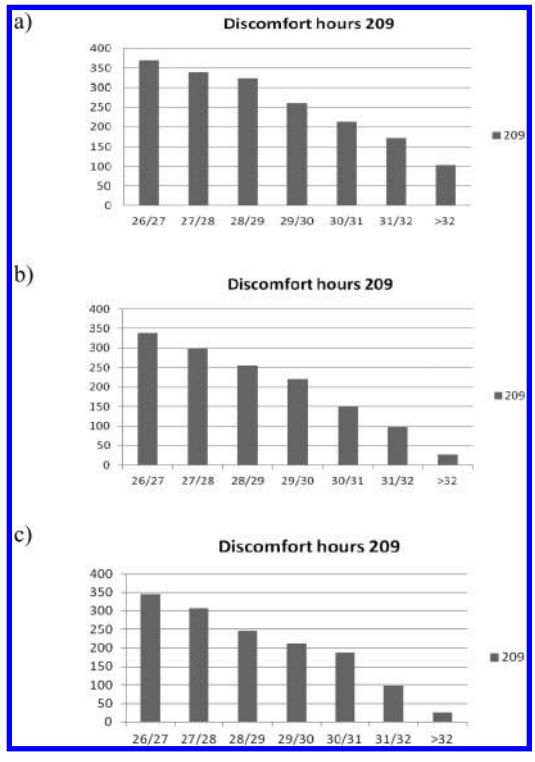

Figure 13. a) Number of overheating hours for lecture class 209; b) Number of overheating hours for room 209 with the internal and external shadings; c) Number of overheating hours for room 209 with the internal and external shadings combined with the reduced window areas.

For the lecture class 209, with the surface area of 93,51m^2, the proposed solutions do not improve the thermal conditions as significantly as in case of office rooms. The base simulation results for lecture class shown in Figure 5, for office rooms in Figure 13.

Such lecture class with 45 percentage of glazing and high occupancy density requires applying of air-conditioning systems in order to obtain the thermal comfort of users.

The significant influence of the external temperature drops on the lowering of PMV factors may be observed in Figures 4, 5, 6 and 11.

The users way of dressing is affected by the atmospheric conditions. If in the analyzed spring and summer periods the external temperat333ure drops below 15°C, than the higher clothing factor clo should be assumed. In the all conducted simulation the clo value was constant, equal to clo = 0.5. That explains the periodic drop of PMV factor below −0.5.

6 CONCLUSIONS

Most of the new office and commercial buildings are designed with extensive south facing window sections, which in most cases are poorly shaded from solar radiation. Glazing is the source of the excessive heat gains

and may result in the overheating of the entire building but specifically of separate rooms located at the south side of the building. The work conditions in those specific rooms appear to be very uncomfortable.

When using glass facades in building construction it is necessary to consider, at the designing stage, the thermal comfort conditions both for the entire building and for separate rooms.

The conducted simulations result in the following conclusions:

1. Modernization of the building should be preceded by the extensive analysis of how the changes influence thermal comfort of the rooms.
2. In the rooms with a significant glazing ratio the level of solar protection, shadings and window area appear to have the greatest influence on the thermal comfort.
3. Cooling of the rooms must be applied if none of the external or/and interior shading systems are used to avoid overheating.
4. The building surroundings, buildings and trees may affect the thermal comfort of individual rooms.

ABSTRACT: Experimental and numerical modelling program was performed in France. It concerned tests on steel-to-timber connections with various mechanical loadings, in normal and fire conditions. The experimental results show the failure modes of the connections including the brittle or ductile character. They are used to calibrate the developed numerical models simulating the mechanical and the thermo-mechanical behaviour of the tested connections. The accuracy of the mechanical model is evaluated on the basis of the global behaviour of the connections until failure. The thermo-mechanical model is evaluated comparing the calculated and the measured values of temperatures and fire duration resistances. The nonlinear behaviour of materials is considered in normal and fire conditions. In this study, the experimental and the numerical results are summarized for normal and fire conditions. The results show the failure mechanisms in steel-to-timber connections and illustrate the accuracy of the numerical approaches used in the modelling of the real behaviour of steel-to-timber connections in normal and fire conditions.

1 INTRODUCTION

In fire situation as well as in normal condition, the connections govern the bearing capacity and the mechanical behaviour of timber structures. Regarding the actual architectural trends and high strength requirements, connections with slotted-in steel plates are commonly used to improve the mechanical resistance in normal and fire conditions. The complex mechanical behaviour of timber connections is influenced by connection geometry, plastic moment of the fastener and the embedding properties of wood. As the stress distribution along the dowels is not uniform, 3D-FEM model is proposed to investigate the mechanical performance of timber connections (Xu et al 2009a, Xu et al 2009b).

Numerical studies using the 3D-FEM model with Hill yield criterion for orthotropic material showed that the mechanical behaviour of timber connections with multiple dowel-type fasteners is stiffer than the experimental ones (Racher et al 2010). However; the numerical models taking into account the progressive failure of timber using the Hoffman and Tsai-Wu criteria showed a good prediction of the real behaviour of timber connections (Xu et al 2009a).

For dowel-type connections with ductile failure mode, the behaviour is characterized by the bending of the fastener and/or the embedment of the fastener into the wood.

Although experimental and numerical studies exist in the literature (Buchanan 2000, Racher et al 2010) and the progress given by EN1995-1-2 (EN1995 2004) to the design of timber connections, large limitations still exist due to the lack of data (Audebert et al 2010, Audebert et al 2012). As for normal conditions, numerical models are proposed to study the behaviour of timber joints in fire conditions. Thus, a numerical modeling approach is initiated at Blaise Pascal University and CSTB to simulate the thermo-mechanical behaviour of dowelled timber connections in fire with mechanical loading.

The model represents well the thermal and thermo-mechanical behaviour of the connections in fire situation mainly the discontinuities at the interface between steel and timber. Some results are presented for the steel-to-timber connections loaded in tension parallel or perpendicular to grain in fire situation. The fire exposure of the connections considered in the tests and the models is based on the nominal fire given by the ISO 834 curve (EN1991-1-2 2003).

In this paper, the Hoffman failure criterion associated with the Hill criterion to control the plastic yielding is used. A non-linear 3D-FEM model predicts well the behaviour of steel-to-timber joints loaded in tension parallel or perpendicular to grain (Xu et al 2009a, Xu et al 2009b, Audebert et al 2011, Audebert et al 2012). This approach, validated by comparison with experimental results, is used in normal conditions

and fire. The thermal and the mechanical modeling are done using the finite element software MSC-Marc (Msc.Marc 2005).

2 CONNECTIONS IN NORMAL CONDITION

2.1 *Test setup*

The tests concern double shear steel-to-timber connections with 2*4 fasteners (6 dowels and 2 bolts) for the specimen in tension parallel to grains and 2*2 dowels for the specimen in tension perpendicular to grain (Figure 1). The bolts are generally used to prevent the separation between the connected members. Two or Three diameters of fasteners are considered (12, 16 and 20 mm) to cover the main range of diameters used in practice.

The experimental results of the steel-to-timber connections loaded in tension parallel or perpendicular to grain are used to validate the mechanical 3D-FEM model. The tests performed in normal condition provided the load-displacement curves and the failure modes.

The dimensions of the tested connections are chosen according to the requirements of spacing and size of EN1995-1-2. In addition to these minimum requirements, the end and edge distances towards the fasteners have been increased by a value a_{fi}. This additional thickness is used to take into account the charring rate of wood. The thickness t_1 is chosen considering the usual glulam dimensions and the thickness to dowel diameter ratio.

The tension load is applied on the steel plate with a fixed timber parts (Figure 1). Two or three replications were realized for each connection configuration. During tests, the relative displacement is measured between the steel plate and the wood members.

2.2 *Failure loads in normal conditions*

Figure 4 shows the load-slip curves of cold tests. Different failure modes are observed, depending on the ratio between the member thickness t_1 and the fastener diameter. In the connections loaded in the direction parallel to grain and the diameters of 16 mm, the ultimate failure arises mainly by wood block shear or splitting but with significant yielding of the fastener combined with wood embedment. With diameters of 20 mm, the connections exhibit generally a brittle failure in block shear or splitting of wood. In the direction perpendicular to grain, the failure arises mainly in splitting on one line of the fasteners (Figure 5) with yielding of the dowels.

2.3 *Finite element model*

3D-FEM model is developed where timber and steel materials with contact were modelled. Considering the symmetry, only one quarter of the connection geometry was modelled. The loads are introduced by increasing controlled displacements applied on all nodes in the top of timber member (Figure 2).

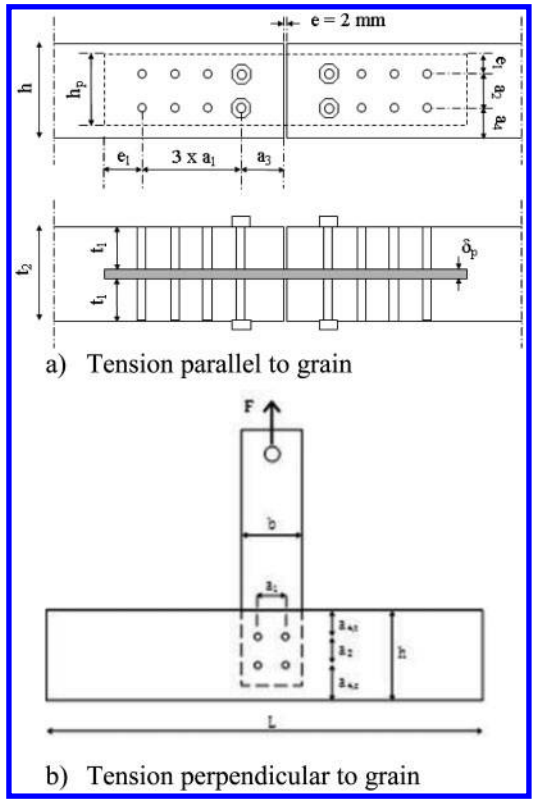

Figure 1. Tested steel-to-timber connections.

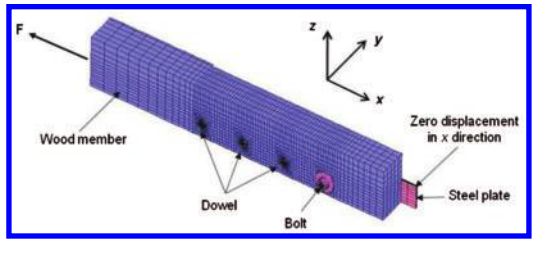

Figure 2. Meshing of a tested timber connection.

Steel is considered isotropic with elastic-plastic behaviour and its yielding is managed using Von Mises criterion. Timber is considered as orthotropic with elastic-plastic behaviour. The Hoffman failure criterion is used to control the damage evolution of timber during the load. It is an adaptation of the Hill criterion to allow unequal stresses in tension and compression.

$$\left[\begin{array}{l} C_1(\sigma_y-\sigma_z)^2+C_2(\sigma_z-\sigma_x)^2+C_3(\sigma_x-\sigma_y)^2+ \\ C_4\sigma_x+C_5\sigma_y+C_6\sigma_z+C_7\tau_{yz}^2+C_8\tau_{xz}^2+C_9\tau_{xy}^2 \end{array}\right] / F$$

$$\text{With}: C_1=\frac{1}{f_{t,90}f_{c,90}}-\frac{1}{2f_{t,0}f_{c,0}}; C_2=C_3=\frac{1}{2f_{t,0}f_{c,0}};$$

$$C_4=\frac{1}{f_{t,0}}-\frac{1}{f_{c,0}}; C_5=C_6=\frac{1}{f_{t,90}}-\frac{1}{f_{c,90}}; C_{7,8,9}=\frac{1}{f_v^2}.$$

Figure 3. Failure mode in tension parallel to grain (test and model).

The damage evolution is simulated through a reduction of the elastic modulus at the integration point where the criterion is reached (Xu et al 2009a). In order to control the plastic yielding with the damage evolution of timber, the Hoffman failure criterion, combined to the Hill yield criterion, is used in the finite element model. The contact at the interfaces between the components of the connection is managed using the deformable contact elements and the direct constraint method in MSC.Marc.

The 3D-FEM model is validated on the basis of the load-slip curves of timber connection and the failure modes.

Figure 3 shows the failure mode and figure 4 illustrates the comparison between the load-slip curves given by the 3D-FEM model and those from experiments using two models. In model 1, timber is elasto-plastic orthotropic with Hill yield criterion. In model 2, the Hoffman failure criterion is associated with the Hill criterion to control the plastic yielding combined with the damage evolution of timber. The failure load is determined when the load starts to decrease with the increase of the controlled displacement. The comparison between tests and models shows that the numerical load-slip curve of model 1 is stiffer than the experimental one. However, the model 2 predicts well the resistance of the connections. It shows a relative error less than 5% in comparison with the experimental values. Thus, this 3D-FEM model with Hoffman failure criterion is an appropriate tool to represent the nonlinear behaviour until failure of timber connections.

3 FIRE RESISTANCE OF THE CONNECTIONS

Based on the connections analyzed in normal condition, similar specimens are tested in fire conditions. The failure loads obtained in normal conditions are used to define the load to be applied on the connections during fire test using the chosen load ratio η_{fi}. Several thermocouples are introduced at different locations inside the connection members to measure the temperatures during fire tests. The thermal and the thermo-mechanical 3D-FEM models are validated on the basis of measured temperatures and the time to failure of connections.

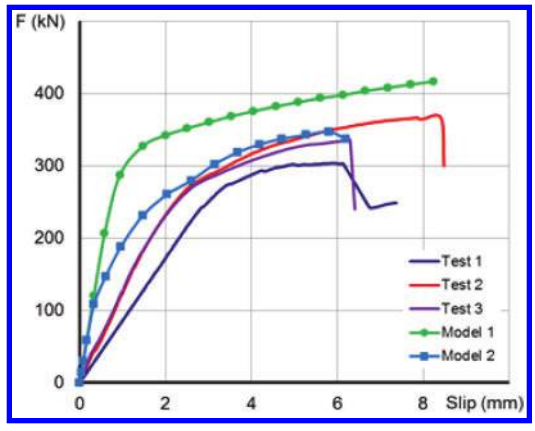

Figure 4. Comparison of experimental and numerical load-slip curves.

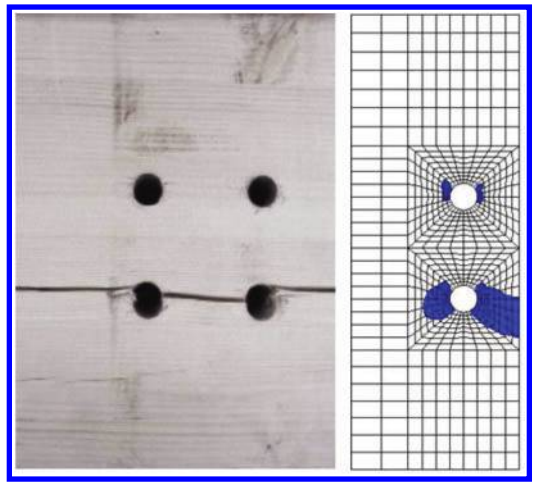

Figure 5. Failure mode in tension perpendicular to grain (test and model).

The thermo-mechanical behaviour of timber connections in fire is very complex because of the difficulty to analyze the mass transfer of water inside the wood members and the degradation of materials in fire (Audebert et al 2011, Audebert et al 2012). In the study, the evolutions of the physical and mechanical characteristics depending on the temperature are considered. Thus, the thermo-physical parameters, mainly the thermal conductivity, considered are called effective because they combine the coupled heat and mass transfers. In the approach, the thermo-mechanical problem is analyzed in two phases (König 2005). The thermal analysis is performed to obtain the temperature field inside the connection components. Then, the thermo-mechanical model is built with constant applied external load considering the evolution of the mechanical characteristics of the materials depending on the temperature.

During the fire tests, the temperature in the furnace and in various parts of the connection and the displacement between the connected members are measured.

Figure 6. Failure along the fasteners rows in tension parallel to grain.

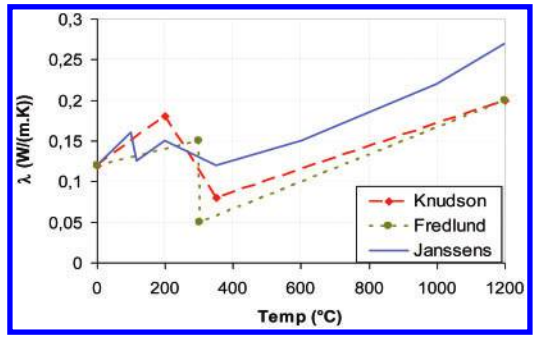

Figure 7. Thermal conductivity of wood.

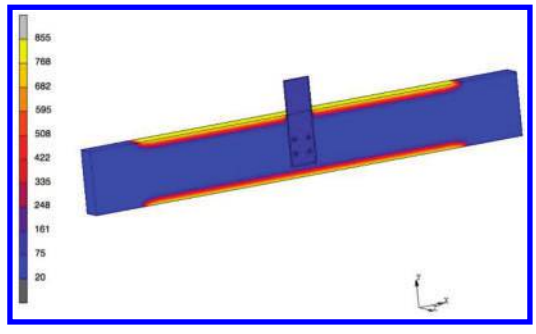

Figure 8. Temperature fields (direction perpendicular to grain, t = 30 min).

The time to failure of the connection corresponds to the acceleration of the displacement during fire exposure. The thermo-mechanical model is validated comparing its failure time with that from tests. In fire tests, the protocol for mechanical loading is defined with a pre-loading up to 40% and unloading to 10% of $F_{u,test}$, where $F_{u,test}$ is the failure load given by tests in normal conditions, the specimen is reloaded to a load ratio η_{fi} equal to 10%, 20% or 30% of $F_{u,test}$. Then, the fire exposure according to the curve ISO 834 starts. The load ratio is kept constant throughout the exposure to fire until the failure of the connection. The supports of the tested specimen are located out of the furnace where the fire action is considered homogeneous.

The obtained results show that, for all the considered loading ratios, the fire resistance is always greater than 30 minutes (Audebert et al 2011). The final failure mode observed for all the tests, in tension parallel to grain, is the shear in the wood members along the fasteners rows (Figure 6). However, the dowels showed a significant plastic deformation in bending mainly for the dowels of 12 and 16 mm.

3.1 *Thermo-physical properties of materials*

The heat transfer within the connection is modeled considering the evolutions of the apparent thermo-physical properties of wood such as the thermal conductivity and the specific heat (for example see figure 7). The well known thermo-physical properties of steel are given by Eurocode 3 (EN1993-1-2 2005). However, the evolutions of the thermo-physical properties of timber depending on temperature are taken from the bibliography. As wood is a complex material, many differences are shown in the available characteristics, particularly the thermal conductivity.

Under thermal and pressure gradient actions, a part of water vapor migrates outside the specimen and another part migrates toward the coldest parts inside the connection. This internal migration of water vapor is condensed back on a certain thickness of wood in contact with the steel plate, then, evaporates with heating. Thus, the apparent values of conductivity represent well the evolution of temperature inside wood only in the zones far from the steel plate. Some adaptations of the apparent values of thermophysical parameters are made to take account of the near the steel plate inside the connection (Audebert et al 2011, Audebert et al 2012).

A sensitivity analysis was performed to find the most appropriate thermo-physical characteristics to be used in the modeled connections. It shows that for wood components the best combination of thermal conductivity and specific heat, giving the best numerical results is obtained using the thermal conductivity values proposed by Janssens and the specific heat values proposed by Fredlund/Janssens.

An adaptation of specific heat is done to take account of the physical effects of the evaporation peak at 100°C near to steel plate playing the role of barrier. Thus a peak of specific heat to 100 kJ/(kg.°K) is taken into account in the model, for a layer of wood with a thickness of 3 mm, near the interface between the wood and the metal plate.

3.2 *Thermal model*

For the thermal calculation, it is assumed that all interfaces wood-steel plate, steel plate-fasteners and wood-fasteners are in perfect contact with continuous meshing. The faces in contact with the hot gases are subjected to thermal actions. The heat transfer modeling gives the distribution of the temperature field on the nodes of the elements constituting the connection components for each step of time or gas temperature (for example, see figure 8).

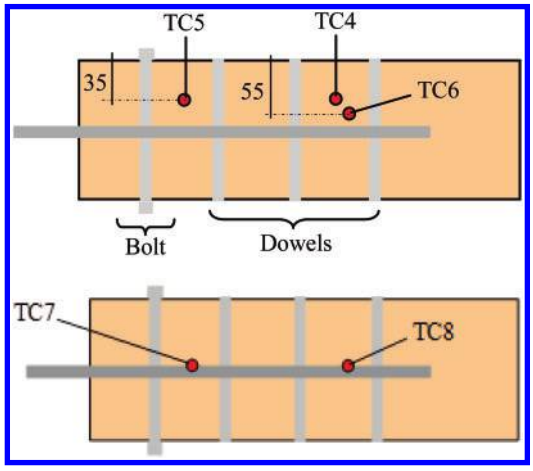

Figure 9. Thermocouple locations in wood member and metal plate.

The temperature values given by the numerical model are compared with those measured by the thermocouples in some locations in the connection along the fasteners, inside the wood members and on the steel plate. Figure 10 shows the evolution of the temperature versus time of fire exposure in the points of measurement given on figure 9.

The comparison between the temperature-time curves given by the numerical model (FEM) and the experimental results (Test) show the good accuracy of the numerical model. In wood members, the thermocouples TC4 and TC5 are located at 40 mm from the metal plate area and the thermocouple TC6 is placed at 20 mm from the interface wood-metal plate.

Differences between simulated and measured temperatures in the wood member appear beyond 300°C (Figure 10). The model does not represent accurately the temperatures in burned area. However, these differences have no influence on the thermo-mechanical behaviour of connections because the wood has no strength beyond 300°C. The measured temperatures at the metal plate area show a quasi-constant temperature between 80 and 100°C on a significant period of time confirming the barrier effect of the steel plate (Figure 10). The results obtained by the numerical model, using a local high value of the specific heat for wood, are in good agreement with the experimental values.

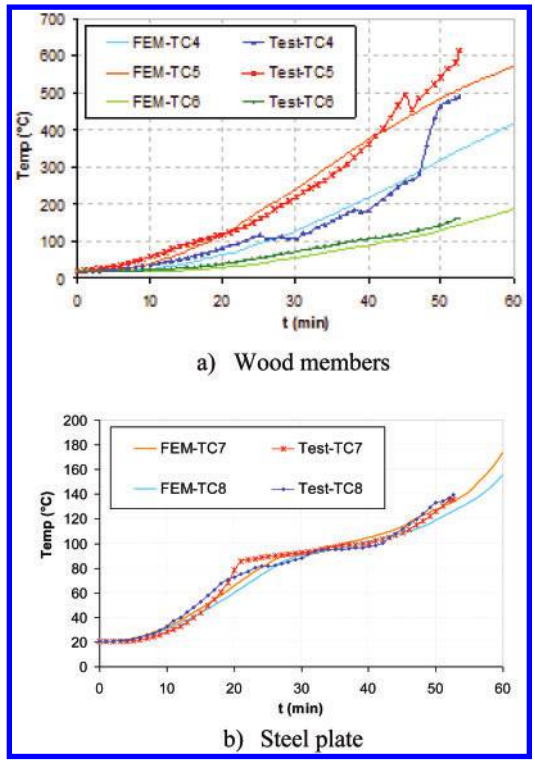

Figure 10. Numerical and experimental temperatures.

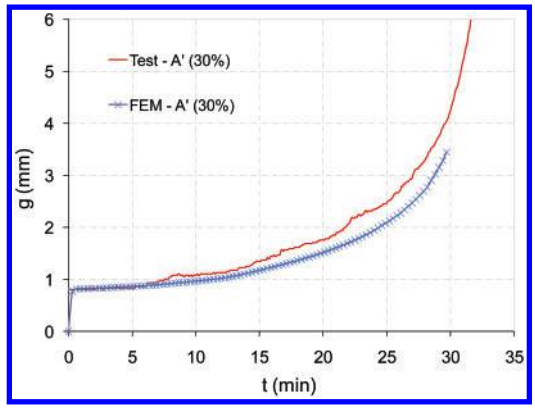

Figure 11. Time-slip comparison (FEM/test) with a load ratio of 30% (direction parallel to grain).

4 THERMO-MECHANICAL MODEL

The thermo-mechanical analysis of the connections takes into account the evolution of mechanical properties of materials depending on temperatures. This evolution is considered using reduction coefficients of the mechanical properties depending on the temperature at each point of integration in the finite elements of the mechanical model. The reduction factors used are those provided by the Eurocodes EN1993-1-2 (EN1993-1-2 2005) for steel and EN1995-1-2 (EN1995-1-2 2004) for timber.

The comparison of the fire resistance obtained by numerical model and tests is based on the evolution of the connection slip depending on the time of exposure to fire. The increment of time used in the model is constant and the duration of fire resistance is defined as the time from which there is a high increase of the slip (displacement between the connected components of the connection). These curves show comparable tendency where the numerical model represents well the linear and the nonlinear phases of the experimental slip-time curves. The model is used to predict the time

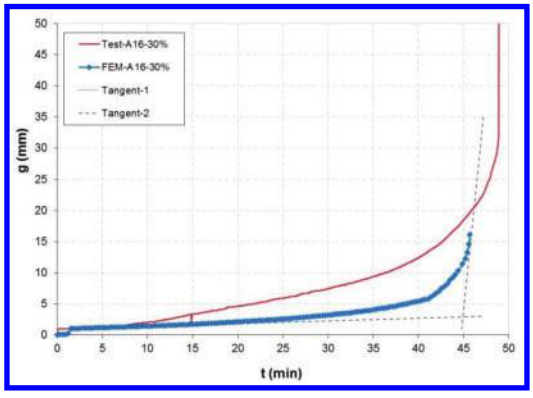

Figure 12. Time-slip comparison (Fem/test) with a load ratio of 30% (direction perpendicular to grain).

of failure of the connection exposed to fire. Figures 11 and 12 show the comparison for connections loaded in the direction parallel and perpendicular to grain.

5 CONCLUSIONS

3D-FEM model for steel-to-timber connections loaded in the direction parallel or perpendicular to grain is developed. Hoffman failure criterion associated with the Hill criterion is proposed to control the plastic yielding combined with the damage evolution of timber. The material model considers not only the asymmetric mechanical behaviour of timber in tension and compression, but also the elasto-plastic compression and the stiffness degradation governed by failure criterion with stress interactions. The proposed FEM model shows the capacity to describe the behaviour of timber connections made with dowel type fasteners. This is confirmed by the comparison of experimental and numerical load-slip curves.

The numerical model is extended to simulate the thermo-mechanical behaviour of the connections. The methodology developed for the thermo-mechanical analysis of the connection makes a distinction between the thermal and the mechanical models and use different meshes for each model. It is thus possible to create a continuous mesh for the thermal study, to guarantee the thermal continuity between the various components of the connection, and a discontinuous mesh for the mechanical calculation to take account of the contact between the different components of the connection.

The thermal model is validated by the comparison of the calculated and the measured temperatures during fire tests. The numerical model, with the chosen values of thermal characteristics, represents accurately the heat transfer in the connection components (timber, fasteners and metal plate). It should be noted that the hypotheses considered in this model, mainly the evolutions of the physical and the mechanical properties versus the temperature, have been validated for the connections considered in the study.

This 3D-FEM model is a practical tool to investigate timber connections with multiple dowel-type fasteners. It allows saving the experimental time and cost and also predicts well the stiffness and ultimate load of timber connections. Besides, there are only few 3D-FEM models for timber connections available in literature, which makes the proposed model as important contribution.

ACKNOWLEDGEMENT

The authors wish to thank the WoodWisdom-Net ERA-NET Project (FireInTimber, 2007–2010), the French Ministry of Agriculture (MAP), European wood industry through BWW Building With Wood, CSTB and Blaise Pascal University for the support provided to the study.

Shaking table tests on a large scale moment resistant timber frame with post-tensioning and energy dissipating system

F.C. Ponzo, A. Di Cesare, M. Simonetti & D. Nigro
School of Engineering, University of Basilicata, Potenza, Italy

T. Smith & S. Pampanin
Department of Civil and Natural Resources Engineering, University of Canterbury, Christchurch, New Zealand

ABSTRACT: Post-tensioned timber is a new form of seismic resisting timber construction which already has real building applications in New Zealand. The innovative high seismic performance system combines the use of precast concrete PRESSS technology and engineered wood products combining post-tensioning rods with large timber members. These two elements provide elastic recentering to the structure when subjected to horizontal seismic excitation. Additional steel dissipation devices are often also placed in order to provide additional strength and dissipative capacity. The following paper describes the dynamic testing to be performed in the structural laboratory of the University of Basilicata, Potenza, Italy on a 3-storey post-tensioned timber structure. The specimen is 2/3rd scale and made up of frames in both directions. Testing will be performed both with and without the addition of dissipative steel angles. This paper describes the testing set-up, the details of the frame, the steel angle devices and the shaking table testing program.

1 INTRODUCTION

This paper presents the design and planned test set-up for the experimental investigation into the seismic performance of a 2/3rd scale three-storey post-tensioned timber frame building in the structural laboratory of the University of Basilicata in Potenza, Italy. This work is part of a collaborative experimental campaign between the University of Basilicata (UNIBAS), and the University of Canterbury, in Christchurch, New Zealand. An extensive dynamic experimental testing programme is scheduled to be performed. The aim of the project is to further evaluate the seismic performance of the system and improve understanding of its dynamic performance in its use for multi-storey timber construction.

The post-tensioned timber concept (under the name PRES LAM) has been developed at the University of Canterbury and extensively tested (beam-column, wall/column-foundation, 3d frame and wall structure) in the structural laboratory of the university (Newcombe et al. 2010; Palermo et al. 2005; Smith et al. 2007). This testing has however solely used Laminated Veneer Lumber (LVL) a product widely available in New Zealand but not globally.

In stage one of this current collaborative project a full-scale beam-column joint was designed, fabricated, constructed and tested in the structural laboratory of UNIBAS. This beam-column joint was the first to use glue laminated timber (glulam) in post-tensioned timber construction. The experimental programme was completed midway through 2011 providing excellent results and began to answer key questions regarding system performance. During testing the application of the post-tensioned timber concept to glulam timber was confirmed. Testing was performed both with and without dissipative elements and the system displayed the same excellent performance under static and seismic loading as when the system was employed with laminated veneer lumber (LVL).

The dissipative devices used were based on yielding steel angles which activate at low drift levels, both increasing the moment capacity of the system and adding energy dissipation (reducing seismic demand through damping) without inducing plastic deformations in other elements. A new method of vertical load transfer was also designed and tested, using a hidden steel pipe to resist shear loading without hindering the rocking movement of the beam-column joint. Modelling and design procedures were also implemented and verified (Smith et al. 2012).

In stage two of the project a 3-dimensional, 3-storey timber structure made up of frames in both directions composed of post-tensioned timber is to be dynamically tested at UNIBAS laboratory considering 7 natural earthquake inputs. This paper will describe the detailing and testing set-up of the experimental model.

2 THE FACTOR β

The key to this type of system is made up of the ratio β, between the moment resistance provided by the

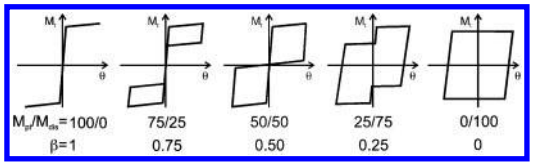

Figure 1. Influence of the factor β on moment response.

post-tensioning (M_{pt}) and the moment resistance provided by the dissipation (M_{dis}). Although a simple concept, this ratio provides the cornerstone in the understanding of system performance (Figure 1). Clearly, during design this choice affects both damping and moment capacity of the system and therefore changing this value will have a direct effect on both capacity and demand.

This experimental campaign will focus on how changes in the factor β relate to overall structural performance.

In order to do this an extensive Non-linear Time History Analysis (NTHA) in order to verify building performance under design seismic loading has been performed defining the selected test cases described in this paper. From the conception of the post-tensioned jointed ductile concept it has been clear that the nature of the controlled rocking mechanism lent itself well to the use of a lumped plasticity approach in modelling. This approach combines the use of elastic elements with springs which represent plastic rotations in the system. Description of these investigations, along with a comparison between SAP2000 (2004) and Ruaumoko (2006) structural calculation softwares is described in the companion paper by Di Cesere et al. (2013), which can be found in the conference proceedings.

3 EXPERIMENTAL TESTS

3.1 *Experimental model*

The prototype structure is three stories in height and has a single bay in both directions. All design has been performed in accordance with the current version of the Italian design codes (NTC 2008). The interstorey height of the building is 3 m and the frame footprint is 6 m by 4.5 m. The building has been designed to represent an office structure (live loading Q = 3 kPa) with the final floor being a rooftop garden. The flooring of the building is made from solid glulam panels. The lateral resistance of the building is governed by seismic loading. The test frame (Figure 2) is made from glulam grade GL32h (EN 1995-1-1 2004). A scale factor of 2/3 has been applied to the prototype structure resulting in the test specimen having an interstorey height of 2 m and a building footprint of 4 m × 3 m.

Seismic loading during testing will be monodirectional applied along the north-south axis of the building. Many of the design details developed for stage one of testing have been used in the design of the frame. The section sizes to be used in the frame

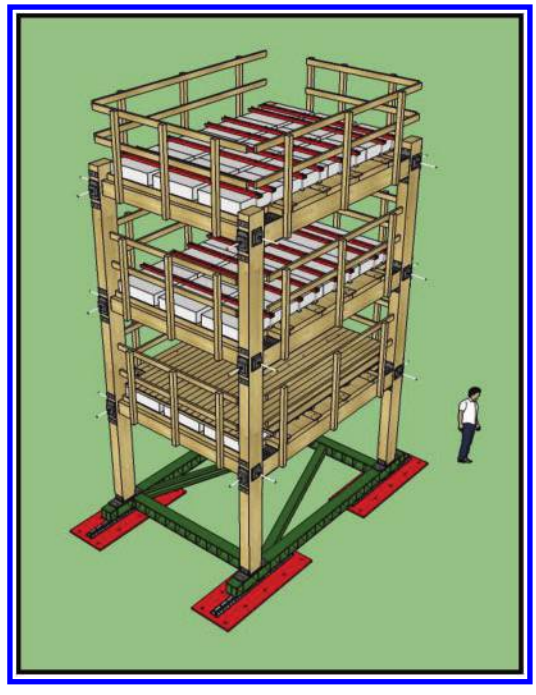

Figure 2. Rendering of test specimen.

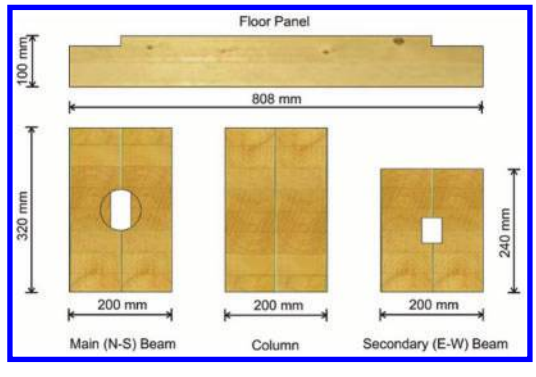

Figure 3. Section size used in PRESLAM dynamic testing.

are shown in Figure 3 with post-tensioning passing through the beams in both directions.

The flooring transfers load directly to the beams in the principle direction, therefore secondary beams are only required to provide torsional stability. The design of this type of structure can be complicated due to the rocking motion which occurs at the interface of the beam-column members during seismic loading. Rocking creates a concentrated displacement which must be accounted for in design and should not create damage to secondary members, flooring or non-structural elements.

The beam-column connection in the principle direction (Figure 4a) is based on the connection type which was tested successfully during stage one. Passing through the centre of the beam is a single 26.5 mm diameter bar which will be tensioned to varying

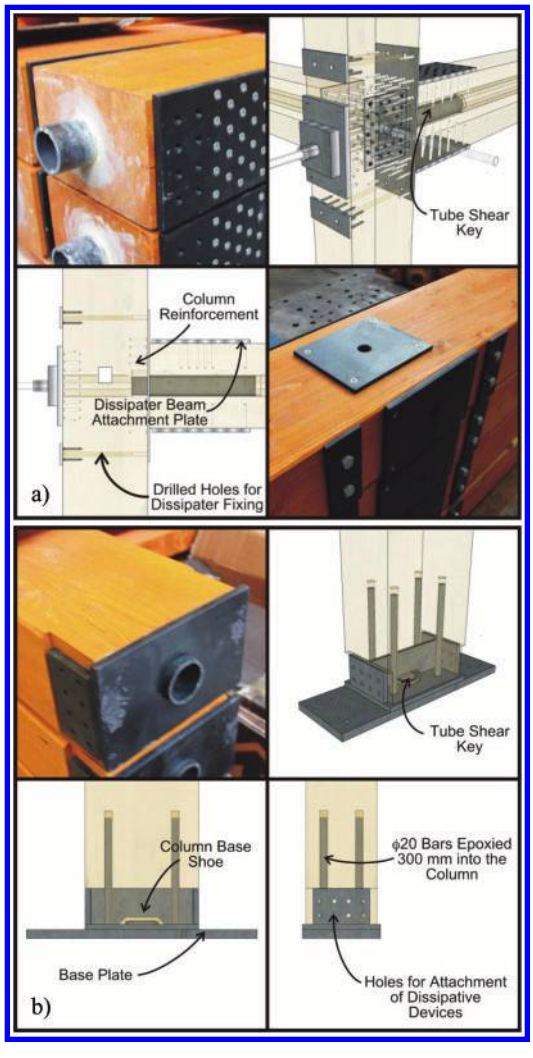

Figure 4. Details of a) beam-column, b) column-foundation joint.

values of initial loading throughout the test programme. This is a high strength steel bar with a yield strength $f_y = 1050\,N/mm^2$ and a Young's modulus of $170\,kN/mm^2$. Dissipation in the form of a yielding steel angle will be used (further described in Section 3.3). Screws have been used both to protect the column face and to connect each dissipater attachment plate. Vertical loading will be transferred through a ϕ 76.1 mm steel tube which extends 66 mm from the beam and sits inside the column. The beam-column connection in the secondary direction is similar to that in the principle direction however does not allow for dissipation attachement.

The base of the column (Figure 4b) is fitted with a steel shoe which is epoxied into the base of the column and left free to rock on a base plate (which will be used to represent the building foundations). Shear transfer is achieved using a ϕ 76.1 mm steel tube which extends

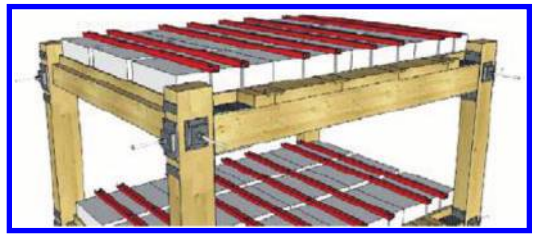

Figure 5. Additional mass arrangement for glulam test frame using concrete blocks and steel hold downs.

15 mm from the steel shoe and slots into a cavity in the base plate. Holes have been drilled and tapped in the steel shoe in order to facilitate the attachment of energy dissipation devices. In order to keep the base of the column as aesthetically pleasing as possible the steel shoe has been recessed into the column.

The floor is made from a series of deep glulam beams oriented flat-wise in order to make flooring panels running between the principal (N-S) beams. Each 808 mm wide panel is connected to the next using a 20 mm thick strip of plywood which is screwed (ϕ 6 mm, 80 mm length) at 150 mm centres. Attachment to the perimeter beams will be through the use of 16 pairs of skewed fully threaded screws ϕ 7 mm, 220 mm in length the N-S direction and 15 pairs of skewed partially threaded screws ϕ 6 mm, 240 mm in length in the E-W direction. During design the decision was made to skew these screws due to the significant increase in both stiffness and strength when a screw is placed on an angle.

Skewing of the screws in the direction of loading was also performed in order to mitigate the tearing of the flooring panel under tension during loading. As gap opening occurs the flooring panel near the gap opening is placed in tension as it is attached both to the principle and secondary beams. A section of the floor will be cut out in order to allow the attachment of dissipating devices and it is possible that stress concentrations will occur in the corner of the cut section. By significantly increasing the stiffness of the screw group in the loaded (N-S) direction when compared to those of the secondary (E-W) direction which are skewed in the opposite direction to loading, a fuse is created which will allow the flooring panel to slide over the top of the secondary beam. In order to further reduce stresses in the removed area the screw groups in both directions will begin at least 500 mm from the column.

In order to calculate the required amount of mass to be added to the test frame the masses of the prototype building must be multiplied by the scale factor of 2/3rd. Due to the fact that the frame is 2/3rd scale, mass similitude must be maintained. This is related to the use of Cauchy-Froude similitude laws which are to be used in testing. This means that additional mass must be added which will also represent the presence of a factored live load. The additional mass required is made up of a combination of concrete blocks and

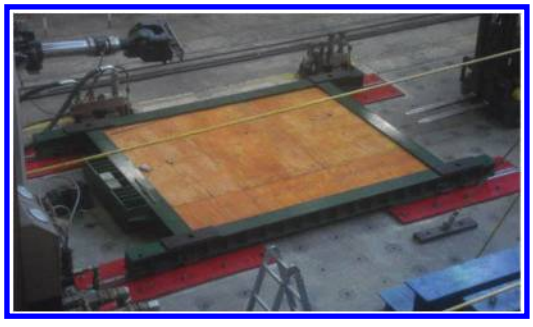

Figure 6. UNIBAS uni-axial shaking table.

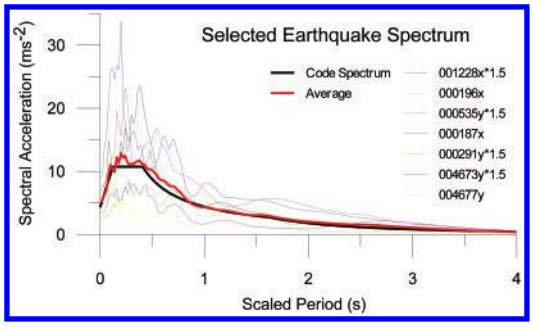

Figure 7. Selected Earthquake Input for Shaking Table Testing.

steel hold downs: 12 blocks are spread out across the flooring (Figure 5).

3.2 *Shaking table apparatus and seismic inputs*

Testing will be performed under dynamic loading in real time. This will be done using a shaking foundation testing rig. The testing apparatus consists of a shaking foundation present in the laboratory of the University of Basilicata (Figure 6). The foundation has a single degree of freedom in the N-S direction and consists of a steel frame made up of HEM300 sections. The foundation is driven by an MTS 244.41 dynamic actuator which has a capacity of ±500 kN and a stroke of ±250 mm. The actuator is fixed to a hinge at the base of the foundation and pushes against a 6 m thick strong wall. Pressure for the actuator is provided by 3 MTS SilentfloTM 505-180 hydraulic pumps. The foundation is situated upon 4 SKF frictionless sliders (Model LLR HC 65 LA T1) with one each situated under the four columns. These sliders sit upon a series of levelling plates which are adjustable to ensure that a system with a coefficient of friction of less than 1% is obtained.

The testing input will be a set of 7 spectra compatible earthquakes selected from the European strong-motion database (Figure 7). The characteristics of these are shown in Table 1. The code spectrum which was used when selecting the records was defined in accordance with the current Eurocode for seismic design (EN 1998-1:2003 2003) having a PGA of

Table 1. Earthquake characteristics.

ID Code	Location	Date	M_W	PGA (g)
001228x	Izmit, Turkey	17/08/99	7.6	0.357

Table 2. Dissipating devices.

Name	$F_{pt,i}$	β	ID angle – beam to column joint
Hybrid Cases (with the addition of steel elements)			
PT50_0.80	50 kN	0.8	ID10_2A/B
PT100_0.70	100 kN	0.7	ID5A/B

$a_g = 0.35$ and a soil factor of $S = 1.25$ (Soil class B – medium soil) giving a PGA for the design spectrum of 0.4375.

3.3 *Dissipative steel angles*

During testing passive energy dissipation devices will be added to the structure in order to add strength and reduce displacements without the increase of accelerations or base shears. 'Yielding steel angle' passive hysteretic energy dissipation devices are to be added to the frame (Di Cesare et al. 2013b) as shown in Figure 8c. The steel angle devices were applied with great success during stage one of the project, yielding at low levels of design drift and supplying high levels (up to 15% equivalent viscous damping at the joint, 10% when applied as part of a full frame) of stable hysteretic damping (Smith et al. 2011).

Two different types of steel angle have been considered (Table 2). The first of these, shown in Figure 8a, involves the milling down of a certain section of a steel equal angle in order to provide a zone of concentrated yielding. The second option, shown in Figure 8b, involves the removal of two holes in order to provide a concentrated yielding zone. The second steel device is taken from a section of square hollow section.

Throughout the testing programme several characteristic of the post-tensioned timber concept will be investigated. During the experimental campaign the size of the structural members, building layout and mass will not be altered, however different values of post-tensioning and steel moment capacity contributions (thus variations in the value β) will be investigated with the four cases shown in Table 3 being selected.

The above options are based around the standard case of PT100_1.00 which has an ultimate connection moment capacity of $M_t = 27$ kN. Adding steel without reducing the post-tension moment contribution (PT100_0.70) has the effect of both increasing capacity and decreasing demand. Adding steel in

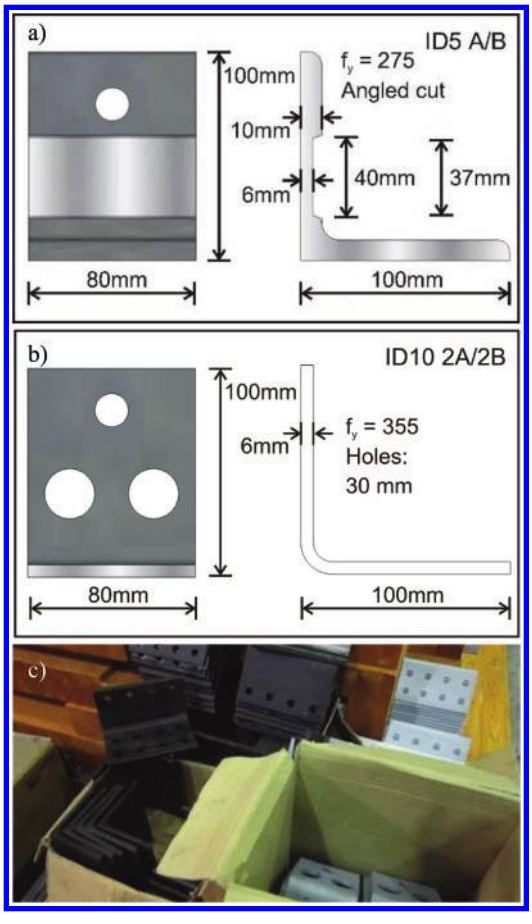

Figure 8. Steel angles considered for beam to column joint, c) Yielding Steel Angle Dissipation Devices.

Table 3. Experimental Cases.

			Moment Capacity at 2% connection rotation		
Name	$F_{pt,i}$	β	M_{pt}	M_s	M_t
Post-tension Only Case					
PT50_1.00	50 kN	1.00	22.5	0.0	22.5
PT100_1.00	100 kN	1.00	27.2	0.0	27.2
Hybrid Cases (with the addition of steel elements)					
PT50_0.80	50 kN	0.80	22.5	6.0	28.51
PT100_0.70	100 kN	0.70	27.1	13.1	40.1

combination with a decrease in post-tensioning force (PT50_0.80) decreases demand but retains equal capacity of elements.

3.4 *Fabrication of experimental model*

The fabrication of the frame (Figure 9a and 9b) was performed by Holzbau Sud SpA in Calitri, Italy. Although the beam and column were of the same

Figure 9. a) Beams pressed together, b) secondary beams fabricated, c) Timber elements with plates in UNIBAS laboratory.

dimension slightly different methods of fabrication were used. Due to the presence of the space inside the beam section to accommodate the post-tensioning tendon two separate sections were glued together after a hollow was made in each part using a computer numerical controlled (CNC) woodworking machine. The column was made of a single piece of glulam in which a hole was made for the tendon to be placed.

Timber elements have been fabricated off-site and arrived with all plates attached (Figure 9c) rendering the building truly modular.

4 CONCLUSIONS

An extensive dynamic experimental testing programme on a multi-storey timber frame building is scheduled to be performed in the structural laboratory of the University of Basilicata in Potenza, Italy. The aim of the project, in collaboration with the University of Canterbury in Christchurch, New Zealand is to develop the innovative post-tensioned timber concept (under the name PRES LAM) by extending its application to glulam timber and steel angle devices. In addition important knowledge regarding the systems dynamic behaviour will be obtained through dynamic testing.

Mono-directional shaking table testing will be performed on a 3-storey single bay frame scaled to 2/3rd. The dynamic testing input will be a set of 7 spectra compatible earthquakes selected from the European strong-motion database. In this paper the design and

detailing of the 2/3rd scale post-tensioned frame has been presented along with the details of the testing set-up. Testing results under dynamic conditions will provide additional information for the design of this innovative method of timber construction.

ABSTRACT: Fracture processes due to the natural drying of green wood slices are investigated by experimental, analytical and numerical methods. The shrinkage of Douglas fir slices is observed in a test room where the environmental conditions are constant. In order to take into account stress relaxation coupled with hygrothermal effects, an ageing elastic behavior, including shrinkage–swelling effects with inhomogeneous properties in the radial and transversal directions, is considered. Results obtained from the experimental approach are compared with numerical modeling to predict crack growth initiation in a cylindrically and orthotropic material tree disk. The efficiency of the proposed model in the prediction of drying and fracture processes in wood material is proved.

1 INTRODUCTION

Among several building materials, the wood brings many responses in the regulation of environmental effects. Then, the use of the wood materials in engineering development or in timber structures appears very important. However, the wood material is difficult to understand due to its many complex behaviors (Saifouni et al. 2013). In addition, these behaviors are improved when the material is submitted to moisture content variation. In fact, the natural or artificial shrinkage due to drying is commonly responsible of strains and crack appears in wood peaces (Omarsson et al. 1998). Moreover, the initial crack presence after drying process can decrease the timber structure lifetime by inducing stress concentrations and the crack propagation.

The literature's background shows that the strain and the evolution of drying-induced stresses in wood are studied in terms of analytical (Cave, 1972; Husson et al. 2010), experimental (Kowalski and Smoczkiewicz, 2007; Moutou Pitti, 2012) aspects. Among them, Kowalski et al. (2004) have presented a model of drying that permits evaluation of moisture content distribution in dried wood during the drying rate periods with the acoustic emission method (AE). In numerical approaches, Dubois et al. (2012) have proposed a numerical model taking into account mecano-sorptif and cracks effects during relaxation loading. In the present work, the image analysis technique (Peuchot, 1993), is applied in order to measure the mechanical fields in a drying wood slice. A numerical model is developed for evaluating strain distributions according to transverse orthotropic and a mechano-sorptive approach inducing strain blockings during drying phase. This model then extrapolates stress distributions until the crack appear.

The first part presents the protocol and the experimental device. The green wood slice is directly placed on an electronically balance providing the weight measure versus time. In parallel, the mark tracking method composed of an acquisition system data, records the displacement of target posted on the sample surface during the drying phase. The second section deals with the analytical approach about the strains calculations. The method is based on a mathematical model coming from cylindrical strain calculations. The finite element routine and the incremental approach have shown in the last part. The model is based on a mechano-sorptive concept in which a hygro-lock

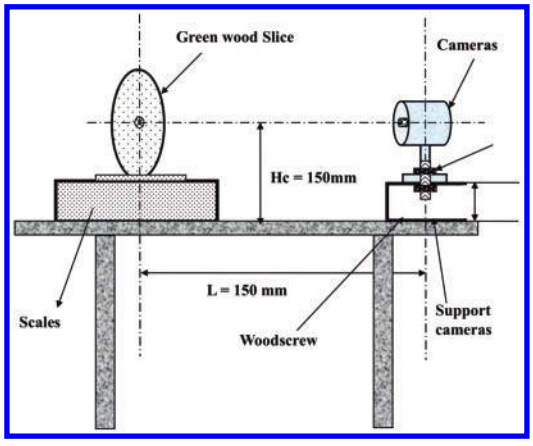

Figure 1. Experimental device (Moutou Pitti et al. 2013).

model is activated. Then, the experimental and numerical tangential strains are compared. Simultaneously, the identification of crack initiation is justified.

2 MATERIALS AND METHOD

2.1 *Description of materials and methods*

A green wood slice, debited on a peace log with an electric saw is placed on a sensitive scale, Figure 1. The sample is initially conditioned in water in order to assure its saturation. A flat of 40 millimeters is machined on the basis of the slice in order to assure stability on the side of the scale. Hence, the specimen is positioned on the experimental table, taking care to ensure its horizontality. The height between the table and axis of the camera and the slice center is hc = 150 mm. Also, the camera was immediately placed on a slidable support fixed on the table in order to reduce any disturbances due to external shocks. This ensures that the axis of the camera is absolutely horizontal and the distance between the between the actual text and figure (including caption). Seat of it and the specimen on the side of the scale is 100 mm (± 20 mm). Note that the distance between the axis of the slice and the axis of the support camera is L = 150 mm.

2.2 *Experimental protocol*

The experimental protocol is based on a green wood slice in Douglas fir with a thickness of 30 mm just peeled, Figure 2(a). In this picture, the left side of the slice corresponding to the hardwood region, and the right side represents the normal wood. The preparation of the specimen consists on draw black marks according to a polar reference centered at the sample heart. A marking tracking protocol is implemented in order to record displacements of these marks using the videometric technology (Peuchot, 1993), figure 2(b). Note that 23 images are recorded per second, with an automatic record of five seconds every 2 hours in order to reduce storage requirements of images during the

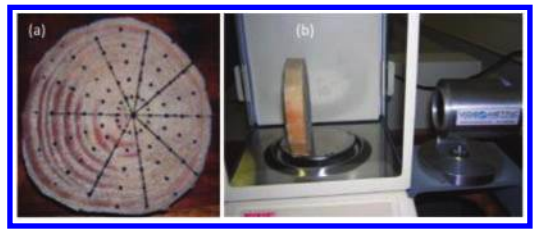

Figure 2. (a) Green wood slice and black marks. (b) Experimental device (Moutou Pitti et al. 2013).

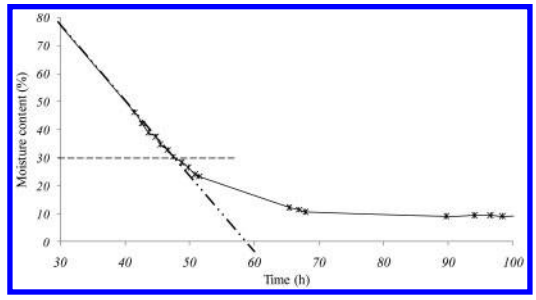

Figure 3. Fibre saturation point (FSP) localisation.

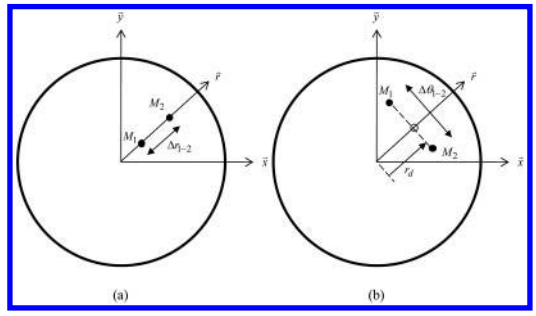

Figure 4. Referential radial (a) and tangential (b) representation.

test. The specimen is placed on a precision balance in order to measure the masse evolution during the drying process.

2.3 *Fibre saturation point*

Assuming that the fibre saturation point gives a non-linearity on the time – moisture content curve, an estimation for the specific moisture content value of 30% (figure 3) corresponding to the fibre saturation point limit is obtained.

2.4 *Analytical approach*

2.4.1 *Referential cylindrical coordinate*

In order to identify each black mark, Figure 4 proposes a notification by the intersection between radiuses and rings.

The radial strain is show by figure 4(a), where Δ^r_{1-2} is the length between M_1 and M_2. The tangential strain is defined by figure 4(b), where $\Delta\theta^r_{1-2}$ is the distance

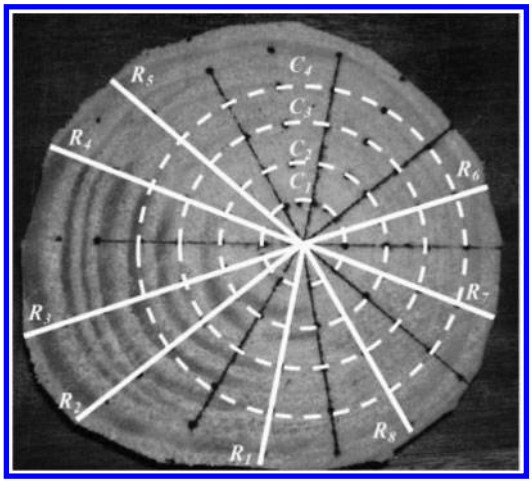

Figure 5. Radius and rings.

between M_1 and M_2 that $\vec{r}$ is their symmetric axis. r_d is the distance between the referential origin and the projection of the two points on $\vec{r}$.

For example, the mark M_i^j traduce the point at the intersection between the radius R_i and the ring C_j. Let us note that radial and tangential strains are defined at the middle point comprised between M_1 and M_2. With this consideration, the radial strain is calculated at the point M_2^{1-2} corresponding to a point placed in the radius n°2 and between rings 1 and 2, figure 4 (a) and 5. With the same way, the tangential strain is calculated at the point M_2^{2-3} placed in the ring n°2 and between radiuses 2 and 3, see figure 4(b) and 5.

2.4.2 *Strain analytical computation*

The mark tracking method calculating the displacement field in a Cartesian's referential (U_x, U_y), it's necessary to project this field in the polar system. In order to identify the crack initiation, only the tangential strains have been considered in this work. In this condition, we note the following transition formula

$$U_\theta = U_x \cdot \sin\theta - U_y \cdot \cos\theta \tag{1}$$

U_θ is the tangential displacement components, respectively. The tangential component of the strain tensor called $\varepsilon_{\theta\theta}$ is defined by

$$\varepsilon_{\theta\theta} = \frac{1}{r} \cdot \left(\frac{\partial U_\theta}{\partial \theta} + U_r \right) \tag{2}$$

According to figure 4(b), the tangential component can be evaluated as follow

$$\varepsilon_{\theta\theta} = \frac{1}{r_d} \left(\frac{U_\theta(M_1) - U_\theta(M_2)}{\Delta\theta_{1-2}} \right) + \left(\frac{U_r(M_1) + U_r(M_2)}{2} \right) \tag{3}$$

Figure 6 shows tangential strain evolution between the intermediary radius R_1 and R_2. The tangential strains are on the whole in compression, which increases during the drying process. Heterogeneity can be observed around the crack initiation vicinity

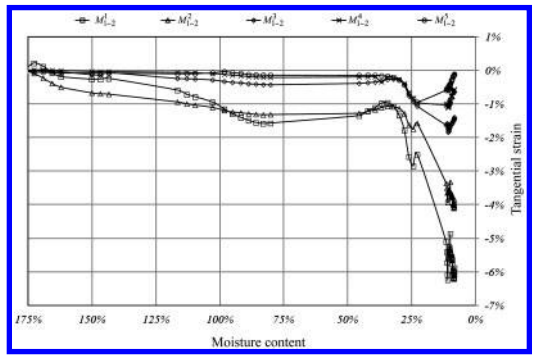

Figure 6. Tangential strains between radiuses R_1 and R_2.

(R_1, R_2). At around 18% moisture content, we can observe a jump in tangential strain near radius R_1 near the sample edge, which can be explained by crack growth initiation.

3 FINITE ELEMENT APPROACH

3.1 *Drying model and incremental law*

The coupling between moisture content variations and mechanical behavior is based on the addition of shrinkage-swelling response and mechano-sorptive behaviour. During drying process, Husson et al. (2010) have shown one hygro-lock effect affecting elastic and viscoelastic responses. In this study, let us limit our investigation for elastic properties with a time decreasing of elastic modulus with an uncoupling between elastic behavior and shrinkage process represented by the elastic and shrinkage deformations ε_e and ε_w. In this case, the mechanical model can be assimilated at a Bazant's (Bazan and Carol, 1993) model according to a hardening behavior during drying phases. The mechanical behavior representing the drying model written in terms of strain rate ε_w as follow:

$$\dot{\underline{\underline{\varepsilon}}}(t) = \mathrm{C}(t) \cdot \dot{\underline{\underline{\sigma}}}(t) + \underline{\underline{\alpha}} \cdot \dot{w}(t) \tag{4}$$

The total stress rate tensor is called $\underline{\underline{\sigma}}$. $C(t)$ is the four order compliance tensor adapted for a cylindrical orthotropic properties. In a 2D representation, C can be defined according to elastic moduli such as:

$$\mathbf{C}(w) = \begin{bmatrix} \frac{1}{E_R(w)} & -\frac{\nu_{RT}}{E_R(w)} & 0 \\ -\frac{\nu_{RT}}{E_R(w)} & \frac{1}{E_T(w)} & 0 \\ 0 & 0 & \frac{1}{G_{RT}(w)} \end{bmatrix} \tag{5}$$

$E_R(w)$, $E_T(w)$ and $G_{RT}(w)$ are the radial, tangential and shear modulus, respectively. $\upsilon_{RT}(w)$ is the Poisson's ratio.

$\underline{\underline{\alpha}}$ is the shrinkage-swelling expanse tensor. In the orthotropic referential, this tensor is diagonal. In this study, we assume a constant tensor in the hygroscopic domain. $\dot{w}(t)$ is the moisture content rate.

The implementation of the behavior law, expressions (4), requests its moisture content integration in the global RT base. By analogy with Randriabololona's developments (Dubois and Randriabololona 1997), the equation (4) can be solved using the following finite derivation method solving according to Ghazlan approach (Ghazlan et al. 1995)

$$\Delta\underline{\underline{\varepsilon}}(t_n)=\left[\frac{1}{2}\cdot\Delta C(t_n)+C(t_{n+1})\right]\cdot\Delta\underline{\underline{\sigma}}(t_n) +\underline{\underline{\alpha}}\cdot\Delta w(t_n) \quad (6)$$

where $\Delta\sigma$ and $\Delta\varepsilon$ are the stress and the strain increment, respectively.

In order to solve equation (6), the following finite element formulation, proposed by Ghazlan, is applied:

$$K_T\cdot\{\Delta u\}(t_n)=\{\Delta F^{\sigma}_{ext}\}(t_n)+\{\Delta F^{w}\}(t_n) \quad (7)$$

where K_T is the tangent matrix defined by using the Jacobian matrix B connecting displacements and strains and the equivalent compliance tensor present in expression (5) such as:

$$K_T=\int_{\Omega}B^T\cdot\left[\frac{1}{2}\Delta C(t_n)+C(t_{n-1})\right]^{-1}\cdot B d\Omega \quad (8)$$

$\{\Delta F^{\alpha}_{ext}\}(t_n)$ is the increment of nodal force vector induced by the external increment loading and incremental stresses $\Delta\sigma(t_n)$. $\Delta\underline{\underline{\sigma}}(t_n)$ designates the supplementary moisture content load vector representing the effect of moisture content variations in the time step.

3.2 *Finite element routine*

In order to implement the incremental law (4) in finite element software Castem, the following subroutine is applied.

Firstly, the referential state corresponding to the fiber saturation point is fixed. If we ignore growth constraints and relaxation effects after the tree felling, we can impose $\underline{\underline{\varepsilon}}(t)=\underline{\underline{0}}$ and $\underline{\underline{\sigma}}(t)=\underline{\underline{0}}$. In the same time, we admit an initial moisture content homogeneity w_{ini} in the disk surface and in this thickness. For each algorithm step, we consider, firstly, that mechanical state is known at time t_n and t_{n+1}, in the other hand, that moisture content variation is measured by weighing for the time t_i.

The compliance tensor C is updated according to the moisture content w. All terms of the equilibrium equation (6) are defined. The tangent matrix (8) is calculated and the balance equation (7) is solved by the finite element process. Mechanical state is updated in terms of displacements, strain and stress tensors. The crack growth initiation is detected by comparing the transverse component of the stress tensor and its critical value.

Table 1. Elastic properties.

E (MPa)	E (MPa)	G (MPa)	ν
1300	900	125	0.39

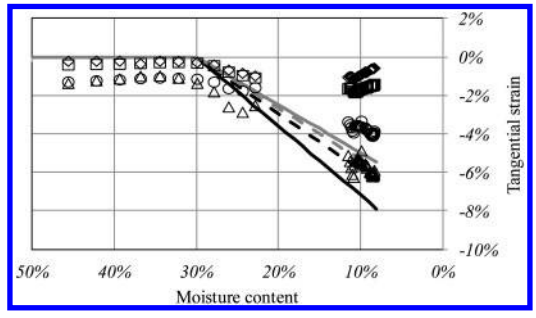

Figure 7. Experimental and numerical tangential strains.

4 TANGENTIAL STRAINS AND FRACTURE ANALYSIS

4.1 *Finite element mesh*

The finite element mesh is obtained according to an overall positioning system centred on the specimen heart, enabling the definition of the centre of the cylindrical orthotropic reference. The contact surface between specimen and balance is operated by blocking its vertical displacements. A reference point is also blocked vertically in order to eliminate a rigid body displacement. Specific lines (radius and crowns) have been integrated into mesh in order to have a concordance with the experimental black mark displacements, figure 5.

In the numerical process, the Poisson's ratio is assumed to be constant. The elastic properties of Douglas fir at w = 12% are given by the Table 1.

Elastic properties must be corrected by taking into account a linear formulation versus moisture content such that

$$E_{\alpha}=E^{0}_{\alpha}\cdot\left(1-0.03\cdot(w-12)\right) \quad (9)$$

Also, the shrinkage–swelling coefficients values are given by Guitard (1987): $\alpha_R=0.08\%$ and $\alpha_T=0.35\%$.

4.2 *Tangential strains*

According to the finite element routine detailed before, the green wood slice, presented in figure 5, is implemented in finite element software

Figure 7 shows the comparison between experimental and numerical results of tangential strains along the radius R_1. We note that the maximum strain is around 8% traducing the coming crack due to the drying process.

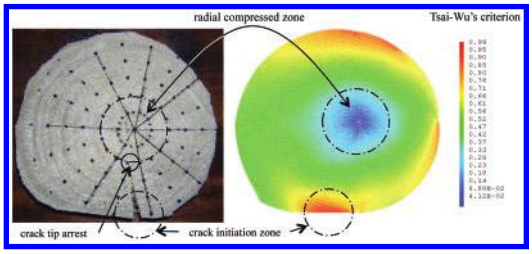

Figure 8. Crack initiation zone.

4.3 *Crack process*

4.3.1 *Crack growth initiation*

The crack growth initiation phase can be studied using an elasticity limit criterion, like Tsai or Hill (Tsai and Wu, 1971) have done, based on the combination of stress tensor components. In a plane stress configuration, the criterion can take the form of the following function f such that

$$f = \frac{<\sigma_{RR}>^{+}}{\sigma_{RR}^{c}} + \frac{<\sigma_{TT}>^{+}}{\sigma_{TT}^{c}} + \frac{|\sigma_{RT}|}{\sigma_{RT}^{c}} \quad (10)$$

σ_{RR}^{C}, σ_{TT}^{C} and σ_{RT}^{C} are critical values for radial, tangential and shear stresses, respectively, corresponding to the uniaxial elastic limit and fracture initiation assuming a brittle fracture process. The notation $< >$ designates the positive part of fields corresponding to tension parts. The criterion inducing crack initiation can be written as follows:

$$f < 1: \text{ no crack; } f = 1: \text{ crack propagation } f < 1 \quad (11)$$

The combination of tangential and shear stresses illustrates that crack growth initiation is based on a coupling between tangential tensions and shear state, depending on a mixed mode configuration.

In fact, by considering the Tsai-Wu's criterion, equation (10), figure 8 shows a stress concentration in the crack growth zone vicinity given by a finite element computation.

The radial compression state can explain a local mechanical containment that hinders the process zone development in front of the crack tip. This fact can explain the crack tip arrest at the limit between the tension and compression zones.

5 CONCLUSIONS

The strain evolutions and the crack growth initiation have investigated during the drying process in this work. The changes of tangential or circumferential strains versus the distance to the slice centre for different moisture have been studied. These strains are computed by defining a local orthotropic referential. During the evolution of moisture content between the FSP level and its critical value inducing the crack initiation (w = 11.48%) the numerical and experimental results illustrate a very good agreement. In the same time, the finite element model allows the localization of the crack initiation during drying process. In the coming work, the fracture analysis will apply and coupling with the viscoelastic model and the drying model in order to study the behavior of wood material under environmental variations crack growth processes.

The resilience of timber buildings

George Faller
Ove Arup and Partners SAU, Madrid, Spain

ABSTRACT: The issue of resilience of buildings is becoming an important consideration in the design of the built environment. The drive for more sustainable design has awaked a new interest in timber as a structural material due to its low or negative carbon emissions. A large body of work has been going into research into the performance of timber to get a better understanding of the robustness, structural stability, reaction to extreme natural conditions such as flooding, fire and seismic activities. The low weight-to-strength ratio of timber is being utilsed by developing industrialized off-site fabrication and quick construction techniques. A good case for timber for a resilient alternative is being made. More work however needs to be done to fully understand its capabilities, and also to explore its capacity to address a further characteristic of resilience; the ability for quick repair and re-use of the building.

1 INTRODUCTION

1.1 *The built environment*

As engineers for the built environment when looking at the building stock for the future we would want to see buildings with the following characteristics; buildings that are:

- Sustainable in construction and use
- Robust and structurally sound
- Resilient to occasional extreme natural events
- Safe for occupants and emergency services in fire
- Durable and with flexibility of use
- Easily restored to full use after an extreme event

When we consider what building materials are used for our buildings today we can observe that timber is one of the most traditional building materials, and yet it has only a 5–10% share of the construction market. The nineteenth and twentieth centuries saw the rise and dominance of steel and concrete as structural materials; this paper explores the case for a return to timber as one of the prime construction materials for the twenty first century.

The question of how timber measures up as a structural construction material and how it meets the multiple performance characteristics and usability requirements is discussed below.

2 TIMBER CONSTRUCTION

The intention of this paper is not to promote timber as a construction material that is better than other more traditional materials per se, but rather to explore where timber may provide a better solution on its own or in combination with other materials. It has tended to be ignored in evaluating alternative solutions by many structural engineers at concept design stage for a large range of typical building types. As new drivers begin to shape decision making as to which structural materials to recommend for a project, the relative advantages of using timber are changing.

2.1 *Sustainable construction and use*

A significant percentage of the total energy consumption during the typical lifetime of a building is related to the embodied energy of the structure and building fabric (typically 15–25%). The carbon emissions due to the production of the timber components for construction are usually small compared to other building materials, and represent net negative emissions in a 'cradle to gate' scenario (i.e. more CO_2 fixed in the new building than given off in the production process). This assumes use of timber from sustainable (renewable) sources of course. In addition to that timber is a 100% renewable material, reducing its carbon footprint further. Even in the 'cradle to grave' scenario, allowing for disposal of the timber at end-of-life, timber typically performs better than other construction materials regarding net emissions.

Another consideration to take into account is the ease of transport to site due to the relative lightness of the material. The main components of timber buildings are typically manufactured off site and the components transported to site for quick erection. The advantages of this type of construction are many; it results in savings and reductions in accidents on site due to easier handling, faster erection times and minimization of wet trades, and minimizes the requirement for storage of combustible materials on site.

Therefore when considering the use of timber from a sustainability point of view, little more needs to be said.

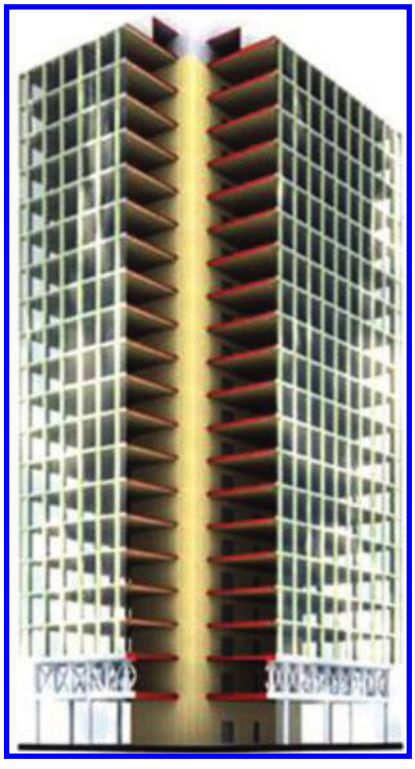

Figure 1. The Life Cycle Tower structure.

2.2 *Robust and structurally sound*

Over the past few centuries timber became seen as a 2nd rate structural material, a material more associated with low-rise buildings of little importance. The limited use of timber was largely related to the code limitations on maximum height, which arose out of fire safety considerations. Timber was seen as a combustible material, and as such not capable of providing the robustness demanded of larger and more valuable buildings that would stand the test of time.

As a result timber was largely ignored during the period in the 18th and 19th centuries when great technical advances were being made in understanding the material properties of construction materials and developing a better understanding the structural behaviour of structures under different loading conditions. With the recognition of the potential contribution of timber to sustainable design, this has changed and a number of research projects have been initiated to investigate the potential of timber as a structural material.

One of such projects is the Life Cycle Tower (LCT) project in which Arup participated, together with developer Rhomburg, the University of Gräz, timber contractor Wiehag and architect Hermann Kaufmann. The objective of the project was to demonstrate the feasibility of a commercial timber high-rise construction of 20 storeys in a densely populated urban context at detail design level (Figure 1). It sought also to demonstrate that this type of building could be built of timber without compromising on performance when compared to a steel or concrete building.

The main structural components of this prototype building with plan dimensions of 27 m wide × 43 m long were:

- Nucleus of solid load bearing glulam panels, 16 to 30 cm thick, providing structural stability and enclosures for lifts, stairs and service risers
- Solid timber glulam perimeter columns on a 2.7 m grid
- Composite concrete timber flooring system, the introduction of a light concrete topping was primarily to address acoustic issues.

This project demonstrated the structural feasibility of timber structures for high-rise buildings, and indicated a large unrealized potential for the use of timber in buildings.

Numerous other timber structural systems have been developed in parallel to the glulam component solution, such as cross laminated panel (CLT) system, which further demonstrate the versatility of timber as a structural material.

3 RESILIENCE OF TIMBER BUILDINGS

When talking about resilience in a more general sense there are many definitions of what it is, but what most have in common is that central to defining resilience is:

"the ability to withstand a severe/extreme event (shock) and recover".

Incremental change or disturbance including trends and seasonality however may also be the cause of stresses that occur over a longer period than shocks (Department for International Development, UK, 1999).

In the context of buildings resilience could be seen as an ability to withstand the effects of earthquakes, extreme winds, flooding and fire, and their ability to be quickly returned to normal use after such an event. Resilience of buildings to these events is increasingly being seen as an important design objective for all types of buildings.

3.1 *Extreme winds and seismic events*

Timber systems, due to their ability to deform while maintaining load carrying capacity, behaves well under seismic loading, but until recently not much work had been done to study the seismic behavior of medium- to high-rise timber structures. Over the past few years work has been done by the University of Canterbury (Buchanan, Palermo, Carradine & Pampanin 2011), to develop structural systems for timber using post tensioned self-centering vertical LVL wall panels to counter seismic loading, and Arup has collaborated on parts of this research. These systems make use of mild steel connections between the post-tensioned elements that act as energy dissipaters under extreme loading conditions, such as those resulting from seismic effects.

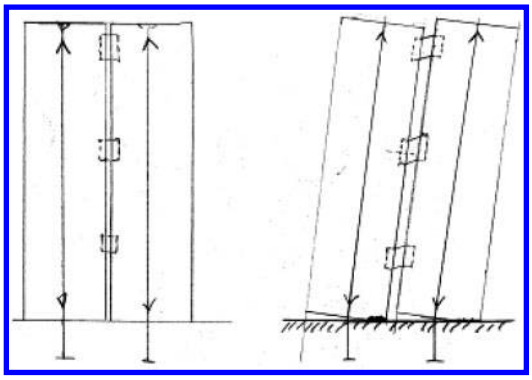

Figure 2. Self-centering post tensioned shear wall panels.

Figure 3. Shear walls with energy dissipaters linking panels.

Others such as the University of Columbia and CNR-IVALSA in Italy are investigating the use of load dissipating shear wall connectors without post-tensioning as alternative systems to address seismic and extreme wind loading.

3.2 *Flooding*

One of the drawbacks to timber as a structural material is the possibility of fungal decay of the material, which can occur under high moisture conditions in the timber. Any design solution for timber must take measures to prevent this, which normally takes the form of a plinth structure of moisture resistant material (e.g. concrete) and a weather tight exterior façade enclosure. Detailing must also be such that excessive internal water vapour or the possibility standing water in unseen cavities is eliminated.

Extreme weather conditions could result in flooding that result in the structure being exposed to water above the plinth designed to keep the timber above the moisture line. This occasional flooding should not be detrimental to the timber structure provided that adequate detailing is provided to drain the excess water after the incident without leaving any standing water in concealed spaces.

3.3 *Fire resistance*

Fire safety code limitations on the maximum height of buildings in the past, which limited the use of timber as a structural material for buildings over a certain height, have also resulted in a lack of research and development into timber structural solutions. These restrictions came about as a response to incidents in the past, without much differentiation between types of timber construction and the design application.

For timber particularly the fire safety measures governing its use have been based on gut feel reaction, without much scientific work to back them up. Prescriptive code requirements that govern the use of timber in many countries have not evolved in the same way as for other materials due to minimal demand for its use in many types of structure.

The introduction of a performance based approach to fire safety design in many countries towards the end of the 20th century has removed the legal height restriction. In this new legal environment, if it can be shown that the structure can meet all the stipulated performance requirements in the fire condition, including fire spread considerations and structural stability when subject to all plausible fire scenarios, then it can be considered as an acceptable solution. In other words, instead of applying a recipe of fire safety measures that may or may not be appropriate for the given case, a more rational engineering approach has been recognized as a valid alternative.

The shift towards a performance based environment has led to a spate of pioneering work in the field of fire safety design for timber structures over the past few decades, which has shown that timber buildings can be designed to be safe in fire.

For the 20-storey LCT building referred to above, the research project focused on numerous structural issues, but also on structural fire safety issues. In this programme there were three principal areas that were investigated that were of particular interest to fire engineers:

i The char rate of the solid load bearing glulam panels and solid timber columns
ii The performance of the solid glulam timber columns in fire
iii The performance of the composite lightweight concrete-timber slab panels

The behavior of the solid timber elements is well understood and the traditional way of ensuring continued structural stability after a certain period of fire, is to provide a sacrificial char layer which is assumed to provide no load carrying capacity. With the solid glulam panels in the LCT project it was found to be more economical to provide a plasterboard lining to the glulam load bearing panels than to provide additional thickness to the panels in order to achieve the 90-minute fire rating required for the core structure. The plasterboard lining also helped to address some acoustic issues, so this was felt to give the optimum solution.

Figure 4. Composite concrete-timber slab panel after 90-minute standard fire test.

The solid glulam columns on the other hand were provided with sufficient thickness of sacrificial char layer to resist the design fire duration. However the designers wanted also to address the issue of combustibility of the timber and the possibility of late fire brigade intervention, so a fiberglass 'interlayer' fabric was devised that could be inserted between the residual column section and the sacrificial layer in the build-up of the glulam column. This was intended to prevent the fire from progressing beyond the sacrificial layer even if the fire was not put out by the fire fighters.

The effectiveness of this measure has been tested theoretically, but further large scale testing is required to confirm that it can achieve the objective of halting the fire penetration into the core material.

A composite concrete-timber floor was developed for this project and was tested for acoustic and fire performance. The main function of the concrete topping was to address the acoustic issues, to which timber flooring systems are prone. It was also subject to full scale fire testing to determine its performance subject to a 90-minute standard fire.

The timber beams were mechanically connected to provide some shear connection but the shear resistance was provided principally by a glued interface, with the timber beam glued to the underside of the concrete topping. It was feared that due to the different rates of thermal expansion, a banana effect could develop that would cause the timber to peel away from the concrete topping or that the glue connection to fail. This did not happen and the tests demonstrated adequate performance in the fire condition.

The research and testing behind the development of the design for this 20-storey prototype building demonstrated that the fire safety requirements for structural timber even if applied to high-rise buildings can be met.

4 FLEXIBILITY OF USE

A sustainable and resilient building should be capable of being used for many different uses over its lifetime. One of the drawbacks of the timber panelized solutions is that a large number of structural walls can be needed for vertical load transfer and lateral stability. This limits the flexibility of use as the internal layout is fixed by the structural solution. Furthermore the panelized solution does not provide simple vertical load paths down to the foundations which can be problematic when considering lateral loading such as that due to wind on the building. It is not ideal either for design against seismic effects, for which the simpler the vertical load path, the easier it is to deal with the large horizontal forces induced in a seismic event.

Work has been done at the University of Canterbury to address this issue with the use of open post-tensioned timber moment frames (Buchanan, Palermo, Carradine & Pampanin 2011).

Unbonded post tensioned cables inserted in timber box beams are also capable of increased spans that allow more free space within the building. The beams can be used spanning continuously over columns to create moment resisting timber framed structures that can provide large free interior spaces. This allows the interior space to be divided up by non-structural partitions to suit the intended use, and it can then be easily modified for later alternative uses.

5 REDUNDANCY AND RE-USE

Another consideration for a resilient building is to consider how easily the building can be restored for use after an extreme event or other type of shock loading.

In the development of structural solutions for timber buildings a lot of effort has gone into developing designs that use an industrial process and systems approach. Using this approach the timber building components are manufactured in factories off-site and then transported to site and crane lifted into place and secured using quick fastening connection details. The relative lightness of the timber components lends itself to this approach, it avoids the need for storage space on site and it saves a lot of time in the construction process.

Panelized buildings however raise the question of progressive collapse, and the designer would normally be obliged to consider the redundancy of the structure by considering the failure of any one structural component and ensuring continued stability under these conditions. The designer would assume that damaged panels offer no further structural resistance and would have to show that stability is maintained under these conditions.

To take into account the ease of re-use this type of study needs to be extended to a study for the removal and replacement of the damaged component, particularly for timber wall panels spanning vertically and picking up loads from multiple floors.

According to the definition of resilience outlined above, a resilient building should also be capable of being returned to full use as soon as possible after an event that partially damages the structure, be it

due to a natural extreme event, a blast event or other unexpected impact.

Many countries would lack the expensive presses necessary to sandwich, glue and cure the wood into glulam or CLT panels. That means that often, particularly if large timber panels are used, the damaged components would need to be ordered from a distant source country. In these cases it would be preferable to develop alternative local manufacturing technologies to produce the components used in the design of the structure and in that way ensure much quicker reinstatement times.

Cutting out damaged pieces and glueing infill pieces into the damaged areas may provide a solution. The glue connections that have been tested to date have provided promising results, but the effectiveness of face glueing pieces in solid timber panels to restore continuity has still to be researched and validated.

More work therefore needs to be done into the area of repair and/or replacement of the structural components of timber buildings to address all the issues related to how timber buildings measure up to the resilience test.

6 CONCLUSIONS

Timber as a structural material has largely been ignored over the last few centuries; the period in which structural analysis techniques and systems for steel and concrete were developed. With the drive for more sustainable design of buildings, timber has come to the fore as the ideal structural material when it comes to minimizing the embodied energy in the built environment.

This paper considers the issues related to the resilience of buildings and discusses the issue in relation to timber as a structural material. There has been a lot of good work done over the past few decades investigating all aspects of design using timber as the structural material. The case for sustainable design has been well established, and systems for large and robust buildings, capable of good performance when exposed to extreme natural conditions, fire and explosion have been have been developed.

An industrial processes and systems approach has been developed to promote quick and safe construction methods, and redundancy of the designs has been considered. However one aspect associated with resilient design seems to have received less attention; that related to the repair and re-instatement of damaged components after a shock event, and this applies to all construction materials, not just timber.

More work needs to be done in this area to address all the issues related to how good a material timber is when measured against all factors that define the resilience of a building.

ABSTRACT: The following paper describes the numerical modelling used to predict the dynamic behaviour of a post-tensioned timber building with the addition of a hysteretic energy dissipation system. This modeling is in support of a shaking table test programme about to commence on a 2/3rd scale, 3-dimensional, 3-storey post-tensioned timber structure made from post-tensioned timber frames in both directions in the structural laboratory of the University of Basilicata in Potenza, Italy. This research is part of a joint collaboration with the University of Canterbury in Christchurch, New Zealand. The test frame has been modeled combining the use of elastic elements with a series of rotational springs which represent the moment rotation behaviour of the beam-column joints. These springs were calibrated against the moment rotation design procedure used for post-tensioned timber connections. Modeling was done by considering two non-linear finite element codes, SAP2000 and RUAUMOKO. This paper compares numerical results obtained from the model with and without additional dissipative elements in order to better understand the dynamic behaviour of post-tensioned timber structures.

1 INTRODUCTION

This paper presents the numerical modeling of a 2/3rd scale three-storey post-tensioned timber frame building to be tested in the structural laboratory of the University of Basilicata (UNIBAS) in Potenza, Italy. This work is part of a collaborative experimental campaign between UNIBAS and the University of Canterbury, in Christchurch, New Zealand. The complete study will evaluate the feasibility of applying jointed ductile post-tensioning technology, originally conceived for use in concrete structures (Priestley et al. 1999), to glue laminated timber (glulam). The aim of this phase of the project is to evaluate the dynamic seismic performance of the system and further develop the system for use in multi-storey timber buildings.

The post-tensioned timber concept (under the name PRES LAM) has been developed at the University of Canterbury and extensively tested in the structural laboratories of the university. In stage one of this current project a full-scale beam-column joint was designed, fabricated, constructed and tested at the structural laboratory of UNIBAS providing excellent results and beginning to answer key questions regarding system performance. During testing the application of the post-tensioned timber concept to glulam timber was confirmed. Testing was performed both with and without dissipative elements and the system displayed the same excellent performance under static and seismic loading as when the system was employed with laminated veneer lumber (LVL) (Smith et al. 2011). The dissipative devices used were based on yielding steel angles which activate at low drift levels, both increasing the moment capacity of the system and adding energy dissipation (thus reducing seismic load through damping) without inducing plastic deformations in other elements.

During this stage modeling and design procedures were also implemented and verified (Smith et al. 2012) using the quasi-static test results.

An extensive dynamic experimental testing programme is scheduled to be performed in the Structural Laboratory of the University of Basilicata (Ponzo et al. 2013). This paper will build on the techniques to be used during dynamic testing campaign, employing them as part of a time-history modeling investigation.

2 EXPERIMENTAL TEST MODEL

The prototype structure is three stories in height and has a single bay in both directions (Ponzo et al. 2013). All design has been performed in accordance with the current version of the Italian design codes (NTC 2008). The interstorey height of the building is 3 m and the frame footprint is 6 m by 4.5 m. The building has been designed to represent an office structure (live loading

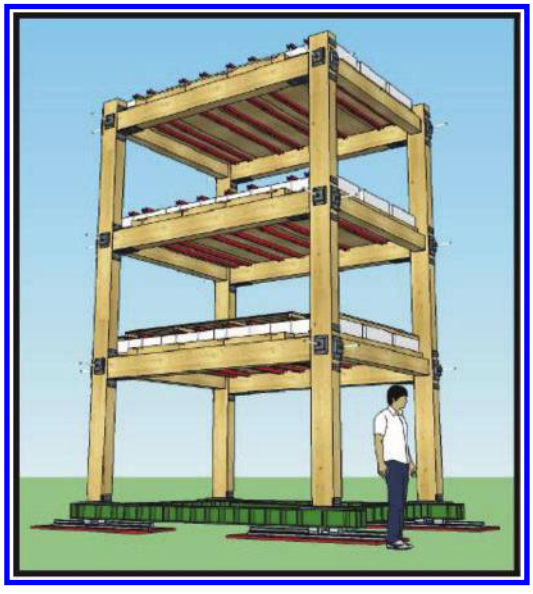

Figure 1. Rendering of test specimen.

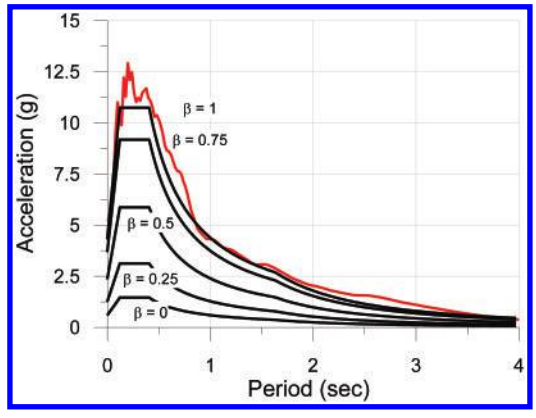

Figure 2. Effect of the parameter β on seismic structural demand.

Q = 3 kPa) with the final floor being a rooftop garden. The flooring of the building is made from solid glulam panels. The lateral resistance of the building is governed by seismic loading.

The test frame (Fig. 1) is made from glulam grade GL32h (EN 1995-1-1 2004). A scale factor of 2/3 has been applied to the prototype structure resulting in an interstorey height of 2 m and a building footprint of 4 m × 3 m.

The beam-column connection in the principle direction is based on the connection type which was tested during stage one. Passing through the centre of the beam is a single 26.5 mm diameter bar which will be tensioned to varying values of initial loading throughout the test programme. This is a high strength steel bar with a yield strength $f_y = 1050$ N/mm^2 and a Young's modulus of 170 kN/mm^2. Dissipation in the form of a yielding steel angle will be used. Screws have been used to protect the column face and also connect each dissipater attachment plate. Vertical loading will be transferred through a ϕ76.1 mm steel tube with extends 66 mm from the beam and sits inside the column. The beam-column connection in the secondary direction is similar to that in the principle direction.

The base of the column is fitted with a steel shoe which is epoxied into the base of the column and left free to rock on a base plate (which will be used to represent the building foundations in the case of the test building). Shear transfer is achieved using a ϕ76.1 mm steel tube which extends 15 mm from the steel shoe and slots into a cavity in the base plate. Holes have been drilled and tapped in the steel shoe in order to facilitate the attachment of energy dissipation devices. During testing passive energy dissipation devices will be added to the structure in order to add strength and reduce displacements without increasing accelerations or base shears. The passive hysteretic energy dissipation devices to be added are the 'yielding steel angle' (Di Cesare et al. 2013).

The testing input will be a set of 7 spectrum compatible earthquakes selected from the European strong-motion database with the characteristics shown in (Ponzo et al. 2013). The code spectrum which was used when selecting the records was defined in accordance with the current Eurocode for seismic design (EN 1998-1:2003 2003) having $a_g = 0.35$ g and a soil factor of S = 1.25 (Soil class B – medium soil) giving a PGA for the design spectrum of 0.44 g.

During testing several characteristic of the post-tensioned timber concept will be investigated. The key to this type of system is made up of the ratio β, the ratio between the moment resistance provided by the post-tensioning and the moment resistance provided by the dissipation. Clearly, during design this choice affects both damping and moment capacity of the system and therefore changing this value will have a direct effect on both capacity and demand.

The effect of the parameter β on demand is displayed in the acceleration spectra shown in Figure 2. With a decrease in the factor damping is introduced and therefore demand is decreased.

During the experimental campaign the size of the structural members, building layout and mass will not be altered, however different values of post-tensioning and steel moment capacity contributions (thus variations in the value β) will be investigated with the cases shown in Ponzo et al 2013 being selected for testing.

These options are based around the standard case of PT100_1.00 which has an ultimate connection moment capacity of $M_t = 27$ kN. Adding steel without reducing the post-tension moment contribution (PT100_0.70) has the effect of both increasing capacity and decreasing demand. Adding steel in combination with a decrease in post-tensioning force (PT50_0.80) decreases demand but retains equal capacity.

3 NUMERICAL MODELLING

3.1 *Local modeling*

The ABAQUS finite element programme (ABAQUS Inc. 2011) was used to model the behaviour of each of the dissipative angles to be applied to the frame. A 3D deformable solid made up of 2 mm tetrahedral mesh elements was used. The steel material was modelled using a plastic yield model with (combined) cyclic hardening. The boundary conditions of the angle were set in order to mimic as closely as possible the loading of the steel angle however displacements were calibrated in order to represent the rotations of the top connection seen throughout testing and taken as being inherent to the systems design. The experimental test and the numerical model for the dissipative angle are shown in Figure 3.

Figure 4 shows a comparison between a selection of testing results and the ABAQUS model. Fatigue was not accounted for in the model. As shown the model provides a sufficiently accurate representation of the angles performance with close prediction of the key parameters of stiffness, both pre and post yield, yield and ultimate strength/displacement.

The model does however over-predict hysteretic dissipative capacity during larger cycles. This is likely due to the material degrading from low-cycle fatigue which is not accounted for in the model. More details are reported in Di Cesare et al. (2013).

3.2 *Global modeling*

Increasingly in the design of structures, engineers rely on the use of Non-linear Time History Analysis (NTHA) in order to verify building performance under design seismic loading. In the use of these models several trade-offs are made between complexity, accuracy, programming time, and processing time. In design it is crucial that simple models exist which provide sufficiently accurate building response without requiring a large amount of time in processing or programming.

From the conception of the post-tensioned jointed ductile concept it has been clear that the nature of the controlled rocking mechanism lent itself well to the use of a lumped plasticity approach in modelling. This approach combines the use of elastic elements with springs which represent plastic rotations in the system.

During the course of the post-tensioned timber project several authors have used finite element modeling in order to successfully replicate testing results. This was done using the RUAUMOKO (Carr, 2006) program. As mentioned previously, during stage one of this project these methods were further verified against quasi-static testing, this was performed using the widely spread SAP Non-linear (SAP2000, 2004) structural calculation program.

Two essentially identical numerical models have been set up in both RUAUMOKO and SAP 2000. These models combine elastic elements with rotational springs which have been calibrated against current design methods. Although the two models are essentially identical the length of the rotational spring differs between the two models. In the RUAUMOKO analysis the standard practice of setting the spring length to 1 mm was employed however this proved unstable when applied to the SAP model and a 10 mm spring length was used. The parameters of the rotational springs were set to match the predicted rotational response; Figure 5 shows representations of each springs moment-rotation characteristics.

Post-tensioning was represented using tri-linear elastic elements for both models with bounded Ramberg-Osgood and Buoc-Wen rotational spring models used to represent the steel elements in the RUAUMOKO and SAP2000 model respectively. A summary of both models is presented in Figure 6a and 6b.

As mentioned previously the base connection of the frame is also a rocking connection. With a column-foundation connection however moment capacity is provided by the axial load in the column in addition to the steel devices, if present. Under horizontal loading the axial load in the column changes and therefore a simple rotational spring was not adequate in modelling response. Work is ongoing in order to understand the most adequate way in which this base connection can be modelling and therefore two models have been

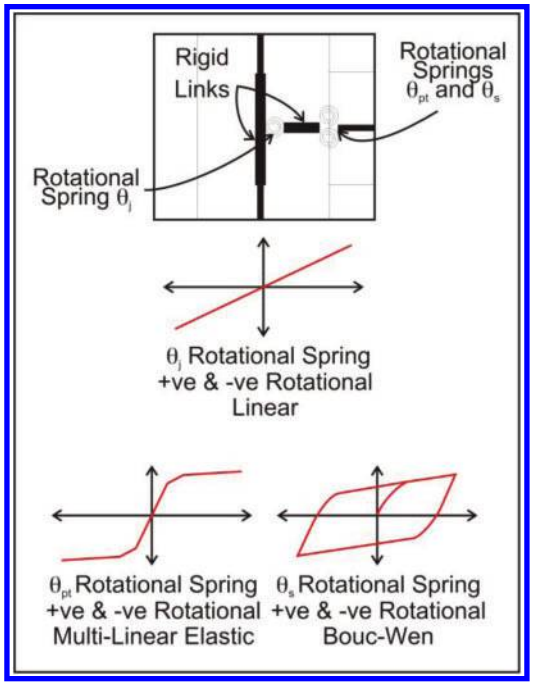

Figure 5. Local Modelling of beam to column joint.

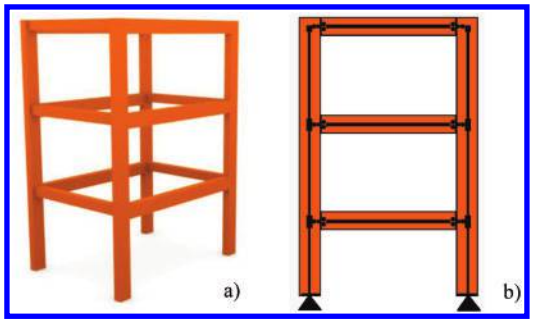

Figure 6. Global Modelling a) 3-dimensional numerical model for predictions, b) post-tensioned timber frame-pinned base model.

developed; one with a pinned based and one with a fixed base.

Recent studies have also recognised the importance of modelling and accounting for the elastic joint rotation in the calculation of the connection rotation. In order to model this, a rotational spring is added in the joint panel region. This linear elastic spring was given a rotational stiffness based on the moment-rotation relationship of the joint panel using formulas presented in Newcombe et al. (2010).

4 RESULTS OF NUMERICAL STUDY

In order to define the differences between the RUAUMOKO and SAP2000 model NTHA have been carried out for each testing configuration. Figure 7

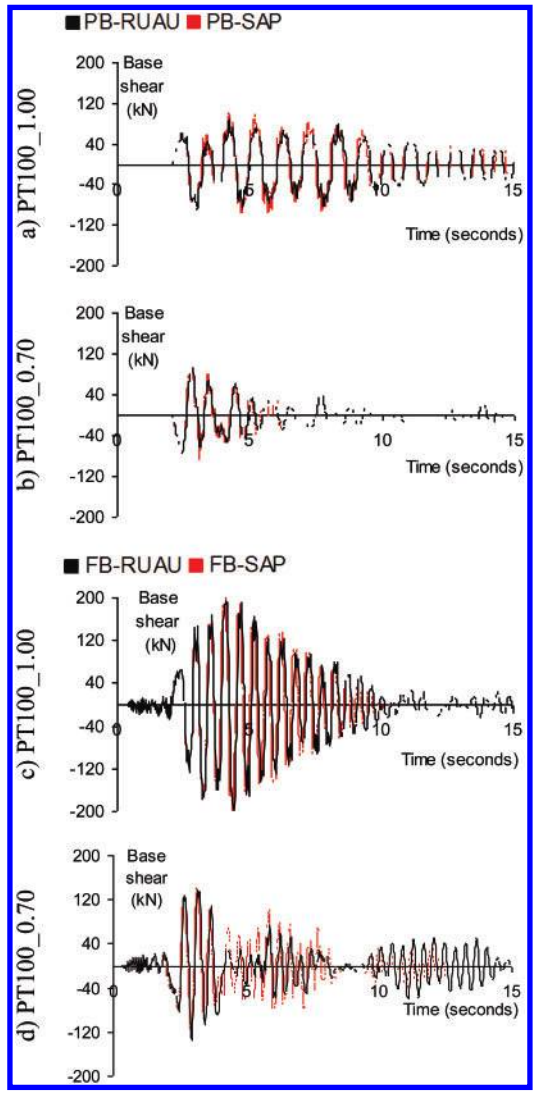

Figure 7. Time history base shear subjected to earthquake 535ya of Pinned Base model a) PT100_1.00 and b) PT100_0.70 and Fixed Base model c) PT100_1.00 and d) PT100_0.70.

compares the base shear response of the experimental model for the reference configuration (post-tension only case, PT100_1.00) and one of the hybrid cases with the addition of steel elements (PT100_0.70). The figure shows the time history results of base shear of the model with pinned based and with fixed base boundary conditions subjected to earthquake 535ya.

Figure 8 shows the RUAUMOKO and SAP2000 results in terms of i) maximum interstorey drift MID, ii) maximum accelerations MA at each floor and iii) maximum base shear MBS averaged across 3 input accelerograms (000196xa, 000535ya and 001228) for a) PT100_1.00 and b) PT100_0.70 configurations

As can be seen in Figure 7, the base shear of the structure reduces in amplitude when additional steel

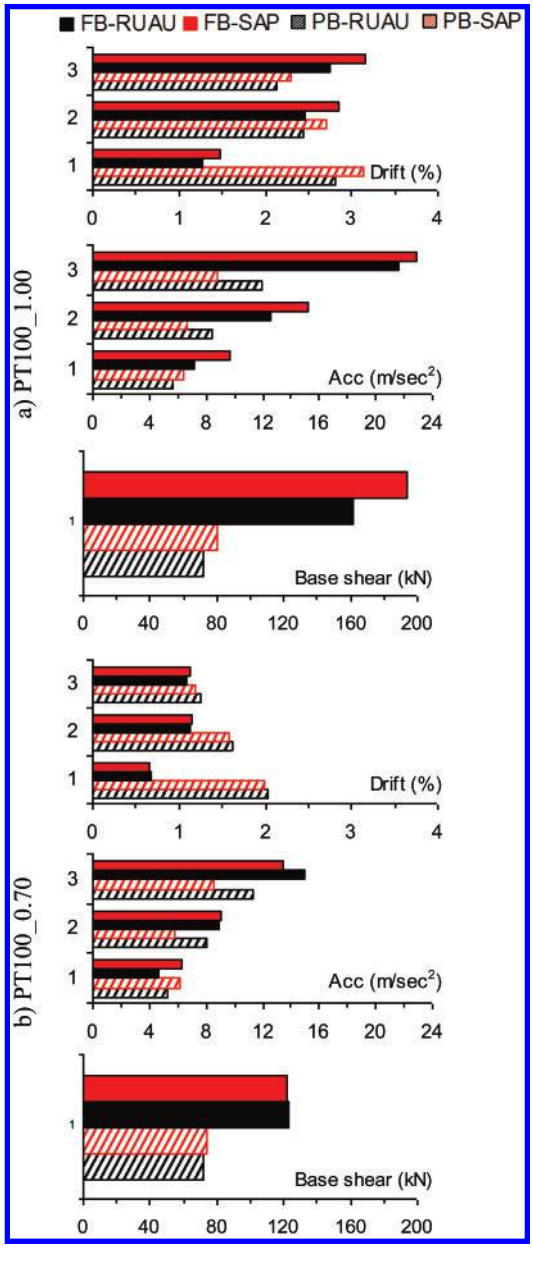

Figure 8. Comparisons SAP-RUAUMOKO results in terms of i) maximum acceleration MA, ii) maximum interstorey drift MID and iii) maximum base shear MBS averaged across 3 input ground motions for a) PT100_1.00 and b) PT100_0.70 cases.

devices are introduced (decreased demand). Comparisons between RUAUMOKO and SAP2000 non-linear time history analysis show that the results have the same trend in time with a small difference in maximum values (less than 10%) both for PT100_1.00 and PT100_0.70 configurations.

The comparison shown in Figure 8 clearly shows the difference that the base assumption makes in the

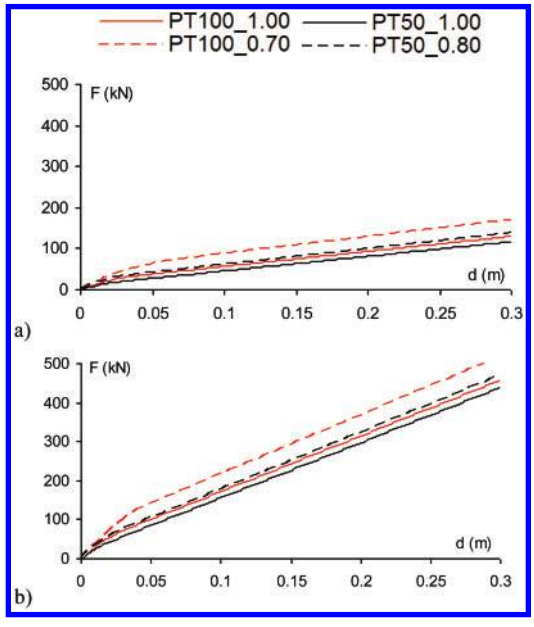

Figure 9. SAP Pushover comparisons between configurations to be tested with a) Pinned Base, b) Fixed Base.

response of the model and therefore in its ability to predict likely behaviour. Clearly the introduction of a pinned base in modelling reduces accelerations and base shears but leads to large levels of drift which can govern design of a flexible system such as post-tensioned timber. It is clear however that this discrepancy decreases with the addition of additional damping to the structure which also has a significant effect in reducing the values of all of the key performance parameters studied

In Figure 9 the numerical results of the pushover analysis considering pinned base and fixed base configuration are compared. These studies were performed with only SAP2000 in order to predict the variation in stiffness of the case studies. As can be seen in the figure, PT100_1.00 and PT50_0.80 display the same force-displacement behaviour however significant differences are present with relation to their base connection assumptions. The choice of pinned based of fixed base also therefore impacts on seismic demand (through change in period).

5 CONCLUSIONS

Non-linear analyses have been performed in order to define and better understand the test cases which will be used during the dynamic experimental tests on a 2/3rd scale, 3-dimensional, 3-storey, post-tensioned timber structure that will be performed in the structural laboratory of UNIBAS, Italy, in collaboration with the University of Canterbury, New Zealand. Time history analyses were performed in order to define total system behaviour of the considered configurations.

The numerical model has been considered with and without the addition of dissipative steel angles which are designed to yield at a certain level drifts with constant PT and varying PT.

As part of this testing programme a series of investigative tests have been performed in order to characterise the performance of the steel angles. In all different angle specimens the stress and strain distributions have been studied by means of local modelling.

Considering that the base of the column will also be left to rock against the foundation two assumptions have been made regarding the fixity of the base of the column. This displayed the significant impact that the boundary conditions of the column have on the total response of the structure and lead the authors to conclude that further attention and recommendations should be made regarding this point in day to day design.

NTHA results proved the effectiveness of dissipative steel devices in reducing seismic effects when compared to a PT only case. The configurations which will be used during the dynamic experimental tests have been identified.

These numerical results will now be compared against testing outcomes in order to provide useful guidelines for the non-linear dynamic modelling of post-tensioned timber structures.

ABSTRACT: Regarding to old masonry response under seismic actions, destructive testing campaign was planned. It was directed to rubble masonry, with particularly reference to L'Aquila old masonry type. The 6th April 2009 Earthquake, strongly damaged L'Aquila historical centre; in the hearth of the so-called "red zone", a corner palace permanent damaged was chosen. The main masonry features are: no ordinary setting, small size of the stones, regular flattens made in bricks, no transversal links and stones contact; these marks are representative of the Italian smallest historical centres and European one.

Consolidation approach detection is obviously hard; therefore, in order to research and obtain an effective strategy of intervention, strictly connected to the above masonry type, seven panels were selected. Five strengthening approaches were pointed out; starting from the common injections until more advanced methods like "the reticolatus", without overlook the tradition techniques. This paper will be focused on the out-of-plane answer; in relation to consider the first collapse mode the primary cause of building break-down, during earthquake.

1 L'AQUILA CITY AFTER EARTHQUAKE

1.1 *The site*

The destructive in situ testing campaign was performed involving one old Palace permanently damaged by L'Aquila earthquake in L'Aquila city. It is placed in Saint Peter' Square, in the heart of the historical center (Figure 1).

L'Aquila is one of the Italian cities listed into UNESCO sites; it is the administrative centre of the Abruzzi region, (see Figure 2). During the 2009 seismic activity a great part of its historical centre was damaged; in order to research and obtain an effective strategy of intervention, strictly connected to the old masonry local features, the above testing campaign for full-scale specimens were carried out.

Seven panels were chosen as structural elements suitable as specimens. They were placed at the building first floor and tested in order to identify mechanical properties and in-plane and out-of-plane response.

1.2 *L'Aquila old masonry: the main features*

Before explain both testing campaign program and strengthening measures, it is really important point out L'Aquila old masonry features. L'Aquila built setting show several masonry typologies all closed into

Figure 1. Chosen building photo after the 6th April 2009 Earthquake.

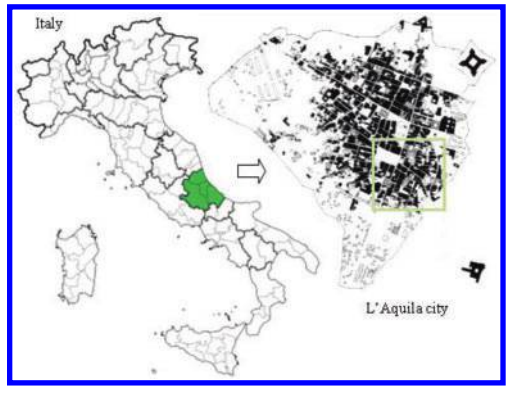

Figure 2. Italian Peninsula, Abruzzi region (in green), L'Aquila city (historical centre map).

Figure 3. Masonry typologies detection in relation to stonework failure.

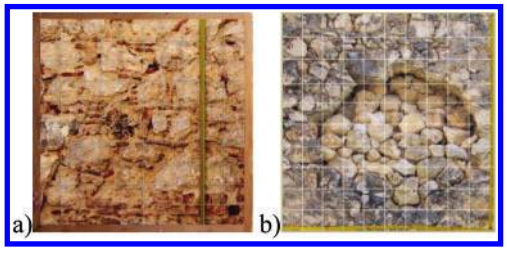

Figure 4. Masonry sampling (1 m × 1 m); a) type one, L'Aquila historical centre; b) type two, L'Aquila surrounding area.

rubble masonry category (see Figure 3); but it follows that two of them are most representatives, respectively widespread in L'Aquila city and in the neighborhood (Formisano et al. 2012).

The first type constructive scheme takes into account no ordinary stones setting, with no regular shape and small size. As a direct consequence of it, total absence of headers is noticed and lacks among the stones or thickness mortar joints can be pointed out. However some regular courses made by bricks and stones irregularity filled up by wedges elements can be identified. Therefore, regular flatten made in bricks and stretcher elements are present (see Figure 4a) (Ceradini 2004) (Candela and Fonti, 2010).

Instead, the second typology show a masonry setting lacking in many mechanical features: stone size smallest, no transversal section links, no stretcher elements, no bricks layers, no contact between the bigger stones, no vertical and horizontal interlock (see Figure 4b.). All that makes hard strengthening approach detection.

The building chosen for the full-scale tests match the first masonry typology; therefore, the followings strategies were focused on this specific masonry type. Regarding this first step two principal lacks were carried out: *absence of headers* and *no contact among stones*; they were all over posted like starting dates for strengthening approaches detection.

2 THE TESTING CAMPING

2.1 *The testing program*

Two façade involved:

Only first floor masonry elements – The panels selected are physically separated by a regular progression of windows, therefore, each masonry part closed to the openings was identified like a singular rigid block. Panel dimensions: wide 60 cm, high 400 cm, large – variable

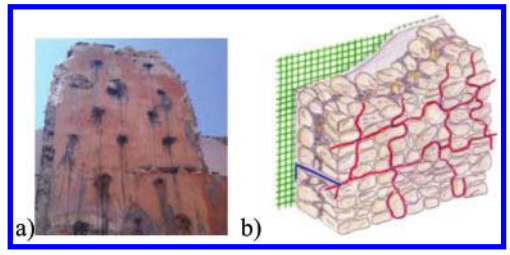

Figure 5. Specimen n.4; a) Masonry reinforcing with anchors; b)Specimen n.1 – reinforcement approach: Reticolatus (external surface) and GFRP reinforced plaster (internal surface).

Seven panels were tested:

Two panels were posted useful for masonry mechanical parameters characterization and behavior identification under horizontal actions (in plane and out-of plane tests in static conditions). Moreover, test with no destructive methods were applied.

Five panels were strengthened with different approaches and finally tested out-of-plane in static conditions.

University involved:

- *Sergio Lagomarsino working group, University of Genoa, Italy*
- *Antonio Borri, University of Perugia, Italy*
- *Michele Candela, University of Reggio Calabria,*
- *University of Naples "Federico II", Italy*

2.2 *The strengthening methods*

In order to provide different strengthening levels, the five reinforcement strategies take into account basic approach like injections or more advanced methods as artificial headers addition, without overlook tradition techniques. Starting from the no reinforced panel response, for out-of-plane mechanisms, the final goal is obviously improve panels resistance against horizontal actions in order to obtain the maximum possible resistance related to panel geometrical dimensions. The panels are considered rigid blocks.

Following panel strategies of intervention overview show – according to fault adjustment improving (Borri et al. 2012) (Fonti, 2013).

2.2.1 *Panel n.4*

Fault corrected: none;
Strengthening method: Injections (See Figure 5a);
Executive phases:

1) Panel drilling (n.17); 2) Anchors setting in the holes, pitch 60 cm; 3) Masonry cleaning; 4) The injection. Grouting (lightweight mortar) was injected with light pressure near 2 bar.

2.2.2 *Panel n.1*

Fault corrected: no transversal section links;
Strengthening method: "Reticolatus";
Strategy of intervention description:

The reinforcement approach applied use two different solutions for both internal and external surfaces. The last one surface was strengthened by the

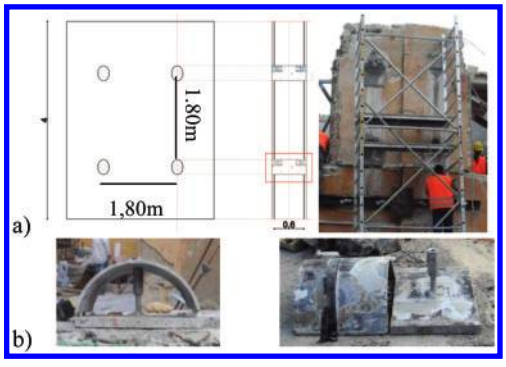

Figure 6. Specimen n.2 – a) technique applied design; b) photo of pushing metallic elements; b) final result.

"Reticolatus" technique related to restoration criteria for no plastered masonry. Instead, second one use GFRP reinforced plaster, like show in Figure 5b.

The transversal connections between the two differ solutions applied was realized by some little bars. A particular cable (Dyneema rope) was rolled around these tie elements; the rope setting follow the stones as a mesh. Therefore, bars connect the two meshes, one in GFRP and another in rope.

2.2.3 *Panel n.2*

Fault corrected: no transversal interlock;
Strengthening method: Traditional technique with original "headers";
Strategy of intervention description:

The strengthening idea starts from the traditional reinforcement technique of "headers" addition to achieve a new one, in order to guarantee good transversal connection and re-establish regular stresses conditions. The headers regarding their bigger dimensions can tie panel from side to side.

The innovative "header" is made of lighten concrete with a T shape modeled in order to fill the empty areas by pushing metallic elements. (See Figure 10).

Executive phases: (Figure 6)

1) Panel drilling; the horizontal boreholes were placed full in wideness, four in numbers; 2) The header's built up; elements dimensions 30 cm × 20 cm made about lighten concrete; 3) Setting of the T headers; 4) Setting of the pushing metallic elements.

2.2.4 *Panel n.3*

Fault corrected: no transversal section links;
Strengthening method: original "header" with Bossong system technology – injection anchors with sock;
Strategy of intervention description:

The strengthening idea begins from the improvement of drilling techniques, which allow the embedding of reinforcement steel anchors inside masonry walls with a minimum impact. This system patented by the Bossong Spa it's well-know namely "injection anchors with sock". It the special sock wraps the metal bar and guarantees the total control of injection and to

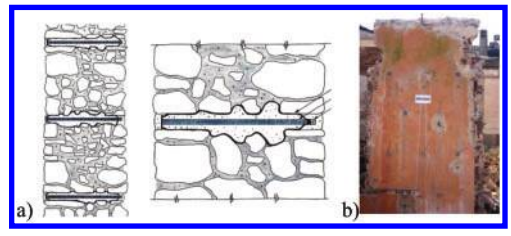

Figure 7. Specimen n.3; a)Injection anchors with sock-as headers; b) Panel final result.

create a strong mechanical interlock a long all over the section. The steel bars enclosed in a mesh fabric sleeve into which a specially developed grout is injected under low-pressure. Therefore, the injection anchors with sock arrange artificial headers perfectly bonded to masonry inner surfaces (Figure 7a).

Executive phases:

1) Panel drilling. The horizontal boreholes were placed full in wideness with variable length from 560 to 800 mm and diameter 60 mm;

2) Bars setting. bars, type GBOS, diameter 60 mm and 500 mm placement. The sock mesh is a porous membrane designed in order to contain the aggregates that constitute the mixture, and allow cement flow into the sock. chemical bond with the substrate is guarantee.

3) Very smallest nylon tube was used in order to give the injection. The injection devices are designed according to anchors size and features, in this case the diameter is about 8 mm.

At the end, thirteen headers were added into the panel with a pitch of 65 cm in the horizontal direction and 70 cm in vertical one. (See Figure 7b).

2.2.5 *Panel n.5*

Fault corrected: no transversal section links and no contact among stones
Strengthening method: Traditional technique – headers setting and mortar joints replacement.
Strategy of intervention description:

The strengthening idea (Fonti, 2013) start from Abruzzi' local structural engineering features for old masonry constructions. The Abruzzi built widespread employ wooden elements for masonry connections and building safety against horizontal actions. Therefore, some wooden headers were placed in order to obtain the mechanical interlocks (in transversal section); instead, little bricks elements were placed in order to increase compression resistance for vertical loads and avoid the modification of the hinge position during panel overturning under horizontal loads.

Executive phases: (See Figure 8)

1) Panel drilling. The horizontal boreholes were placed full in wideness with 4 holes diameter 200 mm; 2) Replacement of the mortar joints with little bricks elements; 3) Setting of the wooden headers and wooden wedge-elements in order to reestablish regular stress condition.

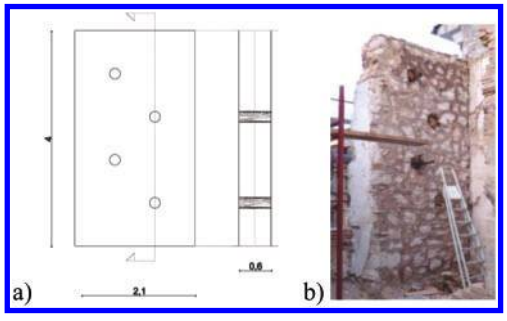

Figure 8. Specimen n.5. a) Schematic plan for wooden headers setting; b) Panel final result.

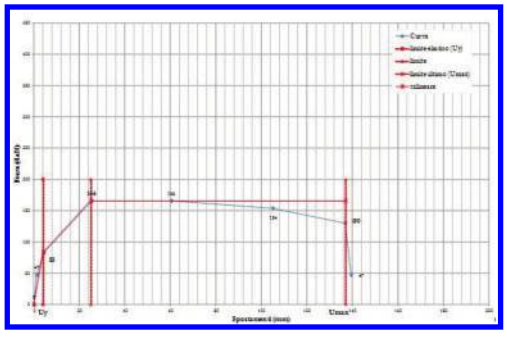

Figure 9. Specimen n.6. force-displacement constitutive curve.

3 THE OUT-OF-PLANE TESTS

3.1 *The pull-out tests*

According to the panels placement possibility, the specimens were tested by monotonous "force-control" or cyclic tests. No axial load has been applied.

Regarding the monotonous tests, the setup adopted use metallic anchor and cable positioned in the geometrical panel dimensions centre, in order to apply horizontal force.

The main marks obtained are the following (Borri et al. 2012): (from the no-reinforced to the best) Specimen n.6 – no reinforcement

3.1.1 *Specimen n.6*

The comparison between the no reinforced global panel force-displacement constitutive curve and the theoretical one show no codified response for L'Aquila masonry: three-linear curve trend with no frail behavior it's generally noticed. Gradual development of relevant horizontal displacements after the maximum strength is recognized.

From 0 to 4 mm pseudo-elastic behavior is identified with corresponding strengths values respectively equal to 47 daN and 83 daN(Uy).

Nonlinear response is noticed after the elastic limit with significant horizontal displacements increasing without strength one until the maximum displacement equal to 250 mm and the corresponding force value equal to 166 daN. (See Figure 9)

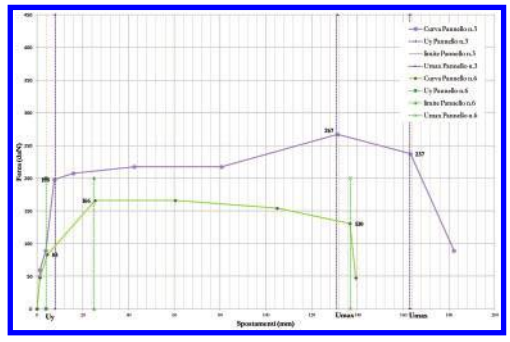

Figure 10. Specimen n.4 and 6 force-displacement constitutive curve comparison.

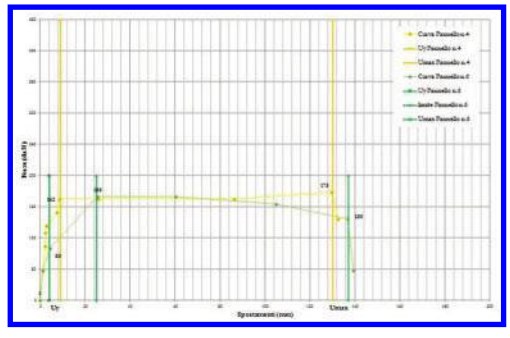

Figure 11. Specimen n.3 and 6 force-displacement constitutive curve comparison.

3.1.2 *Specimen n.4: Injection*

The comparison between the two experimental curves for specimens n.4 and 6 shows very similar response. (See Figure 10)

The force-displacement constitutive curve recognized for panel n.4 take into account a starting linear trend from 0 to 9 mm that show a pseudo-elastic behavior with corresponding strengths values respectively equal to 47 daN and 162 daN (Uy).

Nonlinear response is noticed after the elastic limit with significant horizontal displacements increasing without strength one until the maximum displacement of 130 mm.

3.1.3 *Specimen n.3*

The comparison between the experimental response of the panels n.3 and 6 shows a very similar trend curve with different resistance values (Figure 11).

In fact, from 0 to 8 mm a pseudo-elastic behavior is noticed with corresponding strengths values respectively equal to 49 daN and 198 daN (Uy). This last is more than double, in front of the specimen n.6. After the elastic limit nonlinear response is noticed, two different line segments could be distinguished: growing and plateau with significant horizontal displacements increasing until the maximum displacement of 163 mm. the maximum strength recognized is equal to 267 daN.

Therefore, in global panel response the artificial headers gave a little improvement contribution. This

Figure 12. Specimen n.3 experimental work – out-of-plane test, photo.

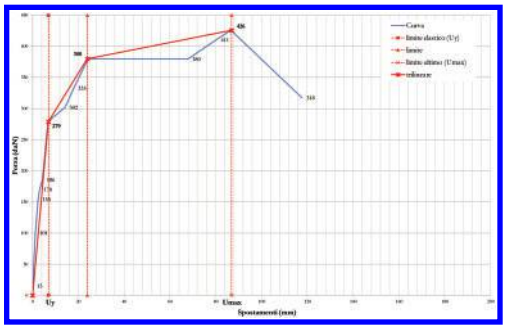

Figure 13. Specimen n.2 – force-displacement curve.

is mainly due to excess in number of them; in fact during the panel overturning they could be recognize as weak points. (See Figure 12)

3.1.4 *Specimen n.2*

The force-displacement constitutive curve recognized for panel n.3 is ever-grooving; it take into account a starting linear trend from 0 to 7 mm that show a pseudo-elastic behavior with corresponding strengths values respectively equal to 105 daN and 279 daN (Uy).

Nonlinear response is noticed after the elastic limit with both significant increasing of horizontal displacements and strength values until the maximum displacement 87 mm and relative strength value equal to 426 daN (See Figure 13).

It is obviously evident that the addition of artificial headers, good in number, could realize very well interlock in the transversal section avoiding partially hinge position modification during panel overturning under horizontal force (See Figure 14).

Therefore, a perfect rigid-block behavior was experimental noticed (See Figure 20); however, it was no taken in advance of all panel weight force against horizontal loads.

Note: In order to make a comparison all values listed were prorated to masonry specimens reduced in largeness to 1m.

3.1.5 *Specimen n.1*

The force-displacement constitutive curve recognized for panel n.1 is ever-grooving. It take into account a starting linear trend from 0 to 5 mm with corresponding strengths values respectively equal to 115 daN and 299 daN (Uy) (See Figure 15).

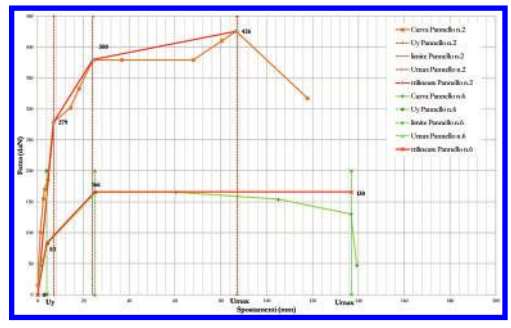

Figure 14. Specimen n.2 and 6 force-displacement constitutive curve comparison.

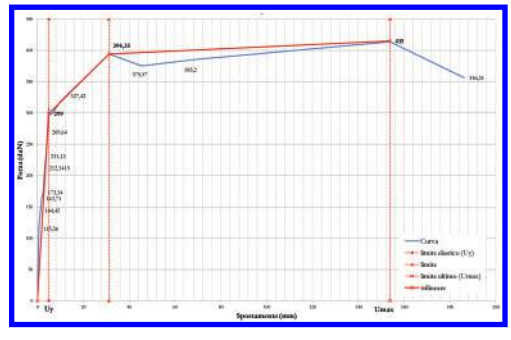

Figure 15. Specimen n.1 – force-displacement constitutive curve.

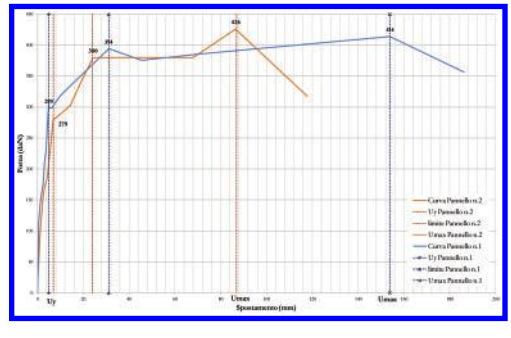

Figure 16. Specimen n.1 – force-displacement constitutive curve.

Nonlinear response is noticed after the elastic limit with both significant increasing of horizontal displacements and strength values until the maximum displacement 154 mm and relative strength value equal to 415 daN.

By comparing panel n.1 and 2 analogue responses were noticed (See Figure n.16).

3.2 *Cyclic test: the panel n.5*

The specimen n.5 was test by applying alternate horizontal action with loading and unloading cycles. The "force-control" tests was carry out with no axial load applied. The setup adopted use an horizontal actuator of 500 kN, in order to apply the alternated loading

Table 1. Specimen n.5 test.

cycles number	Maximum strength (daN)		Displacement (mm)	
Tot n: 5	Positive Phase	Negative Phase	Positive Phase	Negative Phase
I	1.101	1.014	30	−30
II	1.235	1.241	60	−60
III	1.422	1.276	91	−92
IV	1.448	1.380	124	−120
V	1.469	1.453	157	−161
Overturning	1.183		180	

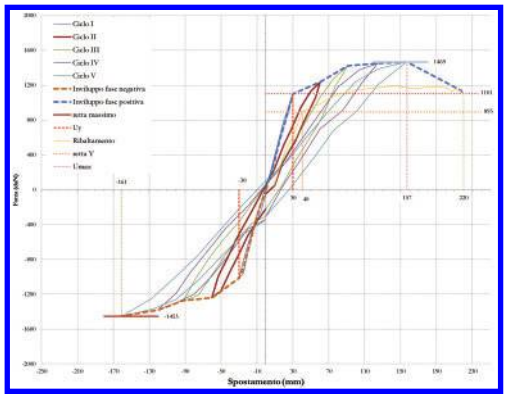

Figure 17. Specimen n.5-Cyclic test.

conditions to the panel which is free to roll on the top. The actuator was anchored by a steel beam placed in the geometrical panel dimensions centre. The mark obtained is the following:

The cycles were five in numbers with growing step 3 cm by 3 cm. latest overturning phase was performed.

The trend curve that interpolates the experimental maximum values filled in Table n.1 is described by a three-linear force-displacement constitutive curve.

It take into account a starting linear trend from 0 to 25 mm with corresponding strengths values respectively equal to 24 daN and 590 daN (Uy). The panel shows a starting rigidity very similar to the no reinforced one; this occurrence is mainly due to the reinforcement method aims. It was developed according to old masonry traditional techniques in order to guarantee seismic improvement with no constitutive curve trend changing. In fact, the resistance values and relative displacements result increased until the top strength of 787 daN with a corresponding displacement of 140 mm.

Therefore, after the elastic limit strong nonlinear response is noticed with significant increasing of both horizontal displacements and strength values until the maximum displacement of 240 mm recognized during the turning phase. (See Figure 17).

The response shows a symmetrical answer with asymptotic trend.

By comparing the specimen's n.6, 2 and 5 it is possible notice that mortar joints replacement gave a strong contribute during first collapse mode mechanism activation in order to obtain the maximum efficiency of the panel against seismic failure.

4 FINAL REMARKS

The final result of the experimental work consisting in two main outcomes: (i) identification of mechanical properties of individual stone elements inside the panel and (ii) derivation of force-displacement constitutive curves for global panels.

Therefore, the following experimental evidences pointed out (Fonti, 2013):

- different response for out-of-plane test were noticed, according to both masonry setting panel deviation from the rule of art and specific strengthening measures adopted; the above observations are referred to masonry resistance value checked during panel overturning under static horizontal loads;
- the check of header elements contribution in the out-of-plane collapse mechanisms and the importance of mortar joints replacement by small stone elements, in order to increase the compression resistance and to avoid the modification of the hinge position during panel overturning under horizontal loads;
- no possibility to consider masonry perfectly unilateral and infinitely resistant to the compression.
- The introduction of an additional parameter "the shape interlock" is proposed.

As a final remark: the comparison with the available technical literature reference about masonry mechanical models showed a significant gap between the experimental force-displacement constitutive curve and the theoretical ones.

Seismic behavior of masonry walls with soft-layer wall bearings

N. Mojsilović, B. Stojadinović, A. Barandun & C. Vögeli
Institute of Structural Engineering, ETH Zurich, Zurich, Switzerland

ABSTRACT: A research project at ETH Zurich on the seismic behavior of masonry wallettes with two different soft-layer membranes (extruded elastomer and rubber granulate) placed in the bed joints is underway. The main goals of the research project are to investigate the influence of the soft layer on masonry behavior under static-cyclic shear, to assess the shear mechanical properties of different bearing layers, and to establish if and how it modifies the lateral load resistance mechanism of the wall. The preliminary analysis of the results of tests on seven wallettes show that, due to prevalently sliding failure, especially with built-in rubber granulate layer considerable energy dissipation and quasi ductile behavior, i.e. a large deformation capacity could be expected in actual masonry structures with soft layer placed in the bed joints. Such behavior would be desirable for enhanced seismic performance.

1 INTRODUCTION

A research project at ETH Zurich on the seismic behavior of masonry wallettes with soft-layer membrane placed in the bed joints is underway. The main goals of the research project are to investigate the influence of the soft layer on masonry behavior under static-cyclic shear, to assess the shear mechanical properties of different bearing layers, and to establish if and how it modifies the lateral load resistance mechanism of the wall.

This paper presents some preliminary results and discusses their significance in relation to current design practice. A number of conclusions as well as recommendations for future research are given.

In previous investigations, a series of static, static-cyclic and dynamic tests on masonry specimens with different types of soft layer, i.e. damp-proof courses (DPC), was performed. The results indicated that shear load can be transmitted through a joint containing a DPC. Griffith & Page (1998) performed monotonic, static-cyclic and dynamic shear tests on small masonry elements (triplets) with different types of DPC membranes (bitumen coated aluminum; polythene/ bitumen coated aluminum and embossed polythene) and reported the corresponding friction coefficients. The DPC membranes were placed in both mortar joints of the brick triplet; in one series the middle brick was made of concrete in order to simulate the concrete floor slab. Test specimens were initially subjected to a given level of pre-compression, which was kept constant during the test. The shear load was applied in the out-of-plane direction. The masonry materials used in these tests were typical extruded clay bricks with standard mortar. Similar results were reported by Zhuge & Mills (1998) and Simundic et al. (2000). Recently, static-cyclic tests were performed on masonry wallettes subjected to static-cyclic shear loading with embossed polythene DPC incorporated either in a mortar joint or at the masonry-concrete slab interface, see Mojsilović et al. (2010). Results from this investigation also confirmed good performance of the DPC subjected to cyclic loading. Finally, within the framework of the recently completed research project at ETH Zurich on the shear behavior of masonry elements (triplets) with DPC membrane placed in the bed joints, load tests on ten series of masonry triplets with three different DPC membranes (elastomer-, bitumen- and polythene-based membranes) have been done, see Mojsilović (2012). The shear behavior of the specimens was highly influenced by the applied pre-compression level, while influence of the location of the DPC membrane was much smaller. A considerable energy dissipation and large deformation capacity, compared to conventional masonry, can be expected in masonry structures with a soft layer incorporated in the bed joints.

2 TEST PROGRAM AND MATERIALS

Static-cyclic load tests on a series of masonry wallettes with incorporated soft layer have been performed at the Institute of Structural Engineering of ETH Zurich. Test series consisted of seven clay block masonry wallettes that were nominally 1200 mm wide and 1200 mm high (four units long and six courses high). The thickness of the wallettes was 150 mm. The wallettes were built in running bond using standard cement mortar, which had mean compressive strength of 21.5 MPa. Both the bed and the head joints were 10 mm thick and fully filled. Typical Swiss perforated clay blocks with

WE5	5	extruded elastomer
WE10	10	extruded elastomer
WG3	3	rubber granulate
WG5	5	rubber granulate
WG10	10	rubber granulate

nominal dimensions 290 × 190 × 150 mm and void area of 45% were used to build the specimens, see Figure 1. Block compressive strength was 25.5 MPa. Two types of soft-layer membrane have been used: extruded elastomer (E) and rubber granulate (G), see Figure 1. Three different thicknesses, t_{sl}, of each soft layer were tested, namely 3, 5 and 10 mm. During the wallette construction the soft layer strip was placed directly on the first block course. The bed joint mortar was then placed on top of the membrane and the blocks of the next course were laid on that mortar bed. Note that for the wallettes with 3 and 5 mm thick soft layers the total bed joint thickness was 10 mm. The total bed joint thickness was 15 mm in the two cases with 10 mm thick soft layers.

In addition to the specimens with built-in soft layer, a control specimen with the same dimensions and without soft layer was built. A summary of the test program is given in Table 1.

All specimens were built by a professional mason and were air cured at the testing site. After preparation and prescribed curing time (at least 28 days) the wallettes are first subjected to a gravity load pre-compression of 0.6 MPa (10% of the masonry compressive strength), which was kept constant during the test, and subsequently subjected to the cyclic shear load which was applied in an incrementally increasing displacement-controlled sequence. Prior to testing, the specimens were painted white in order to follow the crack development during the test.

3 WALLETTE TESTING PROCEDURE AND MEASUREMENTS

Figure 2 shows the test set-up. The axial load, i.e. pre-compression was applied by means of the hydraulic jacks (2) placed between the support frame (1) and the upper spreader beam (3). A roller support (5) was

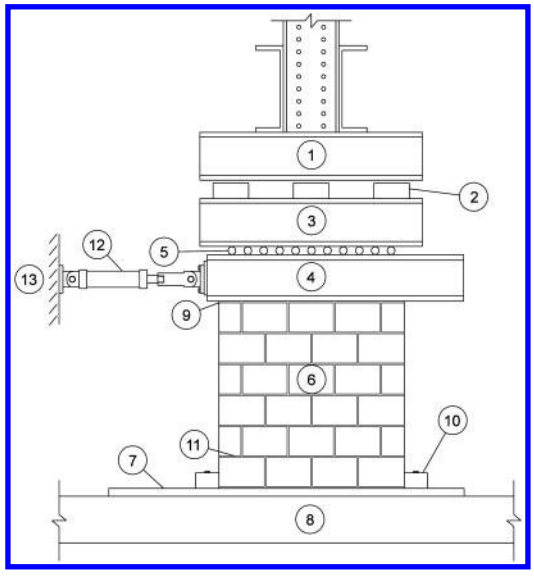

Figure 2. Test set-up.

installed between the upper (3) and the lower spreader beam (4). The test specimen (6) was placed between the lower spreader beam (4) and a thick steel plate (7), which lay directly on and was fixed to the laboratory strong floor (8). A mortar layer (9) was applied between the specimen (6) and lower spreader beam (4) in order to ensure a uniform vertical load distribution. Steel elements (10), which were fixed to the steel plate (7), ensured that the first wallette course remains static, i.e. that possible sliding takes place in the bed joint with the soft layer (11). After applying the vertical pre-compression the specimens were subjected to cyclic shear loading by means of the hydraulic actuator (12) which was fixed to the reaction wall (13).

The cyclic shear load was applied in computer-controlled displacement steps. Each step was repeated twice in a form of a sinusoidal wave. At the beginning of the test, i.e. for small displacements, the loading speed was only 1 mm/min. For the larger displacement steps the loading speed was gradually increased up to 20 mm/min for the maximum applied displacement of 40 mm, see also Table 2. This Table also gives information on the duration of each load stage. Using this procedure, test duration varied from 74 to 130 minutes.

Apart from the applied vertical and horizontal load and displacement (jack travel), measurements included vertical, horizontal and diagonal deformations of the specimen, see Figure 3. Horizontal and vertical deformations were measured by means of two potentiometers each, POT4 and POT5 and POT6 and POT7, respectively. Diagonal deformations were measured by means of another two potentiometers, POT8 and POT9. Slip of the specimen over the joint with soft layer (POT 10 and POT11) as well as the uplift of the wallette toes (POT16 and POT17) was measured

in relation to the strong floor. The horizontal displacement of the top of the specimen was captured by means of the potentiometer POT15. All measuring devices were connected to a computer, which processed the data in real time. The potentiometer measurements were zeroed after the vertical pre-compression was applied. During the test, the nature and extent of the cracking was continuously observed.

4 TEST RESULTS

Table 3 shows the values of the extreme (maximum and minimum) horizontal forces, H, recorded during the testing as well as maximum and minimum horizontal displacement (jack travel), v. For all tests, the jack initially extended to push the wallette (negative displacement and shear force). From Table 3 it is clear that the wallettes with extruded elastomer developed higher shear strength than those with rubber granulate. However, comparing the control specimen, a decrease of shear strength for the wallettes with built-in soft layers is obvious (except for Specimen WE3). On the other hand, wallettes with soft layers developed larger

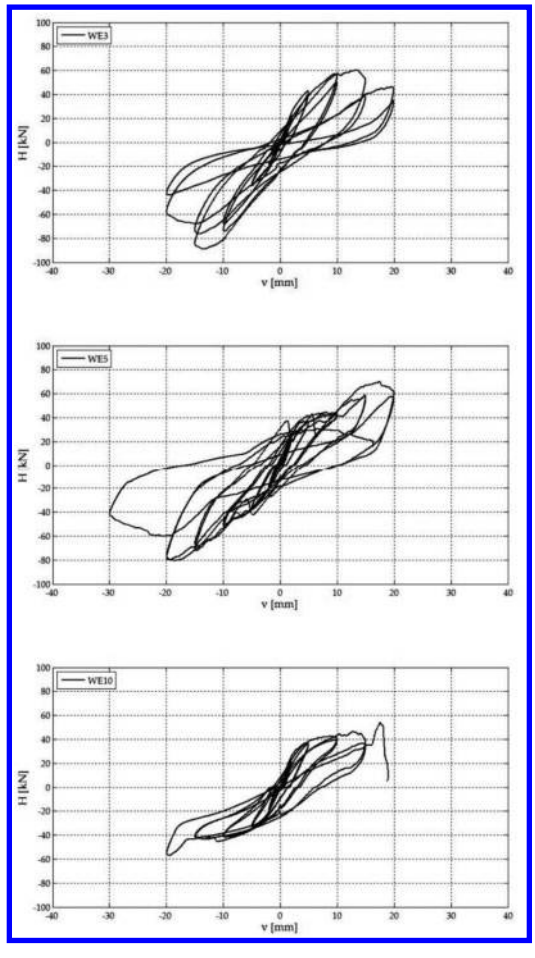

Figure 4. Hysteresis for specimens with extruded elastomer soft layer WE3, WE5 and WE10.

horizontal displacements prior to failure. It should be noted that there were problems in keeping the vertical force constant during the tests on Specimens W0, WE3 and WE5: vertical force increased with increasing horizontal displacement.

Figure 4 shows the shear force-deformation characteristics of specimens with built-in extruded elastomer soft layer subjected to cyclic loading. The deformation value shown in the diagram is the jack travel, v. The

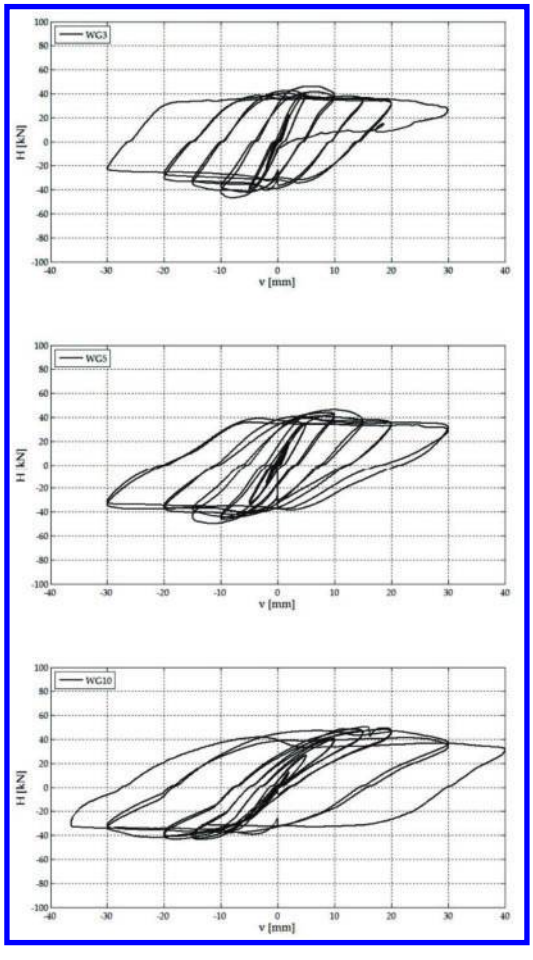

Figure 5. Hysteresis for specimens with rubber granulate soft layer WG3, WG5 and WG10.

cyclic force-deformation response (hysteresis) curves for all three soft-layer thicknesses are fairly typical: the response is initially linear-elastic, but becomes significantly non-linear when displacements exceed 2 mm. All specimens exhibited moderate energy dissipation (area under the hysteresis envelope) and behaved in a quasi-ductile manner.

From Figure 5 it can be seen that the specimens with rubber granulate soft layers, especially Specimens WG3 and WG5, were essentially linear-elastically up to the maximum value of shear resistance. Thereafter, with increasing deformation the response evolved into an ideal-plastic horizontal branch (plateau). All specimens exhibited considerable energy dissipation and behaved in a quasi-ductile manner.

A staircase-wise cracking of the specimens was observed during the tests, see Figure 6. Larger number of cracks as well as larger openings of the vertical cracks (along head joints) was observed for specimens with extruded elastomer soft layer than for those with the rubber granulate soft layer (at the same applied horizontal deformation). A similar outcome

Figure 6. Typical crack pattern (Specimens WE3 and WG3).

Figure 7. Sliding along the bed joint with soft layer (Specimens WG3 and WE10).

Figure 8. Failure of Specimens WE5 and WG5.

was observed for the thinner soft layers, independently of the layer material. A slip in the bed joint with soft layer was observed. Figure 7 shows, typically, shear deformation (sliding over the soft layer) in Specimens WG3 and WE10. The sliding planes formed between the layer membrane and adjoined block course. This means that, during the cycling, the soft layer moves together with the upper part of the wallette along the first block course.

The failure patterns observed during the tests were characteristic for masonry failing in sliding. Failures of the specimens with rubber granulate soft layer occurred due to exceeding the (very low) tensile strength of the blocks in the first course. These failures were induced by cycling movement of the upper part of the wallette over the first course, see, e.g. the failure pattern of Specimen WG5, shown in Figure 8. For the specimens with extruded elastomer soft layer a combined sliding and compression failure occurred, exemplified by crushing of the blocks in the first course, shown on Specimen WE5 in Figure 8. Prior to failure, the extruded elastomer specimens developed additional inclined, compression induced, cracks in the lower part of the wall. Simultaneously, uplift of the wallette corners was observed during the cycling.

5 DISCUSSION

Test data on the strength, deformation capacity, energy dissipation and overall behavior of the masonry wallettes with built-in soft layers subjected to static-cyclic loading has been obtained. In the following, the test results are discussed in respect to sliding in the soft-layer bed joint and the influence of different materials and thicknesses of the soft layer on the response mechanism. Soft layer degradation during the cycling is also briefly addressed.

5.1 *Sliding failure and friction coefficient in the bed joint with a soft layer*

Sliding observed in the soft-layer bed joint can be described by the classical Coulomb's failure criterion $\tau = c + \sigma \tan \varphi$, where c denotes the cohesion and φ is the angle of internal friction, i.e. $\tan \varphi$ is a friction coefficient. Taking into consideration the results of wallette tests with rubber granulate, which failed by sliding, cf. Table 3, a friction coefficient in the bed joint can be estimated from the levels of compression and shear in the joint once sliding has occurred. Since the soft layer was placed directly on the block course the cohesion can be set to zero. Thus, an average friction coefficient, calculated from WG3, WG5 and WG10 tests of $47.1/108.0 = 0.44$ was determined. As mentioned before, the wallettes with extruded elastomer soft layer exhibited a mixed sliding-compression failure, thus not allowing for an estimate of the friction coefficient.

5.2 *Influence of the soft layer material and its thickness*

Analyzing the influence of the type of soft layer it could be concluded, as seen from Figure 9, that the specimens with different types of soft-layer material behaved somewhat differently. All specimens with rubber granulate soft layer exhibited nearly the same values of shear resistance and dissipated a considerable amount of energy (exhibited large area under the hysteresis). The wallettes with built-in extruded elastomer exhibited smaller energy dissipation, for the same layer thickness. However, these specimens attained higher shear resistance. From Figure 9 it can also be seen that all specimens had a similar initial stiffness. As expected, the mechanical characteristics of the wallettes progressively degraded with an increasing number of cycles.

The observed energy dissipation obtained by soft-layer sliding, high compared to conventional masonry, is most desirable as it can provide additional damping to typically stiff masonry structures and thus reduce their seismic demand. It is clear from the obtained hysteresis, that considerable energy dissipation could be expected in practical applications, especially when the rubber granulate soft layer is incorporated in the shear wall.

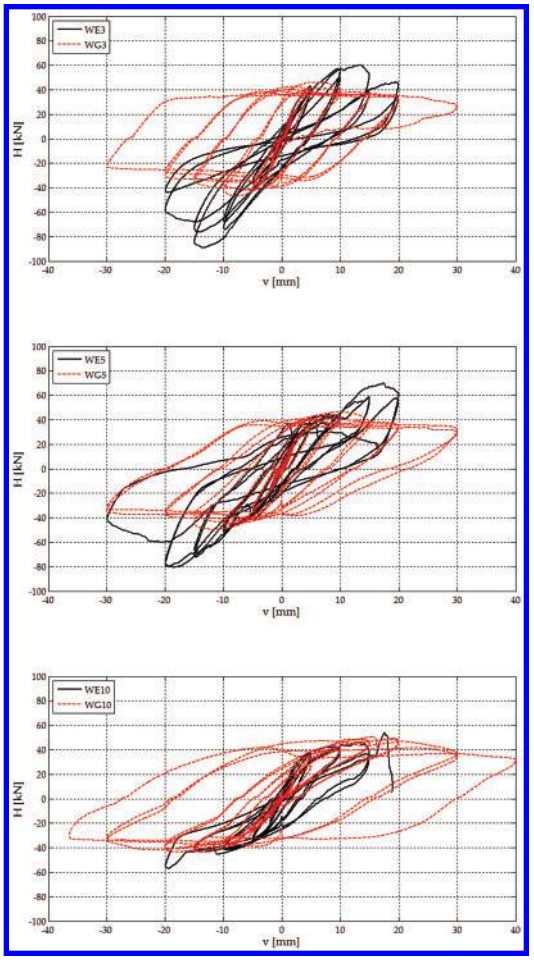

Figure 9. Hysteresis comparison for different soft-layer materials.

The influence of the layer thickness on the specimen response can be seen from the graphs in Figure 10. Specimens with extruded elastomer had the same initial stiffness, but the wallettes with thinner layers were stronger. It seems that the layer thickness had no influence on the shear resistance of the wallettes with built-in rubber granulate layers, but it affected their initial stiffness, see Figure 10, with thicker layers making for a softer initial response.

5.3 *Soft layer degradation*

With decreasing layer thickness, the degradation of the soft layer increased. Figures 11 and 12 show the extruded elastomer and rubber granulate soft layers after the tests, respectively. Degradation was greatest for Specimens WG3 and WG5, where rupture and crumbling of the layer was observed. For extruded elastomer layers, however, such pronounced degradation was not observed. This fact should be taken

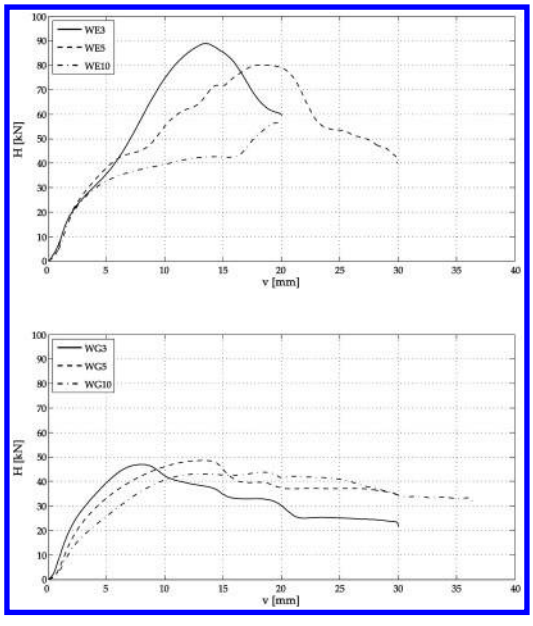

Figure 10. First-cycle force-displacement hysteresis envelopes.

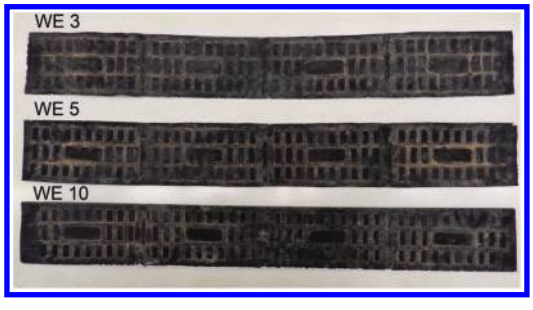

Figure 11. Soft layer damage after cycling: extruded elastomer.

Figure 12. Soft layer damage after cycling: rubber granulate.

into account in the case of cyclic (seismic) loading of masonry with soft layer built into the bed joint.

6 CONCLUSIONS

The presented analysis and discussion of the preliminary results of tests on the series of masonry wallettes with two different types of soft layer allow following conclusions to be drawn:

- Shear strength of the specimens was influenced by the type of the soft layer: the specimens with extruded elastomer layer were stronger. Further, the shear strength of the specimens with rubber granulate was independent on the layer thickness.
- A Coulomb failure criterion with zero cohesion can be applied to predict the horizontal shear capacity for wallettes with rubber granulate soft layer.
- Considerable energy dissipation and quasi ductile behavior, i.e. a large deformation capacity, compared to that of conventional masonry, could be expected in actual masonry structures with soft layer placed in the bed joints. Such behavior is desirable for enhanced seismic performance.

The extension of the presented research will include a new series of tests on the wallettes with the soft layer placed between the masonry wall and concrete base slab. The main parameter will be the pre-compression level and the soft-layer thickness. Further, due to the above-mentioned problems with the control of the applied pre-compression tests W0, WE3 and WE5 will be repeated.

ABSTRACT: Brittle failure behavior is an intrinsic characteristic of slender masonry towers that behave as cantilever beams. The application of the classical nonlinear finite element analysis (NLFEA) methods for the seismic assessment of such structures often involves difficulties in the definition of post-peak behavior, which can be characterized by a sudden decay. In order to investigate the post-peak behavior of such structures the Sequentially Linear Analysis (SLA) method has been used as possible alternative tool to the usual nonlinear static analysis methods. Both NLFEA and SLA have been applied to a historical Italian masonry tower. A 2D plane stress and a 3D solid finite element model of the tower have been set up. The nonlinear behavior of the masonry material, both in tension and compression, has been taken into account. The different modeling approaches and the different analysis methods allowed for the comparison of the results. NLFEA showed a very brittle collapse, with convergence problems after the attainment of the peak load. The application of SLA confirmed the results of NLFEA in terms of base shear-top displacement curves and in terms of damage patterns at the peak load. In addition SLA allowed for the investigation of the post-peak behavior and confirmed the very brittle nature of collapse of the tower, since equilibrium has no longer been found after the peak. In conclusion, the application of SLA to the case study demonstrated the potential of the SLA method as alternative and very robust tool for seismic assessment of masonry towers.

1 INTRODUCTION

1.1 *Seismic vulnerability of masonry towers*

In the last decades, the interest of scientific community for the preservation of historical and architectural heritage has grown significantly. A lot of these historical structures are constructed with masonry, some of them being located in earthquake prone sites.

Towers represent a relevant part of this architectural heritage in many countries around the world, especially in Europe. Generally they have been erected before the last century and made of stone or brick masonry. The particular vulnerability of these structures is evidenced by the collapse of some towers under the effect of static loads only. For very high massive towers, the axial stress arising from the gravity loads can be similar to the compressive strength of historical masonry. Therefore these structures become rather vulnerable to low-intensity earthquakes. This phenomenon has been widely evidenced by a recent earthquake that occurred in Italy on May 20th 2012. The earthquake caused extensive damage of many historical masonry towers and for some of them even a collapse (Fig. 1). The presented scenario about possible damage and collapse of ancient masonry towers highlights the need to safeguard this important segment of our architectural heritage.

1.2 *Drawbacks of classical nonlinear analysis methods*

The protection for potential seismic actions requires an effective seismic assessment of the structures, which can be achieved through suitable finite element models and advanced nonlinear finite element analyses (NLFEA).

However, dealing with nonlinear analysis of masonry structures often leads to convergence problems and numerical instabilities. Several factors contribute to such computational issues. Firstly, both

Figure 1. Damaged and collapsed masonry towers after Emilia's earthquake: (a) Poggio Renatico Bell Tower; (b) Finale Emilia Tower.

the softening laws in tension and compression that describe the behavior of masonry after the attainment of the resistance imply the introduction of negative stiffness contributions. This will often lead to an ill-conditioned stiffness matrix and so to divergence of the numerical solution. Secondly, in case of slender towers, the limited ductility of the masonry combined with their slenderness generally provides an even more brittle behavior.

Moreover, such slender structures can be treated as vertical cantilever beams fixed at the base. This isostatic scheme is inherently brittle, which makes these structures particularly vulnerable to seismic actions. Finally, for large-scale structures the localization of damage involves a very narrow zone with respect to the dimension of the whole structure. As a consequence, the curves that express the global behavior of the structures (e.g. in terms of base shear-top displacement) often presents snap-backs and/or snap-through points.

Due to the above mentioned reasons, classical incremental-iterative methods are not always successful in solving this type of nonlinear problems, even when combined with complex computational strategies as arch-length methods or indirect displacement control.

1.3 *Philosophy of Sequentially Linear Analysis*

Within this context, a new analysis procedure, namely the Sequentially Linear Analysis (SLA) method, has been developed (Rots & Invernizzi 2004) to overcome these numerical difficulties with the incremental-iterative procedures. This robust approach can be an efficient alternative tool to the standard NLFEA for seismic assessment of masonry structures.

The SLA method involves the running of a series of subsequent linear analyses, in which strength and stiffness are locally reduced in each step. These strength and stiffness reductions can be applied by approximating the softening curve that describes the material behavior in tension and/or compression with a so-called saw-tooth diagram.

Due to the absence of an iteration process in the SLA method, convergence difficulties are avoided. The approach generally enables to capture the overall behavior of brittle structures, including their post-peak responses. Consequently, the effective ductility of existing structures can be assessed, which is of significant importance in the modern performance-based design/assessment methods.

In the present paper SLA has been applied to a historical Italian masonry tower, called the Civic Tower of Soncino (Fig. 2). Comparison of the results from pushover analyses using standard NLFEA and SLA confirmed the extremely brittle failure mode of the tower subjected to lateral loads.

Figure 2. Civic Tower of Soncino (Cremona, Italy).

2 THE CIVIC TOWER OF SONCINO: VALIDATION WITH STANDARD NONLINEAR ANALYSIS

The medieval Civic Tower of Soncino (Cremona, Italy) is a historical masonry structure that characterizes the landscape of the small town located in the northern Italy (Fig. 2). The tower of 41.8 m height was erected in the 12th century and presents a square plan with 6 m by 6 m sides. It is characterized by brick masonry walls with thickness varying from 1.55 m at the base to 0.98 m at the top.

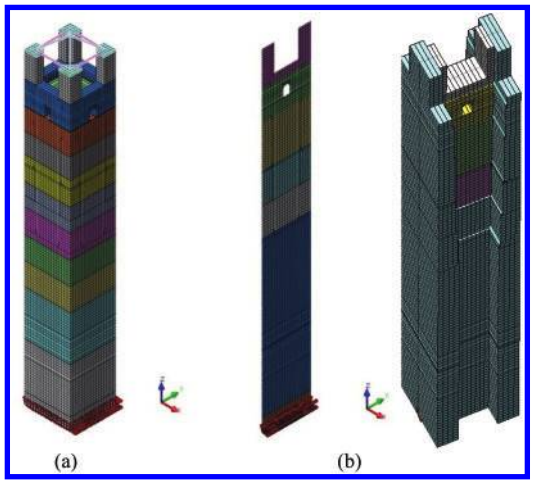

Figure 3. (a) 3D FEM; (b) 2D FEM and extruded view.

Previous studies have been carried out on a 3D finite element model of the tower (Fig. 3a), consisting of standard nonlinear pushover analyses and nonlinear dynamic analyses (D'Ambrisi et al. 2012). With the aim of performing analyses with SLA, a 2D plane stress model of the tower has been set up (Fig. 3b). The model is made of eight-node quadrilateral plane stress elements with 0.3 m by 0.3 m average dimensions. The self-weight and a system of lateral loads has been assigned to the tower, consistent with those assigned in the 3D model of the previous studies.

The 2D model has been preliminarily validated through NLFEA by comparing results of a pushover analysis with the results obtained from the 3D model. Comparisons are made between analyses that only consider nonlinear tensile behavior of the masonry and with analyses that include nonlinearities both in tension and compression.

2.1 *Comparison 3D-2D: nonlinear tensile behavior*

In the first validation of the 2D model the nonlinear behavior of the masonry material in tension is modeled by a Total Strain Fixed Crack Model (Feenstra et al. 1998). The behavior in compression is assumed as linear elastic. A tensile strength of 0.1 MPa and linear softening with an ultimate cracking strain of 1‰ have been adopted, consistent with D'Ambrisi et al. (2012). A reduction of the shear modulus based on the damage due to cracking is also assumed.

The comparison of the results obtained with the two different finite element models has been done by considering the global behavior (pushover curves) and damage patterns at the peak. Figure 4 shows the pushover curves by plotting the shear force at the base against the lateral displacements at the top of the tower models. The two dashed lines are in reasonably agreement. The 2D model shows an overestimation of about 12% and 6% in terms of top displacement and base shear respectively, compared to the 3D model. All the

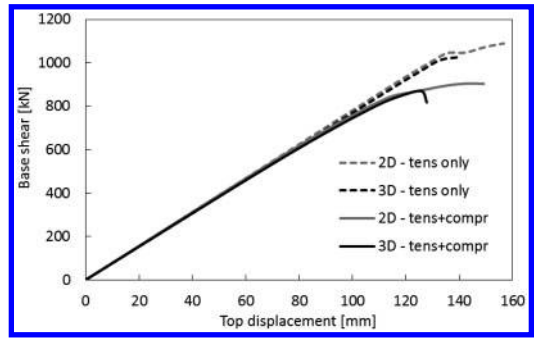

Figure 4. Comparison of the pushover curves obtained with the 3D model and the 2D plane stress model for nonlinear behavior in tension only (dashed lines) and for nonlinear behavior both in tension and compression (solid lines).

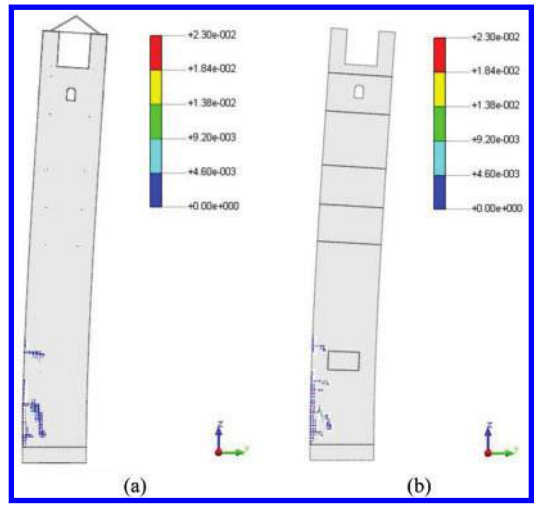

Figure 5. Crack strain contours at the collapse load step of the pushover analysis performed on a (a) 3D and (b) 2D model for nonlinear tensile behavior only.

performed analyses have shown a very brittle collapse, with no substantial softening branch and no convergence of the standard nonlinear analysis procedure after the attainment of the peak load.

Figure 5 shows the crack patterns of both analyses in the deformed shapes of the models. Again reasonable agreement is visible. The observed collapse mechanism involves the formation of a cracked area at the base, accompanied by the development of a severe diagonal macro-crack on the left tensile side.

2.2 *Comparison 3D-2D: nonlinear tensile and compressive behavior*

Subsequently, the nonlinear compressive behavior of the masonry has been considered in the 2D model and 3D model, by assuming elastic-plastic behavior with a compressive strength of 1.1 MPa and a maximum compressive strain of 3.5‰, consistent with D'Ambrisi et al. (2012). Again the pushover curves

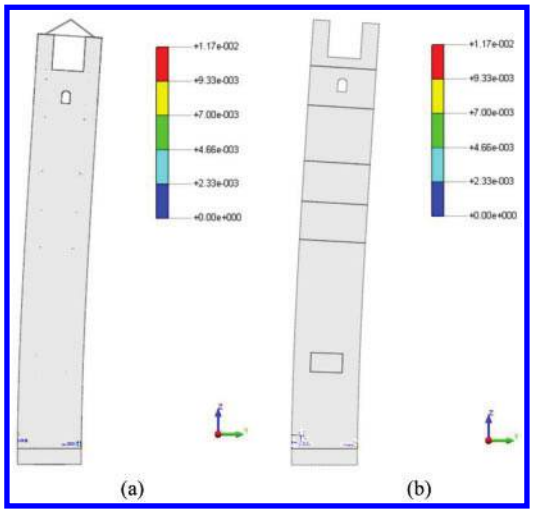

Figure 6. Crack strain contour at the collapse load step of the pushover analysis performed on the (a) 3D and (b) 2D model for nonlinear tensile and compressive behavior.

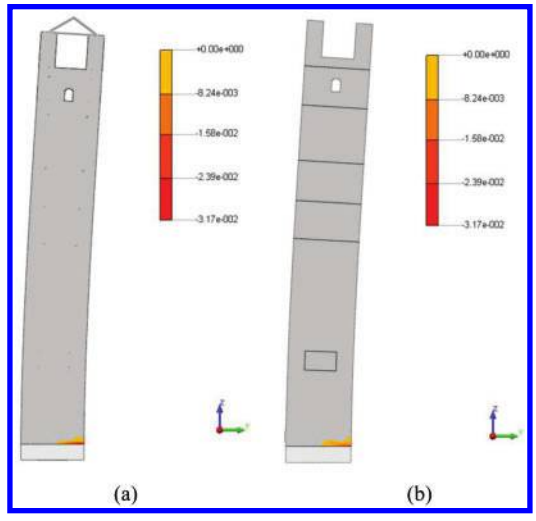

Figure 7. Principal plastic strain contour at the collapse load step of the pushover analysis performed on the (a) 3D and (b) 2D model for nonlinear tensile and compressive behavior.

(solid lines) are plotted in Figure 4. As in Section 2.1, the 2D model provides higher values of maximum top displacement and base shear with an overestimation of 15% and 4% respectively.

Concerning the damage patterns, a good agreement of results has been found, in terms of both cracked and crushed areas, as evidenced in Figures 6 and 7.

3 SLA APPLIED TO SEISMIC ASSESSMENT OF THE TOWER

3.1 *Review of the Sequentially Linear Analysis approach*

The SLA method (Rots & Invernizzi 2004, Rots et al. 2008) captures physically nonlinear behavior by performing a series of linear analyses. After each analysis the applied non-constant load is scaled, so that only in one integration point of the model a critical stress state occurs. Such a "critical event" can happen either in the tensile regime or in the compression regime. Subsequently, the strength and stiffness properties are reduced in the critical point. To apply this damage increment the used softening curves needs to be discretized, resulting in a so-called saw-tooth curve (see Section 3.2).

The nonlinear response of a structure is extracted by linking consecutively the results of each cycle. Especially its robustness and relatively simplicity make this damage controlled procedure attractive to analyze brittle failure behaviors.

The identification of the load scale factor in cases with only non-constant loads is relatively easy. When a constant load is involved the procedure becomes more complicated.

Suppose the structure carries an existing constant load F_A and the task is to sequentially add a new load F_B. The aim is to keep load multiplier λ_{const} for load A at 1, while searching for the critical load multiplier λ_{sca} for the scalable load B by comparing for all points their total principal tensile stress $(1\sigma_A + \lambda_{sca}\sigma_B)_1$ with the current saw-tooth strength. This leads to sets of quadratic equations in λ_{sca} and a unique solution not always exists.

Different points may lead to conflicting constraints for λ_{sca}. Physically, the new cracking for load B leads to redistribution of the constant load A in the system, which in turn may violate the stress criterion for other points and inner cascade cracking may result.

A solution to deal with above mentioned situation is the double-load multiplier method (Graaf, van de 2013). If required the last present total load $(F_A + \lambda_{sca,previous}\ F_B)$ on the system is temporarily scaled via λ_{temp}, allowing for redistribution cracking until all points recover, i.e. all stresses are below their current saw-tooth strength. Thereafter, $\lambda_{temp} = 1$ and the scaling for just load B via λ_{sca} proceeds.

3.2 *Definition of a decoupled saw-tooth material law*

Generally, the analyses with SLA in literature adopted discretized stress-strain curves for nonlinear material behavior only in tension or only in compression. For the present study a saw-tooth material law has been developed to define nonlinear behavior in both tension and compression simultaneously. Figure 8 shows a representation of the saw-tooth material law that has been used in this study.

For simplification it is assumed that for a fixed direction no switch will occur in an integration point from the tensile to the compression regime and vice versa. Within the adopted fixed crack model this means that an integration point can experience only

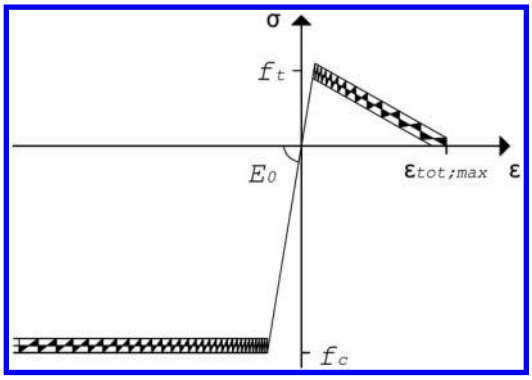

Figure 8. Generalized saw-tooth diagram with linear softening behavior in tension and elastic-plastic behavior in compression.

crushing or cracking in one of the orthogonal crack axes directions. If an integration point is cracked in one direction, it can only be crushed in the other orthogonal direction, and vice versa. Such restrictions were deemed acceptable within the application of a monotonic load, as in the present case. Note that cyclic loading cannot be captured properly with this model.

3.3 *Application of SLA to pushover analyses.*

After the validation of the 2D model for classical nonlinear pushover analyses in Section 2, the SLA method has also been applied on this model for the seismic assessment of the tower. The same material properties have been adopted, and again two load cases were considered. The "constant load" is the self-weight of the tower that will be associated to the λ_{const} multiplier, while the "scaled load" is the lateral load system reproducing the seismic action. Latter will be gradually increased through the λ_{sca} multiplier.

Firstly, the SLA has been applied in the case of nonlinear tensile behavior only in order to verify the reliability of previous results. In Figure 9a the top displacement-base shear trend has been plotted and compared with the pushover curve from the corresponding standard NLFEA in Section 2. The two curves show good agreement in terms of maximum base shear and maximum top displacement. Moreover, SLA confirms the very brittle nature of the collapse, since after the attainment of the peak load a sharp snap-back behavior is visible. However it should be noticed that, at the attainment of the peak load, SLA is no longer able to find equilibrium with the fully applied self-weight of the tower. Therefore the total load is scaled (see Section 3.1), as shown in Figure 9b by the downward trend of λ_{temp} with increasing step number. The convergence problems observed from the standard NLFEA, together with the results of this robust SLA method, indicate that an extremely brittle and large failure of the tower occurs after the peak load.

Secondly, a SLA is performed using the decoupled material law, as described in Section 3.2. The used saw-tooth constitutive relation is shown in Figure 8.

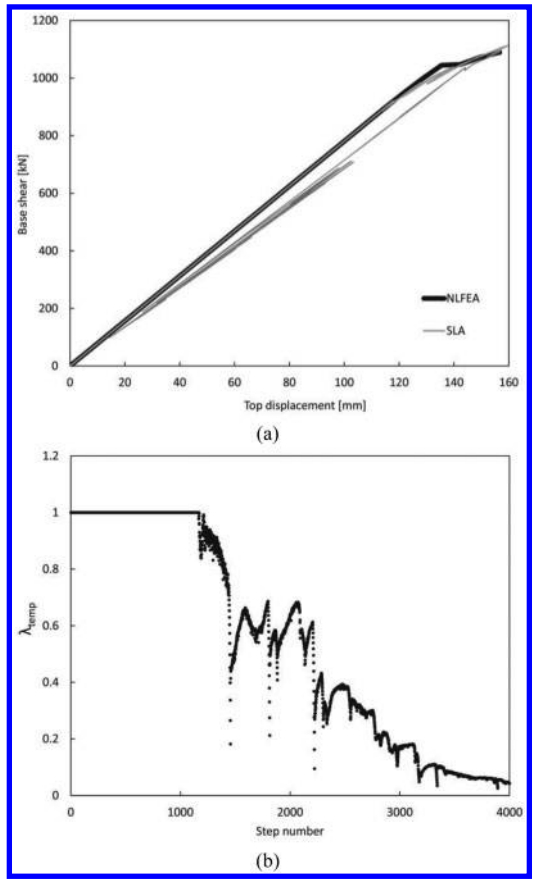

Figure 9. (a) Comparison of pushover curves from SLA and standard nonlinear approach for nonlinear behavior in tension only. (b) Values of λ_{temp} with increasing step number for SLA.

Figure 10a shows the resulting base shear-top displacement trend (light line). Again, comparison is made with the corresponding NLFEA pushover curve from Section 2 (dark line). Good agreement is observed regarding the predicted ultimate capacity of the structure. Differences of 6% with respect to the maximum base shear and 7% with respect to the maximum top displacement has been found. Once again, the SLA detected a snap-back behavior after the attainment of the peak load, confirming the very brittle nature of collapse due to loss of stability of the structure. Again after the attainment of the peak load, the SLA procedure has no longer been able to find equilibrium and consequently the total load has been scaled through the decrease of λ_{temp}, as shown in Figure 10b. This evidence implies that no reasonable solution can be found after the peak load and a very brittle collapse is observed.

Figure 11 shows the overall damage patterns at the peak load of SLA performed in the case of nonlinear tensile behavior only (Fig. 12a) and in the case of decoupled material law (Fig. 12b). While in the first case several macro-cracks develop at the tension side, in the second case the damage is more localized

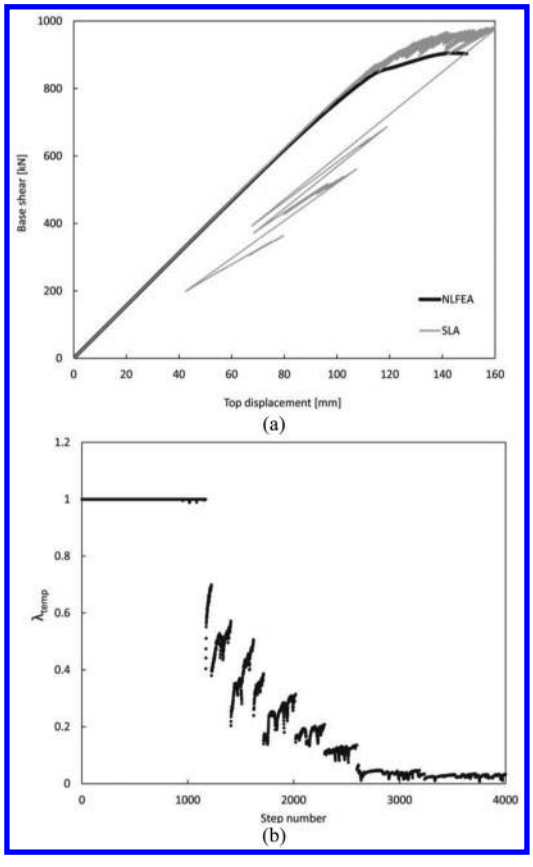

Figure 10. (a) Comparison of pushover curves from SLA and standard NLFEA for nonlinear tensile and compressive behavior. (b) Values of λ_{temp} with increasing step number for SLA.

at the base, where the formation of a wide hinge is observed. Reasonable agreement with the corresponding NLFEA damage patterns (Fig. 5a and Figs. 6b, 7c respectively) has been observed.

4 CONCLUSIONS

The Sequentially Linear Analysis method has been applied for the seismic assessment of the Civic Tower of Soncino. A 2D model of the structure has been set up and preliminarily validated through NLFEA by comparing the results of a pushover analysis with the results obtained from the 3D model developed in previous studies. Afterwards, the SLA procedure has been applied to the 2D model; firstly, considering nonlinear behavior in tension only and then defining a saw-tooth decoupled material law, with nonlinear behavior in both tension and compression simultaneously. Comparison of SLA and standard NLFEA results shows reasonable agreement in terms of pushover curves and crack/damage patterns. The standard NLFEA failed to overcome the peak load due to the occurrence of convergence problems.

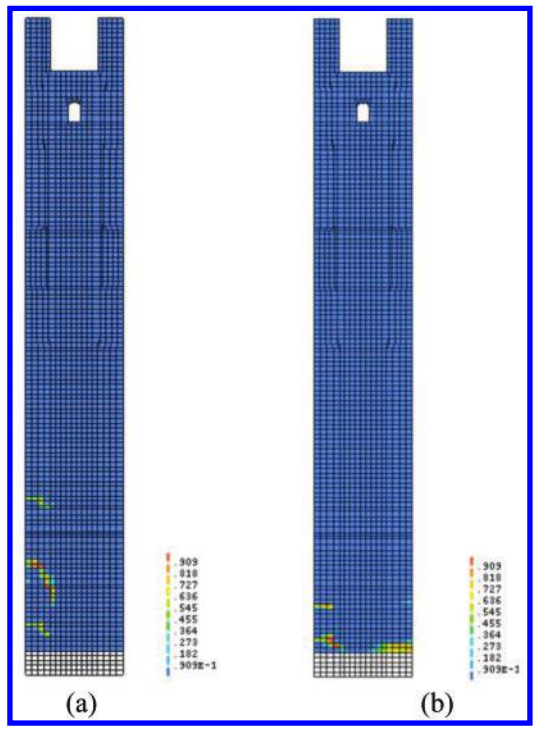

Figure 11. Contour of damage indicators at the collapse load step of the SLA for (a) nonlinear tensile behavior only and (b) nonlinear behavior in tension and compression.

From the results of the SLA method it can be observed that after the attainment of the peak load equilibrium can no longer be found with fully applied self-weight of the tower, meaning that the collapse occurs for the development of a very brittle mechanism.

In conclusion the application of the SLA procedure to the case study has shown its potential as possible robust alternative to the classical nonlinear analysis methods for the seismic assessment of masonry towers.

Experimental evaluation of the response of ferrocement strengthened lightweight masonry walls to impact loads

Mohamed A.N. Abdel-Mooty
Structural Engineering Department, Faculty of Engineering, Cairo University

ABSTRACT: Lightweight Autoclaved Aerated Concrete (AAC) blocks are used in external building's façade due to their favorable heat insulation characteristics that result in energy saving. However, such nonstructural unreinforced lightweight masonry walls have weak or no resistance to blast loads. They shatter under shock loads resulting in flying debris that increase the possibility of casualties and injury. Retrofitting and upgrading external masonry walls in existing buildings in high explosion-risk areas can provide the needed life protection for the users of those buildings. The use of ferrocement technology in strengthening of existing unreinforced nonstructural lightweight masonry wall to enhance their resistance to blast and short duration impact loads is proposed in this research. Two layers of ferrocement are applied to the external and internal face of the wall creating a sandwich structure with lightweight infill. The composite action of the strengthened wall is enhanced using shear connectors between the AAC masonry and the ferrocement. In this research program, the necessary laboratory tests to evaluate the dynamic response of ferrocement strengthened AAC masonry walls to short duration impact load simulating blast effect are carried out. The test programs included testing 7 full scale wall panels under impact. Different ferrocement reinforcement layouts are tested in this research. Three different types of shear connectors are used and their effect on the impact response of the wall is evaluated experimentally. The impact test apparatus developed in this research program is versatile enough to test a large variety of specimens modeling façade units.

1 INTRODUCTION

Blast resistant measures can be taken into consideration during the design stage of new structures ranging from choosing the building layout, the safe stand-off distance, appropriate construction materials and structural systems, and suitable details to resist a blast effect. However, existing structures do not have that advantage. Yet, existing buildings may be located in high risk area while they are not equipped to provide the needed protection to their occupants. In recent years, a significant amount of research work has been carried out to assess the resistance of structures under shock and impact loads and in particular blast loads (Abdel-Mooty *et al* 2010a and 2012a, Schenker *et al* 2008, Baylot *et al* 2005, and Jones 1989).

The primary causes of injuries and death in vehicle-bomb attacks against buildings are glass fragmentation, the impact of other debris from façade shattering, and building collapse. Resistance to these vulnerabilities is generally provided by passive features such as additional reinforcement and the use of composite fiber wraps and other coatings to prevent shattering of columns, slab and walls (Schenker *et al* 2005).

The use of ferrocement technology for strengthening existing lightweight masonry walls against impact and blast loads is proposed in this research. Lightweight autoclaved aerated concrete (AAC) blocks are used in external building's façade due to their favorable heat insulation characteristics that result in energy saving. However, such nonstructural unreinforced lightweight masonry walls have weak or no resistance to blast loads. They shatter under shock loads resulting in flying debris that increase the possibility of casualties and injury. Properly retrofitted façade elements should remain integrated to minimize the devastating effects of flying debris on occupants. A building façade should also minimize the blast load effect transmitted to the main structural frame to prevent building progressive collapse under such extreme loads.

Ferrocement is a type of reinforced mortar commonly constructed of hydraulic cement mortar reinforced with closely spaced layers of relatively small diameter wire mesh (IFC-Committee 2001). The ferrocement mortar matrix is a homogeneous mix composed primarily of Portland cement, well graded fine aggregate (sand), and water. It may contain chemical admixtures such as super-plasticizers and mineral admixtures like fly ash or silica fume to improve its properties. Intensive researches were conducted on ferrocement material to study the structural behavior of ferrocement sandwich load bearing wall panels (Swamy *et al* 1988, Fahmy *et al* 2006, and Abdel-Mooty *et al* 2010b and 2012b).

In this research an experimental program is developed to evaluate the dynamic response of wall panels to short duration impact loads. Two layers of ferrocement

are applied to the external and internal face of the wall creating a sandwich structure with lightweight infill. The composite action of the strengthened wall is enhanced using shear connectors between the AAC masonry and the ferrocement. The test programs included testing 6 full scale wall panels under impact in addition to one specimen tested under static load.

2 TEST PROGRAM AND SETUP

The impact test apparatus developed and used in this research is capable of testing different types of specimens with different supporting conditions. It is basically a pendulum mass that is released to fall freely from a specified height and hits the specimen at the lowest height of the pendulum (Figure 1). The apparatus is firmly attached to a concrete foundation to ensure its stability. The pendulum of the apparatus could be adjusted to have masses between 68.52 kg and 433.97 kg and a drop height between 100 and 300 mm. The impact mass is made of a steel plate with rigid impact head hung horizontally using four cables attached to the top of the pendulum support frame. The impact mass can be adjusted by securely attaching additional steel plates to the impact mass plate. Attached to the impact head is a fatigue rated impact load cell to measure the input impact load on the specimen. The impact load cell is of mass 2.68 kg and has maximum capacity of 200 kN impact. Four other load cells of the same type are attached to the specimen support frame between the back face of the specimen and the vertical columns of the support frame to measure the reactions forces transmitted to the support frame during impact (Figure 2).

The overall nominal dimensions of the tested specimens are 1800 mm wide, 1400 mm high and 250 mm thick as shown in Figure 2. The specimens are built using lightweight Autoclaved Aerated Concrete (AAC) blocks of dimensions 600×200×200 mm with a 25 mm thick mortar layer placed on each face. The normal mortar layers are replaced with ferrocement layers of the same thickness for strengthened specimens. Each specimen is placed vertically in the impact test frame, resting on a short bracket fixed to the steel columns. The specimen is horizontally supported on the vertical columns of the test frame where the reaction load cells are attached. The horizontal span between the load cell support points is 1280 mm, while the vertical span is 1000 mm. The applied impact force is measured by the load cell attached to the impact head that hits the specimen at the center point of the front face, while the reactions are measured by the four load cells at the supports on the back face of the specimen. A high speed data acquisition system is used in this study to measure the dynamic response parameters in terms of the applied load history, and reactions at supports.

Plaster layer of normal strength mortar 25 mm thick is applied on the two faces of the wall specimens. For ferrocement reinforced walls, high strength mortar reinforced with steel welded wire mesh is used in place of the normal plaster. Different types of connectors are used in the wall testing (Fig. 3). The first type is 50 mm steel nails placed in the fresh mortar joints during specimen preparation every 200 mm in both directions. The embedded part of the nail is 35 mm while the projected part is 15 mm which is connected

Figure 1. Impact test apparatus.

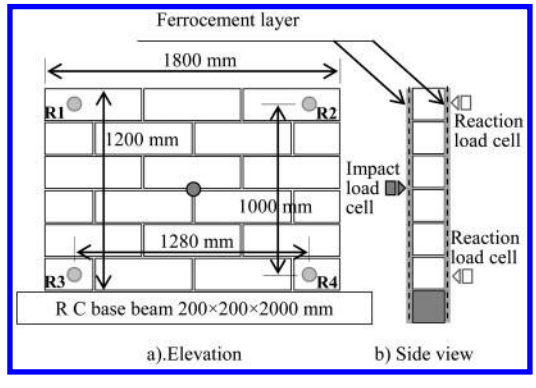

Figure 2. Specimen and instrumentation layout.

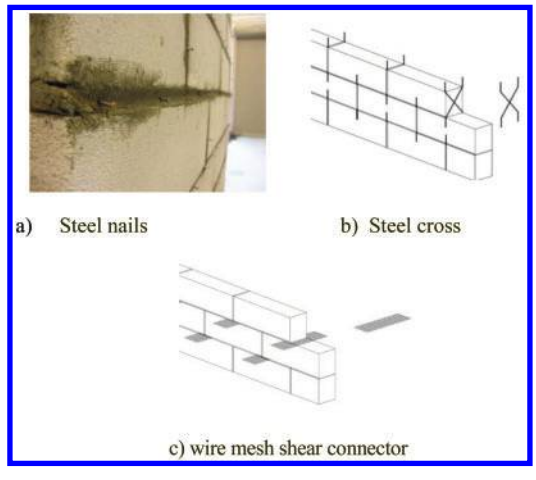

Figure 3. Different types of shear connectors.

to the welded wire mesh reinforcement. The other type of the connectors is welded wire mesh strip layed in the mortar bed joint during construction with 100 mm projected strip to be bent vertically and overlapped with the ferrocement reinforcement mesh. A third type of shear connector is made of steel cross bracing of 3 mm diameter steel bars placed in the vertical joints of the wall. The ferrocement mortar was applied using a standard plastering process. First mortar layer of thickness approximately 10 mm is placed then the welded wire mesh is placed on the mortar and attached to the shear connectors; then the rest of the mortar layer is applied to a total thickness of 25 mm. The test programs included testing 6 full scale wall panels under impact in addition to one specimen tested under static load as shown in Table 1.

The physical and mechanical properties of the component of the ferrocement reinforced AAC masonry wall specimens are experimentally measured. Compressive strength tests are conducted on cube specimens of 100 mm edge length tested in an air dried condition. The average compressive strength of the tested cubes is 3.13 MPa. The average dry density of the AAC blocks measures 597 kg/m^3 while the average moisture content measures 10.2% of weight.

The mortar used in this research consists of two different types. The first type of mortar is normal strength mortar used in joints of the wall specimens and in normal plastering on both faces of the control wall. According to common practice, the cement to sand ratio is 1 to 2.5 with cement content 350 kg/m^3 of mortar and water/Cement ratio 0.5 resulting in average compressive strength of 21.03 MPa. The second type of mortar is used in applying the ferrocement layer on the walls. To provide the needed strength and protection to the reinforcing wire mesh the ferrocement mortar matrix should be workable, high strength, and well compacted mortar. The cement to sand ratio is 1 to 2 with cement content 665 kg/m^3 of mortar and water/Cement ratio 0.3. Superplasticizer was used in the mix at 2.5% of the cement weight, to provide the mortar mix with high workability. Silica fume was used in the mix 12% of the cement weight to attain high strength. Standard cubes 50 × 50 × 50 mm cured for 28 days yields average compressive strength of 60.84 MPa.

Table 1. Test program for full scale ferrocement strengthened AAC masonry walls.

Specimen	Wall strengthening	Shear Connectors
Impact Load Test:		
Wall-1	Control (no ferrocement)	N/A
Wall-2	Ferrocement strengthened	Steel nails
Wall-3	Ferrocement strengthened	Steel nails
Wall-4	Ferrocement strengthened	Cross bars
Wall-5	Ferrocement strengthened	wire mesh strip
Wall-6	Ferrocement with RC Vertical ties on the sides	Steel nails
Static Load Test:		
Wall-7	Ferrocement strengthened	Steel nails

Galvanized steel welded wire mesh of diameter 1 mm at spacing 15 mm is used as reinforcement of the ferrocement layers. Samples of the steel wire mesh were tested to determine the yield and ultimate stress according to ASTM A 370. The average tensile strength of the tested wire meshes is 400 MPa.

3 TEST PROCEDURE AND RESULTS

The impact mass of 240 kg and drop height of 200 mm were kept constant for all tested specimens. The impact load and the reactions at the four supporting points are recorded with time for each hit. The specimen was visually inspected after each hit and cracks and damage are recorded. The impact test is repeated from the same height until failure of the specimen. The crack patterns and mode of failure are recorded for each specimen. The number of hits that a specimen can sustain before failure presents a quantitative measure of the ability of the specimen to resist impact load and maintains its integrity. The control specimen without ferrocement reinforcement failed at first hit where the wall broke into three large pieces as shown in Fig. 4, at a relatively low impact load of 7.59 kN. All other tested walls sustained several impacts before failure. Furthermore, the failure of all ferrocement reinforced specimens was ductile where the wall remained integrated. Typically, a vertical crack initiated in the back side of the specimen at the center. With successive hits, the crack propagates and widens then bifurcates to the corners of the RC beam. Finally a mechanism of failure formed and the specimen loses its strength. The mechanism of failure for Wall-6 with two columns on the sides was slightly different. It started with a crack that propagated vertically, followed by punching failure (Fig. 8).

The time history of the impact and the reactions at the four supports are recorded for all tests. Figure 4 shows the time history record for impact and reactions for the control specimen Wall-1. The initial (highest) impact record for specimen Wall-3 with steel nails connectors is shown in Fig. 5. It is clear from the figure that Wall-3 sustained much higher impact

Figure 4. Failure of control specimen Wall-1 at the first hit.

Figure 5. Failure of Wall-2 with nails connectors.

Figure 6. Failure of Wall-4 with cross connectors.

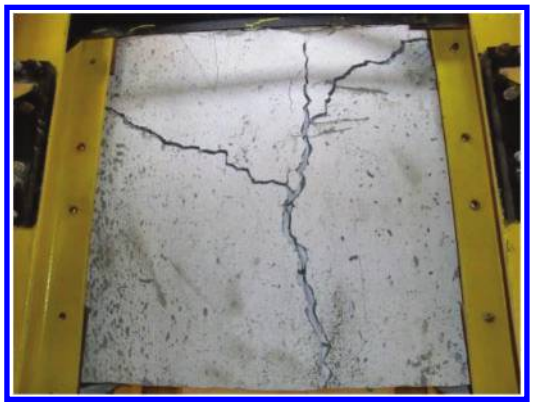

Figure 7. Failure of Wall-5 with mess connectors.

load than Wall-1 (control) with only hair crack and no failure. Wall-3 sustained 6 impact hits before its failure. Of course, with successive hits and increased propagation of cracks, the stiffness of the specimen decreases and the value of recorded impact decreases. It was also observed that the reactions at the support recorded exceed the impact force. This is expected due to the dynamic nature of the problem and the associated inertia force of the wall.

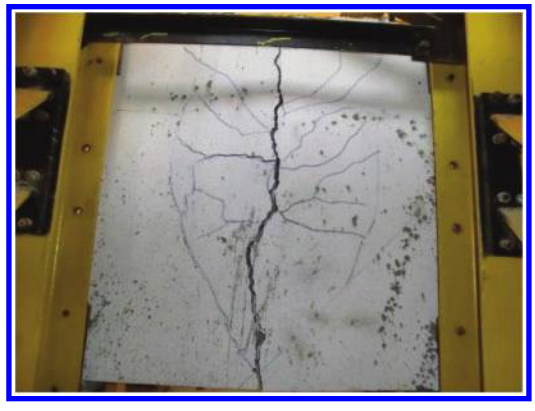

Figure 8. Failure of Wall-6 with two columns on the sides.

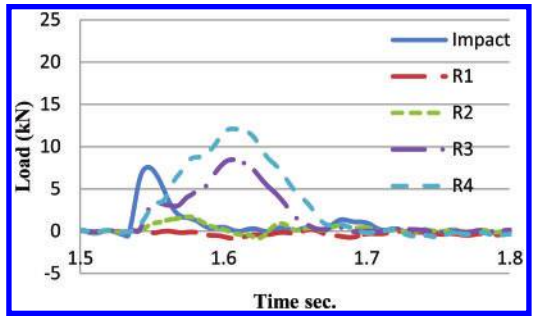

Figure 9. Impact record for control specimen Wall-1.

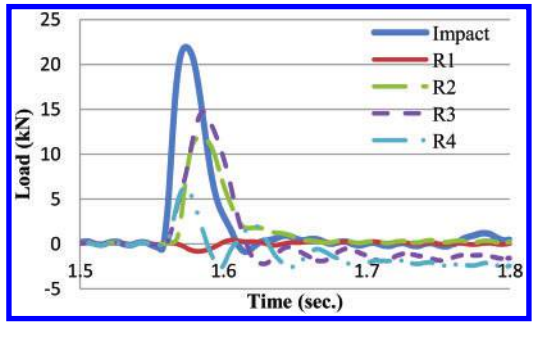

Figure 10. First impact record for Wall-3.

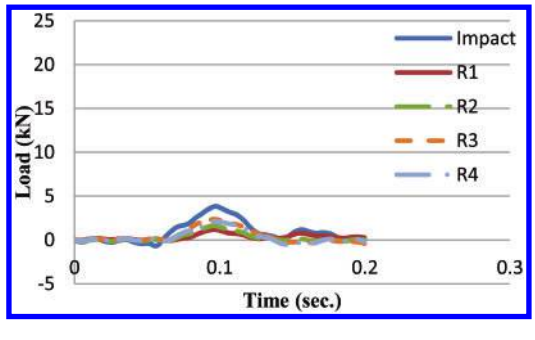

Figure 11. Sixth (final) impact record for Wall-3.

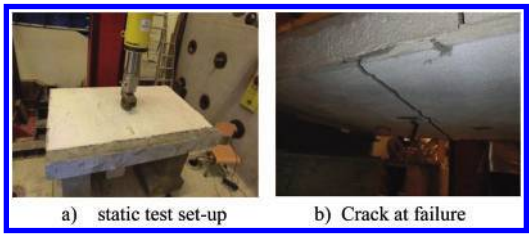

Figure 12. Failure of Wall-7 under increasing static load.

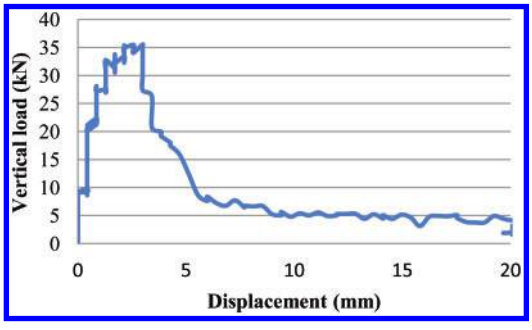

Figure 13. Static load-deformation relationship for Wall-7.

Table 2. Summary of impact test results.

Specimen	No. of impact hits to failure	Initial/high impact (kN)	Final/Failure impact (kN)
Wall-1	1	7.587	–
Wall-2	6	19.282	6.882
Wall-3	6	21.941	3.847
Wall-4	6	23.391	7.137
Wall-5	11	21.417	6.425
Wall-6	19	26.124	6.982

Wall-7 was tested under monotonically increasing vertical load up to failure. The test setup and cracks at failure are shown in Fig.12. Failure occurred suddenly at load 35 kN at which a longitudinal crack developed at the center of the specimen under loading point (Fig. 12b). Sudden decrease in load capacity occurs at failure as shown in Fig. 13.

4 ANALYSIS OF TEST RESULTS

The test results in terms of number of impact hits sustained by each specimen up to failure, the initial/maximum impact load and the final/failure impact are displayed in Table 2. Figure 14 shows the maximum initial impact for the tested wall. It is clear that the ferrocement reinforcement of the AAC masonry wall increases the initial strength almost three-fold. Furthermore, the toughness of the wall, represented by the number of impact hits that the specimen could sustain up to its failure, is significantly increased due to the addition of ferrocement as indicated in Table 2.

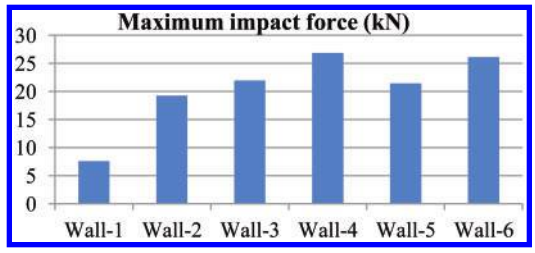

Figure 14. Initial maximum impact load for tested specimens.

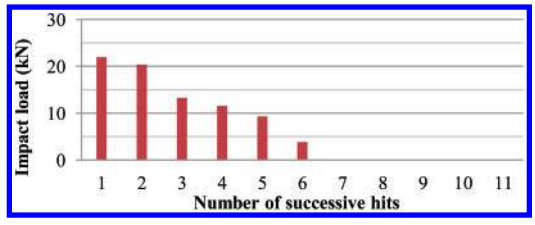

Figure 15. Variation in impact load for successive hits on Wall-3.

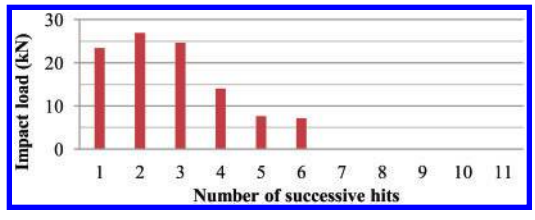

Figure 16. Variation in impact load for successive hits on Wall-4.

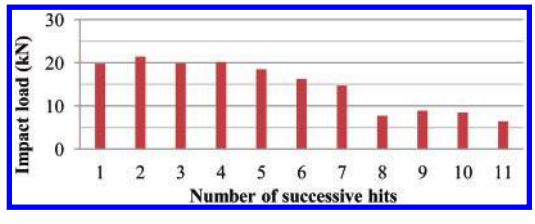

Figure 17. Variation in impact load for successive hits on Wall-5.

It is observed in all strengthened specimens that the recorded impact load gradually decreases with each successive hit up to failure. This is due to the initiation and propagation of cracks and the associated loss in stiffness of the specimen. Figures 15-18 show the variation in impact load with successive hits up to failure for Wall-3, Wall-4, Wall-5 and Wall-6.

The reactions at the four supporting points were measured and recorded for all tests. It is observed that the total reaction in general exceeds the applied impact for all tests. The difference between the applied impact and the reactions at support increases with the successive hits for all specimens. Initially, for sound specimens before damage, the measured reaction was approximately 150% of the applied impact. As the

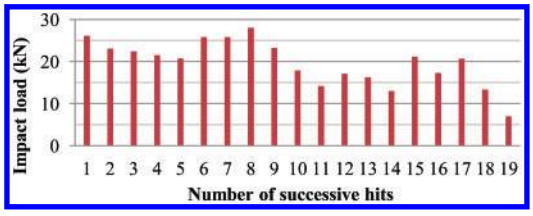

Figure 18. Variation in impact load for successive hits on Wall-6.

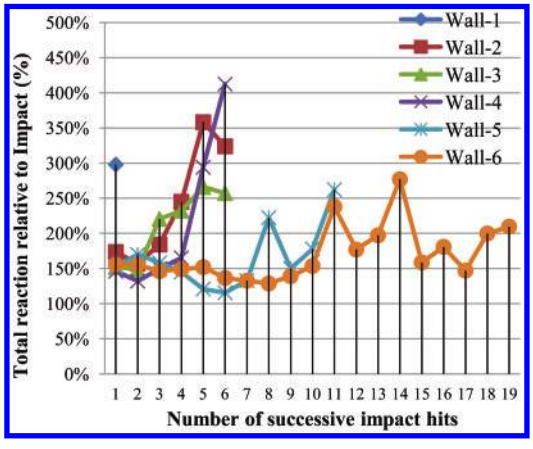

Figure 19. Variation in total reaction for successive hits.

cracking and damage in the specimen increase and propagate, the reactions increase by 2 or 3-fold near failure. This is due to the reduced stiffness of the specimen and increased period.

5 SUMMARY AND CONCLUSIONS

The performance of ferrocement reinforced AAC masonry walls under impact load is evaluated in this paper. The normal plastering on each face is replaced by a 25 mm thick ferrocement layer. Seven wall specimens were tested in this research, six under impact load and one under static loading to failure. Each specimen was subjected to several impacts up to its failure. The impact mass and the drop height were kept constant for all tests.

It is found that the ferrocement reinforcement improves significantly the impact performance of the specimens. While the unreinforced specimen failed at the first hit and disintegrated into pieces, all reinforced specimens survived several hits and remain integrated even after failure. This would result in better protection to the building and its occupants from the damaging effect of flying debris during the impact event. Ferrocement reinforced specimens sustained higher impact forces up to three folds of the unreinforced walls. With repeated impact hits, the strength of the specimen decreases which is represented by reduced impact load.

The total reactions measured at the support generally exceed the applied impact. This effect becomes more pronounced as the cracking and damage of the specimen increases with successive impact.

Several types of shear connectors were tested in this research, namely steel nails, cross bars, and wire mesh strips. It is found that the wire mesh connector provide better performance of the wall under impact. Furthermore, the addition of vertical RC ties at the edge of the wall significantly adds to the strength of the specimen and improves its impact response.

Externally applied retrofit system for existing masonry buildings subject to progressive collapse

A. Kousgaard & E. Erdogmus
University of Nebraska-Lincoln, Nebraska, USA

ABSTRACT: This study proposes the design of a cost effective retrofit method for progressive collapse that can be externally applied to existing masonry structures. An existing load-bearing masonry wall structure was investigated for progressive collapse resistance considering various wall-opening scenarios. Using commercially available finite element programs and the guidelines set forth by UFC 04-023-03, progressive collapse analysis was carried out on the macro model of the existing structure (i.e. entire building). Based on the deficiencies found, an externally applied retrofit system was then investigated using micro models of a deficient isolated wall with the appropriate boundary conditions. The analysis and design of retrofit carried out followed the relevant codes in United States.

1 INTRODUCTION

1.1 *Background*

Modern-era disasters have implemented standards for design against progressive collapse. After the explosion and subsequent progressive collapse at the Ronan Apartment towers in 1968, revisions of design criteria were adopted in England and the United States (Pearson & Delatte 2005). In 1995, after the bombing of the Alfred P. Murrah Building, the United States government adopted interim guidelines for design against progressive collapse (Marchand et al. 2006). Finally, after the collapse of the World Trade Center Towers in 2001, the United States Department of Defense developed and adopted the Unified Facilities Criteria (UFC) 04-023-03: Design of Buildings to Resist Progressive Collapse (Stevens et al. 2011).

Under the current codes and standards, in the case of an adaptive reuse, masonry wall buildings may require the evaluation of their resistance against progressive collapse. Due to the brittle material characteristics and otherwise complex behavior of masonry wall buildings, the progressive collapse analysis and the necessary retrofits for such existing buildings are challenging and costly to implement.

1.2 *Goals*

The goals of this study are to develop a parametric study of a load-bearing masonry wall structure using various opening scenarios and to design a cost effective retrofit for a deficient isolated wall from the parametric study.

1.3 *Scope and assumptions*

The studied building is based on an actual building in the United States. However, it is revised and idealized both for project confidentiality and parametric study purposes; and studied as a hypothetical three-story structure. The building is assumed to have a capacity of 250 people and to have a structural system composed of fully grouted load-bearing 20.3 cm CMU walls with a 9.2 cm architectural brick veneer. The interior is a reinforced concrete frame and slab. For the purpose of this study, the interior frame and slab were not investigated. The exterior load-bearing walls are continuous with the slab framed into each floor. This study also does not include seismic or blast effects on the structure, soil structure interaction and overturning, plastic deformations, and lateral loading. For this study, the following assumptions were also made:

- The building is a non-essential, government facility.
- Lower bound strength values are based on guide lines and values from UFC 04-023-03 (2009), ASCE 41 (2006), and MSJC (2008).
- The load-bearing exterior masonry walls have force-controlled modes of failure.
- The failure occurs before plastic deformations.
- The framing plans for each floor are the same.
- The floor system is a one-way rigid diaphragm.

2 METHODOLOGY

2.1 *Parameters*

The parameters that remained constant in this study can be seen in Table 1.

The variable parameters in this study included:

- Flexural lower-bound strengths used to determine structural adequacy
- Window scenarios/layout
- Reinforcement [unreinforced (URM) or reinforced (RM)]

Table 1. Constant parameters.

Parameter	Description
Building use	3 story office building
Occupancy category	II
Load bearing wall	20.3 cm* fully grouted hollow CMU
1st story height	4.06 m
2nd story height	3.91 m
3rd story height	3.91 m
Reinforcement	2# 4 in lintels

*The standard U.S. size of 8" CMU

Table 2. ASCE 41-06 masonry default properties.

Property	Masonry condition	
	Good	Fair
Compressive strength (f 'm)	6205 (kPa)	4137 (kPa)
Elastic modulus (E)	3411 (MPa)	2274 (MPa)
Modulus of rupture (f_r)	138 (kPa)	69 (kPa)

Modulus of rupture (f_r)	1034 kPa

*Source: MSJC-08

– Compressive strength (f'_m)
– Elastic modulus (E)
– Modulus of rupture (f_r)

Material properties that were used to model the masonry building in SAP2000 were taken from ASCE 41-06 and MSJC-08. The ASCE 41-06 properties can be seen in Table 2. These material properties are based on the deterioration and condition of the masonry. As the mode of failure investigated in this study is flexural tension, good and fair conditions of masonry were investigated; poor condition was not considered because it is assumed to have no tensile capacity. The material properties from MSJC-08 can be seen in Table 3. These material properties are representative of new masonry or masonry that has not yet deteriorated.

Lower-bound strengths for reinforced masonry were taken as the calculated strength of the masonry lintel (ΦM_n). Lower-bound strengths for unreinforced masonry were taken as the modulus of rupture (f_r) multiplied by phi (Φf_r). The respective lower-bound strengths based on ASCE 41-06 and MSJC-08 material properties can be seen in Table 4 and Table 5, respectively.

The openings are treated as a variable parameter to test the increased vulnerability of a masonry wall

Table 4. ASCE 41-06 flexural tension lower-bound strengths.

Property	Masonry condition			
	RM		URM	
	Good	Fair	Good	Fair
$\Phi Q_{CL} = \Phi f_r$ (kPa)	N/A	N/A	83**	41**
$\Phi Q_{CL} = \Phi Mn$ (kNm)	82.8*	82.5*	N/A	N/A

*$\Phi = 0.9$
**$\Phi = 0.6$

Table 5. MSJC-08 flexural tension lower-bound strengths.

Property	Masonry condition	
	RM	URM
$\Phi Q_{CL} = \Phi f_r$(kPa)	N/A	620**
$\Phi Q_{CL} = \Phi Mn$ (kNm)	82.9*	N/A

* $\Phi = 0.9$
** $\Phi = 0.6$

Table 6. Window scenarios.

Code or standard	Masonry type	Windows
MSJC-08	RM	No windows
		1.83 m × 1.22 m
		2.44 m × 1.83 m
		3.05 m × 1.83 m
ASCE 41-06	RM	No windows
	URM	No windows

with change in the amount and size of window/door openings. The tested "window" scenarios can be seen in Table 6. Each of the window scenarios was analyzed with each of the three removal cases presented in section 2.2.

2.2 *Removal cases*

Removal cases are based on UFC 04-023-03 (2009). Removals along the east wall, the south wall, and at the corner of the building were made. Each removal is made one at a time, followed by a linear static analysis to determine if failure has occurred. For load-bearing masonry walls, the length of the wall removed is twice the length of the story height (2H). For corner removals, each side of the corner has a length of the story height removed (H). The removal cases can be seen in Figure 1. All removals were done on the first story of the building.

UFC 04-023-03 specifies that removals along the wall should be made in the middle of the wall. For the south wall, this was done. However, based on judgment, the engineer can shift the wall removals by length H. For this study, the east side removal was shifted due to a door opening in the wall; this shift created a more vulnerable structure.

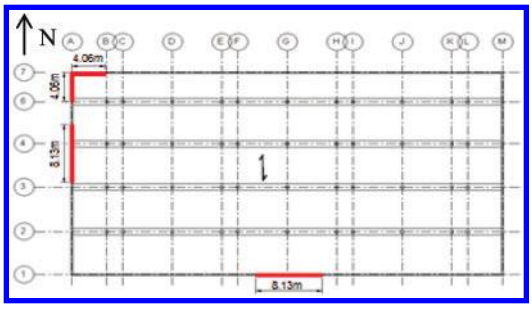

Figure 1. Removal locations.

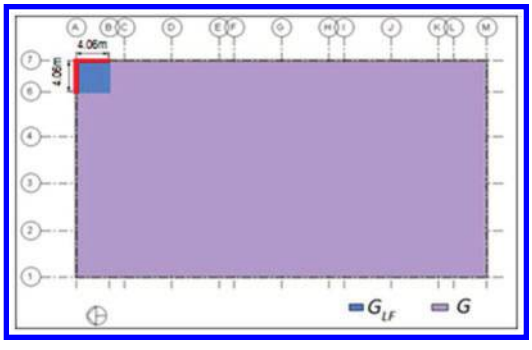

Figure 2. Gravity loading distribution.

2.3 *Loading*

Loading is determined by UFC 04-023-03. Increased gravity loading is required adjacent to the removed wall or element. The different gravity loadings used are defined by the floor areas away from the removed wall and adjacent to the removed wall in Equation 1 and Equation 2, respectively. The different loading areas can be seen in Figure 2.

$$G = [(0.9 \text{ or } 1.2)\, D + (0.5\, L \text{ or } 0.2\, S)] \quad (1)$$

$$G_{LF} = \Omega_{LF}\, G \quad (2)$$

where LF indicates force-controlled linear static analysis; Ω_{LF} = load increase factor; D = dead load; L = live load; and S = snow load.

The load increase factor is defined in UFC 04-023-03 and in this study was taken as 2.0.

For this study, no lateral loading was considered. The 2009 UFC 04-023-03 specifies the only lateral loads to be considered as notional loads. After preliminary results, notional loads were determined to not control the mode of failure of the building. Therefore, lateral loads and their effects are not discussed here.

2.4 *Analysis*

Modeling and analysis for this study was done using SAP2000 finite element analysis software. Because the masonry was fully grouted, it was modeled using the "concrete" elements but with modified material properties. A linear static analysis was used for the parametric study because it was assumed failure occurred before reaching plastic deformation. In order to consider material nonlinearities and geometric nonlinearities in the studied isolated wall, a nonlinear static analysis was used for the retrofit investigation.

Each removal case was modeled with the corresponding material properties and window scenarios presented in Table 2, Table 3, and Table 6, respectively. In total, there were 24 different models that were analyzed for progressive collapse. In order to account for the reinforcement tensile strength in the reinforced masonry, if the moment from the SAP2000 results was greater than ΦM_n from the respective Table 4 or Table 5, the building was considered inadequate for progressive collapse resistance. If the resulting tensile stress for unreinforced masonry was greater than the respective lower-bound strength in Table 4 or Table 5, the building was considered inadequate for progressive collapse resistance.

3.3 *South wall removal*

The results for the south removal analysis for reinforced masonry and unreinforced masonry can be seen in Table 11 and Table 12, respectively.

It is worth noting that because of the window layout for the south side removal, the removal is larger than twice the height of the story. At a removal length of 2H, the removed area intersects with windows; this would leave unsupported masonry in the location of the windows. The unsupported masonry would not provide additional strength to resisting progressive collapse, therefore it was removed and the final removal length was 12.6 m. With respect to the removal length and the resulting tensile stress, this was the worst case scenario in the parametric study, thus it is selected for the retrofit design.

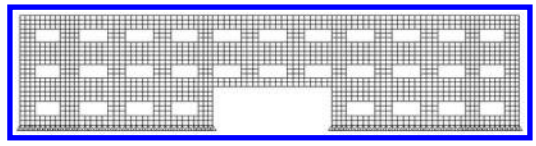

Figure 3. Elevation of south wall with removal.

3.4 *Observations*

The results from the parametric study showed that openings in a masonry wall create vulnerability to failure from flexural tension. Failure occurred around openings or removals due to in-plane gravity loading.

4 RETROFIT DESIGN

4.1 *Deficient isolated wall*

The worst case scenario and the selected wall to be investigated was the reinforced south wall with 3.05 m × 1.83 m windows and MSJC-08 properties seen in Table 4. Based on the results presented in section 3, the south wall was deemed vulnerable to failure. An elevation view of the south wall with the removal can be seen in Figure 3.

4.2 *Proposed Retrofit Scenarios*

A common technique used to increase the tensile strength of masonry is to apply fiber reinforced polymer (FRP) to the tension face of the masonry. However, the cost for FRP can be high. In 2011, Radik, Erdogmus, and Schafer showed that fiber reinforced cement (FRC), when used as an externally applied retrofit layer similar to FRP, has a comparable increase in tensile capacity to glass-fiber-reinforced polymer (GFRP) but could be as much as 215% less expensive.

In this study, FRC was investigated as a retrofit to the south wall with the removed area. The FRC was modeled after the properties found in the study done by Radik, Erdogmus, and Schafer. Type N PCL mortar was used with a 1% volume ratio. The fibers used were polypropylene synthetic fibers. The properties found and used in this study can be seen in Table 13.

Three types of retrofit scenarios were studied. The first retrofit (R-1) was a 2.5 cm layer of FRC applied to the backside of the entire wall, as it would be with typical out-of-plane failure. This was studied based on the hypothesis that increasing the wall thickness would decrease the flexural stresses due to in-plane gravity loads because of the increased moment of inertia.

Table 13. Properties of FRC.

Property	Value
f'_c	8.07 MPa
$f't$	0.11 MPa
E	10,204 MPa
γ	1922 kg/m^3

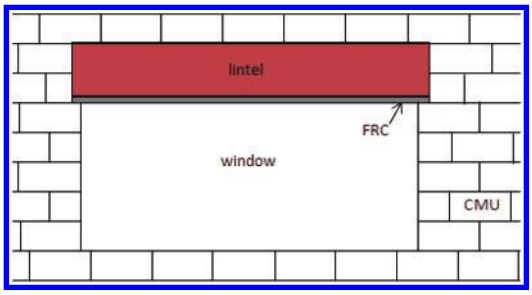

Figure 4. FRC layer under CMU lintel*Not to scale.

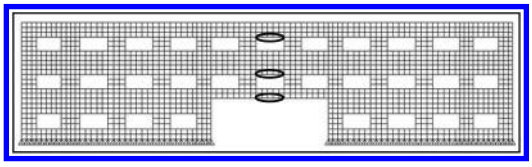

Figure 5. Investigated areas for failure.

The second retrofit (R-2) applied a 2.5 cm layer of FRC underneath the CMU lintel. The 2.5 cm layer was chosen based on the study done by Radik, Erdogmus, and Schafer. In that study, the 2.5 cm layer provided the highest tensile capacity gain and provided the largest cost difference (215%) compared to the GFRP retrofit. An example image of the 2.5 cm layer of FRC retrofit can be seen in Figure 4.

The third retrofit (R-3) applied a 20.3 cm layer of FRC underneath the lintel. The 20.3 cm layer of FRC reflects the size of a standard CMU in the U.S. (8 inches). As such, this 20.3 cm layer could be easily modeled as an additional course of masonry with the FRC material properties. As an externally applied retrofit, the 20.3 cm layer decreases the window size and the architectural alterations may need to be considered in a real life application.

4.3 *Results*

Before and after the application of the retrofits, tension stresses were investigated at the mid-span of: a) the removal area, and b) at the two window openings above the removed area. The areas investigated for failure are circled in Figure 5. Negative values within the following tables indicate compression stress.

The tensile stresses with retrofit R-1 can be seen in in Table 14.

The tension stresses with retrofit R-2 can be seen in in Table 15.

Table 14. Stresses before and after 2.5 cm FRC layer over entire wall per SAP2000 (R-1).

Opening	initial f_u (kPa)	f_u with R-1 retrofit (kPa)	pass/fail with R-1
Top window	−1070	−9.37	pass
Middle window	1210	1250	fail
Removal	1920	1710	fail

Table 15. Stresses before and after 2.5 cm FRC layer over openings per SAP2000 (R-2).

Opening	initial f_u (kPa)	f_u with R-2 retrofit (kPa)	pass/fail with R-2
Top window	−1070	−6.75	pass
Middle window	1210	8.20	pass
Removal	1920	1720	fail

Table 16. Stresses before and after 20.3 cm FRC layer over openings per SAP2000 (R-3).

Opening	initial f_u (kPa)	f_u with R-3 retrofit (kPa)	pass/fail with R-3
Top window	−1070	−7.17	pass
Middle window	1210	13.6	pass
Removal	1920	2010	fail

The tension stresses with retrofit R-3 can be seen in in Table 16.

5 CONCLUDING REMARKS

Higher stresses were seen in the wall where there were larger openings and openings that were near the removed area. Higher stresses were also observed at the corners of the openings. This is because the reinforcement was designed to be just longer than the lintel per appropriate development and embedment length provisions of older masonry structures. Modern lintel design horizontal reinforcement is continuous throughout the masonry. This development length provides added resistance to tensile forces. When the lintel is designed to have a development length of just longer than the lintel, there are areas of unreinforced masonry that are vulnerable to tensile stress. This stress often resulted in failure of the masonry.

The retrofit of the entire wall being layered with FRC does not decrease the stress above the removed area and the opening enough to adequately resist progressive collapse.

The retrofits using layers of FRC above the openings reduces the stress above the openings. However, the stress over the removal was not decreased enough to be adequate to avoid progressive collapse. It would be worth investigating a retrofit that involves placing FRC at floor level in order to strengthen the entire wall.

Another way to strengthen the entire wall may be to replace a portion of mortar joints with FRC. Because of the decreased tensile stress in the 2.5 cm layer of FRC above the openings, it would be worth investigating replacing this retrofit. This type of retrofit would require modeling the wall with differentiated CMU and mortar instead of modeling the wall as modified concrete.

Finally, because CMU and FRC have different material properties, the cohesion and bond between the FRC and CMU needs to be investigated further. If the joint between the FRC and CMU fails, the retrofit may become inadequate because the FRC would disengage from the CMU; the wall would return to the original state before a retrofit was applied.

Non-linear static analysis of masonry-infilled RC frames

A. Koçak & B. Doran
Yıldız Technical University, Istanbul, Turkey.

A. Kalyoncuoglu & B. Zengin
Istanbul Gelisim University, Istanbul, Turkey

ABSTRACT: A common type of construction is low-rise and mid-rise reinforced concrete buildings with unreinforced masonry walls which are usually referred to as infill walls filling the spaces bounded by their structural frames. The effect of these walls may be ignored if the frame is to be designed against gravity. However, ignoring the effect of infill walls against seismic loads may lead to a highly vulnerable situation under earthquake motions. Therefore, in non-linear analysis, this effect should be taken into account in numerical model using equivalent diagonal strut approaches for accurate solution. This study aims to explore the effect of masonry-infilled frame on the non-linear static analysis. In this context, non-linear static analysis (pushover) has been performed based on FEMA 356 for these approaches separately. Besides, the effect of thickness of the wall on the lateral response is also studied. Results show that frames with unreinforced masonry walls infills generally enhance lateral capacity and energy dissipation.

1 INTRODUCTION

Masonry-infilled walls as architectural elements of a typical frame structure can be found as interior and exterior walls in reinforced concrete and steel-framed structures. They are mostly considered as non-structural elements, and their presence is often ignored by structural engineers. Infill walls are often neglected in the analysis of building structures (Bare RC frame) because of their complex nature and also the absence of a realistic analytical model. Ignoring the effect of the infill in stiffening and strengthening the surrounding frame is not always a conservative approach, especially in seismic design. Different analytical models had been used considering experimental results to simulate the behavior of infill walls.

Infilled frames were first studied by Palyakov (1956). The infill walls placed in reinforced concrete frames did increase the rigidity of the building; and thus, it was suggested that infill walls should be modeled like diagonally crossing rods (Bounopane and White, 1999). Mehrabi et al. (1996) conducted experiments on bricks with and without hollow spaces and concluded that when vertical loads on the infill walls are increased, then the total horizontal bearing capacity of the composite frame also increases by 25%. Dolšek & Fajfar (2008) found that masonry infill highly increases the stiffness and strength of a structure as long as the seismic demand does not exceed the deformation capacity of the infills. On the other hand, Amanat & Hoqueb (2006) observed that, the beam and column stiffness have negligible effect on the period. This study also shows that randomness in the distribution of infill does not have a significant effect on the period; instead, it is the total amount of infill that is important. In their study regarding reinforced concrete frames with and without infill walls, Altın et al. (1992) reported an increase of 6 to 28% of the initial rigidity if a whole connection between the infill wall and the frames are considered. Puglisi et al. (2008) proposed a model for the behavior of infill panels in framed structures which is based on the equivalent strut model, the plastic concentrator concept, and damage mechanics. Hong et al. (2002) and Asteris (2003) observed the effects of reinforced concrete framed infill walls at earthquake conditions and the effects of infill walls with or without the door and window openings. They concluded that frames with door and window openings are less rigid and have higher periods than those without any openings. Dowrick (1987) concluded that infill walls did increase the structural strength and rigidity; Aytun (1972) and Bayulke (1998), on the other hand, stated that infill walls decreased the building periods while also increasing the rigidity of the system. Sivri et al. (2006) carried out a time history analysis utilizing the records of the Düzce and Erzincan earthquakes to a building which was also analyzed experimentally by Negro and Colomba. The structure was analyzed under three different conditions

for infill walls: no infill walls, with infill walls, and with infill walls above the ground floor. They concluded that infill walls had a significant effect on the building period and ignoring their effects negatively influences the safety of the building. Govindan et al. (1986) subjected cyclic loads to two different seven-storey buildings with infill walls and bare frames. They calculated and compared the horizontal rigidity, ductility and energy dissipation capacities of infill walls and frames. Govindan et al. found twice as high bearing capacity of infilled walls, five times higher rigidity and 2.6 times smaller displacement ratio at the top of the frame. Güler et al. (2008), performed a numerical analysis of data collected from an experimentally vibrated building, in which infill walls were defined as diagonal compression struts. Korkmaz et al. (2007) performed pushover analysis on a 3-story R/C frame structure with different amount of masonry infill walls using diagonal strut approach. Pushover curves were obtained for the structures using nonlinear analyses option of commercial software SAP2000. The effects of irregularities were determined in the structural behavior under earthquake. Hossein Mostafaei & Toshimi Kabeyasawa (2004) achieved three dimensional non-linear time history analyses for both bare frame and infilled frame in order to obtain an analytical answer for the performance of an existing building and an approach was developed to model masonry infill walls with or without opening. Kappos, A.J & Panagiotopoulos, CG. (2003) performed extensive analysis of typical R/C building including brick masonry infill walls arranged either regularly or irregularly. A nonlinear constitutive law was used for describing the contribution of infills with a diagonal strut model. Pereira et al. (2009) conducted a parametric study of pushover analyses of a RC frame of an office building to represent the influence of the masonry infill panels using three commercial software packages (SAP 2000, SeismoStruck and MIDAS/CIVIL). Due to length and location of the plastic hinges forming near the end of the structural elements and different loading patterns, the structural behavior and non-linear capacity curves of the RC frame were also studied.

In this study, the effect of infills on seismic performance has been investigated employing the nonlinear static analysis using commercial SAP 2000 package.

2 THE INFLUENCE OF DIFFERENCE EQUIVALENT STRUT MODELS ON THE LATERAL LOAD BEARING CAPACITY

Experimental and theoretical remarks have showed that a diagonal strut with appropriate geometrical and mechanical characteristics could simulate the behavior of infill walls. Polyakov (1960) first suggested the possibility of considering the effect of the infilling in each wall as equivalent to diagonal bracing. Holmes (1961) replaced the infill by an equivalent pin-jointed

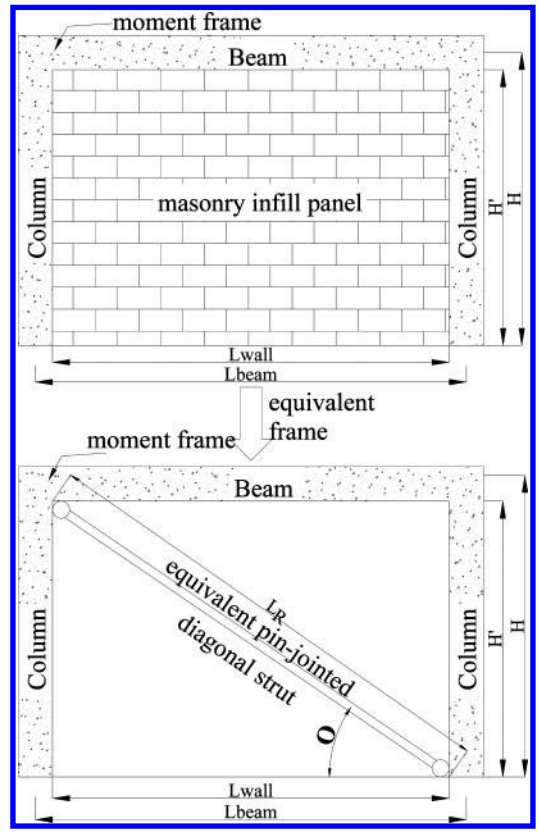

Figure 1. Equivalent strut model for masonry infill walls.

diagonal strut made of the same material and having the same thickness as the infill wall and a width equal to one third of the infill diagonal length (L_R) (Figure 1).

Stafford Smith (1966) and Stafford Smith & Carter (1969) suggested two pin- connected equivalent diagonal struts related the width of the equivalent diagonal strut to the infill/frame contact lengths using an analytical equation. Proposed model based on the elastic theory and frame/infill contact length has been related the effective width of the diagonal strut with a dimensionless relative stiffness parameter, λ:

$$\lambda_h = \sqrt[4]{\frac{E_{wall} \times t \times \sin(2\theta)}{4 \times E_{concrete} \times I_{column} \times H}} \quad (1)$$

where, E_{wall} is the modulus of infill, t is the thickness of infill, θ is the angle between diagonal and horizontal of infill, H is the height of infill (Fig.1). Based on the frame/infill contact length, alternative proposals for the estimation of the equivalent strut width are given in Table 1.

In this study, Eqs.(2–8) are used to simulate the mechanical behavior of infill walls considering compression failure mode. Geometrical properties together with the contact detail of sample 2D

infilled frame are depicted in Figure 2 and mechanical properties are given in Table 2.

Furthermore, considering unreinforced wall with the effective width according to different researchers (Table 1), sample 2D frame system is modeled and nonlinear load-deformation characteristics of individual elements of the structure is formed. All frames were designed in accordance with Turkish Seismic Code (TEC 2008) for peak ground acceleration equal to 0.40 g, a medium soil and a high ductility class. Reinforcement details are depicted in Figure 3.

The pushover analyses were then performed with the following assumptions. The vertical distribution of the horizontal forces was always assumed according to an inverted triangle shape. Beams and columns were simulated with Takeda-type non-linear elements. All infills were simulated using equivalent diagonal struts with force-displacement curves (Fig. 4). The initial periods of vibration obtained for the different numerical models with different effective width predictions (Eqs.2–8) are reported in Figure 5. Finally, pushover curves are depicted in Figure 6 for comparison.

Furthermore, the change in wall thickness is also investigated throughout of this study. In this context, struts are modeled using Mainstone (1971) approach

proved to be the most popular over the years because of the ease with which it can be implemented practically into FE models. Considered applicable thicknesses, calculated effective widths and natural periods are given in Table 3. Pushover curves are than depicted in Figure 7 for comparison purposes.

3 CONCLUSIONS

The parametric analyses in this study aims to establish the influence of the modeling concepts of masonry infill mechanism on the performance of the structure to gather with the changes in wall thickness. It has therefore been shown that the establishment of masonry infill is always beneficial in terms of the energy dissipation (Figs.6,7), but depends on the choice of the mechanical modeling approaches which led to simulate the wall behavior accurately. In Figure 6, except Smith and Carter (1969), all curves look similar; when the first crack occurs in walls, a brief descending arises in total base shear of the structure. This is the expected effect for the infill mechanism on the lateral load bearing capacity of the whole structure. Same behavior can also be seen in Figure 7, for the case of increment in wall thickness.

Sisal reinforced cement-based masonry units

G. Coetzee & W.P. Boshoff
Department of Civil Engineering, Stellenbosch University, South Africa

R.D. Toledo Filho
Department of Civil Engineering, Universidade Federal do Rio de Janeiro, Brazil

ABSTRACT: Sisal Fibre Reinforced Concrete (SFRC) blocks has been proposed as a construction material that has the potential to address the economic and environmental issues typically associated with the low cost housing sectors of developing nations. Sisal, a natural fibre, is widely available in Brazil and East Africa. A high-alkalinity environment and the presence of Ca^{2+} causes rapid degradation of the durability properties of sisal fibre. This work addresses the strength and volumetric properties of SFRC blocks. Sisal fibres of length 10 mm were used to reinforce 290 × 140 × 90 mm concrete blocks. Two concrete matrices were developed. One matrix contained cement and fly-ash. To ensure durability, the second matrix had 10% of its cement content substituted by Condensed Silica Fume (CSF). Each matrix was reinforced with 0, 0.5 and 1% fibre by volume. The results showed a decrease in strength with an increase in fibre content. An increase in strength was also observed in blocks containing fibres and 10% CSF. Drying shrinkage tests revealed an increase in shrinkage strain with an increase in fibre content and CSF. Samples were also subjected to four cycles of wetting and drying to establish the effect on dimensional stability. The addition of fibres and CSF was found to improve dimensional stability significantly.

1 INTRODUCTION

A lack of adequate housing is not a problem restricted to Africa, nor to developing countries. Worldwide, there are a reported one billion people living in slums (United Nations, 2007). In South Africa, where 12 million people (or 23% of the population) live in slums (Statistics South Africa, 2012), the low cost housing (LCH) sector has been plagued by problems such as inadequate structural performance, poor policies and management and a lack of acceptance by beneficiaries. The need has arisen for a sustainable, economically viable building material that uses the existing construction methods and political structures.

Natural fibres have been used as reinforcing material, in some way or another, since man started building shelters. In more recent years, since the popularization of plastics and other synthetic materials, natural fibres have come to be considered a traditional building material. With mounting pressure worldwide to develop economically viable, sustainable construction materials, there has been growing interest in the development of new materials that enhance the optimal usage of natural resources, particularly renewable resources.

Sisal fibre, extracted from the leaves of the *Agave sisalana* plant, has been identified as a natural fibre with the potential to be used as reinforcement in cementitious matrices. The plant is widely cultived in Brazil, Tanzania, Kenya and China and smaller plantations exist in Mozambique and the northwest of South Africa (FAO, 2009).

The chemical composition and structure of a natural fibre is quite complicated. Rong et al. (2001) have stated that a fibre cell is essentially a composite in which cellulose microfibrils are embedded in a hemicellulose and lignin matrix. Microfibrils are helically wound around the fibre axis. The microfibular angle and lignin content essentially determine the amount of energy needed to uncoil a fibril, thus determining its strength. A single fibre can consist of many cells that are linked together through the middle lamella, which consists of hemicellulose and lignin. According to Bentur & Mindess (2007) both lignin and hemicellulose can easily be broken down in an alkaline environment, such as found in the pore water of concrete.

Sisal fibre bundles tend to have lengths of between 600 and 1000 mm and widths of between 50 and 400 μm (Müssig, 2010). The tensile strength of sisal ranges between 280 and 750 MPa while the modulus of elasticity is in the range of 9.4-26 GPa. Sisal fibre has a moisture absorption of between 60 and 110% by mass (Bentur & Mindess, 2007; Müssig, 2010). These properties can vary greatly by region of cultivation, extraction practices and age of leaves being harvested.

Natural fibre reinforced concrete (NFRC) tends to undergo an ageing process in which it loses strength

and toughness, especially in humid environments (Silva et al., 2010). The ageing process is mainly due to fibre mineralisation, caused by the migration of hydration products such as $Ca(OH)_2$, to the fibre structure. As mineralisation increases, the failure mechanisms of NFRC tends to shift from fibre fracture to fibre pull-out.

Efforts to improve the durability of NFRC have shown promising results (Tolêdo Filho et al., 2002; Mohr et al., 2005; Gram, 1988). To ensure durability, various matrices have been developed that are free of calcium hydroxide, through the partial substitution of cement content with pozollanic materials such as condensed silica fume (CSF) and metakaolin by as much as 50% by mass.

To address the environmental, structural and economical issues typically associated with low cost housing in South Africa, it was proposed to investigate the mechanical and dimensional properties of sisal fibre reinforced concrete blocks. Blocks of size $290 \times 140 \times 90$ mm, as is often used for LCH applications in inland regions of South Africa, were produced and subjected to compression and drying shrinkage tests as well and dimensional stability tests during cycles of wetting and drying.

2 EXPERIMENTAL PROGRAM AND SETUP

2.1 *Materials and processing*

2.1.1 *Matrix*

The matrix was designed using Mauá CPV-ARI cement, manufactured by Lafarge Brazil. It is fast reacting cement that reaches a relatively high strength in the first days of application. The clinker used is more or less the same as that used for conventional cement, although it stays in the mill for longer. CPV-ARI typically contains very little or no pozzolanic additives (Cimento.org, n.d.). It is comparable to the CEM I type found in South Africa. The ARI designation refers to a minimum 7 day compression strength of 34 MPa.

For the present work two different matrices were developed: one containing CSF to improve durability and one reference matrix. Both matrices were further reinforced with 0, 0.5 and 1% sisal fibre by volume, respectively (see Table 1). The fibre length used was 10 mm. Both matrix types contained a partial substitution of 30% of cement with fly-ash, in order to lower the matrix cost. The fly-ash used for this research was Pozofly, provided by Comércia de Conzas Lima Ltda.

Table 1. Mix proportions

Mix	Content [%]			
	Cement*	Fly-ash*	CSF*	Fibre**
M1	70	30	0	0
M2	60	30	10	0
M3	70	30	0	0.5
M4	60	30	10	0.5
M5	70	30	0	1
M6	60	30	10	1

*% by mass of total cementitious content
**% by volume of concrete

By replacing 10% of the cement content of a matrix with CSF, a matrix with a lowered calcium hydroxide content was developed. Silmix Sílica Ativa condensed silica fumes (CSF), provided by Indústria Brasileira, was used for this research.

The sand used had a relative density of 2.64 and a fineness modulus (FM) of 2.68. A nominal stone size of 9.5 mm was used with a relative density of 2.68 and a FM of 5.7.

The mix proportions were based on various literature sources and trial mixes (Holcim, 2004; Hydraform, 2006; Government of India Development Institute, 2011). All sources specified a low cement content leading to a very dry mix, which is acceptable for producing reasonable strength blocks cheaply. M1, M3 and M5 were all essentially the same (no CSF content), with the only difference being the fibre content. They all had a cementious material content ratio by weight of 7:3 (cement:fly-ash). Similarly, M2, M4 and M6 had the same mix (10% CSF content), with the fibre content being the varying factor. They had a cementitious content ratio of 6:3:1 (cement:fly-ash:CSF). All mortar matrices had a design mix ratio of 1:4.2:2.8:0.62(cementitious material:sand:stone: water by mass).

2.1.2 *Sisal fibre*

The fibres used in this research were obtained from the Municipality of Valente situated in the state of Bahia in the northwest of Brazil. The fibres were provided by the Association for Sustainable Development and Solidarity of the Sisal Region.

The leaves of the sisal plant are smooth with a length and width of about 150 and 10 cm, respectively. To obtain fibres, the leaves were cut and decorticated, after which they were beaten to remove excess decortication waste and left to dry. Lastly the fibres were made into bales.

The fibre bundles used had a length of between 90 and 100 cm. The surface of the fibres showed signs of waste from the extraction process, such as sugar and mucilage. To prepare the sisal fibre for use in concrete reinforcement it was washed in hot water (80–100°C) for two hours followed by a 56 hour drying period in a room held at a constant temperature of 40°C.

After drying, the fibres were brushed with a nail brush to align and separate fibres, after which they were cut to length of 10 mm with a paper guillotine. It should be noted that the brushing process resulted in a fibre loss of around 30% by mass. The fibre used had an average relative density of 1.1.

2.1.3 *Block production*

All matrices were mixed using a pan mixer. Batches of 18 to 24l were mixed at a time, producing 5 to 8 blocks. The aggregate was dry mixed for one minute, after which all cementitious material was added and

allowed to mix for another 30 seconds. For the mixes containing fibres, the fibres were loosened by hand and added to the drum in small volumes to prevent fibre balling. The mixture was allowed to mix for a further 30 seconds. The water was slowly added to the rotating drum and the final mix was allowed to mix for a further 2 minutes.

All test specimens were prepared with dimensions of 290×140×90 mm. Wet concrete was added to steel moulds in four thin layers and hand compacted with a small trowel following each new layer. Using a thick steel plate and an Amsler compression testing machine, each block was compressed to 500 kPa while still wet. Shrinkage test samples were produced similarly, using moulds of 280 × 70 × 70 mm. Blocks were allowed to cure for 12 hours in the moulds at 100% relative humidity (RH), after which they were removed and stored in a curing chamber at 100% RH and 23 ± 1°C.

2.2 *Test methods*

2.2.1 *Compression test*

A Shimadzu UF-F 1000 kN machine was used to determine the compression strength of blocks at 28 day age. The tests were performed under displacement control at a crosshead displacement rate of 3 mm/min. Five specimens of each mix type (M1-M6) were tested. Before testing, blocks were capped using capping mortar and a suitable table. Blocks were tested within 5 minutes of removal from the curing chamber. They were orientated so that the 290×140 mm faces lay horizontal.

2.2.2 *Drying shrinkage test*

Four specimens of each matrix type was tested, starting at an age of 28 days. Drying shrinkage tests were performed over a two month period for all samples. The environment where storing and testing was done was held at a temperature of 23 ± 1°C and relative humidity of 60±5%. During production all samples were embedded with 25 mm steel pins in the middle of the two 70 × 70 mm faces that protruded the faces by approximately 5 mm.

Shortly after removal from the curing chamber each sample was wiped with a damp cloth and weighed. A shrinkage testing rig was set up and the measuring device was zeroed using a metal calibration rod with a length of 295 mm. Each sample was measured pin to pin and the results were tabulated. The samples were stored on a rack, resting on two thin metal wires to allow for free drying shrinkage with minimum friction. For the first two days, measuring was done each hour within office hours. In the following 5 days samples were measured three times a day. In the next two weeks measuring was done once a day and over the remaining weeks, once every three days. In total the test was run for two months.

2.2.3 *Dimensional stability*

Three samples of each matrix type was tested for dimensional stability. Each block was cut to a length of 270 mm (from 290 mm). Three days prior to reaching an age of 28 days, the blocks were allowed to dry in an oven at 60°C for 48 hours. After drying, blocks were moved to a storage room at 34°C and allowed to cool down for 24 hours after which they were weighed.

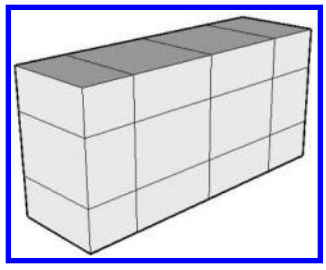

Figure 1. Block segments used for measuring dimensional stability.

Using a marker each block was subdivided into 12 segments as shown in Figure 1. A Vernier calliper was used to measure the lengths, widths and heights of the segments along the edges of the block where possible. Where impossible, linear interpolation was used to estimate values.

The blocks were then soaked in water for 48 hours at 34°C. This was deemed sufficient time to completely saturate the blocks. After removal, the blocks were wiped with a damp cloth so as to remove any excess surface moisture. The dimensions and mass of the blocks were once again measured.

After measurements, the blocks were dried in a wind tunnel at 34°C for 48 hours. This was deemed sufficient to properly dry out the blocks. The dimensions and weight of the blocks were measured once again and the whole process was repeated three more times. In total there were four wet and four dry values for each sample.

The Qhull algorithm (Qhull.org, 2012), used for calculating the volume of a convex hull, was used to determine the volume of each of the 12 segments. The volume of the block after each wet or dry cycle was taken as the sum of the volume of the segments.

3 RESULTS

3.1 *Compression test*

Typical force-displacement curves for the different matrix types obtained from the compression tests are shown in Figure 2.

The average compressive strength for each matrix type are shown in Figure 3. The dotted lines surrounding the curves represent the standard deviation band (distance between standard deviation above and below average). Also, the standard deviation (σ) and coefficient of variation (CoV) are displayed on graph.

3.2 *Drying shrinkage test*

The shrinkage strain was calculated by dividing the change in length at each time interval by the original

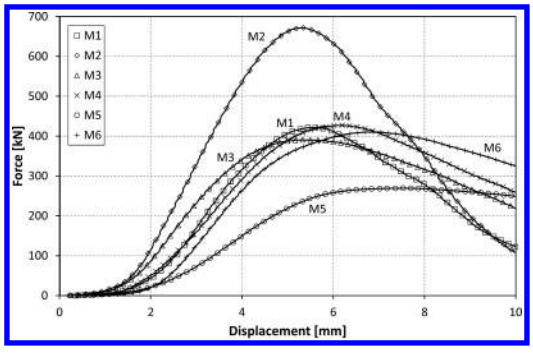

Figure 2. Force-displacement curves for all matrices.

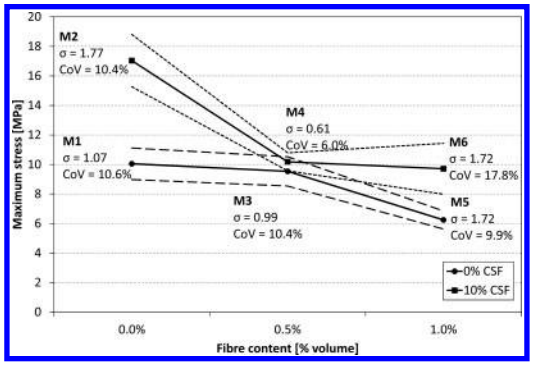

Figure 3. Average maximum compressive stress.

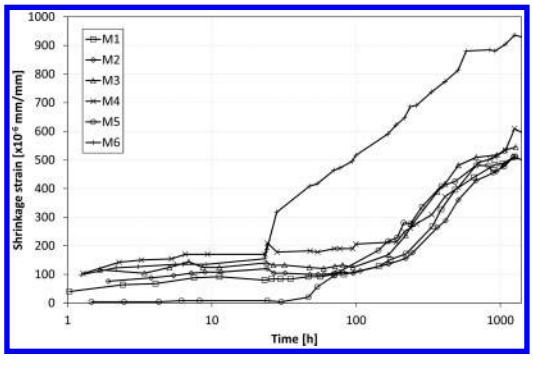

Figure 4. Shrinkage strain-time curves for all matrices.

length between the two metal pins. Typical shrinkage-time curves for each matrix type are presented on a logarithmic scale in Figure 4.

Figure 5 shows the average maximum shrinkage for all six matrices after two months.

3.3 *Dimensional stability*

The volume for each block during each cycle was calculated and the results are represented as a percentage of change in volume relative to the original dry volume (D1). The average change in volume for each matrix type was determined and the results are depicted in Figures 6 and 7.

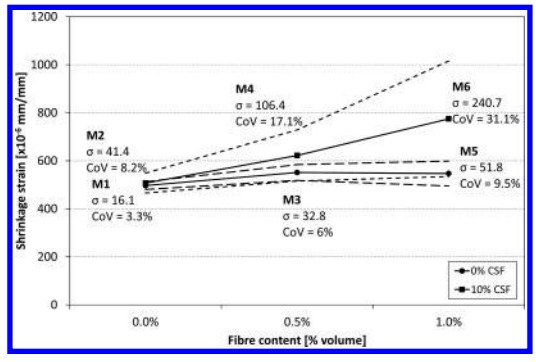

Figure 5. Average maximum drying shrinkage after two months.

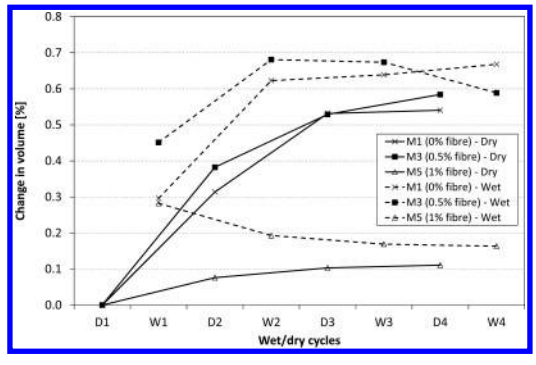

Figure 6. Average change in volume during wet/dry cycles (mixes with 0% CSF).

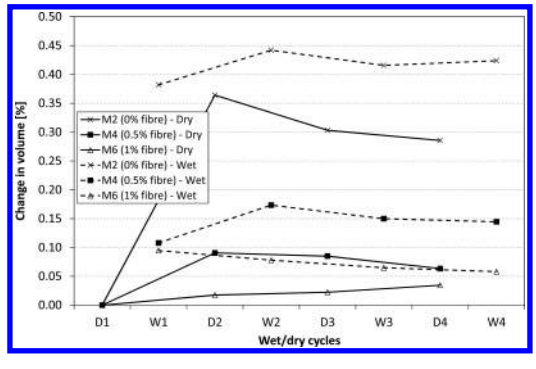

Figure 7. Average change in volume during wet/dry cycles (mixes with 10% CSF).

4 DISCUSSION

4.1 *Compression test*

Considering Figures 2 and 3 it is clear that there is a strong correlation between the compressive strength and fibre content. As fibre content increased, strength decreased as well. From Figure 2 it can be seen that for mixes containing CSF, the stiffnesses during loading (linear part of curve before reaching maximum) reduced with an increase in fibre content (see curves

M2, M4 and M6). The same is true for mixes without CSF (see curves M1, M3 and M5). Also, mixes containing CSF tended to have a higher strength and stiffness than similar fibre volume mixes without CSF. Blocks with higher fibre contents did exhibit higher ductility. The ductility was however not quantified.

Figure 3 shows that, as fibre content increases, the extra strength provided by the addition of CSF decreased from about 70% (0% fibre) to 7% (0.5% fibre) and then increased again to 56% as fibre content is increased to 1%. For 0% CSF mixes, the addition of 0.5% and 1% fibre reduced the stress by about 5 and 38%, respectively. Similarly, the reduction in stress of 10% CSF mixes was about 40 and 43%, respectively. The variation of all mixes was in the region of 10%, with the exception of the M6 results (CoV of 17.8%).

The loss in strength and stiffness with an increase in fibre content could be attributed to the fibre's tendency to increase the air void content and therefore the porosity of the concrete. This results in a lower the strength and stiffness. All strengths are however within the typical required specification for masonry units.

4.2 *Drying shrinkage test*

All matrices displayed a fairly constant shrinkage slope (rate at which shrinkage happens) for the first 50–160 hours (Figure 4). This rate increased significantly up to a time of 500–1000 hours, where after the slopes decreased slightly. It can be concluded that the addition in fibre increased the initial rate of shrinkage. After the first rate change, the effect of added fibres diminished and there seemed to be no significant difference between shrinkage rates. Similarly, the addition of CSF only significantly increased the initial rate of shrinkage, but after the first rate changes the effect became substantially less. The shrinkage result of M6 is seen as an outlier.

Figure 5 shows that in blocks without CSF, the addition of 0.5% fibres led to an increase of 11% in drying shrinkage after two months. Increasing the fibre content to 1% had no significant effect on the total drying shrinkage. For the blocks containing CSF, an addition of 0.5% fibre led to an increase in drying shrinkage of 22%. Similarly, increasing the fibre content to 1% led to a further increase in shrinkage of 24%. Furthermore, the blocks containing CSF showed a considerably higher variation in total shrinkage than the blocks without CSF.

Silva et al. (2010) have stated that the drying shrinkage of a cement matrix is related to the magnitude of its porosity and to the size, shape and continuity of the capillary system in the hydrated cement paste. The porous nature of the fibres creates more paths through which moisture can escape. The addition of sisal fibres therefore increases the porosity of the matrix which leads to higher shrinkages.

Siddique & Khan (2011) mentioned that the substitution of up to 15% of cement (by mass) for CSF in a cement matrix does not have a significant effect on drying shrinkage. This corresponds to the results for matrices without fibres, where the difference in shrinkage between M1 and M2 was less than 2%. However, with the addition of fibres the difference between matrices with and without fibres becomes larger. At 0.5% fibre content the shrinkage was 13% more for the samples containing CSF and the difference increased to 41% at 1% fibre content.

4.3 *Dimensional stability*

Figure 6 shows that the average curves for mixes M1 and M3 have a similar shape for both wet and dry cycles, although the initial change in volume of M3 after the first wetting cycle was about 52% higher than that of M1. Both dry and wet cycle volume changes increased rapidly during the first couple of cycles, but stabilised soon after.

The results of M5 (1% fibre) showed a very different trend. The initial increase in volume change was slower for dry cycles and for wetting there was a decrease in volume change. After a couple of cycles the volume change stabilised. After four cycles there was a difference in change in volume between wet and dry cycles of about 0.05%.

The final average wet change in volume of M5 was 0.163%. For M3, this value was 0.589% (3.6 times more) while the value for M1 was 0.668% (4.1 times higher).

For the average dry volume changes the final value for M5 was 0.111%, for M3 it was 0.584% (5.3 times higher) and for M1 it was 0.541% (4.9 times higher).

Figure 7 shows the average change in volume of mixes with 10% CSF. The blocks containing CSF showed a trend where there was an initial increase in volume during wet cycles, but a decrease as cycles continued. There is a clear decrease in change in volume as the fibre content of the blocks increases. The final average wet change in volume of M6 was 0.058%. For M4, this value was 0.144% (2.5 times more) while the value for M2 was 0.423% (7.3 times higher).

For the average dry volume changes the final value for M6 was 0.034%, for M4 it was 0.063% (1.8 times higher) and for M2 it was 0.285% (8.3 times higher).

For both matrix types (0 and 10% CSF content) there was a decrease in change of volume between wet and dry cycles with an increase in fibre content. Also, the initial change in volume decreased with an addition of fibre content.

Figures 6 and 7 show that at all fibre contents blocks with CSF displayed a smaller initial volume change, as well as a smaller difference between wet and dry blocks. The blocks without CSF and fibres had a 1.9 times higher change in volume for dry cycles than the blocks containing CSF. The final change in volume was about 1.6 times higher for wet cycles.

Similarly, at 0.5% fibre content the blocks without CSF had a 9.2 times higher change in volume for dry cycles and 4.1 times higher change for wet cycles. For blocks containing 1% fibre, the changes were 3.2 and 2.8 times higher, respectively.

It can be concluded that both an addition of fibre and CSF has a significant effect on the change in volumes during wet/dry cycles. Both additions tended to decrease the initial change in volume as well as the difference between wet and dry volumes, indicating that they improved dimensional stability.

5 CONCLUSION

The addition of short sisal fibres to a cementitious masonry unit does lead to a decrease in compressive strength and an increase in ductility. The addition of CSF to matrices did increase compressive strength, but the extent of the effect was lowered as fibre content increased.

Regarding the volumetric properties of blocks, mixed results were achieved. The addition of fibres led to an increase in total and rate of drying shrinkage, while the dimensional stability of blocks, after repeated wet-dry cycles, was significantly improved. The addition of CSF to matrices reduced pore sizes, leading to a significant increase in drying shrinkage and dimensional stability. Sisal fibre does seem to have a use as a means of dimensional stabilisation.

It was also shown that the use of sisal fibre as a cement content reducing material cannot be recommended. The study investigated blocks with fibre contents of 0.5 and 1% by volume and it was found that even at these low volumes the adverse effect on strength was significant. With respects to the results obtained in this research, the positive effects of volume that is added to concrete through the addition of fibre is diminished through the negative effect the fibre has on strength.

Structural design for earth buildings

A.C. Heath & P.J. Walker
BRE Centre for Innovative Construction Materials, Department of Architecture and Civil Engineering, University of Bath, Bath, UK

ABSTRACT: Earth (unfired clay) is used in construction around the world. Buildings can be constructed using compressed earth blocks, mud brick (adobe) or modern extruded earth masonry blocks. The alternative to masonry blocks is to construct as a monolithic structure as used for rammed earth and cob. Higher strength earth masonry systems can give advantages over lower strength alternatives as there is scope to utilise the flexural capacity and bond strength to provide similar structural capacity to fired masonry or concrete block alternatives while having lower embodied energy. Stabilisation of earth masonry can increase both strength and durability but this needs to be balanced with potentially greater environmental impact.

1 INTRODUCTION

Earth is one of the oldest building construction materials and is still in widespread use today, particularly in developing countries. While there are examples of earth building in wetter regions, such as the UK, areas with drier climates tend to have more vernacular earth buildings as earth is susceptible to water damage unless appropriately detailed or otherwise protected.

In 1994 it was estimated that nearly a third of the world's population still lived in a home built of earth (Houben and Guillaud, 1994). The majority of these earth dwellings were in developing countries and with the rapid urbanisation and population growth that has subsequently occurred, this proportion may have decreased, but is still a significant proportion of the world housing stock.

All masonry walls are required to support load, whether just the self-weight of the wall or applied permanent or variable actions. Earth masonry has many benefits over fired clay or concrete block masonry, including environmental sustainability, occupant health, building quality and cultural continuity (Morton, 2008, Minke, 2006) but can suffer from strength reduction with increasing moisture content (Heath et al., 2009, Jaquin et al., 2009). In order to design with these innovative materials, it is necessary to provide sufficient strength and durability while considering the environmental impact.

2 STRUCTURAL DESIGN

Some forms of earth construction (e.g. mud brick (adobe) or compressed earth blocks (CEB)) are similar to more conventional masonry structures where there are bricks/blocks and mortar, but with other forms such as cob and rammed earth, the wall is constructed monolithically resulting in different behaviour to walls with mortar joints.

The structural capacity of earth wall construction can be separated into its ability to carry vertical (compressive) loads or lateral (out of plane flexural or in plane racking) loads. As with other forms of masonry construction, the compressive strength is high compared with the tensile strength, leading to increased efficiency in compressive applications (such as walls, domes and arches) than in purely bending applications (such as beams or other spanning structures).

The analysis of earth buildings could be according to standard procedures such as Eurocode 6 (EN 1996) used in Europe, but the properties (strengths, etc.) will be very different and standard values for other masonry types should not be used. The standard test methods are also not necessarily appropriate and an increased material partial factor can be used to account for increased variability in properties and variations in moisture content.

All structural properties of earth are affected by the moisture content, as shown for a particular modern earth masonry system in Figure 1.

For this particular masonry system there is a sodium silicate based mortar which is stronger than the masonry units (Lawrence et al., 2010). As a result, the flexural strength of the masonry is similar to the flexural strength of the masonry units (blocks). The compressive strength of the masonry is lower than the units because of the increased height to width (aspect) ratio of the masonry.

2.1 *Compressive strength*

The compressive strength for earth masonry should always be presented as "standardised" values where the strength is corrected for the dimensions of the samples and correction factors are presented in masonry test standards. While the change in strength and stiffness

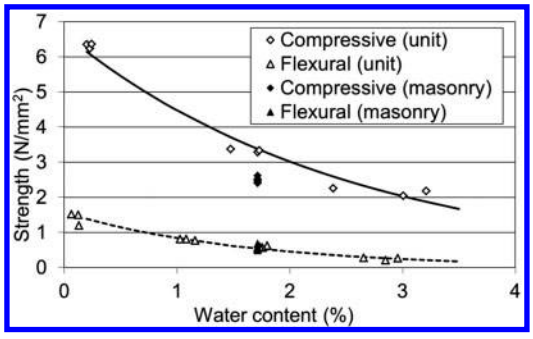

Figure 1. Decrease in strength with water content.

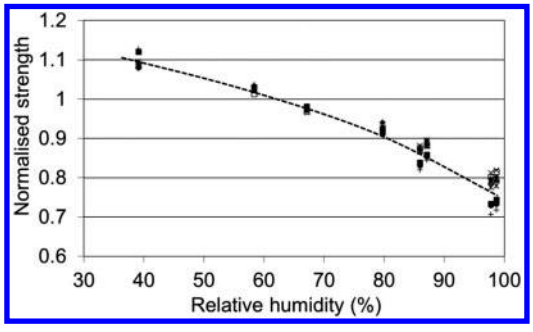

Figure 2. Effect of relative humidity changes on compressive strength of unstabilised earth blocks.

with changes in moisture content is important, it should also be viewed in the context of likely moisture contents to be experienced in a wall. Moisture may be added to a wall by an increase in the relative humidity, through wet trades during construction (mortar/render) or by accidental wetting (e.g. failure of a water pipe). While it is possible to predict the first two, it is not possible to predict the moisture content from accidental wetting, but detailing can help to minimise the risk of this occurring.

The effect of changes in relative humidity on earth masonry unit strength, for ten different commercially produced unstabilised earth masonry blocks, is illustrated in Figure 2. The information is presented with the compressive strength normalised to 65% relative humidity for each particular block type.

As shown, even at a very high relative humidity which is maintained for an extended period, the strength will not reduce to close to zero, showing that the walls are unlikely to collapse from being exposed to high relative humidity. For all of the 10 different block types, there is less than 30% strength reduction as the relative humidity increases from 65% to 97.5%.

A more onerous testing condition (such as immersion in water before testing) is inappropriate for unstabilised earth masonry as these materials should not be used in a situation where full saturation could occur. Immersion before testing can, however, be used for stabilised earth materials.

The Eurocode methodology uses material partial factors to quantify the reduction in strength as a

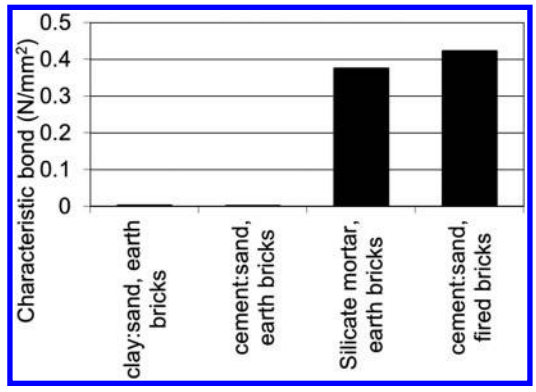

Figure 3. Bond strength of different mortars and unstabilised earth bricks.

result of variability in materials and construction, and of uncertainty in behaviour. Eurocode 6 specifies a minimum partial factor, γ_m, of 2.0 for Category II masonry (higher if perforated). While earth masonry is not included in Eurocode 6, it is recommended that γ_m is increased to at least 2.85 for unstabilised commercially produced earth masonry (very high quality control and low variability) to include the effect of a potential 30% strength reduction with increasing humidity shown in Figure 2.

For a more variable material such as rammed earth, Walker et al. (2005) recommend a minimum γ_m of 3.0 for experienced contractors with good quality control, increasing to 6.0 for contractors with limited experience with the material. In all cases these should always be applied while considering accidental wetting, and the resistance to erosion.

For materials produced under well controlled conditions and tested in a saturated state (such as cement stabilized CEB), the lower partial factors from Eurocode 6 for concrete blocks may be considered.

2.2 *Flexural strength*

Many traditional earth buildings have thick (300 mm or greater) walls and a large portion of their bending resistance comes from the self-weight of the walls. These walls often have sand/clay mortars which provide very little bond strength, as shown in Figure 3.

Included in Figure 3 is the characteristic bond strength for a cement mortar with earth bricks and fired clay bricks. The silicate mortar comprises a clay:sand mix with 8% by mass sodium silicate power with a molar ratio of 2.0 ($Na_2O{\cdot}2SiO_2$).

The thick walls of traditional earth construction can reduce available space and require additional material, thereby increasing costs and environmental impact. The structural requirements for flexural capacity are illustrated in Figure 4, showing how increased thickness results in a lower bond strength (flexural strength along bed joints) to provide the same lateral resistance.

As shown, with the wall thickness decreasing from 300 mm in traditional construction to 100 mm commonly used for concrete block and fired clay

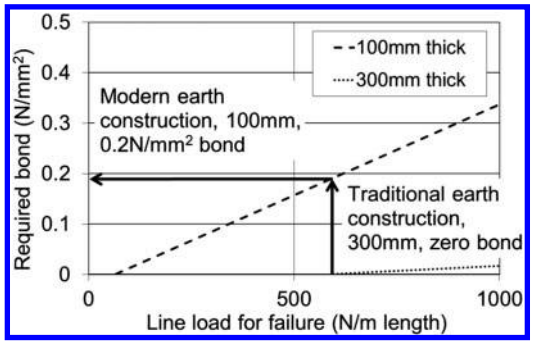

Figure 4. Required flexural strength to resist lateral loading for different thickness walls (no additional vertical loads applied).

masonry construction, the required bond strength increases from zero (typical design value for rammed earth or earth blocks with earth mortar) to approximately 0.2 N/mm^2 which is a typical characteristic value for 100 mm thick lightweight concrete blockwork in Eurocode 6.

As shown in Figure 3, the only mortar able to provide the required strength with 100 mm thick earth masonry is a sodium silicate based mortar. As sodium silicate is water soluble, when the wet mortar is applied to earth blocks, some silicate is transferred from the mortar to the dry block through initial absorption, leading to a strong bond across the interface between block and mortar. A higher percentage of sodium silicate can, however, inhibit mortar drying as the resulting gel structure can block pores leading to a decrease in vapour permeability.

These sodium silicate mortars are stronger than the earth blocks, leading to bond strengths which are similar to flexural strength both parallel and perpendicular to the mortar bed joints.

While achieving 0.2 N/mm^2 bond strength is possible with a 100 mm thick cement stabilized CEB and a cement based mortar, this is difficult with unstabilised earth blocks. At the time of writing, the only unstabilised earth block that has been shown to provide this is modern extruded earth masonry with very high density and excellent quality control of materials and end products. These were the type of blocks used for the testing shown in Figure 3 and examples available in Europe are shown in Figure 5. For other earth masonry forms such as CEB or mud bricks (adobe), it may not be possible to construct 100 mm thick walls without stabilization or a secondary structure (e.g. timber frame).

2.3 *Shear resistance*

In plane racking (or shear) behaviour of earth walls can be subdivided into two types:

- Walls where failure is along weak mortar joints (as with conventional masonry)
- Walls where the construction has no mortar joints or where the mortar joints are stronger than the masonry units.

Figure 5. Modern extruded earth masonry products available in Europe.

Figure 6. Racking failure of monolithic cob test wall.

Even walls of monolithic construction such as rammed earth or cob have joints which are normally weaker than the rest of the material, leading to reduced racking resistance and preferential along these planes, as illustrated for a cob test wall in Figure 6.

Where the earth wall is to be made of individual masonry units, a standard masonry triplet shear test can be used to determine both components of shear resistance: the initial shear strength (shear strength with zero normal load) and the coefficient of internal friction (representing an increase in shear capacity with increasing normal load).

While Eurocode 6 does provide typical design values for the initial shear stress and coefficient of internal friction for conventional masonry systems, earth masonry is not included. Unless a manufacturer provides information on the initial shear capacity of the masonry system (monolithic construction or brick/mortar system) these properties should be tested if the shear capacity is a concern for the particular construction.

There is not the body of evidence for earth masonry as there is for other forms of masonry construction, but testing on stabilized and unstabilised earth test walls have indicated the characteristic coefficient of

internal friction of 0.4 specified for masonry construction in Eurocode 6 appears appropriately conservative for earth masonry. The initial shear stress is more variable and testing is required to obtain this parameter.

3 STABILISATION

3.1 *Reasons for stabilisation*

Although some may consider densification (compaction/compression) of soil as stabilisation, it is assumed that all earth construction materials will include this, so this section is focussed on other materials added to the earth with a view to increasing performance. Stabilisation is usually performed for two reasons:

- To improve strength
- To improve durability (water resistance, abrasion, etc.)

If there is no requirement to improve strength or durability, there is no need to stabilise and the option of no stabilisation should always be considered. Any decision on stabilisation should be taken with great care as, although there are currently over 100 potential stabilisers available for use with earth, there has been no single stabiliser that has dramatically outperformed others.

The most commonly used modern stabilisers are cement and lime (with or without other pozzolanic materials). Various forms of bituminous, chemical and enzyme based stabilisers have also been used with the aim of improving strength and durability. Certain forms of earth construction (e.g. cob or adobe) will often have fibres such as straw added to the earth to limit tensile cracking and potentially increase flexural resistance, but these do little for durability and strength loss when wet.

The embodied energy in a stabiliser may result in a stabilised earth product with higher embodied energy than a more conventional counterpart such as a concrete block (see later). "Given similar local conditions, there may be no guarantee that a CEB will use less cement than a cement block." (Rigassi, 1995).

3.2 *Geopolymeric stabilisation*

There has been recent interest in the use of gepolymerisation of earth blocks, particularly using the Low Temperature Geopolymeric Setting (LTGS) methodology proposed by Davidovits (2011). Geopolymers are formed by activating an aluminosilicate powder (the precursor or clay minerals in this case) with an alkaline hydroxide and/or silicate solution (the activator). The term "geopolymer" was first used for alkali-activated calcined clay-based binders in the 1970s by French chemist Joseph Davidovits, but only since 2000 has there been concentrated research and in 2008, the world's first large scale geopolymer concrete manufacturer started production in Australia with fly ash and slag as precursors (Van Deventer et al., 2012). Most international research has focussed on geopolymers as an alternative to high environmental impact Portland Cement (PC) in concrete. The increasing move to geopolymers as an alternative to PC concrete is partly because of significantly lower Carbon Dioxide Equivalent (CO_{2e}) emissions and costs for large projects. Industrial by-products and slags are generally preferred to clay-based precursors in concreting applications as the water content required to achieve flow in clay based geopolymers is very high, leading to decreased strength (Provis et al., 2010).

Clay-based geopolymers can be based on either natural clays or clays which have been calcined (dehydroxylated by heating to 750–950 °C, depending on clay mineral). The goal for geopolymers from uncalcined (natural) clays is to achieve a solution molar ratio of 1:1 between silicon (Si) and aluminium (Al) once dissolved using the activator solution which is high in hydroxides (OH^-). This limits applications to clay minerals in the kaolinite group. For calcined clays such metakaolin, a molar ratio of 2:1 between Si and Al is preferred and higher strengths can be achieved but at a higher environmental impact. The 2:1 Si:Al ratio normally requires additional soluble silicate activators such as $Na_2O{\cdot}2SiO_2$.

Very little work has been done on uncalcined geopolymer earth blocks, although there are a number of research programmes around the world investigating this, including one at the University of Bath. To date, there are no published studies confirming saturated compressive strengths of 12 N/mm^2 for uncalcined clays mixed with 2% Sodium Hydroxide (NaOH) activator, and heated to 85 °C, as reported by Davidovits (2011). This strength is comparable to that for dense concrete blocks or earth blocks stabilized with 5% cement. Recent work at the University of Bath have shown that there is potential for this technology and that it is possible to develop materials with improved strength and durability than unstabilised earth. The mineralogy of the clay is, however, very important and small changes in mineral composition can have a large effect on final properties.

4 ENVIRONMENTAL IMPACT

While the environmental impact of construction materials covers a broad range of areas, the section is focused on Global Warming Potential (GWP) and figures refer to the 100 year CO_{2e} emissions based on a cradle to factory gate system boundary (extraction of materials to manufacture of products). Data is from the Ecoinvent database focused on western Europe with additional data from other sources if not in the Ecoinvent database. In order to provide consistency, data is provided per m^2 of wall, assuming a material density of 1800 kg/m^3 and also ignoring the effect of mortar.

Data for earth blocks is based on work by Morton (2006) which indicated approximately 86% of the

Table 1. GWP for different wall types.

Type	GWP per m^2 ($kgCO_{2e}$)
Fired clay brick, 100 mm	42.9
Dense concrete block, 100 mm	22.3
Unstabilised earth block, 100 mm	6.0
5% Cement stabilized earth block, 100 mm	12.4
2% NaOH geopolymer earth block, 100 mm	11.5*
Unstabilised earth block, 300 mm	18.0
Pneumatically rammed earth, 300 mm	26.1**

* includes 0.83 $kgCO_{2e}/m^2$ from heating by 60 °C
** all other walls should include mortar, disadvantaging rammed earth in this table

embodied CO_{2e} in fired brick comes from the firing process, and that this is eliminated for earth blocks. It is assumed no additional mixing will be required for stabilized earth as mixing to the required manufacture water content should be sufficient. The GWP value for rammed earth is from Lax (2010) but this could be considered artificially inflated in this analysis as it does not require mortar which would increase the GWP of all other wall types. The value for geopolymer stabilized earth includes heating by 60 °C (from 25 °C to 85 °C). It was assumed earth has a specific heat capacity of 1.0 kJ/kgK (Minke, 2006) and heating was using electricity at an 80% efficiency with no heat recovery, based on 6.4×10^{-5} $kgCO_{2e}/kJ$ for Europe (IEA, 2012). Data for the different wall types is summarized in Table 1.

The lowest GWP was for 100 mm thick earth walls and the lowest for the stabilized blocks was for the geopolymer stabilized earth block.

As shown in Table 1, as the wall thickness increases to 300 mm, the GWP of unstabilised earth walls can exceed that of 100 mm concrete block alternatives. There are other advantages to using thick earth walls including increased thermal mass leading to reduced energy consumption in use, but disadvantages include the increased use of materials.

In addition to increasing the embodied energy, stabilisation can have a negative impact on some of the beneficial properties of earth. This is a concern for the hygrothermal behaviour where stabilisers can limit the vapour permeability and can therefore limit the capacity to passively regulate humidity, but experimental studies have shown this effect may not be as significant as many believe with both cement and geopolymer stabilization having a limited effect (Mcgregor et al., 2012).

5 CONCLUSIONS

Earth masonry has the potential to provide reduced embodied energy and improved building performance if it is used as a replacement for concrete block masonry, but the structural behaviour needs to be quantified before it is used with confidence.

Modern earth masonry with unstabilised blocks and sodium silicate based mortars can provide similar structural capacity to light-weight concrete masonry, provided the risks of moisture susceptibility of the material can be successfully mitigated. This could be either through detailing (for example, a plinth of moisture resistant material), design (for example, the use of a timber frame as a secondary structure) or through modifying material properties to limit moisture susceptibility (through addition of a stabiliser).

Any decision on stabilisation should be taken with caution as stabilisation can increase the embodied energy, reduce the passive environmental control provided by the earth masonry and can actually decrease the material strength.

Geopolymer stabilisation may be able to provide good strength and durability at a lower environmental impact than cement stabilized earth blocks, or conventional fired clay or concrete block alternatives, but this aspect requires further investigation.

Affordable, sustainable, and resilient tornado shelter design using compressed stabilized earth block construction

Benjamin Wagner, Ece Erdogmus & Avery Schwer
University of Nebraska-Lincoln, Nebraska, USA

ABSTRACT: Non-engineered earthen construction is critiqued for being fit only for dry climates and performing poorly against extreme loads. The authors, as part of a National Science Foundation funded collaborative research project, are studying the performance of engineered earthen masonry against tornado-level wind pressures. This paper introduces an affordable, sustainable, and resilient construction system for residential units in high-wind regions utilizing compressed stabilized earth blocks (CSEBs). Interdisciplinary (architectural, structural, construction related) design criteria are considered for the determination of the required strength levels both for the entire residential units and dedicated tornado shelters to be tornado-resistant. The structural capacity required for high wind pressures is calculated using available analytical methods and current codes after the interdisciplinary criteria are optimally negotiated. A preliminary experimental program is then carried out to determine the resistance capacity of lime and cement stabilized CSEB construction. Parameters considered in the experimental work include, but are not limited to: soil characteristics, water to binder ratio, volume fraction of the stabilizer, stabilization type (lime and cement) and mortar composition. A preliminary testing program for CSEB prisms with and without a proposed externally applied strengthening method is also conducted. This paper presents the current findings of this on-going study.

1 INTRODUCTION

While the performance of CSEB subjected to compressive vertical loads has been examined in previous research, the performance of CSEB subjected to lateral wind loads requires further investigation (Heathecote 1991). Both tornados and hurricanes pose significant threats to structures including high wind speeds and thrown debris. Tornados annually cause an average of $1.1 billion of damage throughout the United States, $13.75 million of damage locally in Nebraska and $10.9 million of damage locally.in Florida. Hurricanes result in additional billions in damage throughout the United States annually, Florida alone experiences on average 2 hurricane events per year, and averages $9.6 billion in damage (Malmstadt, Schietlin, & Elsner 2009). Adequate design of structures to resist the mentioned climatic events can help to reduce such levels of damage.

CSEB is a sustainable building material that is composed of indigenous soils and a mineral stabilizer, commonly lime or cement. The compressive strength and resistance to moisture penetration of these CSEB units are derived from the proportional composition of the indigenous soil and the mineral stabilizer (Heathcote 1991). CSEB can be classified as a sustainable material as less energy is required in their production as compared to fired clay bricks. Unlike fired clay bricks, CSEB do not require kiln-firing and simply cure after molding much like concrete. By using local soils as an aggregate, CSEB eliminate energy used in shipping from a production facility to the job site.

The primary motivation is to develop a sustainable structural system of CSEB that can resist the considered high-wind loads. A solution for the demand for affordable and sustainable housing can be achieved by designing a system capable of resisting structural damage and promoting energy and material efficiency. For the purposes of this project, only threats from high wind speeds and associated pressures acting on the considered structure resulting from tornados and hurricanes were considered. The design of three structures focused on the specifications of the masonry walls. It was assumed that the foundations would be designed to continuously support the Main Wind Force Resisting System (MWFRS) exterior walls, and that the horizontal diaphragms within the three structures behaved rigidly.

2 DESIGN OF STRUCTURES

The proposed structures presented were developed to offer multiple design solutions for residential structures constructed of CSEB. Each structure was designed for wind events considered in two regions in the United States: 1) Eastern Nebraska and 2) Southern Florida Coast. Three two-story structures are designed by the authors and labeled as Structures 1, 2, and 3 (Figures 1–6).

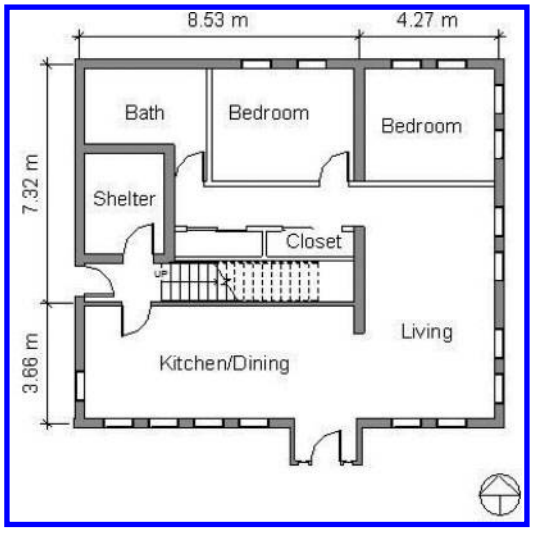

Figure 1. Structure 1 first floor plan.

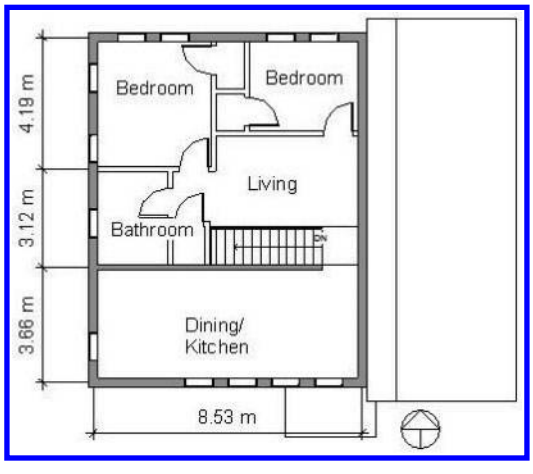

Figure 2. Structure 1 second floor plan.

Structure 1 was designed as a two-story, four-bedroom residence, to represent a larger single-family dwelling. ***Structure 2***, is a redesign of Structure 1 that accommodates three smaller single-family units instead of a larger single family unit. To accommodate the architecture for the new family units, the structural element configuration of Structure 2 is also different. The external wall openings of structure 2 were realigned to create continuous shear walls from roof to foundation. ***Structure 3*** presents a larger multi-family residential complex formed of 3 two-bedroom and 1 one-bedroom units between two floors. The floor plans of the units are nearly identical, allowing wall openings to coincide from floor level to floor level.

The intent of the study with 3 different architectural designs and structural configurations is to present a variety of affordable options for dwellings that may be used for ranges of tenant incomes and lifestyles, and to present multiple structural layouts to investigate the change in the distribution of lateral loads due to plan torsion.

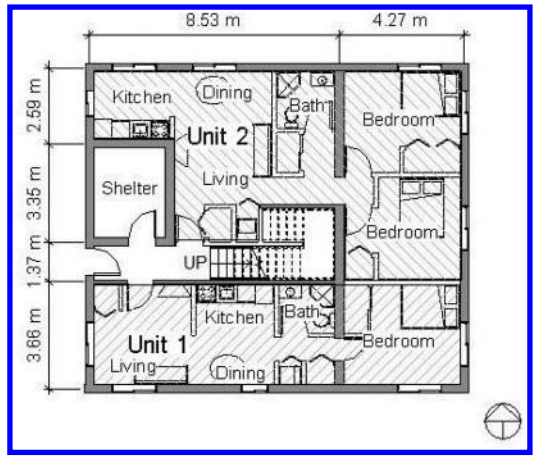

Figure 3. Structure 2 first floor plan.

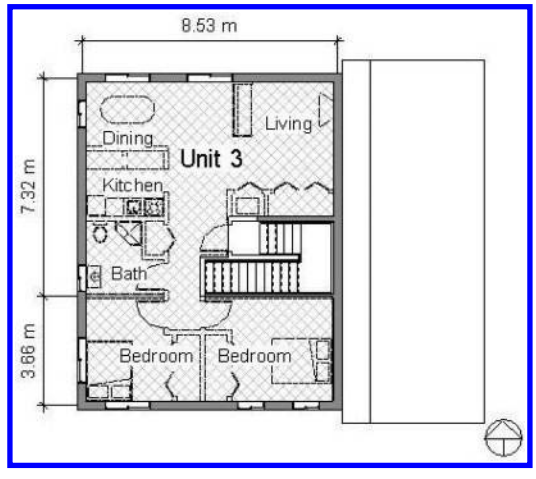

Figure 4. Structure 2 second floor plan.

2.1 *Design parameters*

Table 1 presents the general design parameters of each structure and considered wall thickness. The plans of the structures are presented in Figures 1–6. The floors will be considered simple, rigid diaphragms for the analysis of the walls. The interior walls were designed to reinforce the exterior MWFRS walls against shear, and considered to be of the same thickness and construction as the exterior MWFRS walls.

2.2 *Applied loads*

The wind speeds considered were 145 km/h, 241 km/h, 321 km/h, and 402 km/h. The 145 km/h and 241 km/h wind speeds were established by the minimum design wind loads as detailed in ASCE 7-05: Minimum Design Loads for Buildings and Other Structures

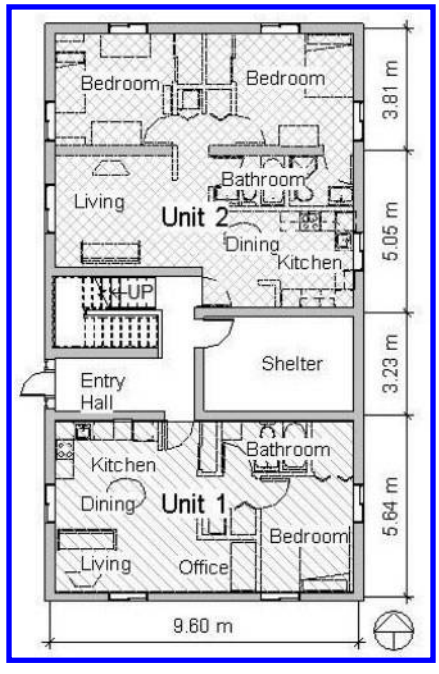

Figure 5. Structure 3 first floor plan.

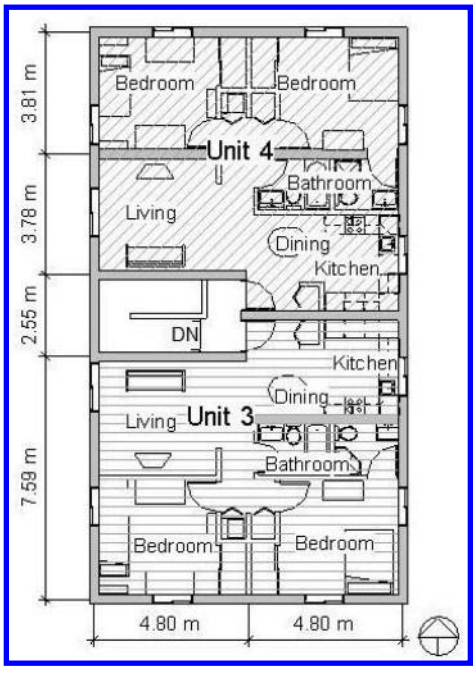

Figure 6. Structure 3 second floor plan.

for Nebraska and Florida, respectively. The 321 km/h wind and 402 km/h speeds were established by the FEMA 361: Design and Construction Guidance for Community Shelters, 2nd edition for Nebraska and Florida, respectively. The proposed structures were classified as Occupant Category II with an Importance

Table 1. General design parameters.

	Foot Print	Usable Area
Structure 1	12.8 m × 10.97 m	182.8 m^2

Factor of 1.0, located in an Exposure C environment, and considered as enclosed and rigid by ASCE 7 – 05. Table 2 presents the considered gravity loads for all structures, in addition to the self weight of materials.

2.3 *Material and geometric parameters*

The modulus of elasticity, E, of the CSEB was considered to be $E = 700f'm$, in accordance with Masonry Standards Joint Committee Code, Specifications and Commentaries 2008 for clay masonry units.

The following properties of the walls in each structure were calculated for each wind load orientation: the bearing eccentricity of the floor and roof loads acting upon the supporting masonry wall segments, e, the moment arm between the internal tensile and compressive stresses, c, the cross-sectional area per foot of length, A, the cross-sectional moment of inertia per foot of length, I, the cross-sectional radius of gyration, r, and the slenderness ratio, k.

3 STRUCTURAL ANALYSIS AND RESULTS

Analyses of the structures were completed using the strength method as established by the MSJC 2008. The loads used in the analysis of the structures were determined in accordance with ASCE 7 – 05. The walls of the structures were assumed to be initially unreinforced barrier walls of solid cross-section. If the initial unreinforced design was found to be

inadequate, the minimum reinforcement with steel and fiber reinforced concrete (FRC) was determined for each wall segment in each structure for each wind case where the initial design failed.

3.1 *Unreinforced CSEB wall design*

The minimum modulus of rupture, f_r, and ultimate compressive strength, f'_m, required was calculated for each wall segment in each structure for each wall thickness and wind load condition. Table 3 presents the results of this analysis for the wall segments experiencing the greatest stresses in each considered load case.

The required material strengths of unreinforced CSEB for an entire structure exceed the MSJC 2008 code maximum compressive strength, $f'_m = 41.4$ MPa. None of the structures meet this requirement with a wall thickness of 30.5 cm. The required flexural strength required by each structure also exceeds the maximum flexural strength of the mortar joints. Reinforcement strategies must be considered.

3.2 *Steel reinforced CSEB design*

After each wall segment was designed as an unreinforced assembly, the wall segments exhibiting the greatest flexural and compressive stresses were redesigned with traditional steel reinforcement. The minimum area of steel reinforcement, A_s, required to resist the flexural and compressive stresses was determined by the equation below (MSJC 2008):

$$\Phi M_n = \Phi A_s f_y d\left(1 - \frac{0.63 A_s f_y}{b d f'_m}\right) \geq M_u \qquad (1)$$

Solving equation 4.24 for A_s:

$$A_s \geq \frac{-\Phi f_y d \pm \sqrt{(\Phi f_y d)^2 - 4\left(\frac{0.63\Phi {f_y}^2}{b f'_m}\right) M_u}}{2\left(\frac{0.63\Phi {f_y}^2}{b f'_m}\right)} \qquad (2)$$

Where: M_n = nominal moment capacity of the wall segment (N-cm/m), b = effective reinforcement width (cm), d = depth of steel reinforcement (cm), f'_m = specified ultimate compressive strength of CSEB (N-cm/m), ρ = reinforcement ratio, A_s = area of steel reinforcement (cm^2), f_y = yield strength of steel (MPa), M_u = factored ultimate moment due to wind and eccentricity of axial loads at the mid-height of wall per foot of wall length (N-cm/m), and Φ = reduction factor = 0.9.

The minimum required area of steel reinforcement is the smaller of the two solutions produced by the above quadratic. The minimum area of reinforcing steel, A_s, of the wall segments is present in Table 4. This minimum value is associated with a minimum specified f'_m, also presented in Table 4.

The CSEB blocks can allow up to a single reinforcing #25 metric bar per cell, or 5.09 cm^2 per cell, or 33.44 cm^2 per meter of wall length. With this limitation in consideration, only Structures 1 and 3 can be adequately reinforced at a wall thickness of 61 cm. While steel reinforcement may be achieved, a more practical solution is to consider only a part of the structure to resist the high-wind loads.

3.3 *FRC reinforced CSEB design*

Fiber Reinforced Concrete (FRC) is produced by adding fiber reinforcement to the composition of traditional concrete. This FRC is then applied to the extremities of slabs or wall segment experiencing tensile loads to provide additional flexural strength. The specific modulus of rupture of the FRC required for reinforcement of the three structures was determined in this project, and presented in Table 5.

The nominal moment capacity of a FRC strengthened CSEB wall can be determined similarly to a

Structure 3	t_{frc}	15.24 cm	15.24 cm	10.16 cm	402 WE
Wall 2.7	f_{frc}	73.5 MPa	39.1 MPa	33.2 MPa	

FRC strengthened reinforced concrete panel (Radik, Erdogmus, & Schafer 2011). The equations presented by Radik, Erdogmus, and Shafer were adapted for use in the design of FRC reinforced CSEB. The equations for the nominal moment capacity of a FRC strengthened CSEB wall were determined to be:

$$M_n = bt_{frc}f_{frc}\left[h + \left(\frac{t_{frc}}{2}\right) - \left(\frac{a}{2}\right)\right] \quad (3)$$

Where:

$$a = \frac{t_{frc}f_{frc}}{0.6f'_m} \quad (4)$$

And: b = effective slab width (cm), t_{frc} = FRC thickness (cm), f_{frc} = compressive strength of FRC (MPa), h = slab thickness (cm), and f'_m = compressive strength of CSEB (MPa).

The required flexural strength of FRC, f_{frc}, that must be applied to the extreme fiber of the CSEB wall segment for a given thickness, t_{frc}, of a FRC strengthening layer was determined using the equation below:

$$f_{frc} = \frac{-\left(bht_{frc}+\frac{bt_{frc}^2}{2}\right) \pm \sqrt{\left(bht_{frc}+\frac{bt_{frc}^2}{2}\right)^2 - \left(\frac{bt_{frc}^2}{1.2f'_m}\right)M_n}}{\frac{2bt_{frc}^2}{1.2f'_m}} \quad (5)$$

Where: b = effective slab width (cm), t_{frc} = FRC thickness (cm), f_{frc} = flexural strength of FRC (MPa), h = slab thickness (cm), f'_m = compressive strength of CSEB (MPa), and M_n = nominal moment capacity (kNm).

The solution of this quadratic with the least value is the minimum required flexural strength of FRC, f_{frc}, for a given thickness of FRC, t_{frc}, for a considered CSEB wall segment. The thickness, t_{frc}, was considered to range between 1.27 cm and 15.24 cm. Table 5 presents the minimum thickness required of the FRC layer and the corresponding flexural strength for the considered wall segments.

The results of this analysis indicate that each structure would require an excessively thick FRC layer to adequately resist the considered wind loads. It is therefore recommended to consider the design of tornado shelters, instead of providing an entirely tornado-resistant building.

3.4 *Shelter design*

A room in each structure was selected to be designed as a tornado shelter. The laundry room of each structure was selected to fulfill this purpose. The locations of these shelters are presented in Figures 1–6. It should be noted that the shelter in Structures 1 and 2 are identical, and presented only once in the results tables.

Each shelter was designed in the same manner, using the same procedure and assumptions, as the entire structures. Table 6 presents the results of the analysis of each of the shelters.

Table 6. Minimum strength requirements of shelter CSEB wall segments.

Wall Segment		Wall Thickness 30.5 cm	45.7 cm	61 cm	Wind Case (km/h)
Shelter 1 and 2					
Unrein.	f'_m	25.1 MPa	11.2 MPa	6.33 MPa	402 NS
	f_r	19.9 MPa	8.83 MPa	4.95 MPa	
Steel Rein.	f'_m	13.7 MPa	10.3 MPa	10.3 MPa	402 NS
	A_s	10.5 cm^2	5.05 cm^2	3.39 cm^2	
FRC Rein.	t_{frc}	12.7 cm	7.62 cm	5.72 cm	250 NS
	f_{frc}	33.5 MPa	33.6 MPa	32.3 MPa	
Shelter 3					
Unrein.	f'_m	54.7 MPa	24.3 MPa	13.7 MPa	402 NS
	f_r	43.6 MPa	19.4 MPa	10.9 MPa	
Steel Rein.	f'_m	27.6 MPa	10.3 MPa	10.3 MPa	402 NS
	A_s	24.4 cm^2	14.1 cm^2	8.0 cm^2	
FRC Rein.	t_{frc}	15.24 cm	15.24 cm	11.43 cm	402 NS
	f_{frc}	67.2 MPa	35.4 MPa	33.0 MPa	

Based on the results presented above, it is not possible to use unreinforced CSEB for a tornado shelter. However, the shelters in Structures 1 and 2 can be adequately designed with a standard #25 metric bar (5.09 cm^2) every other cell of steel reinforcement for a wall thickness of 45.7 cm, and the shelter for structure 3 can be adequately designed with a standard #22 metric bar (3.87 cm^2) every cell of steel reinforcement for a wall thickness of 61 cm. It also possible to reinforce the shelters of Structures 1 and 2 with a 5.72 cm layer of FRC, or reinforce the shelter of Structure 3 with a 11.43 cm layer of FRC. All three shelters would require FRC with a modulus of rupture of 32.3 MPa or greater.

4 CSEB BLOCK AND PRISM TESTING

After the analytical work that determined the target strength levels for the system, a preliminary experimental work was carried out to understand the available compressive strength levels of various CSEB block compositions. CSEB with varying stabilizer type, weight fraction of stabilizer, and water-to-binder ratios were considered in this preliminary study. The blocks were cast and allowed to cure over a 28 day period. Table 7 summarizes the experimental program of the CSEB blocks.

The CSEB blocks were tested in compression in accordance with ASTM C67 – 09: Standard Test Methods for Sampling and Testing Brick and Structural Clay Tile. The blocks were loaded normal to bed joints, simulating gravity loads. Table 7 and Figure 7 present the results of the compressive testing.

CSEB block prisms were also assembled for testing the flexural capacity in out-of-plane bending. The

D5	15% NHL 5 lime	0.20	3.22 MPa
D6	15% NHL 5 lime	0.25	2.03 MPa

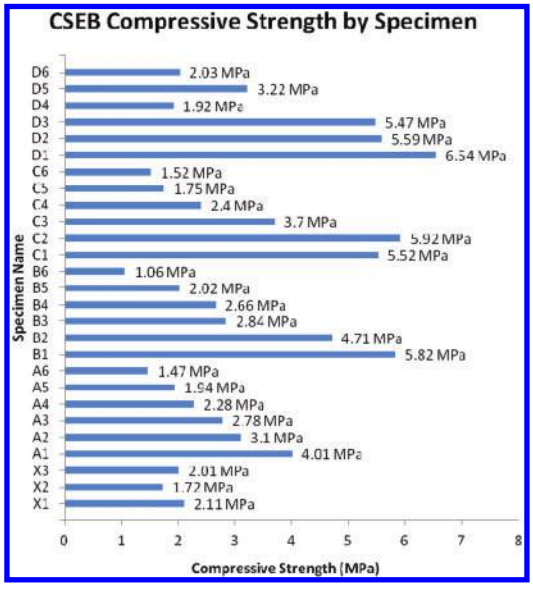

Figure 7. CSEB Compressive Strength.

prisms were constructed of five courses of CSEB with a 15% by weight Portland cement stabilizer and a 15% by weight water content. The blocks were bonded together using Type N PCL mortar. However, the CSEB and Type N mortar failed to bond, and the prisms were not suitable for flexural testing. Failure of the mortar joints occurred along the face of the CSEB and joint. The detailed causes of this failure, beyond apparent material incompatibility, are being investigated and an experimental program to optimize a more appropriate soil mortar mixture is ongoing.

5 CONCLUSIONS

From the design and analysis of the three structures, it can be concluded that shelter walls constructed of 45.7 cm thick, fully grouted CSEB, reinforced with 1 – #22 metric bar every other cell, can resist lateral loads from wind speeds up to 402 km/h.

It can also be concluded that shelter walls constructed of 61 cm thick, fully grouted CSEB, reinforced with a 5.72 cm layer of 33.09 MPa FRC can resist lateral loads from the highest wind speeds up to 402 km/h. As expected, tensile stresses due to out-of-plane bending will control the material failure of CSEB within the considered structures.

Based on the analysis of the considered structures and shelters, it is recommended that the structure 2 be selected to resist high wind loads. Structure 2 offers flexibility in occupancy of three residential units, and provides a shelter capable of resisting wind loads of up to 402 km/h with the reinforcement strategies described above. Based on the results of the compressive testing, it is recommended that CSEB comprise of a 15% by weight Portland Cement stabilizer and a 15% by weight water content, however, further experimental investigation into the flexural capacity of the CSEB is required.

Global structural behavior in fire and consolidated testing of steel structures

M. Fontana, M. Knobloch & A. Frangi
ETH Zurich, Institute of Structural Engineering, Zurich, Switzerland

ABSTRACT: The fire behavior of steel structures in prescriptive design is commonly assessed by fire tests on single structural members under standard fire special testing furnaces; however the behavior of an entire steel structure is in most cases more complex due to a redistribution of loads (global behavior of the structure) as a result of large deformations in fire or even a change in the structural system. Favorable structural behavior of global structures was observed in full scale fire tests and in many real fires. However the huge costs of full scale fire tests on global structures prohibit their wide use. Therefore fire tests on global structures are usually replaced by numerical simulations. However numerical simulations have still difficulties to precisely model details like connections or cannot detect some failure modes if no test data is available (e.g. spalling, brittle failure modes, shear or anchorage failures, etc.). Consolidated testing merges testing and numerical simulations. Data measured in the test become input for the numerical calculation and results from calculation control the test. Consolidated testing is based on deformation and strain-based structural analysis and has a huge potential for fire safety and economy of structures and for the development of realistic structural modeling in fire. The paper first describes the basic principles of a deformation-based approach to global structural behavior and its study with consolidated testing technique. Then, it shows the benefits of considering global structural behavior in fire and its assessment by consolidated testing for fire safety and gives some applications and impacts.

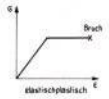
1 INTRODUCTION

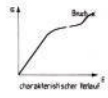
Today most structural engineers analytically verify the resistance of their structures based on ultimate limit states mostly using simplified rules given in codes. The verification usually concentrates on single structural members like columns or beams as well as their connections. The ultimate state of a member, however, may not be representative for the behavior of the global structure. It only represents one state of the relevant element and the influence of the member interaction is often either neglected or considered in a simplified way, e.g. critical buckling length of columns in frame structures.

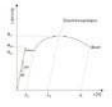
Deformation-based design forms the basis of numerical methods like finite element analysis, which have become widely used during recent years thanks to the spread of specialized software and electronic tools. However the way of thinking and education in structural engineering is for most engineers still stress- and resistance-based. Global deformation-based methods and models are rarely applied, with the exception of plastic design methods (Thürliman 1979; Bruneau, Uang and Sabelli 2011), where deformation (e.g. rotation capacity of plastic hinges) capacity must explicitly be considered.

With the development of structural analysis and modeling, design based on constructional detailing and observation has become less important while rigorous structural analysis and the verification of structural elements according to codes is governing todays design practice to protect the engineer and the public against structural failures.

To make analysis feasible and economical often simplified rules based on strength and stresses are given in codes. They will lead to good results for standard structures, where a rich knowledge and experience exist. However they cannot cover novel types of structures and are an obstacle to innovation and will quickly become boring for well-educated engineers.







A performance-based approach (Hadjisophocleous et al. 1998; Meacham and Custer 1995) to structural design is based on basic principles and objectives as well as on functional requirements. It is therefore also applicable to novel types of structures and will foster innovation. The influence of deformation-based approach to structural analysis and its application to global structures and testing may lead to new knowledge and strongly future structural design.

2 STRUCTURAL ANALYSIS

Structural behavior can be studied on different levels (Tab. 1), mainly

- material
- cross-section
- structural element
- global structure.

Table 1. Interdependence of structural level of analysis and material-theory (cp. Fontana 2012).

Theory/ Level	Elastic	Plastic	Nonlinear
Material	linear-brittle 	rigid plastic linear elastic-perfectly plastic 	Nonlinear 
Cross-section 	Hook Bernoulli/ Navier elastic FEM/Eigenvalues local buckling 	Plastic hinges – Rotation capacity Post buckling behaviour Bernoulli/ Navier 	Nonlinear – strain-based nonlinear FEM Bernoulli/ Navier 
Member	Hook/Euler Elastic buckling, LT 	Redistribution of loads Mechanism Buckling curves	Nonlinear deformation-based alternative modells: Membranes-cables
Global structure	Hook/Euler Linear statics: (I. and II. Order Theory) Deformations Stresses Principle of work and energy Deformation method	Redistribution of loads Load transfer Bending -> Membrane action 	Redistribution of loads plastic springs – robustness Load transfer 

On the material level nonlinear material behavior is often simplified by linear behavior up to a limited stress level or by linear elastic, perfectly plastic behavior (Marti. 2013). Uniaxial behavior found by material test is mostly considered as basis for design.

The cross-sectional level applies the strain-stress curves found on the material level to the geometry of the two dimensional cross-section, additionally local buckling must be considered (Knobloch et al. 2012) Local buckling is generally strain dependent (Dubas & Gehri 1986). Therefore in an advanced design the available and required rotational capacity must be considered. However this is circumvented in many code designs by simplifications like e.g. cross-sectional classes (Fig. 1).

On the element level the third dimension is considered leading to additional influences caused e.g. by second order effects like global and lateral-torsional buckling or bearing conditions.

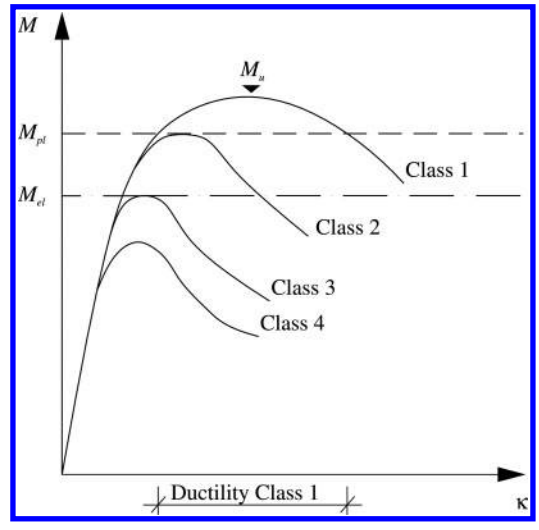


Figure 1. Cross-section classes depending on rotation capacity- according to EN 1993-1-1 (2005).

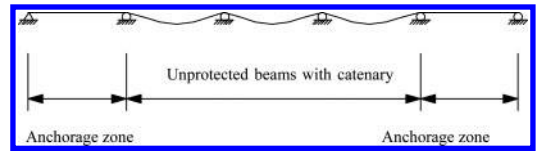

Figure 2. Change in structural system with large deformations e.g. from beam to catenary behavior.

On the global structural level elements are connected and their interaction may lead to reversible or irreversible deformations and load transfer and constraints. Deformation may even lead to changes in the structural system (Figs. 2, 3), reducing or increasing the resistance of the structure.

A realistic ultimate state analysis of a structure must not stop on the element level but should consider the global structure. This will need to consider strains and deformation not only ultimate strength of members and connections.

3 DEFORMATION-BASED ANALYSIS AND DESIGN

Nonlinear material behavior and the combination of elements with different nonlinear component and connection behavior, (e.g. glue and nails in timber) can only be assessed by a strain-based approach considering the whole stress – strain behavior of the component. A simple superposition of ultimate loads would lead to an overestimation of the total resistance cp. Figure 4.

However in general a deformation-based approach is very complex and time-consuming. Therefore simplifications are usually proposed for analytical

Structures in fire or fires in structures? Assessing the true performance of structures in fire

J.L. Torero
School of Civil Engineering, The University of Queensland, Australia

ABSTRACT: When addressing the performance of structures in fire it is common to treat the fire as an imposed load. The analysis of the structural behaviour follows. The analysis of the structure can follow different levels of complexity and in some cases can lead to detailed finite element studies that incorporate complex models for the constitutive properties of the materials involved as well as detailed analysis of connection behaviour. When addressing the load, an attempt is made to establish a "worst case" condition together with statistically based error bars. This approach follows similar treatments used for dead loads, snow, wind, blast or earthquakes. While this approach seems to be useful, it poses two fundamental questions, first is "what is a worst case fire scenario when assessing the performance of structures in fire?" and second, "is it possible to separate structural behaviour from fire behaviour?" As opposed to other loads, fire behaviour can be drastically modified by the nature of the structure in as much as the structure can be affected by the fire. Thus, true optimization of structural design needs to address structural and fire behaviour in a coupled manner. A comprehensive analysis of fire and structure is the only means by which terms such as extreme events, failure and fire resistance can be defined. Furthermore, detailed structural analysis is only justified if an equally detailed fire analysis is conducted guaranteeing consistency. If the consistency of complexity is not respected the results are misleading in their pretence of precision and in the validity of the conclusions. Only if a coupled analysis with consistent complexity throughout the integrity of its components is conducted a true assessment of performance of the behaviour of a structure in fire can be achieved.

1 INTRODUCTION

The performance of a structure is a fundamental component of a fire strategy, thus its performance within the context of this strategy needs to be defined. Acceptable performance is therefore a relative term that will vary depending on the requirements posed by the strategy on the structure. Different strategies and buildings will require different acceptance criteria depending on what the structure is intended to deliver. In an industrial storage facility structural failure is an acceptable performance given that the structure has only secondary life safety functions. In contrast, in a tall building, stringent requirements of structural integrity are necessary because the structure has a fundamental role in life safety. Independent of the specific requirements to be met, a true assessment of performance for a structure needs to be established. Only then failure criteria can be stipulated to meet the needs of the fire strategy.

To be able to define the temporal and spatial evolution of a structure during the event of a fire, the following issues need to be resolved:

1. The temporal and spatial evolution of the fire needs to be specified in a manner that gas phase temperature, the velocity field and the concentration of different species (CO, CO2, H20, soot, etc. concentrations can be defined.
2. The evolution of the gas phase will enable to quantify the temporal and spatial evolution of the heat exchange between the structural elements and the gases. Thus a real thermal boundary condition can be stipulated.
3. With the boundary condition defined heat transfer through the structural elements needs to be resolved. For materials like steel the transient energy equation consists only of heat conduction and enthalpy terms with variable thermal properties but for other more complex materials such as concrete or plaster board, complex mass transfer equations need to be resolved to account for the vaporization enthalpy as well as moisture migration.
4. The spatial and temporal evolution of the temperature of the structural elements allows then to compute the solid mechanics equations to determine stresses and deformations within the structure.
5. The results of these calculations can then be used to establish quantitative failure thresholds.

The comprehensive formulation of the problem requires the coupling of gas and solid phase because the evolution of the structure can influence the evolution of the fire. Explicit finite element models coupled with transient CFD models become a necessity if the complete interaction is to be resolved. Despite many

attempts to do this, there is currently no combination of models that solve the coupled effects of fire and structure. Furthermore, there is currently no CFD model that comprehensively resolves the fire at the necessary scale and with full detail. Finite element models are more advanced but many of the mechanical and thermal properties that serve as inputs are still unavailable.

Numerous alternative approaches can be found in the literature, some of them are well argued simplifications that use the characteristics of the problem to either relax the coupling between gas and solid phase or to simplify certain terms of the equations. Among these simplifications are simplified connection models, constitutive property models, total heat transfer coefficients and spatial and temporal averaging of the gas phase. These simplifications take advantage of the very different time and length scales of the solid and gas phase problems to decouple and simplify many of the processes. When correctly argued these approaches are perfectly valid and provide a true assessment of the performance of the structure as well as quantified error bars linked to uncertainties and simplifications.

A second approach that is equally valid is that of establishing a series of constraints in the form of codes and standards. These constraints guarantee a simplified environment that can be quantified by means of a simple representation. The most common of these code based constraints are the requirements for compartmentalization. By reducing all buildings to a summation of standardized compartments, the evolution of the fire can be reduced to an energy balance and thus both gas and solid phase behavior can be deeply simplified. This particular approach still provides a true assessment of performance. The error bars, in this case, are linked to the simplifications of the physical models defining the gas and solids but also to the deviation of the real compartments from the standardized ones.

An approach that is acquiring popularity is that of using simplified models coupled with probabilistic estimations of error. These methods, based on theories of risk and reliability, are only valid if the representation of the physical phenomena incorporates in a correct manner all the necessary variables and couplings and the probabilistic distributions for all poorly defined properties are available. In this case a probabilistic distribution of true performance can be established.

A final method is the relative assessment of performance. This method creates a realistic scenario and assesses the performance of a system against it. The realistic scenario can be a standardized temperature vs. time curve, a parametric temperature vs. time curve to provide a relative performance of a structural component or system but also a standardized compartment to assess the relative severity of a fire given different fuels. While this approach can be used for the purpose of understanding or for classification, it will never provide true performance assessment.

This paper provides a brief analysis of some of these different methods, identifying potential areas where true performance assessment can be obtained and those where the methodology does not enable such assessment.

2 BACKGROUND

The history of explicit fire modeling is not very old with the first attempts done at the beginning of the 20th century but only formalized in the 1960's and 70's (Hottel (1984)). Probably the first descriptions of the fire are associated to fire resistance and attempts to guarantee adequate structural behavior. In the absence of most of the fundamental knowledge of combustion, heat and mass transfer, the fire was modeled by attempting to reproduce reality within a furnace (Ingberg (1928)). A combustion reaction was sustained within a realistic scale compartment in which the structural element was introduced. Heat transfer was bypassed by measuring directly the temperature of the structural element and the fire was generalized by attempting a "worst case" condition. The worst case condition was generated by reproducing the fastest possible temperature rise to the highest possible temperature. This "worst case" fire was formalized as the "standard fire" and the "standard fire" gave birth to the "structural temperature vs. time" concept. The "standard fire" could then be reproduced in a furnace according to a pre-defined "temperature vs. time" and structural systems tested within that furnace. No real fire could produce a faster temperature rise nor attain the temperatures obtained in the furnace. The exposure time was defined on the basis of attaining burn-out of the estimated fuel load, thus no real fire could last longer. The time required for burn-out was labeled the required structural fire resistance rating. While this "worst case" scenario allowed for confident extrapolation, it is clear that an important safety factor was embedded in this primitive form of fire modeling.

Understanding of structural behavior at high temperatures was limited to the characterization of the material properties as a function of temperature. Typical safety factors for structural design established how far the loss of mechanical properties could be tolerated. This loss of mechanical properties was then correlated with a temperature resulting in a failure temperature criterion. The time necessary for the structural element to attain this critical temperature in the furnace was then established as the failure time. If the failure time was greater than the required fire resistance rating then the structural element could be used without any thermal protection, if not, thermal protection should be added in quantities that enabled the time to attain the failure temperature to exceed the required fire resistance rating (Drysdale (1998), Buchanan (2002)).

An important concept associated to the extrapolation between thermal behavior in the furnace and real fire behavior was the compartment size. While there

was no clear understanding of the role of compartmentalization, it was inferred that extrapolation could only be robust if the conditions of burning were similar. Furthermore, accepting that single element behavior, based only on material properties, could be extrapolated to real scale structural behavior could only be tolerated heating was localized. If a zone of comparable size to the furnace was the only heated area, then the surrounding structure will remain cold and maintain its strength. Any stresses generated in the heated area could then be transferred (redistributed) to the rest of the building and will be of lesser magnitude than those tolerable by the cold structure. In modern terms this represents a requirement of mechanical restraint that is guaranteed by effective compartmentalization. As a consequence, very restrictive compartmentalization requirements were imposed by building codes of the time.

Combustion science progressed through the 20th century nevertheless these issues will not be revisited until the 1960's. Advancement in the understanding of fluid mechanics, heat transfer and combustion did not permeate into fire modeling because the complex problem of fire could not be effectively linked to fundamental knowledge in any of these areas. Modeling the fire from fundamental principles was not possible, the gain was not evident and the existing design methods seemed to provide satisfactory results. At the time excessive safety factors were not a matter of consideration.

The 1960's brought two fundamental changes to the construction industry, (1) the relaxation of compartmentalization and (2) the introduction of plastic materials. In the past, "worst case" fires were defined on the basis of burning wood and were limited to a compartment of a size and characteristics regulated by building codes. As buildings became more complex and features such as ventilation ducts and false ceilings were introduced, it became unclear how to maintain compartmentalization. Given that the link between compartmentalization and fire safety performance had not been established on the basis of fundamental principles, it was difficult to establish the implications of the changes associated to new forms of construction. The loss of some level of compartmentalization occurred unnoticed. The consequences of losing compartmentalization were made evident in several tragic fires (NFPA (2003)). In a similar manner, the migration towards plastics introduced novel failure modes induced by physical phenomena such as melting or dripping. These failure modes resulted in burning conditions that were different to those defined by the burning of cellulosic materials (e.g. wood). The need to better representation of the fire by incorporating these new features became the driver to a significant research effort that for the first time brought combustion knowledge into fire safety (NFPA (2003)).

In an attempt to describe the complexity of the fire in combustion terms, the problem was broken down into numerous components. The interaction between the compartment and the combustion reaction was named compartment/enclosure fire dynamics (Karlsson and Quintiere (2000)). The link between the fire and stoichiometry was established by quantifying buoyant flows that serve to supply oxygen to the pyrolyzing fuel (entrainment). The compartment itself was also linked to stoichiometry by quantifying heat transfer from the fire to the walls and from the walls to the fire (feedback). As the fire heats the walls, radiative feedback to the fuel increases leading to an increasing supply of gaseous fuel to the compartment. The global stoichiometry of the compartment then drifts from the lean to the rich and the transition results in the migration of the flames from the interior of the compartments towards the openings. Terminology such as flashover, oxygen limited and fuel limited fires were introduced to describe these phenomena (Drysdale (1998)).

In what concerns assessment of structural performance a better understanding of the burning behaviour lead to the better characterization of the compartment fire temperature distributions (Thomas and Nilsson (1973), Thomas (1967)) and the development of design "temperature vs time" curves that were meant to be realistic representation of the evolution of the temperature of a compartment. Notable is the study by Pettersson et al. (1976) that lead to the parametric curves. Nevertheless, all these work relies on the principle of compartmentalization and requires the dimensions of the compartment to be such that mixing dominates and results in a homogeneous compartment with very thick smoke (small extinction distance) that can be described with a single temperature that is spatially homogeneous and only a function of time. Thomas (1967) explores the limitations of homogeneity, but only Harmathy and Lie (1970) and Harmathy (1981) discuss the role of the compartment and its dimensions. Figure 1 presents the comparison between the standard fire and the parametric curve corresponding to a realistic fire (The Dalmarnock Fire Test – DFT (Rein et al. (2007)). The average temperature of the compartment is also presented. As it can be seen, the parametric curve brings some of the realistic features of the fire, nevertheless tends to be over-dimensioned.

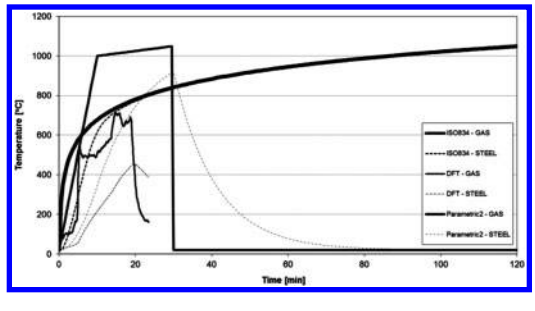

Figure 1. Temperature evolution of the gas phase of a compartment fire and a small cross section unprotected steel beam. Standard temperature time curve per ISO-834 (1999), DFT stands for Dalmarnock Fire Test as per Rein et al. (2007).

This is mostly due to the nature of the compartment used which had a very low thermal conductivity and thus retained the heat. For a similar reason the cooling curve was not introduced because it is defined by the walls, thus is not a representation of the gas phase. A very simple heat transfer calculation towards a beam was introduced only to show that the temperature evolution of the gas phase could potentially have drastic consequences on the structure. So, even without taking any heat transfer considerations or the limitations of the compartment, none of the design curves is a true representation of the fire.

It is clear that the capability of these procedures to lead to a true performance assessment is doubtful. No performance can be defined beyond establishing very simple failure criteria and methods to define if failure is attained.

3 TEMPERATURE VS. HEAT FLUX

When analyzing the heat transfer from the fire to a structural element the problem needs to be formulated in terms of heat fluxes. While temperatures result from the solution to the energy conservation equation, all quantities to be balanced are energies (Incropera and DeWitt (2002)).

Heat is transferred from gases to surfaces via radiation and convection resulting in a total heat flux, $\dot{q}''_{Tot}$, where

$$\dot{q}''_{Tot} = \dot{q}''_{rad} + \dot{q}''_{con} \quad (1)$$

and $\dot{q}''_{rad}$ is the heat transfer via radiation and $\dot{q}''_{con}$ is the heat transferred via convection. For simplicity the problem will be assumed as one dimensional, then the boundary condition for a solid element (structural element) becomes

$$\dot{q}''_{Tot} = -k_i \frac{\partial T}{\partial x} \quad (2)$$

where the thermal conductivity (k_i) is a property of the solid and the gradient of temperature is taken at the surface. In other words all the heat arriving is conducted into the solid. If there are multiple layers then at each interface the following boundary condition should apply:

$$-k_i \frac{\partial T}{\partial x} = -k_s \frac{\partial T}{\partial x} \quad (3)$$

where the gradients correspond to each side of the interface. Once the boundary conditions are defined, the energy equation can be solved for each material involved. Then the energy equations take the form

$$\rho_i Cp_i \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k_i \frac{\partial T}{\partial x}\right) \quad (4)$$

$$\rho_s Cp_s \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k_s \frac{\partial T}{\partial x}\right) \quad (5)$$

If the geometry is complex, then the problem needs to be resolved in all dimensions. If the properties vary with temperature then, as the temperature increases, these properties need to evolve with the local temperature. Variable properties thus require a numerical solution. If a simple analytical solution is to be obtained then adequate global properties need to be defined. It is important to note that whatever the solution methodology adopted, the temperature of the structure is the result of the resolution of equations (4) and (5) using potential boundary conditions such as those presented in equations (2) and (3).

To obtain the numerical solution it is necessary to input material properties for the insulation and the steel. The material properties required are all a function of temperature and are as follows:

ρ_i, Cp_i, k_i
ρ_s, Cp_s, k_s where the sub-index "i" stands for insulation and "s" for steel. For some materials such as steel the properties of are well known and thus very little difference can be found between the literature (EN (1993)). For other materials such as concrete, wood or different thermal insulations the scatter is much greater (Buchanan (2002), UL (1962)). The uncertainty is associated to the presence and migration of water but in the case of wood and insulation also to degradation. The wood and insulation that gets consumed (changes thickness) and retracts from the heating source increasing the overall thermal conductivity and density. Figure 2 shows an example for timber, a sample is heated (25 kW/m^2) and its temperature distribution monitored and presented in Figure 3. Figure 2 shows clearly the water front moving ahead of the degradation front and the degradation front close to the heat source. Figure 3 shows the experimental temperature 5 mm in depth on the exposed side of the sample.

As it can be seen, the temperature plateaus at approximately 400 K and then at 700 K. The first plateau corresponds to the evaporation of water, the second to the endothermic pyrolysis of the char. The

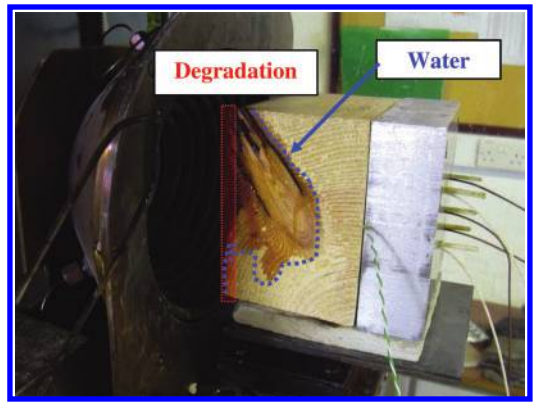

Figure 2. Timber sample heated at 25 kW/m^2 showing degradation and water fronts.

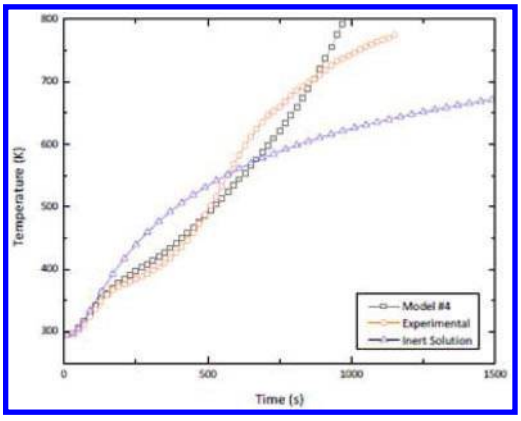

Figure 3. Evolution of the temperature of the temperature of a timber sample exposed to 25 kW/m^2 of heat. The values presented correspond to the temperature 5 mm below the exposed surface.

numerical models presented show the importance of including these processes. The data in red shows the experimental value while the models are presented in blue and black. The first model (blue) ignores the degradation and the water missing the water plateau (400 K) resulting in a faster initial heating but then reaching a plateau at 700 K. The second model (black) includes the water and the energy released by the char consumption nevertheless ignores the regression of the surface. The model captures well the water plateau but misses the final tampering of the temperature. While this example serves only to illustrate a point, it shows the importance of defining well the intricacies of the heat and mass transfer processes.

4 CONCLUSIONS

This paper has surveyed a number of different issues associated to the proper estimation of the fire input to the thermal evolution of a structure. It is essential that the thermal boundary condition is properly defined to be able to establish the performance of a structural system in a fire. While the analysis is not exhaustive and does not pretend to provide solutions to all these issues, it attempts to provide some clarification. The following main conclusions can be extracted:

- The evolution of the fire has to be established taking into consideration the specific geometry of the structure to be analyzed.
- When imposing constraints for simplification, the results cannot be extrapolated to spaces of different characteristics.
- The energy equation to be solved has to include all heat sources and sinks in particular those associated to water. It is also important to include in the properties and modeling domain processes such as surface regression and degradation.
- The thermal boundary condition associated to a fire has to be treated as a heat flux boundary condition and not a temperature boundary condition. Even in the case when this simplification is possible it is essential to formulate the problem in the correct way so that constants are evaluated correctly.
- Analysis of furnace results cannot avoid resolving the heat transfer between the furnace lining, the gas and the sample. Even if eventually the problem can eventually be formulated with a single gas phase temperature, this needs to be demonstrated by fully resolving heat exchange within the furnace. Furnaces are in many cases a more complex system to resolve.

Numerical simulation of thin RC structures exposed to fire

R. Harte
Department of Civil Engineering, University of Wuppertal, Germany
Krätzig & Partner Civil Engineering Consultants, Bochum, Germany

ABSTRACT: Building structures in general are designed with respect to the requirements of ultimate and serviceability limit states, considering ambient and operational temperatures. In addition, accidental design situations need to be investigated, like explosion, earthquake, impact or fire. In the past the fire case has been considered with different design philosophies, depending on the traditional practice in the different countries. Some have preferred active precautions to fight against fire, either by human facilities, like fire brigades and trained employees or porters, or by technical facilities, like automatic detectors, extinguishers and sprinkling systems. Other countries have favored passive fire protection measures, like defined fire walls and slabs to prevent fire from spreading across the whole building. In Europe, the introduction of Eurocode standards enables to internationally equalize the safety levels of fire design and proof. Following the Eurocode philosophy, the paper will present some numerical developments to analyze thin reinforced concrete structures in case of fire.

1 INTRODUCTION

In the past, the fire resistance of RC structures mainly has been determined by tabulated classes of structural elements, which were based on numerous fire tests. But those tests consume time and material and by this are very expensive. Thus the need for advanced and validated simulation models for the fire proof of RC structures is growing. Such an analysis is very complicated, because of the various factors which influence the structural behavior, mainly material properties, which are drastically reduced depending on high temperatures.

The Eurocode for RC structures (EN 1992-1-2:2004) offers three methods (Level 1–3) to prove the structural fire resistance:

The classical method Level 1 is based on tabulated limit values for the cross-section, concrete cover, grade of reinforcing steel, etc. of an individual structural element. This method is rather conservative and less economic and not valid for the overall bearing capacity of a structural system.

Level 2, called "simplified calculation methods", is more realistic by considering the time-dependant temperature profile across the structural element, by this quantifying a fire-reduced cross-section and the temperature-dependant reduction of the concrete compressive strength and of the reinforcement tensile and compressive strength.

The most realistic, but most expensive method Level 3, called "advance calculation models", is characterized by a holistic numerical simulation of the heat transfer in the "thermal response model" and structural behavior in the "mechanical response model"; it should be able to determine the structural behavior of the entire structure or of any part of it.

The present paper will touch the Level 2 methods for thin reinforced structures, but will mainly present numerical models on Level 3. For the fire proof of reinforced and composite beams a 3D-finite beam element has been developed, considering temperature-dependant material and geometrical nonlinearities. This element has been implemented in the software tool FS3D (Mihajlov 2009). For the holistic numerical simulation of RC plate and shell structures exposed to fire a coupled thermo-mechanical model has been developed and implemented in the finite element system FEMAS 2000 (Mannsfeld 2011).

2 RC BEAM STRUCTURES

2.1 *Simulation method*

In case of fire structural members heat up relatively quickly. This temperature change leads to material degradation which is characterized by rapid decrease of material strength and stiffness, changing the typical linear-elastic or perfectly-plastic material stress-strain relationship to nonlinearity. As a result, large structural deformations will appear which in case of compression might cause stability failure.

Numerical analyses of such complex problems need the application of finite element models considering material and geometrical nonlinearities. Such a numerical model is implemented in the program FS3D (Mihajlov 2009). This program is based on a 3D nonlinear beam finite element with arbitrary cross section. The calculation procedure is based on the formulations proposed by (Bathe 1982, Bathe 1996), but improved for analyses of steel, concrete and composite framed structures exposed to fire and high temperatures.

The cross section of the element is defined in segments (fibers), where each segment can obtain different materials, temperatures and mechanical properties. So-called "void" fibers allow the modeling of arbitrary cross section shapes. The beam element has 3 nodes, with 6 degrees of freedom in each node. Thermal expansion, cracking or crushing of concrete and changing of material properties of reinforcing steel are implemented regarding to the constitutive law defined in (EN 1992-1-2:2004). In addition the program involves modules which enable the calculation of the heat distribution in the cross sections which are exposed to an arbitrary heating/cooling action defined by specific time-temperature curves.

Calculation of the structural behavior in fire condition using the program FS3D is divided into two main steps. In the first step the program is evaluating the heat transfer and the resulting temperature profiles for all fire exposed elements which belong to the fire compartment. Regarding to the adopted integration time step, each heat distribution in the cross sections which appears in a certain time of the fire scenario is saved as separate thermal load case which later will be used in the static analysis. The second calculation step involves evaluation of the structural behavior during the fire process. The structural response under external loading at normal temperature is adopted as initial structural configuration. The solution strategy is to establish the new structural equilibrium under the previously calculated thermal load cases. The structural bearing capacity is defined with the first thermal load case which will not establish structural equilibrium. Beside this, the program enables analysis of post-fire structural behavior. This program option allows evaluation of the structural bearing capacity of the construction which already survived a certain fire scenario.

2.2 *Thermal response model*

In case of fire, the structure of a building is subjected to mechanical and thermal actions. The mechanical actions follow from the permanent loads like dead weight of the construction and the combination of existing live loads. The thermal actions follow from the increase of the gas temperature in the fire compartment. As a result, the thermal profile in the structure will lead to increased temperatures and to thermal elongation and curvature and to deterioration of the material properties of the structure. To determine this uneven thermal profile across the cross section, the following balance equation has to be solved.

$$(\rho_c c_c)\dot{\theta} = \mathrm{div}\left[\lambda \cdot \mathrm{grad}\,\dot{\theta}\right] + Q \qquad (1)$$

where ρ_c = density of dry concrete; c_c = specific heat capacity of concrete; λ = thermal conductivity matrix; θ = temperature; Q = heat source or sink; $(\dot{})$ = time derivative.

The temperature-dependency of these material parameters has to be considered. The differential equation (1), combined with initial and relevant boundary conditions, mainly convection and radiation, describes the initial value problem, which has to be converted into a finite element formulation. By this the thermal behavior in the structure can be determined.

Assumption for the uniform temperature distribution along the beam element length is adopted, which enables to simplify the 3D heat transfer problem into a 2D problem to be applied on the beam cross section. The program FS3D uses 4 and 8 nodes finite elements for calculating the heat distribution in the cross section. The implemented algorithm enables to solve the steady state and the unsteady state heat transfer problems. Using FEM for calculation of the heat distribution in the cross section enables to simulate heating and cooling of arbitrary shape composite cross sections, which can be exposed to any kind of fire load, defined by any time-temperature relationship. This approach allows consideration of nonlinear heat transfer effects like temperature dependent material thermal properties and radiation.

2.3 *Mechanical response model*

Material non-linear behavior caused by elevated temperatures is implemented in the numerical model by the temperature-dependant material properties. The program FS3D incorporates the material non-linear constitutive laws for steel and concrete according to (DIN EN 1992-1-2:2010). In general the concrete tensile strength is ignored for the proof and dimensioning the structural RC members. In order to achieve a realistic structural response by an advanced calculation model, the residual concrete tensile strength at elevated temperatures is employed in the program FS3D. The tension zone is described with the bilinear constitutive law according to Figure 1. The maximum tensile strength is a function of maximum compression strength of the concrete defined for a certain temperature level. After reaching maximum tensile strength,

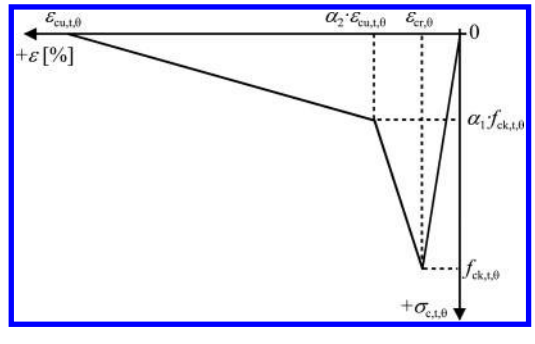

Figure 1. Schematic presentation of tension stress-strain relationship of concrete at elevated temperature θ; where $\sigma_{c,t,\theta}$ = tensile concrete stresses at θ; ε = tensile concrete strains; $\varepsilon_{cu,t,\theta}$ = ultimate tensile dilatation at θ; $\varepsilon_{cr,t,\theta}$ = concrete cracking tensile dilatation at θ; $\alpha_1 = 0.33$ (coefficient); $\alpha_2 = 0.22$ (coefficient); $f_{ck,t,\theta}$ = characteristic value of ultimate tensile concrete strength at θ.

a crack appears in the respective concrete fiber. For each cracked fiber, the constitutive matrix D involves zero values for the matrix members which are function of the concrete modulus of elasticity. All other members from the constitutive matrix D which are functions of the shear modulus have non-zero values as given in equation (2).

$$D = \begin{bmatrix} 0 & 0 & 0 \\ 0 & \mu G_c & 0 \\ 0 & 0 & \mu G_c \end{bmatrix} \tag{2}$$

The history of previous heating of the concrete fibers is also adopted into the material model. The concrete fibers which previously experienced higher temperature than the current one, are obeying constitutive law which is defined with the so-called residual concrete strength (ECCS TC3 2001). A short description of this concrete behavior is given in Figures 2 and 3. The solid line in Figure 3 represents the stress-strain relationship of the concrete when the fiber is heated up to temperature θ_1. After reaching the maximum temperature θ_{max} the process of cooling is starting (Figure 2). When the concrete fiber is cooled down to temperature $\theta_2 = \theta_1$ the material constitutive law (presented with the dashed line in Figure 3) is defined over residual concrete strength $f_{c,\theta 2}$, where $f_{c,\theta 2} < f_{c,\theta 1}$ even though the temperature $\theta_2 = \theta_1$.

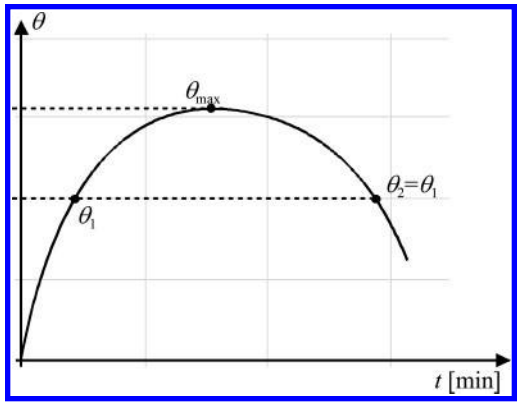

Figure 2. Time history of concrete heating, where θ = concrete temperature; t = time.

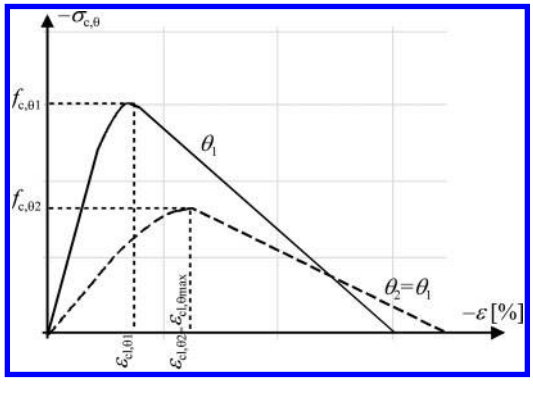

Figure 3. Stress-strain relationships for concrete with respect to heating history, where $-\sigma_{c,\theta}$ = compressive concrete stresses at elevated temperature θ; $-\varepsilon$ = compressive concrete strains; $\varepsilon_{c1,\theta}$ – strains at maximum compressive concrete strength at θ; $f_{c,\theta}$ = compressive concrete strength at θ.

This constitutive law for the concrete is implemented into the program FS3D. It enables the analysis of structural response during the cooling down process, finally simulating the post-fire load-bearing capacity.

2.4 *Non-linear 3D-finite beam element*

A general continuum mechanic equation for large displacements is used for deriving a non-linear stiffness matrix for a finite beam element employed in FS3D. The beam stiffness matrix is derived using the "equation of motion" (3) and is applied on the general body considering large displacements, large rotations and nonlinear constitutive response. The equilibrium of the body in motion for certain time configuration t can be obtained using the Total Lagrangian formulation.

$$\int_{0V} {}^{t+\Delta t}_{0}S_{ij}\ \delta\ {}^{t+\Delta t}_{0}\varepsilon_{ij}\ d^0V = \Re \quad i,j = 1,2,3 \tag{3}$$

where ${}^{t+\Delta t}_{0}S_{ij} = 2^{nd}$ Piola-Kirchhoff stress tensor at time configuration $t + \Delta t$; $\delta\ {}^{t+\Delta t}_{0}\varepsilon_{ij}$ = variation of Green-Lagrange strain tensor at time configuration $t + \Delta t$; ${}^{0}V$ = volume at time configuration 0; $\Re$ = components which describe external virtual work.

By using the Total Lagrangian incremental decomposition and employing the linearization procedure, a governing linearized form of the equation of motion is obtained.

$$\int_{0V} {}_0C_{ij}e_{rs}\delta e_{ij}d^0V + \int_{0V} {}^{t}_{0}S_{ij}\ \delta\eta_{ij}d^0V = \Re - \int_{0V} {}^{t}_{0}S_{ij}\delta e_{ij}d^0V$$

$$\text{with} \quad {}_0C_{ij} = \frac{\partial\, {}^{t}_{0}S_{ij}}{\partial\, {}^{t}_{0}\varepsilon_{rs}} \tag{4}$$

where ${}^{t}_{0}S = 2^{nd}$ Piola-Kirchhoff stress tensor in known time configuration t; ${}_0S$ = incremental 2^{nd} Piola-Kirchhoff stress tensor; ${}^{t}_{0}\varepsilon$ = Green-Lagrange strain tensor in known time configuration t; ${}_0\varepsilon$ = unknown incremental Green-Lagrange strain tensor; δe_{ij} = variation of linear part of the strain tensor; $\delta\eta_{ij}$ = variation of non-linear part of the strain tensor.

All terms in (4) are linear in the incremental displacements. The first integral from the left side of this equation defines the linear stiffness matrix of the beam, the second integral defines the nonlinear stiffness matrix and the integral on the right side represents the vector of unbalanced forces. This equation is implemented on a 3-nodes beam finite element shown in Figure 4.

Each node of the element has 6 degrees of freedom. The general definition of the beam cross section is

rectangular. Using the segmentation of the cross section and allowing some segments to be "void" (with zero mechanical and strength properties), modeling of arbitrary cross sections is possible. Further, the cross section can be offset from the beam reference line. The offset is defined by the distance Δt and Δs. The main assumption of the beam model can be summarized as follows:

- Plane section originally normal to the reference axis remains plane after the deformation, but not necessary normal to deformed axis. It is assumed that there is no slip between the fibers.
- Deformations and rotations can be arbitrarily large, but strains keep small. Thus the area remains unchanged after deformation.
- Each cross section fiber can obtain different temperature value but which is uniform along the element length.

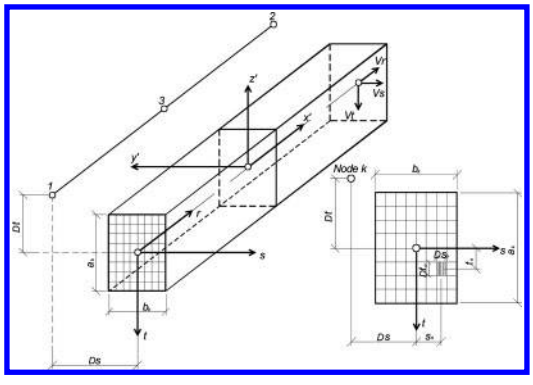

Figure 4. A non-linear beam column element (Mihajlov 2009).

- For each fiber within the cross section only the longitudinal stresses and two shear stresses are not zero.

Using the mentioned assumptions together with the beam shape function and employing in addition the second-order approximations (Argyris 1982), the linear and nonlinear beam-column stiffness matrix can be obtained. For more details see (Mihajlov 2009).

2.5 *Numerical example – RC cantilever column*

Figure 5 shows a RC cantilever column, which is exposed to fire from the left side only. The ultimate limit state of nonlinear load bearing is calculated to t = 64 min. duration of fire according to the numerical model of (Mihajlov 2009). The inner cold core of the cross section is totally cracked due to thermally induced tensile stresses, whereas the outer hot zones have to completely carry the compressive stresses. These zones are deteriorated due to the hot temperatures and the column is no longer stable and will collapse.

3 RC PLATE AND SHELL STRUCTURES

3.1 *Simulation method*

In case of fire, the slabs of buildings and the shells of curved structures like domes, tunnels and tanks, are subjected to mechanical and thermal actions, too.

Again the thermal behavior in the structure, in this case the thermal profile across the plate or shell thickness, needs to be determined.

For the mechanical calculations of reinforced concrete plate and shell structures exposed to fire, the

Figure 5. existing Finite Element System FEMAS 2000 is used and extended by the component "fire or elevated temperature". The finite element, which is used, is a 4-node isoparametric Reissner-Mindlin-type finite shell element, where the shell theory is middle-surface orientated with rotational variables. By use of an interface element formulation (Wörmann 2004) combining the thermal simulation in thickness direction and the existing multi-layered concept (Krätzig 1997), it is possible to simulate the nonlinear behavior considering all temperature-dependant material data like strength, Young's modulus, etc. in each layer of the plate element. Both the thermal and the structural model with different number and spacing of layers and the respective transformation procedure is shown in Figure 6.

Figure 7. Fire test stand, slab and water drums to simulate the uniformly distributed load (Lim & Wade 2003).

3.2 *Numerical example – concrete slab*

The new developed model is verified by a comparison of experimental results and the results from the numerical simulations. Based on real fire tests in Cardington, England 1995/96, further fire tests of 6 two-way concrete slabs were realized by BRANZ Limited in 2002.

The selected reinforced concrete slab, called "661 flat slab" according to (Lim & Wade 2003), is 4.3 m wide, 3.3 m long and 10cm thick. The test stand is shown in Figure 7, and in Figure 8 you find the resulting deformation pattern after the fire test. Further information about the test program is given in (Lim & Wade 2003 and Mannsfeld 2011).

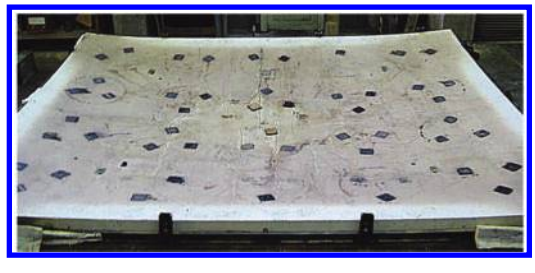

Figure 8. Top view of the slab after the fire test (Lim & Wade 2003).

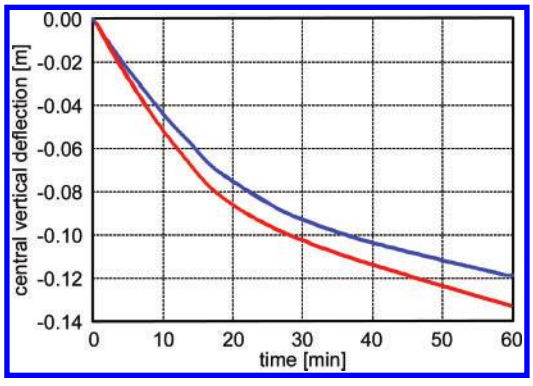

Figure 9. Numerical simulation with FEMAS 2000 – Central vertical deflection of the slab; upper line – experiment (Lim & Wade 2003); lower line – numerical simulation (Mannsfeld 2011).

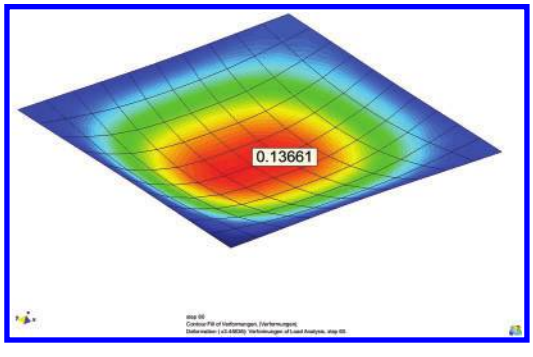

Figure 10. Deformation pattern after fire duration $t = 60$ min (Mannsfeld 2011).

To heat the slab the ISO 834 standard fire curve has been used both in the experiment and in the numerical simulation. The slab is modeled and calculated with FEMAS 2000 considering the coupled thermal and mechanical nonlinear simulation strategy according to (Mannsfeld 2011). Figure 9 and 10 show results at time-step $t = 60$ min. The central deflection according to the numerical simulation is slightly higher than the measured deformations, which is caused by the conservative assumptions for the material degradain case of elevated temperatures.

Shear capacity of steel plate girders with slender webs in fire

T. Ohtsuka
Meijo University, Nagoya, Japan

M. Knobloch & M. Fontana
ETH Zurich, Zurich, Switzerland

ABSTRACT: A simplified model for calculating the shear load-displacement relationship of steel plate girders with slender webs at high temperatures is proposed based on numerical results by FEM. This model uses the buckling degradation function which depends on the buckling parameter, and the post-buckling shear strength is given either by full plastic shear strength or full plastic moment using the buckling degradation function.

1 INTRODUCTION

The shear capacity of steel plate girders with slender webs can be calculated using Tension field theory proposed by Basler and other researchers (Galambos, 1998). Kimura et al. (2001) proposes the post-buckling shear strength of thin aluminum alloy plates by using the elastic limit width-to-thickness ratio and the plastic limit width-to-thickness ratio. Salminen and Heinisuo (2012) discuss the shear resistance of thin plate girder web panel at elevated temperatures and compare numerical results with results of an analytical model based on Eurocode.

This paper proposes a simplified analytical model for calculating the shear load-displacement curve of steel plate girders with slender webs at elevated temperatures. This model bases on the results of comprehensive numerical parametric study using the finite element approach.

2 NUMERICAL PARAMETRIC STUDY

The numerical parametric study considered three different finite element models. Model 1 (web plate model) just considered the web of the girder. The influence of the flanges was neglected. Model 2 (Plate girder model composed flange with beam element) considered the influence of flanges using beam elements. Thus, the influence of local flange buckling was neglected. Finally, model 3 (Plate girder model comprised of shell elements) considered both web buckling and local flange buckling using shell elements for the entire model.

The material coupon furnace test results for 500°C of Ave et al. (2011) are used in this study (Fig. 1). The following material properties were used: Young's modulus 156 [GPa], Yield stress 183.4 [MPa] and Tensile strength 241.7 [MPa]. This corresponds to reduction factors, given as the ratio of the material property at elevated temperature and corresponding property at ambient temperature, of $k_E = .0.74$, $k_y = 0.64$ and $k_u = 0.55$. In addition to the actual nonlinear stress-strain response (②)(Fig. 2) a linear elastic, perfectly plastic stress-strain relationship using Young's modulus and yield stress at 500°C(①) are used for comparison.

The finite element software SHIDEN (developed by Motoyui laboratory, Tokyo Institute of Technology) was used for all models of the numerical parametric study. The study considered three aspect ratios ($L/d = 1$, 2, 4, $d = 200$[mm]) and two width-to-thickness ratios ($d/t_w = 100$, 200, $t_w = 2$, 1 [mm]) for all models. The 1st and 2nd eigen mode were applied in all cases as the initial imperfections and it's maximum deflection was $t_w/100$.

2.1 *Web plate model*

The analytical model and its elastic buckling mode for an aspect ratio of $L/d = 2$ and a width-to-thickness ratio of $d/t_w = 100$ are shown in Fig. 3,4 as an example. All edges of the web plate model were simply supported, the boundary condition was simple shear (not pure shear) and the loading edge was allowed to move in the longitudinal direction but the rotation in plane was clamped.

Fig. 5 shows the load-displacement relationship. In Fig. 5, solid and dotted curve signify the results of material ② and ①, respectively. The shear force V is normalized by full plastic shear capacity ($V_p = dt_w\tau_Y$, τ_Y is shear yield stress) and displacement δ is

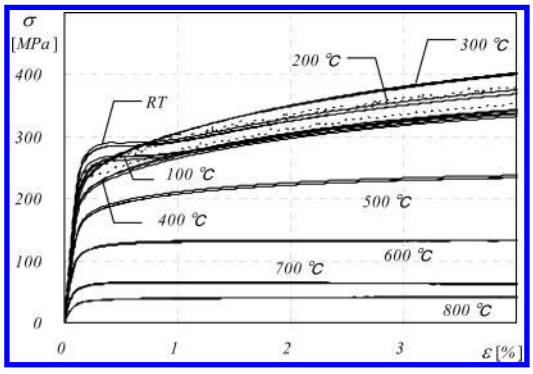

Figure 1. Stress-strain curve of coupon test.

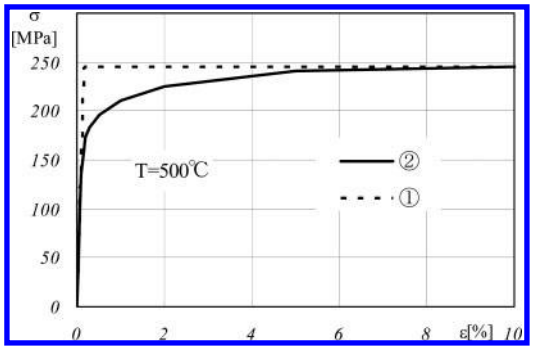

Figure 2. Stress-strain curve at 500°C in this paper.

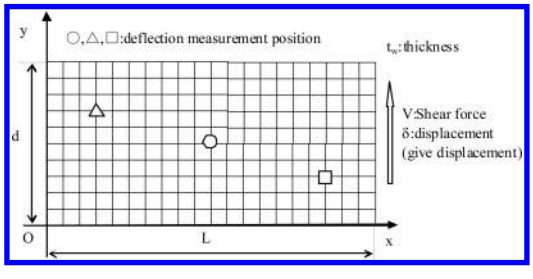

Figure 3. Analytical model (L/d = 2).

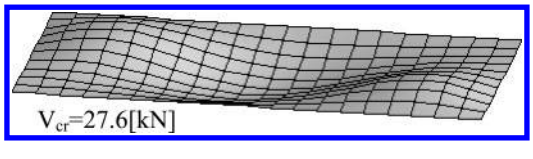

Figure 4. 1st eigen mode (L/d = 2,d/t_w = 100).

normalized by length L. In addition, Fig. 5 shows the elastic buckling shear force $V_{cr.}$(▲) The nonlinear stress-strain respond of material ② had a marked influence on the shear strength. Furthermore, V_{max}/V_p decreased for increasing aspect ratios.

Fig. 6 shows the out-of-plane deflection at locations given in Fig. 3. The displacement δ is normalized

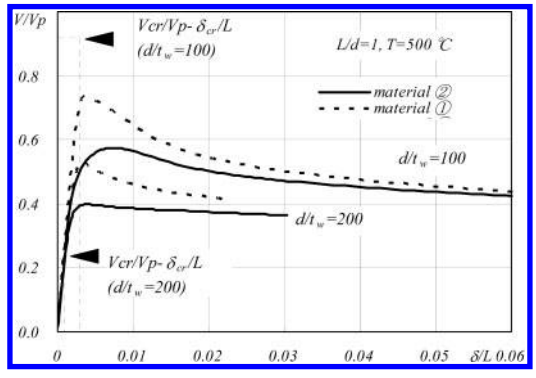

Figure 5(a). Load-displacement curve(L/d = 1).

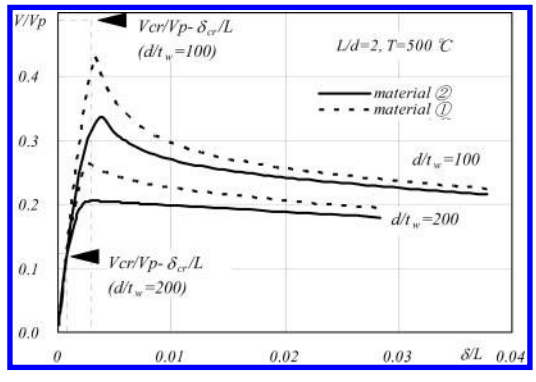

Figure 5(b). Load-displacement curve (L/d = 2).

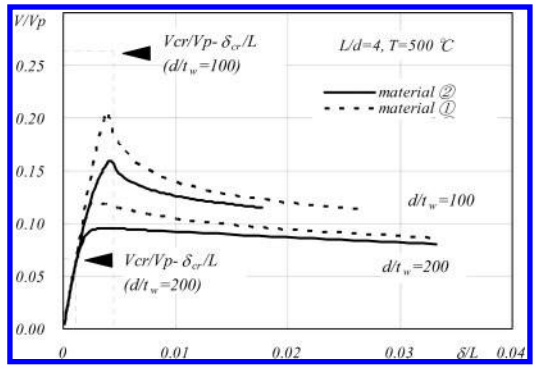

Figure 5(c). Load-displacement curve (L/d = 4).

by elastic buckling displacement δ_{cr} which is calculated by an eigenvalue analysis. Fig. 6 shows that the out-of-plane deflection strongly increased after the in-plane displacement exceeded the elastic buckling displacement.

Fig. 7 shows the bending moment at loading edge. The bending moment is normalized by full plastic bending moment capacity M_p and the in-plane displacement is again normalized by the elastic buckling displacement. In these models, the maximum load and post buckling behavior were limited by bending moment.

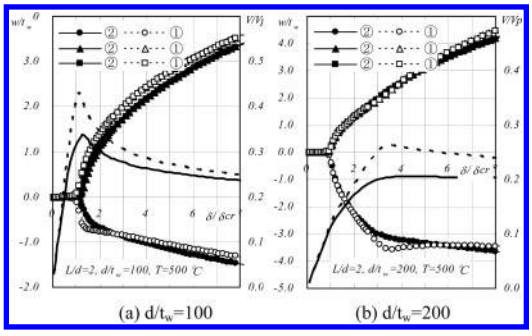

Figure 6. Deflection of out of plane (L/d = 2,T = 500°C).

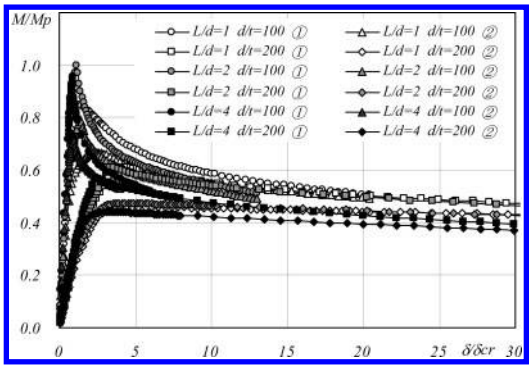

Figure 7. Bending moment-displacement relationship.

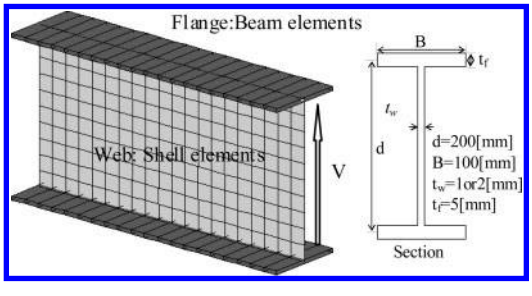

Figure 8. Analytical model (L/d = 2).

2.2 *Plate girder model composed flange with beam element*

Fig. 8 shows the numerical model. Beam elements were used to model the flanges of the girder, neglecting the influence of local flange buckling.

Fig. 9 show the elastic buckling mode calculated by an eigenvalue analysis. In comparison to the results of the web plate model, the elastic buckling load for aspect ratios L/d of 1 and 2 were bigger, but buckling modes were similar.

Fig. 10 shows the load-displacement relationship. The aspect ratio again markedly influenced the shear resistance V_{max} However, the shear resistance calculated with the plate girder model was significantly larger than the resistance calculated with the web plate model.

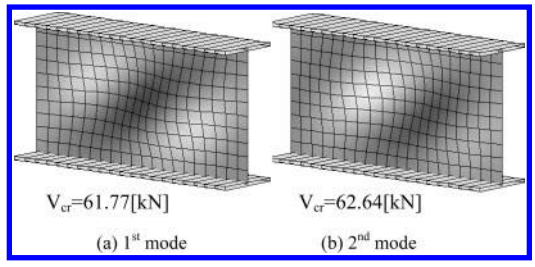

Figure 9. Eigen mode (L/d = 2, d/t$_w$ = 100).

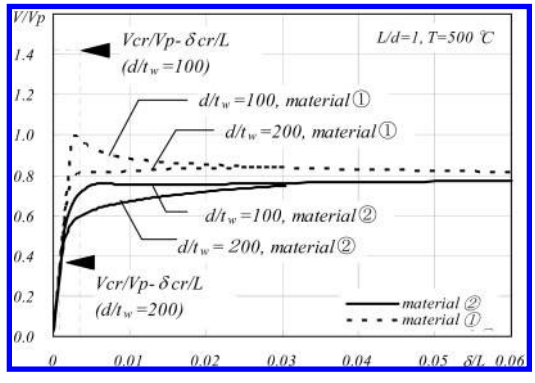

Figure 10(a). Load-displacement curve (L/d = 1).

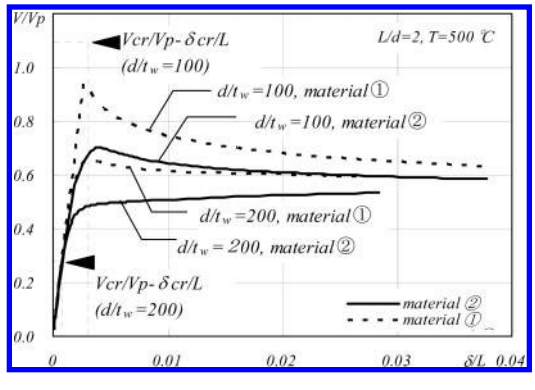

Figure 10(b). Load-displacement curve (L/d = 2).

2.3 *Plate girder model composed all of shell element*

Fig. 11 shows the model of the plate girder. The model consists of shell elements for the entire girder. In addition to a model without a stiffener, the study also analyzed the influence of a stiffener attached to the loading and supporting edge using a rigid beam for modeling.

Fig. 12 shows the elastic buckling mode. For an width-to-thickness ratio d/t$_w$ = 100, the flange was deformed by web buckling, but for d/t$_w$ = 200, the flange was not deformed.

Fig. 13 shows the load-displacement relationship of the model without a stiffener. Due to the rather

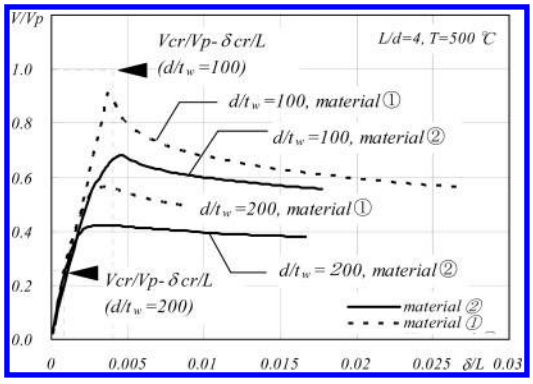

Figure 10(c). Load-displacement curve (L/d = 4).

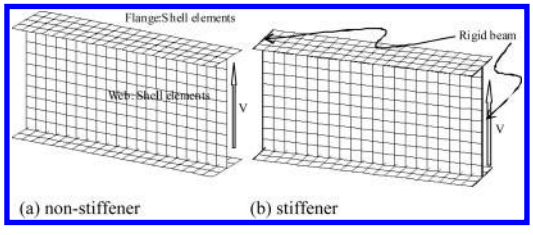

Figure 11. Analytical model (L/d = 2).

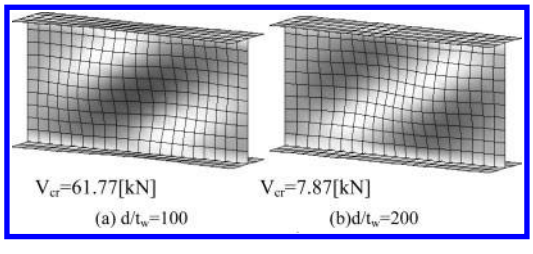

Figure 12. 1st eigen mode (L/d = 2, non-stiffener).

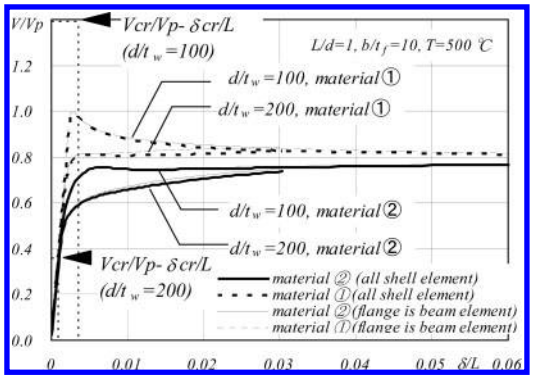

Figure 13(a). Load-displacement curve (L/d = 1).

low flange slenderness ratio the results of all shell element models were similar to the results of the model which used a beam element for flange modeling. For large in-plane displacements the relative shear loads V/V_p were 0.8 (L/d = 1), 0.6 (L/d = 2) and 0.4-0.5 (L/d = 4), respectively. The tension field might lead to the almost constant values for large displacements.

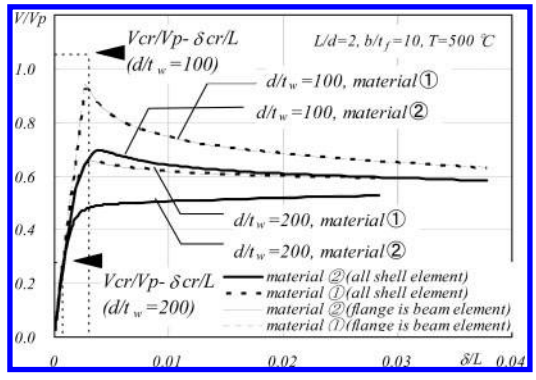

Figure 13(b). Load-displacement curve (L/d = 2).

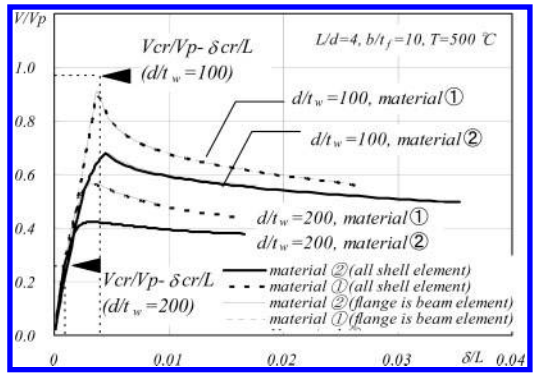

Figure 13(c). Load-displacement curve (L/d = 4).

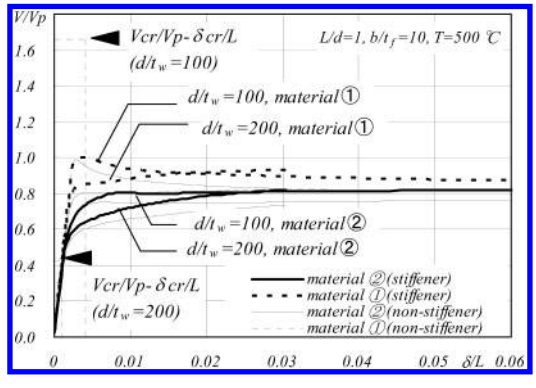

Figure 14(a). Load-displacement curve (L/d = 1).

Fig. 14 shows the load-displacement relationship of the models that considers stiffeners. The stiffener had almost no influence on the shear resistance and led to a small increase of the shear load for large displacements and small aspect ratios L/d. For small aspect ratios L/d the tension field might spread by attaching stiffeners.

3 SIMPLIFIED MODEL FOR SHEAR LOAD-DISPLACEMENT BEHAVIOUR AT ELEVATED TEMPERATURES

3.1 *Proposed simplified model*

A simplified model for calculating the shear load-displacement relationship using a buckling degradation function $\bar{S}$ is proposed based on the results of the numerical study in this chapter.

The total displacement δ is divided into shear components δ_S and bending components δ_M.

$$\delta = \delta_S + \delta_M \tag{1}$$

Linear stiffness' given by Eq.(2) are used for calculating the shear load.

$$k_S = \frac{GA_w}{L},\quad k_M = \frac{12EI}{L^3} \tag{2}$$
$$V = k_S\delta_S,\quad V = k_M\delta_M$$

Three phases are considered.

1st phase: Elastic

The 1st phase is characterized by an elastic relationship between the shear load and the displacement (Eq. 3). The elastic buckling displacement can be calculated by either a numerical eigenvalue analysis or analytical models, e.g. Suzuki and Ikarashi, (2012).

$$\frac{V}{V_{cr}} = \frac{\delta}{\delta_{cr}} \tag{3}$$

2nd phase: Elastic shear buckling

After elastic buckling occurred the shear load can be calculated using Eq. (4)

$$\frac{V}{V_{cr}} = \bar{k}_{eb}\frac{\delta}{\delta_{cr}} \tag{4}$$

with $\bar{k}_{eb} = 0.7$

3rd phase: Plastic shear buckling

The 3rd phase constitutes plastic shear buckling. For this phase, the normal strain and shear strain can be calculated using Eq. (5). The yield normal stress σ_Y and yield shear stress τ_Y is then obtained by Eq. (6).

$$\varepsilon = \frac{6}{L^2}\frac{d}{2}\delta_M,\quad \gamma = \frac{1}{L}\delta_S \tag{5}$$

$$\delta_M = \frac{k_S}{k_S+k_M}\delta,\quad \delta_S = \frac{k_M}{k_S+k_M}\delta$$
$$\dot{\sigma} = \frac{E_{PT}E}{E+E_{PT}}\dot{\varepsilon},\quad \dot{\tau} = \frac{E_{PT}G}{3G+E_{PT}}\dot{\gamma} \tag{6}$$

with $\dot{\sigma} = sign(\sigma)E_{PT}\dot{\lambda}^p$, λ^p: plastic parameter.

The buckling degradation function $\bar{S}$ is given by Eq. (7). Using the buckling degradation function, the shear strength can be calculated with Eqs. (8) and (9), respectively, considering the full plastic bending moment and full plastic shear force.

$$\bar{S} = C_1 + (1-C_1)\{1-C_2(\Theta-\Theta_0)\}EXP\{C_3(\Theta-\Theta_0)\} \quad \{\Theta \ge \Theta_0\}$$
$$= 1.0 \quad \{\Theta < \Theta_0\} \tag{7}$$

where, buckling patameter $\Theta = \delta/\delta_{cr}$ and C_1, C_2, C_3 is softening coefficient for buckling.

$$\frac{V}{V_{cr}} = \frac{2Z_p\sigma_Y}{LV_{cr}}\bar{S},\qquad \frac{V}{V_{cr}} = \frac{A_w\tau_Y}{V_{cr}}\bar{S} \tag{8),(9)}$$

The shear strength is calculated as the minimum of Eqs. (3) or (4), (8) and (9).

$$\frac{V}{V_{cr}} = Min\{Eq.(3)or(4), Eq.(8), Eq.(9)\} \tag{10}$$

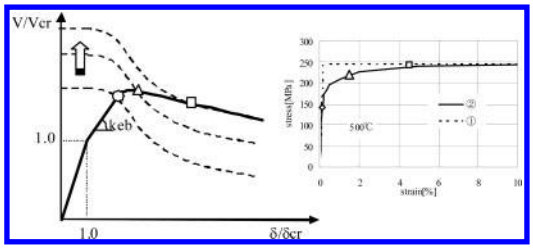

Figure 16. Illustrate the concept of proposed method.

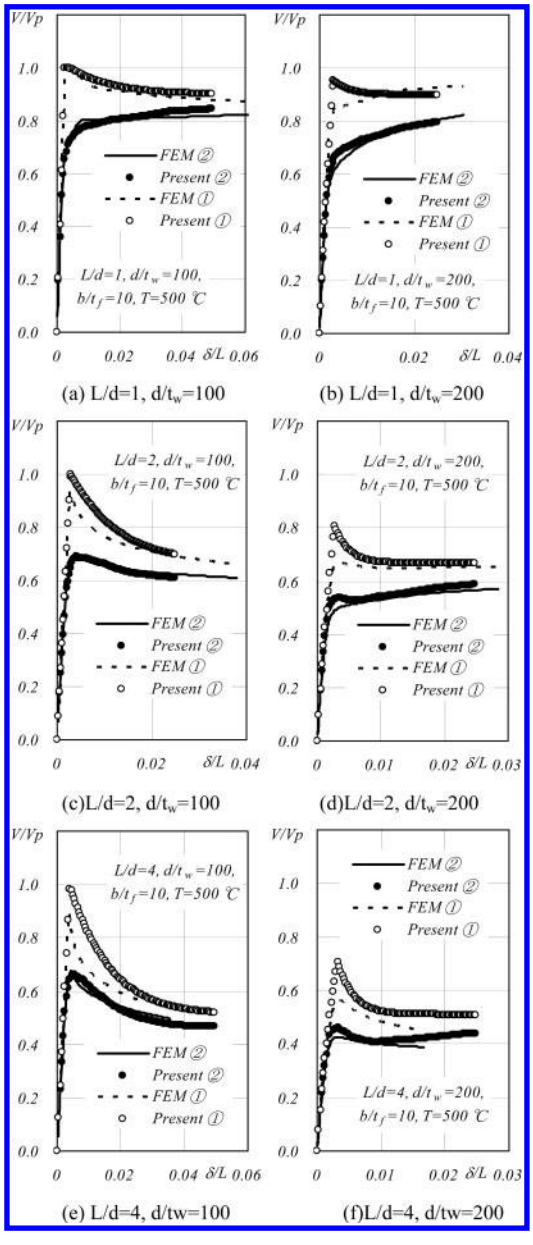

Figure 17. Comparison for stiffener models.

The concept of this simplified analytical model is illustrated in Fig. 16. For an elastic perfectly plastic material behavior, there is only one way of the plastic degradation curve. Considering strain hardening, the plastic degradation curve move according to the strain evolution.

Constant values are used for the softening coefficients C_2 and C_3 ($C_2 = -0.1$, $C_3 = -0.4$) The softening coefficient C_1 represents the shear load for large displacements. Thus, the aspect ratio affects C_1, and is calculated with Eq. (9) (girders with stiffeners) or Eq. (10) (girders without stiffeners).

$$C_1 = \begin{cases} 0.6\theta + \frac{1}{3} & \{\theta \le \theta_0\} \\ 1.0 & \{\theta > \theta_0\} \end{cases}, \quad \theta_0 = \frac{10}{9} \tag{11}$$

$$C_1 = \begin{cases} 0.72\theta + \frac{1}{3} & \{\theta \le \theta_0\} \\ 1.0 & \{\theta > \theta_0\} \end{cases}, \quad \theta_0 = \frac{100}{108} \tag{12}$$

with $\theta = \tan^{-1}(L/d)$[rad].

3.2 *Validation*

Figure 17 compares results according to the simplified analytical model (◯, ●) to numerical results. For all cases, the simplified model led to adequate results.

4 CONCLUSIONS

A simplified model for the shear load-displacement curve of steel plate girders with slender web in fire has been proposed. In this model, the buckling degradation function according to the buckling parameter Θ ($=\delta/\delta_{cr}$) is used. The shear strength is strongly influence by the shape of the stress-strain relationship. A distinct nonlinear stress-strain response decreases the shear strength. However, the shape of the material behavior has no influence on the shear load for large displacements.

ABSTRACT: Due to the significant weight of the elements, which raise the construction and transportation costs and the CO_2 production, concrete buildings may not meet the requirements for sustainable constructions. Furthermore, concrete is quite vulnerable to fire, as it undergoes a permanent degradation of its mechanical properties at temperatures commonly reached by structural elements during a fire in a building. As a consequence, several multi-story concrete buildings have collapsed or suffered major structural damages because of fire, and caused injuries and casualties among the occupants. Even in those cases, where a safe evacuation of the building is ensured, the high costs associated with the downtime and reparation of the building can be very high and not acceptable in the view of a safe and sustainable design of structures. In this respect, the newly patented building technology of superlight elements invented at DTU seems very promising in reducing the weight of the elements and improving their structural integrity in case of fire or other accidental actions. In particular, the behaviour under fire of a superlight floor slab element (SL-deck) is investigated in this paper. The implementation of a three-dimensional Finite Element Model (FEM) of the SL-deck is described and modelling aspects are discussed with particular reference to the sensitivity of the model to the thermal properties of the strong and light concrete. The results of the investigation are compared with the outcomes of a fire test performed on a prototype slab. The implementation of a FEM is useful in order to predict the structural behaviour of the slab under different fire and boundary conditions. However, the relevance of the study lies in particular in the presentation of a methodology for the investigation of the fire performances of complex concrete elements and in the focus on modelling issues related to the handling of the uncertainties.

1 INTRODUCTION

1.1 *Sustainability of concrete*

Concrete constructions are typically characterized by a significant weight of the elements. This has an impact on both the construction and transportation costs and on the increment of the CO_2 as well.

In the view of a more sustainable building process, the employment of light but resistant concrete elements, such as hollow core slabs (HCS) or high resistant concrete beams and columns, could favour the sustainability of buildings. Nevertheless, the behaviour of these elements under accidental actions such as a fire or an explosion can be critical, e.g. in case of spalling of the high resistant concrete (Hertz, 2003), loss of anchorage of the reinforcement (Hertz, 1982), and opening of the holes and consequent loss of insulation in a HCS (Jensen, 2005).

In particular, the integrity of slabs is essential in case of multi-storey building fires, where the failure of a concrete floor element may trigger a vertical propagation of both the damages and the fire, and potentially lead to a progressive collapse of the building, as happened in few recent building fires (Ikeda & Sekizawa, 2005), (Mecham, et al., 2010).

Even if quite rare, fire-induced collapses of buildings have very severe economical and societal consequences, as they imply high demolition costs and cause often several casualties or injuries among the occupants and the rescue personnel.

Also in those cases, where a major collapse is avoided and the safety of the occupants can be ensured by a rapid egress, fire-induced damages in concrete buildings have high economical repercussion in term of downtime and renovation costs. This is due to the fact that, contrarily to a common belief, concrete is quite vulnerable to fire. Unlike ordinary mild steel, which regains its initial strength and stiffness after cooling, concrete undergoes a permanent degradation of the mechanical properties when heated over 300°C

(Hertz, 2005). Despite the low conductivity of the concrete, this is a temperature that is easily overcome in the concrete cover of the reinforcement after the first 30 min of exposure and that can penetrate the inner part of a floor slab during the cooling phase a fire.

In addition to the weight of concrete elements, which affects the construction and transportation costs, sustainability issues should be therefore considered also in relation to the fire vulnerability of the elements, which significantly affects the reparation costs.

1.2 *Superlight elements*

The newly patented building technology that goes under the name of superlight structures (Hertz, 2010) seems able to combine sustainability issues related to both the weight and the vulnerability to fire of concrete elements (Hertz & Bagger, 2011).

The technology is based on encasing a core of strong concrete in a very light concrete aggregate. The light material stabilizes the core and protects it from accidental actions, such as fire, impacts, and explosions.

The result is a light, resistant, economic and robust structural element, which has proved to possess very good performances under ordinary loads and a very high resistance under fire in a test recently performed at DBI (Hertz, in publication).

In particular, super-light deck elements (Christensen & Hertz, 2012), referred in the following as SL-decks, are obtained by casting an ordinary concrete over an array of lightweight concrete blocks with pre-stressed wires acting in the longitudinal direction. The ordinary concrete contains the compression zone and surrounds the wires, while the light concrete, which contribute only very little to the overall resistance of the deck, is used in the remaining parts, in order to reduce the weight of the slab and consequently of the whole building.

Furthermore, the light concrete on the bottom of the deck works as a layer of insulating material for both the transmission of sound (Christensen, et al., 2012) and temperature. With respect to fire in particular, the high porosity and low conductivity of the light aggregate ensure low temperatures in the reinforcement and in the compression zone.

1.3 *Purpose of the study*

Being a new technology, the SL-deck requires the use of new methods for the assessment of the structural capacity in case of ordinary and accidental action. Analytical simplified methods for the calculation of load bearing capacity under ordinary actions have been developed in the framework of a M.Sc. project carried on at DTU (Halldórsson, 2012).

In the present study instead, an advanced numerical model has been used in order to investigate the fire behavior of a SL-deck. To this aim, a finite element model (FEM) of the slab has implemented and validated against data from the fire test.

Modelling aspects are presented, concerning the interaction of a high-resistant concrete and a light aggregate, the effect of pre-stressing and tension-stiffening of the concrete, the thermal degradation of the material. In particular, the sensitivity of the model to uncertainties, such as the thermal properties of the concrete aggregates, is investigated and discussed.

2 SL-DECK MODEL AND INVESTIGATION

2.1 *Geometry and properties of the slab*

The SL-deck here considered is made by casting a C50/60 concrete on three adjacent rows of Light Expanded Clay Aggregates (LECA™) concrete blocks.

The light blocks have a pyramidal shape with an outer box dimension of 500 × 400 × 185 mm and are covered with ordinary concrete. The concrete is cast up to a height of 30 mm from the highest point of the block, so that the height of the slab cross-section is 215 mm and the width is 1200 mm, as seen in Figure 2.

Two pre-stressing wires are placed in the ordinary concrete in between the light blocks at a depth of 75 mm from the bottom surface of the deck. One pre-stressing wire is placed on each side of the slab at a depth of 85 mm. The wires have a diameter of 12.5 mm made of S1860 steel.

In order to provide better anchorage to the pre-stressing wires, the last 100 mm at each deck end are made of solid ordinary concrete. A total length of 6.2 m has been considered for the slab.

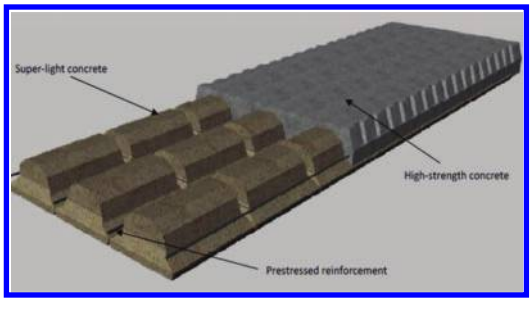

Figure 1. Sketch of a SL-deck element before and after the cast of ordinary concrete on the light blocks.

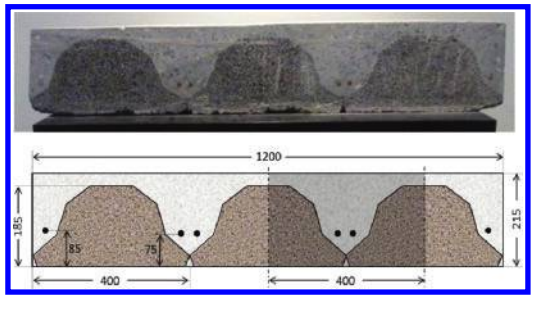

Figure 2. Cross section of a SL-deck. Top: picture of a deck slice; bottom: sketch of the section geometry.

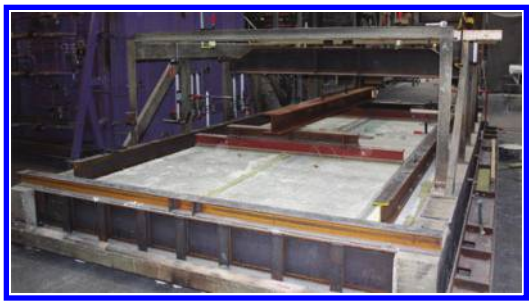

Figure 3. Setup for the fire test of the SL-deck at DBI.

2.2 *Fire test*

A fire test of the slab (Hertz, in publication) was performed in the laboratory of the Danish Institute of Fire and Security Technology (DBI).

In the test, two 1.2 m wide and 6.2 m long deck elements were placed side by side in a frame, which provided a support of 100 mm at each slab end, leaving a free span of 6 m. Mineral wool was placed along the deck junction and all around the slab sides, in order to avoid heat dispersion from the gaps without hindering the free expansion of the slab.

The frame was then placed above a large furnace and a load equivalent to a distributed load $p^{fi} = 2.5\,\mathrm{kN/m^2}$ was applied. This corresponds to the sum of service load $q_k = 1.5\,\mathrm{kN/m^2}$, as indicated by the Eurocodes for a domestic building (EN 1991-1-1, 2002), and a permanent load $g_k = 1.0\,\mathrm{kN/m^2}$ corresponding to the expected weight of the flooring and tributary separation walls. The load was applied by means of a hydraulic jack acting on a longitudinal steel beam, which transmitted the load to two transversal steel beams spacing 2 m from each side of the slab (Figure 3). An equivalent pointed load of 36 kN is found from the considered distributed load, by imposing the identity of the maximum moment corresponding to the two load distributions. By subtracting the weight of the three steel beams to this value the load to be applied by the hydraulic jack was found equal to 31.8 kN.

After having loaded the slab, the furnace was turned on and calibrated in order to reproduce a standard fire (ISO834-1, 1999) for 120 min. During this time, the load on the slab was kept constant by lowering the hydraulic jack, so that the vertical displacement of the slab could be followed. The temperatures in the slab were registered by means of thermocouples previously placed on the top and bottom surface of the slab and on the pre-stressing wires as well, before casting the concrete.

After 120 min, the vertical load on the deck was increased at a rate of ca. 18 kN/min. The intention was to reach the ultimate capacity of the slab, but the maximum force that the hydraulic jack could exert was reached before any slab failure occurred. The maximum force applied by the hydraulic jack plus the weight of the beams corresponded to 249 kN. The distributed load that would induce the same maximum moment at the mid-span can be calculated as $p_u^{120} = 17\,\mathrm{kN/m^2}$, whereas the load bearing capacity before fire had been assessed as $p_u = 23\,\mathrm{kN/m^2}$ in a previous test (Halldórsson, 2012).

3 FEM MODELING AND ANALYSES

3.1 *Structural and thermal model*

Two different models have been implemented in Abaqus™ (Simulia Corp., 2011): i) a thermal model, where the temperature distribution caused by the fire exposure has been computed along the slab section; and ii) a structural model, where the response to the mechanical and thermal load has been evaluated in terms of vertical displacement of the mid-span of the slab during the fire.

3.1.1 *Structural model*

A three-dimensional finite element model of a strip of the slab has been implemented. The strip is 400 mm wide and includes the wedge-shaped ordinary concrete with two wires on the bottom and half of the light blocks on each side (highlighted area at the bottom of Figure 2). This simplification is acceptable in consideration of the one-way action of the slab and allowed for a significant reduction of the computational onus.

The two types of concretes have been modelled with 8 node linear brick elements, while the two reinforcement wires pertinent to the slab strip have been modeled as one-dimensional rod elements embedded in the three-dimensional concrete elements. A mesh seed of 45 mm has been used, which corresponds to 9510 elements. The mesh size has been calibrated by means of a sensitivity study and on the basis of the minimum number of nodes required for a smooth variation of the thermal load.

The mechanical properties of the two concrete aggregates and of the steel wires are reported in Table 1 with respect to the values at 20°C. The degradation of these properties with the temperatures has been considered as specified in the Eurocodes for the steel

(EN 1993-1-2, 2005) and the ordinary concrete (EN 1992-1-2, 2004). With respect to the light concrete, no indication is given in the codes, but a model for the strength degradation can be found in literature (Hertz, 2005). However, the consideration of a refined model for the light concrete strength has been disregarded in this study and the same indications given for the ordinary concrete have been followed. Nevertheless, given the low contribution of the light concrete to the mechanical resistance of the element and the fact that compressive stresses are expected to develop only within the strong concrete, this simplification is not expected to affects the results significantly.

An elastic-plastic bilinear constitutive model has been assumed for the steel, while a damage plasticity model has been adopted for the ordinary and light concrete. The latter requires the definition of compressive hardening and tension-stiffening models. In order to overcome the problem of possible strain localization and mesh-dependent solutions (Bontempi & Malerba, 1997), the material law has been calibrated on the mesh chosen, so that the fracture energy at 20°C has been preserved (Feenstra & De Borst, 1995). It has to be noted that, since the fracture energy varies with the temperature, this calibration is not rigorously valid during fire. Nevertheless, in lack of experimental knowledge on the variation of the tensile fracture energy with temperature (Carstensen, et al., 2013), the temperature dependency of the tensile relation has been modelled by assuming the same stiffness of the compressive branch.

Due to the presence of geometric nonlinearities, the thermal expansion is expected to affect, even if in a limited way, the vertical displacement of the slab. In addition to the degradation of the mechanical properties of the materials, a temperature dependent expansion coefficient has therefore been considered in the structural models for the three materials, according to the Eurocodes specifications.

3.1.2 *Thermal model*

Since the section of the slab is constant and the whole length of the slab is considered to be exposed to the same temperature, the thermal model of the slab could be limited to a two-dimensional model of just one section of the slab strip. Nevertheless, due to the low computational onus of the thermal analysis and the convenience in importing the temperature history of the nodes into the structural model, the same three-dimensional geometry and mesh used for the structural model of the slab strip has been adopted for the thermal model too.

In this model 8-node brick heat-transfer elements have been used for the concretes, while the steel wires have not been represented. The reason is that, due to the small size of the wire and the high steel conductivity, the temperature in the wires can be assumed to be constant and equal to that one at the surface of the surrounding concrete.

In Table 1, the thermal properties assigned to the two concrete types are reported with respect to the values at 20°C. The degradation of the thermal properties of the ordinary concrete has been defined according to what specified in the Eurocodes (EN 1992-1-2, 2004), while for the light aggregate the thermal properties, defined in accordance to what specified in Hertz (2009), have been assumed to stay constant in a first stage of the study. This choice was motivated by past tests presented in literature (Pettersson & Ödeen, 1978), which showed that the conductivity of light aggregate concrete does not vary much with temperature.

However, in absence of a well-established modeling procedure of superlight elements, the presence of uncertainties should be taken in proper consideration. In particular, the uncertainties on the moisture content and on the composition of the light aggregate could influence the diffusivity of the light blocks and consequently the thermal and structural response of the slab under fire exposure. A validation of the steel temperatures against the test results has been therefore performed with the aim of improving the thermal model. In the following, results related to the original (a-priori) and the improved (a-posteriori) thermal model are compared.

3.2 *Boundary conditions and analysis steps*

The slab is considered to be simply supported. This is realized by restraining the displacements of the nodes lying on the horizontal axis of the outmost sections of the slab, in order to minimize the localization of stresses and favour the convergence.

The slab is pre-stressed to the 70% of the maximum wire strength, corresponding to a pre-stressing force of 128.25 kN. The effect of the pre-stressing force is accounted in the model by means of a negative temperature applied on the wires before the application of the distributed vertical load and of the thermal load due to fire. The negative temperature to be applied on the wires in order to simulate the compression of the pre-stress has been calculated as −540°C and applied to the wires in a fist load step. This temperature has been used to scale the degradation of all steel properties, in order to reproduce the correct loss of the pre-stressing effect and strength of the steel during the fire, so that the steel properties at 20°C corresponds to the properties at −540°C in the model. The slab is also considered to carry a distributed load at the time of fire assessed as $p^{fi} = 2.5\ \mathrm{kN/m^2}$, as specified in the previous section. This is accounted in a second load step, by means of a uniformly distributed load applied on the upper surface of the element. The slab is then considered to be exposed to a standard fire for 120 min. Since the thermal and mechanical problems are uncoupled, the thermal load history can be computed by means of a separated analysis on the thermal model of the slab.

In this analysis, the sides and the upper surface of the slab have been considered insulated and modelled as adiabatic surfaces. The bottom surface of the slab has been instead considered to be fire exposed and a standard temperature-time curve has

been applied to the nodes of the bottom surface of the slab model. In the analysis, a heat transfer coefficient $\dot{h} = 25\,\mathrm{W/(m^2K)}$ and a resultant emissivity $\varepsilon_r = 0.7$ (Purkiss, 2007) have been used. The temperature history obtained in each node was then imported in the structural model and applied in a third load step to the correspondent nodes of along all slab length.

Finally, a fourth load step was considered, where the temperature corresponding to 120 min of fire has been maintained constant and the vertical load has been incremented up to the crisis of the slab.

4 RESULTS OF THE INVESTIGATION

4.1 *Thermal analysis*

The results of the thermal analysis related to the original thermal model are reported in Figure 5. The temperature at the bottom surface is in good accordance with the temperature calculated with simplified analytical methods. As an example, a bottom surface temperature of 1033°C is given by the thermal analysis after 120 min, whereas the formulas of Hertz (1981) and Wickström (1986) gives temperatures of 980°C and 1015°C respectively, for the same time of exposure. For a more detailed comparison, reference is made to the M.Sc. project report this paper is based on (Campeanu & Giraudo, 2011)

The results reported in Figure 5 refer to a first thermal model, where the assumptions specified in the previous section have been taken with respect to the uncertainties present in the initial thermal properties of the concretes and in their variation with the temperature.

After the test has been performed, it has been possible to compare the results yielded by the thermal model with the outcomes from the test. The comparison proved the inaccuracy of the thermal model in predicting the temperature after the first 40 min of fire. In particular, the temperatures of the steel wires registered during the test were significantly lower than the ones predicted by the model, as shown in Figure 6.

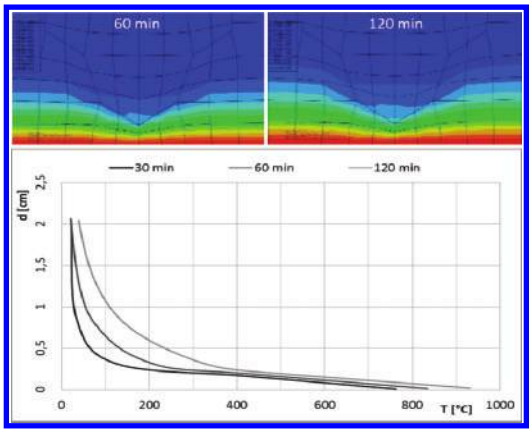

Figure 5. Thermal map (top) and temperature profile along the section central vertical axis at given times (bottom).

The thermal model has been therefore modified and calibrated in a way to better fit the results of the test. In particular, it has been seen that a very good fitting of the steel temperatures is yielded by accounting for the degradation of the conductivity of the light concrete and by assuming for the ordinary concrete the lowest conductivity curve indicated in the Eurocodes (corresponding to a value at 20°C of $\lambda_c = 1.36\,\mathrm{W/(m{\cdot}K)}$ and of the value $\lambda_c = 1.95\,\mathrm{W/(m{\cdot}K)}$ initially assumed).

4.2 *Structural analysis*

The results of the structural analyses performed with the temperatures obtained from the a-priori and a-posteriori thermal models are presented in the following. In Figure 7 the vertical displacements of the mid-span during fire is reported in both cases and compared with the data from the test.

It can be seen that the displacements related to the two thermal models are very similar in the first phase of the fire. However, after ca. 40 min of fire the displacement calculated with the a-priori model continues to increase almost linearly with the temperature, while the displacement-temperature curve obtained from the a-posteriori model assumes a convex form. This corresponds well to the test, where the increment of the vertical displacement was constant for the first 40 min of fire and then slowed down and stopped after ca. 90 min at the value of 2.5 cm, displacement that was kept constant until 120 min.

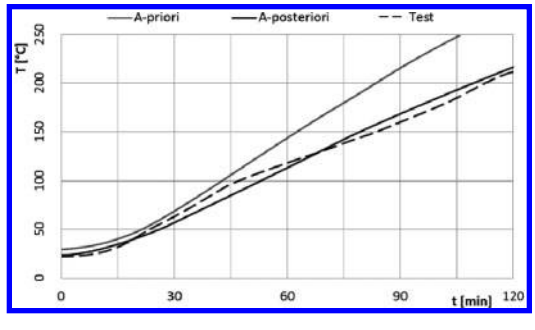

Figure 6. Temperature of the wire in the test and comparison with the a-priori and a-posteriori thermal model.

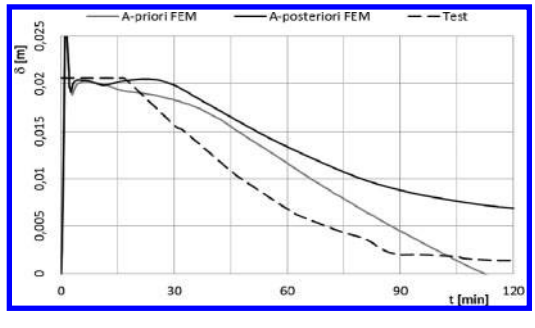

Figure 7. Mid-span displacement registered during the test and predicted by the a-priori and a-posteriori FEMs.

Even if there is a discrepancy between the displacement at 120 min registered in the test and the one of 1.3 cm predicted by the a-posteriori model, the difference between the two displacements stays almost constant between 40 and 120 min of fire. Therefore, the global behaviour of the slab can be said to be correctly predicted.

This is not the case for the a-priori model that predicts a final displacement of 2.7 cm (value, which is closer to the test than what predicted by the a-posteriori model), but doesn't catch the global trend of the displacement, which is underestimated up to 105 min of fire and overestimated afterwards.

5 CONCLUSIONS

In this paper, the behaviour under fire of a superlight floor slab element (SL-deck) has been described with respect to the results of a fire test performed on a prototype and the outcomes of numerical investigations performed on a three-dimensional thermal and structural FEM of the slab.

The implementation of the FEM is described and modelling aspects such as the sensitivity of the results to the thermal properties of the concrete are discussed. In particular, the validation of the model against test data showed a high sensitivity of the results to the conductivity of the concrete, which affects the accuracy of the temperature profile of the slab at a given temperature and also strongly influences the structural response. While very little information are given in the codes on the conductivity of the different type of concretes, the evaluation of this property and an accurate assessment of its variation with temperatures seem essential factors for a reliable structural fire design.

In particular, the methodology highlighted in this study for the implementation of a FEM of complex concrete elements such as the SL-deck seems relevant in the framework of a sustainable design of buildings, where the use of new technologies is envisaged in order to improve the fire response of structures and mitigate the consequences of accidental events.

Composite floors with steel fibre reinforced concrete slabs exposed to fire

J. Bednář & F. Wald
Department of Steel and Timber Structures, Czech Technical University in Prague, Czech Republic

J. Vodička & A. Kohoutková
Department of Concrete and Masonry Structures, Czech Technical University in Prague, Czech Republic

ABSTRACT: The composite steel and concrete floor slabs reinforced with steel fibres were tested at ambient and at elevated temperature at Czech Technical University in Prague. During the tests at elevated temperatures the slabs and secondary beams were fire unprotected. The edge beams were protected only. The concrete slabs were reinforced by steel fibres only without added steel bars. The tests demonstrated the suitable properties of the steel fibre reinforced concrete in fire, which enable creating the membrane action. The material properties of the fibre-concrete allowed forming a beam, the plate and tensile membrane mechanisms, which increase the fire resistance of the floor slabs. For the fire resistance of the floor slabs was utilised the tensile strength and ductility of the steel fibre reinforced concrete. The material properties tests at ambient and at elevated temperature, summarised in this contribution, approved the required ductility and tensile strength of the steel fibre concrete reinforced by 70 kg per cubic meter.

1 INTRODUCTION

The design of concrete, composite steel and concrete and composite timber and concrete slabs for fire resistance is usually based on prescriptive ratings that specify the minimum slab thicknesses and the required concrete cover of the reinforcement. These ratings are generally based on standard fire resistance tests of particular elements using furnaces or simple design models of behaviour of slab as separated element. However, such approach does not represent a real structure as a whole as it does not account for overall floor behaviour, see (Bailey & Moore, 2000). Fire resistance ratings of properly designed full floor systems is higher than those of single elements because the compressive restraint in the edging of the slab allows in the central part of the slab for membrane action to develop increasing the time to failure of the elements compared to the standard tests. For design of floor slabs et elevated temperature based Eurocode rules, see (EN1994-1-4, 2005), may be applied advanced procedures by FEM analyses and simple procedures, see (Vassart & Zhao, 2011). The ductility of steel fibre reinforced concrete (SFRC) broadens the range of application of the reinforced concrete and composite steel-concrete structures. These materials are characterized by high resistance to cracking, corrosion, abrasion, impacts, fatigue and good resistance in exposition to the high temperatures, see (Lie & Kodur, 1996). Steel fibre reinforcement helps to maintain the strength, residual strength, ductility and fracture toughness after being heated, see (Rustin & Kodur, 2011).

In the last years, composite SFRC floor slabs at ambient and at elevated temperature have been tested at the Czech Technical University in Prague. Concrete slabs were reinforced by steel fibres only without added steel bars. The main aim of the tests was to demonstrate the sufficient properties of the SFRC slab in fire, the ductility and adequate tensile and shear strength to assure the fire resistance of the floor slab. These material properties of the SFRC should allow for the slab to create a appropriate load bearing mechanism, which increases its fire resistance.

2 FURNCE TESTS

Six slabs were tested with sizes of 4.5×3.0 m. The slabs of the thickness 40 mm were concrete to trapezoidal sheets TR40/160/0.75. The concrete was reinforced by 70 kg per cubic meter. Added steel fibres had the sizes of 0.75×50 mm and its strength was 1100 N/mm^2. Four slabs were tested at the ambient temperature and two at elevated temperature. The tests at ambient temperature were performed in Prague in UTAM and the tests at the elevated temperature in Veselí nad Lužnicí in PAVUS, see Figures 1 and 2. The first floor slab tested at elevated temperature reached the collapse in 195 min of the test. Integrity of the slab was maintained during 75 min and criterion of isolation was transgressed after 65 min. The second floor slab tested

at elevated temperature approved the resistance of R120.

3 MATERIAL TESTS

3.1 *Material properties at ambient temperature*

For the prediction model developed under the project were created tests of the materials properties. Concrete mixtures were two. In concreting plants, for each mixture there was made 9 cubes and 9 scantlings. Concreting plants were in the towns Jindřichův Hradec and Písnice. Sizes of the cubes were 150 × 150 × 150 mm and scantlings 150 × 150 × 700 mm. The cubes were tested in simple compression and scantlings by for point bending test to describe the tensile properties of concrete according (EN12390-5. 2009), see Figure 3. The scantlings were tested at 20°C, at 500°C and 600°C

The six cubes from concreting plant Písnice reached an average compression strength of 80.9 N/mm^2 and three cubes in lateral tension showed by the tests an average tensile strength of 7.4 N/mm^2. This concrete was used on the tests of the slabs at ambient temperature. The six cubes from concreting plant Jindřichův Hradec reached the average compression strength 68.3 N/mm^2 and three cubes in lateral tension showed by the tests an average tensile strength 7.1 N/mm^2. This concrete was used on the test of the slab at elevated temperature.

There were tested 2 × 3 scantlings at 21°C. The scantlings were tested by four-point bend, see Figure 3. There is shown a specimen after creation of the macro-crack. The fibre concrete achieved average tensile strength of 6.42 N/mm^2 and its average ductility was 1.1‰ (concrete plant Jindřichův Hradec). Second concrete mixture achieved average tensile strength of 7.22 N/mm^2 and average ductility was 0.92‰. This ductility was measured at the initiation macro-cracks. After creating the macro-cracks, stretch was increasing and load bearing capacity was decreasing.

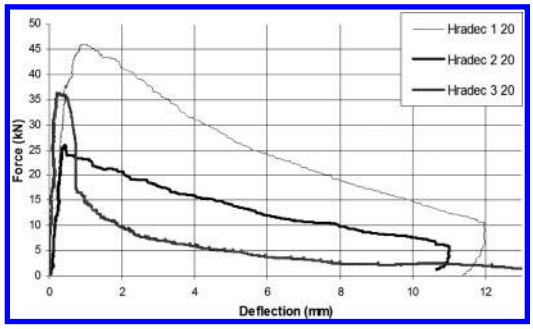

Figure 4. Force–deflection relation from four point bending test at 20°C.

Figure 5. The specimen during heating.

The force–deflection relation from four point bending test at 20°C is shown in Figure 4.

3.2 *Material properties at elevated temperature*

Materials property tests were performed on the specimens, which were heated up by five electrical heaters to the temperatures of 500°C and 600°C. The specimens were thermally protected and were heated up four hours so that the temperature in the scantling is uniformly distributed. The temperature was control by four thermocouples. The deflections were measured by two mechanical deflectometers, which were due to the temperature installed a before the loading of a specimen. The loading scheme was the same as by the test at ambient temperature. The heating was performed directly in the press, see Figure 4. Figure 5 shows the specimen during the heating and loading. Table 1 summarizes the measured values of tensile strengths at ambient and elevated temperature, Table 2 average values of tensile strengths at ambient and elevated temperature, and Table 3 related reduction coefficients calculated for selected relative deformations.

There were tested 2×3 scantlings at 500°C and 600°C by four-point bending. The ductility was calculated at the initiation macro-cracks. The fibre

was 6.99‰. Figures 7 and 8 show force – deflection relation at four point bending tests.

4 CONCLUSIONS

Homogeneity of the results of material tests of fibre concrete was good. The steel fibre reinforced concrete demonstrated appropriate ductile behaviour. Based on experiments the reduction coefficient of decrease strength of SFRC was prepared, see (Bednář et al, 2011 and 2012). The ductility of SFRC by 500°C was higher than by 20°C but also than by 600°C.

The evaluation of the material properties of SFRC and the tests with floor slabs allows the preparation of FEM model and analytical prediction model. The models are taking into account the contribution to the behaviour of the steel beam and SFRC slab in bending and the development of membrane behaviour at large deformation at elevated temperature.

Engineering solutions for structures in fire: Should concrete care?

L.A. Bisby
Arup Professor of Fire and Structures, School of Engineering, University of Edinburgh, UK

ABSTRACT: So-called 'fire engineered solutions' for designing and assessing the performance of structures in fire have advanced a great deal in recent decades. This been enabled by the emergence of performance based design codes in Europe and elsewhere, which rather than prescribing the specific means by which fire resistance is achieved, allow designers to take any approach provided that it can be *shown* that the solution will meet *acceptable*, *quantifiable* performance objectives. In structural fire engineering, this typically refers to collapse prevention during fire. Whilst the benefits of performance-based structural fire engineering design are available to all sectors of the construction industry, only the steel-framed building construction sector has truly embraced these approaches. The steel industry continues to promote performance based design for fire largely because this can justify removal of passive fire protection from large portions of steel structures, where it would otherwise be required by prescriptive guidance. This makes steel framed structures more economical, most notably in competition with concrete buildings. In the face of these advances the concrete industry has expressed concern about the evolution of Fire Safety Engineering methods, the shortcomings that might be observed, and the potential level of risk they could create. In general the concrete industry appears to be opposed to further regulatory advances. Whilst concrete structures generally perform well during fire, this paper discusses current opportunities and challenges resulting from performance based structural fire design of modern structures. An attempt is made to address the issue of how advanced, performance based structural fire engineering can positively influence the optimized design and construction of concrete buildings, particularly as compared with steel-framed buildings. The overarching objectives are: to provide a balanced and rational assessment of the challenges and opportunities for design and construction of concrete buildings with inherent structural fire safety; and to demonstrate that rather than being a threat to the concrete construction industry, performance based structural fire engineering may represent a considerable opportunity.

1 INTRODUCTION

Structural design for fire is concerned primarily with the provision of 'fire resistance' to protect against loss of life and spread of fire to adjacent buildings. Fire resistance has historically been defined as the time of exposure to the standard fire (ASTM 2012, ISO 1999) during which an isolated structural element (beam, column, slab, etc), typically tested in a standard fire testing furnace, can resist failure due to one of: (1) loss of load bearing capacity under service loads; (2) unacceptable temperature rise at the unexposed face; and (3) passage of flames or hot gas through the element.

The historical approach to fire resistance design based on furnace testing is unrealistic and irrational for reasons too numerous to discuss here (Bisby et al. 2013). During the 1990s, the emergence of performance-based fire codes (e.g. CEN 2004, 2005) enabled the use of more rational approaches to fire resistant design. With regard to structural fire resistance, the fire and the structural response can be rationally assessed and the performance of the structures quantified and compared against fundamental performance objectives. Designers can take any approach they choose to meet these performance objectives for the structure. In practice, in the absence of more rational and quantifiable performance objectives, this typically means that structures are engineered to perform 'at least as good' as structures which meet the available prescriptive guidance.

Beginning in the early 1990s, the steel industry has devoted considerable funding and effort to understanding the true response of steel structures in fire in an effort to be able to demonstrate (primarily through the development of validated computational modeling tools) the ability to performance engineer steel structures in fire. A range of large scale non standard fire tests of steel structures have are discussed by Bisby et al. (2013); these have led to the development of several bespoke structural fire design software (e.g. www.vulcan-solutions.com).

The most significant result of this dedicated research effort has been an ability to justify removal of large amounts of passive fire protection from steel structures, leading to market advantage in the building construction. The concrete industry appears to have made little effort to capitalize on performance based structural fire engineering, and has devoted comparatively little resource to research in this area. On the contrary the concrete industry has expressed

concern about the emergence of performance based codes, the shortcomings that might be observed, and the perceived risks they might create.

This paper attempts to provide an assessment of the challenges and opportunities for design and construction of concrete buildings with inherent structural fire safety, and to demonstrate that rather than being a threat to the concrete construction industry performance based structural fire engineering may represent an opportunity on various levels.

2 STATE-OF-THE-ART

The current state-of-the-art in performance based structural fire engineering, from a practical and regulatory perspective, is best represented by the Structural Eurocodes for fire design of concrete (CEN 2004) and steel (CEN 2005) structures. These codes provide simplified means by which engineers can approximate natural or 'parametric' design fires based on a compartment's geometry and lining materials, its fuel load, and its ventilation during fire. It is noteworthy that the parametric fires include a cooling phase; this is far more realistic than the perpetual heating of a standard fire. The Eurocodes also allow designers to take various approaches, of increasing complexity, to assess a structure's performance during exposure to a parametric fire. These range from adhering to simple tabulated requirements (e.g. limiting temperatures of steel or minimum concrete cover to internal reinforcement), through simplified analytical techniques, to advanced thermal-structural finite element models which rely on a detailed understanding of material and structural response to heating.

Details of all of the above approaches are not included here. Instead, this paper touches on various relevant issues in an attempt to present possible opportunities for concrete structures in a performance based structural design for fire environment.

3 OPPORTUNITIES

3.1 *More realistic fire exposures*

The most obvious benefit to concrete structures in a performance based design for fire environment is that, provided engineers rationally account for the challenges discussed in Section 4, concrete structures are likely to perform much better under realistic fire scenarios compared to standard fires. All that this requires is a regulatory recognition that real fires have a cooling phase as in the Eurocode parametric fires (e.g. ISO 1999, ASTM 2012).

This benefit can be demonstrated simply by considering the thermal criteria which are widely applied to steel and concrete structures in North America to define the fire resistance. For reinforced concrete flexural elements this means exceeding a steel reinforcement temperature of 593°C.

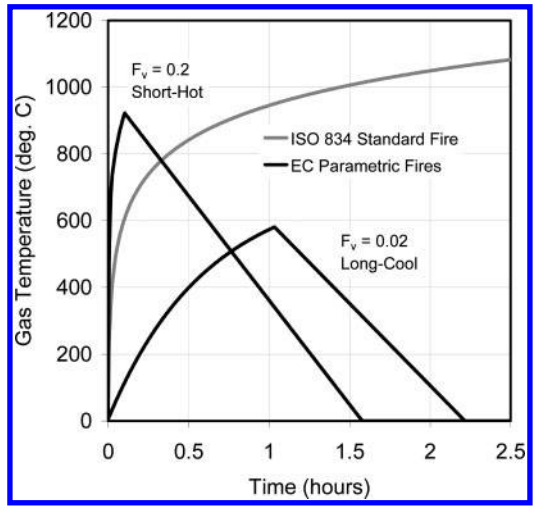

Figure 1. ISO 834 (ISO 1999) standard fire and Eurocode (CEN 2002) parametric fires similar to those applied by Lamont et al. (2004).

Figure 1 shows temperature versus time profiles for the standard (ISO 834) fire along with two possible Eurocode parametric fires. The details of the derivation of the parametric fires is not important to the current discussion; suffice it to say that these two curves are assumed to represent the possible extremes of permissible fire behaviour for a compartment within a reinforced concrete structure with a fuel load representing the 80th percentile value for an office occupancy in Europe (CEN 2002).

For illustrative purposes Figure 2(a) shows the predicted temperatures of steel reinforcement within a 150 mm thick carbonate aggregate concrete slab, with a moisture content of 5% by mass and 25 mm axis distance to the bottom steel; assuming fire from below. The predictions were made using a 1-dimensional finite difference heat transfer code written and validated by Bisby and Kodur (2005).

Figure 2(a) shows that with 25 mm of concrete cover the fire resistance of the concrete slab would be reached after about two hours of standard fire exposure, whereas it would 'never' be reached for either of the parametric fires (the fires would burn out due to full consumption of the available fuel).

By contrast, and again simply for the purposes of illustration, for a steel-framed building with unprotected secondary beams all three fires would result in secondary beam temperatures close to or exceeding 550°C in less than two hours. Whilst this may not correspond to structural failure, it would likely result in considerable permanent damage to the structure (and very large deflections, as shown in the following section).

It seems reasonably assured, however as yet unproven, that the concrete structure would perform better under a parametric fire provided that spalling an unexpected failure modes can be avoided.

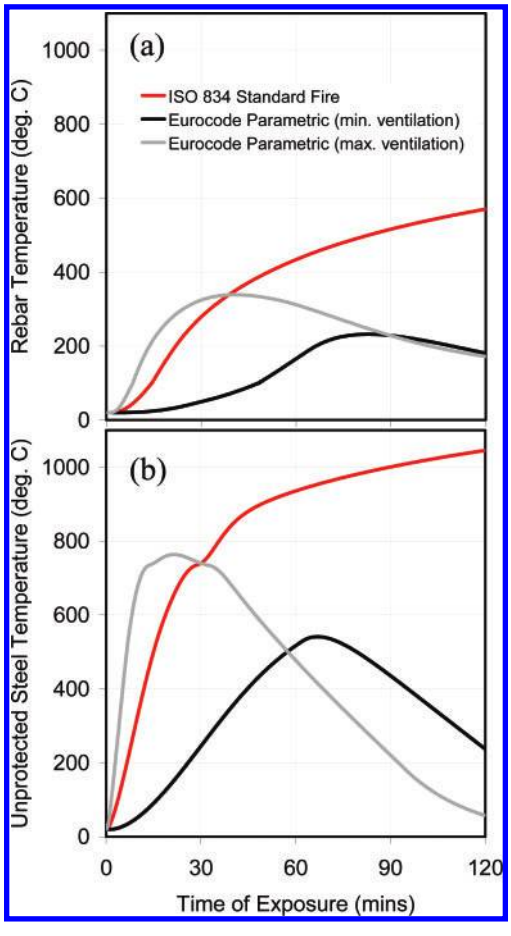

Figure 2. Predicted temperatures in (a) internal steel reinforcement in a concrete slab with 25 mm cover and (b) unprotected secondary steel beams in a steel frame with a steel-concrete composite deck slab, in both cases subjected to the three temperature versus time curves given in Figure 1.

3.2 *Shifting the design goal posts*

At present, the fundamental functional objectives which are used in performance based structural fire engineering design in most jurisdictions are firmly rooted in the available prescriptive guidance and are, in general, relatively poorly quantified. Structural fire designers are required to demonstrate protection of human life and adjacent properties by comparison with prescriptive 'deemed to satisfy' requirements.

There is currently little (if any) regulatory requirement to protect buildings themselves against fire. Thus, structural fire engineers operating in a performance based environment are typically required only to demonstrate that a building can resist collapse and prevent spread of fire from the compartment of origin for the required period; or for the full duration of a parametric fire (i.e. 'burnout'). Little consideration is given to the degree of damage that the building might suffer, to whether it is likely to be re-occupied, or to other considerations such as business continuity, economic loss, or sustainability.

For structural fire design and assessment of steel structures the use of advanced finite element software is now commonplace (e.g. Flint et al. 2013). This has become possible in large part to the seminal tests performed on a steel framed building at Cardington (Bailey et al. 1999), which allowed computational models for steel structures in fire to be extensively validated. A similar testing program has not yet been performed for concrete structures (notwithstanding the single concrete building test performed at Cardington by Bailey (2002).

For steel structures, detailed computational models are created and exposed to a number of credible design fire scenarios (most often defined using the Eurocode parametric fires for a range of possible ventilation conditions). The response of the structure is tracked to watch for 'problematic' behavior. Structural fire engineers use these models to evaluate trends in structural response including runaway deflections, large (plastic) strains in structural steelwork and in steel reinforcement of concrete, large tensile strains in concrete (with concrete cracking almost universally modeled using a 'smeared cracking' approach), connection forces (during heating *and* cooling) and lateral deflections and the resulting secondary moments in columns. This allows a relatively confident assessment of structural response during fire. Using this approach structural fire engineers can demonstrate in many cases that steel-framed structures with unprotected slabs and secondary beams will perform satisfactorily (i.e. will not collapse) under exposure to fire, however at comparatively large deflections, through tensile membrane action (see Bailey et al. (1999) and below).

It is noteworthy that the available models do not deal well with singularities arising from failure localization, discrete cracking, tensile rupture, shear failures, reinforcement anchorage, etc. Indeed, many of these are not explicitly modeled in most cases. For concrete structures use of such advanced techniques is currently limited, both because test data do not exist for credible model validation and, more importantly, because the practical benefits of the additional analysis effort are marginal within the context of current regulatory drivers.

In a life-safety only design environment, advanced structural fire analysis is unlikely to provide a competitive advantage for concrete. If the goal posts for design were to move, however, such that avoiding a given level of structural damage was the functional requirement, it is possible that conventional concrete structures might drastically outperform conventional steel framed structures.

To interrogate this issue one could perform structural fire analyses of comparable cast in place concrete and steel framed concrete composite deck structures under the same design fire. No such comparative analyses are available in the literature, although a number of relevant studies are available which do provide a useful initial comparison.

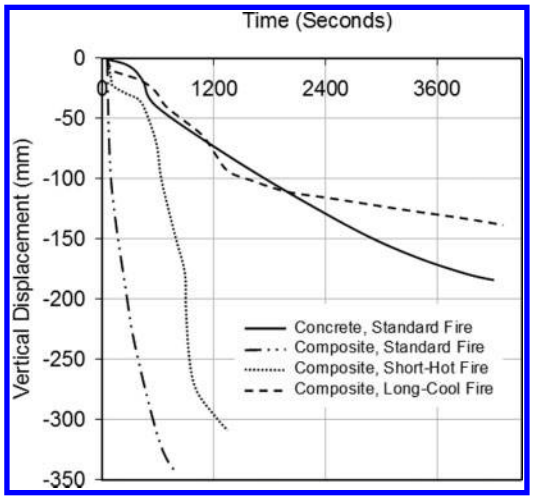

Figure 3. Approximate deflection versus time for typical cast in place concrete frame (Huang et al. 2006) or steel frame with steel-concrete composite concrete deck and unprotected secondary beams (Huang et al. 2004, Lamont et al. 2004).

As far as computational studies of steel structures in fire are concerned, Huang et al. (2004) present a detailed finite element study on a steel framed building with a steel-concrete composite slab on steel beams. Full details of the structure are not presented here; the overall bay size is 9 m × 9 m in plan, with two unprotected secondary beams in each bay. Data are presented on the vertical deflection of an interior bay with the temperature of the unprotected secondary beams, using temperature histories measured during the Cardington tests (Bailey et al. 1999). The deflection data can be approximately transposed into deflection versus time of standard fire exposure using the Eurocode 3 (2005) method for determining the temperature of unprotected steelwork in fire. This has been done and the resulting approximate mid-bay vertical displacement for this structure is shown versus time of exposure to the standard fire in Figure 3. Lamont et al. (2004) have also presented deflection versus time predictions for a steel framed composite deck structure with bays 6 m × 6 m in plan including a single unprotected secondary beam. In this case the structure was subjected to non-standard fires; a short-hot fire and a long-cool fire, both with cooling phases (similar to the two Eurocode parametric fires shown in Figure 1). The predicted mid-bay deflections are also given in Figure 3.

As far as computational studies of concrete structures are concerned, Huang et al. (2006) have presented an analysis of a typical cast in place reinforced concrete frame structure. In this case the structural bays were 7.5 m × 7.5 m in plan. The predicted mid-bay vertical deflection in this concrete structure (albeit with slightly smaller spans) is also shown in Figure 3.

Even accounting for the subtle but potentially important differences between the structures compared in Figure 3, it seems clear a steel framed composite slab structure with unprotected secondary beams is likely to deflect considerably more rapidly during fire than a comparable concrete frame structure with a cast in place concrete slab. While clearly not an exhaustive comparison, Figure 3 hints that concrete frame structures may perform 'better' during fire than steel frame structures with unprotected secondary beams. Of course, this assumes that total vertical deflection during fire is a useful damage index for these types of structures, and as already noted research is needed to determine whether this is the case. This also assumes that the challenges for concrete structures in fire, discussed in Section 4, are rationally addressed.

The potentially superior resistance to fire damage of concrete structures described above requires a change in the performance drivers for buildings in fire, with life-safety and protection of adjacent buildings no longer being the only goals, as well as a shift towards performance based design for fire.

3.3 *More realistic structural response assessment*

Another group of potential advantages for reinforced concrete structures in fire from performance based approaches might arise from moving away from the prescriptive approach of defining fire resistance on the basis of isolated structural elements tested in furnaces subjected to the standard fire. Standard fire testing is widely acknowledged as unrealistic on various thermal and physical bases (Bisby et al. 2013). Most notably the thermal and structural boundary conditions (e.g. restraint, redistribution, continuity) are not well accounted for in such tests.

The steel industry has openly acknowledged the shortcomings of standard furnace testing and this, combined with extensive research and computational modeling studies, has allowed the structural fire design community to develop fire resistance design procedures for steel-framed composite slab structures which explicitly rely on *tensile membrane action* to prevent collapse during fire. This is a drastic departure from the traditional approach to fire resistant structural design based on fire resistance testing; it explicitly uses structural actions which would never be observed during a standard furnace test.

With sufficient research, the concrete industry may be able to take similar advantage of structural actions which arise in real buildings but which are not observed during standard furnace tests. There are two main structural actions which may be beneficial and which are relevant to this discussion: continuity and membrane actions.

Continuous beams are statically indeterminate and continuous over multiple supports. Unlike simply-supported beams, which require only a single location of flexural failure for collapse to occur, continuous beams require multiple failure locations before a failure mechanism can form. Continuous beams are therefore redundant structures, and they can benefit from moment redistribution, both at ambient temperature

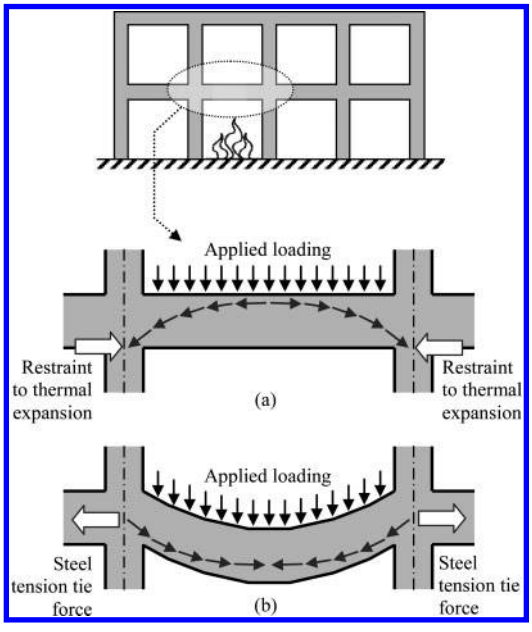

Figure 4. Schematic two-dimensional representations of (a) compressive membrane and (b) tensile membrane actions in concrete slabs in fire.

and during fire. Techniques to account for moment redistribution during fire are described in detail elsewhere (e.g. Buchanan 2001). This is a potential serious advantage for concrete structures in fire which is rarely considered, providing that structural damage during fire is acceptable.

An additional structural action which often plays an important role in the response of real structures during fire is membrane action. Membrane action, which can be either compressive or tensile, manifests itself in planar structures such as steel-concrete composite and reinforced concrete slabs. Figure 4 shows two-dimensional idealizations of both tensile and compressive membrane actions.

Compressive membrane action is particularly important in continuous reinforced concrete structures during fire, where restrained thermal expansion can lead to the development significant lateral restraint forces resulting in arching action during fire (provided of course that the thrust forces have a line of action below the neutral axis of bending of the slabs). This type of behaviour has been observed in large scale fire tests of real concrete structures (Bailey 2002).

Tensile membrane action is particularly important during the late stages of fires for structures with relatively thin concrete or steel-concrete composite slabs. In these cases tensile membrane action can prevent structural collapse (however under very large vertical deflections as already noted) for durations of fire exposure much greater than would be expected on the basis of a single element analysis. This may present advantages for highly optimized concrete structures with thin floorplates over large spans, for instance post tensioned concrete slabs (provided of course that sufficient bonded reinforcement is provided such that tensile membrane actions can be accommodated and anchored).

Membrane actions are discussed in detail in specialized references (e.g. Buchanan 2001, Wang et al. 2012), however typically with reference to steel-concrete composite slabs rather than cast in place reinforced or prestressed concrete slabs.

4 CHALLENGES

It is crucial to recognize that there are a number of potential challenges for modern concrete structures in fire; these have yet to be properly addressed through research but must be accounted for in order for the potential advantages for concrete structures noted above to be fully realized in practice. The most important of these are: concrete cover spalling and unexpected or unaccounted for failure modes.

4.1 *Explosive concrete cover spalling*

The majority of the potential advantages for concrete in fire noted previously can only be realized if the concrete cover to the reinforcement remains in place. Spalling refers to the sudden and explosive deterioration of the surface of a concrete element during heating, resulting in loss of concrete cover and thermal exposure of the internal steel reinforcement; thus decreasing the element's load carrying capacity and risking structural collapse. Propensity for spalling is exacerbated by many factors, including concrete age, strength, mix design, compressive stress, moisture content, aggregate type, and restraint to thermal expansion, as well as the specific fire exposure and resulting thermal gradients and restraint. A large body of research (e.g. Koenders and Dehn 2011) has shown that inclusion of polypropylene microfibers within the concrete mix can reduce spalling, but little is known regarding the mechanisms causing this and there is no ability to model the beneficial effects of the fibres nor to optimize concrete mixes and fibres to prevent spalling.

Furnace testing of large scale concrete elements for spalling is required in most real project applications when spalling represents a serious concern (e.g. in tunneling projects), and this is expensive and time consuming. Considerable additional research is needed before the concrete community can defensibly assume that spalling is guaranteed not to occur for a given concrete in a given structural application.

4.2 *Unexpected failure modes*

Over the years a number of problematic failure modes, which are generally not accounted for in structural fire design of concrete structures and which could, by definition, not be observed during standard furnace testing, have been observed in real concrete structures

during real fires. The factors leading to these failure modes need to be understood in order for rational performance based structural fire design of reinforced concrete structures to be performed with confidence. The most notable of these, which should be studied in more detail, are:

- explosive spalling of the concrete cover as discussed in the previous section;
- shear failure of perimeter columns (and generation of secondary column moments) due to lateral thermal expansion of the floorplate which is not considered during design;
- punching shear failure of concrete slabs (particularly in the cooling phase) (Bamonte et al. 2012);
- anchorage and shear failure of prestressed precast concrete elements (notably hollowcore slabs) (Fellinger et al. 2005); and
- tendon rupture in locally heated unbonded post-tensioned concrete slabs (Gales et al. 2011).

5 CONCLUSIONS

This paper has suggested that, rather than being a threat to the reinforced concrete construction community, performance based structural fire design of concrete buildings provides numerous possible advantages for the concrete industry. However, these advantages will only be achieved if:

- the concrete industry takes a positive approach to performance based design for fire; supporting research directed at addressing the challenges noted in the current paper and promoting, rather than opposing, regulatory advances in this area;
- the regulatory approach to provision of fire safety in buildings moves away from a 'life safety only' approach to one which also considers property protection, business continuity, sustainability, etc (i.e. the 'goal posts' are shifted);
- explosive concrete spalling is prevented with a high level of confidence; and
- all possible failure modes are understood and rationally accounted for during the design process.

ACKNOWLEDGEMENTS

I am grateful to Prof JL Torero and Dr TJ Stratford for useful discussion on the ideas presented. I would also like to thank my team of stellar PhD students (notably C Maluk and JA Gales) for digging up numerous references and ideas relevant to the paper.

The application of fire engineering methods for the design of open steel car parks

G. Woźniak
Building Research Institute, Warsaw, Poland

R. Obiała
Arcelor Mittal, Long Products R& D, Esch-sur-Alzette, Luxembourg

ABSTRACT: The paper aims to present a new method of the fire design of open steel car parks based on fire safety engineering approach (FSE). According to the fire safety regulations in many European countries, steel buildings have to be fire protected, sometimes without sufficient technical grounds. For economic reasons certain types of buildings, like multi-storey open car parks, practically can be built only as concrete structures. However, when applying performance based concept of fire safety, steel or composite structures turn out to be equally effective in meeting fire resistance requirements.

The paper presents theoretical background and experimental evidence supporting this attitude. The concept of natural fire in car parks is accompanied by the discussion of possible fire scenarios. The background engineering knowledge concerning thermo–mechanical behaviour of composite floors, as well as methodology of the fire design of car park structures is presented.

1 INTRODUCTION

This paper summarizes the development of the project "Open Steel Car Park Design for the Polish Market" (Project CAPP 2011). The project was completed in the years 2009–2011 as a result of co-operation between the following companies: ArcelorMittal R&D Esch, ArcelorMittal Construction Poland, Building Research Institute ITB, Warsaw and Poznan University of Technology.

The main aim of the project was to propose fire engineering approach to the open steel car park design. Based on the experimental results the appropriate fire scenarios were proposed and applied to car park structures. Fire actions were determined and the behaviour of structural elements in fire conditions was evaluated by numerical methods. As the result of the project conclusions were formulated and practical design methods were developed in relation to open steel car parks structures in Poland.

2 OPEN CAR PARKS CHARACTERISTICS

2.1 *Technical description*

According to Polish Building Regulations a car park is considered open if the total area of openings (at each level) is greater than 35% of overall wall area and the distance between walls with openings is less than 100 m.

These conditions ensure the natural ventilation which helps to avoid accumulation of smoke and additional increase of temperature in case of fire (see Figure 1).

Open car parks are typically multi-storey buildings. In Poland they are almost always erected as concrete structures. The basic technical problem which was dealt with during CAPP project, was whether it is possible to adhere to Building Regulation principles when constructing car parks with composite slabs and steel hot rolled beams.

According to Polish Regulations the following minimum dimensions have to be ensured for open car parks:

- Single parking space: 2.3 m × 5 m
- Height (between floor and ceiling): 2.2 m
- Height (between floor and installations under ceiling): 2.0 m
- Width of access road: 5.7 m.

All research and analyses were performed for structures with composite slab system (profiled steel decking with casted "in situ" concrete slab), steel hot rolled I beams, acting compositely with slabs, and steel columns.

The aim of the research was to investigate fire resistance of structural elements, assuming no fire protection of slabs and beams. Steel columns were assumed to be fire protected by traditional means (intumescent coatings, sprayed mortars or insulating boards) and were not the object of investigation.

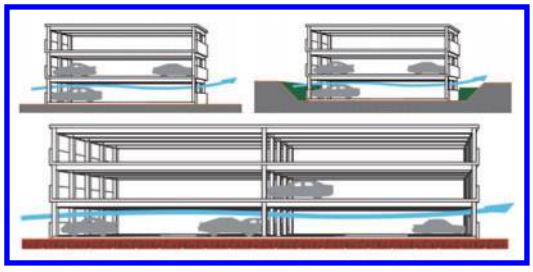

Figure 1. Natural ventilation in open car parks.

2.2 *National building regulations and current fire safety approach in Poland*

According to Polish Building Regulations, open car parks not higher than 25 m have to satisfy requirement of 30 minutes of fire resistance (R 30 class for beams and columns and REI 30 class for slabs). Technical bases are given in European classification standard (EN 13501-2 2007) and are associated with fire resistance of single elements under standard fire conditions. Current regulations do not allow for alternative approach based on fire safety engineering and analysis of fire performance of the whole structures and natural fire concept.

The performance based approach has been adopted for the design of car parks in many European countries e.g. France, Germany and United Kingdom. Fire safety engineering methods, when compared with traditional, prescriptive approach allow for different view of fire performance of building elements and especially of whole structural system. Individual fire scenarios (natural, parametric or localized fires) and realistic assessment of fire actions together with ventilation conditions can be applied. Furthermore, these methods allow to analyse interactions in structural system, redistribution of inner forces and additional effects which may appear in fire conditions.

Traditional fire safety concept may lead to unrealistic, conservative solutions. Open steel car parks, commonly used in many countries, as probably the best choice, cannot be constructed in other countries (e.g. Poland) because single steel elements, without additional fire protection, cannot meet requirement of 30 minutes standard fire resistance.

3 FIRE TESTS

In the fire engineering approach with application of the natural fire concept it is important to establish location of the fire and its power represented by rate of heat release (RHR). It is essential that fire scenario which is most critical for the structure is selected for the design. It should be most realistic, based on tests, research and numerical analysis.

In Table 1, results from fire tests in open car parks recorded in the last decades are given.

The results of fire tests, especially well documented tests from Vernon, 2002, were analysed by

Table 1. Results of fire tests in open car parks.

Test	Fire spread among cars	Temperature [°C]	
		Beam	Column
England 1968	No	275	360
Japan 1970	No	245	242
USA 1973	No	226	
Australia 1985	Yes	340	320
France 2002	Yes	700	640

Figure 2. The fire test of car park, France, 2002.

means of calculation methods and served as the basis for the development of advanced calculation models, including actions, fire scenarios and models of thermo-mechanical response of structures.

The simulations for real steel car parks, the development of which dates back to years 2001–2004, included the most dangerous, and yet realistic, fire scenarios. Those simulations were applied on the stage of designing open car parks with steel and composite structure, allowing for the conclusions to be drawn and assessments to be made regarding fire resistance of elements and stability of the entire structure in fire conditions.

4 FIRE SCENARIOS AND ACTIONS

The assessment of actions in fires in open car parks is based on the following factors:

a) Rate of heat release in a single car fire
b) Data related to spread of fire among cars
c) Fire statistics (the number of cars exposed to fire, their class)

In a fire scenario analysis usually 3rd class cars are used (i.e. Passat, Laguna, Mondeo). RHR curve for a single 3rd class car is shown in Figure 3. The highest RHR value recorded after 25 minutes of burning is 8.3 MW.

Figure 4 shows a RHR curve for three burning, neighbouring cars (curves are shown separately for each car). The ignition of the 2nd and 3rd cars occurs after 12 minutes of the first car being on fire.

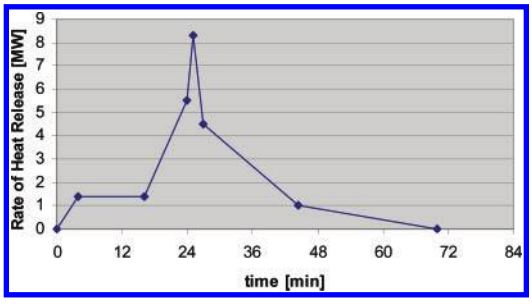

Figure 3. RHR curve for a single burning car.

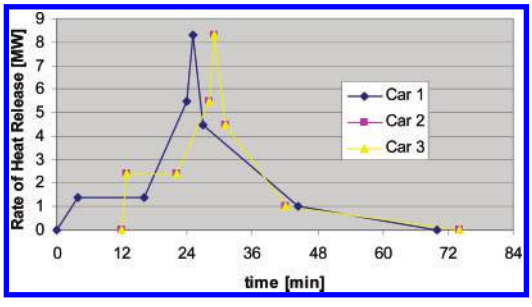

Figure 4. RHR curve for the fire of 3 cars (seperate curves for individual cars).

Based on the above characteristics of cars burning, it is possible to determine thermal actions on structural elements in open car parks exposed to fire.

Real fires statistics in open car parks indicate that the number of cars in fire practically never exceeds 3 vehicles and in 80% fire cases only one car gets burned.

5 STRUCTURAL PERFORMANCE OF CAR PARK STRUCTURE IN FIRE

5.1 *Design scenarios*

The car parks structural behaviour analysis was carried out by means of two basic fire scenarios:

- the fire involving 4 cars located around the central column,
- the fire involving 3 cars standing in one row beside the parking corner.

Scenario 1

The analysed configuration of cars along with the RHR curve are presented in Figure 5. The fire starts with the ignition of the car no. 1. After the time $\Delta t = 12$ minutes the cars no. 2 and 3 are ignited, and subsequently the fire spreads onto the car no. 4 after $\Delta t = 24$ minutes. The maximum total rate of heat release reaches RHR = 23 MW after 29 minutes of fire.

Scenario 2

The analysed configuration of cars along with the RHR curve are presented in Figure 6. The fire starts with the ignition of the car no. 1. After the time $\Delta t = 12$ minutes the cars no. 2 and 3 are ignited. The maximum rate of heat release reaches RHR max = 20.5 MW after 30 minutes of fire.

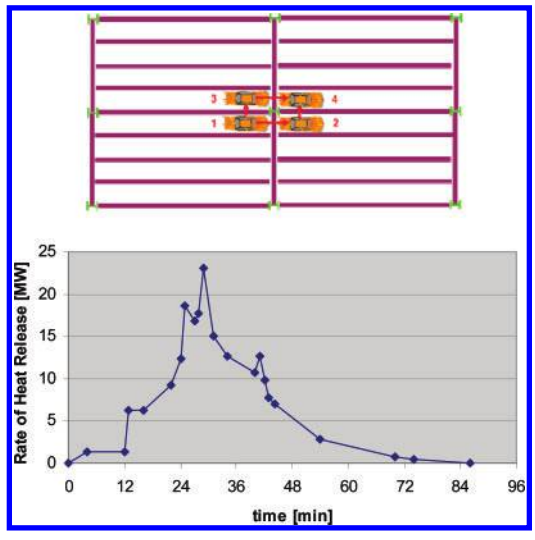

Figure 5. Scenario 1 for the fire involving 4 cars along with the total RHR curve.

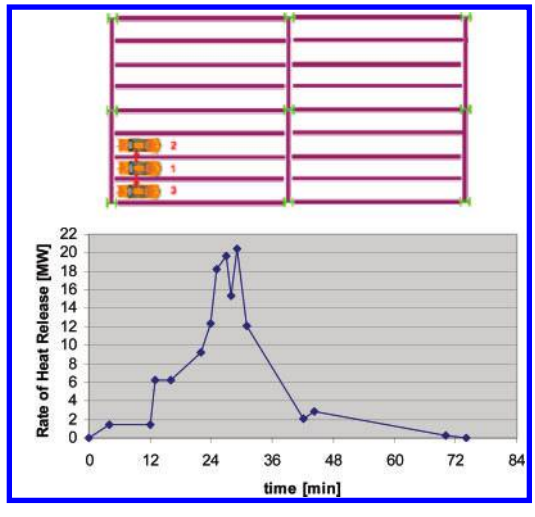

Figure 6. Scenario 2 for the fire involving 3 cars in the corner along with the total RHR curve.

5.2 *Thermal actions*

The model of localized fire has been applied to analyse thermal actions on a car park structure. The heat flux received by the elements is the function of their positioning with regard to vehicles in fire and time. Calculations were carried out in accordance with Eurocode 1 (EN 1991-1-2 2002). The following parameters indicated in Figure 7 were applied.

As a result of calculations, the net heat flux $\dot{h}_{net}$ [kW/m^2] is determined depending on RHR of burning cars and geometrical parameters of car park. The total

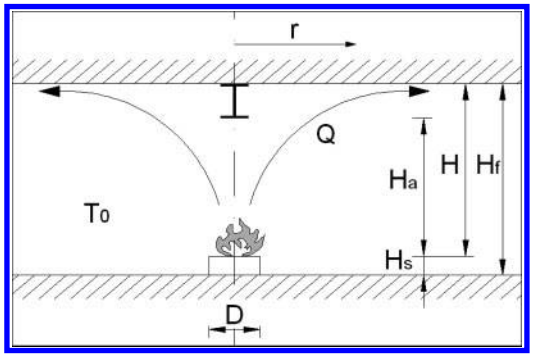

Figure 7. Parameters of the localised fire.
Q [W] – RHR of cars
Ha [m] – vertical distance from the beam lower flange to the floor,
Hs [m] – vertical distance from the fire source to the floor. For the fire coming from the cars it is taken Hs = 0.3 m (Schleich 1999),
D [m] – diameter of fire. For the car park calculations D = 3.9 m (Schleich 1999),
r [m] – distance between the fire axis and the point where the net heat flux is computed.

net heat flux (the sum of fluxes from single burning items) is limited to $\dot{h}_{net} = 100\,\mathrm{kW/m^2}$.

5.3 *Heat transfer*

From the thermal actions (see clause 5.2), time – dependant temperatures in structural members are determined. For a non-homogenous field of temperature in element (variable across the section), the calculation of the heat transfer must be performed by means of numerical methods, applying non-linear analysis system. In the CAPP project software SAFIR (Franssen 2005) was applied.

For homogenous temperature fields, the simplified model of calculations according to the Eurocode 3 (EN 1993-1-2 2005) was applied. From the total neat flux received by the structure, the net heat flux $\dot{h}_{net}$ received by the exposed unit surface on the level of the ceiling needs to be deducted.

The following formula applies:

$$\dot{h}_{net} = \dot{h} - \alpha_c\,(\Theta_m - 20) - \Phi\,\varepsilon_m\,\varepsilon_f\,\sigma\,[(\Theta_m + 273)^4 - (20 + 273)^4] \quad (1)$$

where:

α_c – the coefficient of heat transfer by convection of the material of the element,
Θ_m – surface temperature of the element [°C],
Φ – shape factor,
ε_m – emissivity of the surface of the element,
ε_f – emissivity of flames,
σ – Stephen Boltzmann's constant ($=5.67 \cdot 10^{-8}\,\mathrm{W/m^2K^4}$).

Increase of temperature during the time interval Δt, can be determined from:

$$\Delta\theta_{a,t} = k_{sh}\,\frac{A_m/V}{c_a\rho_a}\,\dot{h}_{net}\,\Delta t \quad (2)$$

where:

k_{sh} is correction factor for the shadow effect,
A_m/V is the section factor for unprotected steel member [1/m],
A_m is the surface area per unit length [m^2/m],
V is the volume of the member per unit length [m^3/m],
c_a is the specific heat of steel [J/kgK],
$\dot{h}_{net}$ is the design value of the net heat flux per unit area [W/m^2],
Δt is the time interval [sec],
ρ_a is the density of steel [kg/m^3].

5.4 *Mechanical actions*

Designing open car park structures under fire situation, accidental load combination compliant with Eurocode (EN 1990 2002) should be applied:

$$\sum_{i\geq 1} G_{k,i} + \Psi_{1,1}\,Q_{k,1} + \sum_{i\geq 1} \Psi_{2,i}\,Q_{k,i} \quad (3)$$

where:

$G_{k,i}$ is a characteristic value of permanent actions,
$Q_{k,1}$ is a characteristic leading variable action,
$Q_{k,i}$ is a characteristic value of accompanying variable action,
$\Psi_{1,1}$ is a factor for frequent value of variable action,
$\Psi_{2,i}$ is a factor for quasi-permanent values of variable actions.

Applying the recommended values of Ψ_1 and Ψ_2 given in table A 1.1 of Eurocode (EN 1990 2002) the accidental combination for fire situation in the car park is as follow:

$$1{,}0\,G + 0{,}7Q \quad (4)$$

For comparison, the basic combination of loads at strength design (STR) for normal conditions is:

$$1{,}35\sum_{i\geq 1} G_{k,i} + 1{,}5Q_{k,1} \quad (5)$$

The load reduction coefficient in fire situation for car parks design is $\eta_{\mathrm{fi}} = 0.6$–0.65. The same value is given in Eurocodes 3 (EN 1993-1-2 2005) and 4 (EN 1994-1-2 2005) for steel and composite structures.

6 NEW METHOD OF CAR PARKS DESIGN

6.1 *Construction of car parks*

The main purpose of CAPP project was to investigate possibilities of complying with Polish Building Regulations in steel open car parks (30 minutes of fire resistance) by application of fire safety engineering

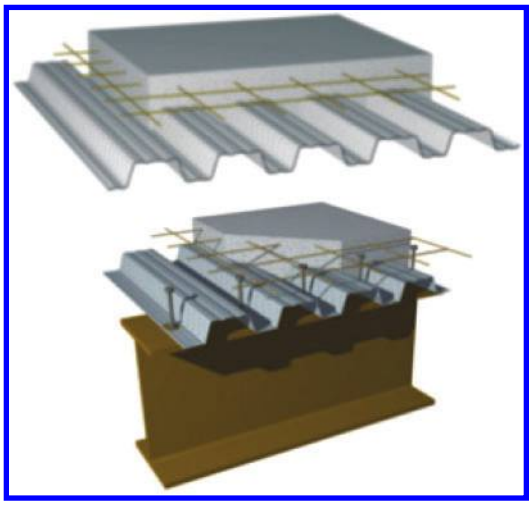

Figure 8. Composite slab and composite beam.

methods and developing design methodology for these structures in fire conditions.

Composite slabs comprise profiled steel decking as a permanent formwork to concrete slabs. Light mesh reinforcement is placed in the concrete mainly to act as "fire reinforcement" but also to reduce cracking from shrinkage.

The composite I beams form essentially T profile with wide upper flange. The concrete flange is in compression and the steel section is mainly in tension. Forces between two materials are transferred by shear connectors.

A composite slab and a composite beam are shown in Figure 8. Steel columns of car park structure were not analysed in the project. It was assumed that they are fire protected in traditional way and fulfil fire resistance requirements.

Steel and composite elements, when constructed with appropriate materials and connectors, may gain higher load bearing capacity in normal conditions and higher fire resistance than are expected in traditional approach. The improvement is due to the interaction of structural elements and additional beneficial effects, e.g. a membrane effect in composite slab.

Proper selection of structural materials is assured by:

- Steel grade S 235 or S 355 for beams
- Concrete class C30/37 for slabs
- Steel grade S 500 for reinforcement of slabs

Welded studs should be supplied between steel beams and a slab in order to provide lateral restraint of beams and their buckling resistance. Special type of beam to beam and beam to columns connections were designed. Additional reinforcement between outermost columns and slabs should be supplied.

6.2 *A membrane effect in composite slabs*

Under the influence of high temperatures steel elements lose their stiffness and strength. It is directly

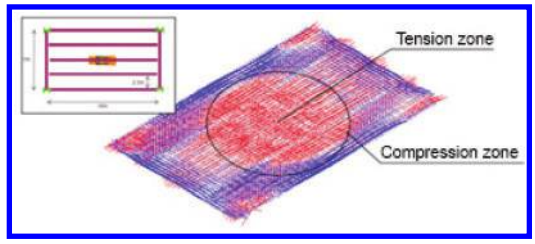

Figure 9. Membrane effect in the slab above a burning car.

Figure 10. Visible membrane effect in the slab.

affecting the performance of structure in fire conditions. In the discussed open car park structures made of steel frame and composite slab the membrane effect is observed when the structure is exposed to fire.

This effect is connected with the development of membrane forces in composite slabs with the simultaneous growth of the deflection, when beams lose their capacity and stiffness. The deflection may reach 30–40 cm for 10 m distance between columns. This effect is beneficial to the capacity of the structure because the arising membrane forces maintain the balance between compression in concrete and tension in reinforcement mesh inside the slab.

Figure 9 shows the deflections of slab under membrane effect. Tension zone is located in the centre of the slab and the compression ring runs along its edges. The same effect is shown in Figure 10.

6.3 *Numerical analysis and design calculations*

On two column grids of 16×10 m and 16×5 m five different types of open car parks were designed, following the method described above.

Composite slabs constructed on the profiled steel decking Cofraplus 60 reach 12 cm or 15 cm in thickness.

Analysis and calculations of the performance of the open car structures in fire conditions were carried out using the program of non-linear structural analysis system SAFIR. Finite elements method calculations were conducted in two stages: thermal analysis and mechanical analysis.

Calculations of the transient heat flow were conducted for a two-dimensional model consisting of a steel beam and a composite slab, exposed to a heat

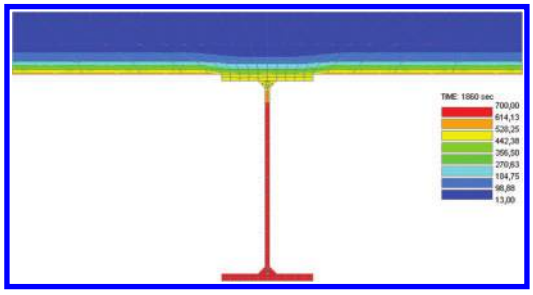

Figure 11. Calculated temperature field in the cross section.

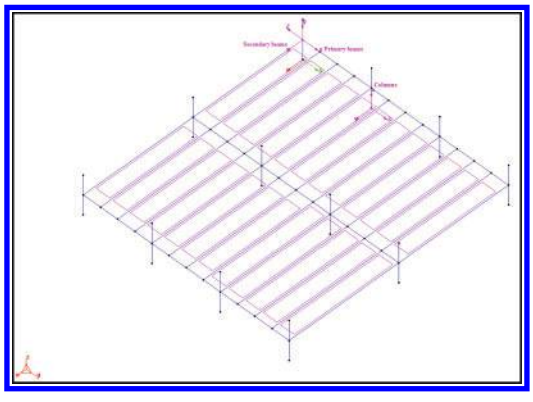

Figure 12. Mechanical calculation model of designed structure.

flux determined for the localized fire conditions. A sample temperature field is shown in Figure 11.

The calculation model used for the mechanical analysis of structure consisted of beam elements representing columns and beams and shell elements representing slabs. The model is shown in Figure 12. Design calculations were conducted for different varieties of geometrical and structural features of open car parks.

7 CONCLUSIONS

– Fire safety engineering approach presented in the paper made it possible to use fire scenarios and thermal actions on structure in accordance with the fire test results. Structural performance described by results of numerical calculations proved to be very similar to the performance observed in real fires. Thus, it can be said that this approach has been well documented and empirically verified.
– The results of tests and numerical analysis confirm that designing and building of open car parks as steel structures with composite steel and concrete slabs provides the satisfactory level of fire safety. Properly designed slabs, without additional fire protection, preserve their stability for not less than 30 minutes of fire caused by burning cars.
– FSE method applied during presented design process of open car parks is currently successfully applied in several European countries i.e. France, United Kingdom, the Netherlands, Switzerland. It can be expected that prescriptive rules currently given in national fire safety regulations in Poland and other counties will be soon replaced by fire safety engineering approach and the design method proposed in the paper will be applicable in engineering practice.

Numerical study on structural behaviour of cold-formed steel columns under fire conditions

S.J.C. Almeida & J.M. Neto
Engineering School of Sao Carlos, University of Sao Paulo, Sao Carlos, Brazil

J.P.C. Rodrigues
University of Coimbra, Coimbra, Portugal

ABSTRACT: This paper presents the results of numerical studies on the behaviour of cold-formed galvanized steel columns under fire conditions, based on results of experimental tests, previously conducted by the authors. This numerical study was performed by the finite element program ANSYS. First, it is presented the details of the finite element models used in this research and compared the finite element analysis results with those obtained in the experimental tests. Moreover, it is carried out a parametric study in order to investigate the influence of the axial restraining to the thermal elongation of the column, the axial preload ratio on the columns mechanical behaviour.

1 INTRODUCTION

The behaviour of cold-formed steel members at room temperature has been widely investigated and is somewhat well known. On the other hand, the fire performance of cold formed steel members is not well understood. The researches on cold-formed steel members in fire situation are recent and thus the knowledge about the behaviour of these members at elevated temperatures is still being built.

Concerning cold-formed steel columns it is known that is important evaluate the influence of the columns surrounding structure in order to investigate their behaviour at elevated temperatures in a consistently way, once the restraining to the thermal elongation has an important role on the mechanical behaviour of these members in fire situation.

However to date the number of information about the behaviour of cold-formed structural members at elevated temperatures based on test results is small. Consequently, there are few theoretical studies on compressed cold-formed steel members under high temperatures validated by experimental results.

Nevertheless, studies have been done to establish analytical formulations for determining the fire resistance of compressed steel members with axial restraining to the thermal elongation. These formulations beyond prescribe the fire resistance of these members can be useful to the simplified design methods available in design codes for steel structures in fire situation.

With regard to the steel columns, there are some analytical models proposed for determine the strength of steel columns with restraining to the thermal elongation (Cabrita Neves et al., 2002), (Cabrita Neves, 1995), (Valente & Cabrita Neves, 1999) and (Wang, 2002). However, these models were designed for hot rolled sections and the usefulness of these models to represent the behaviour of cold-formed steel columns needs further investigation.

In this context the numerical modeling becomes extremely important. Since that a numerical model performs satisfactorily the aspects of interest regarding the behaviour of cold-formed steel members at elevated temperatures, it may be used to support analytical formulations which subsequently can be implemented in simplified design methods.

In the present work was performed a numerical analysis on the behaviour of compressed cold-formed steel members at high temperatures considering the influence of the restraining to the thermal elongation. The numerical models were constructed based on the tests carry out in Almeida (2012).

2 NUMERICAL ANALYSES

The finite element analyses were performed using the computer code ANSYS. The analyses were conducted at ambient temperature and at high temperatures. The numerical analyses at high temperatures have been divided into two steps, namely thermal analysis and thermo-structural analysis.

The present study was performed using only one cross-section, a lipped channel, $150 \times 43 \times 15 \times 1.5$, (called here C section) with length of 3000 mm, chosen according the tests conducted in Almeida (2012). The columns were simulated with fixed-end and pin-ended supports conditions.

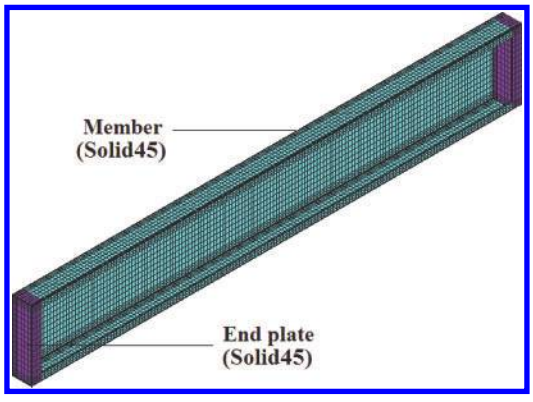

Figure 1. Three dimensional finite element model.

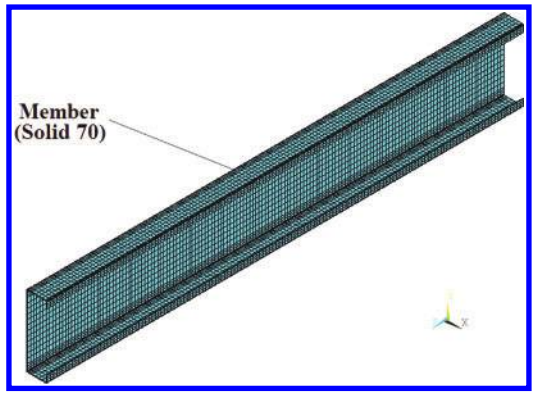

Figure 2. Thermal model: built with element type SOLID70.

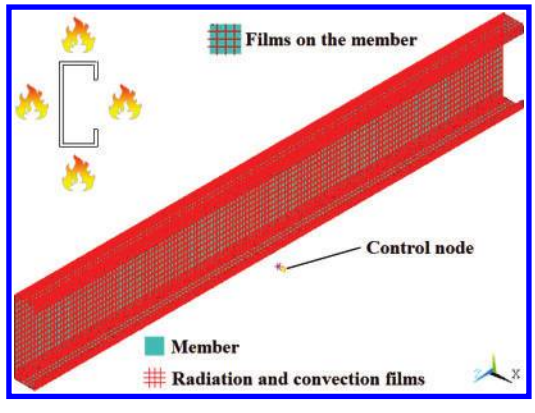

Figure 3. Thermal model: application of the convection and radiation films and the fire exposure condition.

The selected finite elements, the thermal and mechanical properties of steel at high temperatures and the strategy of modeling the axial restraining to the thermal elongation are given in the following items.

2.1 *Room temperature analyses*

The numerical analyses at room temperature were performed to assess compliance of numerical models before being used in the numerical analyses at elevated temperatures.

Moreover, the results of ultimate loads obtained numerically at room temperature were used to compare with those obtained by Eurocode 3 part 1.3 (2006), which were used for calculate the preloads applied to the numerical models of the thermo-structural analyses. The models built at room temperature were calibrated based on the results of ultimate loads obtained by the Eurocode 3 part 1.3 (2006) and ABNT NBR 14762 (2010) design methods, as shown in the item 3.1.

The geometric imperfection was generated through eigenvalue buckling analysis. The global flexural mode was adopted to represent the geometric imperfection. The out-of-straightness of L/500 was used for the amplitude of initial imperfection.

The stress–strain relationship at room temperature used in this study is based on the models in Eurocode 3 part 1.2 (2005) with material properties at 20 °C. Figure 1 shows the general outline of the model used in these analyzes, which were constructed with element type SOLID 45.

2.2 *Thermal analyses*

From the thermal analysis were obtained the temperature fields to be implemented in the thermo-structural analyses. The *temperature vs. time* relationships used in the thermal analyses were obtained based on the tests results presented in Almeida (2012). The numerical models for the thermal analyses were built with element type SOLID70. The thermal action and the effects of radiation and convection were simulated with the aid of element type SURF152.

The values adopted for thermal conductivity, specific heat and thermal elongation of the steel were those available in the Eurocode 3 part 1.2 (2005).

Regarding the parameters inherent to the mechanisms of heat transfer, the coefficient of heat transfer by convection used was equal to 25 W/m2 °C and the emissivity resulting, ε, was adopted equal to 0.5.

The temperature distribution along the height was modeled considering a non uniform distribution of temperature based on the distribution of temperature measured experimentally in Almeida (2012).

The Figure 2 shows the model used in the thermal analyses. The Figure 3 illustrates the application of the films of convection and radiation on the numerical models and the fire exposure condition used in the thermal analyses.

2.3 *Thermo-structural analyses*

The results obtained from the thermo-structural analyses were: (i) ultimate load, (ii) critical time and (iii) critical temperature.

The stress–strain relationship at elevated temperatures adopted for the steel is based on the models in

Eurocode 3 part 1.2 (2005) to temperatures ranging between 20 and 1100 °C.

The effects of the thermal action on structural analysis at high temperatures were considered by the reduction factors of the mechanical properties according EN 1993-1-2:2005 for the design of class 4 sections.

The numerical models used to perform structural analyses at elevated temperatures were built with element type SOLID45 which is compatible with the SOLID70 used in thermal analyses, allowing the transference of the thermal field obtained in the thermal analyses to the models of thermo-structural analyses.

The boundary conditions applied to the models at elevated temperatures present a difference in relation to those imposed at room temperature. In Almeida (2012), the columns were tested at elevated temperatures considering a surrounding structure. Thus, it was possible evaluate experimentally the influence of the restraining to the thermal elongation on the behavior of the columns.

Then, in the numerical models built to perform the thermo-structural analyses was considered the restraining to the thermal elongation through the strategy presented in Dorr (2010), which simulated a spring by means of a bar element (LINK 10) and the elastic properties of steel of the structural members.

In Dorr (2010), several studies were conducted to define the geometric properties of the element LINK10 used to modeling the restraining to the thermal elongation. According to the results of these studies was determined that a single element is sufficient to discretize the finite element LINK10 and the length of 0.1 m adopted for the LINK10 was adequate to represent the restraining to the thermal elongation.

The stiffness of the restraining to the thermal elongation was determined based on the axial stiffness (EA) of the members according to equation 1, where R is the elastic constant of the spring constraint (LINK10), k_r is the coefficient of proportion, E is the modulus of elasticity of the steel, A is the cross-sectional area, L is the member length and L_s is the length of the restraining to the thermal elongation. Figure 4 shows the scheme used to model the restraining to the thermal elongation.

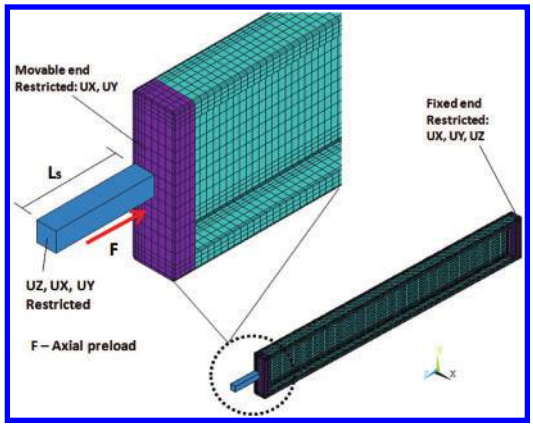

Figure 4. General scheme of the axial restraining to the thermal elongation.

$$R = k_r \frac{EA}{(L / L_s)} \quad (1)$$

The global flexural mode was adopted to represent the geometric imperfection. The out-of-straightness of L/500 was used as the amplitude of the imperfection. The mechanical action was performed using increments of load keeping agreement with the experimental procedures.

In summary, in the thermo-structural analysis first of all the geometric imperfection generated by eigenvalue analysis is introduced into the members. After that, it is applied the preload, which in this study was taken as a percentage of the ultimate load at room temperature determined according to Eurocode 3 Part 1.3 (2006). Finally the temperature field obtained from transient thermal analysis is incremented.

3 RESULTS

3.1 *Room temperature analyses*

Table 1 shows the comparative results between the ultimate load obtained numerically and those calculated by the design methods of the Eurocode 3 part 1.3 (2006) and ABNT NBR 14762:2010, where $F_L/500$ is the maximum compressive force obtained numerically for the global imperfection of L/500 and λ is the global slenderness. The labels C-F and C-P refer to the numerical models end support conditions, fixed-ended and pin-ended respectively.

According to the results shown in Table 1, the numerical models showed agreement with the results prescribed by the design codes confirming the compliance of the models. Moreover, these results attest the consistency of the preloads applied to models in the thermo-structural analyses.

3.2 *Thermo-structural analysis*

In the analyses conducted at elevated temperatures were evaluated (i) two values of preloads (30% and 50% of ultimate load determined according to EN1993-1-3:2006) and (ii) three values of restriction to thermal elongation ($k_r = 0.13$, 0.26 and 0.52), where k_r is the proportion coefficient according to

Table 1. Ultimate loads at room temperature.

Model		λ (L_{ef}/r)	EC3 P1.3 (kN)	NBR (kN)	$F_{L/500}$ (kN)	$\frac{F_{L/500}}{EC3}$	$\frac{F_{L/500}}{NBR}$
P01 P02	C-F	192	46.5	49.1	44.0	0.95	0.90
P07 P08	C-P	154	17.5	18.0	17.2	0.98	0.96

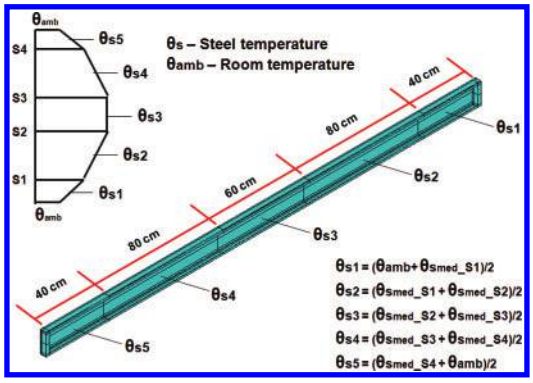

Figure 5. Non uniform temperature distribution along the height: simplified model.

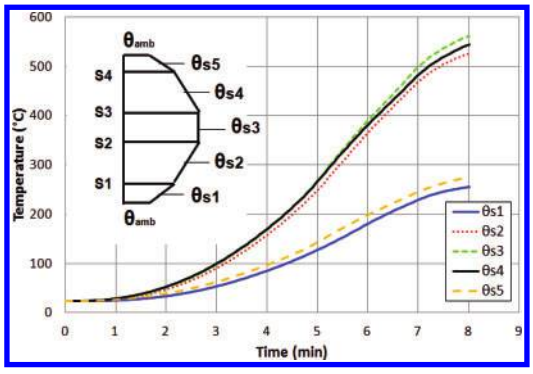

Figure 6. *Temperature* × *time* relation: Model C-F with non uniform temperature distribution along the height.

equation 1 and $k_r = 0.13$ is the value corresponding to the axial rigidity imposed experimentally to members. It follows the analysis and discussions of the results.

The fields of temperature was defined as shown in Figure 5, where θa1, θa2, θa3, θa4 θa5 are calculated as a function of average temperatures recorded in the sections S1, S2, S3 and S4 distributed along the height of the members as shown in the detail in Figure 5.

Figure 6 shows the heating curves used for the members with fixed ends. These curves were built based on the *temperature* × *time* curves recorded for column P02. For the members with pinned ends the heating curves were built based on the *temperature* × *time* recorded for the column P07.

Tables 2 and 3 show the summary of the results found for the C-F and C-P models respectively, where k_r is the proportion coefficient from the equation 1, F is the maximum numerical compression force, P is the maximum experimental compression force, θ_s is the critical temperature, t is the critical time and the preload is a percentage of the ultimate load determined with EN1993-1.3:2006.

According these tables, the numerical and experimental ultimate loads were close. On the other hand, the critical temperatures prescribed numerically showed a significant difference from the value found

Table 2. Numerical results: Model C-F.

		Numerical			Experimental

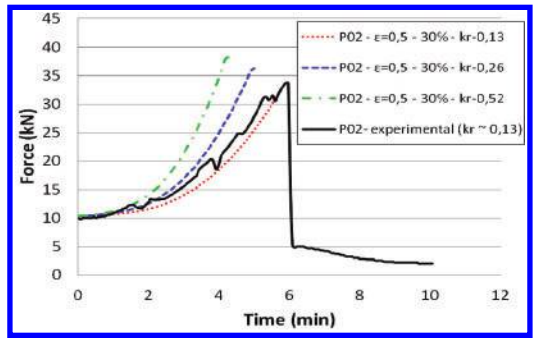

Figure 7. *Force* × *time* relation: numerical to experimental comparison: Model C-F with non uniform temperature distribution.

experimentally. Regarding the critical time, the numerical prescriptions were close the values recorded experimentally.

Figures 7 and 8 shows the comparisons between the experimental and numerical relationships, *force vs. time* and *force vs. temperature*, for the models with fixed-end supports. According to the Figure 7, the numerical model represents, satisfactorily the experimental *force vs. time* curve and as shown in Figure 8 the numerical model tends to simulate satisfactorily the experimental *force vs. temperature* curve.

Figures 9 and 10 shows the comparisons between the experimental and numerical relationships, *force vs. time* and *force vs. temperature*, for the models

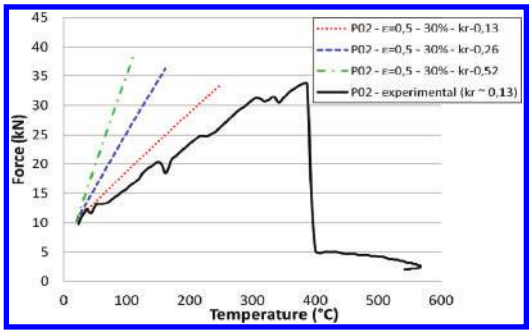

Figure 8. *Force* × *temperature* relation: numerical to experimental comparison: Model C-F with non uniform temperature distribution.

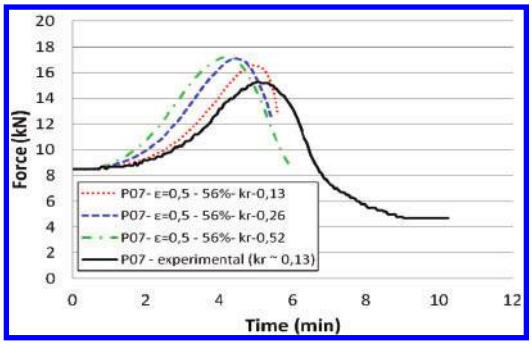

Figure 9. *Force* × *time* relation: numerical to experimental comparison: Model C-P with non uniform temperature distribution.

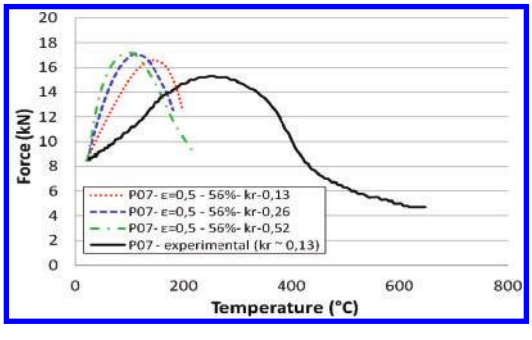

Figure 10. *Force* × *temperature* relation: numerical to experimental comparison: Model C-P with non uniform temperature distribution.

with pin-ended supports. According to Figure 9, the numerical model represents satisfactorily, the experimental curve *force vs. time*. On the other hand, the numerical model showed rigidity much greater than that registered experimentally, as shown in Figure 10.

Figures (11 and 12) and (13 and 14) show the *force vs. time* and *force vs. temperature* curves obtained numerically for different combinations of parameters, for the models with fixed-end and pin-ended respectively.

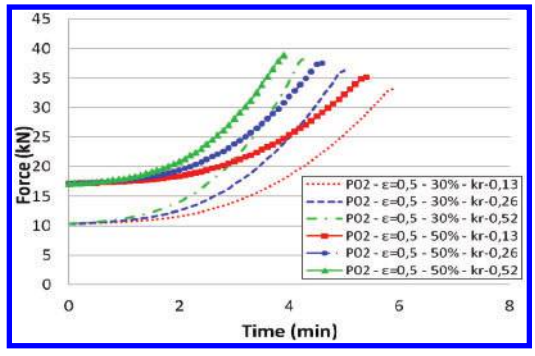

Figure 11. *Force* × *time* relation for different parameters combinations: Model C-F with non uniform temperature distribution.

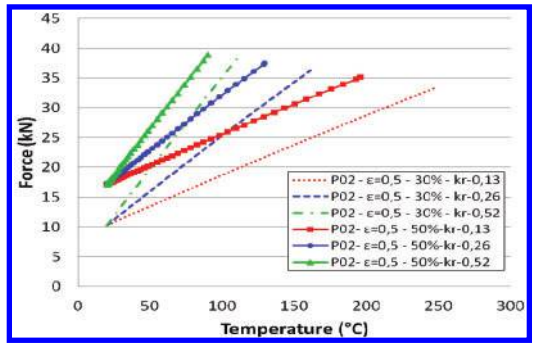

Figure 12. *Force* × *temperature* relation for different parameters combinations: Model C-F with non uniform temperature distribution.

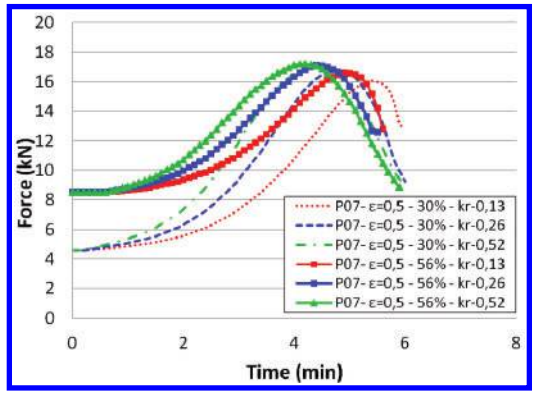

Figure 13. *Force* × *time* relation for different parameters combinations: Model C-P with non uniform temperature distribution.

According to Figures 11 and 12, for the models with fixed-end, the variation of the ultimate load with the preload was negligible. Similarly, the intensity of ultimate load practically not varied with the axial restraining to the thermal elongation imposed to the models.

From the Figures 13 and 14, similar to the models with fixed-end, the ultimate load practically not varied

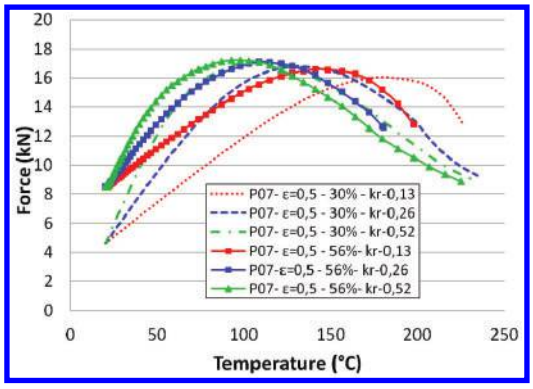

Figure 14. *Force* × *temperature* relation for different parameters combinations: Model C-P with non uniform temperature distribution.

with the preload nor with the axial restraining to the thermal elongation for models with pin-ended.

However, a particularity of the models with the pin-ended was the identification of the descending branch of the curve *force vs. time*. This behaviour was not observed in the models previously analyzed and until then had no knowledge of the capability of the numerical model built to capture this information.

With the results, it is proved the efficiency of the model to represent the descending branch of the curve *force vs. temperature*, which means that the model is able to represent the post-critical behaviour of the compressed steel member with restraining to the thermal elongation.

4 CONCLUSION

In the present work we carried out numerical analyses on the behaviour of cold-formed steel members at elevated temperature submitted to compression with restraining to the thermal elongation. The numerical models presented some limitations to reproduce satisfactorily the critical temperature. On the other hand, the modeling strategy was capable to prescribe the ultimate load and the critical time with reasonable error margin compared to test results obtained in Almeida (2012). Moreover, the models also reproduced satisfactorily the experimental curve *force vs. time*. The model has potential to represent satisfactorily the post-critical behavior of cold formed steel members submitted to compression with axial restraining to the thermal elongation. Using the simplified non-uniform temperature distribution the model could obtain the descending branch of the *force vs. time* curves and *force vs. temperature* observed in the experimental investigation of pinned end compressed cold formed steel members with restraining to the thermal elongation.

An analytical method for determining the loading on connections in heating and cooling during a fire

David Lange & Joakim Albrektsson
SP Technical Research institute of Sweden

ABSTRACT: This paper presents a proposed analytical method for calculating the mechanical loading on a beam column connection in fire. The behavior of connections in fire has received considerable interest over the last decade since it is well known and demonstrated experimentally that composite steel concrete construction is able to adopt alternative load bearing mechanisms in fire as a result of large displacements. This global behavior is different from behavior which is studied in standard furnace testing and places additional loads on the supporting structure which must be able to support elements which are effectively 'hanging' in tension as opposed to supporting the load through shear and bending, as at ambient.

First, this paper explores the mechanisms which lead to time varying mechanical loading on a beam / column connection in fire. Then a simple method for calculating a loading envelope of the connection is proposed. The analytical method is derived from fundamental principles of structural behavior at high temperatures and is a development of previous work published by the authors elsewhere. New developments presented include a discussion of the mechanisms which govern the response of composite structures during cooling following a fire and inclusion of these in the analytical model. The analytical method is then compared with the results of finite element analyses and is shown to compare favorably.

1 INTRODUCTION

Design of connections in steel concrete composite frames for fire traditionally assumes that the connections do not lose as much of their strength at high temperatures as the structure as a result of their high massiveness. Work conducted has focused on evaluating the response of connections in fire – evaluating their capacity at elevated temperatures and when exposed to forces with large horizontal components arising from large thermally induced deflections in the structure (Wang et al. 2011), (Yu et al. 2008). Researchers at Sheffield University have also developed a component model for steel connections in fire (Block et al. 2013).

The focus of the work presented in this paper is the study of the forces which act on connections as a result of the mobilization of membrane or catenary action of a structure in fire. These large displacements in horizontal building elements are known to induce large horizontal loads on the supporting construction. This paper presents a simple analytical method for determining the loads on connections in fire which is based on other work by the main author and which is published elsewhere (Lange et al. 2012).

2 NUMERICAL ANALYSIS

The basis for the validation of the analytical model for determining the load on connections in fire is a simple finite element model comprising solely beam elements representing a composite floor system. All three of the slab, beam and reinforcement were considered in the finite element model and a range of section sizes were used in the study. A separate heat transfer analysis was conducted using simple analytical techniques and this was used as input to the finite element model and to the analytical model.

2.1 *Thermal model*

The thermal model was based on simple or codified solutions. Two fires were used in the analyses, an ISO fire of duration 2 hours and a parametric fire with floor area of 225 m^2, total area of 612 m^2, Ventilation opening of 46.6 m^2, c_p of the enclosure linings of 837 J/kgK, conductivity of the enclosure linings of 0.48 W/mK, density of the linings of 1442 kg/m^3 and a fuel load of 511 MJ/m^2. A medium fire growth rate was used. The two fires used in the analysis are shown in Figure 1.

Heat transfer to the steel beam was carried out using the simple methods described in Eurocode 3 Part 1–2, assuming lumped capacitance. The steel beam is assumed unprotected in this study.

Heat transfer to the concrete was carried out using a finite difference heat transfer algorithm, with material properties as defined in Eurocode 2.

Output from the heat transfer analysis was used both for the finite element calculation, with temperature at 7 points through the depth of the concrete slab being exported to abaqus as well as the temperature

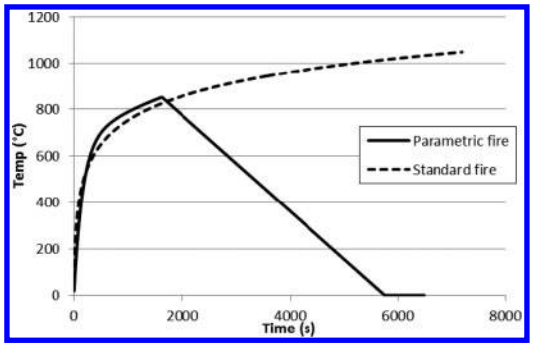

Figure 1. The standard fire and the parametric fire used in the analysis.

of the beam. In addition to this, a sectional analysis was carried out on the heated floor system taking account of the reduced modulus and modular ratios at different temperatures and different depths in both the concrete and the steel. Cooling was considered during the parametric fire exposure by not allowing the concrete to recover strength during cooling when carrying out the sectional analysis, while allowing the steel to recover all of its strength during cooling. From the sectional analysis an equivalent thermal gradient, T_z, and equivalent uniform temperature increase in the entire section, ΔT, were determined.

2.2 *Finite element model*

Finite element analysis of the response of the composite floor comprising 9 different beam section sizes and 4 different loading levels was carried out using the abaqus explicit finite element solver and were time scaled by a factor of 1000 (no rate dependent material properties were used in the models). The system was modeled using beam elements representing the steel beam, the concrete slab and the reinforcement within the slab. All parts were tied at the nodes to represent composite action between the slab and the beam and the concrete and the reinforcement. The beam was offset from the slab to account for the thickness of the slab and the depth of the beam. The beam was pinned at both ends, representing a non-continuous concrete construction, it should be noted however that this influenced primarily the deflected shape – with no restraining moment applied at the ends – and that the reinforcement was also subject to the support conditions through the constraint between the different parts in the model.

The slab was 100 mm thick, and the floor spanned 6 m in all cases, with a 6 m distance between the beams.

The steel beam acting in composite with the slab varied from an IPE 180 section to an IPE 450 section (including IPE 200, IPE 220, IPE 240, IPE 270, IPE 300, IPE 330, and IPE 400 sections). Reinforcing steel was provided in the form of an A142 anti cracking mesh, providing a total area of reinforcement of 852 mm^2. The steel reinforcement was located at the mid depth of the concrete slab.

The abaqus Concrete Damaged Plasticity model was used for the concrete material, with a maximum compressive load of 35 MPa at ambient and a maximum tensile strength of 2 MPa at ambient. The steel had a modulus of elasticity of 210 000 MPa, and an elastic limit of 355 MPa and yield modulus of 455 MPa at a strain of 0.045, and ultimate strain of 0.2. The steel for the anti-cracking mesh was the same as the steel for the structural beam.

Strength and stiffness reduction of both concrete and steel at high temperatures are taken from Eurocode 2 Part 1–2 and Eurocode 3 Part 1-2 respectively.

Uniform loading was applied to the model at magnitudes of 30, 45, 50 and 60 N/mm length of the floor. All models were run for both the standard fire for a period of two hours and the parametric fire shown. To include cooling during the parametric fire, a user subroutine was used within abaqus which maintained the temperature of concrete at the maximum temperature observed for determination of the temperature dependent material properties. The material properties of the steel beam and the reinforcement were allowed to return to their unreduced properties at ambient.

2.3 *Results and discussion*

For brevity, not all results are presented here. However an exemplar of the horizontal load at the supports and the mid span deflections is shown in Figure 2 for both the standard and the parametric fire; results are plotted against 1000's of seconds. Figure 2 a) shows the response of a floor comprising the IPE220 beam under a load of 30 N/mm length exposed to the standard fire and Figure 2 b) shows the response of a floor comprising an IPE 300 section under a load of 60 N/mm exposed to the parametric fire.

The overall behavior of the floors is similar in both the standard and the parametric fire. In both cases the floor experiences a short period where it 'pushes' against the support. Further heating results in the development of large deflections and the adoption of a catenary mechanism and a corresponding large horizontal load 'puling' on the connection. In figure 2 b) it can be seen that the catenary mechanism is actually mobilized in the floor exposed to a parametric fire after approximately 2000 seconds, corresponding with a sudden increase in the deflection and the reversal of the overall compressive force in the floor to a tensile force. It should be noted that some of the floors were unable to carry the load in either bending or a catenary. In these cases very large deflections resulted. These were the models of floors with a small beam section and the largest applied loads, typically those exposed to the long standard fire.

During the cooling phase and the post cooling phase of the parametric fire, there is little or no relaxation of the deflections beyond the peak deflection observed. In addition to this, the horizontal load shows little or no increase as the floor system cools. This is perhaps

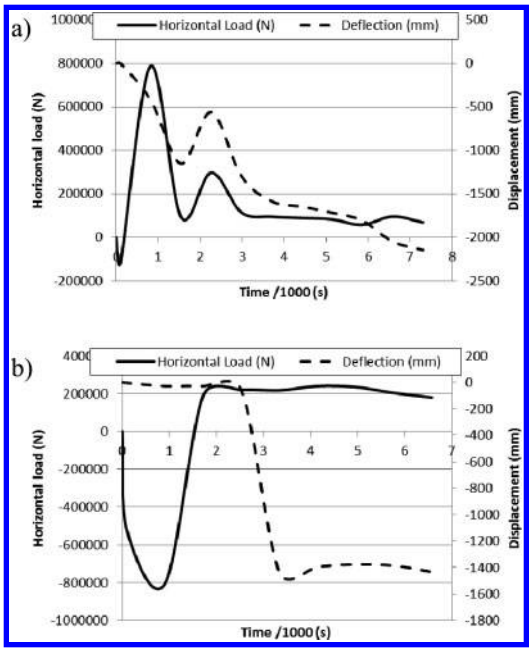

Figure 2. Example of horizontal load and displacement of floor system under a) a standard fire and b) a parametric fire (tension positive, compression negative).

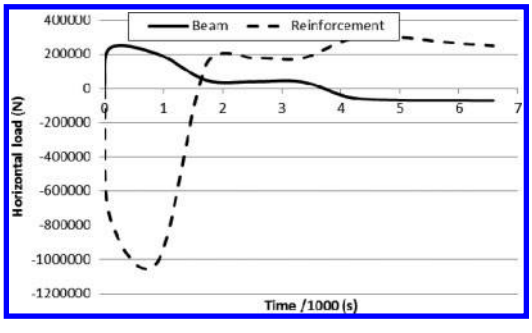

Figure 3. Reaction from the beam and the reinforcement of a floor comprising an IPE 300 section when exposed to the parametric fire described.

contrary to what may be expected as contraction of the steel beam upon cooling may intuitively be expected to result in a significant increase in the horizontal load on the connections, further; experience from a number of tests has shown that there is little to no reduction in the total deflection of a composite floor following a fire, which should serve to increase the tension in the steel beam. Figure 3 shows the contribution to the horizontal load at mid span from the beam and the reinforcement in the slab. It can be seen that in fact the horizontal force at mid span in the steel beam is in fact small and compressive rather than tensile following cooling.

The following explanation is proposed in order to explain why the horizontal load does not significantly increase as the steel beam cools and contracts.

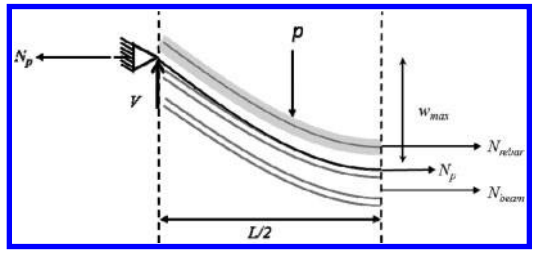

Figure 4. The contribution to horizontal load from both the reinforcement and the beam in a catenary is shown. The slab, reinforcement and steel beam are shown in grey. The load resultant is shown rather than the distributed load.

Figure 4 shows the contribution to the horizontal load from the reinforcement in the slab and the steel beam. At the peak of heating of an unprotected floor system the two components of the horizontal load, N_p, may be determined based on the sum of these two components, N_{rebar} and N_{beam}. N_{rebar} is based on mechanical strain and the temperature dependent modulus of elasticity in the floor for the reinforcement assuming that it is still in the elastic region of the stress strain curve, equation (1a). If the rebar is no longer in the elastic range then the force may be approximated by the product of the temperature dependent yield stress and area of the steel reinforcement, equation (1b). N_{beam} at high temperatures may always determined from the temperature dependent yield stress of the steel beam since at high temperatures associated with the peak of heating in a fire the yield stress of the steel beam will have been exceeded by the entire floor adopting the deflection required to support the load.

$$N_{rebar} = \varepsilon_s A_r E_r(T) \tag{1a}$$

$$N_{rebar} = A_r \sigma_{yr}(T) \tag{1b}$$

$$N_{beam} = A_b \sigma_{yb}(T) \tag{2}$$

At the end of a heating phase, the floor has adopted the deflection required to support the load in a catenary. Based on the relative magnitudes of equations 1 and 2 the majority of the tensile load is supported by the steel reinforcement in the floor rather than the beam. This is because the temperature dependent yield stress of the beam is considerably lower than either the yield stress or the modulus of elasticity of the much cooler reinforcement located within the slab.

Once heating stops and the temperature of the steel begins to reduce, thermal strain decreases. However the total deflection is still required by the floor system to sustain the load and therefore the majority of the thermal strains are 'locked in' to the steel beam as plastic deformations. As the temperature decreases, this effect will reduce however the additional tensile load on the floor boundaries will not be as high as were the beam able to contract without absorbing the expansion strains as plastic strains. With increasing section size, the beam will absorb less of the expansion

strain as plastic strain since the relative magnitude of the forces in the beam and the rebar are higher and the tensile load on the beam connections will be larger as a result, however they will not be as large as were the beam able to contract unhindered.

Finally, during cooling of the steel beam the slab in the model is subject to some reversal of the thermal moment which may result in some compressive load on the steel beam, an effect which is slower than cooling of the steel beam. This effect may however be unlikely in practice as a result of tensile cracking of the concrete.

3 ANALYTICAL METHOD

There are three stages in the calculation of the load on a beam-column connection in fire:

1. Calculate the thermal loading on the floor. This can typically be carried out via a 1D heat transfer analysis, or similar. It is assumed that the temperature distribution is 1 dimensional, i.e. varies only through the depth of the floor system. Regardless of the method employed, the ultimate goal is to obtain an equivalent temperature distribution consisting of an average temperature increase and a uniform thermal gradient.
2. Calculate the thermally induced deflection of the floor system, based upon the results of the heat transfer analysis.
3. Calculate the combined thermal and mechanical response of the floor system, and evaluate the total loading at the boundary from both the beam and the reinforcement before splitting this load into the component from the beam (supported by the connection) and the reinforcement (supported by overlap and continuity of the reinforcement

3.1 *Thermal deflection*

The thermal response of the floor system can be deduced by considering in turn the thermal expansion caused by the average temperature increase, ΔT, and the thermal bowing induced by the temperature gradient, T,z.

At interior columns, the in-plane restraint to expansion is large. In contrast, at exterior columns in-plane restraint to expansion is much smaller. However, where fire exists on only one floor, the translational stiffness of the column may be assumed to be large, and therefore the lateral translation of the connection is assumed to be fully restrained by this stiffness.

The thermal deflection, w_T in Figure 5, is given by the following equation:

$$w_t = \frac{2L}{\pi}\sqrt{\varepsilon_\phi + \varepsilon_T + \frac{(\varepsilon_\phi + \varepsilon_T)^2}{2}}, \qquad (3)$$

where $\varepsilon_\phi = 1 - \frac{\sin L\phi/2}{L\phi/2}$ and $\phi = \alpha T_{,z}$, $\varepsilon_T = \alpha \Delta T$, L is the length of the floor system, α is the coefficient of thermal expansion , ΔT is an equivalent temperature of the floor system, and $T_{,z}$ is the equivalent thermal gradient calculated for the whole floor system according to (Usmani 2000).

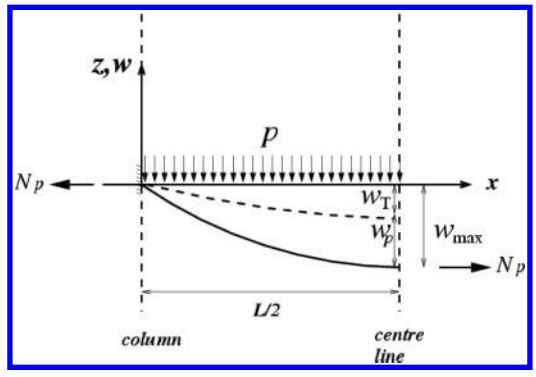

Figure 5. Deflected shape and forces acting on the floor system.

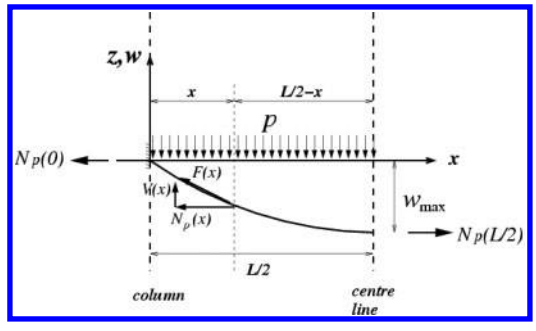

Figure 6. Tension in the floor is calculated as shown.

3.2 *Mechanical loading during heating*

The deflected shape and forces acting on the floor system, after a catenary mechanism has been adopted, are shown in Figure 5.

Considering the total tension in the floor system, N_p, at distance x along the span, Figure 6, and taking moments about the mid span of the floor then the horizontal reaction is given by:

$$N_p = \frac{pL^2}{8w_{\max}} \qquad (4)$$

Consistent with other work, at large displacements, the contribution from concrete to the floor system is ignored due to widespread tensile cracking of the concrete (Cameron & Usmani 2005). The maximum possible tension before failure, F_{max}, in the floor system may be determined from the yield stress of the available reinforcement and the steel.

$$F_{\max} = A_s\sigma_{ys}(T) + A_r\sigma_{yr}(T) \qquad (5)$$

This maximum tension occurs at the support, where the shear reaction is highest.

The shear reaction is given by:

$$V(x) = p\left(\frac{L}{2} - x\right) \tag{6}$$

The maximum possible horizontal reaction for the entire floor may therefore be calculated based on the resultant reactions of the floor system at $x = 0$:

$$N_{p\max} = \sqrt{F_{\max}{}^2 - p^2\left(\frac{L}{2}\right)^2} \tag{7}$$

This value of $N_{p\max}$ is an upper bound for the horizontal load which could by placed on the support of the composite floor adopting a catenary. It is also important to note that this load is the total load carried by both the reinforcement and the steel beam. In order to determine the load on the connection and the load which must be carried either by horizontal shear connection at the perimeter beams or through continuation of the steel reinforcement to adjacent bays the total force must be split into these two components.

However, inspection of equation (4) indicates that at high deflections the total horizontal load is reduced below the maximum possible tension in the floor system. Previous work by the main author of this paper has included a formulation for determining the increased length required to support a distributed load in a similar floor system (Lange et al. 2012). However this formulation assumes that the reinforcement in the floor remains elastic.

The simpler formulation proposed in this article therefore includes a simpler estimation of the total deflection based on the assumption that strain hardening of the steel reinforcement as it yields will lead to the yield strain being distributed along the length of the reinforcement before any increase in plastic strain occurs. As with the numerical models, initial strain hardening of the reinforcement is assumed to occur at a strain of $\varepsilon_{pl} = 0.0185$ and this is therefore taken as the strain in steel in the floor when determining the total deflection.

$$w_{\max} = \frac{2L}{\pi}\sqrt{\varepsilon_{pl} + \frac{\varepsilon_{pl}^2}{2}} + w_T \tag{8}$$

Substituting equation (8) into equation (4), the horizontal load on the connection at this increased deflection is given by:

$$N_{p\delta} = \frac{pL}{16\pi\sqrt{\varepsilon_{pl} + \frac{\varepsilon_{pl}^2}{2}} + w_T} \tag{9}$$

The horizontal load on the connection therefore lies between the maximum given by equation (7) at the transition between bending and catenary action and the value given by equation (9) at high deflections. During cooling, equation (9) may be used as a reasonable upper bound since it may be assumed that no reversal of the deflections which develop during heating occur.

The component which is taken by the connection between the steel beam and the column should first be determined from equation (2) since it is assumed that the steel beam has yielded as a result of the high temperatures and the tensile load which is placed on it as it is forced to follow the deflected shape of the concrete. The component which is taken by the steel reinforcement is then determined based on the difference between either $N_{p\delta}$ and $N_{p\max}$ as appropriate and N_{beam}.

4 VALIDATION AND CONCLUSIONS

Validation of the analytical method in comparison to the numerical results is presented in this section for the parametric fire for the maximum horizontal load on the connection during the heating phase and at the end of the. Comparison of the analytical method with the maximum horizontal load during a standard fire will be made elsewhere however it can be reasonably assumed that validation against the heating phase of a parametric fire may represent a good approximation to the results with the standard fire.

Figure 7 shows the maximum horizontal load which may be expected to occur during the heating phase of the parametric fire. The analytical results for each of the analysis are plotted against the numerical results for the same. The dashed line in the figure represents equivalency between the results and therefore everything below the dashed line shows conservatism over the numerical results. These results are given for a time of approximately 600 seconds, approximately one third of the way through the heating phase of the parametric fire, with the temperature dependent properties of the steel beam chosen accordingly.

It can be seen that the simple method compares favorably with the numerical results, with every example being on the conservative side.

Figure 8 shows the comparison between the simple solution presented here and the numerical results

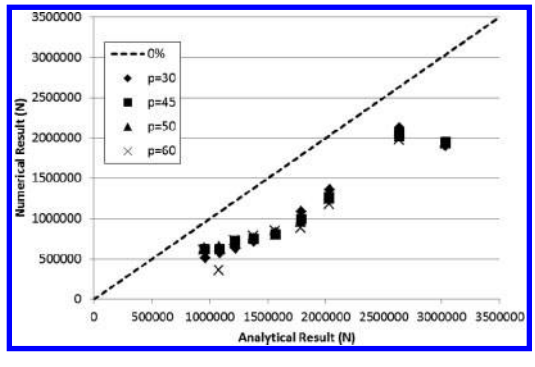

Figure 7. Maximum horizontal load during a parametric fire.

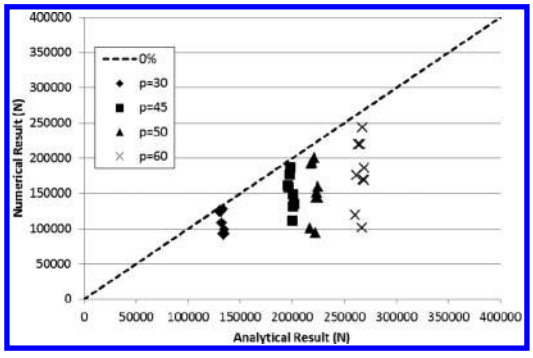

Figure 8. Minimum load during a parametric fire and load during cooling.

during the cooling phase of the fire, representative of the minimum bound of the horizontal load imposed on the connections during the parametric fire. The results are presented in the same way as the maximum results during the heating phase, with everything below the equivalency line being on the conservative side. Again, all of the results of the simple method presented are on the conservative side in comparison with the numerical results.

The horizontal loads presented may then be separated into the components carried by the beam and the reinforcement using equation (2) to determine the load on the beam and using equation (1) to determine the load on the reinforcement at the maximum horizontal load or based on the remainder of the load during the cooling phase.

Fire protection of multi-storey straw bale buildings

J. Wachtling, D. Hosser & J. Zehfuß
Institute of Building Materials, Concrete Construction and Fire Protection (iBMB),
Technische Universität Braunschweig (Institute of Technology), Braunschweig, Germany

ABSTRACT: Straw bale buildings consist of load bearing timber frame elements with straw bales used as insulation. These constructions with special emphasis on sustainability can be found worldwide (FASBA 2013, Minke & Krick 2009, King 2007, Jones 20010). As a lighthouse project, a multi-storey building is planned in Germany with the iBMB in charge of the fire safety concept and supporting research. The Model Building Code of Germany (MBO 2008) allows buildings with timber frame structures for a height of 13 m (from ground level up to the floor of the highest occupied room) with noncombustible insulation, a classified fire protection coating and a fire resistance of 60 minutes (REI 60 $K_2$60). In case combustible insulations are used, researches showed that not only ignition but even thermal decomposition must be prevented. To reach this objective the outer surface of the straw bale walls will be protected by a lime coating and the inner surface by a clay coating. The fire protection properties of the coating materials with different aggregates and thickness have been investigated by small and intermediate scale tests (Kampmeier & Wachtling 2012). Also the thermal parameters of the coating materials, which are needed for numerical simulations using state-of-the-art FE-software, are determined in laboratory tests. Some results of the research are presented in this paper.

1 INTRODUCTION

Building with timber, straw and clay is one of the oldest building techniques. During the course of the time this technique was replaced by modern building materials and methodologies. But since sustainability is becoming more important there is a trend of ecological building design (Kampmeier & Wachtling 2012).

As a lighthouse project, a multi-storey building is planned in Germany with the iBMB in charge of the fire safety concept and supporting research. It is planned to establish such straw bale buildings up to five stories and a height of 13 m (Kampmeier & Wachtling 2012).

The research is supported by the German Federal Ministry of Economics and Technology. Some of the fire protection research results for multi-storey straw bale constructions are presented below.

2 STROW BALE CONSTRUCTIONS

Straw is a by-product of grain production, in which carbon dioxide (CO_2) is stored. In the form of bales it is suitable as insulating material due to its low thermal conductivity ($\lambda = 0.052\,W/(m \cdot K)$). The energy required for the production of straw bales is very low compared to other insulation materials such as polystyrene (about 1/30). Straw bales are also available locally, so the transport is highly favorable in the eco-balance compared to other building materials. The produced amount of straw bales in Germany would be sufficient to insulate about 350.000 single-family homes in this way every year. In fact, Germany has about 150 buildings in straw bale construction; an example is shown in figure 1. The oldest inhabited straw bale building was built about 100 years ago. At the end of the life-cycle the straw and timber can be biological decomposed (Minke & Krick 2009, Scharmer 2011, King 2007, Jones 2010).

To spread straw bale constructions in Germany the German national organization of straw bale building (FASBA) has obtained a general building approval for building straw bales. In this approval, building straw bales are classified with a normal flammability (B2). Figure 2 shows building straw after the fire test according to DIN 4102-1 (1998). In addition, "commercial" building straw bales have to be dry and the density must be between 85 kg/m^3 and 115 kg/m^3 (Kampmeier & Wachtling 2012).

In Germany straw bale constructions are approved only in combination with a load bearing timber construction. In the traditional way of building, the straw bales are plastered directly with clay which, like straw, has a very good eco-balance. There are straw bale houses with clay on the outer surface, but in general the use of more weatherproof lime plaster (figure 3) is recommended (Kampmeier & Wachtling 2012).

A great disadvantage of this design is the combustibility and smoldering of the straw bales. These problems must be solved by constructive solutions.

Figure 1. Straw bale house in Leiferde, Germany (Scharmer 2011).

Figure 2. Fire test according to DIN 4102-1 (Scharmer 2011).

Figure 3. Straw bale house plastered directly with lime in Bösel, Germany (Scharmer 2011).

3 BUILDING CODE AND RISK ASSESMENT

Prior to the amendment of the Model Building Code of Germany (MBO 2002) in the year 2002, timber constructions were limited to low buildings with a maximum height of 7 m. For an extension of the application range of buildings with a height up to 13 m researches had to demonstrate that the fire risk will not increase in comparison to solid construction with concrete or masonry. Evidence was provided in a research project completed in the year 2001. The additional fire risks resulting from the use of timber can be mainly offset by so-called "effective fire protection coating" as main structural compensation measure. The purpose of these coating materials is to protect the wooden components against ignition during the required fire resistance of 60 minutes. In addition, prevention of smoke propagation is often required. In standards harmonized at the European level, these structural components would be classified as "REI 60 $K_2$60" according to DIN EN 13501-2 (2010) (Kampmeier & Wachtling 2012).

In further studies (Hosser & Kampmeier 2007, Kampmeier 2007), it could be demonstrated that combustible insulation materials can also be used with additional constructive measures without lowering the safety level below the accepted level of fire protection. It must be considered that below the ignition temperature of flammable insulations combustible gases can be produced during thermal decomposition. This can be dangerous for the fire fighters, who must open the coating to extinguish the fire inside the construction. When oxygen is supplied at sudden, these gases can be ignited abruptly.

The objective of effective fire protection coating must be extended when using combustible insulation. In addition, there cannot be any weak spots in the form of sockets, switches and distribution boxes in the fire protection coating, which could cause a fire or allow a fire to enter the combustible insulation material. Likewise, no electrical wires are allowed as potential ignition sources in or on the renewable raw material without effective fire encapsulation (Kampmeier 2008).

Fire tests have to demonstrate that the previously described expanded protection objectives of the protective coating for straw bale insulation can be fulfilled. It has to be shown that the constructions behave the same way as components of fireproof materials would during the protection period of 60 minutes.

4 FIRE SAFETY ENGINEERING STUDIES

4.1 *Limit temperature of thermal decomposition of straw*

For the definition of the required performance of the fire protection coatings, the limit temperature of the thermal decomposition of straw had to be determined. In case of fire, not only ignition, but even the smallest

thermal change of the insulation material must be prevented during the entire protection period of 60 min. As part of a feasibility study (Niemann 2010) straw was examined in the cone calorimeter according to the method described in (Kampmeier 2008). Figure 4 shows the cone calorimeter according to ISO 5660 (2002).

By assessing the discoloration in figure 5 at different temperatures, a value of 200°C was determined as temperature limit for the thermal decomposition of straw bales (Niemann 2010).

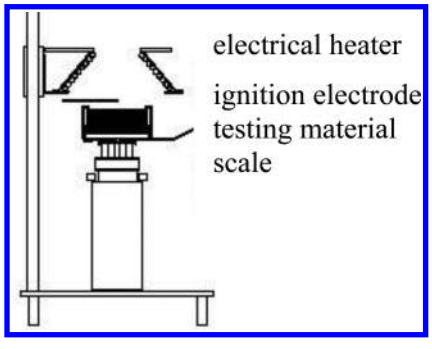

Figure 4. Cone calorimeter (Kampmeier & Wachtling 2012).

Figure 5. Determining the limit temperature of the thermal decomposition (Niemann 2010).

4.2 *Coating requirements*

On the outer surface of the straw bale walls a lime plaster is planned (Fig. 6). It must be demonstrated, that the fire protection coating protects the straw against temperatures greater 200°C during a full-scale fire exposure for 60 minutes (Kampmeier & Wachtling 2012).

On the inner surface of the exterior walls the coating is planned to be installed on 18 mm thick OSB panels (Fig. 6) to improve the building stiffness. This reduces the required fire protection properties of the clay coating for the protection of timber constructions according to DIN EN 13501-2 (2010): On the surface of the timber construction, temperature increase may not exceeded 270°C on average, and 290°C at the maximum ($K_2$60-coating). From a previous research project (Hosser & Kampmeier 2007, Kampmeier 2007) is known that even 8 mm thick timber panel in combination with a $K_2$60-classified coating reaches the protective requirements of the straw (Kampmeier & Wachtling 2012).

4.3 *Fire protection investigations of clay coatings*

To assess the performance of various clay coatings, comparative experiments were also performed in the cone calorimeter. Before it was decided to use a timber panel on the inner surface of the exterior walls to stiff the building, investigations concentrated on examining whether clay coatings can protect the straw against temperatures of greater than 200°C.

The heater of the cone calorimeter produces a nearly continuous heat flux. For these investigations, the heat flux was set to 40 kW/m^2; this is nearly equal to the heat flux of standard fire tests with uniform-temperature-time-curve (ISO-curve) according to ISO 834 (1999). Nevertheless, the results of the cone calorimeter tests are not directly transferable to standard fire tests. The cone calorimeter tests are for orientation and comparison of samples with one another, so that a reasonable

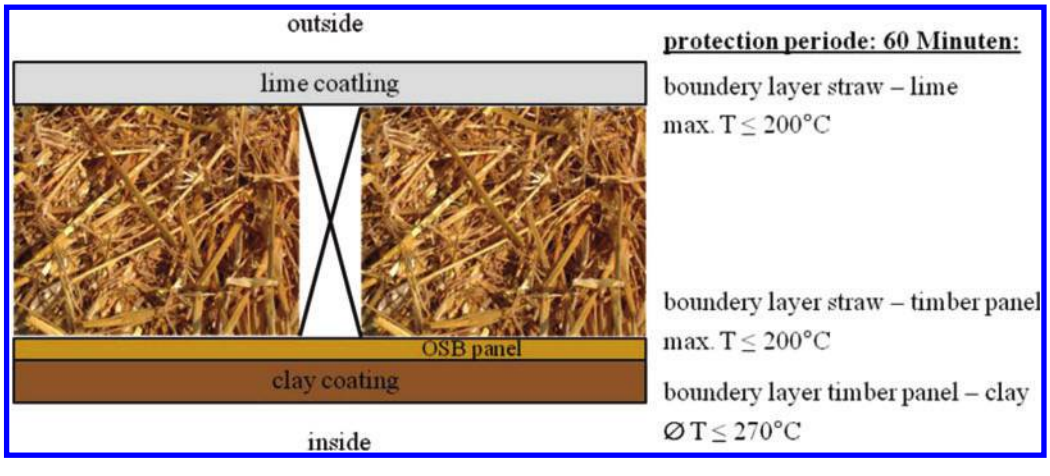

Figure 6. Coating-requirements (Kampmeier & Wachtling 2012).

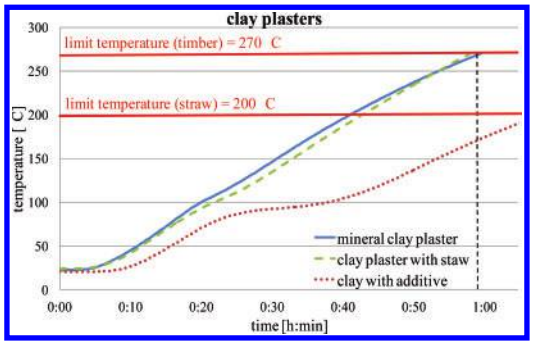

Figure 7. Clay plaster samples in the cone calorimeter.

Figure 8. Sample in furnace according to DIN 4102-8 (2003).

choice can be made for more expensive standard fire tests (Kampmeier & Wachtling 2012).

Straw clay plaster, mineral clay plaster and clay plaster with a fire protection additive were investigated at a 6 cm thickness. The results are shown in figure 7.

These initial test results showed that plastered clay layers ≥6 cm directly on straw bales would be necessary to meet the fire protection requirements. This is problematic for technical and economic reasons, so it was decided to replace part of the clay plaster layer by prefabricated clay boards. Therefore, clay boards were developed by the project partner Claytec with lightweight aggregates and a fire protection additive. These boards were investigated in various thicknesses in the cone calorimeter and a preliminary selection was made (Kampmeier & Wachtling 2012).

Pure board coatings would cause continuous joints, which could allow the passage of hot gases. Therefore, in addition, various plasters were examined in different thicknesses. The combination of a 45 mm thick clay board with a 10 mm thick mineral clay coating yielded promising results, so that an examination under standard fire conditions in a small scale test according to DIN 4102-8 (2003) was carried out. In this test, the specimen size is approximately 50 × 50 cm^2 (Fig. 8) (Kampmeier & Wachtling 2012).

The cost of testing at this scale is much lower than in the large-scale furnaces, so it is suitable for

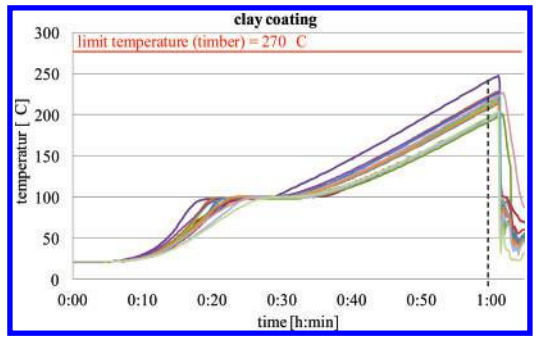

Figure 9. Temperature evolution in the boundary layer between the clay coating and the chipboard (Kampmeier & Wachtling 2012).

preliminary testing. Due to the positive results of this small-scale test, an intermediate scale test according to DIN EN 13501-2 (2010) and modeled after DIN EN 14135 (2004) in a ceiling fire chambers followed. This furnace chamber has a base area of 1.0 × 1.5 m^2 and a height of 1.5 m. The space is open at the top, which enables the installation of a ceiling element. Testing a ceiling element is the worst case scenario for the plaster, and thus envelopes the use as wall construction (Kampmeier & Wachtling 2012).

The samples were made of timber-frame construction with chipboard as an indicator to detect any discoloration. They were manufactured under practical conditions by the participating companies: The newly developed 34 × 60 cm^2 clay boards were attached on the chipboard. A newly developed thermal clay adhesive with a cellulose proportion of less than 1% was used to attach the full board surface to the chipboard. This adhesive was also used to complete the joints between the boards. Additionally, the boards were fixed with screws. The boards were then plastered with 10 mm mineral clay. Near the surface a flax tissue was plastered to avoid cracks during drying (Kampmeier & Wachtling 2012).

For determination of the temperature in the boundary layer between the clay coating and the chipboard 15 thermocouples were positioned. The temperature evolution is shown in figure 9. Throughout the fire resistance period of 60 minutes, the maximum temperature of 270°C was not reached. This also applies to the thermocouples arranged behind the joints of the clay boards.

After 60-minutes under standard fire conditions, the sample was removed from the fire chamber and it became visible that the plaster layer was intact and had no cracks. The sample was water-cooled immediately after the test and the clay was chopped off. No thermal damage in the form of discoloration or burning was found on the chipboard and near sunk screws. Under these conditions, the requirements were achieved for a fire protection coating in $K_2$60-quality. If the screws are not sunk and only flush with the board surface, discoloration can be localized at these areas. (See right half of the sample in figure 10) (Kampmeier & Wachtling 2012).

Figure 10. Chipboard behind the clay coating after 60-minutes under standard fire conditions (Kampmeier & Wachtling 2012).

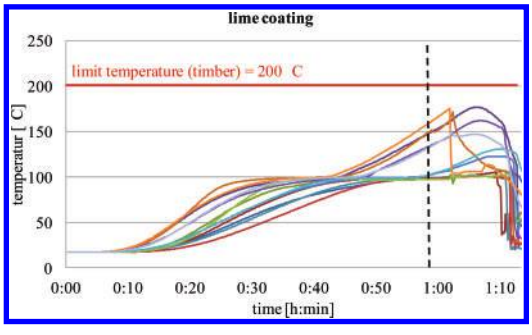

Figure 11. Temperature evolution in the boundary layer between the lime coating and the straw.

4.4 *Fire protection investigations for lime coatings*

For the outer surface the plaster is applied directly to the straw, the layer of mixed straw and lime is not counted when determining the plaster thickness. The straw should be flush with the timber, so that the plaster thickness can be defined from here.

For lime plasters from the participating company Endress, preliminary investigations with the cone calorimeter and small scale tests according to DIN 4102-8 (2003) were performed. They yielded promising results for a 6 mm thick lightweight lime plaster and a 5 mm lime plaster with fire protection additive. Yet, the intermediate scale tests (according to DIN EN 13501-2 (2010) and DIN EN 14135 (2004)) showed that only the 6 mm thick plaster could fulfill the requirements (Fig. 11).

The samples were manufactured under practical conditions by the participating companies like the clay sample. But in this application, the coating was applied directly to the straw, since the coating has to protect the straw against the limit temperature of 200°C. The temperatures in the boundary layer between straw and plaster are shown in figure 11. The limit temperature is not reached during 60-minute standard fire conditions (Kampmeier & Wachtling 2012).

During and after the test, no cracks or other damage of the plaster could be noticed. After the experiment, the sample was cooled with water, and the plaster was chopped off. This was followed by a visual test, in which no discolorations on straw were noticed (Fig. 12). Hence, it could be shown that the protection of straw bales with the directly applied 6 cm thick lightweight lime plaster can be ensured for 60 minutes fire exposure (Kampmeier & Wachtling 2012).

Figure 12. Plaster surface and coloration of straw behind the lime coating under standard fire conditions (Kampmeier & Wachtling 2012).

4.5 *Thermal properties of the coating materials*

As part of the research project, the thermal properties of the coating materials were determined. These are needed for numerical simulations of the material properties using state-of-the-art FE-software. These simulations could enable performance-based fire protection concepts with optimization of the newly developed coatings.

The experimental parameters from the standard fire tests were fed into a simple FE-software utilizing an isotropic formulation of the Fourier equation. It was found that this approach is not suitable for this application, because the temperature plateau (Figs. 9, 10) at about 100°C cannot be represented realistically. This plateau is an essential criterion for the fire protection ability, especially in case of plasters. For that reason, a suitable software has yet to be found or developed. It is considered to modify the software model DEPHIN (Nicolai & Grunewald 2006), which is currently used for the determination of detailed physical processes like convective transport processes in the porous media. This software is capable of reproducing diffusion processes. In addition, the required input parameters are already available, because the physical construction investigations also being part of the research project.

5 CONCLUSION

As described above, the additional fire risk of using straw bale insulation (instead of noncombustible insulation required for multi-storey timber frame constructions in Germany) can be compensated by constructive

Figure 13. Study of the planned multi-storey straw bale building in Germany (NZNB 2012).

measures. In addition, fire protection coatings of clay and lime were investigated and can now be classified as $K_2 60$ according to DIN EN 13501-2 (2010). They also show a better eco-balance than conventional products.

The fire protection coatings must fulfill additional requirements: Any thermal decomposition of the insulation material has to be prevented during the fire protection period of 60 minutes. Furthermore any weak spots like electrical installations must be avoided within the construction in general. Solutions for these and other details were developed in the research project.

From the fire protection research point of view there is no bar to the realization of the planned multi-storey straw bale building in Germany (Fig. 13). Further information on the fire safety concept is provided in (Kampmeier & Wachtling 2012). As a lighthouse project it can contribute to the spread of the multi-storey buildings with renewable raw materials.

Structural analysis at the fire limit state: Practical applications

A. Jowsey & P. Scott
Structural Fire Design Department, International Paint, Felling, UK

ABSTRACT: Structural engineers consider a multitude of load cases in design, ranging from standard dead and imposed loading through to snow, wind and seismic loading. Recent years have seen a new load case take an ever important role in structural designs – that of fire. Structural codes and guidance documents present methodologies to take advantage of steelwork to demonstrate substantial savings in passive fire protection. These methodologies range from advanced numerical models to simplified structural checks. It is these simplified approaches combined with a fundamental understanding of structural assessments that can quickly and easily produce robust and quantified designs at elevated temperature.

This paper presents the analysis of a structural member in terms of cost of steel and fire protection combined with direct attention being given to structural fire engineering approaches. The analysis considers the development of a structural member from initial design by the structural engineer through to modifications by the steelwork fabricator with respect to weight optimisation. Consideration of the fire protection material in direct conjunction with the structural analysis clearly demonstrates that the lightest and most structurally-efficient design is not always the most economic.

1 INRODUCTION

Structural design standards including British Standards and the Eurocodes both cover the design of steel structures in fire. These provide designers with the opportunity to exploit the properties of structural steel to its maximum capacity in the fire limit state, termed Structural Fire Engineering. This allows passive fire protection to be integrated into structural design as part of the steelwork specification. If used effectively it can bring significant benefits to the project, including robust and safe designs, quantified structural performance and cost savings.

The reality is that many structural engineers are not familiar with the fire design of structures as this aspect of design may not fall within the remit of their work or it is taken as being the responsibility of the architect or an appointed fire engineer. In the absence of structural calculations at high temperature, the design of fire protection for the vast majority of jobs is assumed based on conservative assumptions.

2 OPTIMISATION

Structural engineers often design for the most efficient use of structural steelwork for the variety of structural load cases or load combinations that they are considering. Efficient in this context is taken as being the lightest steel member, while load combinations are likely to incorporate dead, super dead, imposed, wind, snow and potentially seismic loads (EN, 2002). Most structural engineers have a good grasp of the price of steelwork and can therefore come up with indicative steelwork costs for their designs. However, few structural engineers at present have sufficient understanding of passive fire protection and their associated costs to appreciate what impact fire protection has on the cost of their designs and the potential for optimisation.

Figure 1 illustrates a high-level cost comparison for a single steel member in terms of steel cost and fire protection cost. If the weight of a member is increased, for example an increase in the serial size with respect to its weight or an increase in the web or flange thickness, then it is obvious that the cost of the steel will increase. However, the increase in steel weight can generally have a large impact on the amount of fire protection required. A heavier (thicker) steel section will heat more slowly than a light (thin) steel section. As such, it will have an increased inherent fire resistance and therefore require a comparatively thinner thickness of applied fire protection to achieve the same level of required fire resistance. From Figure 1 it is intuitive that there is likely to be an optimum weight that results in the cheapest design by factoring steel and fire protection costs together.

When considering fire protection costs it is important that the overall volume of material for a project is not priced in isolation. The application costs of various fire protection options are important too.

A structure that has been subject to a structural fire assessment should ideally take a full cost benefit analysis into account to arrive at the optimum design. This should account for the combined cost of steel, fire protection and application costs as a minimum.

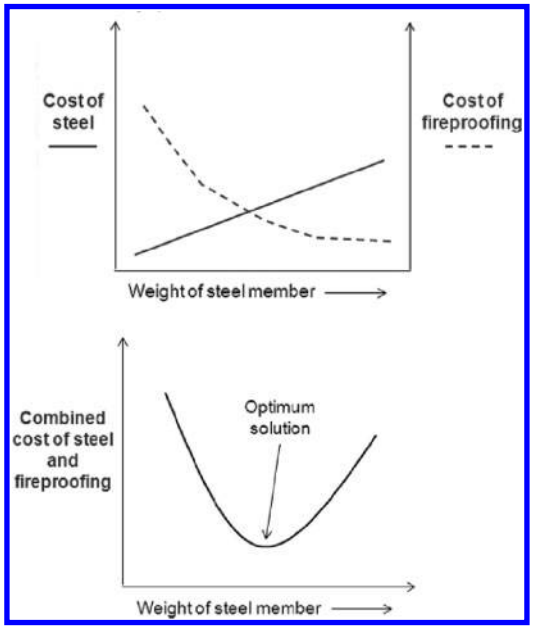

Figure 1. (Left) Illustration of the typical steel and fire proofing costs associated with an increase in the weight of a steel member, (right), combined cost of steel and fire proofing, showing optimum solution with respect to steel weight.

3 STRUCTURAL ANALYSIS AT ELEVATED TEMPERATURES

Many structural design codes and guidance documents include 'fire resistant' design. In the UK the relevant standard is BS 5950 Part 8:2003 (BS, 2003) and in Europe the relevant codes are EN 1993-1-2:2005 (EN, 2005) for steel and EN 1994-1-2:2005 (EN, 2005) for composite steel and concrete design.

In BS 5950-8 and the Eurocodes methods are given for determining the thermal and mechanical response of the structure and evaluating the fire protection required, if any, to achieve the required performance. An important feature of the standards is that they use the concept of a variable steel temperature, i.e. they allow the limiting steel temperature to be evaluated. The following sections provide examples of the application of these methods.

A common method of assessment is to assess the degree of utilisation of a structural member in the fire limit state through a single element analysis. This approach considers beams or columns in isolation with conservative boundary support conditions and effectively reproduces the load-bearing scenario of a standard fire test as close as possible by calculation. Depending on the member subject to the analysis, a number of checks at elevated temperature may need to be accounted for including:

- Tensile or buckling resistance for tension or compression members
- Moment resistance and shear capacity for beams
- Lateral torsional buckling resistance moment for beams

Manufacturers of passive fire protection subject their products to a fire test package that comprises unloaded and loaded beams and columns at minimum and maximum product thicknesses. In the UK and Europe (BS 476, EN 13381), the result of this test package is a dataset that defines the required protection thickness for structural sections over a range of limiting steel temperatures, typically 350°C to 700°C in 50°C intervals. Certified product listings (Certifire, LPCB, etc.) typically only show the thickness of material required to satisfy the accepted industry standard temperatures. In the interest of commercial sensitivity, manufacturers do not typically publish their product-specific multi-temperature assessment (MTA) thicknesses.

The following sections in this paper use the Eurocode approach to demonstrate the benefits of a single member analysis in the context of design for standard beams and columns, and long span beams with web openings.

3.1 *Typical beams and columns*

The majority of structural members in buildings including high rise are typical serial sections, including I-sections, H-sections, W-shape and tubular columns and beams. With these members there is potential to make big economic savings in the volume of fire protection using simplified structural assessments.

A sensitivity study was presented by (Jowsey & Scott, 2012) in which the failure temperatures and intumescent coating thicknesses for 203 × 203 × 52 UC section in compression were calculated using Eurocode calculations in accordance with the UK National Annex. The steel strength, column height and degree of loading were all varied and comparisons for all cases were made back to the corresponding thickness of fire protection for the UK adopted temperature of 550°C (in the absence of a calculated limiting steel temperature) for fire resistance periods of 90 and 120 minutes. It was shown that a simple structural check using conservative assumptions could reduce the amount of fire protection by approximately 28% with potential further reductions being possible with more accurate loading information.

Figure 2 depicts the compression member and also shows the calculated limiting steel temperature for a range of column heights and occupancy types assuming a fully loaded column and grade s355 steel. It is evident that the UK industry adopted temperature of 550°C for a column is generally conservative.

In order to appreciate the benefit of calculating the limiting steel temperature, the corresponding thickness of fire protection is used to quantify the saving in fire protection material volume. Figure 3 shows the potential saving for the 203 × 203 × 52 UC section at a height of 4.5 m at 90 and 120 minutes fire resistance in comparison to assuming a conservative limiting steel temperature of 550°C.

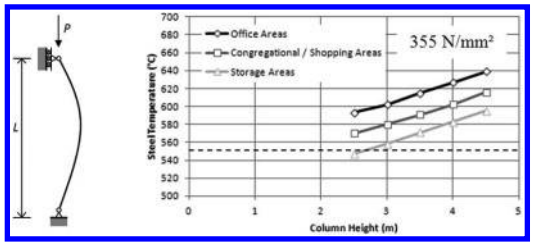

Figure 2. (Left) Column acting in compression. (Right) Limiting steel temperature variation for a fully loaded, Grade s355, 203 × 203 × 52 UC for a range of column heights and occupancy uses. The dashed black line represents the UK industry adopted temperature of 550°C (Jowsey & Scott, 2012).

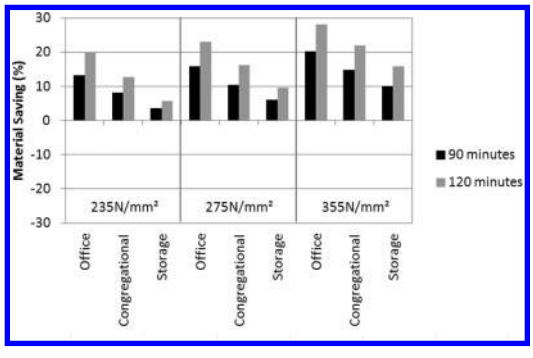

Figure 3. Fire protection material saving by calculating a limiting steel temperature for a fully loaded 4.5 m high 203 × 203 × 52 UC in comparison to an UK adopted temperature of 550°C (Jowsey & Scott, 2012).

3.2 *Beams with web openings*

Beams with web-openings are becoming more and more popular with tall building design as they are a relatively lightweight and efficient method to achieve long spans to facilitate open plan floor layouts. They permit services to be passed through the openings rather than below the steel beam and are therefore efficient in terms of increasing the number of floors in high-rise buildings. These beams are commonly referred to as cellular beams in the UK and Europe or smart beams in North America.

The behaviour of these beams in fire has been the subject of much research over recent years both in terms of structural response (SCI, 2011) and thermal behaviour (EN, 2012). The openings in the web create a complex distribution of temperature on the web, specifically at the areas between adjacent openings (web-posts). It is important that such a temperature distribution is taken into consideration as part of structural assessment. Indeed, there are no industry adopted temperatures for these types of beam and a limiting temperature must be calculated and given to a fire protection manufacturer to determine an appropriate thickness of fire protection (ASFP, 2010). The structural response of these beams is more complex than solid-web beams. The distribution of force around the

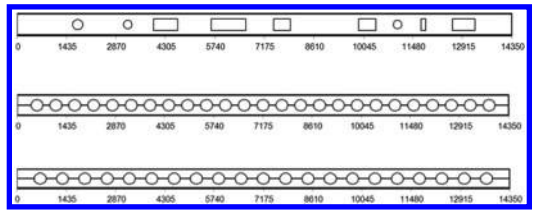

Figure 4. (Top) Initial beam design from the structural engineer, (middle) an alternate lightweight beam design from the steel fabricator, and (bottom) a lightweight design that is optimised for fire protection.

openings on the web means that in addition to bending and shear, the following failure modes are important to assess (SCI, 2011):

- Vertical shear check at openings
- Bending moment check at openings
- Vierendeel bending moment check at openings
- Web-post buckling
- Web-post bending
- Web-post horizontal shear

4 COST BENEFIT ANALYSIS

The following example considers three beam designs to span 14.35 m as shown in Figure 4. The initial plate girder beam design was proposed by the structural engineer. The steel fabricator produced an alternate lightweight beam design, based on stock serial sections that reduced the cost of the steelwork; however this proved to be an overall more expensive solution as the fire protection costs were not factored into the design. Following a value engineering exercise by the authors, a final revised design was created that was optimised for fire with respect to steel cost, fire protection cost and application cost.

Figure 5 shows the relative cost and weight savings of the alternate and revised beam designs with respect to the original beam design. The fabricator's alternate solution resulted in a 9% saving in the steel weight, with a corresponding 9% saving in the cost of steel. However this design now had closely spaced web-openings creating hotter web-posts in the event of a fire – the result being an increased thickness of intumescent coating to the extent that the application had gone from one coat of paint to two, with an associated increase in application cost. This has the effect of increasing the fire protection cost to 180% of the original beam. Following the value-engineering exercise with close attention paid to the fire protection, a revised structural design was proposed in which the openings were spaced further apart to create relatively cooler steel in the web-posts and the web thickness was increased to add 2 kg/m to the linear weight of the beam. This had the effect of providing enhanced structural capacity to combat the web-post buckling structural failure mode. The effect of these modifications was a beam that was 7% lighter and cheaper in terms of steelwork than the original design, but

Figure 5. Representation of the three beam designs in terms of cost saving of steel and fire protection, both with respect to weight saving of steel.

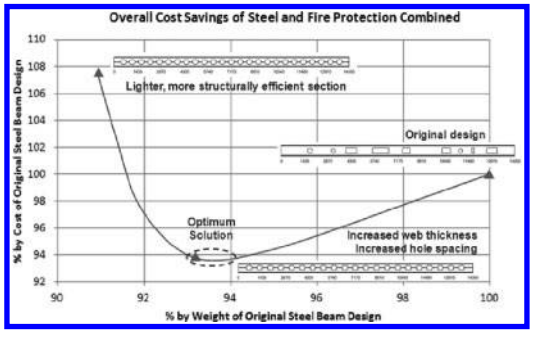

Figure 6. Overall cost savings of steel and fire protection combined for the three beam designs with respect to weight saving of steel.

also approximately the same cost in terms of fire protection, i.e. it remained a single coat application of intumescent paint.

Figure 6 shows the combined cost of the steel and fire protection saving with respect to the original design for the alternate and revised beam designs. It is seen that the alternate design, although being 9% lighter in terms of steel weight, is 108% of the cost of the original beam design due the cost of the additional fire protection. The revised solution with an increased web thickness and opening spacing was shown to be 7% lighter in terms of steel weight, however it was 6% cheaper overall than the original beam design.

This example demonstrates that an optimum cost structural solution based on cost of steel and fire protection is possible and importantly it shows that the lightest structural design is not necessarily the cheapest solution. Given that these long-span structural members are commonly used in tall building design, the economic savings of analysing beams in this manner can be significant.

5 CONCLUSIONS

The issue of structural fire resistance is one that has been developing with a fast past over recent years. Structural engineers are now starting to acknowledge and recognise that they can add significant value to their designs by considering fire as a load case in its own right. Structural design codes provide engineers with the opportunity to exploit the properties of structural steel to its maximum capacity in the fire limit state. If used effectively, benefits of structural fire engineering include significant cost and time savings on projects.

The following conclusions are noted:

- A structural fire engineering assessment leads to informed performance, rather than assumed performance in the event of a fire.
- In the absence of a structural fire engineering assessment to determine a member's limiting steel temperature, fire protection manufacturers will assume generally conservative temperatures for the purpose of defining volumes of fire protection for a project.
- Simple approaches are available in published codes and standards to permit structural engineers to determine limiting steel temperatures for individual members.
- A truly optimised structure for fire should take into account the combined cost of steel, fire protection and application costs as a minimum.

This paper has shown that through simple structural checks, a quantified performance of a member can be made at elevated temperatures through the definition of a limiting steel temperature. This can then be used to determine a volume of passive fire protection and compared to industry adopted approach to demonstrate a value-engineered solution. The worked examples included are for a single member in isolation, however the same approach can be adopted for all structural members within a building. This approach has the benefit of reducing passive fire protection requirements for an entire project.

Alternatively, structural steel sections may be deliberately oversized and then structural checks repeated to reduce passive fire protection requirements.

Fire design of wooden box floors

Dhionis Dhima
CSTB, Champs sur Marne, Marne-la-Vallée cedex 2, France

Renaud Blondeau-Patissier
METSÄ WOOD, Construction, Courbevoie Cedex, France

ABSTRACT: The design of the floors made up of prefabricated wood-based loadbearing box elements facilitates the construction of these floors and reduces significantly their cost. According to the fire requirements of different types of building, where this type of floor is used, different wooden box slab configurations are designed: unprotected, protected by plasterboard or other protections and with or without insulation inside the box. The behaviour in fire of these configurations are different. EN1995-1.2 proposes a simplified method for the design of the floor assemblies with cavities, but this method does not take into account correctly the reduction of strength and stiffness of wooden elements at elevated temperatures. Consequently, the design of wooden box slabs according to this method could lead to a very high risk concerning the fire stability of these floors.

The fire behaviour of box floors made up of Laminated Veneer Lumber (LVL) has been studied. The numerical modelling of heat transfer, by finite element program, allows investigation of the influence of each component of the floor over its fire resistance. The numerical results have been validated by experimental results of floors tested under ISO fire conditions. Different parameters are defined and a simplified procedure is proposed in order to design LVL box floor classified REI30 and REI60. The results of this study are inserted in the French technical approval in order to be used by the industrialists. Finally, the results of research will be used to improve the methods suggested by EN 1995-1.2 for the design of safety wooden floor assemblies in fire conditions.

1 CONTEXT

1.1 *Introduction*

Building context, particularly in France, but more generally in Europe, requires better understanding of each building component, considered separately, but also when it is integrated in the building (floor, partition wall, roof). Reliability of such co*m*ponents must be now guaranteed regarding thermal behaviour, acoustic properties, cold situation design and fire design.

Sticks built structures, the traditional way of building timber structures is now more and more often replaced by prefabricated ready-made components. These components integrate wooden structure, insulation (acoustic, thermal, fire), protection and finishing (plasterboards, wooden acoustic panels. . .) but also installations (electricity, ventilation, pipes..) when required. Wooden panels are then assembled on site, in a short time, with few technical workmen and provide high level quality of the building.

1.2 *Multifunctional prefabricated wooden elements*

Using prefabricated elements allows architects and builders to achieve higher performance and to reduce significantly cost deviations.

Separate elements assembled on site can lead to a large number of non-conformities compared to prescribed and design structures. Acoustic and fire weaknesses are recognized as main disorders for the final customer. Using 2D components (panels) reduces significantly non-conformities. Indeed these continuous structures are prefabricated in controlled mills and limit number of joints which have to be sealed on site. Management of quality in industrial prefabrication units, mandatory in Europe for building components (CE-marking with external controls), must guaranty performances of building components. And site controls can be improved and concentrated on limited number of elements.

In that context, wooden panels, in general, and wooden floors are now widely used as building components. The performances of such elements are now more and more studied on a multifunctional level (mechanic, acoustic, thermal. . .).

Despite good behaviour of wooden structure, the fire resistance remains the main criteria for most of wooden constructions to enter market and convince authorities.

Performance of wooden floors are following principles of EN 1995-1-2 “Design of Timber Structures – Structural fire design”, design instructions validated

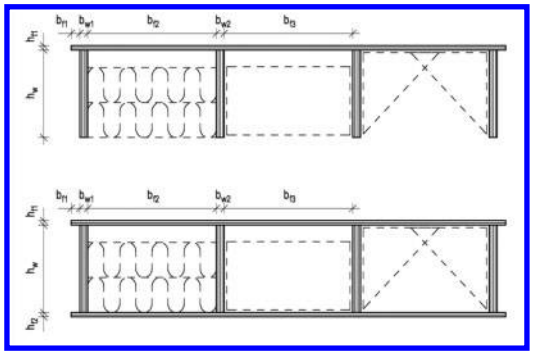

Figure 1. Cross section of ribbed or box Kerto-Ripa elements.

and further described with additional tests under ISO fire conditions.

1.3 *Kerto-LVL wooden box elements – Kerto-Ripa®*

MetsäWood Company (former Finnforest) has developed since the late 90's wooden structurally glued loadbearing panels. These "Kerto-Ripa®" elements are composite slabs made of Kerto, structural laminated veneer lumber (LVL). The adhesive is of type I (full exposure to the weather) as defined in (EN 301). Large horizontal panels (Kerto-Q panels, max. 2.5 m × max. 25 m) are structurally assembled with vertical ribs (Kerto-S beams, max. 0.6 m × max 25 m) using structural gluing to form hollow box elements. Kerto-Ripa elements may contain thermal or acoustic insulation inside the cavities and plasterboards in fire side in order to improve their fire resistance. These elements may or may not have wooden bottom slab (see figure 1).

The products are shaped according to the specification of the customer and design according to project requirements. The maximum size of the elements is 25 m × 2.5 m and the height varies from 150 to 1200 mm, for roofs and floors. Typical distances between supports are 4 m to 12 m for floor panels and 7 m to 18 m for roof panels (see also ETA 07/0029).

The panels are produced in dedicated production units and assembled on site to build horizontal diaphragms as roofs and floors (see figure 2).

The design of such elements is covered by Eurocode 5 (EN 1995-1-1) in cold situation, but in fire situations it is not completely covered by the standards (EN 1995-1-2) which may lead to insufficient reliability.

2 EXPERIMENTAL APPROACH

2.1 *Test setup*

Two floors made up of Kerto-Ripa box elements have been tested in fire conditions and analyzed. In this paper has been briefly described a floor composed with three Kerto-Ripa box elements exposed to ISO-fire (No RTE1057/04) in accordance with EN 1365-2

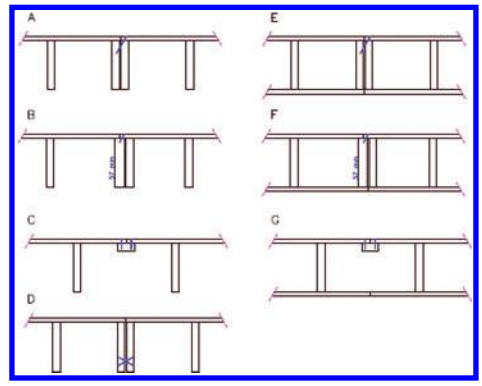

Figure 2. Typical connections between panels to create roof and floor surfaces.

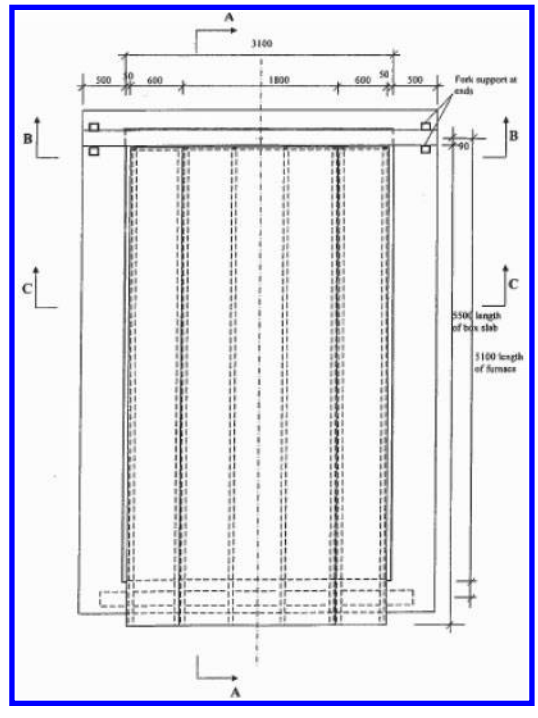

Figure 3. Horizontal view of tested floor.

"Fire resistance tests for loadbearing elements – Part 2: Floors and roofs" (see figures 3, 4 and 5). Only "boxed" panels are suitable for fire exposure without any additional protection (plasterboards ceiling).

The height of the tested floor elements was 337 mm. The bottom and the deck plate, with thickness respectively 37 mm and 26 mm, were composed by Kerto-Q, and joists (b × h = 50 mm × 274 mm) were composed by Kerto-S. Inside each box 100 mm stone wool were installed on the bottom slab. The dimensions of the tested floor were 3100 mm × 5500 mm. It was composed by three elements (see figures 3, 4 and 5). The tested floor was loaded by 32 concentrated loads and 4 hydraulic jacks. Finally the applied load was equal to 5.4 kN/m^2 distributed live load.

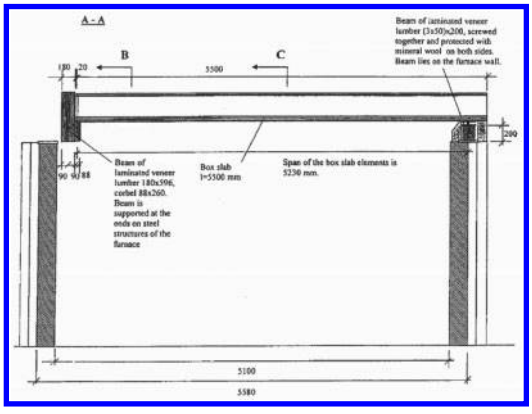

Figure 4. Vertical cut of tested floor in main span direction.

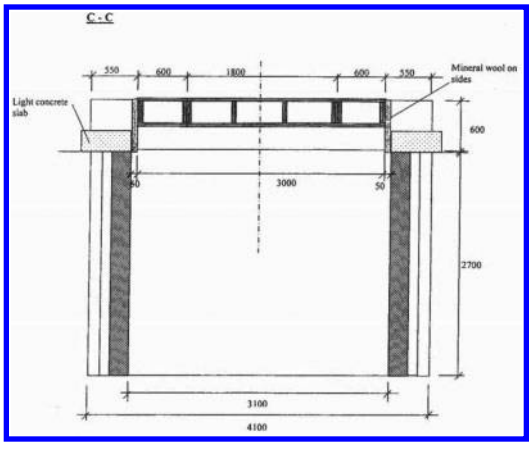

Figure 5. Vertical cut of tested floor in transversal direction.

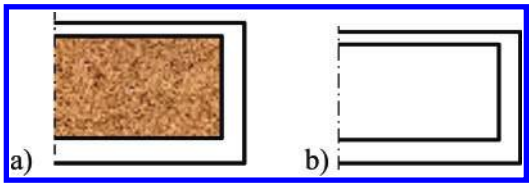

Figure 5. Modelled floor box: a) with insulation, b) without insulation.

45 different temperatures were monitored during the test in order to measure the evolution of the temperature on different points of the floor elements. These measurements allow to define the charring rate of timber elements. Observations inside the furnace and on the opposite side of the specimen have been recorded during the fire test (smokes, visible disorders...). Deflections have also been measured in six locations.

2.2 *Test results*

In order to avoid the collapse of tested specimen the fire test has been stopped after 70 minutes. The bottom plate burnt completely after 47 minutes. Consequently the mean charring rate defined by this test was 0.79 mm/min. The maximal vertical displacement measured in the mid-span of the floor was about 17 mm. The maximum temperature measured on the top of the floor, at the end of the test, was 80°C. Consequently the fire integrity and fire insulation were not affected during the fire test.

In fact the charred boards of the bottom plate remained fastened and supported the insulation until the 62nd minute.

Nearly the same results have been observed in a second fire test (No RTE344/04) realized with a floor of dimensions 1200 mm × 1400 mm, but having the same composition and thickness that the floor described here-above for the first fire test.

3 MODELLING AND DISCUSSION

3.1 *Modelling results*

The figure 6 represents the modelling section of the floor box. The boundary conditions take into account de symmetric thermal actions. Two modelling are realized. In the first one the cavity between the bottom and deck plate was filled with mineral wool and in the second one the cavity is empty. The objective of these two modelling was to study the influence of the insulation over the charring rate of the bottom plate.

Two steps were necessary for the modelling of floor box. The first one allows simulating the heat transfer of the tested floor, given by the figures 3 to 5, in order to find by calculation the same mean charring rate like the one defined by the test.

The second step has been used to simulate the heating of the floor box without insolation and to define the mean charring rate of bottom plate in this case.

The results showed that the charring rate of the bottom plate for the floor box without insulation in the cavity was about 0.72 mm/min. This value is lower that the charring rate of the bottom plate with insulation in cavity.

3.2 *Design of wooden box floors in fire conditions*

The simplified method proposed for the design of wooden box floor takes into account the difference charring rates of the different elements that compose these types of floors. The principle of different charring rates is given by EN 1995-1.2 in section 3.4.3 (see figure 6). It takes into account different charring rates in function of conditions that elements are exposed to fire.

In figure 6 for timber cladding protection or plaster boards type A, (t_{ch}) is equal to (t_f).

The charring rate values for each phase of the curve given by the figure 6 are defined in function of the tests and numerical results.

In the tables 1 and 2 are given the charring rates defined respectively for the design of wooden box floors with or without insulations in cavities.

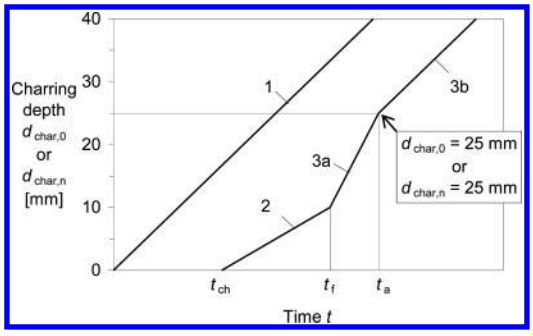

Figure 6. Charring depth vs. time when charring takes place behind the fire protection ($t_{ch} < t_f$).

2, 3a, 3b Relationship for initially protected members where charring starts before failure of the fire protection:

1 Charring starts at t_{ch} at a reduced rate when the fire protection is still in place

3a After the fire protection has fallen off, charring starts at increased rate

3b After the char depth exceeds 25 mm, the charring rate reduces to the rate for initially unprotected members.

Table 1. Data for design of Kerto-Ripa box floors without insulation in cavities.

Classification	Minimal thickness of the bottom plate of Kerto-Ripa wooden box (mm)	Bottom member	Design charring rates (mm/min)	
			For bottom member	For top member and webs
REI 30	21	without protection	0.7	1,4
REI 30	20	protected by one BA13 plasterboard layer, type A	0 : during 15 minutes, 1,3 : during minutes	1,4
REI60	42	without protection	0.7	1,4
REI60	39	protected by one BA13 plasterboard layer, type A	0 : during 15 minutes, 1,3 : during 15 minutes, 0,7 during 30 minutes	1,4
REI60	31	protected by one BA15 plasterboard layer, type F	0 : during 20 minutes, 0,35 : during 7 minutes, 1,3 during 15 minutes, 0,7 during 18 minutes	1,4

The load bearing capacity and the deformations of the elements composing a self-supporting box Kerto®-Ripe, subjected to fire, must be calculated in accordance with EN 1995-1-2, taking into account the charring rates and the assumptions given in tables 1 and 2.

Moreover, the load level of the wooden floor box in cold conditions (applied load/resistant capacity) will not have to exceed 40%.

In fire conditions the maximal vertical displacement (δ_{max}) should not exceed the value given by the following relation:

$$\delta_{max} = L^2/(4300 \cdot (h_1 + h_2 + h_3))$$

Table 2. Data for design of Kerto-Ripa box floors with insulation in cavities.

Classification	Minimal thickness of the bottom plate of Kerto-Ripa wooden box (mm)	Bottom member	Design charring rates (mm/min)	
			For bottom member	For top member and webs
REI 30	24	without protection	0,8	1,4
REI 30	20	protected by one BA13 plasterboard layer, type A	0 : during 15 minutes, 1,3 : during minutes	1,4
REI60	41	without protection	0,8	1,4
REI60	37	protected by one BA13 plasterboard layer, type A	0 : during 15 minutes, 1,3 : during 15 minutes, 0,8 during 30 minutes	1,4
REI60	27	protected by one BA15 plasterboard layer, type F	0 : during 20 minutes, 0,4 : during 7 minutes, 1,3 during 15 minutes, 0,8 during 18 minutes	1,4

where:

- L is the span of the floor,
- h_1, h_2, h_3, are respectively the height of bottom member, webs and upper member.

In order to improve the fire behaviour of wooden box floors protected by plasterboards, fixed directly in the bottom member, the maximum distance between two screws and the minimal length of the screws have been defined.

4 CONCLUSIONS

The fire behaviour of wooden box floors, Kerto-Ripa types, has been studied experimentally. The influence of the insulation in the cavities of box floor has also been studied by numerical simulations.

The analysis of experimental and numerical results made it possible to define the charring rates for the design of wooden Kerto-Ripa box floors in fire conditions.

Furthermore constructive recommendations such as: the maximal load level of box floors in cold conditions, the maximal vertical displacement of box floors in fire conditions and the maximal distances between screws that fix the plasterboards over the fire side of box floors are defined.

Concerning the panels type A, B, C and D (see figure 2), panels without bottom plate, their fire resistance depends completely on the fire resistance of the screens.

More details about the design of wooden box floors composed with Kerto Ripa elements are given by Dhima in the fire resistance report N° CO10.1821.

No-sway collapse of steel frames under fire conditions: A parametric investigation

A. Monti, T. Pariciani, F. Gentili & F. Petrini
School of Civil and Industrial Engineering, Sapienza University of Rome, Italy

ABSTRACT: Fire represents a significant danger for frame structures hosting industrial activities. In this context, the numerical investigation of fire effects and fire induced collapse mechanisms becomes of interest. According to many studies on the topic, two failure modes are identified for a steel frame in fire: an outward (or sway) collapse and an inward (or no-sway) collapse. Above others the failure mode is determined by the following parameters: i) the acting load combination; ii) the typology of the column base restrain and iii) the two interacting mechanical effects of the fire (thermal expansion of the structural elements and thermal degradation of the steel properties). In this paper, a set of nonlinear transient analyses, which take into account for thermo-plastic material behavior and geometrical nonlinearities, has been performed in order to understand the influence of different parameters on the collapse mode of the frame.

1 INTRODUCTION

Portal frame construction is the most common structural typology used in industrial single-storey buildings. A no-sway collapse is characterized by an implosion of the construction envelope consequently of the failure of structural elements. On the other side a sway collapse is characterized by an outward movement of elements. The sway collapse represents a not acceptable threat for single-storey industrial structures in terms of sustainability of constructions, because it can involve adjacent structures and endanger people who are not inside the building.

In this paper some parameters that influence the collapse mode of single-storey frames in fire are investigated. Starting from an initial geometry and fire condition, different schemes have been defined. By means of the commercial non-linear finite element software ABAQUS®, a model of the frame is defined through beam elements.

This study is aimed to understanding on how and why the collapse occurs, to assess the influence of local action and constructional details on the frame behavior under fire action.

2 BEHAVIOR OF SINGLE-STOREY PORTAL FRAMES IN FIRE

The analysis of the effects of internal fires in industrial buildings requires the definition of different scenarios (Gentili, 2011).

In a two dimensional analysis the number of possible scenarios is relatively low: in fact, the fire could affect only one of the columns, both columns or no one of them, but certainly the hot gases heat the rafter.

In an initial fire phase, the portal rafter begins to heat and expand (for the gathering of hot gasses under the ceiling), this causes an outward deflection of the eaves together with an upward deflection of the apex (Wong, 2000). As the fire continues to burn, the rafter temperature rise and the thermal expansion increase (Bong, 2005).

If the columns have an adequate stiffness to retain the thermal expansion of the rafter, plastic hinges are realized on the rafter which loses its resistance and droop into a catenary causing the columns to lean inwards, defining a no-sway collapse. General condition for this kind of behavior is a moment resistant base connection for the column and a ratio of the span to the height to eaves less than two (Newmann, 1990).

On the contrary, if the columns have not a stiffness that is sufficient to retain the beam deformation, large displacements can occur at the top of the columns, so the sway collapse is more probably. Usually, due to the common presence of pinned connections at the bases of the columns, large rotations are possible and the consequence is a sideways of the frame (Song, 2007).

Also the load combination and fire location have an important role for the whole behavior of the structure. Heated elements experiment a decay of their resistance, so are the firsts to reach plastic yielding, and the load define the mode of the collapse.

3 CASE STUDY

3.1 *Initial configuration*

Starting from an initial configuration for the portal frame, some parametric analyses have been carried out to assess the structural behavior under fire condition.

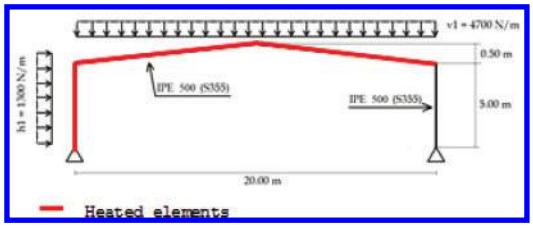

Figure 1. Starting portal frame geometry.

The initial configuration is shown in Figure 1. The IPE 500 standard profile is used for columns and beam, joined with moment and shear resisting connections. The restraints to the ground are assumed to be ideal, frictionless hinges. The constitutive law of steel (S355) used is the relationship defined in the ENV 1993-1-2: Section 3.2 for heating rates between 2 and 50 K/min. Vertical and horizontal loads are also considered as shown in Figure 1.

The considered fire scenario involves the left column and the rafter. This assumption is consistent with the case of a fire triggered in a corner of the structure, so that the most heated elements would be the column near the flame and the beam heated by the hot gasses, that gather under the roof.

The thermal action on the heated element is modeled with the nominal fire curve ISO 834 (European standard curve), shadow effect is not considered. The temperature in the heated elements is assumed uniform and equal to the temperature defined by the fire curve.

The structure is modeled by beam elements; no limits for the rotational capacity of the beam-column connections are considered; bi-dimensional, nonlinear transient analyses have been performed taking into account the effects of displacements on the overall behavior.

3.2 *Collapse mode definition*

With reference to general considerations of the collapse typology given in section 1.1, in the paper, for an asymmetric fire scenario, the following definitions are taken into account:

Inward (or no-sway) collapse is defined when a opposite direction shift of top of the columns is observed at the collapse.

Outward (or sway) collapse is defined when a same direction shift of top of the columns is observed. Sway collapse could be left side or right side direction.

Collapse is defined by the runaway of appropriate parameters.

3.3 *Analysis results*

Three response parameters have been assumed as representative of the structural behavior: the vertical displacement of the mid-point of the beam (dy_{P2}) and the horizontal displacements at the top of the columns (dx_{P1}, dx_{P3}) as shown in Figure 2.

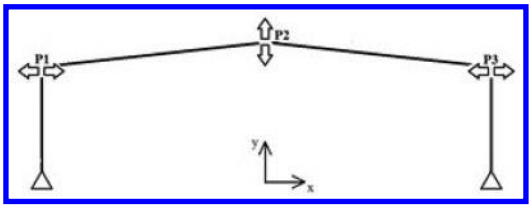

Figure 2. Monitored displacements.

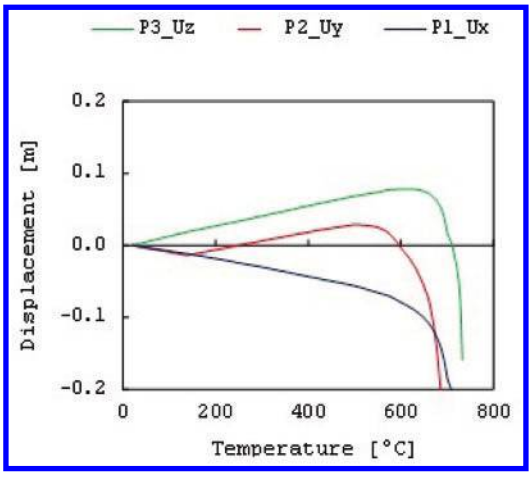

Figure 3. Analysis results.

The trend of these parameters versus the applied temperature for the initial configuration is shown in Figure 3. It is possible to define two different phases. In the first one, under 600°C, the elastic expansion of the rafter causes an outward deflection of the eaves. Then the decreasing of the stiffness of the frame, caused by the plastic hinge formation, lead to a rapid increasing of the displacements. Looking at the direction of the top of the columns displacements is possible to identify a sway collapse to the left side. The critical temperature is 732°C.

4 PARAMETRIC ANALYSIS

4.1 *Problem definition*

A parametric analysis has been carried out in order to understand the influence of the design parameters on the frame collapse modality.

The basic assumptions for the different models are always the same (defined in 3.1), if different specifications are not provided.

The influence of the following parameters on the collapse modality has been investigated: support conditions, load conditions, frame height, column and beam sections. The comparison of the different models is made for eight different column sections.

The outputs monitored are the displacements (defined in 3.3), for the definition of the collapse

mode, and the critical temperature (the temperature of collapse).

4.2 *Pinned vs fixed support conditions*

The first parameter analyzed is the support conditions. A pinned frame (an ideal, perfect, frictionless pinned support) is compared against a fixed frame (rigid, full strength support). The cross section (IPE 500) of the beam has been maintained, while the cross section of the column has been varied.

From the results of the analysis (shown in Table 1) is possible to understand that in case of a pinned support, large rotations are realized and the consequence is a sideways of the frame. In this condition the column's section parameter influences not only the temperature but also the direction of the sway collapse.

A fixed support is able to retain the thermal expansion of the rafter, and the column section variation influence only the temperature and not the mode of the collapse, which is always a no sway typology.

Table 1. Results for pinned vs fixed support.

Columns	pinned	fixed
section	Tcr [°C]	Tcr [°C]
IPE 400	**681**(l-sw)	735(no-sw)
IPE 450	**699**(l-sw)	740(no-sw)
IPE 500	**732**(l-sw)*	746(no-sw)
IPE 550	**726**(r-sw)	756(no-sw)
IPE 600	**723**(r-sw)	765(no-sw)
IPE O600	**723**(r-sw)	776(no-sw)

IPE 750 × 196	**723**(r-sw)	782(no-sw)

(l-sw) left sway collapse (r-sw) right sway collapse
(no-sw) no sway collapse * initial configuration

4.3 *Interpretation of results*

As a result of analysis performed three different collapse typologies have been founded: inward collapse, left side sway collapse and a right side sway collapse.

The only condition able to retain the expansion of the rafter and inducing an inward collapse is a moment resistant for the columns. This can be explained by looking at the evolution of the stress and plastic hinge formation on the structure. Referring to the schematic behavior defined in Figure 4: in the first phase (Figure 4.1.a) due to the thermal expansion of the beam in elastic range, a moment reaction at the base of the columns is induced. That moment increases with the temperature inducing a plastic hinge formation at the base of the heated column (Fig. 4.1.b). The resistance of the beam is reducing so the next plastic hinges are on the beam, due to the plastic expansion (Figs. 4.1.c, 4.1.d) and vertical load (Fig. 4.1.e). The formation of a plastic hinge at the mid-length of the beam creates inward force at the top of the column (due to vertical load), together with an inversion of the moment at the bases of the columns, which rises until reaching the maximum column moment strength.

As expected, increasing the dimension of the columns' section leads to an increasing of the collapse temperature.

Pinned columns' support is not able to retain the expansion of the rafter and inducing an outward collapse. In this case are noticeable two different direction of the sway collapse as defined in Figure 5. The parameter which influences the direction of the collapse is the resistance of beam to column stiffness ratio.

All the left sway collapses happen when the stiffness of the column is less than the beam's one (column's weaker section than the beam's one). As evidenced in Figure 5.1, in this case the first plastic hinge is formed on the top of heated column (Fig. 5.1.b). From this stage both the horizontal load and the force

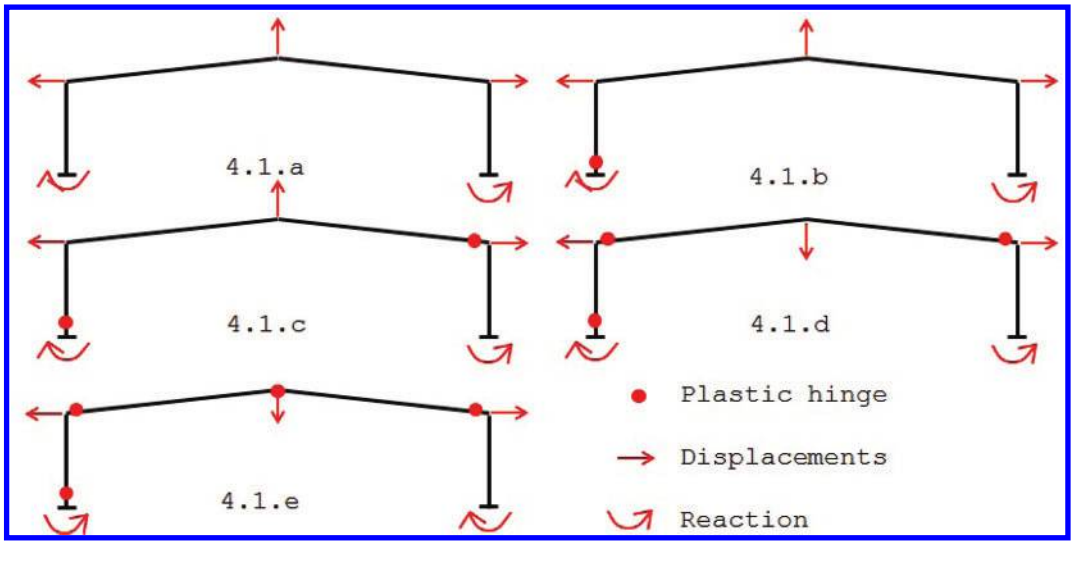

Figure 4. Fixed support collapse scheme.

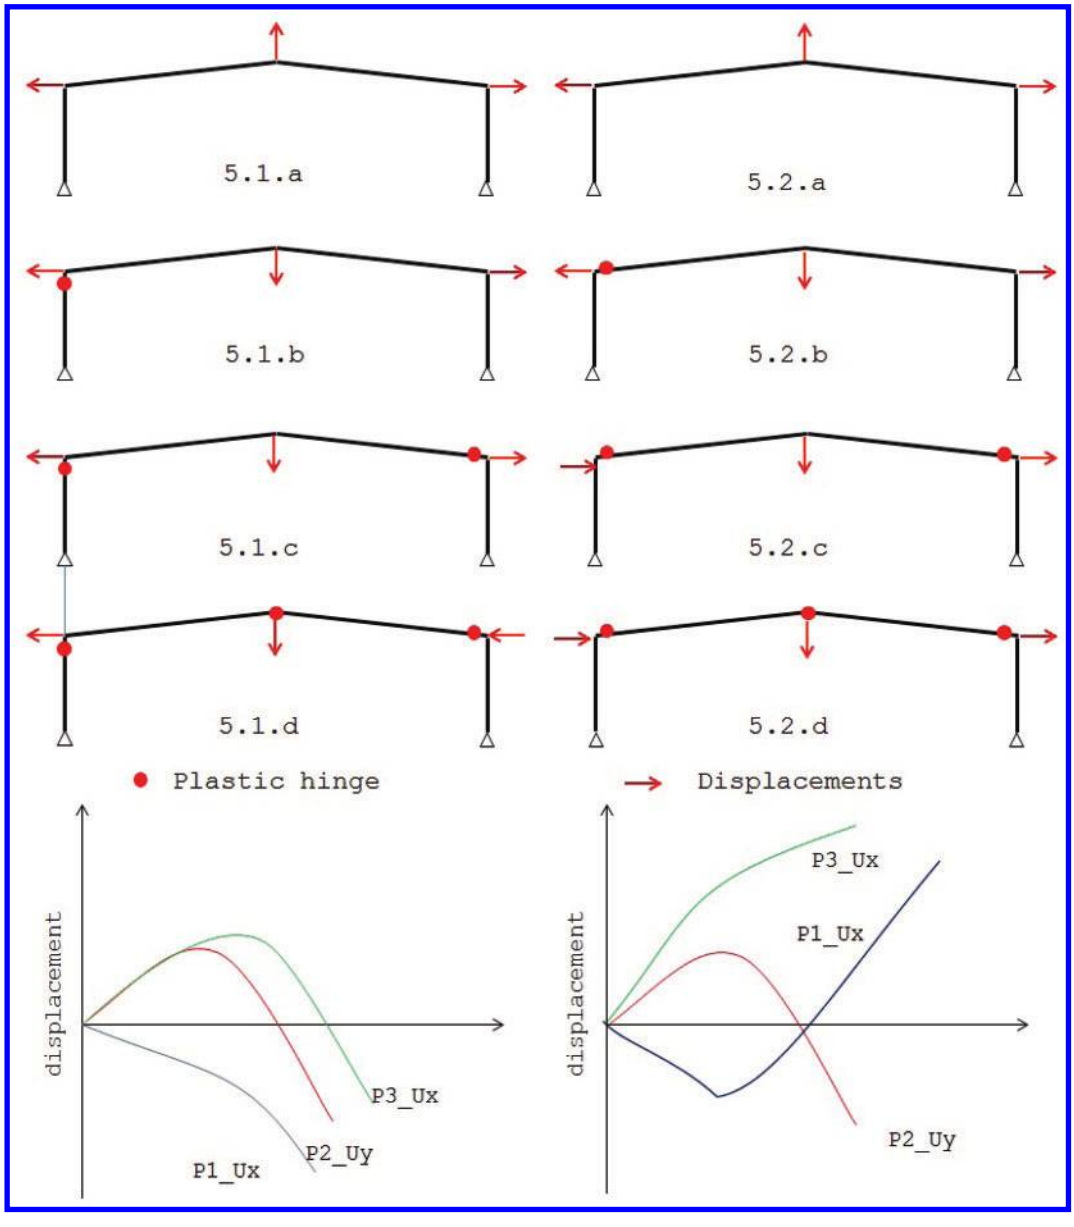

Figure 5. Pinned support collapse scheme. Left sway collapse (left); right sway collapse (right).

induced from the thermal expansion of the beam cause significant deformation of the heated column.

The subsequent loss of stiffness of the structure with the formation of the plastic hinge on the beam, due to the thermal expansion (Fig. 5.1.c) and vertical load (Fig. 5.1.d), determines the collapse towards the heated column, caused from the high plastic deformation on the column and the loss of vertical alignment of the structure. All the right sway collapses happen when the stiffness of the column is greater than the beam's one. As evidenced in the Figure 5.2, this case the first plastic hinge is formed on the beam in proximity of the heated column (Fig. 5.2.b). With the formation of the other plastic hinge on the beam, due to the thermal expansion (Fig. 5.2.c) and vertical load (Fig. 5.2.d) the beam lose its stiffness and the structure became instable for horizontal load, defining by its direction the side of the sway collapse. It is worth to highlight that the value of the collapse temperature increases as the dimension of the columns' cross section grows. This behavior occurs until the cross section of the column is weaker than the beam. While, when the section of the columns became stronger then the beams one (IPE 500) the critical temperature of the portal frame became steady (because the plastic hinge on the rafter happen always at the same temperature).

Is of interest to remark some points:

- when the collapse is induced by the plastic deformation of the beam the temperature of collapse is always equal to the temperature of 723°C due to the collapse of the beam;
- a slight increasing of the temperature of collapse is obtained for frames having the column and the beam with approximately the same stiffness. In these cases the zone of plastic deformation is greater than the previous, the elements are allowed to experiment significant deformations and the stress in the connection between the heated column and the beam are reduced;
- due to the chosen load combination, horizontal load acts in the opposite direction of the thermal expansion induced by the fire, it is possible to point out how, in this condition, the strength of the column in relation to the beam strength is the parameter that influence the direction of the sway collapse.

In conclusion is remarkable that a fixed support frame have a greater resistance to this load combination than the pinned support frame (approximately 3–8% in terms of temperature), this is due to the inversion of the sign of the flexural moment at the base of heated column which delays the collapse.

4.4 *Load conditions*

The second parameter that has been analyzed is the load combination. The section profile of the beam is still a IPE 500 and the columns have a pinned support. Three different load combinations are investigated: LOAD 0 (only vertical load); LOAD 1 (vertical plus horizontal load on the left column pushing to the right side); LOAD 2 (vertical plus horizontal load on the right column pushing to the left side). Results are listed in Table 2.

The results confirm that pinned support is unable to adequately retain the thermal expansion of the rafter and the consequence is a sideways of the frame.

It is important to remark how the LOAD 1 combination is defined from a horizontal load which pushes the frame in an opposite direction from the one of the thermal expansion due to the fire. This is the optimal load condition for the structure and the temperature of the collapse reaches the maximum value. The worst load combination is LOAD 2.

Except for the LOAD 1 case, all the other load combinations cause always a left sway collapse. The collapse explanation is not different from the previous, but when the structure became unstable for horizontal load, the collapse occurs in the direction of the maximum deformation (LOAD 0) or in the direction of horizontal load (LOAD 2).

4.5 *Columns height*

The third investigated parameter has been the columns height. Three different heights are defined, 4, 5 and 6 meters, the span length is always the same, 20 meter. The section profile of the beam is always an IPE 500 and the columns have pinned supports. Results are listed in Table 3. The load combination and the fire scenario considered is the one previously defined as LOAD 1. In this case is important to evidence as the variable parameter is the beam to column stiffness ratio.

The obtained results confirm the consideration given in 4.2.1. When the collapse is induced from the plastic hinge on the heated column, the maximum temperature is not influenced from height and stiffness of the columns. When the collapse is induced by the plastic hinge on the beam the stiffness of the columns has a small influence on the maximum reached temperature (the deformations of slender and longer, column allow greater deformation of the beam).

4.6 *Beam section*

The fourth investigated parameter has been the beam section. Four different beam sections are considered: IPE 450, IPE 500, IPE 550 and IPE 600. The columns have a pinned support and the height of the column is 5 meters while the span of the beam is equal to 20 meters. The load combination and the fire scenario is the one previously defined as LOAD 1. The results are listed in Table 4.1 and Table 4.2.

Table 2. Results for load conditions.

Columns	LOAD 0	LOAD 1	LOAD 2
section	Tcr [°C]	Tcr [°C]	Tcr [°C]

IPE 750 × 196	761(r-sw)	791(r-sw)

(l-sw) left sway collapse (r-sw) right sway collapse
other no- sway collapse * initial configuration

As previously concluded in the 4.2.1 the beam section is the most important parameter in the determination of the resistance of the frame in fire situation. Increasing the strength of the beam the maximum temperature reached from the frame increase. On the other side, is also confirmed how the relationship between the strength of the column and the beam, for asymmetrical fire scenario and opposite horizontal load, is the main factor in the determination of the direction of the sway collapse.

5 CONCLUSION

A wide parametric analysis of a bi-dimensional industrial steel portal frame has been performed in order to understand the fundamental mechanism determining sway or no-sway collapse.

The sway-collapse represents a not acceptable threat for single-storey industrial structures in terms of sustainability of constructions, because it can involve adjacent structures and endanger even people who are not in the building.

From the obtained result is clear how in pinned support columns, large rotations are allowed and a sway collapse always occur. For the sway collapse the beam to column section stiffness ratio and the load combination for asymmetrical fire scenario are the factors that determine the sway direction and the collapse temperature.

Concerning the frames having, In the examined cases, the adoption of moment resisting support for the columns is sufficient to avoid a sway collapse.

Numerical studies of load bearing LSF walls under realistic design fire conditions

P. Keerthan, A. Ariyanayagam & M. Mahendran
Queensland University of Technology, Brisbane, Queensland, Australia

ABSTRACT: Fire safety of light gauge steel frame (LSF) stud walls is important in the design of buildings. Currently LSF walls are increasingly used in the building industry, and are usually made of cold-formed and thin-walled steel studs that are fire-protected by two layers of plasterboard on both sides. Many experimental and numerical studies have been undertaken to investigate the fire performance of load bearing LSF walls under standard fire conditions. However, the standard time-temperature curve does not represent the fire load present in typical residential and commercial buildings that include considerable amount of thermoplastic materials. Real building fires are unlikely to follow a standard time-temperature curve. However, only limited research has been undertaken to investigate the fire performance of load bearing LSF walls under realistic design fire conditions. Therefore in this research, finite element thermal models of the traditional LSF wall panels without cavity insulation and the new LSF composite wall panels were developed to simulate their fire performance under recently developed realistic design fire curves. Suitable thermal properties were proposed for plasterboards and insulations based on laboratory tests and literature review. The developed models were then validated by comparing their thermal performance results with available results from realistic design fire tests, and were later used in parametric studies. This paper presents the details of the developed finite element thermal models of load bearing LSF wall panels under realistic design fire time-temperature curves and the results. It shows that finite element thermal models can be used to predict the fire performance of load bearing LSF walls with varying configurations of insulations and plasterboards under realistic design fires. Failure times of load bearing LSF walls were also predicted based on the results from finite element thermal analyses.

1 INTRODUCTION

Gypsum plasterboard is used as fire resistance material in the building industry due to its ease of fabrication and workmanship, the widespread availability of the primary material for its production, and for the energy consuming (endothermic) dehydration process during fires. Currently, gypsum plasterboard based LSF wall and floor systems are increasingly used in low-rise and multi-storey buildings, but without a full understanding of their fire performance. LSF wall and floor systems are made of cold-formed thin-walled steel lipped channel sections and gypsum plasterboards. Under fire conditions, cold-formed thin-walled steel stud and joist sections heat up quickly resulting in fast reduction in their strength and stiffness. Therefore they are commonly used in structural wall and floor systems with plasterboard linings on both sides used as fire protection (see Figure 1). Gypsum plasterboard protects steel studs and joists during building fires by delaying the temperature rise.

Many experimental and numerical studies have been undertaken to investigate the fire performance of load bearing LSF walls under standard fire conditions. However, the standard time-temperature curve does not represent the modern accessories in typical residential and commercial buildings, where they incorporate both traditional wooden furniture and modern items such as cushion furniture, mattresses, fabric coated partitions and many other items that make use of thermoplastic materials. Therefore finite element analyses were performed to investigate the fire performance of LSF wall systems under recently developed realistic design fire curves (Ariyanayagam and Mahendran, 2012).

2 THERMAL PROPERTIES

In order to develop suitable finite element models of Australian gypsum plasterboard, thermal properties of gypsum plasterboard were summarized based on a series of experimental results (Keerthan and Mahendran, 2012) and past research (Thomas, 2010; Cooper, 1997). These proposed thermal properties were used in the finite element models developed using SAFIR (Franssen et al., 2004). Figure 2(a) shows the proposed thermal conductivity of gypsum plasterboard. In order to include the effect of ablation, the thermal conductivity of plasterboard was modified to 0.80 W/m/K at 1200°C.

Figure 1. LSF wall with gypsum plasterboard lining.

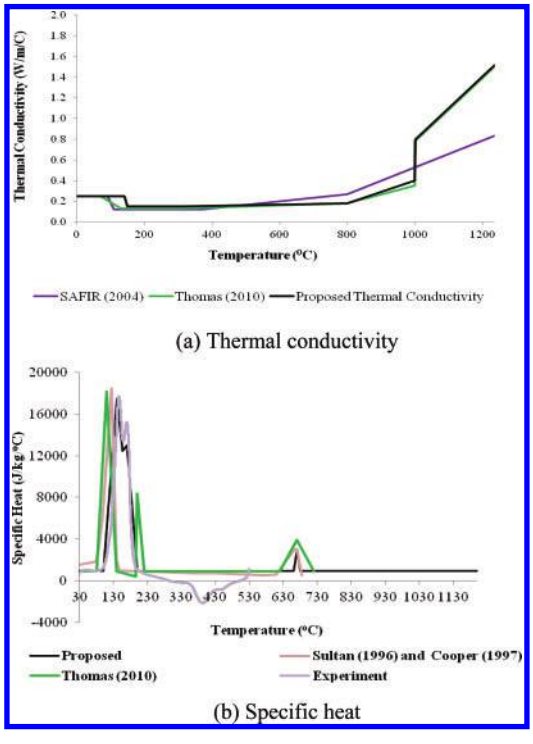

Figure 2. Proposed thermal properties of plasterboard.

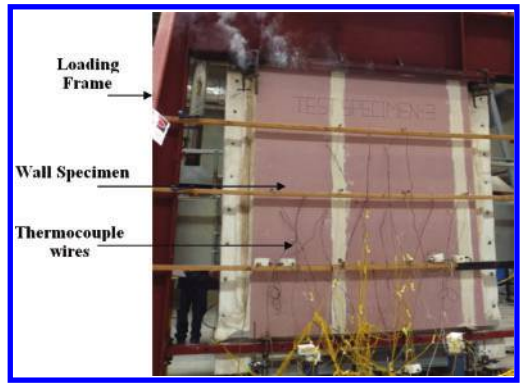
Past research showed some discrepancy in relation to the second dehydration reaction. However, it is concluded that the first and second dehydrations occur at 100 to 150°C and 150 to 200°C, respectively, based on our experiments (Keerthan and Mahendran, 2012). Figure 2(b) also shows the proposed specific heat values as a function of temperature and compares them with test and other researchers' specific heat values (Thomas, 2010; Cooper, 1997). Further details of the proposed thermal properties of plasterboards are given in Keerthan and Mahendran (2012). The specific volumetric enthalpy of gypsum plasterboard is given by the area under the specific heat multiplied by the density versus temperature curve. The proposed specific volumetric enthalpy values were used as input to SAFIR in our thermal analyses.

When the proposed thermal properties were used as input to SAFIR, the time-temperature profiles agreed well with Ariyanayagam and Mahendran's (2012) fire test results.



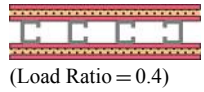


Figure 3. Experimental set-up (Ariyanayagam and Mahendran, 2012).

Table 1. Failure times of LSF walls.

LSF Configuration		Fire Curve	Failure Time
 (Load Ratio = 0.2)	Test 1 Test 2 Kolarkar (2010)	ECS 1 BFD 1 ISO Curve	No Failure 139 min 111 min
 (Load Ratio = 0.2)	Test 3 Test 4 Kolarkar (2010)	ECS 2 BFD 2 ISO Curve	28 min 39 min 53 min
 (Load Ratio = 0.4)	Test 5 Gunalan (2011)	BFD 1 ISO Curve	118 min 134 min

3 EXPERIMENTAL STUDIES

In order to investigate the thermal performance of load bearing LSF wall panels under realistic fire curves, five fire tests of full scale panels of dimensions 2400 mm × 2100 mm were conducted by Ariyanayagam and Mahendran (2012) as shown in Figure 3. The wall assemblies typically consisted of four commonly used cold-formed steel lipped channel section studs (90 × 40 × 15 × 1.15 mm) spaced at 600 mm. The studs were fabricated from galvanized steel sheets (G500) having a nominal base metal thickness of 1.15 mm and a minimum yield strength of 500 MPa. Test specimens were built by lining the test frames with one or two layers of gypsum plasterboards manufactured by Boral Plasterboard under the product name of Firestop. All the plasterboards used were 1200 mm in width and 2400 mm in height with a thickness of 16 mm. There were two groups of wall specimens made of (1) no insulation and (2) external insulation (composite panels). Rockwool was used in composite panels (see Table 1).

Tests were conducted using the recently developed realistic design fire curves (Ariyanayagam and Mahendran, 2012). Figure 4 shows the realistic design fire time-temperature curves used in fire tests while

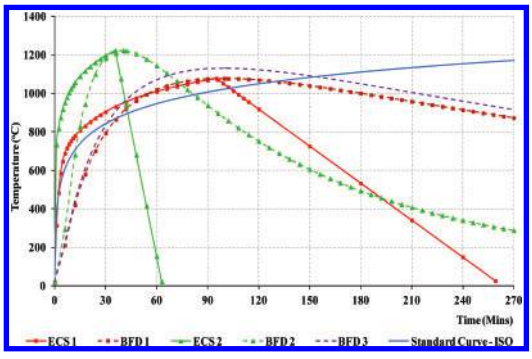

Figure 4. Realistic design fire time-temperature curves used in fire tests.

Table 2. Realistic design fire compartment characteristics used in developing fire test time-temperature curves.

Fire Curve	Opening Factor ($m^{1/2}$)	Compartment Thermal Inertia ($J/m^2S^{1/2}K$)	Fuel load (MJ/m^2)
ECS 1	0.03	702	1268
BFD 1	0.03	702	1268
ECS 2	0.08	715	1268
BFD 2	0.08	715	1268
BFD 3	0.03	585	1268

Table 2 shows the realistic design fire compartment characteristics used in developing fire test time-temperature curves. One face of the test specimens was exposed to heat in a propane-fired vertical gas furnace (Figure 3). Time-temperature profiles at various locations across the specimen thickness were measured during the tests using thermocouples. Table 1 shows the failure times of test specimens. Ariyanayagam and Mahendran (2012) provides a full description of these realistic design fire tests while this section provides their important details and some results.

Table 1 shows that some real building fires (Fire tests 3 to 5) can cause severe damage to LSF wall panels than the standard fire specified in various fire codes while other real building fires (Fire tests 1and 2) are not as severe as the standard fire.

4 NUMERICAL STUDIES

4.1 *General*

This section presents the details of the numerical studies into the thermal behaviour of the tested load bearing LSF wall panels under realistic fire curves and their results. Recently many numerical heat transfer models have been developed (SAFIR, 2004; Alfawakhiri, 2001). There are also many general finite element packages that can be used for thermal analyses. The finite element model employed in this study to predict the thermal behaviour of load bearing LSF wall

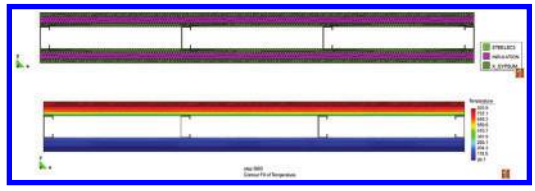

Figure 5. Finite element modelling of LSF wall panels.

panels was based on SAFIR (2004). SAFIR is a special purpose finite element program for the analysis of structures under ambient and elevated temperature conditions. In this research the GID software was used to create the input file for the models as well as analysing the model output results.

4.2 *Thermal boundary conditions and material properties*

The heat flux at the LSF wall boundary conditions can be calculated from the temperature of the fire curve T_g and the temperature on the surface T_s according to Equation (1).

$$q = h(T_g - T_s) + \sigma\varepsilon(T_g^4 - T_s^4) \quad (1)$$

where q is the total heat flux, ε is the relative emissivity, σ is the Stefan–Boltzmann constant (5.67E–08 $W/m^2/K^4$), T_g and T_s are the gas and surface temperatures, respectively. For fire exposure to the standard cellulosic curve, $T_g = 345\log(8t + 1) + 293$. Convective heat transfer coefficient (h) is approximately 25 W/m^2K on the fire exposed side, and it is 10 W/m^2K on the unexposed side. Emissivity of 0.9 was used for both exposed and unexposed surfaces. The proposed thermal properties in Section 2 were used in this research. To investigate the thermal performance of load bearing LSF walls under realistic fire curves, finite element models of Ariyanayagam and Mahendran's (2012) test wall panels were developed. Figure 5 shows the finite element models of LSF walls under realistic fire curves. The developed finite element models were validated using the fire test results of load bearing LSF walls under realistic fire curves (Ariyanayagam and Mahendran, 2012).

4.3 *Validation of finite element models of LSF walls*

To validate the developed finite element models for the thermal analyses of load bearing LSF walls under realistic fire curves, the stud time-temperature curves were compared with the corresponding fire test results from Ariyanayagam and Mahendran (2012). It is noted that load bearing LSF walls exposed to fires are affected by processes not described by heat transfer such as ablation of plasterboard and insulation, migration of moisture vapours and penetration of cool ambient air or hot furnace gases into the cavity. Effects of these processes were taken into account in the models through the use of suitable thermal conductivity values for plasterboards and insulations (Section 2).

Figures 6(a) to (e) show the finite element analysis (FEA) results in the form of temperature versus time curves compare them with corresponding test results. The average time-temperature curves of the studs were considered in this comparison of test and FEA results. These figures indicate that the developed finite element models predict the time-temperature curves of load bearing LSF walls under realistic fire curves with reasonable accuracy. Good agreement was obtained for Tests 1, 2 and 5, where pro-longed fire time-temperature curves are used and in Tests 3 and 4 when rapid fire curves are used FEA overestimated the temperatures. This could be due to the effect of higher rate of temperature increase and corresponding thermal properties. The heating rate of rapid fires is well above 50°C/min, which affected the dehydration reaction of gypsum plasterboard significantly. Also the likely cause for this is the negligence of the processes such as moisture flow and ablation of plasterboards caused by rapid fires in FEA.

In summary, the comparisons between FEA and fire test results confirmed the accuracy of the finite element models in simulating the thermal behaviour of load bearing LSF walls under realistic fire curves and the accuracy of the values used for relative emissivity, convective coefficient and other thermal properties. But for rapid fires FEA predicted temperatures were seen to be higher than the actual test results. In FEA the thermal properties at elevated temperatures used for the standard fire curves were used for both rapid and pro-longed fire curves. Hence a good agreement was obtained for pro-longed fires but not for rapid fire curves. Similar observations were made by Hopkin et al. (2012), Sergey et al. (2012) and Thomas (2010) in their thermal analysis and found that the thermal properties of gypsum plasterboard depends on the heating rate.

Hopkin et al. (2012) found that thermal properties of gypsum plasterboard depend on the heating rate and can result in inaccuracies when they were used in the simulation of temperature development under natural fire conditions. The likely cause of this is the

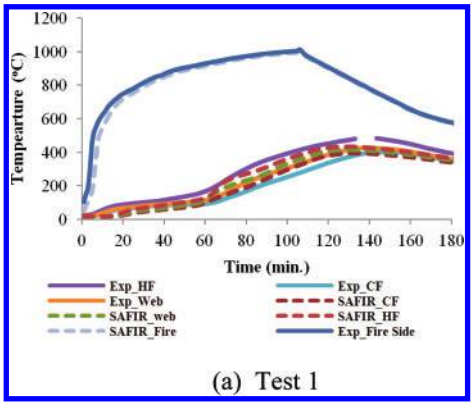

Figure 6. Time-temperature profiles of test specimens (Steel stud).

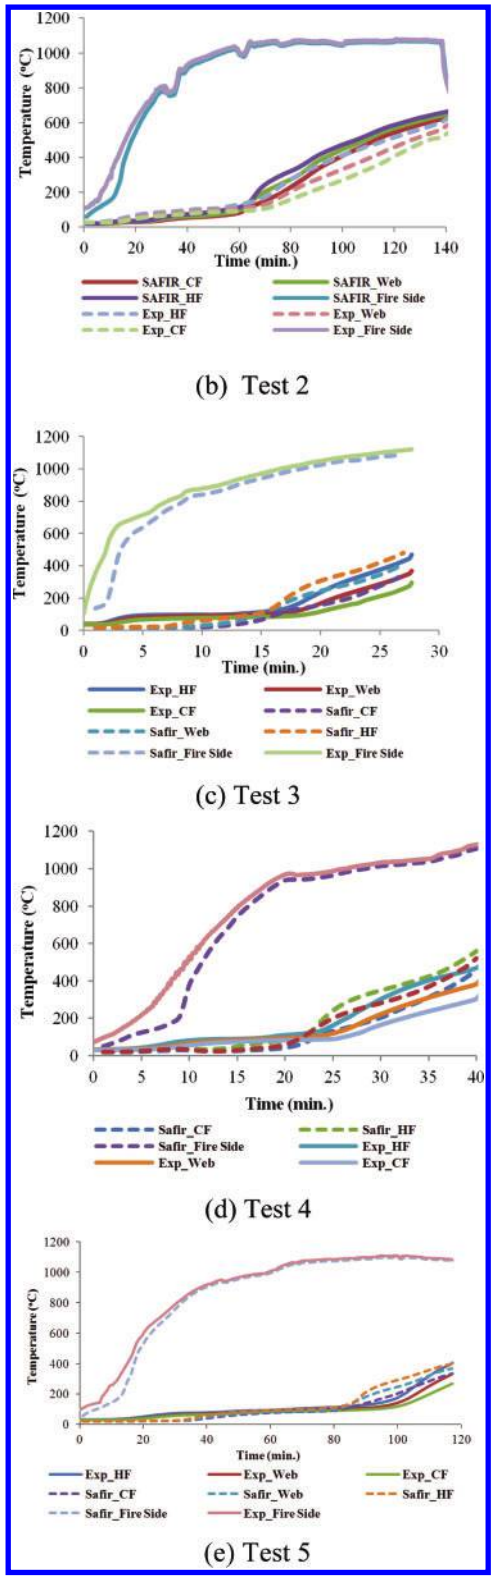

Figure 6. Time-temperature profiles of test specimens (Steel stud). Note: HF- hot flange, CF- cold flange.

relationship between heating rate and other behaviours such as moisture flow, ablation and cracking.

Sergey et al. (2012) developed a mathematical model to investigate the thermal performance of plasterboard panel exposed to hydrocarbon, external and standard fires. Their mathematical models predict the time-temperature profiles of plasterboard panels with good accuracy. However, some discrepancies observed in the early and late stages of the dehydration reaction are shown to be caused by the high local heating rate of the material during those stages. Sergey et al. (2012) found that the heating rate of plasterboard affects the course of dehydration reaction, and it should be accounted for when developing the models of plasterboards.

Thomas (2010) investigated the thermal performance of lined light timber frame walls (LTF) under standard fire, slow developing fire and rapid fire conditions using numerical studies. Numerical studies gave better overall results for slower developing fires than more rapidly growing fires. Their numerical model also overestimated the temperature profiles of LTF walls in the case of rapid fire (Thomas, 2010). Hence detailed experimental and numerical studies will be undertaken to investigate the effect of rapid real fires on the thermal performance of LSF wall panels.

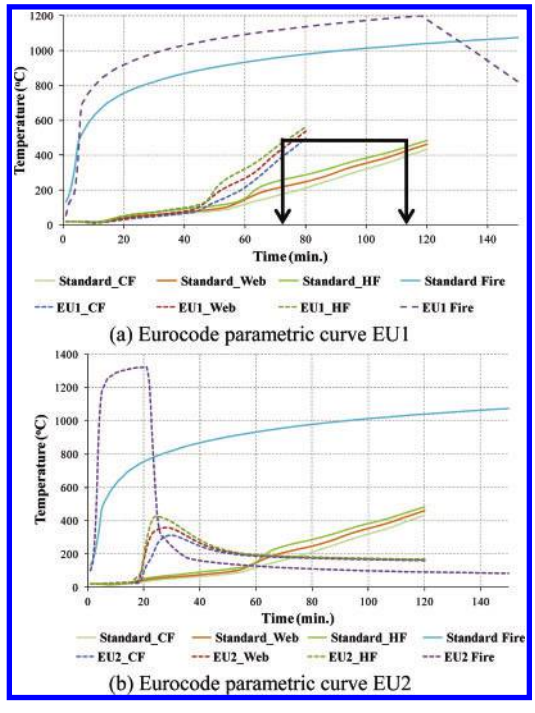

Figure 7. Time-temperature profiles of double plasterboard lined LSF wall under realistic design fire curves (EU1 & EU2).

5 PARAMETRIC STUDIES

A detailed parametric study was undertaken based on the validated finite element model to develop an extensive fire rating data of LSF walls and to investigate the thermal performance of load bearing LSF walls under realistic design fire curves.

Numerical analyses were performed to investigate the thermal performance of three different LSF wall configurations (single plasterboard, double plasterboard and composite panel) under 16 realistic design fire curves (total of 48 FEA). However, only the results for two Eurocode parametric curves (EU1 and EU2) are reported in this section. EU1 and EU2 curves represent the opening factors of 0.02 (EU1) and 0.12 (EU2) as they cover the entire range, and are conservative. Also EU1 (0.02) and EU2 (0.12) are the ideal time-temperature curves for this study on load bearing LSF walls for realistic building fires as they include a rapid (EU2) and a prolonged (EU1) fire curve falling between the two extremes. Figure 7 shows these two Eurocode parametric curves developed for dwellings based on a fuel load density of 1268 MJ/m^2 (ECS, 2002). Figures 7(a) and (b) show the finite element analysis results in the form of temperature versus time for a load bearing LSF wall panel (Double plasterboard) under these two realistic design fire curves (ECS, 2002) and compare them with those under standard fire conditions.

Figure 7(a) shows that the LSF steel stud temperatures under realistic design fires [hot (HF) & cold (CF) flanges, web] are considerably increased in comparison to LSF wall studs under standard fires. This means that the failure time (fire resistance rating) decreases from 111 to 73 minutes based on a limiting temperature of 500°C, ie. 35% reduction. Figure 7(a) shows that the time-temperature profiles of load bearing LSF wall panels under the realistic design fire curve – EU1 are much higher than those under the standard fire curve while Figure 7(b) shows that the time-temperature profiles of load bearing LSF wall panels under the realistic design fire curve – EU2 are lower than those under the standard fire curve. It is clear from Figure 7(a) that realistic design fires such as EU1 can cause severe damage to LSF wall panels protected by two plasterboards than standard fires. However, realistic design fires such as EU2 will not cause severe damage to these wall panels than standard fires (Figure 7(b)). Fire resistance rating is determined based on insulation, integrity and structural failure. This paper uses the limiting temperature of the stud, which is an indirect measure of the structural failure.

Table 3 shows the fire compartment characteristics used in developing Eurocode parametric curves. Figure 8 shows the Eurocode parametric fire curves (ECS, 2002) while Figure 9 shows the stud hot flange temperatures obtained from thermal finite element analyses. Failure times of LSF walls under realistic fire curves can be determined using this figure and the concept of limiting temperature.

6 CONCLUSIONS

This paper has presented the details of a numerical study on the thermal performance of load bearing LSF wall panels under realistic fire time-temperature curves. It included the details of the developed finite element models of load bearing LSF wall panels, the thermal analysis results from SAFIR under realistic design fire curves and their comparisons with fire test results obtained by Ariyanayagam and Mahendran (2012). A reasonable agreement with fire test results showed that accurate finite element models can be developed and used to simulate the thermal behaviour of full scale load bearing LSF wall panels under realistic fire conditions. However, for rapid fires the developed numerical model overestimated the temperature values. This could be due to rapid heating rate and other behaviours such as moisture flow, ablation and cracking. Hence detailed experimental and numerical studies need to be undertaken to investigate the effect of rapid fires on the thermal properties LSF walls.

Numerical study of travelling fire in full-scale experimental building

K. Horová & F. Wald
Department of Steel and Timber Structures, Czech Technical University in Prague, Czech Republic

ABSTRACT: With the view to expand family of traditional design fire models travelling fire is investigated. The paper describes fire test in two-floor experimental building performed in September 2011 in Czech Republic. In upper floor scenario of travelling fire was prepared. As flames were spreading across the compartment considerable temperature gradients appeared. To study travelling fire, FDS 5 was used. Numerical results of gas and beam temperatures validated by experimental measurements were compared to temperatures induced by uniform temperature conditions of zone model and standard temperature-time curve to highlight the level of difference between both assumptions – travelling fire and traditional design fire models. The potential impact of the non-uniform gas temperature on structural behaviour is discussed. The fire test in middle large compartment proved that there were clear needs and benefits in using a travelling design fire as the basis for structural design.

1 INTRODUCTION

The traditional fire design methods used for structural fire analysis are based on assumption of uniform temperature conditions in the entire compartment. Regardless whether the standard temperature-time curve (ISO 834) or parametric temperature-time curve (EN 1991-1-2: 2002) is used, both analytical methods give one temperature distribution in all locations of an enclosure. Zone models as well as introduced analytical methods based on the uniform temperature assumption adopted the justification that there is a small gradient in vertical temperature distribution and even smaller in horizontal direction. However, according to (Stern-Gottfried 2011) the justification has not been evaluated any further. Due to lack of fire experiments in large compartments with real compartment conditions and due to limited number of measuring devices, the presence of horizontal temperature heterogeneity was not investigated and is rarely reported (Stern-Gottfried, 2011).

For the purpose of investigation non-uniform temperature conditions in real compartment (so called travelling fire), a full-scale fire test was executed in Czech Republic in 2011 (Wald et al. 2011). Since the scale of experimental enclosure was not large in comparison to the scale of real buildings, high degree of temperature non-uniformity appeared. Differences in temperature of the upper smoke layer of 400°C confirmed that the homogeneous temperature assumption did not hold well in compartment fires.

Observations of the gas and beam temperature from numerical calculation which were validated by experimental measurements showed that travelling fire had a significant impact on structural behaviour.

2 TRAVELLING FIRE TEST

2.1 *Experimental building*

A two floor composite steel-concrete experimental object of dimension of $10.4 \times 13.4 \times 9$ m was designed (Wald et al. 2011). Composite ceiling slab composed of simple trapezoidal sheets and steel wires reinforced concrete of height 60 mm was supported by IPE 270 and IPE 240 steel beams. Vertical bearing members of round tube columns filled with concrete and columns of sections HEB 200 were used. Ground plan scheme of bearing structure is shown in Figure 1.

2.2 *Fire load*

The fire load using wooden cribs of dimensions 50/50/1000 mm placed into 24 piles (8×3 wooden piles placed closely together) of area 24 m^2 was created. Each pile consisted of 42 cribs. Total volume of ligneous mass of 2.52 m^3 (9.9 kg/m^2) was used. The fire load corresponded to value of 173.5 MJ/m^2. A thin-walled channel filled by mineral wool and penetrated by paraffin placed on the south side of fire compartment served as outbreak of burning. The linear ignition source ensured spreading of fire from the south side of the compartment to the north side, see a scheme at Figure 1. The opening of size 2.0×5.0 m with parapet of 1.20 m ventilated the fire compartment.

2.3 *Measurements*

To measure the gas temperature in the fire compartment 20 jacketed thermocouples with diameter of

3 mm were located at the level of the lower beam flange and the upper beam flange, mainly in direction of fire spread. The temperature of steel beams was measured by 8 jacketed thermocouples located at upper side of lower flange. Besides jacketed thermocouples adiabatic surface temperature was measured by 7 plate thermocouples. In Figure 2 thermocouples to measure gas temperature are marked TG2-TG13. To measure steel beam temperature thermocouple TB2 is highlighted.

The fire spread from the linear ignition source to the opposite side of the compartment accompanied by high degree of non-uniform temperatures was observed. Maximum degree of gas heterogeneity was reached about 15 min between thermocouple TG2 and TG4. Whereas the distance between these thermocouples was only 6 m, temperature difference of 400°C was measured. The highest gas temperature of 979°C was measured on thermocouple TG3 close to the column B2 at 26 min. The maximal steel beam temperature reached 855°C.

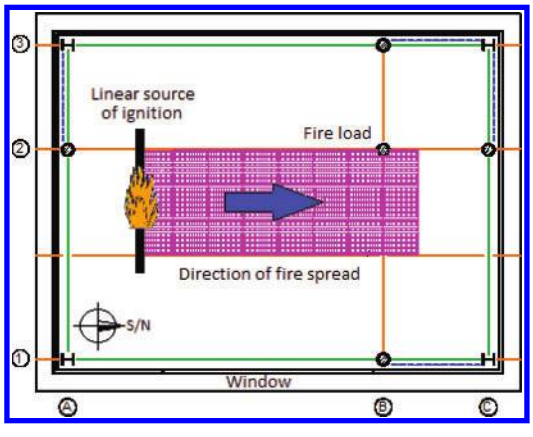

Figure 1. Scheme of fire load in upper floor of the experimental building.

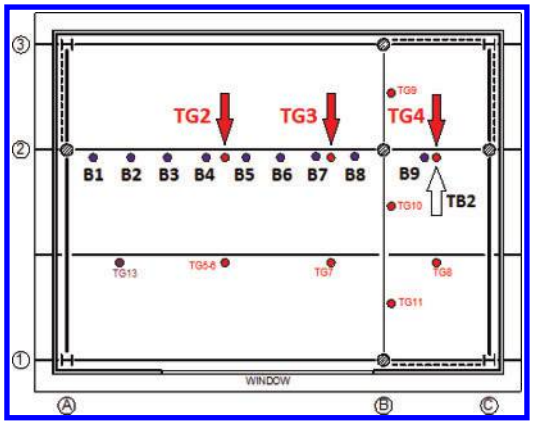

Figure 2. Scheme of gas and beam thermocouples during the experiment and sensor positions during numerical calculation – groundplan.

3 NUMERICAL SIMULATION

3.1 *Model description*

To study the travelling fire scenario numerically, a model corresponding to the size of the upper floor of the experimental building was created. The gas temperature and steel beam temperature were calculated by FDS 5 (McGrattan et al. 2010) to obtain data for evaluation with the fire test.

Four different materials including steel, concrete, mineral wool and wood were used in the model. Properties of wood came from cone calorimeter tests executed immediately after the fire experiment. Obstructions surface properties included steel column filled with concrete, steel beams, concrete walls, floor, ceiling and wooden piles. Burner block of dimensions $0.15 \times 3 \times 0.05\,m^3$ placed under wooden crib in the south edge of the fire load was used to simulate the fire outbreak. Ignition time of wood was ensured by using ramping function. The model was compiled from a total of 24 computational grids of two sizes of cells. Basic cell size was $10 \times 10 \times 10\,cm^3$, cell size around the fire load was $5 \times 5 \times 5\,cm^3$. The total number of computational grid cells reached almost 1 mil.

3.2 *Validation of numerical results*

To validate numerical results, the gas temperature and steel beam temperature measurements from the fire test were used. Figure 3 shows measured (with index *ex*) and calculated gas temperature at thermocouples TG2, TG3 and TG4, located in the direction of the fire spread. Positions of sensors are shown at Figure 2. During growing phase of the fire, slower increase of calculated temperatures compared to the measured values was observed. However the peak temperatures were reached about 25 min by both, calculated and measured values. Regarding maximum temperatures which were closed to 1000°C, tolerable agreement was obtained. In decay phase differences between measured and calculated results were observed. As the increase of calculated gas temperature was slower

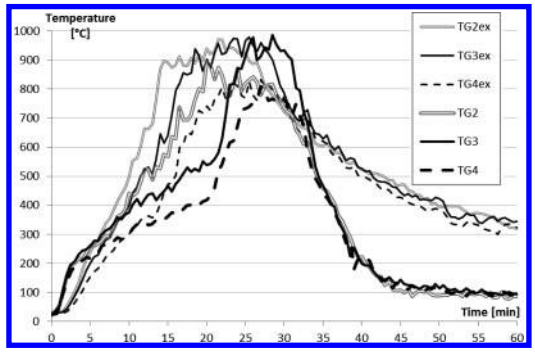

Figure 3. Comparison of measured (index *ex*) and calculated values of gas temperature in three locations in direction of the fire spread.

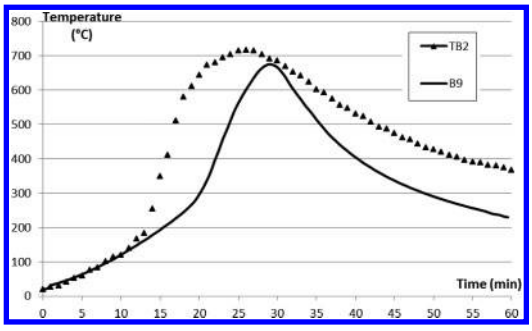

Figure 4. Comparison of measured (TB2) and calculated (B9) beam temperature development.

compared to measured gas temperature, the calculated beam temperature reached its peak temperature in 30 min, 5 min later compared to the measured beam temperature, see Figure 4. The calculated peak beam temperature was 40°C lower compared to the measured values.

However, calculated values of gas and beam temperature were slightly delayed in comparison with the measured values, the numerical model represented the tendency of the measured temperatures mainly in the heating phase, where the highest temperature differences appeared. Numerical calculation confirmed spreading fire phenomena. In order to investigate temperature heterogeneity and its impact on structural behaviour, numerical simulation was applicable.

4 STRUCTURAL RESPONSE TO NON-UNIFORM TEMPERATURES

4.1 *Steel beam temperature during travelling fire*

As the fire spread in the compartment gas temperature under the ceiling fluctuated significantly. In relation to gas temperature variation, structural members were affected. By numerical calculation non-uniform temperature of steel beam was confirmed. Eight sensors were located along the length of the beam 2 with spacing of 1 m from the south side of the enclosure, where the fire started to burn. Beam temperature sensors were placed in the middle of the web (cross-section IPE 270). Length of the beam was 9 m. For positions of sensors B1–B8 see Figure 2. As it is shown in Figure 5 the temperature distribution along the beam length was not uniform. It was highly affected by phenomena of the travelling fire which caused developing of fields with higher and lower temperature of gas. Although heat conductivity of steel was very high, the variance of gas temperature together with direct temperature of flames created temperature fields increasing in accordance to fire spread. In Figure 5, temperature difference between the first (B1) and the last sensor (B8) which reached 250°C is highlighted by lines connecting maximum and minimum values.

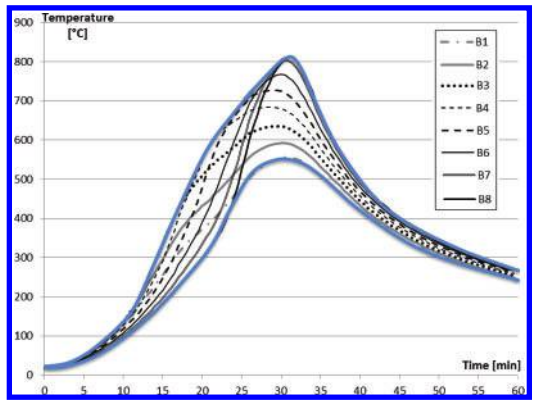

Figure 5. Numerical results of beam temperatures in eight locations with spacing of 1 m.

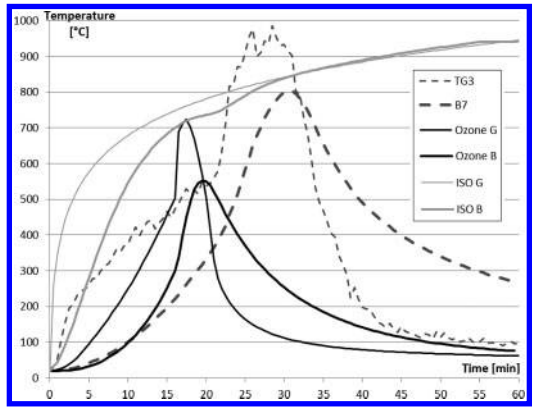

Figure 6. Comparison of gas and beam temperature calculated in FDS (marked TG3 and B7), Ozone (Ozone G and Ozone B) and standard temperature-time curve (ISO G and ISO B).

4.2 *Comparison to traditional design fire models*

In order to compare an impact of the travelling fire on structural behaviour with impact of uniform temperature distribution in the entire compartment, a calculation of the same case was completed in Ozone V2.2 (Cadorin & Franssen 2004). The standard temperature-time curve (EN 1991-1-2, 2002) and curve of uniform temperature distribution in the steel beam 2 calculated by the aid of step-by-step method (EN 1993-1-2, 2005) was introduced as a conservative comparison. The only difference between both assumptions – travelling fire and traditional design fire method was fire outbreak. By both, Ozone and ISO curve which are based on the assumption of uniform temperature across the floor area, it was assumed all wooden piles started to burn in one moment. However, a situation when a fire grew uniformly over an entire floor area could hardly occur. In Figure 6 gas and beam temperatures calculated by both methods were compared. The gas temperature at position TG3 coming from FDS calculation (assumption of travelling fire) induced higher beam

temperature (B7) compared to Ozone gas (Ozone G) and beam (Ozone B) temperature (uniform temperature assumption). The uniformly burning fire within the entire compartment (Ozone) generated high temperature in short time. However, the travelling fire created regions with high temperatures and areas with elevated temperatures with longer duration. In given case the duration of travelling fire was almost double. The travelling fire can therefore cause worse-case fire scenario and more onerous structural conditions. In this figure it can be observed that the highest beam temperature (ISO B) was induced by the standard temperature-time curve (ISO G).

5 CONCLUSIONS

Observations of the fire experiment executed in 2011 in Czech Republic confirmed that the homogeneous temperature assumption did not hold well in compartment fires. Since the scale of experimental enclosure was not large as the scale in real buildings, high degree of temperature non-uniformity appeared.

Numerical simulation of the travelling fire scenario validated by measurement carried out during the fire test verified temperature differences of the upper smoke layer of 400°C. In relation to gas temperature variation, the temperature distribution along the beam length was not uniform. Differences in steel beam temperature varied in 250°C, whereas the length of the beam was 9 m.

However, numerical simulations of large enclosures can have high demands on number of computational operations as well as on time. A compromise between the physical requirements and available potentialities of computer technology can be always found. Accurate prediction of fire growth and spread on the bases of the physical properties of the fire room and the combustibles is a promising approach how to stress the safety and design fire models economy. The method only needs more validation.

The comparison of the numerical simulation of the travelling fire and calculation of compartment fire with uniform temperature conditions finalized in Ozone highlighted different assumptions of temperature by each design fire method. Travelling fire scenario created regions with high temperatures and areas with elevated temperatures with longer duration. However the uniformly burning fire within the entire compartment (Ozone) generated high temperature in short time. In terms of structural temperature the travelling fire caused more onerous temperature conditions. It is therefore important to consider travelling fire scenario into traditional design methods to ensure that the worst-case scenario is considered.

Numerical and experimental investigation of the toxicity and light extinction of fire smoke using experimental data from fire tests of polymers

A. Löhnert, N. Monreal & C. Knaust
BAM Federal Institute for Materials Research and Testing, Berlin, Germany

U. Krause
Otto-von-Guericke-University Magdeburg, Magdeburg, Germany

ABSTRACT: The Fractional Effective Dose model was used to predict the fire smoke toxicity numerically. In this context fire tests were carried out for three different building materials: polyurethane, flame retardant polyurethane and polyvinyl chloride. The fire tests were performed for flaming and smoldering combustion. The aim of the fire tests was to determine the light extinction, the smoke density and the combustion products at varying oxygen concentrations, different temperatures and different irradiance levels. The fire tests were performed in the German DIN-tube and also in the Cone Calorimeter. Stoichiometric coefficients at varying oxygen concentrations and temperatures were determined from measurements. With these stoichiometric coefficients reaction equations were defined and implemented in the Computational Fluid Dynamics (CFD) program, ANSYS CFX. The implemented reaction equations were used to account for different ventilation and temperature conditions in the simulation. The fire and smoke propagation was calculated numerically with CFD in the room corner test geometry. Equations to account for toxicity and light extinction were also implemented and were used to analyse the toxicity and the optical properties of fire smoke with CFD.

1 INTRODUCTION

Fire smoke contains a variety of highly toxic substances and can lead to unconsciousness within a few minutes and to death for critical concentrations. Currently the engineer's methods of fire safety include various procedures to calculate the fire propagation and smoke spread in buildings. However, up to now the evaluation and calculation of smoke concerning its optical properties and toxic potential on the basis of a detailed combustion is still a field of research. Since smoke composition is highly variable and not fully characterised it has to be examined whether and how the chemical composition and the optical properties of smoke are correlating.

A method has been developed that establishes the relation between the smoke components and smoke toxicity.

Increasingly, numerical methods like Computational Fluid Dynamics (CFD) are used to predict fire and smoke spread and for designing fire protection systems. For a given fire scenario (e.g. fire load, smoke exhaust systems, ventilation condition) not only safety parameters such as smoke layer height and visibility but also the influence of heat storage in the component layers of the structure can be predicted taking into account the temperature dependent material properties in the course of time by means of CFD. Several CFD codes with different radiation models, turbulence models and combustion models are available for the user. The temporal and local distributions of chemical components of smoke like CO, CO_2, HCN, HCl and soot can be calculated solving the corresponding balance equations numerically. Experimental and numerical investigations are the major prerequisites of this work.

However, smoke density and toxicity are not scalar quantities and hence a gap exists between the output of the models underlying the CFD simulations and the information needed for fire risk assessment. With respect to this, the development of a method for characterising smoke numerically is a part of a German research project. A smoke model can deliver information about the tenable risk and the rescue situation for people in fire scenarios. It also delivers information about the conditions for fire fighting or how to design smoke extraction systems to prevent fire scenarios. This paper is focused on the analysis of smoke toxicity and the determination of the optical properties of fire smoke from experimental investigations and their numerical calculation with the CFD code ANSYS CFX.

2 FIRE SMOKE, SMOKE TOXICITY AND LIGHT EXTINCTION

There are different ways to characterise fire smoke. Smoke can be divided into two parts. The first part is fire gases and the second part is aerosol properties.

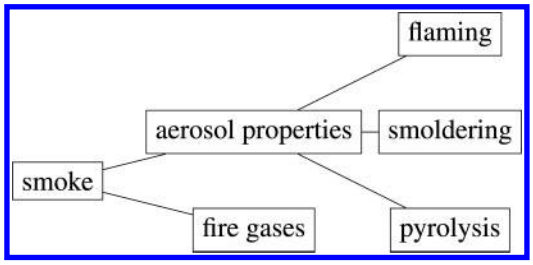

Figure 1. Definition of fire smoke.

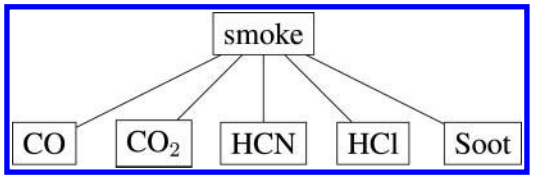

Figure 2. Harmful combustion products of fire smoke.

This is shown in figure 1. Fire gases can be further divided according to the combustion conditions under which smoke is produced (Mulholland 1995).

However, it makes sense to define fire smoke toxicity with those chemical components which affect the toxicity qualitatively and quantitatively. As a consequence a smoke definition was established which includes the relevant harmful products. The composition of the fire gases depends on the available oxygen concentration and temperature in the room and also on the material which is burned. The main harmful combustion products were considered in this investigation and are shown in figure 2.

The fire behaviour of building materials in the combustion process and the combustion products depend on the oxygen concentration and the temperature in the room (e.g. smoldering fire or well-ventilated fire). Therefore two different polyurethanes and a polyvinyl chloride were tested under various oxygen concentrations and temperatures to derive reaction equations for ranges of oxygen concentrations and temperatures.

The assessment of a dose is the first step of calculating fire smoke toxicity. The most important parameters for assessing a dose are the concentration of a toxic substance and the exposure time. The law of the chemist Fritz Haber (Haber's rule) describes the relationship between the concentration of a toxic gas and the duration of exposure until any toxic effect, e.g. incapacitation or death, occurs. The following equation describes the dose by the product of concentration and time, which causes any effect:

$$W = C * t, \tag{1}$$

where W-dose [g*s/l]; C-concentration [g/l]; t-time [s].

2.1 *The fractional effective dose model*

To predict the toxic hazards of fire smoke the concept of the Fractional Effective Dose (FED) is used (ISO13571 2012, ISO13344 2004). The general equation for FED describes a specific dose received at time to that dose, which causes incapacitation or death (Hartzell & Emmons 1988, Purser 1992). The general equation is given below:

$$FED = \frac{\text{dose received at time (Ct)}}{\text{effective Ct dose to cause death}}, \tag{2}$$

where C-concentration [g/l]; t-time [s].

The Fractional Effective Doses of the main components from the fire smoke (CO, CO_2, HCN etc.) are formed for every minute of the exposure interval and then summed up. If the sum of all doses over the exposure time reaches the value 1, incapacitation or death occurs ISO13571 2012.

For the interaction between the main toxic products in fire smoke a fraction of an incapacitating dose for all these narcotic gases is given in equation 3 (Purser 1995):

$$FED_{IN} = [(F_{CO} + F_{HCN}) * V_{CO_2} + F_{O_2}, F_{CO_2}] \tag{3}$$

where FED_{IN} – fraction of an incapacitating dose of all narcotic gases [1]; F_{CO} – fraction of an incapacitating dose of CO [1]; F_{HCN} – fraction of an incapacitating dose of HCN [1] ; V_{CO_2}-multiplication factor for CO_2-induced hyperventilation [1]; F_{O_2}-fraction of an incapacitating dose of low-oxygen hypoxia [1]; F_{CO_2}-fraction of an incapacitating dose of CO_2 [1].

The individual quotients are explained in more detail below.

Carbon monoxide is the result of an incomplete combustion and it is an odourless, colourless, flammable and toxic gas. Already a concentration of 0.15 vol % is critical and 1 vol % leads to death immediately. The fraction of an incapacitating dose for carbon monoxide is given in equation 4 (Purser 1995):

$$F_{CO} = \frac{8.2925 * 10^{-4} * c_{CO}^{1.036}}{30}, \tag{4}$$

where F_{CO}-fraction of an incapacitating dose of CO [1]; c_{CO}-concentration of CO [ppm].

The next toxic component, which has major influence on the smoke toxicity, is hydrogen cyanide (HCN). It is a colourless and a fast acting poison, which diffuses easily through cell membranes. If HCN is absorbed through the lungs oxygen cannot be activated. The lethal dose of HCN is about 0.027 vol %. The fraction of an incapacitating dose of HCN is given in 5 (Purser 1995):

$$F_{HCN} = \frac{1}{exp\,(5.396 - 0.023 * c_{HCN})}, \tag{5}$$

where F_{HCN}-fraction of an incapacitating dose of HCN [1]; c_{HCN}-concentration of HCN [ppm].

Carbon dioxide is a colourless, odourless gas with sour tasting. CO_2 is heavier than air. By no means is it allowed to classify CO_2 as a non-hazardous component

of fire smoke, because a concentration of 3 vol % to 5 vol % causes a low pH-value in the blood. About 12 vol % of CO_2 lead to death. The equation for an incapacitating dose of CO_2 and an equation for a CO_2-induced hyperventilation are given in equation 6 and equation 7 (Purser 1995):

$$F_{CO_2} = \frac{1}{exp\,(6.1623 - 0.5189 * c_{CO_2})}, \tag{6}$$

where F_{CO_2}-fraction of an incapacitating dose of CO_2 [1]; c_{CO_2}-concentration of HCN [ppm].

and

$$V_{CO_2} = \frac{exp\,(0.1903 * c_{CO_2} + 2.0004)}{7.1}, \tag{7}$$

where V_{CO_2}-multiplication factor for CO_2-induced hyperventilation.

Also hypoxia, caused by low oxygen, is integrated in the calculation of all narcotic gases. Hypoxia affects an under supply of adequate oxygen in the body. Dizziness, incapacitation and later death occur if the O_2-concentration decreases under 7 Vol%. The equation 8 is given here (Purser 1995):

$$F_O = \frac{1}{exp\,(8.13 - 0.54 * (20.9 - c_{O_2}))}, \tag{8}$$

where F_O- fraction of an incapacitating dose of low-oxygen hypoxia [1]; c_{O_2}-concentration of O_2 [$vol\%$].

If only the incapacitating dose of CO_2 should be considered then the equation 6 must be applied in equation 3 instead of equation 8.

In addition to the toxicity the light extinction of fire smoke was analysed. The light extinction through fire smoke is responsible for loss of visibility. Furthermore the light extinction is depending on the characteristics of fire smoke. The characteristic of fire smoke is influenced from the chemical components, the size of the particles, the burning behaviour of the material, the combustion conditions, the flow and the temperature field. For the description of the light extinction the transmittance T is used. The transmittance is described with the Beer-Lambert law shown in eq. 9:

$$T = \frac{I}{I_0} = e^{-\kappa * d}, \tag{9}$$

where T-transmittance [1]; I-intensity of the radiation coming out of the media [W/m^2]; I_0-intensity of the incident radiation [W/m^2]; d-path length [m]; κ-absorption coefficient [m^{-1}].

In the numerical simulation the absorption coefficients for the smoke components were specified from literature (Tien et al. 1995).

Both concepts FED_{IN} and the Beer-Lambert law were implemented in ANSYS CFX to predict the smoke toxicity and the light extinction of fire smoke numerically.

3 EXPERIMENTAL INVESTIGATIONS

The smoke production of materials were measured in the German DIN-tube, originally developed to assess smoke production of construction materials. The fire tests in the DIN-tube have been done for the polyurethanes and polyvinyl chloride under different smoldering conditions. Experiments were carried out with oxygen concentrations of 15 vol %, 18 vol % and 21 vol % and temperatures of 473 K, 673 K and 973 K (Loehnert et al. 2012). During the fire test a FT-IR spectrometer was analysing the fire gases. In addition to the FT-IR analysis, the temperature, the oxygen concentration, the flow and the smoke density were recorded during the test. The sample size for the DIN-tube measurements for polyurethane was $10 \times 10 \times 270\,mm^3$. The sample size of polyvinyl chloride is smaller $0.5 \times 0.5 \times 270\,mm^3$ than the sample size of polyurethane, while the masses of the polyurethane and of the polyvinyl chloride samples should be equal. To ensure the reproducibility of the measured values, all measurements were performed at least three times for each test configuration.

In addition to the DIN-tube fire tests further experimental studies were performed with the Cone Calorimeter. This test method is based on the principle of oxygen consumption. The net heat of the combustion is proportional to the amount of oxygen consumed in the combustion process. Approximately 13.1×10^3 kJ of heat is released per kilogram oxygen consumed (Babrauskas 1995). The polyurethanes and the polyvinyl chloride were tested under ambient conditions and with two levels of irradiance (35 kW/m^2 and 50 kW/m^2) (Loehnert et al. 2012).

The sample sizes of the three materials were $100 \times 100\,mm^2$. The thickness of both polyurethane samples was 30 mm and the sample thickness of polyvinyl chloride was 0.5 mm. A more detailed overview of the experiments, which were performed, and a description of the test facilities is available at (Loehnert et al. 2012).

The analysis of the evaluated data and the stoichiometric coefficients e.g. for polyurethane for the different test configurations in the DIN-tube and Cone Calorimeter is shown in figure 3. The x-axis shows the experimental set-up, temperature and oxygen concentration for the DIN-tube and irradiance and oxygen for the Cone Calorimeter. The vertical axis shows the value of the stoichiometric coefficients for every smoke product. Reaction equations for every studied material and test configuration were formed with the generated stoichiometric coefficients. It is assumed that 10% of the mass loss of the specimen goes into soot.

In figure 3 it is shown that the stoichiometric coefficients of CO from the DIN-tube measurements are much higher than from the Cone Calorimeter measurements. Within the DIN-tube measurements the CO-coefficient increases with temperature. It can also be seen that the CO_2-coefficients are much higher in the Cone Calorimeter than in the DIN-tube measurements.

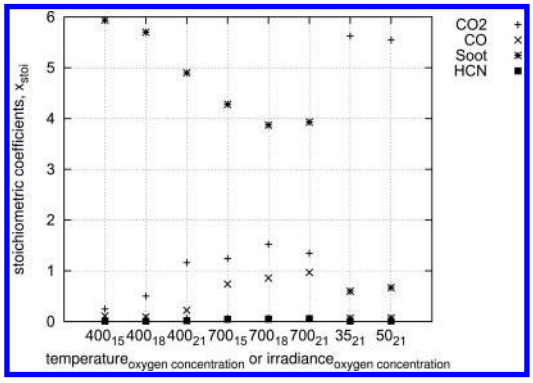

Figure 3. Stoichiometric coefficients x_{stoi} for the smoldering and flaming combustion of polyurethane from the DIN-tube measurements 400_{15}–700_{21} [°C$_{vol\%}$] and the Cone Calorimeter measurements 35_{21}–50_{21} [$\frac{kW}{m^2}{}_{vol\%}$].

By means of the experimental data from the measured concentrations, reaction equations were developed for every range of oxygen concentration, temperatures and irradiance levels. The reaction equations for polyurethane (equation 10) and polyvinyl chloride (equation 11) were formed with the general reaction equations below. The molecular formula for polyurethane is based on literature (Goottuk & Lattimer 2002) and for polyvinyl chloride on (Janssens 2002). Six reaction equations for polyurethane from the DIN-tube and two reaction equations from the Cone Calorimeter measurements can be formed with the values from figure 3:

$$C_{6,3}H_{7,1}NO2 + x_{stoi}O_2 \rightarrow \\ x_{stoi}CO_2 + x_{stoi}CO + x_{stoi}soot + x_{stoi}HCN, \quad (10)$$

where $C_{6,3}H_{7,1}NO_2$-molecular formula for polyurethane; x_{stoi}-stoichiometric coefficient for every smoke product.

In (Loehnert et al. 2012) the same was done for polyvinyl chloride:

$$C_2H_3Cl + x_{stoi}O_2 \rightarrow \\ x_{stoi}CO_2 + x_{stoi}CO + x_{stoi}soot + x_{stoi}HCl, \quad (11)$$

where C_2H_3Cl-molecular formula for polyvinyl chloride; x_{stoi}-stoichiometric coefficient for every smoke product.

4 NUMERICAL INVESTIGATIONS

4.1 *Fundamentals*

The numerical simulation of turbulent fluid flows as well as the heat and mass transfer and chemical reactions are based on physical models of fluid mechanics. The fundamental equations of numerical fluid computation are the continuity equation (conservation of mass), the Navier-Stokes equations (conservation of momentum), the energy equation (conservation of energy) and the turbulence equations. In the present study Reynolds averaging was used and the turbulence model selected was the shear stress turbulence model (SST). All conservation equations mentioned above can be written in a generalized form as transport equation for each mass related and transported quantity (e.g. velocity v, turbulent kinetic energy k), where describes the molecular diffusivity (Yeoh & Yuen 2009, Ferziger & Perié 2002). The generalized form is given in equation 12:

$$\underbrace{\frac{\partial}{\partial t}(\rho\phi)}_{\text{time alteration rate}} + \underbrace{V_j \frac{\partial}{\partial x_j}(\rho\phi)}_{\text{convective transport}} = \underbrace{\Gamma_\phi \frac{\partial^2 \phi}{\partial x^2{}_j}}_{\text{diffusive transport}} + \underbrace{S_\phi}_{\text{production}}, \quad (12)$$

where ρ-density $[kg/m^3]$; ϕ-general scalar quantity (variable); Γ_ϕ to ϕ belonging transport coefficient; S_ϕ-source term of the scalar quantity ϕ.

Radiation is considered by the discrete ordinates approximation model and the calculation of the turbulent flow with the SST turbulence model. The SST model is an eddy-viscosity model, which combines the $k-\omega$ (near-wall region) and the $k-\epsilon$ (in the outer part of the flow) models (ANSYS 2012). The combustion is modeled using the Eddy Dissipation model. The Eddy Dissipation model is an approach to consider the influence of the turbulence using detailed reaction kinetics. When reactants mix at the molecular level, they instantaneously form products (ANSYS 2012).

For the simulation the eddy dissipation combustion model was used. With the use of the eddy dissipation coefficient A it was possible to control the calculation of the different reaction equations. The stoichiometric model used for the combustion of polyurethane is given in equation 10 and the one used for polyvinyl chloride is given in equation 11.

4.2 *Model*

The combustion of polyurethane will be calculated numerically using the commercial CFD solver ANSYS CFX in room corner test geometry (ISO9705 1996) shown in figure 4. The room corner test geometry has the dimension $3.6 \times 2.4 \times 2.4\,\text{m}^3$ shown in figure 5. There is an inlet in the edge at the bottom and a door, defined as an opening. All the other parts are defined as a wall.

A structured mesh with 165.888 elements was generated. The simulation time was $300\,s$ and a time step of $0.01\,s$ was applied for the transient calculation. The convergence criteria were maximum residuals of $1.0 * e^{-3}$ and the conservation target was 1%. The pyrolysis flow rate of polyurethane was 0.015 kg/s for the inlet.

4.3 *Results*

For the numerical calculation of smoke migration and toxicity figure 5 shows the isovolume of a mass

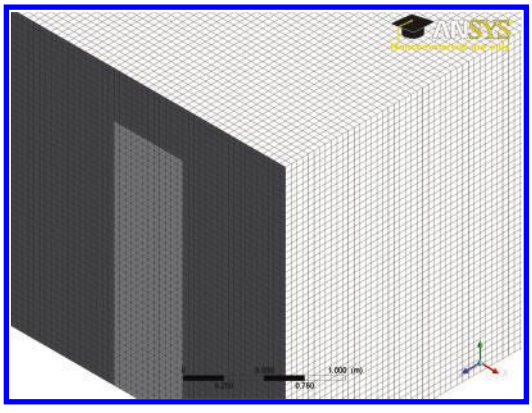

Figure 4. Model of the room corner test with a structured mesh.

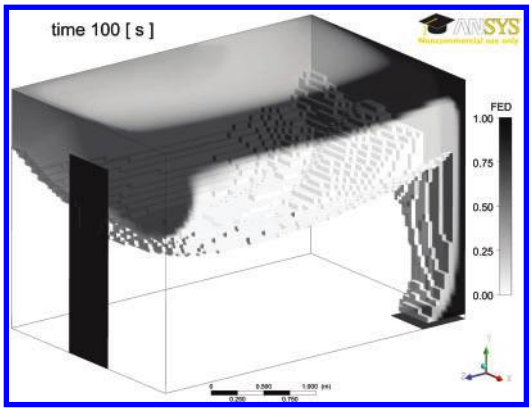

Figure 5. Result of the transient simulation of the FED_{IN} [1] at 100 s for the combustion of polyurethane in the room corner test.

weighted fraction of all fire gases higher than 1% for the combustion of polyurethane at a time step of 100 *s*. The Fractional Effective Dose FED_{IN} is indicated by the greyscale contour within the range of 0 and 1.0. The inhalation of the smoke gases leads to incapacitation or death that is what the FED_{IN} value of 1.0 (dark grey region) means. After 100 *s* the FED_{IN} reaches values from 0.25 to 1.0 for the upper layer in the room. In this case effects like incapacitation have to be expected. If FED_{IN} reaches values equal to 1.0 for nearly every section of the room occurrence of death is very likely. However FED_{IN} values of 0.3 (ISO13571 2012) can already be critical for certain groups of people (e.g. children, old people). Numerical studies of the same scenario without considering HCN lead to lower values for FED_{IN} at the same time. Therefore it is necessary to consider HCN in toxicity assessment for a polyurethane combustion process.

Figure 6 shows the isovolume of a mass weighted fraction of all fire gases higher than 1% for the combustion of polyurethane at a time step of 100 *s*. The isovolume shows the transmittance in greyscale colours.

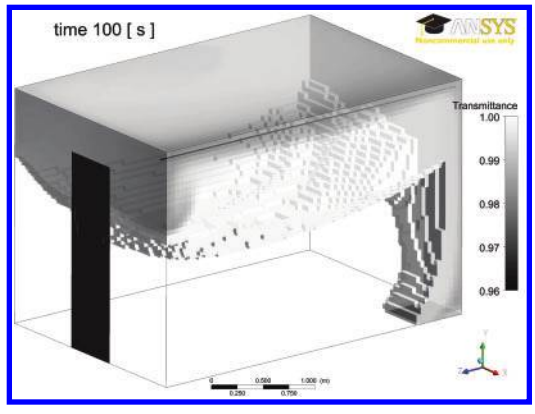

Figure 6. Result of the transient simulation of the value of the transmittance [1] in every cell at 100 s for the combustion of polyurethane in the room corner test.

The transmittance according to equation 9 was calculated for each cell numerically. The calculation of light extinction a long a path and the visibility will be part of the future work and will be shown in the next publication.

5 CONCLUSIONS

The aim to calculate fire smoke toxicity and light extinction with CFD was carried out successfully. The evaluated data from the fire tests in the DIN-tube and in the Cone Calorimeter were the basis to form reaction equations for every studied range of oxygen concentration and temperature/irradiance. At least six reaction equations for the DIN-tube measurements and two for the Cone Calorimeter measurements could be determined for every material. The numerical prediction of fire smoke toxicity and light extinction were realized by implementing the reaction equations from fire tests, the Fractional Effective Dose concept and the equations for calculating light extinction in the commercial CFD code ANSYS CFX. The numerical simulation of fire smoke toxicity respectively the FED value of the fire gases of the combustion of polyurethane could be demonstrated in the room corner test geometry in this paper. With the formed reaction equations from the fire tests and the switching between the reaction equations, it was possible to consider well-ventilated and under-ventilated conditions at the same time. From this follows that different concentrations of the smoldering and flaming combustion products could be consider for calculating the FED and the visibility numerically. The experimental data and the numerical model to calculate smoke toxicity and the optical properties of fire smoke were implemented. From the practical point of view this developed method to predict fire smoke toxicity and visibility could help to guarantee calculated results for fire risk assessment. Also safety parameters such smoke layer height,

temperature and influences of heat storage in a component of a structure can be holistically analysed with the presented method. The next step will be the validation of the model. This is part of recent and future studies. The results will be shown in a next publication.

Development of a simplified design method to predict the fire rating of LSF walls

S. Gunalan & M. Mahendran
Queensland University of Technology, Brisbane, Queensland, Australia

ABSTRACT: Recent fire research into the behaviour of light gauge steel frame (LSF) wall systems has developed fire design rules based on Australian and European cold-formed steel design standards, AS/NZS 4600 and Eurocode 3 Part 1.3. However, these design rules are complex since the LSF wall studs are subjected to non-uniform elevated temperature distributions when the walls are exposed to fire from one side. Therefore this paper proposes an alternative design method for routine predictions of fire resistance rating of LSF walls. In this method, suitable equations are recommended first to predict the idealised stud time-temperature profiles of eight different LSF wall configurations subject to standard fire conditions based on full scale fire test results. A new set of equations was then proposed to find the critical hot flange (failure) temperature for a given load ratio for the same LSF wall configurations with varying steel grades and thickness. These equations were developed based on detailed finite element analyses that predicted the axial compression capacities and failure times of LSF wall studs subject to non-uniform temperature distributions with varying steel grades and thicknesses. This paper proposes a simple design method in which the two sets of equations developed for time-temperature profiles and critical hot flange temperatures are used to find the failure times of LSF walls. The proposed method was verified by comparing its predictions with the results from full scale fire tests and finite element analyses. This paper presents the details of this study including the finite element models of LSF wall studs, the results from relevant fire tests and finite element analyses, and the proposed equations.

1 INTRODUCTION

Cold-formed steel sections are commonly used in various configurations to provide load-bearing Light gauge Steel Framed (LSF) wall systems in buildings. Under fire conditions, cold-formed steel stud sections heat up quickly as they are thin-walled, resulting in fast reduction to their strength and stiffness. Therefore these stud sections are commonly used in planar structural wall systems with plasterboard on both sides as fire protection. Plasterboards protect the steel studs by delaying the temperature rise in the studs during building fires. Since the LSF walls are often subjected to fire on one side, non-uniform temperature distributions will develop across the depth of LSF wall studs. This will induce additional bending moments on the studs due to thermal bowing, neutral axis shift and magnification effects. Hence the thin-walled steel studs will be subjected to combined actions of axial compression and bending moment during a fire event. This fire behaviour of LSF wall panels has been investigated by many researchers in the past and several fire design rules have been proposed. Klippstein (1980) and Gerlich et al. (1996) developed their fire design rules based on AISI design provisions (2007) while Alfawakhiri's (2001) study was based on Canadian cold-formed steel design rules. Ranby (1999), Kaitila (2002), Feng & Wang (2005) and Zhao et al. (2005) developed their fire design rules based on Eurocode 3 Part 1.3 (2006). These design rules are complex and time consuming and hence do not suit routine design purposes.

In order to overcome this problem related to the need for simplified design rules and to address the lack of research data on Australian LSF wall systems, a detailed investigation based on full scale fire tests and finite element analyses was conducted on both conventional Australian LSF walls with and without the use of cavity insulation and the new composite panel system developed recently at the Queensland University of Technology. Details of 10 full scale fire tests and their results including the temperature and deflection profiles measured during the tests are presented in Gunalan et al. (2013) along with the failure times and modes. A suitable finite element model of LSF wall studs subject to fire conditions was then developed using ABAQUS, and validated using the results of fire tests (Gunalan and Mahendran, 2013).

In this paper idealised time-temperature profiles were first proposed for LSF wall studs based on the results from the full scale fire tests. These idealised time-temperature profiles were then used with the validated finite element models to investigate the behaviour of LSF walls. A simple design method was then proposed based on the parametric study results to predict the fire resistance rating of LSF wall panels with varying wall configurations (single and double layers of plasterboards, cavity and externally

insulated) and structural parameters (steel grade and thickness) under varying load ratios.

2 EXPERIMENTAL STUDY

This section provides brief details of the series of full scale fire tests of LSF walls conducted first to evaluate the fire resistance rating (FRR) of load bearing LSF wall assemblies. One wall specimen was tested to failure under an axial compression load at room temperature while ten wall specimens subjected to a constant axial compression load were exposed to standard fire conditions on one side to evaluate their fire performance (Table 1). Conventional Australian LSF wall panels lined with single or double layers of plasterboard with or without cavity insulation were considered. A new LSF wall system based on a composite panel was also included in which external insulation was sandwiched between the two plasterboards (Gunalan et al., 2013).

All the steel frames used in the load bearing LSF wall panels were built to a height of 2400 mm and a width of 2400 mm. The studs and tracks used in the test frames were fabricated from G500 galvanized steel sheets with a nominal base metal thickness of 1.15 mm, a yield strength of 569 MPa and an elastic modulus of 213,520 MPa at ambient temperature. Test frames were lined on both sides by single or double layers of 16 mm gypsum plasterboards manufactured by Boral Plasterboard. Table 1 shows the details of the 10 LSF wall specimens used in this study with two load ratios.

The furnace was designed to deliver heat based on the standard fire curve given in AS 1530.4 (2005). The loading frame was designed (Fig. 1) to load the individual studs of LSF wall specimens in compression from the bottom side using hydraulic jacks.

Figure 1. Experimental Study.

The axial shortenings of the studs and the out-of-plane movements of the wall specimen were measured using linear variable displacement transducers. K type thermocouples were used to measure the temperature development across the wall specimens. The stud (hot flange, web and cold flange) temperatures were measured at three levels for interior studs, namely, at 0.25 H, 0.50 H and 0.75 H, and at mid-height for exterior studs.

In each fire test an axial compression load of 15 kN (for a load ratio of about 0.2) or 30 kN (for a load ratio of about 0.4) was applied to each stud (i.e. 0.2 or 0.4 times the ultimate capacity of each stud at room temperature as obtained by Kolarkar (2010)). The load was held constant at room temperature before the furnace was started and then maintained throughout the fire test. During the fire test, the furnace temperature was regulated to follow the standard time-temperature curve. The test was stopped after one or more of the wall studs failed, and the time to failure was recorded. Table 1 shows the failure times obtained from the experimental study. Further details are given in Gunalan et al. (2013).

3 IDEALISED TIME-TEMPERATURE PROFILES

Table 1 shows the LSF wall test configurations and insulations used in the experimental study. The new externally insulated wall panels with glass fibre and rockwool were tested under two load ratios of 0.2 and 0.4. Hence these 10 full scale fire tests were essentially conducted using eight different wall configurations (Table 2). Therefore idealised time-temperature profiles were developed for these eight wall configurations using the measured hot and cold flange temperature distributions along the wall stud. In the development of idealised time-temperature profiles of studs with externally insulated glass fibre and

W/C – Wall Configuration; HFT – Hot Flange Temperature; CFT – Cold Flange Temperature.

rockwool, the average temperature values of the two fire tests were used (load ratios of 0.2 and 0.4 – Tests 1 & 2; Tests 3 & 6*). The critical stud in a LSF wall panel was the stud with the vertical plasterboard joint against it. The temperature values of this stud were high compared to other studs due to the opening of this vertical joint at higher temperatures. Therefore the average temperatures along this stud were considered in the development of all the idealised time-temperature profiles for LSF wall studs under standard fire conditions.

When the LSF wall was subject to standard fire conditions, the hot and cold flange temperatures of the stud were 20°C for the initial few minutes. They then increased gradually (linearly) to reach 100°C and remained at the same temperatures during the plasterboard dehydration process. After this the steel temperatures increased rapidly with time. Table 2 shows the time-temperature values of hot and cold flanges up to 100°C. Beyond 100°C, Equations 1 to 8 represent the idealised time-temperature profiles for the LSF wall panels with eight configurations shown in Table 2, where T_{HF} and T_{CF} are the average hot and cold flange temperatures in °C and t is the time in minutes.

1) LSF wall lined on both sides by a single layer of plasterboard (Test 1*).

$$T_{HF} = -0.1066t^2 + 20.17t - 165 \quad (15 \le t) \quad (1a)$$
$$T_{CF} = 10.29t - 125 \quad (22 \le t \le 50) \quad (1b)$$
$$T_{CF} = 29.35t - 1090 \quad (50 < t \le 60) \quad (1c)$$
$$T_{CF} = T_{HF} \quad (60 < t) \quad (1d)$$

2) LSF wall lined on both sides by two layers of plasterboard (Test 2*).
