Using the IFFT, in order to get a result compatible with the period of the simulation desired, a correct discretization of the wave spectrum is needed. Let T_{sim} and N be the simulation time and the number of samples, respectively. The time increment is $\triangle t = T_{sim}/(N-1)$, while the time vector is defined as $t_p = p\triangle t$ with $p = 0, 1, 2 \ldots, N-1$. The increment of the wave circular frequency used to discretize the wave spectrum is $\triangle\omega = 2\pi/(\triangle t N)$ and the frequency vector is defined as $\omega_m = m\triangle\omega$ with $m = 0, 1, 2, \ldots, N-1$. In this way the IFFT returns a correct result compatible with the simulation time T_{sim} and with the number of samples N.

Note that before using the IFFT to compute the 2nd-order terms, Eq. (7) is rewritten as

$$\eta_2^{\pm}(t_p) = \Re\left[\sum_{m=1}^{N}\sum_{n=1}^{N}[X_{mn}^{\pm}\exp(-i(\omega_m \pm \omega_n)t_p)]\right] \tag{10}$$

with

$$X_{mn}^{\pm} = A_m A_n B_{mn}^{\pm} exp(-i(\phi_m \pm \phi_n)) \tag{11}$$

The double summation in Eq. (10) is conveniently rewritten using only one summation. This expedient reduces significantly the computational effort.

$$\eta_2^{\pm}(t_p) = \Re\left[\sum_{j=1}^{N} Y_j^{\pm}\exp(-i(t_p\omega_j)\right] = \Re\left[\sum_{j=1}^{N} Y_j^{\pm}\exp\left(-i\left(\frac{2\pi jp}{N}\right)\right)\right] \tag{12}$$

Table 1. Key properties of the NREL 5-MW BaselineWind Turbine.

Rating Power	5 MW
Rotor Orientation, Configuration	Upwind, 3 Blades
Rotor, Hub Diameter	126 m, 3 m
Hub Height	90 m
Cut-In, Rated, Cut-Out Wind Speed	3 m/s, 11.4 m/s, 25 m/s
Cut-In, Rated Rotor Speed	6.9 rpm, 12.1 rpm
Rated Tip Speed	80 m/s
Rotor Mass	110 t
Nacelle Mass	240 t
Tower Mass	347 460 t
Pile length, diameter	30 m, 6 m
Tower top diameter, wall thickness	3.87 m, 0.019 m
Pile wall thickness, total weight	0.060 m, 187.90 t

The term within the summation in Eq. (12) is the definition of the IFFT of $Y_j^{\pm}$. The second-order Fourier coefficients $Y_j^{\pm}$ are given as follows

$$Y_j^+ = \sum_{j=m+n-1} \sum X_{mn}^+ \quad \text{and} \quad Y_k^- = \sum_{k=|m-n|+1} \sum X_{mn}^- \quad (13)$$

In the computation of Y_j^+ and Y_k^- it is necessary to consider all the pair of frequencies that yield to values of j and k included between 1 and N. The second order wave kinematics components may be evaluated using the same procedure and changing only the expression of the Fourier coefficients (Agarwal & Manuel 2011).

4 5-MW WIND TURBINE REFERENCE MODEL

The turbine model used in this study is the 5-MW Reference Wind Turbine for Offshore System Development (Jonkman, Butterfield, Musial, & Scott 2009), whose main characteristics are listed in Table 1. Further details are available in (Jonkman, Butterfield, Musial, & Scott 2009), (Kooijman, Winkelaar, & van der Hooft 2003) and their bibliography. The diameter and the wall thickness vary linearly with the tower height. The base diameter of 6 m is equal to the diameter of the monopile.

5 EFFECTS OF WAVES MODELS ON THE TURBINE RESPONSE

The following results are obtained reproducing a sea state characterized by the $H_s = 6$ m and $T_p = 9.8$ s and a mean hub-height wind speed $U = 24.00$ m/s (Faltinsen 1990). Given that this wind speed is below the cut-out level, the turbine can be either in parked configuration or in power production. The following results are limited to the parked case obtained turning the blades pitched to feather (at a pitch angle of 90°). A total simulation time of 915 s is reproduced.

The domain decomposition strategy is applied considering a steepness threshold $ka_{\min} = 0.22$ which, in the present simulation, is exceeded three times, see Table 2. The selected sea state has a mean wavelength $\lambda = 90.23$ m. The subdomain sizes are $\delta x_t/\lambda = 1.5$, $\delta_1 t_{i_b}/T_p = 14$, $\delta_2 t_{i_b}/T_p = 6$.

Table 2. Time instants and steepnesses of the nonlinear events detected in the simulation.

Number of subdomains	3
$\bar{t}_{\bar{b}}$ [s]	[251.05 475.48 799.77]
$\bar{ka}$	[0.23 0.25 0.24]

Figures 3 and 4 show time series of the hub-height longitudinal wind velocity (top panel), the wave elevations (second panel from the top) and the system response: tower-base shear (TwrBsFxt) and bending moment (TwrBsMyt) and, in the bottom panel, the tower-top fore-aft displacement (TTDspFA).

Around $t = 240$ s, see Figure 3, the FNL model with domain decomposition (FNL w dd) confirms its efficiency in capturing the actual nonlinear behavior of the waves. FNL w dd solution is in fact the same as the FNL model without domain decomposition (FNL w/o dd) that is assumed as target solution. Whereas, it is noted that the 2nd-order model underestimates the wave elevation. Approximatively at $t = 235$ s nonlinearities higher than the second order (see red or magenta curves in Figure 3) are responsible for a significant increase of TwrBsFxt and TwrBsMyt peaks. On the contrary, likewise the linear theory (blue curve), the the 2nd-order model (green curve) results inadequate because underestimates the response.

A very similar pattern is observed in Figure 4. At approximatively $t = 475$ s (center of the subdomain), an excellent agreement is observed between the FNL w dd and the target solution FNL w/o dd. This event is clearly characterized by high-order nonlinearities which make the fully nonlinear solver fundamental to properly reproduce the system response. The small differences between the FNL w dd and FNL w/o dd models observed around $t = 410$ s are caused by the ramp functions.

Peaks due to the higher order components, Figure 3 shows that the resonant vibrations of the tower, see from $t = 215$ s on, at 0.28 Hz (its first fore-aft natural frequency) is amplified and it is more persistent when the FNL models (either with or without the domain decomposition) are employed. Differences are also observed in the tower motion shown in Figure 4 (bottom panel) where again the FNL w dd is closer to the FNL w/o dd, whereas the 2nd-order model is more similar to the linear solution.

6 CONCLUSIONS

A comparison among the use of linear, weakly and fully nonlinear (with and without domain decomposition strategy) irregular wave models on the dynamic

response of an offshore wind turbine has been presented. The main findings of this preliminary study is that 2nd-order components in the wave kinematics are often not able to reproduce the actual response of the system even for moderate sea states. Moreover, it has been shown that the domain decomposition strategy is very efficient – it permits achieving almost the same accuracy as the FNL model the target solution with a saving of about 50% in terms of computational time. (Note that this reduction can be further reduced by increasing the minimum steepness threshold used to identify the subdomains.). Further developments will improve the domain decomposition technique by coupling linear, 2nd-order and FNL solvers. This will permit a significant reduction of the transition zones further increasing the reliability of the domain decomposition approach.

Structural health monitoring for life-cycle estimation of on-shore wind energy converters

R. Höffer, D. Hartmann, S. Lachmann, X. Liu & K. R. Leimbach
Ruhr-Universität Bochum, Faculty of Civil and Environmental Engineering Sciences, Germany

ABSTRACT: The necessity for service and health monitoring for the detection of damages of the structure of Wind Energy Converters (WEC) is science-based as the main hypothesis of this paper. A modern monitoring concept is explained and a damage detection methodology by system identification is adopted. The sensor instrumentation at a reference wind energy converter WEC is shown which forms one of the fundaments of a tailor-made automatic service and health monitoring system. Data from 3D accelerometers, displacement transducers, thermo-elements and 3D ultrasonic wind speed anemometers is continuously logged and stored in a long-term database. In a first step, spatial stress cycles are evaluated from compensated displacement time histories and used for a service strength check of the steel shaft of the WEC. Such approach permits a realistic estimate of damage accumulation and a subsequent estimation of the residual structural life time. In a second step, possible structural damages shall be detected and localized. This requires a drastic increase of the scanning density of displacement quantities. Suitable measurement solutions are described.

1 INTRODUCTION

The direct excitation of structural oscillations of a WEC is in general due to wind forces from stochastic turbulence and from the non-homogeneities of the flow in the wake of windward positioned converters in group configurations. In addition, control errors of the actuators of the blades, hunting (oscillating) of the electric generator and interactions with main fluctuations can amplify vibrations of the entire system. The susceptibility of the plants grows as the next converter generation has larger rotor diameters and hub heights. Obviously, in the future, such wind park configurations will become customary. In this context, main fluctuation due to labile energy feeding input can be more relevant than in the past. Also, investments for surveying and maintenance of wind energy plants will follow the modern concepts mentioned above. The demand of a basic concept for the service and repair that can be applied to the structure of wind turbines is that repair and/or strengthening can be planned and conducted with minimized investments and losses of service time ensuring a reliable serviceability.

Monitoring can be a qualified basis for continuous strength checking of the structure of wind converters. In recent years, structural elements of wind energy converters have been monitored in order to control and steer the blade and gear configuration during power production, to alert about dynamic overloading, and to detect dangerous conditions such as icing. New and modern monitoring concepts aim more at the identification of present or developing damages to provide an advanced estimation of the residual lifetime of the structure of the wind turbine.

To this, the applied sensor systems for periodical and/or continuous monitoring are predominantly acceleration sensors, cycle transmitters, strain-gauges, and inductive displacement transducer, where the accuracy of such systems depends strongly on the local peculiarities. Previous sensor systems have mainly been used for sensing purposes within a specified recording concept. By contrast, relatively new applications employ optical displacement detectors or radar interferometers. Both devices are mostly based at an outside reference positions adjacent to the WEC.

New research aims at the detecting of detrimental alterations of system responses including the rotor, the transmitting power train, the gear mechanism, the generator as well as its interaction with the electricity network, and the load bearing structure of a WEC. To this end, the determination of clear indications for present damages or developing deteriorations using a remote observation data base is mandatory (Volkmer et al. 2011; Lachmann et al. 2011b). A further target is the use of the sensing data for life cycle management strategies.

2 MONITORING SYSTEM

2.1 *Monitoring system and evaluation of stress resultants*

The object of this pilot application is a WEC which has been in operation for the past sixteen years. The present instrumentation concept (Höffer et al. 2012), of the monitoring system has been installed on the WEC four and a half years ago as shown on Figure 1. Following this concept six three-dimensional accelerometers, six

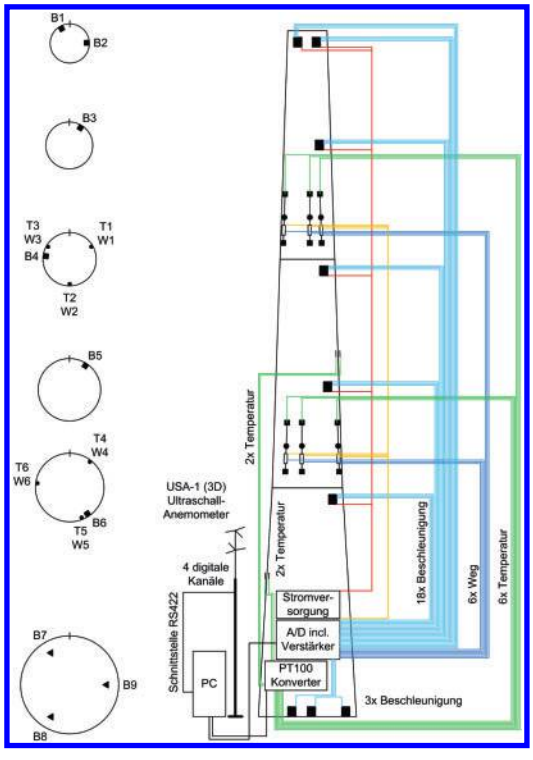

Figure 1. Schematic of the data-acquisition system.

inductive displacement transducers and ten temperature sensors have been installed on the steel tower of the WEC. The accelerometers are distributed over five levels. They mainly serve to identify the free vibration frequencies and mode shapes of the tower structure. The displacement transducers are arranged on two levels each with an angular spacing of approximately 120 degrees. Their nominal range amounts to 5 mm.

If linear material behavior is assumed, the vertical length variations, which are collected over a distance of 500 mm, can be transformed into a corresponding stress distribution of the steel tower. To eliminate the thermal effect of within the measured displacements the temperature of each round steel bar connected to the displacement transducers is measured with a surface temperature sensor. There are two additional points on different elevations on the tower equipped with inner and outer temperature sensors for measuring the temperature gradient of the tower wall.

In addition, three seismic accelerometers have been installed on the foundation. For continuous monitoring of the horizontal wind speed, the wind direction, the vertical wind component and the air temperature, a three-dimensional ultrasonic anemometer is placed on a telescopic mast at an elevation of thirteen meters above ground, adjacent to the tower. The sensing data are collected through three different dataloggers, which are connected to the on-site computer. This computer is also charged with the transfer of the measured data via a high-speed internet connection to

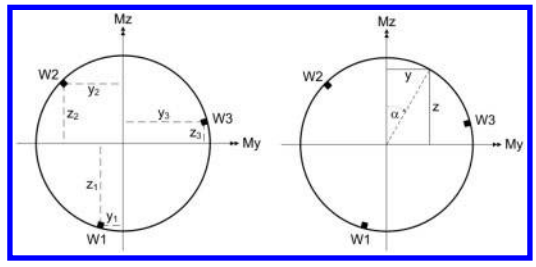

Figure 2. Definition of coordinates for stress analysis.

a remote server system. The latter resides on the remote computer, to synchronize and to transfer the data to a relational database, at which a multi-agent software technology is utilized. For interrogation purposes, the database can be easily accessed by a web-service enabling the creation of plots of various measured signals in parallel.

Signals provided by the customer interface of the wind turbine are logged synchronously such that meaningful comparisons are possible. Details included are the rotor speed in revolutions per minute of the rotor, the amount of electrical power, the azimuth angle of the rotor, the pitch angles of the rotor blades, and the wind speed measured by a cup anemometer at 67 m above ground.

The fatigue analyses (Lachmann & Höffer 2013), are conducted at two levels at elevations 21.5 m and 42.5 m, where the displacement transducers are installed. In relation to a reference length of 500 mm the strains and stresses in the tower wall can be calculated from the measured displacements following the linear elasticity theory. With a structure-embedded coordinate system (Fig. 2) having been defined, the stress plane and the fluctuating parts of the bending moments can be calculated. The fluctuating stresses in each point of the circumference of the steel tower can determined from the fluctuating bending moments.

The fluctuating normal stress, σ_N, is computed as the geometric average of the three measured stresses σ_1, σ_2, σ_3. The fluctuating bending moments can be determined from measured stresses of two sensors. The fluctuating stresses $\Delta\sigma$ at an arbitrary point on the circumference at the angle a is computed from

$$\Delta\sigma(\alpha) = \frac{\Delta My}{Iy} \cdot z(\alpha) + \frac{\Delta Mz}{Iz} \cdot y(\alpha) \qquad (1)$$

2.2 *Rainflow-analysis of fluctuating stresses*

For the analysis of the stress time series a counting procedure is applied. A classification of each single value of the time series is performed before the count of the fluctuating stresses can be performed. In the present application each class equals a bending moment of 10 kNm. On the level of elevation 42.5 m with an elastic modulus of 37899 cm^3 this equals $\Delta\sigma$ of 0.26386 N/mm^2. For the analysis of the classified stresses (Fig. 3) the specific rainflow counting method “Rainflow-HCM” (Clormann and Seeger

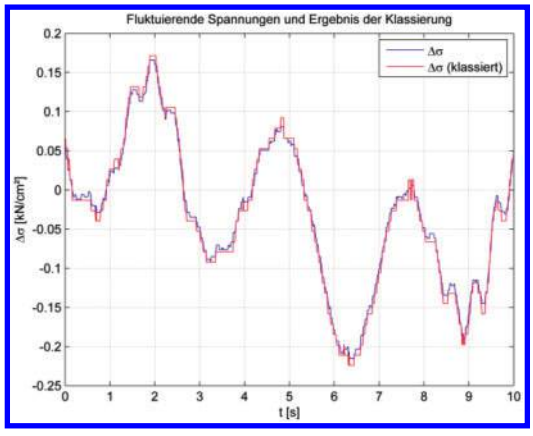

Figure 3. Computed and classified stresses.

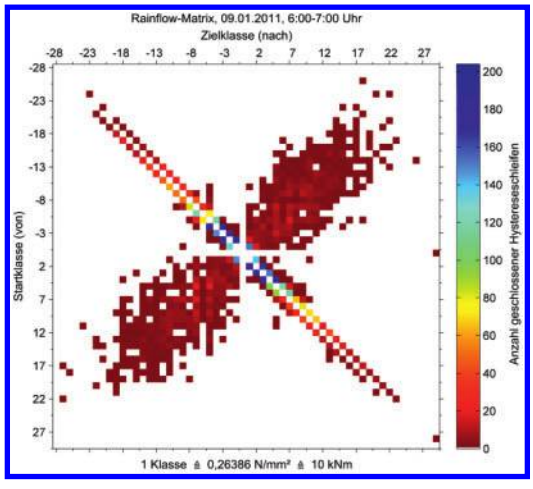

Figure 4. Result of rainflow counting for one hour.

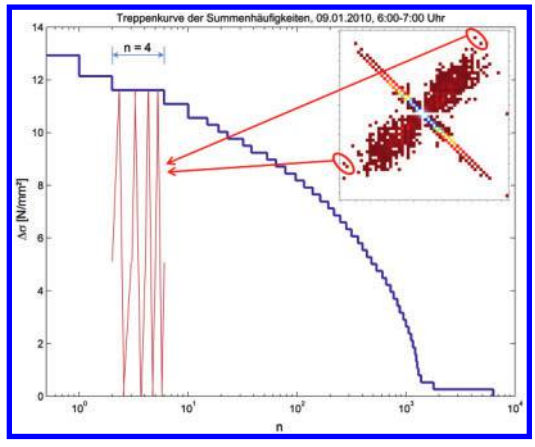

Figure 5. Diagram of accumulated summation of one hour.

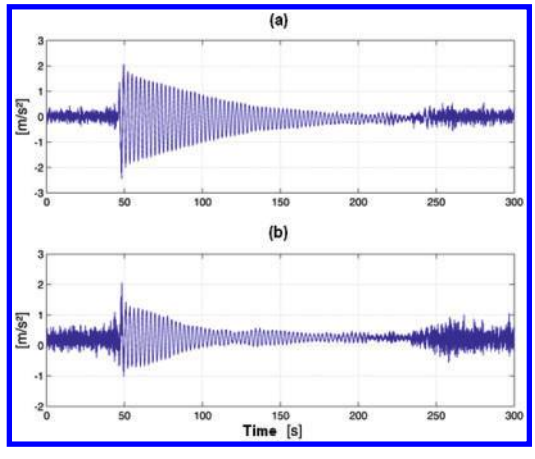

Figure 6. Measured accelerations at B1 during the impulse event: (a) forward-aft; (b) side-to-side.

1986) is used. The result of the counting procedure is in general in a quadratic format (Fig. 4). A closed hysteresis loop is arranged in the matrix by its start and target classes. A closed hysteresis loop starts in the target class, arrives and turns around in the start class and closes in the target class.

The rainflow matrix can easily be transformed into a matrix of mean values and amplitudes, which then can be used to build a spectrum of amplitudes of stress cycles. It is generally assumed that mean stresses have no significant influence on the fatigue strength of welded structures and thus can be neglected. Such an assumption is also adopted for the application of design codes for wind energy converters (Deutsches Institut für Bautechnik 2004, Germanischer Lloyd 2010) also referring to Eurocode 3, DIN EN 1993-1-9. According to the above regulatory codes the threshold value of fatigue strength for more than 10^8 load cycles must not be used. Instead, for more than 10^8 load cycles the Wöhler diagram is extended with a slope of m = 5. Figure 4 shows the result of a rainflow counting for one hour. Neglecting the average values of the rainflow matrix a stress collective is evaluated in Figure 5 which shows an incremented diagram over a time period of one hour. Four stress double amplitudes with a range of 11.6098 N/mm^2 are identified.

3 LIFE-CYCLE ASSESSMENT AFTER AN IMPULSIVE EVENT

Within the rainflow counting process of the year 2010 it was discovered that the dimensions of the rainflow matrix abruptly increased in size. The stress time histories of 11 February 2010 from 2.00 to 3.00 pm result in a 173 by 173 rainflow matrix. The residua (hysteresis loops that are not closed) are arranged in advance of the subsequent hour's worth of records. The results for the hour of 3.00 to 4.00 pm of the same day are summarized in a rainflow matrix which now has the dimension of 317 by 317 classes.

The acceleration time histories of a sample period of 300 sec duration (Fig. 6) show an exponentially decaying free vibration. At the beginning of the sample

period the facility is in a regular production process. Suddenly the structural system is subjected to a strong impulse. The wind velocity immediately before the event is about 8 m/sec, the power production of the WEC is about 200 kW. Both values are recorded at t = 45 sec of the sample period.

The acceleration amplitudes of the accelerometer B1 at an elevation of approximately 63 m (Fig. 1) are in the range of 2 m/sec^2 (Fig. 6). The tower vibration after the impulse decays exponentially for about 175 seconds, after which the facility returns to normal production mode. From the consideration of the decaying free vibration curve it is obvious that this curve cannot be responsible for the dimensional growth of the rainflow matrix. This is because in the succession of positive and negative vibration peaks each peak is numerically smaller than the previous one. The consequence of this is that while passing through the decaying vibration diagram none of the hysteresis loops can be closed. The incomplete hysteresis loops will be stored in the residuum at first appearance, until, at a later time, a new event of the same magnitude appears. At this time the hystereses that are still open can be closed. At an earlier time a corresponding impulse event must have occurred.

The high damping of the soil under the foundation restrains the effects of the impulse event to some extent.

3.1 *Comparison with measurements during two overspeed tests*

A comparison of the free vibration acceleration time history of Figure 6 with published results, for example in Devriendt et al. (2012), shows that it is a decaying free vibration after a sudden shut down of the facility. This situation occurs during the conduction of an overspeed test. Two such tests were executed on the present WEC in the course of maintenance work, on 05 October 2012 at 12.41 pm and 01.13 pm. These two overspeed tests were identified by correlating them with the SCADA data.

During the evaluation of the data of the years 2010 to 2012 several hundred impulse events of this type have been discovered in the records. Frequency of occurrence and magnitude of the stress double amplitudes qualify these events to become effective contributors to fatigue. For causing structural damage, however, several ten-thousand such events are required.

4 SYSTEM IDENTIFICATION AND DAMAGE DETECTION

The term “system identification” has been used in a broad context in the technical literature. In structural dynamics, it refers to the extraction of information about the structural behavior from measurement data, without necessarily requesting a numerical model (e.g., identification of the number of active modes or the presence of natural frequencies within a certain frequency range). However, with the increasing use of the numerical model in the analysis of the structural dynamic behavior, the system identification nowadays more often contains the development (or the improvement) of structural models from the measurements performed on the real structure using vibration sensing devices. In this paper, several important aspects are considered in the frame of system identification, including the modal identification technologies, experimentally validated finite element modeling, and its important application in health monitoring, also referred to as damage detection.

4.1 *Modal identification*

Since the WEC is measured under operational condition, the measurement of all natural excitations is impossible; the modal analysis has to be carried out based on the responses only. This modal identification method is called output-only modal analysis or operational modal analysis (OMA). There are two main groups of operational modal analysis: nonparametric methods essentially developed in frequency domain and parametric methods in time domain. In the current work, the Enhanced Frequency Domain Decomposition (EFDD) method (Brincker et al. 2001) in frequency domain and the Stochastic Subspace Identification (SSI) method (Brincker & Andersen 2006) in time domain are employed to extract the modal parameters of the WEC structure.

Table 1 lists the modal parameters of the first six bending modes of the WEC identified from a set of measurements, including three bending modes in wind direction (mode 2, mode 4 and mode 5) and three bending modes parallel to the rotation plane (mode 1, mode 3 and mode 6). By comparing the eigenfrequencies, the EFDD and SSI methods give almost identical results. However, it is very difficult to get accurate estimation of modal damping ratios under ambient loads, and also the related half-power bandwidth damping estimation method of EFDD is not very reliable. Besides, the modal damping ratios vary with the amplitude of the structural response and are influenced by the wind characteristics, which lead to the existence of aerodynamic damping. Therefore, when the accurate identification of modal damping ratios is required, complementary free vibration tests are recommended.

Table 1. Comparison of modal parameters identified by the EFDD and SSI methods.

	Frequency [Hz]			Damping ratio[%]		
	EFDD	SSI	Dev.*	EFDD	SSI	MAC
Mode 1	0.3760	0.3753	0.187	1.603	2.322	0.9668
Mode 2	0.3765	0.3779	0.370	2.252	4.685	0.9689
Mode 3	2.186	2.171	0.691	4.465	1.311	0.9229
Mode 4	2.208	2.217	0.406	3.245	3.485	0.9529
Mode 5	5.730	5.837	1.833	4.590	1.904	0.9903
Mode 6	5.819	5.857	0.649	3.426	1.997	0.9847

*Dev. = deviation [%].

The consistency of the mode shapes has been validated by the modal assurance criterion (MAC) (Allemang 2003), which takes values from 0.0 (representing no consistency) to 1.0 (representing a full consistency). High MAC values in Table 1 indicate that the modes detected by the EFDD method agree very well with those detected by the SSI method.

4.2 *Model updating*

Finite element (FE) model is increasingly used in system identification to generate the structural model matrices and to predict the structural responses. The underlying FE model customarily deviates from the real world system by approximation or even errors in the physical parameters or boundary conditions. Therefore model validation is compulsory to check the FE model through measurements. To this end, an iterative process of minimizing the defect between the model and the actual system behavior is mandatory, which is known as model updating. In continuous monitoring, the model updating is successively requested to accurately represent the current state of the real world system including damages and deteriorations. With this aim a unifying framework of model updating is developed involving efficient parameter selection method and simulation-based multi-criteria optimization.

Specifying the updating parameters is one of the most difficult yet most critical steps in the whole updating process. The number of updating parameters should be large enough to cover all the relevant uncertain parameters, but as low as possible to avoid ill-conditioning. Rather than using solely engineer's judgment, the error localization method is straightforward and more reliable for selection of updating parameters. The present error localization method bases on the concept of Equivalent Element Modal Strain Energy (EEMSE) (Zang et al. 2008) and makes use of the substructuring technique.

The updating process is dealt with as a simulation-based multi-criteria optimization problem. Formulation of the objective function involves a priori articulation of preferences and the weighted Chebyshev method (Miettinen 1999). Defects between the model and the real structure are measured by modal-domain data (eigenfrequencies and mode shapes) and space-scale-domain data (wavelet modulus), in which the latter is more damage-sensitive and specially used in the process of damage integration.

Furthermore, because the model updating constitutes a simulation-based optimization and the existing simulation software offers normally no powerful optimization tools, the Java-based optimization framework, MOPACK (Nguyen et al. 2010), is adopted in this approach and a simulation adapter is developed to integrate different simulation software into MOPACK. Due to the complexity of the optimization problem, the evolutionary algorithms (EAs) (Eiben 2002) instead of the traditional deterministic techniques have to be considered. The enhanced evolution strategy (EES) (Rechenberg 1973) and the differential evolution strategy (DE) (Storn & Price 1997), in the class of EAs, are employed in the representative numerical test, with which the effectiveness of the proposed solution concept are demonstrated.

4.3 *Damage detection*

Based on the demand of an efficient and robust non-destructive damage detection method for WECs as well as the distinct advantages of the wavelet transform, an integrated wavelet-based damage detection method is presented to accurately detect and localize incipient damage of WEC under operational condition.

The method uses the identified mode shapes as spatial signals and takes synergistic advantages of the stationary wavelet transform (SWT) and the continuous wavelet transform (CWT) (Daubechies 1992). The procedure consists of the following consecutive steps:

1. Signal decomposition. Multilevel wavelet decomposition by SWT is performed on the signal to extract details which keep track of the fluctuations in the signal.
2. Damage localization. By performing CWT on selected details and plotting the wavelet map, discontinuities on the signal can be indicated by peaks in the wavelet modulus. The possible damage position is identified by the abscissa where the line of modulus maxima progresses to fine scales.
3. Damage quantification. To find an effective criterion to quantify the damage extent, the largest wavelet modulus and the Lipschitz exponent (Mallat 2009) are considered. After comparing these two criteria, the largest wavelet modulus is preferred for quantification of small damage.

5 CONCLUSIONS

The presented method is conducted on several numerical tests and on data of an pilot experiment and the following advantages have been demonstrated:

- It is a global non-destructive evaluation technique for locating incipient damage, no prior knowledge of the damage position is required;
- The method can be performed on the large-scale in-service structures under operational condition;
- Intact modes are not necessary if the structure does not contain discontinuities or a reliable finite element model exists;
- No need of higher order modes, only the first four modes are enough for the investigated WEC for instance;
- Relatively small number of sensors are used, e.g., 19 sensors are simulated in the test case;
- Edge effect is eliminated so that damage near boundaries could also be detected;
- Influence of measurement noise on mode shapes can be measured by the indicator of normalized modal difference and reduced using statistical methods.
- The Palmgren-Miner approach in combination with Rainflow Counting of stress cycles at selected

positions of the steel shaft is used. An extension of the approach in order to detect and localize discrete structural damages requires a drastic increase of scanning density of time histories of wind forces, displacements over height, and other related operation values. First results of a conceptual study show that new, innovative sensor instrumentations are required to improve accuracy and precision of the displacement data. Respective sensor systems and measurement strategies have recently become available.

- Verification through real measurement data is of particular interest since noise or measurement errors are present in the signals, which will examine the practicality of the proposed method.
- In the future, special actuators will increasingly be employed as well to be able to instantaneously counteract excessive operational demands.

AKNOWLEDGEMENTS

The financial support of the project through the German Research Foundation DFG under the project numbers HA 1463/20-1 and HO 3286/1-2, and the kind cooperation of the operator of the reference wind converter, the public utility company DEW 21 of the City of Dortmund, is gratefully acknowledged.

Analysis and design of perforated cold-formed steel members in compression

Z. Yao & K.J.R. Rasmussen
School of Civil Engineering, University of Sydney, Sydney, Australia

ABSTRACT: The paper presents a parametric study of the strength of a range of perforated structural sections in axial compression subjected to local, distortional, and global flexural or global flexural-torsional buckling, as well as the interactions between the modes. The sections include lipped C-sections with and without web stiffeners, Z-sections, hat sections, and storage rack upright sections. An extensive range of strength data is obtained numerically to cover the influence of the most common parameters defining perforations, including hole width, hole shape, and hole spacing. Based on the strength data, three Direct Strength Method (DSM) design options are evaluated, including two sets of proposed equations. These equations are complemented by a reliability analysis deriving appropriate resistance factors.

1 INTRODUCTION

It is common to punch holes in one or several component plates of cold-formed steel sections to allow either easy connection to other members or services to run through walls and floors.

Perforations introduce complex stress distributions which can cause early yielding during loading. The direct consequences of holes are changes in the elastic buckling modes and loads, as well as post-buckling failure modes and ultimate strengths.

To date, the design of perforated thin-walled structures has not yet been comprehensively addressed in current design standards for cold-formed steel members, such as the North American Specification (NAS) (2007) and the Australian/New Zealand Standard AS/NZS 4600 (2005). The available design provisions are usually based on the concept of the Effective Width Method (EWM), and are empirical and limited to certain cross-section configurations, hole sizes, shapes and spacings, etc.

As an alternative to the traditional EWM, the Direct Strength Method (DSM) represents an advancement in cold-formed steel design and was first adopted in Appendix I of NAS (2007), and later in Section 7 of AS/NZS 4600 (2005) for the design of non-perforated cold-formed steel columns and beams. The DSM utilises the elastic buckling loads of the gross section (i.e. $P_{cr\text{-}e}$, $P_{cr\text{-}l}$, and $P_{cr\text{-}d}$ for global, local and distortional buckling respectively) to predict the member ultimate strength, and hence provides engineers with a tool to predict the strength of members of any general cross-sectional shape. These buckling loads correspond to three strength limit states considered in the DSM, i.e. global (G) buckling or yielding, local-global (LG) buckling interaction, and distortional (D) buckling. Their respective equations for non-perforated columns are summarised as follows:

(i) Nominal global buckling strength, P_{ne}:

$$\text{For } \lambda_c \le 1.5: \quad P_{ne} = \left(0.658^{\lambda_c^2}\right) P_y \tag{1}$$

$$\text{For } \lambda_c > 1.5: \quad P_{ne} = \left(\frac{0.877}{\lambda_c^2}\right) P_y \tag{2}$$

where $\lambda_c = P_y / P_{cr\text{-}e})^{0.5}$ and $P_y = A_g F_y$.

(ii) Nominal local buckling (including local-global (LG) buckling interaction) strength, P_{nle}:

$$\text{For } \lambda_{le} \le 0.776, \quad P_{nle} = P_{ne} \tag{3}$$

$$\text{For } \lambda_{le} > 0.776, \quad P_{nle} = \left[1\text{-}0.15\left(\frac{P_{cr\text{-}l}}{P_{ne}}\right)^{0.4}\right]\left(\frac{P_{cr\text{-}l}}{P_{ne}}\right)^{0.4} P_{ne} \tag{4}$$

where $\lambda_{le} = (P_{ne}/P_{cr\text{-}l})^{0.5}$.

(iii) Nominal distortional buckling strength, P_{nd}:

$$\text{For } \lambda_d \le 0.561, \quad P_{nd} = P_y \tag{5}$$

$$\text{For } \lambda_d > 0.561, \quad P_{nd} = \left[1\text{-}0.25\left(\frac{P_{cr\text{-}d}}{P_y}\right)^{0.6}\right]\left(\frac{P_{cr\text{-}d}}{P_y}\right)^{0.6} P_y \tag{6}$$

where $\lambda_d = (P_y / P_{cr\text{-}d})^{0.5}$. The nominal design strength P_n of a column is $P_n = \min(P_{nle}, P_{nd}, \text{and } P_{ne})$.

Based on the DSM, recent studies (Tovar and Sputo, 2005, Moen and Schafer, 2011) were carried out to incorporate the effect of openings into the DSM to determine the ultimate capacity of perforated C-section columns and beams. In particular, Moen and Schafer (2011) derived a set of design equations for perforated cold-formed steel columns which

worked in harmony with the existing DSM design rules. By using the simplified methods described in (Moen and Schafer, 2009), the influence of holes was considered in the local, distortional, and global elastic buckling loads (i.e. $P_{cr\text{-}l\text{-}h}$, $P_{cr\text{-}d\text{-}h}$, and $P_{cr\text{-}e\text{-}h}$) of the columns. Six different design options were evaluated using 78 experimental and more than 200 FE simulated column data. The best-performing design option limited the LG buckling strength in Eqns. (3)–(4) to P_{ynet}, and modified the distortional buckling strength Eqns. (5)–(6) to:

$$\text{For } \lambda_d \le \lambda_{d1},\quad P_{nd} = P_{ynet} \tag{7}$$

$$\text{For } \lambda_{d1} < \lambda_d \le \lambda_{d2},\quad P_{nd} = P_{ynet} - \left(\frac{P_{ynet} - P_{d2}}{\lambda_{d2} - \lambda_{d1}}\right)\left(\lambda_{d2} - \lambda_{d1}\right) \tag{8}$$

$$\text{For } \lambda_d > \lambda_{d2},\quad P_{nd} = \left[1\text{-}0.25\left(\frac{P_{cr\text{-}d\text{-}h}}{P_y}\right)^{0.6}\right]\left(\frac{P_{cr\text{-}d\text{-}h}}{P_y}\right)^{0.6} P_y \tag{9}$$

where $\lambda_d = (P_y / P_{cr\text{-}d\text{-}h})^{0.5}$, $\lambda_{d1} = 0.561\left(P_{ynet} / P_y\right)$,

$\lambda_{d2} = 0.561\left(14\left(P_y / P_{ynet}\right)^{0.4} - 13\right)$,

$P_{d2} = \left(1\text{-}0.25\left(1/\lambda_{d2}\right)^{1.2}\right)\left(1/\lambda_{d2}\right)^{1.2} P_y$

2 PARAMETRIC STUDY

A parametric study was carried out by means of nonlinear finite element modelling in ABAQUS on 146207 perforated and non-perforated cold-formed steel columns. These simulations included five cross-section types (i.e. C, stiffened C, Z, rack, and hat sections) which were predisposed to three major buckling modes (i.e. local (L), distortional (D) and global (G)) and all the possible interactions between them (i.e. LD, LG, DG, and LDG). Table 1 summarises the section shapes, and for each predisposed failure mode the number of sections and collapse analyses, as well as the ranges of cross-sectional local and distortional slenderness and member global slenderness. The three finite element models used in the parametric study are shown in Figure 1–Figure 3, for columns predisposed to L, D, and G modes, respectively. In general, these models comprised a certain number of buckling half-wavelengths, i.e. three for local, four for distortional, and one for global failures, with the half-wavelengths calculated by the Finite Strip Method based on the gross section. Corner restraining systems were provided for the columns predisposed to local and distortional failures in order to induce the desired failure modes. Each set of corner restraints was placed between the buckling half-waves. Besides, both ends of all the columns were supported on rigid plates, and a compressive displacement was applied to the section centroid through a rigid plate. Shell elements S9R5 were used to mesh the columns.

The material properties used in the parametric studies conformed to the limits specified in the current codified DSM. The stress-strain curve was specified

by the Ramberg-Osgood expression (Ramberg and Osgood, 1943) using n-values of $n = 5$, 10, and 20. Yield stress enhancement in the corners due to cold work was considered by using the formulae in Clause 1.5.1.2 of AS/NZS 4600.

Initial local, distortional, and global geometric imperfections were imposed on the column models, using the linear elastic buckling modes as the shapes of the geometric imperfections. The magnitudes of the local and distortional imperfections were based on the statistical information provided by (Schafer and Pekoz, 1998), and corresponded to two probabilities of exceedance, i.e. the 25th ($d/t = 0.14$ and 0.64 respectively) and 75th ($d/t = 0.66$ and 1.55 respectively) percentile values, which were used in conjunction with $L/2000$ and $L/1000$ global imperfections. Moreover, the direction of the initial geometric imperfection was explicitly considered in the FE modelling, such as "inward" and "outward" directions for local and distortional imperfections, and bow towards the web or the flanges for global imperfections. It was found that the direction of imperfection can have a profound impact on the structural response and hence the ultimate strength.

Initial residual stresses were not considered in this research, partly because it was reported by (Becque, 2008, Moen and Schafer, 2011) that their inclusion has only minimal influence on the ultimate load-carrying capacity of cold-formed structures and partly because their effect is largely accounted for by using a Ramberg-Osgood stress-strain curve.

The dimensions of the holes are such that the hole width to flat web width ratios were 0, 0.2, 0.4, 0.6 and 0.8, hole length to hole width ratios were 0.5, 1.0, 2.0, and 4.0, and clear hole spacing to hole width ratios were 1.0, 2.0, and 6.0.

3 DESIGN

The column strength database obtained from the parametric studies which involved material models defined by $n = 20$ was used in this paper to evaluate three DSM expressions: the best-performing DSM proposed by Moen and Schafer (2011), and another two methods proposed by the authors (refer to (Yao, 2013) for a total of 19 assessed methods). Statistics, including the mean (P_m) and COV (V_p) of the simulation-to-predicted strength ratios, and the resistance factor ϕ, are calculated for each design method according to the first order second moment (FOSM) reliability analysis outlined in Chapter F of the AISI Specification (NAS, 2007) with the following statistical data: LRFD reliability target index $\beta_0 = 2.5$; mean value of the fabrication factor $F_m = 1.0$ and COV $V_F = 0.05$; mean value of the material factor $M_m = 1.10$ and COV $V_M = 0.10$; representative ratio of dead load to live load $G_n/Q_n = 0.2$; representative ratios of mean dead load to nominal dead load and mean live load to nominal live load of $Q_m/Q_n = 1.0$ and $G_m/G_n = 1.05$; COVs of dead and live loads of $V_D = 0.1$ and $V_L = 0.25$; dead and live load factors of $\gamma_G = 1.2$ and $\gamma_Q = 1.5$; and $C_p = 1$.

3.1 *DSM by Moen and Schafer (2011)*

Using the best-performing DSM method (i.e. Option 4) by Moen and Schafer (2011) described in Section 1, Table 2 presents the statistics of the predictions, along with Figure 4 illustrating the simulation-to-predicted ratios ($P_{u\text{-}FEM}/P_n$) for all perforated and non-perforated columns. The results are classified by failure mode, represented by L, LG, G, D, LD, DG, and LDG.

In general, Option 4 in (Moen and Schafer, 2011) performed better than the existing DSM (results not included in this paper) in terms of a higher P_m value (0.993 vs. 0.929 by 6.89%), a smaller scatter V_p (0.199 vs. 0.212 by −6.13%), and a higher overall ϕ value (0.726 vs. 0.666 by 9.01%). This improvement is reflected in almost all individual failure modes and section types. It is particularly worth noting that the overall ϕ value for the D mode increased most

significantly by 19.0% from 0.638 to 0.759. However, the predictions by this method could not achieve $\phi = 0.85$ as prescribed in the existing DSM. Only the ϕ values for the L ($\phi = 0.830$) and G ($\phi = 0.847$) modes are reasonably satisfactory, whereas the DG mode performed worst with a ϕ value of only 0.606. In terms of section type, Z section was the only section that was just satisfactorily predicted with $\phi = 0.844$.

3.2 *Proposed method 1 – modified DSM without regression analysis*

A new method was developed based on modifying the Option 4 proposed by Moen and Schafer (2011). In particular, $P_{cr\text{-}l}$ and $P_{cr\text{-}d}$ based on gross cross-section were used instead of $P_{cr\text{-}l\text{-}h}$ and $P_{cr\text{-}d\text{-}h}$ (see Section 4 for discussion), while the distortional axial strength Eqns. (7)–(9) were modified to include the interaction with global buckling such that,

$$\text{For } \lambda_{de} \le \lambda_{d1},\ P_{nde} = P_{min} \tag{10}$$

$$\text{For } \lambda_{d1} < \lambda_{de} \le \lambda_{d2},\ P_{nde} = P_{min} - \left(\frac{P_{min} - P_{d2}}{\lambda_{d2} - \lambda_{d1}}\right)\left(\lambda_{d2} - \lambda_{d1}\right) \tag{11}$$

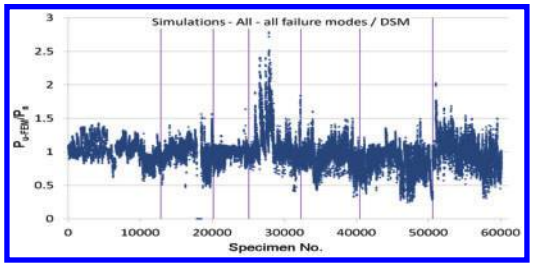

Figure 4. Simulation-to-predicted ratios for perforated columns by Option 4 in (Moen and Schafer, 2011) with classified failure modes (from left to right: L, LG, G, D, LD, DG, and LDG).

$$\text{For } \lambda_{de} > \lambda_{d2},\ P_{nde} = \left[1\text{-}0.25\left(\frac{P_{cr\text{-}d}}{P_{ne}}\right)^{0.6}\right]\left(\frac{P_{cr\text{-}d}}{P_{ne}}\right)^{0.6} P_{ne} \tag{12}$$

where $P_{min} = \min(P_{ne},\ P_{ynet})$, $\lambda_{de} = (P_{ne}/P_{cr\text{-}d})^{0.5}$,
$\lambda_{d1} = 0.561\left(P_{ynet}/P_y\right)$,
$\lambda_{d2} = 0.561\left(14\left(P_y/P_{ynet}\right)^{0.4} - 13\right)$,
and $P_{d2} = \left(1\text{-}0.25\left(1/\lambda_{d2}\right)^{1.2}\right)\left(1/\lambda_{d2}\right)^{1.2} P_{ne}$.

Besides, the local buckling (or LG interactive buckling) strength equations are,

$$\text{For } \lambda_{le} \le 0.776,\ P_{nle} = P_{ne} \le P_{ynet} \tag{13}$$

$$\text{For } \lambda_{le} > 0.776,\ P_{nle} = \left[1\text{-}0.15\left(\frac{P_{cr\text{-}l}}{P_{ne}}\right)^{0.4}\right]\left(\frac{P_{cr\text{-}l}}{P_{ne}}\right)^{0.4} P_{ne} \le P_{ynet} \tag{14}$$

where $\lambda_{le} = (P_{ne}/P_{cr\text{-}l})^{0.5}$. The global buckling strength equations are,

$$\text{For } \lambda_c \le 1.5:\ P_{ne} = \left(0.658^{\lambda_c^2}\right)P_y \tag{15}$$

$$\text{For } \lambda_c > 1.5:\ P_{ne} = \left(\frac{0.877}{\lambda_c^2}\right)P_y \tag{16}$$

where $\lambda_c = (P_y/P_{cr\text{-}e\text{-}h})^{0.5}$.

In addition, in order to achieve an overall resistance factor ϕ of about 0.85 as stipulated in the existing DSM, a penalty factor of 0.85 was applied to the final predicted strength such that,

$$P_n = 0.85 \times \min(P_{nle},\ P_{nde},\ P_{ne}). \tag{17}$$

The statistics of the predictions by Proposed Method 1 are tabulated in Table 3, along with the simulation-to-predicted ratios for all columns illustrated in Figure 5. This method performed better than Option 4 in (Moen and Schafer, 2011) primarily because it resulted in a smaller scatter in prediction

Table 3. Simulation-to-predicted statistics for all columns failing in different failure modes by Proposed Method 1 – modification to Option 4 in (Moen and Schafer, 2011) – replace D equation by DG interaction equation, use $P_{cr\text{-}l}$ and $P_{cr\text{-}d}$ based on A_g.

($V_p = 0.181$ vs. 0.199). The inclusion of the DG interaction Eqns. (10)–(12) proved effective as it decreased the values of V_p for all failure modes involving the D mode (V_p for the D, LD, DG, and LDG modes decreased by 17.7%, 5.2%, 11.7%, and 11.4%, respectively). Moreover, the use of the 0.85 penalty factor raised the mean P_m and hence the resistance factor ϕ uniformly for all failure modes and section types. However, it failed to raise the overall ϕ values to 0.85 for Hat and Stiffened C sections.

3.3 *Proposed method 2 – Modified DSM with regression analysis*

Based on Proposed Method 1, a regression analysis was carried out to further improve its performance.

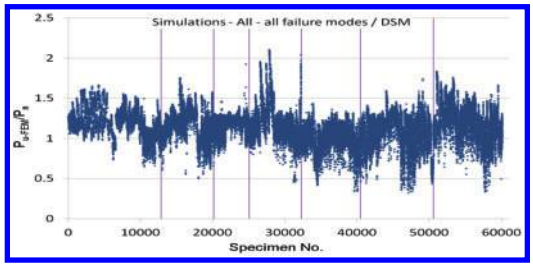

Figure 5. Simulation-to-predicted ratios for all columns by Proposed Method 1 with classified failure modes (from left to right: L, LG, G, D, LD, DG, and LDG).

Table 4. Regression analysis constants for Proposed Method 2.

a	b	c	d	e	f
9.38E-01	6.89E-02	-3.14E-02	5.76E-02	-2.20E-01	-2.46E-02
g	h	i	j	k	m
5.32E-03	1.10E-03	-2.24E-03	-6.76E-03	-7.98E-03	5.57E-02

The resulting DSM Method, i.e. Proposed Method 2, is defined as:

$$P_n = F1 \times \min(P_{nle}, P_{nde}, P_{ne}) \quad (18)$$

where F1 was obtained from a regression analysis and computed as per Eqn. (19) with all the constants defined in Table 4. The slendernesses λ_{le}, λ_{de}, and λ_c in Eqn. (19) are defined in Section 3.2, while HWF = hole width factor = hole width/flat web width, HLF = hole length factor = hole length/hole width, HSF = hole spacing factor = clear hole spacing/hole width, H = overall web width, B = overall flange width, D = overall lip width, t = thickness.

$$g \times HSF + h \times \frac{H}{t} + i \times \frac{B}{t} + j \times \frac{D}{t} + k \times \frac{H}{B} + m \times \frac{D}{B} \quad (19)$$

The statistics of the predictions and the simulation-to-predicted ratios are presented in Table 5 and Figure 6 respectively. By means of the regression factor F1, Proposed Method 2 improved the prediction significantly, demonstrated by a 15.5% decrease in the overall value of V_p. This improvement mainly came from C, Z and Hat sections, while a larger scatter in the predictions

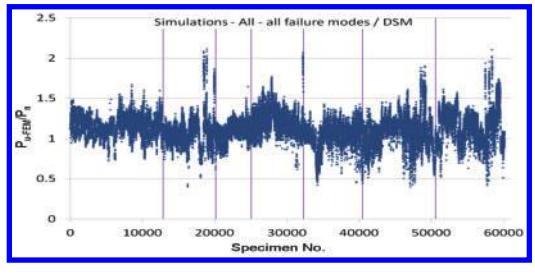

Figure 6. Simulation-to-predicted ratios for all columns by Proposed Method 2 with classified failure modes (from left to right: L, LG, G, D, LD, DG, and LDG).

Table 5. Simulation-to-predicted statistics for all columns failing in different failure modes by Proposed Method 2 – modification to Option 4 in (Moen and Schafer, 2011) – replace D eqn. by DG eqn., use $P_{cr\text{-}l}$ and $P_{cr\text{-}d}$ based on A_g, regression analyses of strengths.

was associated with Rack and Stiffened C sections, as indicated by increases of 5.5% and 14.6% in the values of V_p. Moreover, the overall values of ϕ showed that all section types except Stiffened C section satisfied the prescribed value of $\phi = 0.85$. In particular, when the L, LG, G and D modes (i.e. those covered by the existing DSM) were considered in isolation, $\phi = 0.85$ was satisfied for all section types, whereas it failed to be satisfied for C, Hat and Stiffened C sections when the collection of the LD, DG and LDG modes were considered.

4 DISCUSSION

The research presented in (Yao, 2013) demonstrates that for the great majority of columns, the simplified method proposed by Moen and Schafer (2009) for calculating the elastic local buckling load accounting for the influence of holes, $P_{cr\text{-}l\text{-}h}$, produces the same buckling loads for non-perforated and perforated members. Therefore, it is not necessary to calculate $P_{cr\text{-}l\text{-}h}$ in the strength design equations, and $P_{cr\text{-}l}$ based on gross section can be used instead.

(Yao, 2013) also showed that replacing $P_{cr\text{-}d\text{-}h}$ by $P_{cr\text{-}d}$ in Option 4 of (Moen and Schafer, 2011) reduced the overall value of V_p favourably by 3.5%, although it also reduced the overall ϕ value by 2.1%. This reduced scatter in prediction was observed for a majority of individual sections and failure modes, especially for C section which showed a significant decrease of 10.8% in its overall V_p value. Therefore, considering the complexity and limitations in calculating $P_{cr\text{-}d\text{-}h}$ as per the simplified methods proposed by Moen and Schafer (2009), it is recommended to use $P_{cr\text{-}d}$ in lieu of $P_{cr\text{-}d\text{-}h}$.

Design methods generally performed worse for failure modes involving the D mode (i.e. D, LD, DG and LDG) as shown by their higher values of V_p. It has been shown that including DG interaction in the DSM distortional equations contributed significantly to the reduction of scatter in prediction related to the DG and LDG modes, and an additional regression analysis could further reduce the scatter for the D, LD, DG and LDG modes. In addition, Yao (2013) demonstrates that it is unfavourable to include LD or LDG interaction equations in the DSM because they generally result in a considerable increase in the prediction scatter and thus a decrease in the resistance factor. Future research is warranted regarding the interaction with the D mode.

It is generally true that the variation in the predictions is largely caused by interaction of buckling modes rather than the presence of holes, although it is noticed that the influence of holes to some extent depends on the section type, section dimensions, and failure modes.

Although it remains sound to base the strength on a slenderness that relates elastic buckling and yield (or strength), the statistics of the predictions by the DSM can vary significantly depending on the section type and failure mode. It is virtually impossible to achieve a uniform ϕ value for all section types and failure modes using a particular set of strength equations. From a design viewpoint, it may be preferable to select the accurate ϕ value for a specific section type and failure mode; alternatively, one may use a more conservative approach by adopting the minimum ϕ value of all failure modes for a particular section, or a less conservative approach by adopting the average ϕ value of all failure modes for a particular section.

5 CONCLUSIONS

A comprehensive parametric study was carried out using ABAQUS to determine the strengths of 146207 perforated and non-perforated cold-formed steel columns. The study included five cross-section types (i.e. C, stiffened C, Z, rack, and hat sections) and seven failure modes (i.e. L, LG, G, D, LD, DG, and LDG).

The strength database was then used to evaluate three DSM design methods, including Option 4 in (Moen and Schafer, 2011), and another two methods proposed by the authors. The best-performing method was based on modifying the Option 4 method in (Moen and Schafer, 2011) such that (i) DG interaction was included, (ii) $P_{cr\text{-}l}$ and $P_{cr\text{-}d}$ based on gross section were used, and (iii) a factor based on a regression analysis was added to improve the final design strength. This recommended method outperformed all the other methods in terms of accuracy and generality.

A semi-discretized thin-walled beam element including distortion

Michael Joachim Andreassen & Jeppe Jönsson
Technical University of Denmark, Department of Civil Engineering, Brovej, Lyngby, Denmark

ABSTRACT: An advanced thin-walled beam element including distortion of the cross section is presented. The formulation is based on a generalization of the classical Vlasov beam theory for analysis of open and closed thin-walled cross sections by including distortional displacements. The beam element formulation utilizes a semi-discretization approach in which the cross section is discretized into wall elements and the analytical solutions of the related GBT beam equations are used as displacement functions in the axial direction. Thus the beam element contains the semi-analytical solutions. In a number of related publications the authors have recently presented the semi-discretization approach and the analytical solution of the generalized beam equations. An illustrative example showing the validity and the accuracy of the developed distortional semi-discretized thin-walled beam element is given and it is shown how the novel approach provides accurate results making it a good alternative to the traditional and time consuming FE calculations.

1 INTRODUCTION

An extension of the classic beam theory is considered in this paper and in a number of companion publications published by the authors, (Jönsson & Andreassen 2011, Andreassen & Jönsson 2012b, Andreassen & Jönsson 2012a, Andreassen & Jönsson 2013, Andreassen 2012) where a novel approach to generalized beam theory is formulated. A variety of other formulations and methods taking distortional displacements into account have been proposed for analysis of both open and closed cross sections. Thus, concerning analysis of thin-walled members including distortion of the cross section there are a number of methods available among which are: (i) The use of shell finite elements in the finite element method (FEM), (Zienkiewicz & Taylor 1989), (ii) the finite strip method (FSM), (Cheung & Tham 1998), (Schafer & Ádány 2006), and (iii) the use of approximate GBT-finite beam elements known as GBT (Schardt 1966, Silvestre 2005).

In the present paper a new and alternative approach to conventional GBT is briefly presented. This novel approach to Generalized Beam Theory (GBT) involves a cross-section semi-discretization process as well as a determination of the natural cross-section eigenmodes and related axial solution functions by exact analytical solution of the related first-order GBT equations. Hereby the approach is different from the traditional GBT formulation developed by Schardt in (Schardt 1966) and (Schardt 1989). When Schardt uses the GBT equations to find distortional deformation modes the shear coupling stiffness terms are neglected. This corresponds to modal analysis with orthogonal (Rayleigh) damping in dynamic structural analysis. The solution of the shear coupled GBT equations for closed cross-sections was published by Hanf only in his thesis, (Hanf 1989). For closed (single or multi celled hollow) thin-walled cross-sections Schardt shows in his presentation of GBT in (Schardt 1989), that the theory needs a relaxation of the Vlasov assumption of negligible shear strain in order to include the warping deformation associated with the "Bredt's shear flow" around each cell. However it complicates the solution of the conventional GBT equations by introducing non negligible shear coupling terms (off diagonal) in the GBT equations. The present formulation therefore adheres to the definition of the warping function given in (Kollbrunner & Hajdin 1972), which adds the integral of the shear flow strains, see also (Jönsson 1999).

In contrast to and as a considerable advance on the traditional GBT formulation this novel finite element based semi-discretization approach to generalized beam theory (GBT) solves the fourth-order differential equations to obtain the distortional displacements for a linear beam analysis. This means that we find the analytical solution to the differential GBT equations which through the magnitude of the eigenvalues gives a much better knowledge of the length scales of the modes. This also means that we find the exact mode shapes and amplitude solutions of the reduced order GBT equations related to the discretized cross section. In contrast, the conventional GBT formulation solves the equations using the approximate engineering methods, in which the shear coupling terms are neglected, producing orthogonal axial and transverse normal stress modes. In such a case the differential equations are not solved but a weak solution may be found through introduction of the established approximate mode shapes and use of approximate modal amplitude functions.

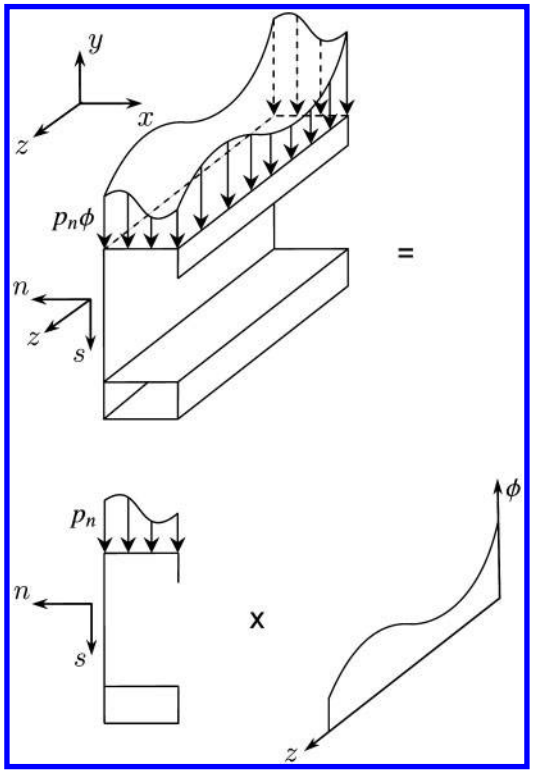

Figure 1. Global and local Cartesian reference frames and load distribution.

Thus the conventional GBT formulations uses the produced approximated modes as shape functions in a virtual work or potential energy formulation leading to approximated finite GBT beam elements and the discretization has to be performed without proper prior knowledge of the problem length scales of the individual modes.

It should be noticed that the paper is dealing with a basic generalized beam theory (GBT) and not an extended finite element formulation of an approximate beam element.

2 BEAM KINEMATICS OF A SINGLE MODE

The considered straight beam of constant cross section is described in a global Cartesian (x, y, z) coordinate system as shown in Figure 1. In the local coordinate system (z, n, s) the displacements u_n, u_s and u_z of a material point are defined as

$$u_n(s,z) = \mathrm{w}_n(s)\,\psi(z) \tag{1}$$

$$u_s(n,s,z) = \left(\mathrm{w}_s(s) - n\mathrm{w}_{n,s}(s)\right)\psi(z) \tag{2}$$

$$u_z(n,s,z) = -\left(\Omega(s) + n\mathrm{w}_n(s)\right)\psi'(z) \tag{3}$$

Here $\mathrm{w}_s(s)$ and $\mathrm{w}_n(s)$ describes the local displacements of the centerline, $\psi(z)$ is the function which describes the variation along the beam and $\Omega(s)$ describes the axial (warping) displacement mode. The local components are shown in Figure 2. The notation indicates the two dimensions of the cross section planes and the single dimension associated with the variation along the beam. The strain components associated with the given displacements are found as

$$\varepsilon_z = -(\Omega + n\mathrm{w}_n)\psi'' \tag{4}$$

$$\varepsilon_s = (\mathrm{w}_{s,s} - n\mathrm{w}_{n,ss})\psi \tag{5}$$

$$\gamma_{zs} = (\mathrm{w}_s - \Omega_{,s} - 2n\mathrm{w}_{n,s})\psi' \tag{6}$$

For a greater explanation and description see paper (Jönsson & Andreassen 2011, Andreassen & Jönsson 2012b)

3 ENERGY POTENTIAL OF A SINGLE MODE

The total potential energy of a single mode can be expressed as

$$\Pi_{tot} = \Pi_{int} + \Pi_{ext} \tag{7}$$

Here Π_{int} is the contribution from the potential energy from the internal properties, see paper (Jönsson & Andreassen 2011), and Π_{ext} is the contribution from the external loads, see paper (Andreassen & Jönsson 2012b). Introducing the strain components associated with the displacements and introducing the load variables $q_s = p_s(s)\phi(z)$, $q_n = p_n(s)\phi(z)$, $q_z = p_z(s)\phi(z)$, the total potential energy takes the following form:

$$\Pi_{tot} = \int_V \left(\tfrac{1}{2}E\varepsilon_z^2 + \tfrac{1}{2}G\gamma^2 + \tfrac{1}{2}E_s\varepsilon_s^2 - (q_z u_z + q_s u_s + q_n u_n)\right)dV \tag{8}$$

The interpolations connected to the cross section are the displacement interpolations for $\mathrm{w}_s(s)$, $\mathrm{w}_n(s)$ and Ω which is fully described in (Jönsson & Andreassen 2011). The interpolation of the cross-section loads p_s, p_n and p_z are fully introduced in (Andreassen & Jönsson 2012b). Introducing these interpolations and the calculation scheme as described in (Jönsson & Andreassen 2011, Andreassen & Jönsson 2012b) the total potential energy can be written as

$$\begin{aligned}\Pi_{tot} = \tfrac{1}{2}\int_0^L \Bigg\{ &\left[\psi\mathbf{v}_\mathrm{w}^T \;\; \psi\mathbf{v}_\Omega^T\right]'' \begin{bmatrix}\mathbf{K}^\sigma_{\mathrm{ww}} & \mathbf{0}\\ \mathbf{0} & \mathbf{K}^\sigma_{\Omega\Omega}\end{bmatrix}\begin{bmatrix}\psi\mathbf{v}_\mathrm{w}\\ \psi\mathbf{v}_\Omega\end{bmatrix}'' \\ &+\left[\psi\mathbf{v}_\mathrm{w}^T \;\; \psi\mathbf{v}_\Omega^T\right]' \begin{bmatrix}\mathbf{K}^\tau_{\mathrm{ww}} & \mathbf{K}^\tau_{\mathrm{w}\Omega}\\ \mathbf{K}^\tau_{\Omega\mathrm{w}} & \mathbf{K}^\tau_{\Omega\Omega}\end{bmatrix}\begin{bmatrix}\psi\mathbf{v}_\mathrm{w}\\ \psi\mathbf{v}_\Omega\end{bmatrix}' \\ &+\left[\psi\mathbf{v}_\mathrm{w}^T \;\; \psi\mathbf{v}_\Omega^T\right] \begin{bmatrix}\mathbf{K}^s & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\psi\mathbf{v}_\mathrm{w}\\ \psi\mathbf{v}_\Omega\end{bmatrix} \\ &-(\psi\mathbf{v}_\mathrm{w}^T)\mathbf{r}_\mathrm{w}\phi + (\psi\mathbf{v}_\Omega^T)'\mathbf{r}_\Omega\phi\Bigg\}dz\end{aligned} \tag{9}$$

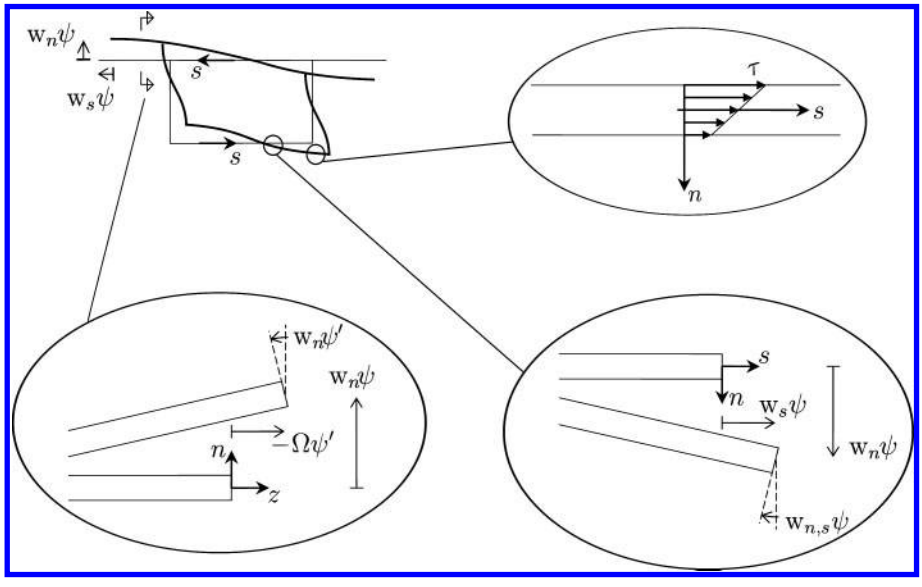

Figure 2. Local components of the displacement field and assumed shear stresses.

To get a formulation resembling a generalization of Vlasov beam theory (Vlasov 1961) the following three main steps are performed:

- In step I the shear constraint equations that bind axial and transverse modes together are introduced and at the same time equation (9) are simplified or condensed. In this process the singularity in the shear stiffness matrix related to pure axial extension is needed to be eliminated.
- In step II two eigenmodes corresponding to transverse translation of the cross section are identified and eliminated. Also a pure rotational eigenmode is identified for elimination in the next step. Furthermore the transverse displacement field is constrained, so that transverse normal strains in the middle surface of the cross section are not allowed, i.e. $w_{s,s} = 0$ is enforced, see equation (5).
- In step III the order of the coupled fourth order differential equations is reduced and the eigenvalue problem is condensed by removing singularities due pure St. Venant torsion.

This reveals the final set of (reduced order) distortional differential equations that have to be solved and the full solution along the beam obtained as

$$\begin{aligned} \mathbf{u}_w(z) &= \mathbf{V}_w[\boldsymbol{\Psi}_h(z)\,\mathbf{c} + \boldsymbol{\Psi}_p(z)\boldsymbol{\phi}] \\ \mathbf{u}_z(z) &= -\mathbf{V}_\Omega[\boldsymbol{\Psi}'_h(z)\,\mathbf{c} + \boldsymbol{\Psi}'_p(z)\boldsymbol{\phi}] \end{aligned} \tag{10}$$

For a more elaborate description see the companion papers (Jönsson & Andreassen 2011, Andreassen & Jönsson 2012b).

4 ELEMENT STIFFNESS MATRIX AND LOAD VECTOR

Now the global beam element stiffness matrix and load vector needed for the determination of the nodal element solution can be found. As the load has no influence on the stiffness contributions we use the full assembled homogeneous solution along the beam found in the companion paper (Jönsson & Andreassen 2011). We also use the homogeneous displacement modes to generate the nodal load vector.

Using the homogeneous solution vectors given in equation (79) in paper (Jönsson & Andreassen 2011) the potential energy including all the homogeneous modes in equation (9) can be written in integrated form as

$$\Pi = \tfrac{1}{2}\mathbf{c}^T(\widetilde{\mathbf{K}}\mathbf{c} - \widetilde{\mathbf{r}}) \tag{11}$$

Here $\widetilde{\mathbf{K}}$ is the stiffness matrix and $\widetilde{\mathbf{r}}$ the load vector related to the modal displacement constants $\mathbf{c}$. The stiffness matrix and the load vector are found by integration and addition of the individual sub matrix products. The stiffness matrix contributions are given i Table 1 and the two load vector contributions are given in Table 2.

4.1 *Generalized displacements*

The generalized displacements of the present GBT formulation are determined by the first variation of the potential energy, shear constrains and the multi point constraint equations, as described in paper (Jönsson & Andreassen 2011). This degree of freedom space is what we refer to as the GBT-space. As in a basic beam

Table 1. Beam element stiffness contributions enabling analytical integration.

$$\widetilde{\mathbf{K}}^{\sigma}_{\mathrm{ww}} = \overline{\mathbf{V}}^{T}_{\mathrm{w}} \mathbf{K}^{\sigma}_{\mathrm{ww}} \overline{\mathbf{V}}_{\mathrm{w}} \circ \int_0^L \overline{\mathbf{\Psi}}'' \mathbf{J} \overline{\mathbf{\Psi}}'' \, dz$$
$$\widetilde{\mathbf{K}}^{\tau}_{\mathrm{ww}} = \overline{\mathbf{V}}^{T}_{\mathrm{w}} \mathbf{K}^{\tau}_{\mathrm{ww}} \overline{\mathbf{V}}_{\mathrm{w}} \circ \int_0^L \overline{\mathbf{\Psi}}' \mathbf{J} \overline{\mathbf{\Psi}}' \, dz$$
$$\widetilde{\mathbf{K}}^{\tau}_{\mathrm{w}\Omega} = \overline{\mathbf{V}}^{T}_{\mathrm{w}} \mathbf{K}^{\tau}_{\mathrm{w}\Omega} \overline{\mathbf{V}}_{\Omega} \circ \int_0^L \overline{\mathbf{\Psi}}' \mathbf{J} \overline{\mathbf{\Psi}}' \, dz$$
$$\widetilde{\mathbf{K}}^{s} = \overline{\mathbf{V}}^{T}_{\mathrm{w}} \mathbf{K}^{s} \overline{\mathbf{V}}_{\mathrm{w}} \circ \int_0^L \overline{\mathbf{\Psi}} \mathbf{J} \overline{\mathbf{\Psi}} \, dz$$
$$\widetilde{\mathbf{K}}^{\sigma}_{\Omega\Omega} = \overline{\mathbf{V}}^{T}_{\Omega} \mathbf{K}^{\sigma}_{\Omega\Omega} \overline{\mathbf{V}}_{\Omega} \circ \int_0^L \overline{\mathbf{\Psi}}'' \mathbf{J} \overline{\mathbf{\Psi}}'' \, dz$$
$$\widetilde{\mathbf{K}}^{\tau}_{\Omega\mathrm{w}} = \overline{\mathbf{V}}^{T}_{\Omega} \mathbf{K}^{\tau}_{\Omega\mathrm{w}} \overline{\mathbf{V}}_{\mathrm{w}} \circ \int_0^L \overline{\mathbf{\Psi}}' \mathbf{J} \overline{\mathbf{\Psi}}' \, dz$$
$$\widetilde{\mathbf{K}}^{\tau}_{\Omega\Omega} = \overline{\mathbf{V}}^{T}_{\Omega} \mathbf{K}^{\tau}_{\Omega\Omega} \overline{\mathbf{V}}_{\Omega} \circ \int_0^L \overline{\mathbf{\Psi}}' \mathbf{J} \overline{\mathbf{\Psi}}' \, dz$$

Table 2. Beam element load vector contributions.

$$\widetilde{\mathbf{r}}_{\mathrm{w}} = \int_0^L \mathbf{\Psi}_h{}^T \, \phi \, dz \, \mathbf{V}^{T}_{\mathrm{w}} \mathbf{r}_{\mathrm{w}} \qquad \widetilde{\mathbf{r}}_{\Omega} = \int_0^L \mathbf{\Psi}_h'{}^T \, \phi \, dz \, \mathbf{V}^{T}_{\Omega} \mathbf{r}_{\Omega}$$

element formulation we will specify the boundary displacements at the two ends of the beam, i.e. at $z = 0$ and at $z = L$ where L is the beam length. Denoting the assembled boundary displacement vector by $\mathbf{u}_b$ we can write the following equation for the determination of the solution constants:

$$\mathbf{u}_b = \mathbf{A}\mathbf{c} \quad \Rightarrow \quad \mathbf{c} = \mathbf{A}^{-1}\mathbf{u}_b \tag{12}$$

Substituting beam boundary displacements for the solution constants into the first variation of equation (11) using equation (12) the formulation is redefined to include the end displacements in GBT-space as follows:

$$\begin{aligned} \delta\Pi &= \delta\mathbf{u}_b{}^T \mathbf{A}^{-T} \widetilde{\mathbf{K}} \mathbf{A}^{-1} \mathbf{u}_b - \delta\mathbf{u}_b{}^T \mathbf{A}^{-T} \widetilde{\mathbf{r}} \\ &= \delta\mathbf{u}_b{}^T (\mathbf{K}_e \mathbf{u}_b - \mathbf{R}_e) \end{aligned} \tag{13}$$

where $\mathbf{K}_e$ is the beam element stiffness matrix in GBT-space and $\mathbf{R}_e$ is the beam element load vector in GBT-space.

For stationarity the first variation of the potential energy must be equal to zero whereby we can write the single element equations as

$$\mathbf{K}_e \mathbf{u}_b = \mathbf{R}_e \tag{14}$$

Using a standard finite element procedure to assemble the global system we obtain

$$\mathbf{K}\mathbf{u} = \mathbf{R} \quad \Leftrightarrow \quad \mathbf{u} = \mathbf{K}^{-1}\mathbf{R} \tag{15}$$

where $\mathbf{K}$ has to be a positive definite "square" matrix and $\mathbf{R}$ is the load vector corresponding to the chosen load. However in order to achieve a positive definite matrix it is necessary to apply boundary conditions, for example as described in the next section.

5 BOUNDARY CONDITIONS AND NODAL LOADS

To introduce boundary conditions in the finite element equations (15) the simple method of adding stiff springs is chosen. The boundary stiffness contributions $\Delta\mathbf{K}_{\mathrm{FE}}$ are formulated in the unconstrained FE-space $\mathbf{u}_{\mathrm{FE}}$ corresponding to all nodal degrees of freedom and the axial derivatives of transverse components of these. Thus the beam end spring stiffness contributions $\Delta\mathbf{K}_{\mathrm{FE}}$ are transformed into GBT space by

$$\Delta\mathbf{K}_{\mathrm{GBT}} = \mathbf{T}^T \Delta\mathbf{K}_{\mathrm{FE}} \mathbf{T} \tag{16}$$

and the nodal loads (at beam element ends and intersections) are transformed from FE-space to GBT-space by the transformation

$$\Delta\mathbf{R}_{\mathrm{GBT}} = \mathbf{T}^T \Delta\mathbf{R}_{\mathrm{FE}} \tag{17}$$

Using this method quite a wide range of situations may be analyzed.

6 INTERNAL ELEMENT DISPLACEMENTS

The internal beam displacements are represented by the cross-section node displacement vectors $\mathbf{u}_z(z)$ and $\mathbf{u}_{\mathrm{w}}(z)$ as a function of the axial coordinate z. In the beam element these internal displacements are found by superposition of (a) the internal displacements induced by the nodal displacements without distributed loading and (b) the displacements induced by the loading on the beam with zero nodal displacements.

Adhering to this concept equation (18) gives us the first contribution as

$$\begin{aligned} \mathbf{u}^{(a)}_{\mathrm{w}}(z) &= \mathbf{V}_{\mathrm{w}} \mathbf{\Psi}_h(z) \, \mathbf{c} \\ \mathbf{u}^{(a)}_{z}(z) &= -\mathbf{V}_{\Omega} \mathbf{\Psi}'_h(z) \, \mathbf{c} \end{aligned} \tag{18}$$

and the second contribution is given as

$$\begin{aligned} \mathbf{u}^{(b)}_{\mathrm{w}}(z) &= \mathbf{V}_{\mathrm{w}} [\mathbf{\Psi}_h(z) \, \mathbf{c}_p + \mathbf{\Psi}_p(z) \boldsymbol{\phi}] \\ \mathbf{u}^{(b)}_{z}(z) &= -\mathbf{V}_{\Omega} [\mathbf{\Psi}'_h(z) \, \mathbf{c}_p + \mathbf{\Psi}'_p(z) \boldsymbol{\phi}] \end{aligned} \tag{19}$$

Finally the two solutions (a) and (b) can be superimposed and the semi-analytically determined internal displacement vectors can be found as

$$\begin{aligned} \mathbf{u}_{\mathrm{w}}(z) &= \mathbf{V}_{\mathrm{w}} [\mathbf{\Psi}_h(z) \, (\mathbf{c} + \mathbf{c}_p) + \mathbf{\Psi}_p(z) \boldsymbol{\phi}] \\ \mathbf{u}_{z}(z) &= -\mathbf{V}_{\Omega} [\mathbf{\Psi}'_h(z) \, (\mathbf{c} + \mathbf{c}_p) + \mathbf{\Psi}'_p(z) \boldsymbol{\phi}] \\ &\text{where } \mathbf{c} = \mathbf{A}^{-1}\mathbf{u}_b \text{ and } \mathbf{c}_p = -\mathbf{A}^{-1}\mathbf{B}\boldsymbol{\phi}. \end{aligned} \tag{20}$$

For a greater explanation and description see paper (Andreassen & Jönsson 2013).

Now we are able to find displacements, strains and stresses at any point in the beam element. In the next section an example illustrating this new approach is given.

7 EXAMPLE

In this section a simple supported lipped channel beam loaded by two point loads symmetrically placed in the

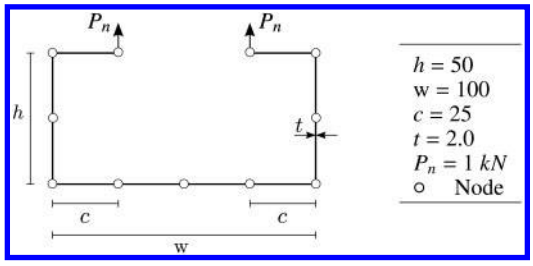

Figure 3. Geometry, in-plane discretization, parameter values and load for the lipped channel beam.

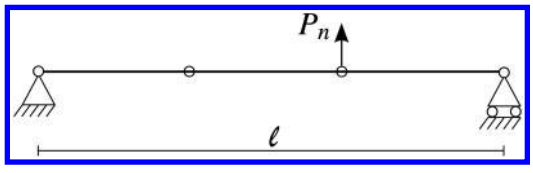

Figure 4. Geometry and discretization for a lipped channel beam consisting of 3 elements.

same cross section as shown in Figure 3 is analyzed. Nodal displacement results as well as stress distribution results of GBT are compared to those found using the commercial FE program Abaqus. A simple supported lipped channel beam with a length of 1500 mm is considered consisting of and assembled by three single beam elements of 500 mm. The end sections are constrained against transverse displacements, but otherwise free to warp (and thus also rotate). Further, one of the ends is fixed at a single node against longitudinal translation. An elasticity modulus $E = 2.1 \cdot 10^5$ MPa and a Poisson ratio of $\nu = 0.3$ have been used.

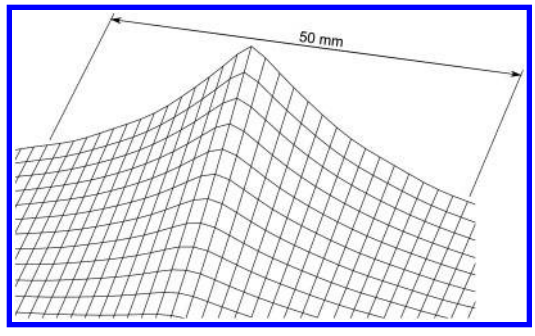

Figure 7. GBT plot of the lipped channel to shown the exponential decrease in the y-z-plane.

Table 3. Nodal displacements of GBT and FE analysis.

	GBT [mm]	Abaqus [mm]	Difference [%]
u_x	−1.424	−1.415	0.6
u_y	4.697	4.772	1.6

The results found using Abaqus are based on isotropic material and the S4 shell element with full 4 point integration. The linear elastic finite element calculations are based on a structured rectangular mesh with a side length seed of 5 mm. The cross section is fixed in the transverse directions at both ends and fixed at a single node against longitudinal translation. Using the parameters as given in Figure 3 and 4 and the full solution in equation (20) leads to the deformed configuration shown in Figure 5. Here it is seen that the global deformation is related to flexure of the beam, non-local distortional deformation of the cross section and a very local plate deformation of the lips related to the location of the point loads. Thus three length scales are represented, the global flexural beam mode as seen in Figure 5, the non-local distortional deformation of the lips as shown in Figure 6 and the local distortional plate deformation of the lip as shown in close-up in Figure 7. This example points out the importance of taking distortion into account in order to obtain a good approximation of the deformation shape. From Figure 7 it is seen that the deflection in the longitudinal z-direction decreases exponentially in the y-z-plane. It should also be noted that the deformation is so local that it is difficult to see that the surface is C^1 continuous. The decreasing non-local distortion is clear in the x-z-plot shown in Figure 6, which represents a part of the beam symmetrically about the loaded cross section. Comparing the nodal displacements of the marked node to the displacement found using a model in the commercial FE program Abaqus gives the displacement values and the corresponding deviations shown in Table 3. From Table 3 the deviation from Abaqus results of the displacement, u_x, in the horizontal direction is 0.6% while the deviation for the vertical displacement, u_y, is 1.6%. Due to the poor discretization of the cross section and

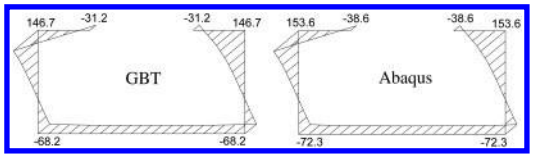

Figure 8. Comparison between the axial normal stress distributions obtained with GBT and Abaqus. All values are in MPa.

σ_s	492.3	481.9	2.1

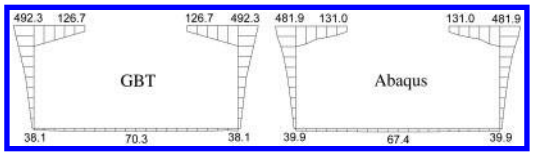

Figure 9. Comparison between the transverse bending stress distributions obtained with GBT and Abaqus. All values are in MPa.

the present approach which is based on a beam theory these deviations may also be expected.

Having compared the nodal displacement obtained with GBT and Abaqus we take a look at the stress distributions. A comparison of the membrane stresses in the z direction is shown in Figure 8. Comparing the stresses in relation to the maximum stress at the cross section a maximum deviation of 4.8% is obtained as shown in Table 4. This deviation level is expected as the chosen point is subjected to very local complex phenomena. The transverse bending stresses are shown in Figure 9. In this case a maximum deviation of 2.1% is obtained.

8 CONCLUSIONS

In this conference paper the formulation of a distortional semi-discretized thin-walled beam element is briefly presented based on a condensed presentation of the novel finite-element-based displacement approach and beam formulation published by the authors in (Jönsson & Andreassen 2011, Andreassen & Jönsson 2012b, Andreassen & Jönsson 2012a, Andreassen & Jönsson 2013, Andreassen 2012). Using the full assembled homogenous solution along the beam, the beam element stiffness matrices have been found. From the full assembled homogenous solution as well as the full assembled non-homogeneous solution the displacements of the full semi-analytical solution along the beam have been found in the context of a beam element. An illustrative example has been given including a simple supported lipped channel beam loaded by two point loads symmetrically placed in the same cross section. The chosen example show a solution which are applicable to the finite element formulation. The novel approach presented in this paper is a considerable theoretical achievement, since it without approximation gives the full analytical solution along the loaded beam for a given discretization of the cross section. Reasonable matches are obtained in all cases confirming that this new developed GBT approach provides reasonable results with a very small computational cost making it an alternative to the traditional finite element calculations and the other available methods.

ABSTRACT: This paper outlines the use of the Generalised Beam Theory (GBT) approach to study the structural behaviour of prismatic thin-walled members with stiffeners of arbitrary geometries. This is particular relevant for bridge applications, where the stiffeners' arrangements are usually optimized in the design. The proposed GBT procedure is expressed in the spirit of Kantorovich's semi-variational method, using the dynamic modes of an unconstrained planar frame as the in-plane conventional deformation modes. The corresponding warping deformations are then evaluated from the post-processing of these in-plane modes, thus reversing the strategy of the classical GBT procedure. Constraint conditions are applied to the stiffened plate elements to provide the rigidity exhibited by the specified stiffeners. The method used is applicable to open, closed and partially closed cross-sections. The efficiency and ease of use of the method are outlined by means of two examples, aimed to describe the linear–elastic behaviour of thin-walled members. The numerical results obtained with the proposed approach are validated against those calculated with a shell finite element model developed in Abaqus.

1 INTRODUCTION

Generalised beam theory (GBT) is an elegant method used to study the behaviour of thin-walled members. Its original formulation was proposed by Schardt (1989) which considers the thin-walled member as an assembly of plate segments which are free to bend in the plane of the cross-section. In this sense, GBT is able to capture the loss of the initial shape of the cross-section. The essence of the approach lies in the description of the displacement field as a linear combination of assumed deformation modes whose magnitudes vary along the member. Consequently GBT transforms a three-dimensional problem into a vector valued one-dimension problem.

A GBT analysis consists of two main stages: (1) the cross-sectional analysis, where the deformation modes are chosen; and (2) the member analysis, where the global response of the thin-walled member is evaluated.

Much progress has been made in this field of research since its original inception. In the 1990's, Davies and co-workers reported a number of studies on the linear-elastic and buckling behaviour of thin-walled members, e.g. (Davies & Leach 1994, Jiang & Davies 1997). Extensive work in this area has been carried out over the last decade by Camotin and his co-workers, who extended the applicability of this approach to deal with anisotropic members (Silvestres & Camotim 2002), closed or partially closed sections (Goncalves et. al 2009), finite element modelling (Dinis et. al 2007), buckling of members and frames (Basaglia et. al 2008), post-buckling-problems (Silvestre et. al 2008) and composite steel-concrete members (Goncalves & Camotim 2010). The simplification in the description of the displacement field, enabled within the GBT with the use of cross-sectional deformation modes and amplitude functions, was applied in recent years to the analyses carried out with the finite strip method (Adany & Schafer 2006) and the finite element method (Casafront et. al 2009). In very recent years, attention has been devoted to generalise Vlasov's classic hypotheses of inextensibility and shear undeformability on which GBT was initially based, e.g. (Goncalves et. al 2009, Silvestre & Camotim 2011, Jönsson & Andreassen 2011, Andreassen & Jönsson 2012).

In this context, this paper outlines the use of the GBT approach to study the structural behaviour of prismatic thin-walled members with stiffeners of arbitrary geometry. This is particular relevant for bridge applications, where the stiffeners' arrangements and geometries are usually optimized in the design. The accuracy of the proposed method is validated against a shell finite element model developed in Abaqus (ABAQUS 2008).

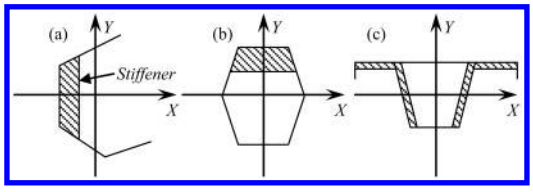

Figure 1. Generic thin-walled stiffened sections: (a) open; (b) closed; (c) partially closed.

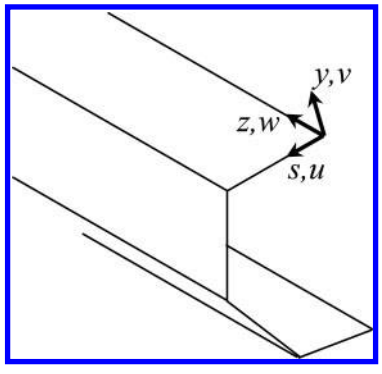

Figure 2. Displacement field.

2 BASIS OF THE GBT APPROACH

Stiffened thin-walled members with open, closed and partially closed cross-sections are considered as an assembly of plate segments (Fig. 1).

The displacement of an arbitrary point $P(s,0,z)$ on the plates mid-surface is described by:

$$\boldsymbol{u}(s,z) = u(s,z)\boldsymbol{e}_s(s) + v(s,z)\boldsymbol{e}_y(s) + w(s,z)\boldsymbol{e}_z(s) \quad (1)$$

using a three-dimensional Cartesian coordinate system, s being the curvilinear abscissa along the mid-line C, y the ordinate and z the coordinate along the member axis with unit vectors $\boldsymbol{e}_s(s)$, $\boldsymbol{e}_y(s)$ and $\boldsymbol{e}_z(s)$ and displacement components $u(s,z)$, $v(s,z)$ and $w(s,z)$ in the same triplet (Fig. 2). In the framework of GBT, Kantorovich's semi-variation method is used to describe the displacement components as a linear combination of assumed deformation modes:

$$\boldsymbol{u}(s,z) = \begin{bmatrix} \sum_{k=1}^{K} U_k(s)\varphi_k(z) \\ \sum_{k=1}^{K} V_k(s)\varphi_k(z) \\ \sum_{k=1}^{K} W_k(s)\varphi'_k(z) \end{bmatrix} \quad (2)$$

where $(')$ denotes differentiation with respect to the variable that follows. $U_k(s)$, $V_k(s)$ and $W_k(s)$ are the three components of the k-th deformation modes (with $k=1,\ldots,K$) and $\varphi_k(z)$ describes their amplitude along the member axis.

2.1 *Displacement and strain field*

The displacement of an arbitrary point $Q(s,y,z)$ lying-within the thickness of the plate can be expressed as $\boldsymbol{d}(s,y,z) = d_s(s,y,z)\boldsymbol{e}_s(s) + d_y(s,y,z)\boldsymbol{e}_y(s) + d_z(s,y,z)\boldsymbol{e}_z(s)$. Employing Kirchoff plate theory, the displacement field is described by:

$$\boldsymbol{d}(s,y,z) = \begin{bmatrix} \sum_{k=1}^{K}[U_k(s) - yV'_k(s)]\varphi_k(z) \\ \sum_{k=1}^{K} V_k(s)\varphi_k(z) \\ \sum_{k=1}^{K}[W_k(s) - yV_k(s)]\varphi'_k(z) \end{bmatrix} \quad (3)$$

The 6 component strain field is comprised of the membrane strains associated with the mid-surface of the plate and the flexural strains which are proportional to the ordinate. From Equation 3, the infinitesimal strain field $\varepsilon = \{\varepsilon_s^M,\ \varepsilon_z^M,\ \gamma_{sz}^M,\ \varepsilon_s^F,\ \varepsilon_z^F,\ \gamma_{sz}^F\}^T$ can be expressed as:

$$\boldsymbol{\varepsilon}(s,y,z) = \begin{bmatrix} \sum_{k=1}^{K} U'_k(s)\varphi_k(z) \\ \sum_{k=1}^{K} W_k(s)\varphi''_k(z) \\ \sum_{k=1}^{K}[W'_k(s) - U_k(s)]\varphi'_k(z) \\ -y\sum_{k=1}^{K} V''_k(s)\varphi_k(z) \\ -y\sum_{k=1}^{K} V_k(s)\varphi''_k(z) \\ -2y\sum_{k=1}^{K} V'_k(s)\varphi'_k(z) \end{bmatrix} \quad (4)$$

where superscripts M and F denote membrane and flexural strains respectively.

Vlasov's fundamental hypotheses for open thin-walled sections specify that the plate segments are: (i) inextensible in the tangential direction, i.e. $\varepsilon_s^M = 0$ and (ii_1) are shear indeformable in their mid-plane, i.e. $\gamma_{sz}^M = 0$. For plate segments belonging to closed loops, the second condition is relaxed and replaced with (ii_2) $\gamma_{sz}^M = constant$, in a piece-wise manner along the abscissa according to Bredt theory for torsion. The displacement components $U_k(s)$, $V_k(s)$ and $W_k(s)$ are chosen in such a way as to satisfy (i) and (ii_1), or (i) and (ii_2) where appropriate.

2.2 *Stress field*

The resulting stress field $\boldsymbol{\sigma} = \{\sigma_s^M,\ \sigma_z^M,\ \tau_{sz}^M,\ \sigma_s^F,\ \sigma_z^F,\ \tau_{sz}^F\}^T$ is composed of an active σ_a and a reactive σ_r part, i.e. $\boldsymbol{\sigma} = \boldsymbol{\sigma}_a + \boldsymbol{\sigma}_r$. In particular for plate on open branches $\boldsymbol{\sigma}_a = \{0, \sigma_z^M, \sigma_s^F, \sigma_z^F, \tau_{sz}^F\}^T$, for plates belonging to closed loops $\boldsymbol{\sigma}_a = \{0, \sigma_z^M, \tau_{sz}^M, \sigma_s^F, \sigma_z^F, \tau_{sz}^F\}^T$ and for all plates $\boldsymbol{\sigma}_r = \{\sigma_s^M, 0, \tau_{sz}^M, 0, 0,\}^T$. Assuming a linear elastic constitutive model, the stress field can be expressed as:

$$\boldsymbol{\sigma} = \boldsymbol{C}_e\boldsymbol{\varepsilon} + \boldsymbol{\sigma}_r \quad (5)$$

where $\boldsymbol{C}_e$ is the elastic matrix and is defined as:

$$\boldsymbol{C}_e = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ & E & 0 & 0 & 0 & 0 \\ & & G & 0 & 0 & 0 \\ & & & \frac{E}{1-\upsilon^2} & \frac{\upsilon E}{1-\upsilon^2} & 0 \\ & sym & & & \frac{E}{1-\upsilon^2} & 0 \\ & & & & & G \end{bmatrix} \quad (6)$$

2.3 *Weak form of the problem*

The principle of virtual work is used to derive the weak form of the problem which and can be expressed as:

$$\int_V \delta\boldsymbol{\varepsilon}^T\boldsymbol{\sigma}dV = \int_S \delta\boldsymbol{u}^T\boldsymbol{f}dS \tag{7}$$

where virtual quantities are denoted by $\delta(\cdot)$ and $\boldsymbol{f}(s,z) = f_s(s,z)\boldsymbol{e}_s(s) + f_y(s,z)\boldsymbol{e}_y(s) + f_z(s,z)\boldsymbol{e}_z(s)$ are the surface loads applied to the member.

Substituting Equations 3–5 into 7, the weak formulation is expressed as a function of the unknown amplitude functions $\boldsymbol{\varphi}$ as follows

$$\int_0^L(\boldsymbol{\mathcal{A}}\delta\boldsymbol{\varphi})^T\boldsymbol{T}(\boldsymbol{\mathcal{A}}\boldsymbol{\varphi})dz = \int_0^L(\boldsymbol{\mathcal{B}}\delta\boldsymbol{\varphi})^T\boldsymbol{g}dz \tag{8}$$

with differential operators $\boldsymbol{A} = [1 \;\; \partial \;\; \partial^2]^T$ and $\boldsymbol{B} = [1 \;\; \partial]^T$; the stiffness terms are grouped as follows:

$$\boldsymbol{T} = \begin{bmatrix} \boldsymbol{B} & \boldsymbol{0} & \boldsymbol{D^a} \\ \boldsymbol{0} & \boldsymbol{D^c} & \boldsymbol{0} \\ \boldsymbol{D^b} & \boldsymbol{0} & \boldsymbol{C} \end{bmatrix} \tag{9}$$

with $K \times K$ stiffness matrices $\boldsymbol{B}$, $\boldsymbol{C}$, $\boldsymbol{D^a}$, $\boldsymbol{D^b}$ and $\boldsymbol{D^c}$, whose coefficients are defined by:

$$B_{hk} = \int_{\mathcal{C}} \left[\tfrac{Et^3}{12(1-\nu^2)} V_h'' V_k''\right] ds \tag{10}$$

$$C_{hk} = \int_{\mathcal{C}} \left[EtW_hW_k + \tfrac{Et^3}{12(1-\nu^2)} V_hV_k\right] ds \tag{11}$$

$$D^a_{hk} = \int_{\mathcal{C}} \left[\tfrac{\nu Et^3}{12(1-\nu^2)} V_hV_k''\right] ds \tag{12}$$

$$D^b_{hk} = \int_{\mathcal{C}} \left[\tfrac{\nu Et^3}{12(1-\nu^2)} V_h''V_k''\right] ds \tag{13}$$

$$D^c_{hk} = \int_{\mathcal{C}} \left[Gt(U_h + V_h')(U_k + V_k') + \tfrac{Gt^3}{3} V_h'V_k'\right] ds \tag{14}$$

The loading terms are collected as:

$$\boldsymbol{g} = \begin{bmatrix} \boldsymbol{g^a} \\ \boldsymbol{g^b} \end{bmatrix} \tag{15}$$

where the coefficients included in the $K \times 1$ load vectors $\boldsymbol{g^a}$ and $\boldsymbol{g^b}$ are defined by:

$$\boldsymbol{g^a} = \int_{\mathcal{C}} f_z W_h ds \tag{16}$$

$$\boldsymbol{g^b} = \int_{\mathcal{C}} [f_s U_h + f_y V_h] ds \tag{17}$$

3 CROSS-SECTIONAL ANALYSIS

The fundamental role of the GBT cross-sectional analysis is the identification of a set of deformation modes able to adequately describe the distortion of the cross-section from its initial shape. In this study the conventional deformation modes are taken as the dynamic eigenmodes of a free planar frame representing the cross-section (Ranzi & Luongo, 2011). The dynamic analysis is carried out on a discrete model using standard finite element procedures (Bathe 2006). This leads to the following algebraic generalised eigenvalue problem

$$(\boldsymbol{K} - \lambda\boldsymbol{M})\boldsymbol{q} = \boldsymbol{0} \tag{18}$$

where $\boldsymbol{K}$ is the stiffness matrix, $\boldsymbol{M}$ the mass matrix and $\boldsymbol{q}$ is the vector of nodal displacements of the section.

3.1 *Inextensibility constraint*

Solving the eigenvalue problem in its current form results in conventional deformation modes which violates Vlasov's first fundamental hypothesis. To enforce inextensibility of the plate segments, internal constraints are introduced into the model. This is carried out following available procedures commonly used in finite element modelling (e.g., ABAQUS 2008), also applied to thin-walled structures in recent years (e.g., Casafront et al. 2009, Adany & Schafer 2008)

In local coordinates the (linearised) constraints can be written as $u_1^e - u_2^e = 0$, and in global coordinates as:

$$(u_j - u_i)\cos\alpha_e + (v_j - v_i)\sin\alpha_e = 0 \tag{19}$$

where element e joins nodes i and j and forms an angle α_e with the X-axis. In matrix form:

$$\boldsymbol{Aq} = \boldsymbol{0} \tag{20}$$

where $\boldsymbol{A}$ is an $M \times N$ matrix where M is the number of constraints (i.e one for each element) and $N > M$ is the number of *dofs* within the system; $\boldsymbol{q} = \{\quad, u_j, v_j, \theta_j, \cdots\}^T$ is an $N \times 1$ vector of nodal displacements of the section in global coordinates (X, Y).

This system of equations can be partitioned as follows:

$$[\boldsymbol{A}_m \quad \boldsymbol{A}_s]\begin{bmatrix} \boldsymbol{q}_m \\ \boldsymbol{q}_s \end{bmatrix} = \boldsymbol{0} \tag{21}$$

where $\boldsymbol{A}_s$ is an $M \times M$ invertible matrix. Therefore the M slave *dofs* $\boldsymbol{q}_s$ can be expressed in terms of the $(N - M)$ master *dofs* $\boldsymbol{q}_m$:

$$\boldsymbol{q} = \boldsymbol{R}\boldsymbol{q}_m \tag{22}$$

where:

$$\boldsymbol{q} = \begin{bmatrix} \boldsymbol{q}_m \\ \boldsymbol{q}_s \end{bmatrix} \tag{23}$$

$$\boldsymbol{R} = \begin{bmatrix} \boldsymbol{I} \\ -\boldsymbol{A}_s^{-1}\boldsymbol{A}_m \end{bmatrix} \tag{24}$$

Substituting Equation 22 into Equation 18, the eigenvalue problem with constraints can be expressed in terms of displacements of the master *dofs* $\boldsymbol{q}_m$:

$$(\boldsymbol{K}_R - \lambda \boldsymbol{M}_R)\boldsymbol{q}_m = \boldsymbol{0} \tag{25}$$

where:

$$\boldsymbol{K}_R = \boldsymbol{R}^T \boldsymbol{K} \boldsymbol{R} \tag{26}$$

$$\boldsymbol{M}_R = \boldsymbol{R}^T \boldsymbol{M} \boldsymbol{R} \tag{27}$$

3.2 *Dynamic eigenmodes and warping functions*

Solving Equation 25, the eigenvalues λ represent the squared eigenfrequencies and provide a natural ordering to the deformation modes. The in-plane deformation modes $U_k(s)$ and $V_k(s)$ from Equation 2 are chosen as the eigenvectors $\boldsymbol{q}$ and their associated shape functions.

The warping displacements $W_k(s)$ are calculated by enforcing (ii_1) nil or (ii_2) constant shear strain assumptions. The membrane shear strain can be expressed as:

$$\gamma_{sz}^M(s) = \sum_{k=1}^{K} \Gamma_k(s)\varphi_k'(z) \tag{28}$$

where:

$$\Gamma_k(s) = W_k'(s) + U_k(s) \tag{29}$$

and $\Gamma_k(s)$ is a piecewise constant function which is equal to zeros for elements lying on open branches and unknown for elements belonging to closed loops. Based on the elements displacements:

$$\Gamma_k^e = \frac{W_k^{i_2} - W_k^{i_1}}{b^e} + U_k^e \tag{30}$$

where W_k^{i1} and W_k^{i2} are the warping displacements at the near i_1 ($s = 0$) and far i_2 ($s = b^e$) nodes respectively of element e of length b^e.

For open sections the warping displacements W^i are determined by imposing for each element:

$$\Gamma_k^e = \frac{W_k^{i_2} - W_k^{i_1}}{b^e} + U_k^e = 0 \tag{31}$$

However one of the unknowns remains arbitrary and represents the uniform extension of the member. To ensure the warping of each mode is orthogonal to the extension, the remaining unknown is chosen such that the average warping of each mode is zero:

$$\int_c W_k(s)ds = 0 \tag{32}$$

For closed sections, or elements belonging to closed braches, the constants Γ_k^e are related via the constitutive law to the (unknown) tangential stress flow Q_k^j acting on the j^{th} loop. In this case Equation 31 is replaced by:

$$Gt^e \Gamma_k^e = Gt^e \left(\frac{W_k^{i_2} - W_k^{i_1}}{b^e} + U_k^e \right) = \sum_j (\pm) Q_k^j \tag{33}$$

where the sum is extended to all closed loops that element e belongs to.

Once the warping displacements have been determined, the stiffness and loading terms, $\boldsymbol{T}$ and $\boldsymbol{g}$, from Equation 8 can finally be determined.

4 MEMBER ANALYSIS

The objective of the GBT member analysis is to determine the global response of a thin-walled element. This is carried out in this study applying the finite element method to the weak form of the problem derived in Section 2.3.

4.1 *Discrete model for the member analysis*

With the finite element approach, the unknown amplitude functions $\boldsymbol{\varphi}$, expressed in terms of the member axis, are approximated by means of polynomials:

$$\boldsymbol{\varphi} \cong \boldsymbol{N}^e \boldsymbol{\varphi}^e \tag{34}$$

where $\boldsymbol{\varphi}^e$ collects the function nodal values and the adopted shape functions are specified in $\boldsymbol{N}^e$.

Substituting Equation 34 into Equation 8, the problem is transformed into the following system of linear equations for the e-th element:

$$\boldsymbol{K}^e \boldsymbol{\varphi}^e = \boldsymbol{p}^e \tag{35}$$

where $\boldsymbol{K}^e$ is the stiffness matrix, defined by:

$$\boldsymbol{K}^e = \int_0^L (\boldsymbol{\mathcal{A}}\boldsymbol{N}^e)^T \boldsymbol{T} \boldsymbol{\mathcal{A}} \boldsymbol{N}^e dz \tag{36}$$

and $\boldsymbol{p}^e$ is the vector of nodal actions, expressed as:

$$\boldsymbol{p}^e = \int_0^L (\boldsymbol{\mathcal{B}}\boldsymbol{N}^e)^T \boldsymbol{g} dz \tag{37}$$

4.2 *Constraint conditions*

Constraint conditions are applied to the stiffened plate elements to provide the rigidity exhibited by the specified stiffeners. The solution is then sought following the procedure already illustrated for the cross-sectional analysis in Equations 20–27.

5 APPLICATIONS

Numerical examples are presented in the following to illustrate the accuracy of the proposed procedure. Two simply supported thin-walled members with 1 mm thick plates, elastic modulus of 200 GPa and Poisson's ratio of 0.3 are considered. Stiffeners are placed at 0.25 m centres along their 1 m length.

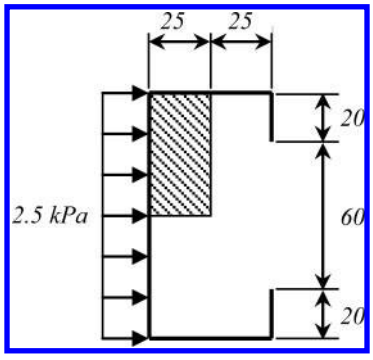

Figure 3. Stiffened lipped channel section (all dimensions are in mm).

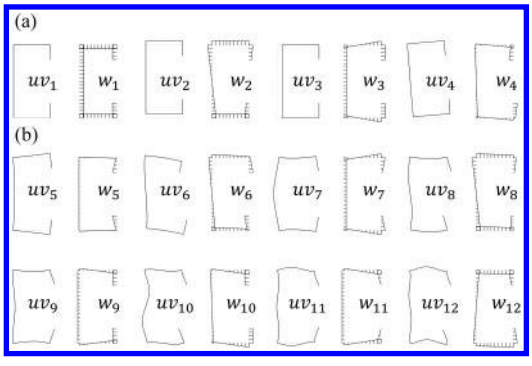

Figure 4. Lipped channel section: (a) rigid modes; (b) deformation modes.

5.1 *Lipped channel section*

The stiffened lipped channel section is depicted in Figure 3, with uniform pressure applied to the web of the section. For illustrative purposes the four rigid body modes and first eight deformation modes are presented in Figure 4.

A summary of the results is presented in Figure 5 at critical locations along the member length (i.e. where the various field outputs reach their maximum values). The results of the proposed procedure are compared to those obtained using GBT for a fully stiffened section (i.e. $\boldsymbol{\varphi}^e$ nil for all non-rigid body modes at the stiffener locations) and a shell finite element model developed in Abaqus which reflects the stiffeners' arrangement outlined in Figure 3. For clarity, the displacements have been scaled to provide a clear overview of the deformations of the section while the stresses are left unscaled to aid in comparisons between their relative magnitudes. This comparison shows a close match between the results calculated with the proposed GBT approach and Abaqus models, while the fully stiffened GBT model underestimates the deformations as expected.

5.2 *Box girder section*

The stiffened box girder section has been loaded with a uniform pressure applied to the left hand half of the top flange with one-quarter of the closed box being stiffened (Fig. 6). A summary of the cross-sectional analysis is provided in Figure 7 with the four rigid body modes and the first eight deformation modes of the section being depicted.

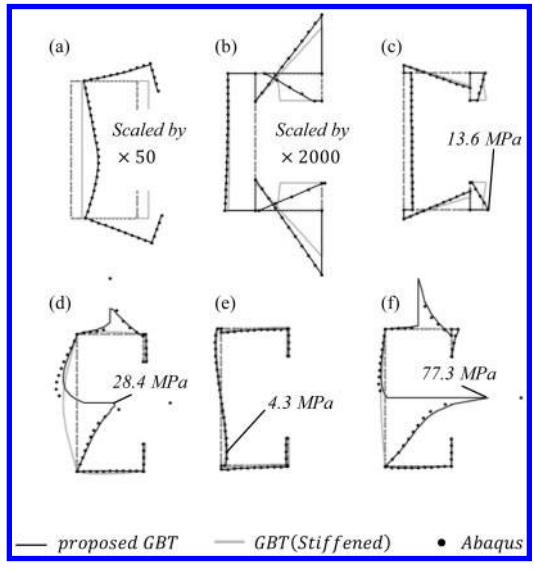

Figure 5. Lipped channel section deformations and stress distributions: (a) uv at $z = L/2$; (b) w at $z = 0, L$; (c) σ_z^M at $z = L/2$; (d) σ_z^F at $z = L/2$; (e) τ_{sz}^F at $z = 0, L$; (f) σ_s^F at $z = L/2$.

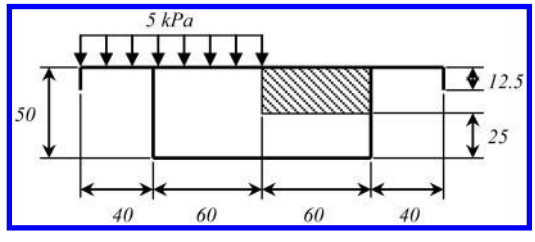

Figure 6. Stiffened box girder section (all dimensions are in mm).

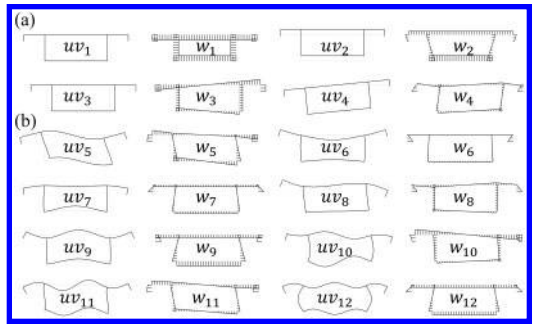

Figure 7. Box girder section: (a) rigid modes; (b) deformation modes.

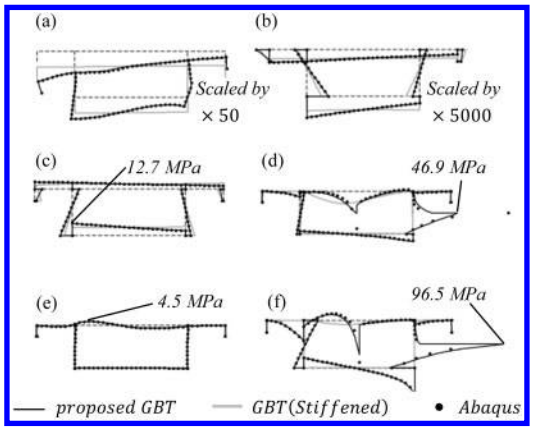

Figure 8. Box girder section deformations and stress distributions: (a) uv at $z = L/2$; (b) w at $z = 0, L$; (c) σ_z^M at $z = L/2$; (d) σ_z^F at $z = L/2$; (e) τ_{sz}^F at $z = 0, L$; (f) σ_s^F at $z = L/2$.

Comparisons of the results obtained from the three models are displayed in Figure 8, with the displacements scaled and the stresses left unscaled as in the previous example. The values obtained with the proposed GBT and the Abaqus models are in close agreement. At the edge of the stiffened regions, the section experiences large flexural stress concentrations which, in some cases, are almost an order of magnitude higher than the membrane stresses. These peak stresses are localised and dissipate within a distance equal to the depth of the section either side of the stiffener location (e.g. 450 mm $< z <$ 550 mm).

6 CONCLUSION

This paper described an approach to account for the presence of arbitrary stiffeners' arrangements and geometries in the framework of Generalised Beam Theory (GBT). With the proposed procedure, the dynamic modes of an unconstrained planar frame are used as the in-plane conventional deformation modes, from which the corresponding warping deformations are determined in a post-processing phase. Constraint conditions are applied to the stiffened plate elements to provide the rigidity exhibited by the specified stiffeners. This approach is applicable indifferently to open, closed and partially closed stiffened sections. Two numerical examples were presented to highlight the accuracy of the method, with close agreement found between the proposed GBT and a shell finite element model developed in Abaqus.

Cold-formed steel design and research assisted by testing

D. Dubina
"Politehnica" University of Timisoara, Romania,
Romanian Academy, Timisoara, Branch, Romania

ABSTRACT: The technical and economic efficiency of cold-formed steel structures, which usually are of thin walled sections, is strongly dependent on the ability of the designer to manage the instability problems and optimize the connection detailing. Due to complicate shapes of cold-formed steel sections, the instability interaction and non-conventional fastening technology, sometimes, it is really difficult to control such types of problems by analytical calculation procedures. On this purpose, modern design codes give the possibility to apply design methodologies assisted by testing. The paper summarizes the European codification for design and research assisted by testing and illustrates the experimental and numerical investigations carried out at the CEMSIG Research Centre of the "Politehnica" University of Timisoara, in order calibrate calculation procedures to some complex structural problems.

1 INTRODUCTION

Cold formed steel members are usually of thin walls, some times of complicate geometry and particular connecting technology. In most of cases the design of structures realized of thin walled sections is dominated by stability problems. Investigation of structural stability problems was based in early stage, e.g 18th–19th century, on experiments, which conducted to empirical solution. Later, research in the structural stability became predominantly theoretical, the extensive theoretical studies being accompanied, at most, by corroborating experiments (Singer et al, 1997), and often, even for complex structural instability problems, the design was based on theoretical assumptions only.

Experimental analysis and testing of structural solutions and calculation models is realized in laboratory or in situ. Simulation of a given problem, using test calibrated numerical models and advanced analysis is also a common research tactics. Both approaches are part of the current research and design methodologies. On this purpose, most of actual Design Codes include relevant provisions related to design assisted by testing and values for calibration of numerical models.

2 EUROPEAN CODIFICATION FRAMING

In Section 5, entitled Structural analysis and design assisted by testing of EN 1990 is stipulated that design may be based on a combination of tests and calculations and that design assisted by test results shall achieve the level of reliability required for the relevant design situation.

The statistical uncertainty due to a limited number of test results shall be taken into account.

Annex D of the code provide the statistical procedures to be applied in order to obtain experimentally the characteristic strengths, R_k, and the partial safety coefficients, γ_M to be applied in the design models in order to calculate the relevant design strengths, R_d.

EN1993-1-3, in its Section 9 it refers to the principles to apply for design assisted by testing, while in the Annex A provide standard procedures for:

- Tests on cold-formed members;
- Tests on profiled sheets and liner trays;
- Tests on structures and portions of structures;
- Tests on beams restrained by sheeting;
- Evaluation of test results to determine design values.

In principle, testing may be undertaken under any of following circumstances:

a) if the properties of steel are unknown;
b) if it is desired to take account of the actual properties of the cold-formed member or sheet;
c) if adequate analytical procedures are not available for designing the component by calculation alone;
d) if realistic data for design cannot otherwise be obtained;
e) if it is desired to check the performance of an existing structure or structural component;
f) if it is desired to build a number of similar structures or components on the basis of a prototype;
g) if confirmation of consistency of production is required;
h) if it is desired to determine the effects of interaction with other structural components;
i) if it is desired to determine the effects of the lateral or torsional restraint supplied by other components;
j) it is desired to prove the validity and adequacy of an analytical procedure;

k) if it is desired to produce resistance tables based on tests, or on a combination of testing and analysis;
l) if it is desired to take into account practical factors that might alter the performance of a structure, but are not addressed by the relevant analysis method for design by calculation.

There are available specific tests based design rules such as those for fasteners here i.e. ECCSS Publication No. 124, 2008: The testing of Connections with Mechanical fasteners in Steel Sheeting and Sections, and ECCS No. 127, 2009 – Preliminary European Recommendations for the Testing and Design of Fastenings for Sandwich Panels

The design of Storage Pallet Rack Systems, is in proportion of 80% based on tests; EN15512:2009, offers relevant procedures on this purpose.

For experimental techniques the reader may found valuable information in the General Report made by Rasmussen (2000) while a state-of-art review of experimental methods applied to study and evaluate stability for buckling of thin-walled structure is presented in the excellent book of Singer et al. (1998).

On the following, two complex structural problems approached by tests will be displayed i.e.

- Experimental evaluation of buckling imperfection coefficient for perforated rack type sections in compression;
- Experimental calibration by laboratory tests and numerical simulation of a Prescriptive Design type methodology for Wall Stud Cold Formed Steel framing house, and its validation by in situ tests.

3 EXPERIMENTAL EVALUATION OF α – IMPERFECTION COEFFICIENT FOR PERFORATED SECTIONS

3.1 *The ECBL method for calibration of the α – imperfection factor*

Since the interactive buckling approach based on ECBL method is already known (Dubina, 2001), herein the principle is summarized only. Assuming the two common mode intraction, in a thin-walled compression member, occurs by coupling of the Euler bar instability mode, $\overline{N}_E = 1/\overline{\lambda}^2$ ($\overline{\lambda}$ = relative member slenderness) and the sectional mode (e.g. distortional instability mode) $\overline{N}_L$ described by means of the reducing factor of area $N_L = Q_L$. The resulting eroded curve for coupled instability mode is $\overline{N}(\overline{\lambda}, Q_L, \psi)$ (see Figure 3).

Critical load maximum erosion (due both to the imperfections and coupling effect) occurs in the instability mode interaction point, M ($\overline{\lambda} = 1/Q_L^{0.5}$) where, the erosion factor ψ is defined as:

$$\psi = \overline{N}_D - \overline{N} \tag{1}$$

in which $\overline{N}(\overline{\lambda}, Q_L, \psi)$ is the relative interactive buckling load and $Q_L = N_L/f_y \cdot A$; A is the gross cross-section area; N_L = the ultimate capacity corresponding to local (or distortional) buckling; $\overline{N} = N/N_{pl}$ the relative axial load; N, the axial load; $N_{pl} = f_y \cdot A$, the full plastic resistance of the member; $\overline{\lambda}$ the relative slenderness of compression member.

If $\overline{\lambda} = 1/Q_L^{0.5}$ is introduced, it results an imperfection factor corresponding to the distortional-global buckling:

$$\alpha = \frac{\psi^2}{1-\psi} \frac{\sqrt{Q_L}}{1 - 0.2\sqrt{Q_L}} \tag{2}$$

Equation (2) represents the new formula of α imperfection coefficient which should be introduced in European buckling curves in order to adapt these curves to distortional-overall interactive buckling.

Even if for a few particular problems analytical procedures might be used to get the erosion factor, ψ, currently the numerical and experimental procedures are only suitable to obtain practical values. Since, anyway, a numerical procedure have to be experimentally calibrated, the experimental approach will be presented. It contains the following steps:

1. Testing of a relevant sample of compression specimens into the coupling range which is defined by the interactive slenderness, $\overline{\lambda} = 1/Q_L^{0.5}$, and also by the points of $\overline{\lambda}_L = \pm 0.1 \cdot \overline{\lambda}_L$ (Fig. 1).
2. Compute the individual value of erosion, $\psi_i = Q_i - N_{i,\exp}/N_{i,pl}$, for the i number, and the mean value of the erosion factor for all n specimens, $\psi_m = \sum_{i=1}^{n} \psi_i / n$.
3. Compute the *design value* of the erosion factor:

$$\psi_d = \psi_d + 2 \cdot s_\psi \tag{3}$$

where s is the standard deviation which is introduced in order to take into account the randomness of numerical results.
4. Compute the value of α, imperfection coefficient, using Eq. (2) using the value of ψ_d, from (3).

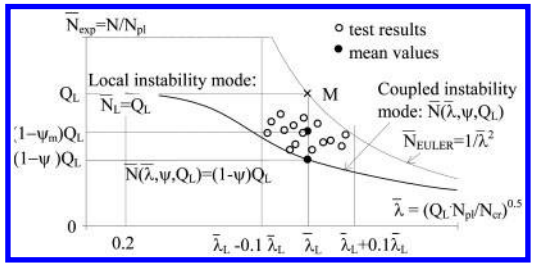

Figure 1. The ECBL model and evaluation of ψ erosion factor.

3.2 *Summary of experimental program*

The ECBL approach was applied to evaluate the α – coefficient for two pallet rack upright sections: RS125 × 3.2 and RS95 × 2.6 (Crisan et al. 2012 a, b).

Figure 2. Failure modes for distortional and interactive buckling specimens.

Table 1. Erosion coefficients.

Interactive length [mm]	Failure load [kN]	Erosion (ψ)	Interactive length [mm]	Failure load [kN]	Erosion (ψ)
RS125 × 3.2			RS95 × 2.6		
2110	296.73	0.153	1510	171.50	0.357
	296.91	0.153		169.07	0.365
	293.63	0.159		178.68	0.332
2310	276.15	0.196	1610	151.69	0.426
	274.22	0.200		160.16	0.396

	244.69	0.261		151.62	0.426
	ψ_m	0.189		ψ_m	0.389
	s	0.038		s	0.036
	ψ_d	0.265		ψ_d	0.461
	α	0.102		α	0.479

Figures 2 display selected failure modes for the tested specimens of distortional and interactive buckling length tests, while in Table 1 are presented the results obtained using the ECBL approach.

3.3 *Results*

The case of RS125 × 3.2 section is a real mode interaction case, where distortional and flexural modes are interacting, the compression reference load for erosion is the distortional ultimate load, while for RS95×2.6 section, there is no interaction of buckling modes, the erosion being caused by the effect of plastic deformations and geometrical imperfections .

In Figure 3 and Figure 4 are presented, comparatively, the buckling curves computed using the specifications of EN1993-1-1 together with the calibrated values of the α imperfection factors, obtained using the ECBL approach (considering the inertia moment of gross section (ECBL B) – solid red line and the

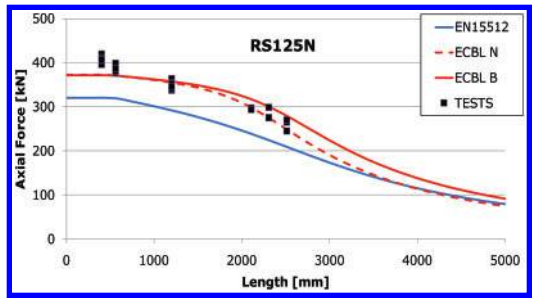

Figure 3. Buckling curve for RS125 × 3.2 section (Crisan et al.)

inertia moment of the section with perforations (ECBL N) – dashed red line) and the ones obtained using the design according to EN15512:2009.

4 EXPERIMENTAL CALIBRATION OF DESIGN METHODOLGY FOR COLD-FORMED STEEL FRAMING RESIDENTIAL BUILDINGS

4.1 *Principle of prescriptive method*

For a proper design of cold-formed steel-framed houses prone to both, gravity and horizontal loadings, (e.g. wind and/or earthquake), the behavior of the shear walls has to be known.

Prescriptive Method applies for design of standardized "wall-stud" structural systems for residential low rise buildings (AISI, 1998). The principle is to compare the wall-stud capacity with corresponding gravity load demand and shear capacity of the wall-stud panels with sear demand induced by horizontal loadings. If for gravity loads the problem is quite simple, for horizontal actions, test and numerical simulations are necessary to get both shear capacity and stiffness of reference shear wall (e.g. 1m span).

Besides the structural walls, the behavior of a house is influenced, at least in the early stage of the shaking, by the non-structural elements which usually is not accounted for in the design. The non-structural finishing elements have a structural contribution that changes the vibration modes and the damping properties of the structure. So, the stiffness, resistance and ductility of cold-formed steel shear walls have to be

evaluated via laboratory tests and after, extended by numerical simulations.

Following, the full procedure applied to obtain reference values for shear capacity, stiffness and ductility and their validation is summarized.

4.2 *Experimental program*

4.2.1 *Tests on shear walls*

First, an experimental program on shear walls with common sheeting solutions has been carried out in order to observe the behavior and to evaluate the structural properties of different wall typologies. Each specimen series consisted of identical wall panels (3600 × 2440 mm), tested under lateral loads under monotonic and cyclic loading (Fig. 5).

The skeleton of the wall panels was made of "C" shaped cold-formed steel elements, with studs at 600mm intervals. Fixing between profiles within the wall skeleton, and between the sheeting and skeleton, was done with self-drilling screws (d = 4.8 mm).

Figure 6 displays load versus lateral displacement curves both for the monotonic and cyclic responses. Wall panels have exhibited highly nonlinear behavior.

As observed during the experiments, the lateral deformation of the panel depends on the shear deformation of the sheeting (e.g. distortion of corrugation); the deformation due to corner uplift, and, most significantly, the nonlinear deformation of the connections between the sheeting and the skeleton.

As experimental curves are nonlinear from the beginning, elastic design capacity of the panels can only be defined in a conventional way. Any assumption of an elastic design limit is to be related to a tolerable deformation within the group of connectors that are subjected to the highest forces and therefore more based on criteria of serviceability rather than strength, at the level of the entire panel. Also, there will be an important strength reserve beyond any elastic design

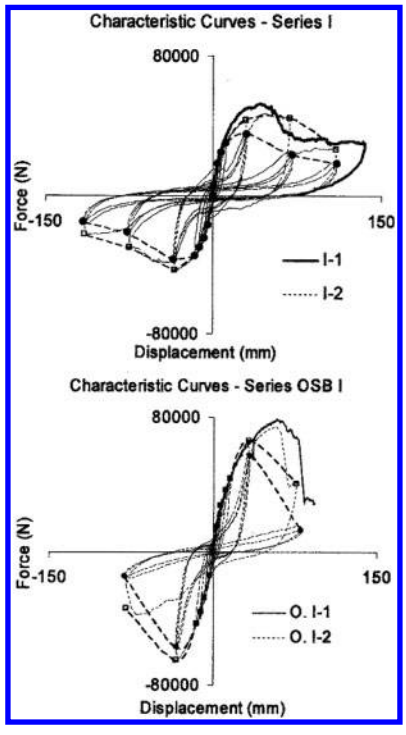

Figure 6. Experimental load versus displacement curves.

limit considered, due to the redundancy of the structural system and to the supplementary load bearing capacity of the remaining active connectors when the most loaded ones show excessive deformations or even failure.

The design strength of the panels was referred to as the minimum of the force at story drift angle 1/300 (F_{300}) and $2/3F_{max}$.

Observing comparatively the monotonic to cyclic behavior, a reduction of strength of about 10–15% can be observed in the case of cyclic loading. Hence if the design strengths of the panels are deduced based on monotonic experiments the performance will be overestimated. An important characteristic of cyclic curves is the strong pinching (a factor of 0.85 – 0.95), the source of it being the slip in the connectors at reverse loading, which implies a reduced energy dissipation. Strength degradation in consecutive loading cycles is also present as a result of accumulated damage in the panel during the loading history, leading to a significant difference between stabilized and unstabilized envelope curves.

Compared to the ones with corrugated sheeting, the failure of the OSB sheeted panels was less ductile.

4.2.2 *Tests on connections*

The second series of experiments was carried out in order to determine the mechanical properties of the connections that were identified to have a crucial effect on the behavior of the panels. Three types of screwed connection were tested, i.e. (1) connection

Table 2. Summary of Tested Connections.

Base thickness [mm]	Connected thickness [mm]	Screw diameter [mm]	Loading velocity: Slow (1 mm/min) Nr.	Slow (1 mm/min) Code	Fast (420 mm/min) Nr.	Fast (420 mm/min) Code

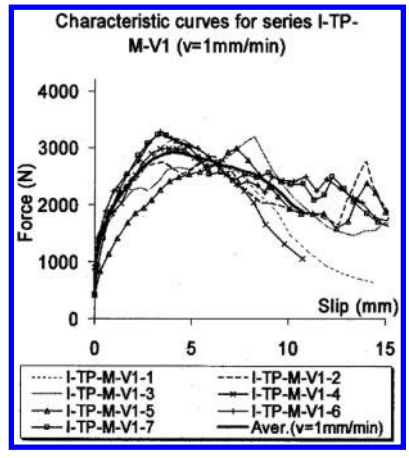

Figure 8. Experimental load versus displacement curves.

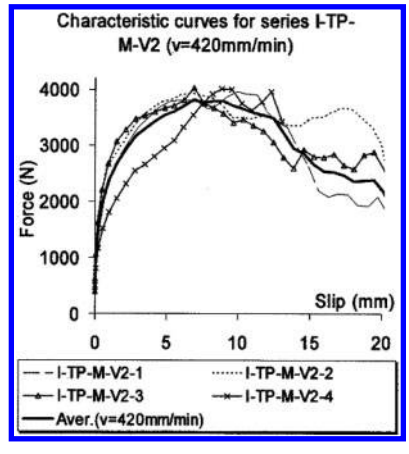

Figure 9. Experimental load versus displacement curves.

between the corrugated steel sheeting and steel profiles; (2) sheeting-to-sheeting seam connections; and (3) connections between the OSB panels and the steel profiles.

The dimensions of the specimens were chosen according to the European ECCS recommendations (1983), the dimensions of the connecting plates being 50 × 220 mm. Table 2 shows the parameters of specimens of type 1.

Figures 7 and 8 show the failure modes and the corresponding load vs. displacement curves.

The fast velocity specimens (I-TP-M-V2) have shown a similar behavior.

In the case of thin-to-thin sheet connections (Type 2), simulating seam fasteners, the failure mode was due to tilting and pulling-out of the screw. Similar failure mode was observed for seam connections during the wall panel experiments. The results are presented in Figure 9.

Figure 10 display the load-deformation curve for OSB steel specimens, while in Figure 11 is presented the corresponding failure modes.

As a general remark, these connection are not only less ductile, but also of lower strength if compared with those for sheeting-to-steel profiles.

4.2.3 *Calibration of numerical models*

Based on the component characteristics determined experimentally, a FE model was made in ANSYS in order to replicate the behavior of the entire wall panel (Fulop & Dubina, 2006).

As a first step, the wall panels of corrugated sheeting were considered because component's behavior was more homogeneous in this case.

The bars of the skeleton were modeled as elastic beam elements (BEAM4) by taking into account that these elements were not heavily deformed in the post-elastic range. The corrugated sheet was modeled as an equivalent orthotropic plate (SHELL43)

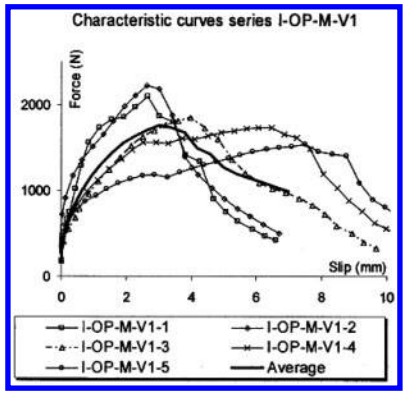

Figure 10. Experimental curves for OSB-to-steel connection.

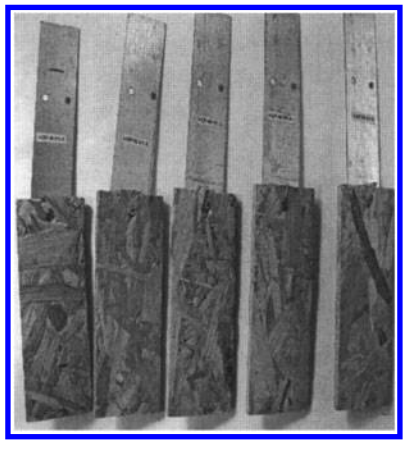

Figure 11. Failure modes for OSB-to-steel connection.

in order to take into account the fundamentally different mechanical properties of the corrugated sheet in the two principal directions and the distortion of the corrugated sheet when loaded in shear. The equivalent elastic modules (E_l – longitudinally and E_t – transversally) have been determined through preliminary modeling of a single corrugation loaded in tension in the two principal directions. The equivalent shear modulus (G_{eff}) has been calculated by taking into account the end distortion of the corrugated sheeting. Connections, both between the skeleton and the sheeting and the seam connections, were modeled using COMBIN39 elements, by considering average deformation properties of the tested connection loaded at 1 mm/min (Fig. 7).

Beside these components it is important to take into account the uplift deformation of the wall panel corners. The FE model was subjected to increasing horizontal loading at the upper part of the panel, similarly to wall panels during the full scale test. The deformation pattern and the nonlinear behavior curve obtained with the FE model was compared with the monotonic curves obtained during the wall panel experiments (Fig. 12), while Figures 13 and 14 prove the remarkable similarities in terms of deformation pattern and

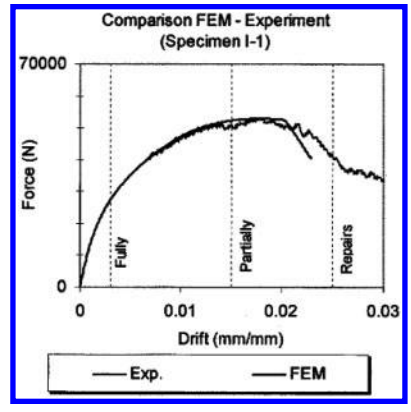

Figure 12. Behaviour curve (experimental vs. FEM–Series I).

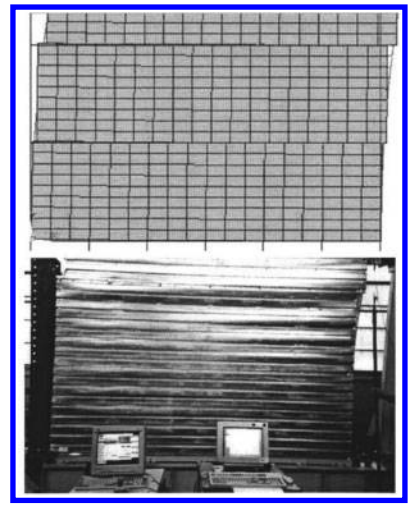

Figure 13. Comparison of deformed shape (experimental versus FEM–Series I – Fulop & Dubina, 2006).

nonlinear behavior between model and tests. By using the described FEM technique, the performance of wall panels can be evaluated, which are using the same basic materials and connection typologies but have a different geometrical configuration.

The calibrated numerical modes have enabled to characterize shear walls of same structural solutions in terms of sear capacity, stiffness and ductility (Dubina et al. 2006, Fulop & Dubina, 2006). Evidence of possibility to frame such kind of structures at least as low dissipative (e.g. $q = 1.5 - 2.0$).

4.3 *Design of house structure using "Prescriptive Method" procedure*

The structure presented in Figure 15 belongs to a two-story single family house. The dimensions of the building are 9m (axes A–D) by 10.5 m (axes 1–4), of which 1.5 m is between axes 3 and 4.

Each level is about 2.75 m high and the slope of the roof is 30°.

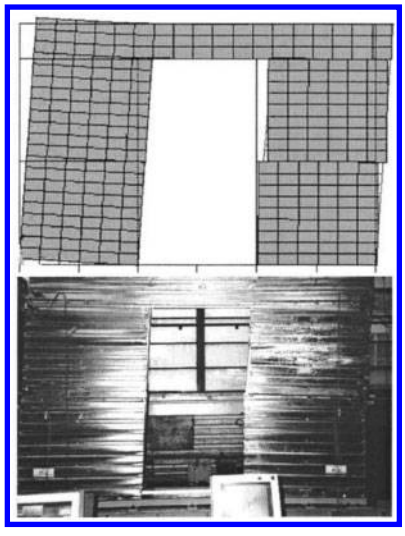

Figure 14. Comparison of deformed shape (experimental versus FEM–Series IV- Fulop & Dubina, 2006).

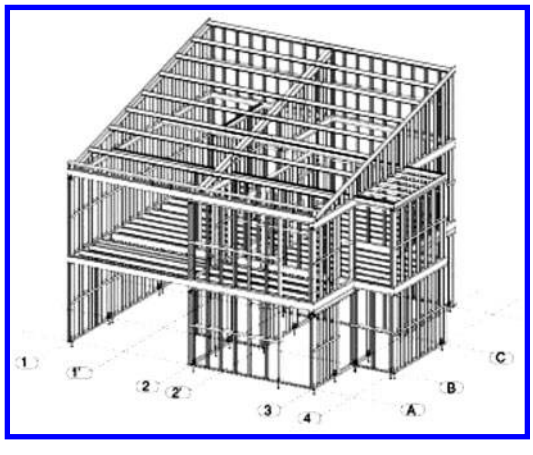

Figure 15. Steel skeleton of the structure.

The structural skeleton was made of cold-formed C-shaped profiles with a core thickness of 1.5 mm (C150/1.5) placed at 600 mm intervals. The elements of the skeleton were connected using 4.8 mm diameter self-drilling screws. The height of the C profile was 150 mm value governing the thickness of the walls. The load bearing beams in the slab are C200/1.5 profiles placed at 600 mm. The size of these profiles resulted from the condition to control the vibrations of the floor not from strength consideration. Roof purlins are Z150/1.5 profiles placed at 1200 mm intervals.

The skeleton was stiffened using 10 mm thick OSB plates fixed to both sides of structural walls. The floor diaphragms were originally designed also to be based on OSB covering. This solution has later been changed into sheathing with trapezoidal steel sheaths, both in the slab and at the level of the roof. No concrete was used in the slab.

The self-weight of the elements was evaluated to: 0.45 kN/m^2 for the roof; 0.70 kN/m^2 for the slab; 0.60 kN/m^2 for exterior and 0.20 kN/m^2 for internal walls. Other loadings for the design were determined according to the relevant Romanian standards. Live load on the slab was 1.50 kN/m^2, snow load on the roof was 1.20 kN/m^2 and wind load on the surface exposed to maximum lateral pressure was 0.4 kN/m^2

The earthquake design was based on PGA of 0.25 g.

One of the problems during the design of such a structure is the evaluation of the load bearing capacity and of the rigidity of the sheathing system of walls and slabs. For this case, the slabs can be covered with general provisions (e.g. some detailing conditions) due to the low level of stresses, but the realistic analysis for the walls is crucial. In this case, extrapolation of experimental results on shear walls was the basis to approach both shear strength and stiffness. Walls with similar skeleton sheathed on one side using identical OSB panels ($t_{OSB} = 10$ mm), with similar fixing plan (e.g. 105 mm screw intervals) and the same diameter screws ($d_{screw} = 4.2$ mm) were previously tested monotonically and cyclically. The tested panels were 2.55 m high, 3.6 m long and the ultimate load obtained from the test was $F_{max} = 69.8$ kN (or 19.4 kN/1m).

The panel's elastic rigidity was $K_{ini} = 4197$ kN/mm. The wall panels used in this case were sheathed on both sides with OSB and the corner details were strengthened compared to the tested case. The design capacity of the walls used for the construction has been evaluated to $F_{des} = 17.6$ kN/1 m. these values enabled to size the necessary length on shear walls along the main axes of the building.

4.4 *In-situ experimental validation*

Ambiental vibration tests have been performed in order to obtain a global validation of design procedure.

The dynamic properties of the building have been studied for small amplitude vibrations by measurements in the 3 stages of construction described earlier.

For each of the three stages of construction, 10 different measurement schemes with 10 velocity sensors were used and for each scheme two vibration recordings of 2 minutes duration were done with a sampling frequency of 100 Hz (Dubina et. al. 2006).

Based on the analysis of recorded vibrations, the building's modal frequencies (periods) have been estimated using two identification techniques: (i) analysis of the Fourier spectra and (ii) spectral and correlation analysis. For the estimation of the modal frequencies and corresponding damping ratios, the Eigen-system Realization Algorithm (ERA) has been used, which also validated the modal periods obtained by the above mentioned.

The first set of measurements has been done when the construction was in the stage when the skeleton of the building was almost entirely completed. The corrugated sheet of the slab was in place together with the OSB panels over it (i.e. the ones which support the finishing layers of the slab). However, the roof of the structure was not yet finished, the roof purlins included. Practically, a flexible diaphragm was

Table 3. Modal parameters obtained by FE modeling.

Stage	T_1 (s)	Type*	T_2 (s)	Type*	T_3 (s)	Type*
1	0.44	Tr	0.39	To	0.35	Lo
2	0.19	Lo	0.18	Tr	0.13	To
3**	0.33	Lo	0.31	Tr	0.23	To

* Note[1]: Tr – Tranversal, Lo – Longitudinal, To – Torsional
** Note[2]: Only the masses changed from Stage 2 to Stage 3

Table 4. Modal parameters based on the analysis of ambient vibrations (in different stages S)

	Mode 1			Mode 2			Mode 3		
S	T_1 (s)	ξ_1 (%)	Type	T_2 (s)	ξ_2 (%)	Type	T_3 (s)	ξ_3 (%)	Type
1	0.546	1.2	Lo	0.437	1.1	Tr	0.456	1.3	To
2	0.103	3.4	Tr	0.096	3.7	Lo	–	–	–
3	0.101	4.1	Tr	0.096	3.8	Lo	.072	.072	To

* Note: Vibration shapes; Tr – Tranversal, Lo – Longitudinal, To – Torsional, ξ_i – damping ratios

provided at the level of the first slab but not at the level of the roof.

The second set of measurements was done when the building skeleton was finished and most of the structural OSB panels were fixed to it. Some OSB panels, only, were still missing in the attic area. The structural part of the roof has also been finished with the outer corrugated sheath being in place. No work on the finishing (i.e. external thermal insulations, inner or outer wall finishes, slab finishing) has been undertaken at this stage.

The third set of measurements was done, before the moving in of the occupants. Therefore, all finishing has been completed but furniture has not been moved in. This can be considered the final stage of construction without live load.

Based on the analysis of the recorded vibrations the modal frequencies (periods), damping ratios and mode shapes of the structure have been identified.

Tables 3 and 4 show, comparatively, the dynamic properties numerically obtained on the structural model of the house with the shear walls sized according to "Prescriptive Method", and the in-situ measurements.

It has to be underlined that the presence of the stiffening OSB panels not only increased the rigidity of the structure considerably, but the weakest rigidity direction has been changed. The supplementary mass introduced with the finishing is counterbalanced by the stiffness increase generated by these finishing elements themselves. When live load will be added (i.e. furniture etc.) the period of vibration will slightly increase compared to the value $T_{3,St2} = 0.101$ s. Most probably the period $T_1 = 0.15$–0.2 s will be reached when the house is fully furnished. Another observation is that the damping ratio $\xi = 5\%$ is a reasonable estimate for a light-gauge steel house.

5 CONCLUDING REMARKS

Laboratory testing and numerical simulations using advanced experimentally calibrated modes are, actually, current research and design tools to be applied to solve complex structural problems of thin-walled steel structures. On this purpose, design codes offer a general guidance and some specific provisions, such as for connections. The experience and skills of structural engineer still play an important role in this matter.

The two case studies summarized in present paper, hopefully, support these concusions

ABSTRACT: This paper summarises the results of an experimental and numerical investigation performed on six series of thin-walled C-sections with intermediate and edge stiffeners. The attention focused on the response under compression and on the influence of geometrical imperfections, which significantly affect the buckling response of the member. First, compression tests allowed for determining loads and modes of failure. The influence on the collapse load of the various parameters as the material properties, the thickness, the height of the cross section and the length of the element was appraised. A comparison between the collapse deformed shape and the pattern of geometric imperfections is performed, in order to correlate the geometrical imperfections to the failure modes. The main results of FE numerical analyses performed with the software Abaqus, incorporating geometric and material nonlinearities, are also reported. The appropriateness of the specifications of the Eurocodes for modelling the geometric imperfections is finally appraised.

1 INTRODUCTION

Residential systems in thin-walled cold formed steel profiles for small and medium size buildings are well established in countries such as North America and Australia. Their peculiar characteristics such as the light weight, the high structural efficiency, the durability, the rapidity and simplicity of installation of the building equipment result in very competitive structural systems.

However, the design of these structures is fairly complex. Thin-walled cold-formed sections usually adopted tend to be very slender both globally and in the cross-sectional components. Consequently, they are subject to global, local and distortional instability, as well as to their interactions. Buckling reduces the members' load capacity, and makes design heavier, of incorporating it.

In order to develop an industrial prefabricated system, building components require studies at different level of complexity from the individual member to 2D and 3D sub-structures. The study of individual members subject to simple forces is the starting point, for it addresses their instability problems.

This paper summarises the results of an experimental and numerical investigation carried out on thin-walled C-sections with intermediate and edge stiffeners designed for an innovative housing system. The attention focused on the response under compression and on the influence of geometrical imperfections, which significantly affect the buckling response of the member.

Despite the wide literature focusing on the response of thin-walled cold formed sections under compression, only a limited number of studies investigate in detail the influence of imperfections. To the authors' knowledge, the first attempt to characterize the imperfections along the length of the element, by measuring their pattern and evaluating the periodicity was performed by Schafer and Peköz (1996, 1998). Additional studies recently carried out by Zeinoddini and Schafer (2010, 2012) focused on both the longitudinal and cross-sectional imperfections.

In the present work, the specimens' geometric imperfections were first measured in detail, by an approach similar to that used by Schafer and Peköz (1996). The subsequent experimental compression tests, enable determination of loads and modes of failure. These results allow for an appraisal of the influence on the collapse load of various parameters, such as the material properties, the thickness, the height of the cross section and the length of the element. A comparison between collapse deformed shape and the pattern of geometric imperfections is also performed, in order to correlate the geometrical imperfections to the failure modes.

The main results of FE numerical analyses carried out by means of the commercial software Abaqus, incorporating geometric and material nonlinearities are also reported in this paper, and the appropriateness of the specifications of the Eurocode 3 Part 1–5 (2006) for modelling the geometric imperfections appraised.

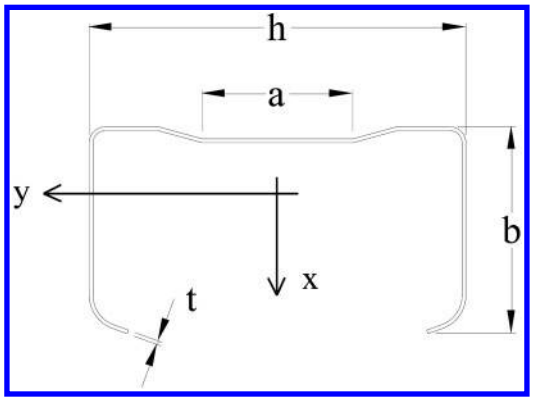

Figure 1. The investigated cross section.

2 SPECIMENS

The study focused on cold-formed channel sections with intermediate and edge stiffeners (Fig. 1). The sections are characterised by nominal web depths (h, in Fig. 1) of 100 mm, 150 mm and 200 mm, respectively. The flange width (b, in Fig. 1) is the same for all the sections. Two values of the nominal thickness, t = 1.0 mm and 1.2 mm, were selected. In summary, the study investigated six series of sections identified as A100, A150, A200, B100, B150 and B200. Letters A and B refer to the thickness of 1 mm and 1.2 mm respectively, and the following number to the nominal web depth (100 mm, 150 mm and 200 mm).

For each cross section three lengths of the specimens were considered, selected on the basis of numerical analyses carried out with the finite strip program CUFSM (Li et al., 2010). For each cross section the buckling curve was plotted and the notional lengths associated to the different forms of instability, i.e, local, distortional and global instability, were identified. The length of the specimens were hence selected so as to get a distortional buckling failure.

The three cross sections, two thicknesses and three specimen lengths for each cross section lead to a total of $3 \times 2 \times 3 = 18$ different specimen geometries. Their main dimensions and the nominal area of the cross section (A_g) are summarised in Table 1. Five specimens were tested for each geometry, in order to make a statistical appraisal. Therefore, a total of ninety specimens were tested.

Test were performed in agreement with the UNI EN 1993-1-3 (2006). At this aim, both ends of the specimen are welded to thin square plates of dimension of $220 \times 220 \times 5$ mm so that the nominal centroid of the plate corresponds to the centroid of the nominal gross section of the profile. Due to the presence of the welds, the warping of the end sections of the profile is prevented. A hole with a diameter of 8 mm driven in correspondence with the centroid of the end plates facilitates the connection to the testing rig and identifies the point of load application.

3 GEOMETRICAL IMPERFECTIONS

Each element presents 'physiological' geometric imperfections, as a deviation from the nominal geometry. Slender sections, such as thin-walled cold formed sections, are particularly sensitive to imperfections, which hence should be appropriately taken into account for in design. Three types of imperfections were considered:

- eccentricity of load application;
- crookedness and out-of-flatness along the length of the element;
- incomplete weld of the end-plates to the specimen.

Measures were only performed for the first two types of imperfections.The influence of the third one was investigated only numerically.

The measurement of the geometrical imperfections requires a rather complex and lengthy procedure. Therefore, measures were taken only for a part of the specimens tested in laboratory; i.e., on 36 of the 90 specimens (2 for each of the 18 geometries).

The eccentricities of the point of load application were evaluated on the two end cross sections. At this aim, the actual position of the cross sections with respect to the relevant end plate was measured. This allowed evaluating the eccentricities of the centroid of the cross sections with respect to the central hole of the plates. Random values but lower than 2 mm were obtained, as shown in Figure 2, which gathers the measures related to the bottom plate.

The imperfections of the profile along its length were gauged by connecting the specimen to the table of a milling machine (Fig. 3), at the two holes of the welded plates (so each measures were related to the hole-to-hole axis, here called z-axis).

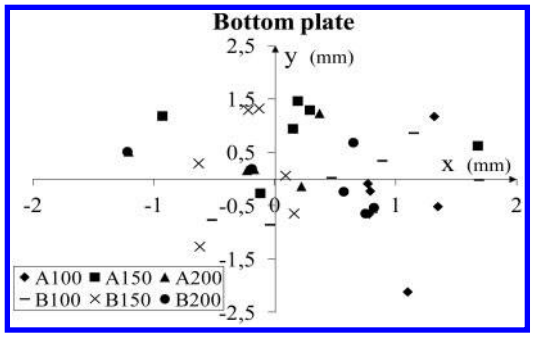

Figure 2. Eccentricities of the point of load application at the bottom plate.

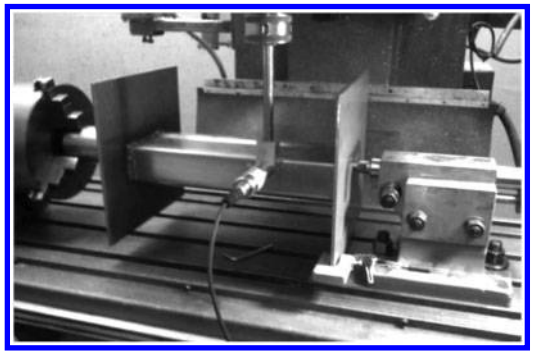

Figure 3. Measure of the out-of-straightness and out-of-flatness along the length of the element.

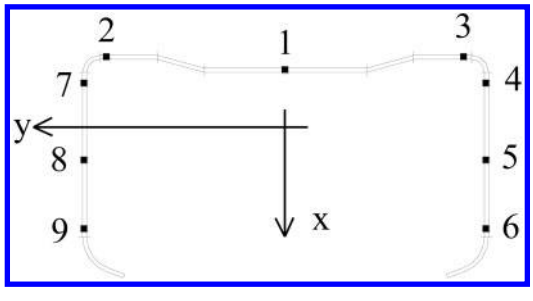

Figure 4. Points for the measurement of the imperfections.

The milling table provides a flat reference surface for measuring relative displacements. The measurement is carried out by replacing the drill bit of the milling machine with a support for a strain-gauge transducer. The transducer is held in place, while the plane of the milling machine slides; the transducer hence scans the element along a longitudinal line. A wire-sensor transducer anchored to the test specimen allows measuring z-coordinate. By synchronizing the two instruments the measure of the strain-gauge transducer was associated with the relevant section along the element. The scan operation is repeated in nine different points of the cross section, as shown in Figure 4.

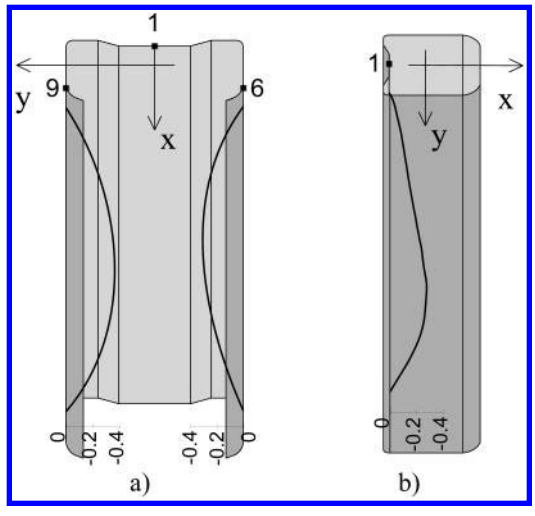

Figure 5. Geometrical imperfections: a) along lines 9 and 6; b) along line 1.

The presence of the weld at the ends of the profile prevented from taking measures along the full length of the specimen. This does not seem of actual importance: the geometry of the section near the end plates is heavily influenced by distortions induced by the welding process rather than by actual geometrical imperfections due to the fabrication process.

The procedure just described allows obtaining the transverse dimensional deviations of the cross section of the element, with respect to the nominal geometry, as a function of the longitudinal z coordinate. Examples of measured imperfections are shown in Figure 5.

It was observed that imperfections in the flanges were typically bigger than imperfections in the web, except in few cases of specimens with large web depth. In most cases the imperfection in the web had a negative sign, namely it bulged inward, that is towards the inside of the section. This trend was also typical of the imperfections of the flanges (Fig. 5)

4 TESTS RESULTS

The results of the compression tests are presented in Table 2, where the mean values of the collapse loads, their standard deviation and the β_a factor are provided. The β_a factors were computed according to EN 1993:1-3 (2006) under the assumption that the specimen is not affected by overall instability, as:

$$\beta_a = \frac{N}{A_g f_y} \quad (1)$$

where N = collapse load; A_g = cross-sectional area and f_y = steel yielding strength.

The material properties were determined by tensile coupon tests. The means values of the material properties are given in Table 3.

Table 2. Compression test results.

B200	296.91	381.70	31.13

The β_a factor, being the ratio between the experimental resistance and the plastic strength of the gross section is an index of the importance of local and distortional buckling, in terms of ultimate resistance. Table 2 shows that the β_a factor tends to decrease when the section depth increases, for both the A and B series. This clearly stresses the importance of the web slenderness on the local and distortional instability of the type of channel considered. Slight variations of β_a factor are observed between the different lengths of the profile, for the same depth of the cross section and the same thickness. This confirms that the global instability has actually little influence on the axial load capacity of these elements. As to the failure modes, the most frequent failure mode observed was by distortional buckling, in accordance with finite strip analyses carried out with CUFSM (Li et al., 2010). Only in few cases of the longer specimens of the series A200 and B200, and of the shortest specimens of the series B100 the buckling shape was closer to the local type.

Table 4. Variations of the β_a factor.

Section type	β_a Spec. A t = 1.0 mm	β_a Spec. B t = 1.2 mm	% increment
100	0.65	0.68	4.1
150	0.45	0.48	6.8
200	0.46	0.41	−11.2

A general reasonable agreement between the imperfections and the failure mode of the specimens was also observed. In particular, the imperfections of the flanges have greater influence on the collapse mode, than the imperfections of the web.

No significant influence of the eccentricity of load application is found on the collapse mode. This can be justified by the very small values of the load eccentricity (Fig. 2).

Some considerations can be done on the 'sectional degree of efficiency' associated with the increase of thickness. To this aim, reference can be made to average values of the β_a factor (Tab. 4) which incorporates the effect of the different yield strength between the test series (Tab. 3). The mean percentage variations of the β_a factor when the thickness is increased are gathered in Table 4 and should be considered in association with the average increase of 19% of the gross area for all geometries (Tab. 1). For the sections depth of 200mm the sectional efficiency appears to be significantly reduced so that the additionally material is basically not used. This result is clearly related to the yield strength parameter which is substantially higher for the B series (Tab. 3). The importance of this parameter seems even greater than assumed in the Eurocode.

5 NUMERICAL ANALYSES

The use of finite element models has become an effective and powerful tool, which enables to achieve an insight of complex problems such as those associated with the instability of thin-walled elements. The FE method was hence adopted aiming at getting a deeper insight in the response of the sections analysed in this study. In this chapter the results of the study of the influence of the imperfections are summarised.

The numerical analyses were carried out by means of the commercial software Abaqus incorporating geometric and material nonlinearities. The FE model comprised of both the profile and the welded end-plates. The end plates were assumed to be rigid while shell elements S4R with uniform size approximately equal to 4 × 4 × 4 mm were adopted for the section. Shell-to-solid coupling constraints are used to simulate adequately the plate-to-section weld.

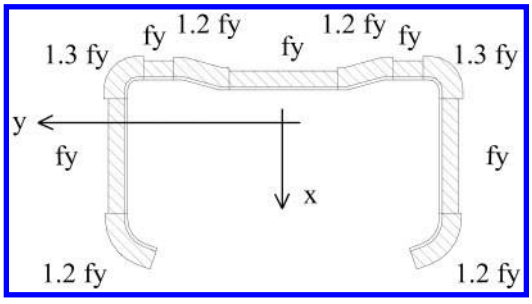

Figure 6. Yield strength and hardening effects.

The material of the specimen was modeled as elastic-perfectly-plastic. The values of the yield stress were, for each of the different cross sections, consistent with the mean values determined via tensile coupon tests (Tab. 3). The elastic modulus was assumed equal to 210000 MPa in all the analyses.

In order to take into account the material hardening in the bent zone, enhanced properties of the material in the rounded corner areas were assumed. The values of yield stress increases are related to the bending angle and were obtained from previous studies on the distribution of the yield stress along the cross section (Armani et al., 2011). In case of folds with obtuse angle, the increase is assumed to be of 20%, while in right angle folds, the increase is of 30% (Fig. 6).

The measured imperfections were incorporated in the finite element mesh. Both the eccentricities of the point of load application (Fig. 2) and the crookedness and out-of-flatness (Fig. 5) were reproduced. The incomplete weld of the edge stiffener to the end steel plate was also considered. This lack in the end connection affects the load transfer, and can be roughly seen as the source of an additional eccentricity in the first phase of loading. In absence of accurate measurement, this imperfection was investigated through a sensitivity study. The results showed their non-negligible influence on the profile response and indicate the more appropriate approach for their modeling. The lips are left completely unconnected to the steel end plates and constraints of no penetration with no friction is imposed. In addition, a thin portion of the lip is removed at both ends, so as to simulate the presence of a gap between the non-welded lip portion and the end plate, caused by the space occupied by the weld of the remaining part of the cross section.

The comparison between numerical and experimental collapse loads is presented in Figures 7 and 8, which are related to specimen A and B, respectively. For the purpose of the analysis the mean value of the experimental results is considered. A more than satisfactory agreement is apparent, with a difference in average of the order of 7%. Similar results are observed for the failure mode, for which the numerical deformed collapse shape and the experimental one match in about the 75% of the cases.

As further issue, the problem of 'standard' design imperfections was considered. The Eurocode 3 Part 1–5 (2006) provides recommendation on this aspect, i.e.,

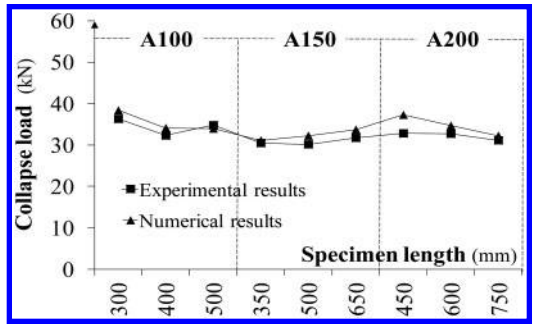

Figure 7. Experimental vs numerical results.

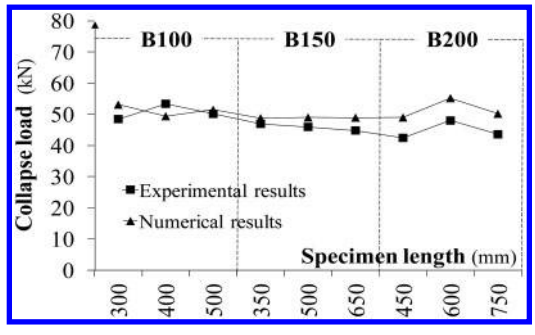

Figure 8. Experimental vs numerical results.

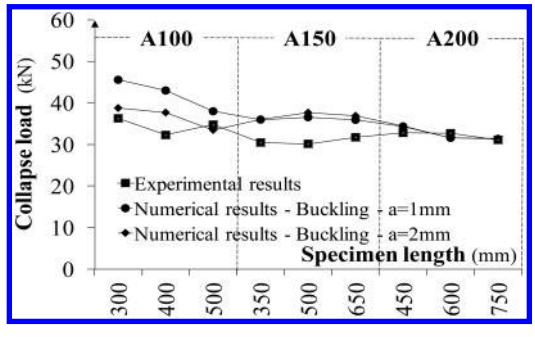

Figure 9. Experimental vs numerical results.

the first buckling shape, with an maximum amplitude equal to 80% of the geometric fabrication tolerance of the element itself, has to be assumed as initial deformed shape. Geometric imperfections in agreement with the Eurocode were then considered with the purpose of appraising the appropriateness of the code. Therefore, a buckling analysis is performed of a model comprising of the section and the end plates. The critical shape obtained is scaled as required by the Eurocode, and then entered into the model as geometric imperfection. Two values of the maximum amplitude of the imperfections (a = 1 mm and 2 mm), were considered. The eccentricity of the load application at the two ends of the specimen (Fig. 2) and material hardening (Fig. 6) were also incorporated.

Figure 9 and 10 show the results of the analyses and the comparison with the experimental outcomes.

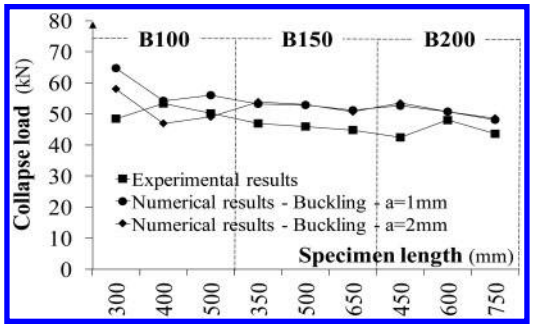

Figure 10. Experimental vs numerical results.

It is apparent that the increase of amplitude affects only the specimens of the 100 series (low depth of the cross section), while for the specimens of the 150 and 200 series the effect is negligible. In particular, in the case of the specimens of the 100 series, differences of the order of 12–13% associated with the amplitude increase are observed. For the specimens with depth of 150 mm and 200 mm, these differences are always lower than 2%. If the results of the numerical analysis are compared with the experimental outcomes, it can be noted that:

- for specimens with depth of 100 mm the imperfection amplitude of 2 mm better approximates the experimental results; the differences in collapse load are of the order of 5% for specimens A and less than 1% for specimens B;
- for specimens with depth of 150 mm the numerical analyses always noticeably overestimate the experimental collapse load, with percentage differences of the order of 17% for specimens A and of 13% for specimens B;
- for specimens with depth of 200 mm the numerical analyses overestimate the experimental collapse load in case of specimens B (differences of the order of 12%), while good agreement between numerical and experimental results is found in case of specimens of the A series.

A key factor for explaining such discrepancies is the collapse deformed shape. The collapse shapes looks alike the experimental one only in 22% of cases. This is due to the fact that the collapse in the nonlinear elasto-plastic analyses is always strongly related to the initial imperfection. If the imperfection (the first buckling shape in this case) is not representative of the actual initial deformed shape of the section, the 'numerical' collapse mode cannot match the experimental one.

6 CONCLUDING REMARKS

The paper summarises the results of a study of six geometries of cold-formed thin-walled C-sections with intermediate and edge stiffeners. Their response under compression was experimentally and numerically investigated.

The study allowed an evaluation of the influence of parameters such as the material properties, the thickness, the depth of the cross section and the length of the element on both the failure modes and the collapse load of this section type. An accurate measurement of the profiles' imperfections, i.e., load eccentricity, crookedness and out-of-flatness along the length of the element and incomplete weld of the end-plates to the specimen, made possible to extend the investigation also to the influence of these parameters. Both experimental and numerical studies confirmed the central role of the imperfections which greatly affect the profile response and stress the vital need for an accurate and reliable model for their representation. Accordingly, the Eurocode model for the geometric imperfections seems not adequate.

ABSTRACT: This paper reports the results of an ongoing investigation on the use of Generalised Beam Theory (GBT) to analyse the vibration behaviour of thin-walled steel frames. After a brief overview of the main concepts and procedures involved in performing a GBT vibration analysis, the formulation and implementation of a GBT-based beam finite element are presented, namely the determination of the finite element and frame linear and geometric stiffness matrices, as well as the frame mass matrix (incorporating the influence of the loading and frame joint configurations). Finally, in order to illustrate the application and capabilities of the proposed GBT-based finite element formulation, numerical results concerning the local, distortional and global vibration behaviour of a symmetric portal frame are presented and discussed. For validation purposes, most GBT-based results are compared with values obtained by means of shell finite element analyses carried out in the code Ansys.

1 INTRODUCTION

The thin-walled steel frames commonly used in the construction industry are often formed by members (columns, beams or beam-columns) with rather slender open cross-sections, which invariably exhibit very low torsion stiffness and a strong susceptibility to local, distortional and/or global buckling phenomena. Furthermore, given the strong mathematical similarity between the buckling and vibration analysis of structures (similar eigenvalue problems), it is just logical to expect the vibration behaviour of thin-walled frames to be also highly influenced by (i) the member cross-section (local and distortional) deformation (*e.g.*, Ahmed & Shimizu 2012), (ii) the localised displacement restraints, due to bracing systems (*e.g.*, Türker & Bayraktar 2011) and (iii) the frame joint behavioural features (*e.g.*, Sophianopoulos 2003).

Since most thin-walled steel frames are subjected to *simultaneous* static and dynamic actions (*e.g.*, the effects of heavy machinery or seismic activity), designers are faced with the need of assessing their dynamic response. Therefore, they must be equipped with numerical tools to determine the local and global frame vibration behaviour, eventually in the presence of more or less significant internal forces or moments. However, this task can only be rigorously performed currently by resorting to shell finite element analysis, a highly computer-intensive approach that (i) requires a large modelling effort (including data input and result interpretation) and, therefore, (ii) is still prohibitive for routine applications (*e.g.*, Moazed *et al.* 2012).

One very promising alternative to the above approach is the use of a one-dimensional model based on Generalised Beam Theory (GBT) – a beam theory incorporating genuine folded-plate concepts. In this context, the authors have been employing GBT-based beam finite element formulations to study the buckling behaviour of frames (*e.g.*, Camotim *et al.* 2010) – however, up until now all GBT vibration formulations dealt exclusively with isolated structural members (*e.g.*, Silvestre & Camotim 2006 and Bebiano *et al.* 2008).

The aim of this paper is to propose and validate an extension of the above GBT-based beam finite element formulations that make it possible to perform local, distortional and global vibration analyses of thin-walled steel frames. In particular, the determination of the finite element and frame linear and geometric stiffness matrices, as well as the frame mass matrix, is addressed. In order to illustrate the application and capabilities of the proposed GBT-based approach, the vibration behaviour of a load-free symmetric portal frame is first analysed. Then, since it is common practice in literature to express the static loading as a fraction of its critical buckling value, the frame buckling behaviour is studied. Finally, the vibration behaviour of the loaded frame is investigated, focusing mainly on the effect of the load magnitude

on the fundamental frequency value and mode shape nature. For validation purposes, some GBT results are compared with numerical values obtained by means of shell finite element analyses performed in the commercial code ANSYS (SAS 2009).

2 GBT VIBRATION ANALYSIS

In a GBT formulation, the cross-section displacement field is expressed as a linear combination of deformation modes, leading to a very convenient and mostly unique form of writing the member equilibrium equations – this is achieved by performing a *cross-section analysis* (Gonçalves *et al.* 2010), which allows for a much better understanding of the member structural behaviour. Figure 1 shows the dimensions and a possible GBT discretisation of the lipped channel cross-sections dealt with in this work – all frame members have elastic constants $E = 205\ GPa$ (Young's modulus) and $\upsilon = 0.3$ (Poisson's ratio). The cross-section analysis yields 15 deformation modes – the in-plane shapes of the 9 most relevant ones, *i.e.*, those contributing to the sought frame vibration modes, are also shown in Figure 1.

The GBT displacement field representation adopts the classical beam theory variable separation

$$\begin{aligned} u(x,s,t) &= u_k(s)\zeta_{k,x}(x,t) \\ v(x,s,t) &= v_k(s)\zeta_k(x,t) \\ w(x,s,t) &= w_k(s)\zeta_k(x,t) \end{aligned} \tag{1}$$

where (i) x and s are coordinates along the member axis and cross-section midline, (ii) functions $u_k(s)$, $v_k(s)$ and $w_k(s)$ provide the longitudinal, transverse membrane and transverse flexural displacements of deformation mode k, (iii) $(.)_{,x} \equiv d(.)/dx$, (iv) the summation convention applies to subscript k and (v) $\zeta_k(x,t)$ are the functions describing the variation of the deformation mode amplitudes both along the longitudinal direction and with time t.

After determining the deformation modes, the equilibrium equation system defining the dynamic problem can be readily established,

$$\begin{aligned} &C_{ik}\zeta_{k,xxxx} - D_{ik}\zeta_{k,xx} + B_{ik}\zeta_k - \\ &Q_{ik}\zeta_{k,xxtt} + R_{ik}\zeta_{k,tt} - X_{jik}(W_j^0\zeta_{k,x})_{,x} = 0 \end{aligned} \tag{2}$$

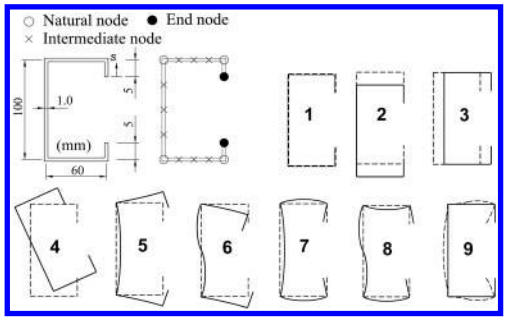

Figure 1. Lipped channel section: geometry, GBT discretisation and in-plane shape of the 9 most relevant deformation modes.

where, C_{ik} (warping displacement), D_{ik} (torsional rotations) and B_{ik} (local deformations) are cross-section modal mechanical properties, (iii) X_{jik} are geometric stiffness components associated with normal stress resultants W_j^0 due to uniform compression ($j = 1$) and/or bending ($j = 2, 3$), and (iv) R_{ik} and Q_{ik} are mass components that account for the influence of the inertia forces on the out-of-plane and in-plane cross-section displacements, and are given by (Bebiano *et al.* 2008)

$$\begin{aligned} Q_{ik} &= \rho h \int_S u_i u_k ds + \frac{\rho h^3}{12}\int_S w_i w_k ds \\ R_{ik} &= \rho h \int_S (v_i v_k + w_i w_k) ds + \frac{\rho h^3}{12}\int_S w_{i,s} w_{k,s} ds \end{aligned} \tag{3}$$

where (i) h is the wall thickness (uniform) and (ii) ρ is the material mass density (deemed uniform and equal to $7.85\ g/cm^3$ in this work).

One solution of system (2) can be found by assuming that the free vibration motions are synchronous, *i.e.*, by adopting the separation of variables

$$\zeta_k(x,t) = \phi_k(x)Y(t) \tag{4}$$

where $\phi_k(x)$ is a longitudinal shape function and $Y(t)$ is a time-dependent function satisfying the free vibration harmonic equation of motion $Y_{,tt} + \omega^2 Y = 0$, where ω is the angular frequency of vibration – thus, it may be written

$$\zeta_{k,tt} = -\omega^2 \zeta_k \tag{5}$$

The incorporation of Eq. (5) into (2) leads to the final system of equilibrium equations

$$\begin{aligned} &C_{ik}\phi_{k,xxxx} - D_{ik}\phi_{k,xx} + B_{ik}\phi_k - \\ &\omega^2(R_{ik}\phi_k - Q_{ik}\phi_{k,xx}) - X_{jik}(W_j^0\xi_{k,x})_{,x} = 0 \end{aligned} \tag{6}$$

3 FRAME ANALYSIS

In isolated members, the solution of (2) is obtained by means of a beam finite element formulation developed and implemented by Bebiano *et al.* (2008): 2-node elements with $2n$ degrees of freedom per node (n is the number of deformation modes included in the analysis) and using Hermite cubic polynomials $\psi_i(x)$ to approximate the mode amplitude functions $\phi_k(x)$ – one then has

$$\begin{aligned} \phi_k(x) = {} & \psi_1(\xi)d_{k1} + \psi_2(\xi)d_{k2} + \\ & + \psi_3(\xi)d_{k3} + \psi_4(\xi)\,d_{k4} \end{aligned} \tag{7}$$

where $d_{k1} = \phi_{k,x}(0)$, $d_{k2} = \phi_k(0)$, $d_{k3} = \phi_{k,x}(L_e)$, $d_{k4} = \phi_k(L_e)$, $\xi = x/L_e$ (L_e is the element length) and

$$\begin{aligned} &\psi_1(\xi) = L_e(\xi^3 - 2\xi^2 + \xi) \quad \psi_2(\xi) = 2\xi^3 - 3\xi^2 + 1 \\ &\psi_3(\xi) = L_e(\xi^3 - \xi^2) \quad \psi_4(\xi) = 3\xi^2 - 2\xi^3 \end{aligned} \tag{8}$$

Thus, the various sub-matrix components of the finite element linear stiffness $[K_e]$, geometric stiffness

$[G_e]$ and mass $[M_e]$ matrices are determined by means of the expressions

$$K_{ik}^{pr} = C_{ik}\int_{L_e}\psi_{p,xx}\psi_{r,xx}dx + D_{ik}\int_{L_e}\psi_{p,x}\psi_{r,x}dx + B_{ij}\int_{L_e}\psi_p\psi_r dx$$
$$G_{ik}^{pr} = W_j^0 X_{jik}\int_{L_e}\psi_{p,x}\psi_{r,x}dx \qquad (9)$$
$$M_{ik}^{pr} = Q_{ik}\int_{L_e}\psi_{p,x}\psi_{r,x}dx + R_{ik}\int_{Le}\psi_p\psi_r dx$$

where (i) subscripts $i, k = 1 \ldots n$ identify the deformation modes associated with each sub-matrix and (ii) superscripts p, $r = 1 \ldots 4$ concern the finite element degrees of freedom involved in each sub-matrix.

The overall linear and geometric stiffness and mass matrices of a given structural system are obtained by "assembling" their finite element counterparts, adopting the well-known "incidence matrix" concept. Although this constitutes a fairly trivial procedure for isolated members, its extension to frames poses several difficulties. Indeed, because the finite elements (members) connected at a frame joint exhibit different orientations, it becomes necessary to account for all the effects stemming from the need to ensure compatibility between the degrees of freedom of the connected member end cross-sections. In order to overcome these difficulties, (i) it is necessary to "transform" the modal degrees of freedom into nodal ones (generalised displacements of the point where the joint is deemed located), by means of a "joint element" concept, and (ii) constraint conditions must be imposed to enforce displacement and rotation compatibility at the connected end sections – more details can be found in the work of Basaglia *et al.* (2008, 2009).

The constraint conditions, denoted by Π_i, (i) depend on the member geometry and joint configuration, and (ii) involve i natural/intermediate nodes of the connected member end sections – these conditions read

$$\Pi_i = \{\Delta\}^T\{\phi_k\} = 0 \qquad (10)$$

where the vector $\{\Delta\}$ components are either (i) warping functions $u_k(s)$ or (ii) wall flexural functions $w_k(s)$. The particular constraint conditions considered in this work are addressed in Basaglia *et al.* (2009).

Once all the member support and joint compatibility conditions are enforced, the frame linear $[\tilde{K}]$ and geometric $[\tilde{G}]$ stiffness matrices and mass matrix $[\tilde{M}]$ are readily obtained, which are expressed in terms of "mixed" degrees of freedom: GBT modal and "conventional" nodal ones. The joint compatibility is incorporated into the stiffness matrix by means of the matrix operation

$$([\tilde{K}] - [\tilde{G}] - \omega^2[\tilde{M}]) = \\ = [\Omega]^T([K] - [G] - \omega^2[M])[\Omega] \qquad (11)$$

where (i) the tilde ($\sim$) identifies the matrices associated with joint compatibility conditions and (ii) the compatibility matrix $[\Omega]$,

$$\{d\} = [\Omega]\{\tilde{d}\}, \qquad (12)$$

contains the joint modal displacement values (*i.e.*, $u_k(s)$, $v_k(s)$ or $w_k(s)$) – $\{\tilde{d}\}$ is a "mixed" vector combining generalised displacements and GBT degrees of freedom.

After determining the frame total stiffness and mass matrices ($[\tilde{K}] - [\tilde{G}] - \omega^2[\tilde{M}]$), one (i) solves the vibration eigenvalue problem and (ii) transforms the nodal degrees of freedom (joint generalised displacements) back into GBT ones, through the operation defined in (12) – this last procedure makes it possible to obtain a fully modal representation of the frame vibration modes (*i.e.*, identify and quantify the individual contributions of the deformation modes of the various members), a feature that provides a decisive contribution towards a more in-depth understanding of the mechanical aspects involved in the local, distortional and global vibration behaviour of thin-walled frames.

4 ILLUSTRATIVE EXAMPLES

In order to validate and illustrate the application and potential of the proposed GBT-based beam finite element approach, numerical results are presented and discussed next. They concern the local, distortional and global vibration of the symmetric portal frame depicted in Figure 2(a), which is formed by three lipped channel members (A, B, C) (i) with identical cross-sections (dimensions given in Fig. 1) and (ii) made of steel ($E = 205\ GPa$ and $\nu = 0.3$). The frame has fixed column bases and joints with flange continuity. One begins by analysing the vibration behaviour of the load-free frame. Then, the buckling behaviour of the frame subjected only to uniform axial compression diagrams ($N_A = N_C = 0.83\,P$ and $N_B = 1.0P$ – see Fig. 2(b)) is analysed. Finally, the vibration behaviour of the loaded frame is investigated – the static applied loading is always expressed as a percentage of the associated critical buckling load (P_{cr}). For validation, most GBT-based results are compared with values yielded by Ansys (SAS 2009) shell finite element analyses.

The GBT analyses are based on frame discretisations into 52 finite elements, which correspond to 106 degrees of freedom for each deformation mode

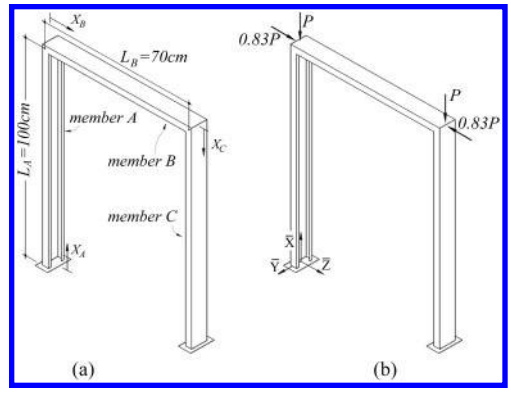

Figure 2. Symmetric portal frame: (a) geometry and (b) loading.

included in the analysis. Thus, an analysis including all *15* deformation modes stemming from the adopted GBT discretisation (see Fig. 1) involves 1590 $d.o.f.$. On the other hand, the ANSYS shell finite element analyses involve more than 16000 $d.o.f.$.

4.1 *Load-free frame vibration*

Table 1 shows the first eight natural frequencies (in rad/s), obtained by means of the GBT analysis (ω_{GBT}) and shell finite element analysis (ω_{ANSYS}). Figure 3 provides, for each of the three frame members, the amplitude functions $\phi_k(x)$ of the deformation modes that participate in the first four frame vibration modes. As for Figure 4, it displays the configurations of theses vibration modes obtained from the ANSYS shell finite element analysis. The observation and comparison between the vibration results yielded by the two numerical models prompts the following main remarks:

Table 1. GBT and ANSYS frame vibration frequencies (rad/s).

Vibration mode	ω_{GBT}	ω_{ANSYS}	Δ (%)
1	392.72	383.54	2.4
2	451.81	446.10	1.3
3	630.90	630.27	0.1
4	653.80	635.17	2.9
5	665.04	645.35	3.1
6	685.12	670.04	2.3
7	779.01	763.66	2.0
8	785.05	768.12	2.2

(i) The natural frequencies yielded by the GBT-based and ANSYS shell finite element analyses practically coincide – the maximum difference is 3.1%.

(ii) There is also a very close agreement between the GBT modal amplitude functions and the vibration mode shapes obtained from the ANSYS analysis. However, it can be easily argued that the GBT representation enables a better quantitative and qualitative insight on this frame vibration behaviour.

(iii) The local and distortional deformation modes become more relevant as the vibration mode order increase. Indeed, wile the global modes **2** and **3** are predominant in the first three vibration modes, in the fourth vibration mode prevail modes **5** and **7**.

4.2 *Frame buckling*

Figure 5 provides two representations of critical buckling mode shapes of the frame considered in this work, namely (i) GBT modal amplitude functions and (ii) ANSYS 3D views. The observation of these two sets of buckling results prompts the following remarks:

(i) The GBT and ANSYS critical loads are very similar – one has $P_{cr.GBT} = 19.25$ kN and $P_{cr.ANSYS} = 18.72$ kN (differences below 2.83 %).

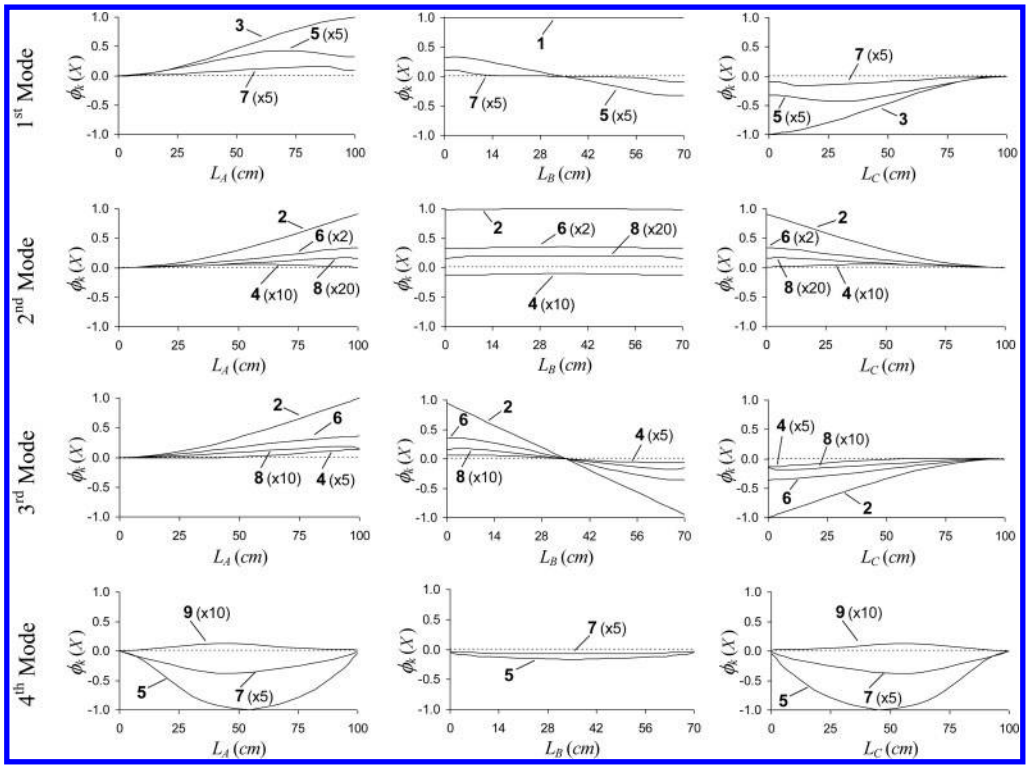

Figure 3. Modal amplitude function $\phi_k(x)$ that participate in the first four frame vibration modes.

(ii) The frame buckles in a combination of local and distortional deformation modes that (ii_1) involves the three members and (ii_2) includes contributions from the GBT deformation modes **5** (distortional) and **7** + **9** (local). The participation of mode **5** is highly dominant (75%), with the maximum values occurring at the member *B* mid-span region, but there are also non-negligible contributions from local modes **7** and **9** in the joint vicinities.

4.3 *Loaded frame vibration*

Finally, one investigates the vibration of frames subjected to uniform axial compression loads – the applied load value is defined by a parameter $P^0 \equiv W_1^0$, which is taken as fraction (α) of its critical value, *i.e.*, $P^0 = \alpha P_{cr}$. Table 2 shows the influence of the applied loading ($\alpha = 0$, 0.25, 0.5, 0.75, 0.95, 0.99) on the frame fundamental frequency ω_1. Moreover, the 3D views yielded by ANSYS and the modal amplitude functions presented in Figures 6 and 7 (three load levels) provide in-depth information on the evolution of the frame fundamental vibration mode as the applied load level increases. After observing the results presented in these figures and table, the following conclusions can be drawn:

(i) The presence of loading only cause a considerable fundamental frequency drop (*i.e.*, more than 5%) for $\alpha \geq 0.75$ – a substantial fundamental frequency drop (*i.e.*, more than 30%) occur for $\alpha \geq 0.95$.

(ii) The GBT and ANSYS fundamental frequencies are again extremely close (differences below 3.4%). Moreover, there is also excellent correlation between the fundamental vibration mode shapes provided by the ANSYS analyses and GBT modal amplitude functions.

(iii) The comparison between the modal amplitude functions for $\alpha = 0$ (see Fig. 3) and $\alpha \neq 0$, shows that the fundamental vibration mode shapes of the load-free frame and the loaded frame with $\alpha = 0.25$ are very similar. On the other hand, the fundamental vibration mode shape is considerably altered by the presence of a load level equal to $\alpha = 0.75$ – indeed, there is an increase of the contribution of the deformation modes **5** and **7**.

(iv) For $\alpha \cong 1$ the vibration mode shape changes quite drastically, approaching its critical buckling mode counterpart – indeed, for $\alpha = 0.99$ the fundamental vibration and critical buckling modes virtually coincide, as attested by the comparison with Figure 5.

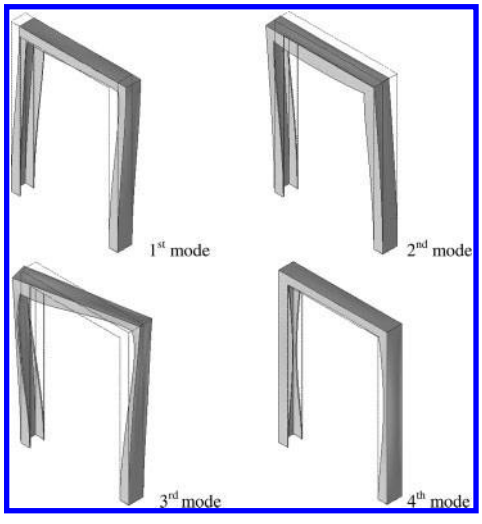

Figure 4. First four frame vibration modes obtained by ANSYS.

Table 2. Variation of the fundamental frequencies (rad/s) with α.

5 CONCLUSION

The paper reported the results of an ongoing investigation on the use of a GBT-based beam finite element approach to analyse the local, distortional and global vibration behaviour of thin-walled steel frames. After a very brief review of the most relevant concepts involved in performing a GBT vibration analysis, the paper described the procedures involved in obtaining the frame overall linear and geometric stiffness matrices, as well as the frame mass matrix, which incorporate the effect of the frame joints. Finally, the application and capabilities of the developed GBT-based beam finite element approach were illustrated by means of the presentation and discussion of numerical results concerning the local, distortional and global vibration behaviour of load-free and loaded symmetric portal frames – the study focused on the influence of the applied load level on the vibration frequencies and mode shapes. For validation purposes, most of the GBT-based results were compared with values obtained by means of shell finite element analyses carried out in the code ANSYS. An excellent agreement was found in all cases, despite the large difference between the numbers of $d.o.f.$ involved in the two analyses.

Moment redistribution in cold-formed steel continuous beams

C. Hui, L. Gardner & D.A. Nethercot
Imperial College London, London, UK

ABSTRACT: Cold-formed steel purlins supporting corrugated roof sheeting are often arranged to be continuous over an internal support. Economic design should be based on failure of the system, recognising the opportunity for redistribution of moments. This paper presents the findings from a numerical investigation of the degree of moment redistribution in continuous cold-formed steel zeta-section beams subjected to a Uniformly Distributed Load (UDL). Three types of nonlinear finite element analysis were validated against reported physical tests: (1) continuous two-span beams subjected to a UDL, (2) single span beams subjected to a central point load producing a moment gradient and (3) single span beams subjected to two point load producing a central region under pure bending. The interior support moments from the continuous beam models were compared with the reference moment capacities from the three-point bending models. Based on various different sections sizes, covering a range of cross-sectional slenderness, full moment redistribution with no drop-off in moment at the interior support was found to be possible only for stocky sections but not for slender sections. In the case of slender sections, local and distortional buckling caused a reduction in interior support moment prior to failure of the system. Hence a design formula is proposed to estimate the post-peak reduction of interior support moment from its initial peak, and use this reduced moment in conjunction with the full span moment to determine the load-carrying capacity of the system. Comparisons show the proposed approach to offer accurate prediction of observed system failure loads.

1 INTRODUCTION

Modern light roof construction for industrial or warehouse buildings normally comprise cold-formed steel purlins covered with sheeting. These purlins are used as secondary steelwork between the main frames. The thin-walled nature of cold-formed steel members makes them susceptible to local instabilities such as local and distortional buckling. With buckling limiting the overall load carrying capacity, the basic assumption for the application of plastic theory that the first hinge for a dual span systems can maintain its moment capacity until a mechanism is formed, is not always guaranteed. This paper reports on a study designed to provide suitable modifications to permit the basic idea of plastic theory to be applied in such cases.

Many research projects have been carried out to investigate the structural behaviour of multi-span purlin systems: Willis and Wallace (1990) conducted continuous single and triple span tests with through-fastened roof panels. Ho and Chung (2006) and Hancock et al. (1992) conducted studies to investigate the behaviour of lapped moment connections for 2-span Z sections. Gutierrez et al. (2011) investigated the connection behaviour for Z sections with slotted sleeves.

As an alternative to conducting full scale testing which can be expensive and time consuming, finite element (FE) models have been increasingly used for research into cold-formed steel. Early publications on FE modelling of cold-formed steel members were by Moreyra and Peköz (1994); since then treatments have become more robust and practical with the use of faster processing power. More recently, Haidarali and Nethercot (2011) successfully analysed FE cold-formed Z sections using ABAQUS (2006) and investigated the local/distortional buckling behaviour for Z sections subjected to pure bending.

Even though there are many reported computational analyses and physical tests on cold-formed steel, studies investigating moment redistribution in multi-span cold-formed steel systems are limited. In this paper, FE models were validated against available tests to ensure that the model can capture the local/distortional buckling behaviour and subsequent moment redistribution. The models were then used to generate a series of parametric results which have formed the basis for a proposed design approach.

2 DESIGN APPROACHES

For the two-span continuous beam shown in Fig.1, a design based on elastic principles would utilise the full cross-sectional moment capacity at the central support but not within the span. However, if redistribution of moments is utilised then there is the potential to use a greater proportion (possibly all) of the unused

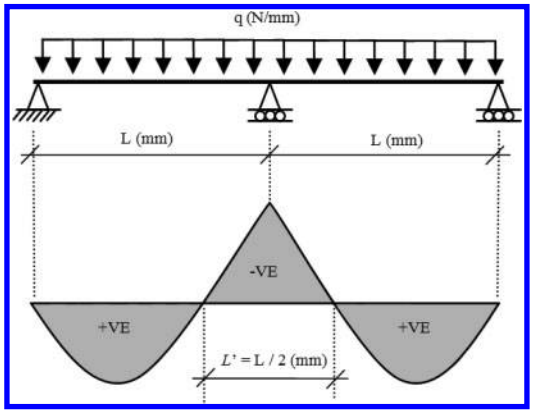

Figure 1. Elastic Bending moment diagram (BMD) for 2-span setups.

moment capacity within the span. The principle is commonly used when designing hot rolled steelwork; it has been adapted for reinforced concrete construction, composite construction and for cold-formed steel construction by recognising certain limitations in the moment-rotation relationships of cross-sections and accepting that full redistribution may not be possible.

In the ideal situation of full plastic redistribution of moments, both the bending moment at the interior support, $M_{support}$ and within the span, M_{span} reach their full cross-sectional capacity because the moment-rotation relationship for the support region is such that no significant fall off in capacity occurs before rotations develop sufficiently to allow the span moment to reach its capacity. Should this not be the case i.e. attaining full capacity within the span is accompanied by a reduction in $M_{support}$, then appropriate allowance must be made.

Thus the design issue for cold-formed steel construction is that the moment-rotation behaviour differs from the ideal arrangement of Fig 1. In cold-formed steel construction the cause is a combination of local and distortional buckling, together with some material nonlinearity.

Knowing the bending moment capacities at the span M_{span}, and supports $M_{support}$, the ultimate design load carrying capacity q for a continuous 2-span system with equal spans subjected to a UDL, can be calculated by solving Eq. 1.

$$M_{span} = \frac{\left(qL^2 - 2M_{support}\right)^2}{8qL^2} \quad (1)$$

3 FINITE ELEMENT (FE) MODELS

3.1 *Outline of different models*

To study the behavior and level of redistribution in continuous systems, for each 2-span FE model, two further single span models were used to create reference values for the interior support and span moments in the

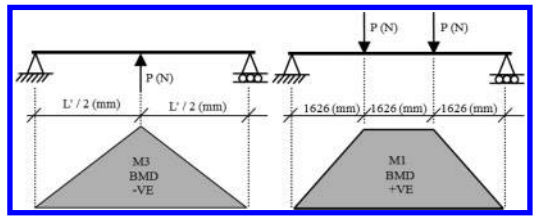

Figure 2. BMD for single span tests.

2-span model: (1) The largest sagging moment (elastically located at 0.375L from the beam ends) M_{span} was compared with a single span model subjected to uniform bending M_1 and (2) the largest hogging moment found at the interior support $M_{support}$ was compared to the maximum moment in the single span model subjected to 3-point bending M_3. Fig 2 shows the single span models used to calculate these reference moment capacities. Relevant comparisons between $M_{support}$ and M_3 were made by ensuring the beneficially sharp parabolic moment gradient observed in the 2-span system was allowed for by modifying the moment gradient in the reference single span test, as shown in the figure. The lengths of the hogging region from the 2-span models L' were used as the beam length for the 3-point bending analyses.

3.2 *FE modelling assumptions*

All FE models were developed in ABAQUS (2007) using S4R shell elements. The two-stage modified Ramberg-Osgood material model proposed by Gardner and Ashraf (2006) was used to model the gradual yielding material behaviour of the cold-formed steel members.

A two-spring model was used to replicate the restraining behaviour of common purlin-sheeting arrangements in which the sheeting is attached to the top flange. A linear translational spring was used to model the retraining behaviour provided by each fastener. A further compression-only spring was attached to the lip/flange junction to prevent any negative vertical displacement. The non-linear spring was assigned negligible stiffness in tension, but high stiffness to replicate bearing of the beam on the sheeting. Inclusion of the springs prevented the flanges buckling upwards (into the sheeting) but offered no restrictions to buckling downwards.

Geometric imperfections were included in the FE models as a superposition of local and distortional buckling modes with independent scaling amplitudes of 0.229 t and 0.099 t, respectively. The buckling shapes for both modes were decomposed using the finite strip software CUFSM (2006). The elastic buckling analysis in CUFSM adopts a constrained finite strip method which systematically increases the half-wavelength of any thin-walled member subjected to pure bending. The first two minima from the signature curve correspond to the elastic critical local and distortional buckling modes respectively. The

individual imperfection shapes were plotted harmonically in the longitudinal direction with periods equal to their half-wavelength obtained from CUFSM.

Stiff plates ($E_{plate} = 10E_{beam}$) were modelled at the loading points and supports to eliminate any premature localised failure such as web crippling. Lateral restraints at modest spacing were adopted to prevent the system failing prematurely by lateral-torsional buckling. The loading for both single span models was applied through the centre of the stiff plates, which were tied to the beam directly. For the 2-span models, the UDL was modelled by applying a pressure load to a narrow portion of the top flange. The modified Riks method (*STATIC, RIKS) was used for all finite element models.

3.3 *FE model validation*

Prior to undertaking parametric studies, the models were first validated against various physical tests from 3 sources. Wang and Zhang (2008) completed single span pure bending and moment gradient tests for various cold-formed members including lipped channel cold-formed steel sections. Bryan and Davies (1979) carried out two studies using various zeta sections: (1) single span tests subjected to a moment gradient and (2) full scale 2-span gravity continuous tests subjected to a UDL. Yu and Schafer (2003) carried out a large number of pure bending tests comprising both lipped channel and lipped zed sections cold-formed steel members. Distortional and lateral-torsional buckling was effectively restricted by suitably located bracing.

A total of 50 comparisons between the FE models and physical tests were made. Table 1 presents a summary of the results in terms of the mean test/FE capacity and coefficient of variation (COV) for each set of tests. The overall validation results indicate excellent agreement with the largest over and under prediction being 2.2% and 0.07% respectively and minimal scatter. The buckling behaviour and the deflected shapes

match the observed failures modes reported by Bryan and Davies (1979) and are shown in Fig. 3. The close agreement of the overall load-deformation response between a typical FE model and physical test is shown in Fig 4.

4 PARAMETRIC STUDY

4.1 *Influence of section slenderness*

Figs 5–7 and 8–10 show, respectively, the different behaviour of stocky and slender cross-sections in a two-span arrangement. For the former, behaviour accords closely with the ideal situation given by plastic theory, with full moment redistribution, the support moment $M_{support}$ being approximately M_3, and the span moment approximately M_1.A condition approximating to full redistribution occurs and the behaviour in the support region, as indicated by $M_{support}$ and approximated by M_3 occurs. However, for more slender arrangements of Fig. 8, Fig. 10 shows how the M_3 plot starts to fall very soon after reaching the maximum moment, whilst Fig. 9 shows $M_{support}$ reducing from its peak as more load is added and M_{span} builds to its maximum. The reduced $M_{support}$ corresponding to attaining the maximum M_{span} and thus the maximum moment for the system is designated αM_3.

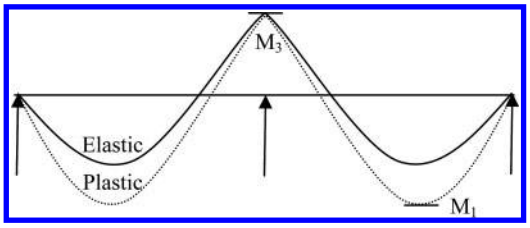

Figure 5. BMD for an ideal situation of full redistribution.

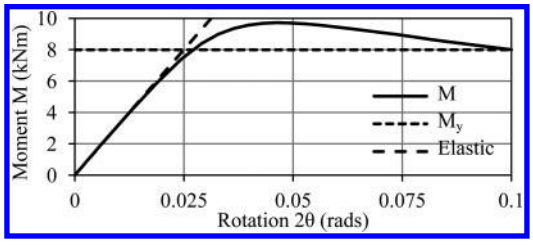

Figure 6. Typical moment-rotation (M-θ) curve for simple beams with stocky sections.

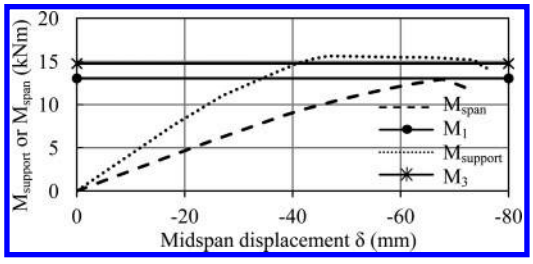

Figure 7. Typical support and span moment-midspan displacement response for stocky sections.

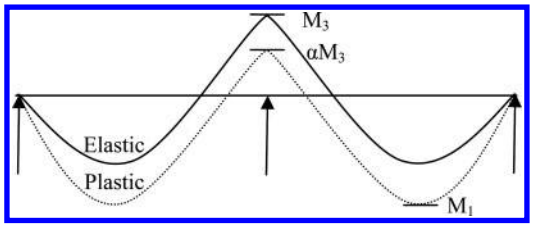

Figure 8. Typical BM redistribution behaviour for slender sections.

The proposed design method therefore utilises the plastic mechanism (redistribution) approach of EN 1993-1-3 (2006), which presumes full redistribution, but replaces the full value of the hogging moment (taken herein to be closely approximated by the M_3 value so as to recognise the beneficial effects of moment gradient) with a lesser value αM_3.

4.2 *Alpha framework*

A total of 9 zeta sections covering section depths from 125 mm to 200 mm and material thicknesses from 1.3 mm to 5 mm were analysed to cover a wide range of

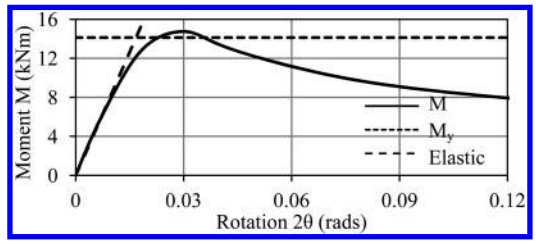

Figure 9. Typical moment-rotation (M-θ) curve for simple beams with slender sections.

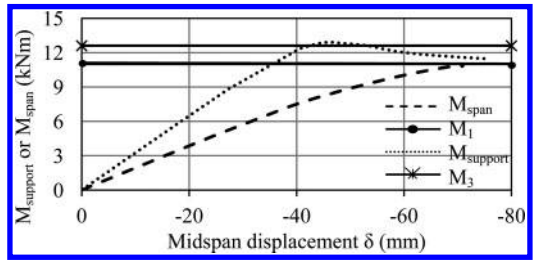

Figure 10. Typical support and span moment-midspan displacement response for slender sections.

cross-sectional slenderness. The 0.2% proof stresses, $\sigma_{0.2}$ and fastener spacing were kept constant for the study at 390 MPa and 300 mm, respectively. For each section, the following models were run: three 2-span FE models consisting of 4,6 and 8 m spans, one 4-point bending single span model with 1.667 m constant distance between point loads, and three 3-point bending single span models with 2,3 and 4 m spans. The study therefore comprised a total of 45 FE analyses.

For each 2-span model, the moment in the support region at the collapse load of the system was compared with the maximum moment from the corresponding reference moment gradient FE model. A reduction factor, α_{FEA} was defined as the ratio of these moments and is given by Eq 2, with full redistribution providing the upper bound value α_{FEA}, which is limited to unity.

$$\alpha_{FEA} = M_{support} / M_3 \qquad 0 \leq \alpha_{FEA} \leq 1 \qquad (2)$$

The cross-sectional slenderness λ_{cs} was defined as the square root of ratio of the yield strength to the elastic buckling stress. The elastic buckling stress was obtained from CUFSM. The interior support moment reduction values, α_{FEA} found from the parametric study are plotted against the cross-sectional slenderness in Fig. 11. The results are classified into their respective span lengths of 4, 6 and 8 m. It can be seen from Fig 11, that the longer spans tend to yield higher α values than shorter spans for the same section. Understanding that the amount of interior moment reduction is also influenced by the span length, a design equation is proposed to estimate α using Eq. 3.

The ultimate load q, was compared for each section between the 2-span FE model and a design load based on a combination of reference single span tests using Eq. 1. Two cases were considered when applying Eq. 1:

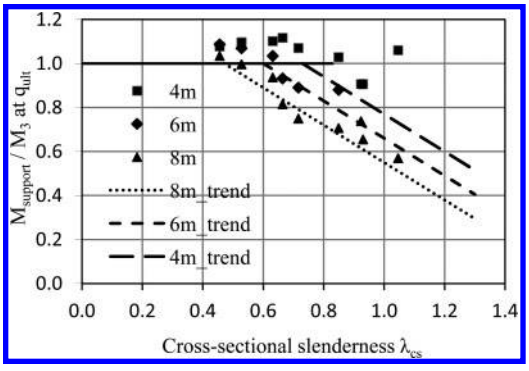

Figure 11. Support moment reduction vs. section slenderness.

(1) assuming full redistribution ($\alpha_{design} = 1$) by using M_1 and M_3 directly, and (2) allowing for a potential loss of support moment by calculating the reduction factor using Eq. 3, and applying M_1 and αM_3.

$$\alpha_{design} = -0.85\lambda_{cs} - 0.055L + 1.84 \quad (3)$$

Where L is the span length (m) and Eq. 3 is valid within the range: 4.0 m < L < 8.0 m.

Table 2 shows the ultimate loads, q from the FE analyses with 2 separate sets of design results: (1) Column q_{M1_M3} assumes α_{design} equals unity when applying M_1 and M_3 as the span and support moments for Eq. 1, and (2) column $q_{M1_\alpha M3}$ incorporates a reduction to support moment by calculating each individual α_{design} value using Eq. 3 and then applying M_1 and αM_3 as the span and support moments for Eq. 1.

Table 3 presents a summary of the two design methods and indicates that assuming full redistribution, q_{M1_M3} gives on average, a 3.2% unconservative ultimate load prediction, whereas the proposed design method which allows for a reduction in the support moment, $q_{M1_\alpha M3}$ gives on average a 2% conservative results with considerably reduced scatter. It should be notes that actual differences between the 2 predictions can be rather large, since in several cases $\alpha = 1$.

5 DISCUSSION

It is of interest to note that as arrangements become more slender so the value of $M_{support}$ at maximum load falls from its peak. Thus the design calculation using M_1 and M_3 overestimates capacity for these cases, whilst that using M_1 and αM_3 provides much closer predictions over the full range of cross-sectional slenderness, with both a mean ratio of design/FEA close to unity and low scatter. Few results are overpredicted and none by more than 5%. Thus inclusion of the α correction as obtained from Eq.3 permits the safe use of the plastic redistribution for the range of zeta sections covered.

Even though only zeta sections have been used for this study, it is expected that Eq. 3 could still be applied to other cold-formed steel sections because it incorporates the cross-sectional slenderness. Other stockier sections such as thick sections with short flanges and sufficiently deep edge stiffeners may result in α_{design} values equal to unity, whereas slender sections such as thin zed sections with no edge stiffeners would tend to yield a large reduction in central support capacity before the ultimate load has reached a peak.

6 CONCLUSIONS

Finite element modelling techniques for cold-formed steel sections have been briefly explained, giving specific ways to model the restraining behaviour of common trapezoidal sheeting methods to prevent premature buckling. The described FE models have been validated against 50 physical tests conducted by various authors. A parametric study consisting of 45 FE models for zeta sections covering a range of slenderness has been conducted to evaluate the loss of

moment at the central support in two-span continuous beams upon reaching the collapse load of the system from its peak moment capacity. The results from the study shows 2-span systems made up of slender sections at large spans could lose up to 50% of their maximum support moment at ultimate load due to a sharp loss of moment at the interior support, whereas, stocky sections can achieve full moment redistribution, since no significant reduction in the central support capacity is observed at system failure. A design formula is proposed to estimate the amount of moment redistribution for a 2-span purlin system by calculating a reduction value, α_{design} for the interior support moment at failure. The revised interior moment can be applied directly with the plastic mechanism approach of EC3. For the range of sections considered, the design approach of assuming full redistribution with the full interior support moment (i.e. $\alpha_{design} = 1$) was found to be unconservative by 3.2% on average and up to 7% for the more slender sections. However, adopting the design approach gives 2% conservative predictions on average and with a greatly reduced scatter (COV = 0.03 compared to 0.06 for αdesign = 1).

Shear strengths of lipped channel beams with stiffened web openings using numerical studies

P. Keerthan & M. Mahendran
Queensland University of Technology, Brisbane, Queensland, Australia

ABSTRACT: This paper presents the details of numerical studies on the shear behaviour and strength of Lipped Channel Beams (LCBs) with stiffened web openings. Over the last couple of decades, cold-formed steel beams have been used extensively in residential, industrial and commercial buildings as primary load bearing structural components. Their shear strengths are considerably reduced when web openings are included for the purpose of locating building services. Our research has shown that shear strengths of LCBs were reduced by up to 70% due to the inclusion of web openings. Hence there is a need to improve the shear strengths of LCBs with web openings. A cost effective way to improve the detrimental effects of a large web opening is to attach appropriate stiffeners around the web openings in order to restore the original shear strength and stiffness of LCBs. Hence numerical studies were undertaken to investigate the shear strengths of LCBs with stiffened web openings. In this research, finite element models of LCBs with stiffened web openings in shear were developed to simulate the shear behaviour and strength of LCBs. Various stiffening methods using plate and LCB stud stiffeners attached to LCBs using screw-fastening were attempted. The developed models were then validated by comparing their results with experimental results and used in parametric studies. Both finite element analysis and experimental results showed that the stiffening arrangements recommended by past research for cold-formed steel channel beams are not adequate to restore the shear strengths of LCBs with web openings. Therefore new stiffener arrangements were proposed for LCBs with web openings based on experimental and finite element analysis results. This paper presents the details of finite element models and analyses used in this research and the results including the recommended stiffener arrangements.

1 INTRODUCTION

The use of cold-formed steel members in low rise building construction has increased significantly in recent times. There are many significant benefits associated with the use of lightweight cold-formed steel sections in buildings. Lipped channel and Z-sections are commonly used in low rise building construction due to their high strength-to-weight ratio, economy of transportation and handling, ease of fabrication, simple erection and installation. Figure 1 shows the use of lipped channel beams (LCB) in floor systems with circular web openings.

At present industry applications in flooring systems include openings in the web of floor joists or bearers so that building services such as electrical conduits and plumbing facilities can be located within them. Three standard opening sizes of 60, 100 and 125 mm are used with the currently available LCBs. Shear force is carried by the web element of LCB. Therefore the use of web openings in LCBs significantly reduces their shear capacity due to the reduced web area. There are many variables that affect the shear capacity of members containing web openings. They include the shape, position and size of web openings and also the web slenderness. Hence Keerthan and Mahendran (2012a,c) investigated the shear behaviour and strength of LCBs with circular web openings using experimental and numerical studies. New design equations were developed by them for the shear capacity of LCBs with web openings, which included the effects of enhanced buckling due to the rigid web-flange juncture, and post-buckling strength in shear.

Figure 1. LCBs with web openings.

Since the loss of shear capacity of LCBs was found to be as high as 70% (Keerthan and Mahendran, 2012a) when the depth of web opening to clear height ratio (d_{wh}/d_1) was 0.7, there is a need to enhance the shear capacity of LCB with web openings. A cost effective way to enhance the detrimental effects

of a large web opening is to attach suitable stiffeners around the web openings. Current cold-formed steel design standards (AISI, 2004, 2007 and SA, 2005) do not provide adequate guidelines to assist the design and construction of stiffeners for LCB floor joists with large web openings. Keerthan and Mahendran (2013) investigated the shear behaviour and strength of LiteSteel beams (OATM, 2008) with stiffened web openings using experimental and numerical studies while Sivakumaran (2008) conducted an experimental study to develop a stiffener system for cold-formed LCBs with web openings. However, limited research has been undertaken to investigate the shear behaviour of LCBs with stiffened web openings. Hence numerical and experimental studies were conducted to develop suitable stiffener arrangements for LCBs with web openings subjected to shear. This paper presents the details of finite element analysis (FEA) based studies of LCBs with stiffened circular web openings, and the results. New plate stiffener arrangements are developed for LCBs to restore the original shear capacity of LCBs without web openings based on test and FEA results.

2 EXPERIMENTAL STUDIES

This section reports the details of the web stiffening arrangements used in Keerthan and Mahendran's (2012d) experimental study. This experimental study was focused on the use of plate stiffeners with varying fastening arrangements to obtain the best fastening method. It was based on a series of primarily shear tests of simply supported LCBs with stiffened web openings subject to a mid-span load (Figure 2). Flanges were restrained by straps to eliminate the flange distortion.

Test specimens of LCBs, 250 × 75 × 1.9 LCB and 160 × 65 × 1.9 LCB, were considered in the shear tests. Three opening sizes of 60, 100 and 125 mm were selected based on the standard sizes. Plate and stud stiffeners were used with varying thicknesses and sizes and screw fastening arrangements in nine tests. Eight tests were also carried out without stiffening the web openings, giving a total of 17 tests. To simulate a primarily shear condition, relatively short test beams were selected based on two aspect ratios (shear span a/ clear web height d_1) of 1.0 and 1.5. Table 1 shows the details of test specimens while Figure 2 shows the stiffening arrangements used in this experimental study.

Stiffeners were not attached in Test Specimens 1 to 4 (Aspect ratio = 1.5). In Test Specimens 5 and 6, the web openings were reinforced with plate stiffeners based on AISI's (2004) minimum stiffening requirements. The thickness of the plate stiffener was equal to the thickness of 250 × 75 × 1.9 LCB section while the plate stiffener extended 25 mm beyond all the edges of the web openings. This provided the dimensions of 110 × 110 × 1.9 mm and 150 × 150 × 1.9 mm for the plate stiffeners of Test Specimen 5 and 6, respectively. The plate stiffener was fastened to the web of the LCB section with No.12 Tek screws at 25 mm spacing along the edges of the plate stiffener with an edge distance

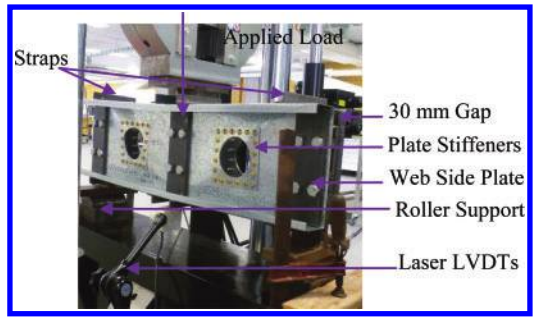

Figure 2. Experimental set-up.

Note: A1 – Arrangement 1, A2 –- Arrangement 2, d_{wh} = Depth of Web Opening, d_1 – Clear Height of Web. For 250 × 75 × 15 × 1.9, fyw = 515 MPa For 160 × 65 × 15 × 1.9, fyw = 515 MPa, For 250 × 75 × 15 × 1.95, fyw = 271 MPa

of 12.5 mm as shown in Figure 3(a). This stiffener arrangement was defined as "Arrangement 1" (AISI, 2004) in this paper.

To investigate the effect of using LCB stud stiffeners on the shear capacity of LCBs with web openings, Test 7 was conducted as shown in Figure 3c. Here 250 × 248 × 1.9 LCB stud stiffeners were attached to LCB specimen with 100 mm web openings. The screw fastening arrangement in Test Specimens 7 to 10 was placed with three screws on each side of the plate stiffener giving a total of 8 screws and enhanced with four additional screws in the diagonal direction giving a total of 12 screws (Arrangement 2) as shown in Figures 3b and 3c. The additional screws along the diagonal direction were located at 10 mm from the edge of the web openings. Test Specimen 10 was used to investigate the use of thicker 3.8 mm (two 1.9 mm plate stiffeners) and wider (225 mm) plate stiffeners to restore the shear capacity in the case of larger 125 mm web openings. Stiffeners were not attached in Test Specimens 11 to 13 and 16 (Aspect ratio = 1.0). In Test Specimens 14, 15 and 17, the web openings were reinforced with plate stiffeners based on Arrangement 2. Table 1 shows the ultimate shear capacities of the LCBs tested in this study. Details of experimental studies are reported in Keerthan and Mahendran (2012d).

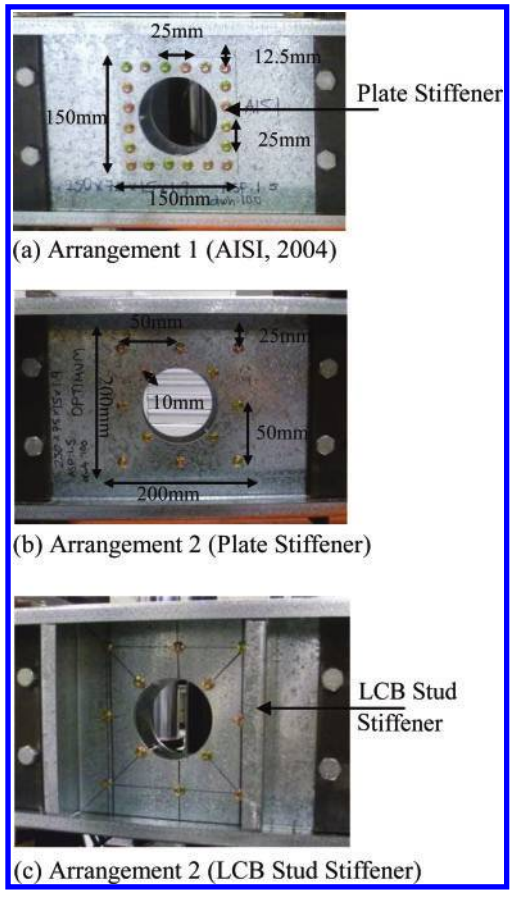

Figure 3. Stiffener Arrangements.

Test Specimen 6 only attained 90% of the shear capacity of LCB section without web openings (56.9 kN vs 63 kN). Therefore this test showed that the plate stiffeners established as per AISI (2004) recommendations are not adequate to restore the shear strengths of LCB with web openings when the ratio of depth of web opening to clear height of web (d_{wh}/d_1) is 0.40.

Experimental results (Table 1) show that by using LCB stud stiffeners with improved Arrangement 2 it was possible to attain 100% of the shear capacity of LCB without web openings (65.2 kN) in Test specimen 7 with 100 mm web openings ($d_{wh}/d_1 = 0.40$). The use of LCB stud stiffeners (Test Specimen 7, 65.2 kN) provided higher shear capacities than plate stiffeners of the same thickness (Test Specimen 8, 62.7 kN). However, LCB Stud stiffener may not be able to fully restore the shear capacity of LCBs without web openings when the depth of web opening to clear height ratio (d_{wh}/d_1) is greater than 0.40.

Tests 9 and 10 were conducted to determine the required web thickness in the case of larger 125 mm web openings. They were conducted with 1.9 mm and 3.8 mm plate stiffeners that were 225 × 225 mm wide and depth (50 mm on either side of the edge of web openings). Test Specimen 9 only attained 85% of the shear capacity of LCB section without web openings (53.7 kN vs 63 kN). However, Test Specimen 10 attained 99% of the shear capacity of LCB section without web openings (62.2 kN vs 63 kN). These tests thus show that plate stiffeners of appropriate thickness screw-fastened using Arrangement 2 were able to restore the full shear capacity of LCBs.

When compared to Test Specimens 8 and 9 (Aspect ratio = 1.5) which were identical to Test Speciemns 14 and 15, shear capacities attained in Test Specimens 14 and 15 (Aspect ratio = 1.0) were slightly lower. This slight reduction in shear capacity is a result of the optimum plate stiffener sizes being reduced for Tests 14 and 15. The aspect ratio of 1.0 meant a smaller shear panel length (a), which led to reduced distance between the web side plates and thus the optimum plate stiffener sizes had to be reduced to fit between the holding plates.

3 FINITE ELEMENT ANALYSES

This section presents the development of suitable finite element models to investigate the ultimate shear behaviour and strength of LCBs with stiffened web openings. For the numerical study, a general purpose finite element program, ABAQUS Version 6.7 (HKS, 2007), which has the capability of undertaking geometric and material non-linear analyses of three dimensional structures, was used. Finite element models were developed to simulate the actual test members' physical geometry, loads, constraints and mechanical properties in the experimental study as reported in the last section. The cross-section geometry of the finite element model was based on the measured dimensions, thicknesses and yield stresses of 17 tested LCBs. Table 1 gives the measured dimensions of the test beams made of 250 × 75 × 15 × 1.9 LCB and 160 × 65 × 15 × 1.9 LCB sections. The shell element in ABAQUS called S4R5 was used to simulate the shear behaviour of LCBs with stiffened web openings. R3D4 rigid body elements were used to simulate the restraints and loading in the finite element models of LCBs with stiffened web openings. Convergence studies showed that an element size of 5 mm × 5 mm provided an accurate representation of shear buckling and yielding deformations. To obtain accurate results, paver mesh was applied around the LCB web and stiffener openings. Figure 4 shows the geometry and finite element mesh of a typical LCB with stiffened web openings used in this numerical study.

The ABAQUS classical metal plasticity model was used in all the FE analyses. The elastic modulus and Poisson's ratio were taken as 200,000 MPa and 0.3, respectively. Simply supported boundary conditions were applied in the finite element models of LCBs with stiffened web openings. The vertical translation was not restrained at the loading point. Figure 5 shows the applied loads and boundary conditions used in the models. Shear test specimens included a 75 mm wide

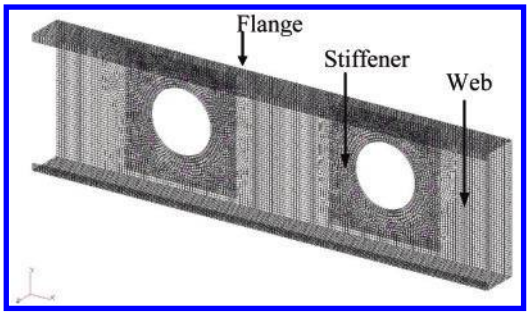

Figure 4. Geometry and finite element mesh of a typical LCB with stiffened web openings (250 × 75 × 15 × 1.9 LCB with 125 mm web openings, Aspect ratio = 1.5).

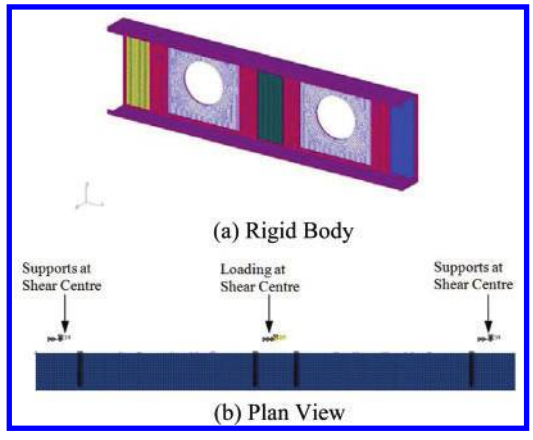

Figure 5. Applied loads and boundary conditions.

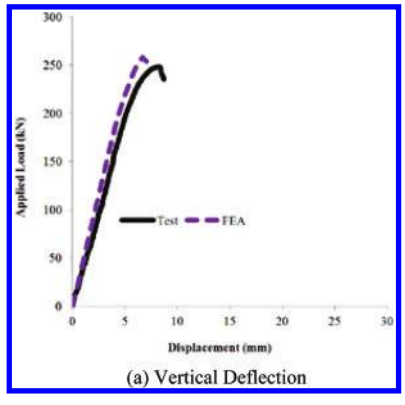

Figure 6a. Applied load versus deflections for Test specimen 10.

plate at each support to prevent lateral movement and twisting of the cross-section. These stiffening plates were modelled as rigid bodies using R3D4 elements. Simply supported boundary conditions were applied to the node at the shear centre to provide an ideal pinned support.

In Keerthan and Mahendran's (2012d) tests, there were no screw fastener failures. Therefore this observation was assumed in all the finite element analyses used here. The screw fasteners connecting the LCB to the stiffeners (Plate or LCB stud stiffeners) were not explicitly simulated in the finite element model. Instead they were simulated using perfect Tie MPCs, which makes all active degrees of freedom equal on both sides of the connection. The fabrication tolerance limit of $0.006d_1$ was used as imperfection in the numerical models of LCBs. It was decided to neglect the residual stresses in the FEA of LCBs with stiffened web openings as the effect of residual stresses on the shear capacity of LCBs with openings is less than 1% (Keerthan and Mahendran, 2012a). Experimental studies (Keerthan and Mahendran, 2012d) showed that strap failures did not occur. Considering this observation, the straps were not explicitly modelled. Instead they were simulated using suitable boundary conditions as follows at strap locations.

$$u_x = 0 \;\; u_y = 0 \;\; u_z = 1 \;\; \theta_x = 1 \;\; \theta_y = 0 \;\; \theta_z = 0$$

In the above, u_x, u_y and u_z are translations and θ_x, θ_y and θ_z are rotations in the x, y and z directions, respectively, and 0 denotes free and 1 denotes restrained.

The developed finite element models for non-linear analyses of LCBs with stiffened web openings were validated by comparing the non-linear analysis results with the results obtained from the shear tests (Keerthan and Mahendran, 2012d). This comparison was planned to establish the validity of the shell element model in the modelling of initial geometric imperfections and shear deformations, and associated material yielding. The FEA results were compared with those from testing, with particular attention given to the ultimate load, load-deflection curves and failure mechanisms. Table 2 presents a summary of the ultimate shear capacity results of LCBs with stiffened web openings from FEA and tests. The mean and COV of the ratio of test to FEA ultimate shear capacities are 0.99 and 0.01. This indicates that the finite element model developed in this study is able to predict the ultimate shear capacity of LCBs with stiffened web openings with very good accuracy. Figure 6 shows the FEA results in the form of load versus deflection for 250 × 75 × 15 × 1.9 LCB with 125 mm stiffened web openings (Test Specimen 10) and compare them with corresponding experimental results while Figure 7 shows the shear failure modes of Test Specimen 9. Figures 6 and 7 show a good agreement between the results from FEA and experiments.

Figure 6b and 7b confirms that LCBs with stiffened web openings have post-buckling strength due to the presence of tension field action.

In summary, FEA and test results in Table 2 show that plate stiffeners with dimensions equal to web opening width and depth plus 100 mm, screw fastened using Arrangement 2, are required to restore the full shear capacity of LCBs.

4 SUITABLE PLATE STIFFENER SYSTEMS

In this section a suitable plate stiffener system is developed for LCBs with web openings based on test and FEA results. Although shear tests were conducted only for 250 × 75 × 1.9LCBs, it is considered that test results reported in this paper can be used to propose a suitable stiffener system that is applicable to other LCBs. FEA and test results showed that LCB stud stiffener was able to fully restore the shear capacity of LCBs without web openings when the depth of web opening to clear height ratio (d_{wh}/d_1) is equal or less than 0.40. Plate stiffeners are proposed with the following minimum dimensions based on FEA and test results. The width of the recommended plate stiffener is $d_{wh} + 100$ mm where d_{wh} is the depth of web opening while its height is lesser of clear web height (d_1) and $d_{wh} + 100$ mm. It is recommended that these plate stiffeners are fastened to LCB webs using No.12 Tek screws and Arrangement 2.

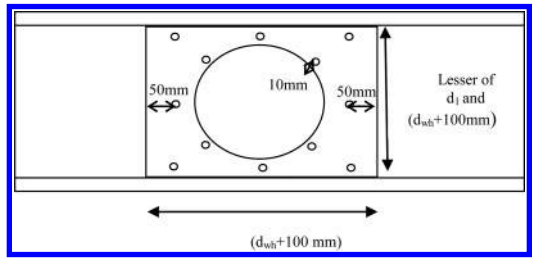

Figure 8. Effective plate stiffener system for LCBs with web openings.

It was found that the required plate stiffener thickness depends mainly on the ratio of the depth of web opening to the clear height of web ratio (d_{wh}/d_1). Therefore suitable predictive equations for the thickness of recommended plate stiffeners (t_{stiff}) were proposed based on d_{wh}/d_1 (Eqns. (1) to (3)). Eqns. (1) to (3) and associated d_{wh}/d_1 ranges were determined based on the test and FEA results reported here.

$$t_{Stiff} = t_w \qquad 0.24 < \frac{d_{wh}}{d_1} \le 0.40 \qquad (1)$$

$$t_{Stiff} = 2t_w \qquad 0.40 < \frac{d_{wh}}{d_1} \le 0.60 \qquad (2)$$

$$t_{Stiff} = 2.5t_w \qquad 0.60 < \frac{d_{wh}}{d_1} \le 0.70 \qquad (3)$$

$$w_{Stiff} = d_{wh}+100 \qquad (4)$$

$$h_{Stiff} = \text{Lesser of } d_{wh}+100 \text{ and } d_1 \qquad (5)$$

where, t_{stiff}, w_{stiff}, h_{stiff} = Thickness, width and height of plate stiffeners
d_{wh} = Depth of web openings
d_1 = Clear height of LCB web element

Since the level of fixity at the web-flange juncture of LCB is the same for the available LCBs (23% fixity level) (Keerthan and Mahendran, 2012b), Eqns. (1) to (3) are considered to be applicable to all the LCB sections.

Keerthan and Mahendran (2012b) proposed suitable equations for the shear capacity of LCBs without web openings. These equations can be used for LCBs with stiffened web openings when the improved, recommended stiffener arrangement (Arrangement 2) is used. Figure 8 shows the schematic diagram of the optimum plate stiffener arrangement for LCBs with web openings.

Keerthan and Mahendran (2013) proposed the following equation to predict the thickness of optimum plate stiffeners for hollow flange channel beams

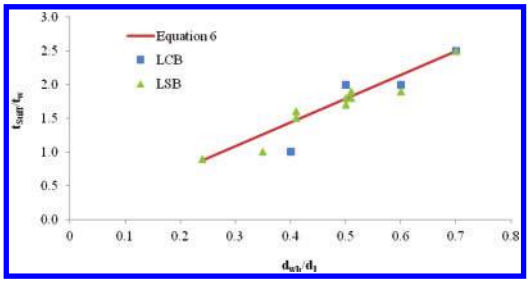

Figure 9. Optimum plate stiffener thickness to web thickness ratio (t_{Siff}/t_w) versus depth of web opening to clear web height (d_{wh}/d_1).

known as LiteSteel beams (LSB). Figure 9 includes the results of both lipped channel beams (LCB) and LiteSteel beams (LSB). It shows that Equation 6 can be also used to predict the thickness of optimum plate stiffeners LCBs.

$$t_{Siff} = \left[3.52\left(\frac{d_{wh}}{d_1}\right) + 0.035\right] t_w \qquad 0.24 < \frac{d_{wh}}{d_1} \leq 0.70 \qquad (6)$$

5 CONCLUSIONS

This paper has presented the details of a study into the shear performance and strength of lipped channel beams with stiffened web openings. Both experimental and numerical studies were conducted to develop the most suitable web stiffening arrangements for lipped channel beams with circular web openings in shear. To investigate the effects of stiffener types (plate and stud stiffeners) and sizes (thickness, width and height) and screw fastening arrangements on the shear capacities of LCBs with web openings, 17 primarily shear tests were conducted using a three point loading arrangement. Suitable finite element models were then developed and validated by comparing their results with corresponding test results. The developed nonlinear finite element model was able to accurately predict the shear capacities, load-deflection plots and failure modes of LCBs with stiffened web openings. Both numerical and experimental studies show that the plate stiffeners based on the recommendations of AISI (AISI, 2004) are not adequate to restore the shear strengths of LCBs with web openings. New plate stiffener systems with optimum sizes and screw-fastening arrangements were therefore proposed to restore the shear capacities of LCBs with web openings based on the results from both experimental and numerical studies. It was found that the width of the recommended plate stiffener is $d_{wh} + 100$ mm where d_{wh} is the web opening depth while its height is the lesser of clear web height (d_1) and $d_{wh} + 100$ mm. The required stiffener thickness was proposed as a function of the web opening depth to clear web height ratio (d_{wh}/d_1).

ACKNOWLEDGEMENTS

The authors would like to thank Queensland University of Technology for providing the necessary facilities and support to conduct this research project. They would also like to thank Mr Liam Rea and Mr Andre Dos Santos for their valuable assistance in performing the shear tests of stiffened LCBs.

Coupled instability behavior of members with thin-walled welded box sections loaded in bending and compression

A. Taras & H. Unterweger

S. Hafner
Ingenieurbüro Prof. Dr.-Ing. H. Bechert + Partner, Stuttgart, Germany

ABSTRACT: In this paper, the behavior of welded box sections with high local (plate buckling) and global (flexural buckling) slenderness is studied by means of numerical analysis and comparisons with code regulations. A remarkable degree of currently unused load-carrying capacity is observed for these sections and typical applications, which stems primarily from the plastic reserves and good post-buckling rotation capacity of this type of cross-section, as well as an inherent – and unnecessary-conservatism of the common design rules based on buckling reduction factors when applied to coupled instabilities.

1 INTRODUCTION

1.1 *Motivation*

The increased use of higher strength steel grades, and the consequent reduction in plate thicknesses in large bridge and building structures, has led to the need to better understand the instability phenomena affecting members with relatively thin-walled (class 3 or 4) steel cross-sections.

This paper focuses on an application of such members: welded box sections with higher plate slenderness ratios, see Figure 1, as found e.g. in (large) truss systems. A number of points must be considered when designing these members:

i. According to common design codes (e.g. the Eurocodes), the structural *analysis* of trusses with thin-walled members must take into account the bending moments due to the rotation impediments at the member ends, i.e. the classical hinged truss analysis is not applicable.
ii. In addition to this, international *design* rules for members with class 4 sections assume a rather strong interaction ("coupling") of the plate- and column buckling modes, with a full reduction to an effective (class 4) area for centric axial force even in cases where a combination with bending is present.

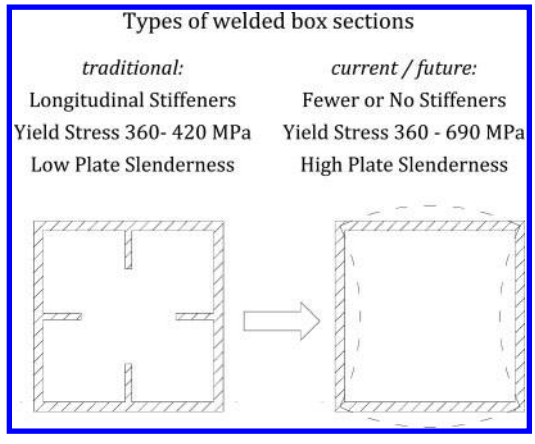

Figure 1. Types of welded box sections; increased plate slenderness due to reduced number of stiffeners and the use of higher-strength steel grades.

1.2 *Scope*

The numerical (geometrically and materially nonlinear FEM analyses with imperfections) and analytical study presented in this paper shows that the current analysis and design approaches often severely underestimate the rotational capacity and strength of the studied type of section. Preliminary recommendations are developed and the need for further experimental investigations and design rule development is highlighted.

All calculations and results presented in this paper consider internally unstiffened welded box sections of square shape (equal width and depth). Concerning the structural system, the following configurations are treated in this paper:

i. Compression members ("columns") subjected to axial force alone, with hinged ends.
ii. Beam-columns with hinged or clamped ends, subjected to variable bending moment diagrams and a compression force.

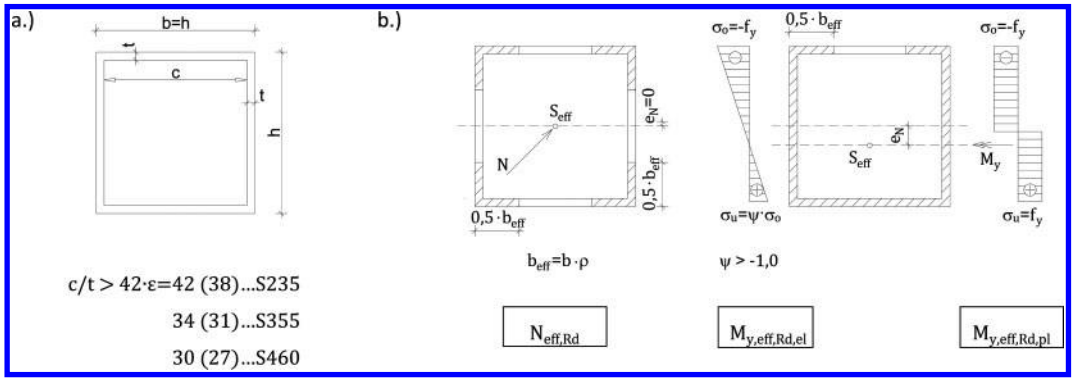

Figure 2. Studied welded box sections of cross-sectional class 4; a) limit c/t values for class 3; b) effective cross-sections and design strength values for compression and bending.

iii. A configuration as a member in a truss, with all boundary stiffnesses at the member ends thus correctly considered.

2 DETERMINATION OF THE STRENGTH OF THIN-WALLED BOX SECTIONS

2.1 *Design standards – Eurocode 3*

The strength predictions according to Eurocode 3 ("EC3", parts EN 1993-1-1 (2006) and EN 1993-1-5 (2005)) are used for comparative purposes in this paper; other international design standards only differ in details, but not in substance, from the principles used in EC3.

In EC3, a modified "Winter curve" equation (Winter, 1947) is used to determine the buckling reduction factor to be applied to rectangular plates in pure compression, see Equ. (1).

$$\rho = \frac{1}{\bar{\lambda}_p} \cdot \left(1 - \frac{0{,}22}{\bar{\lambda}_p}\right) \le 1{,}0 \qquad (1)$$

The slenderness $\bar{\lambda}_p$ is thereby calculated as the square root of the ratio between the yield stress f_y and the elastic critical buckling (bifurcation) stress σ_{cr}. In the EC3 design methodology for thin-walled cross-sections, this reduction factor is then used to determine reduced, "effective" cross-sections; see Figure 2b) for applications with pure compression or pure bending (whereby only the compressed flange is affected by buckling in the representation above). From the above rule, one can easily calculate limit values of the geometric plate slenderness c/t (b/t or h/t), which are given in parenthesis in Figure 2a) above. Interestingly, the current EC3 values used to determine whether or not plate buckling must specifically be checked (written left of the parentheses) are higher, thus creating a certain discontinuity in strength predictions.

The strength of a cross-section is finally determined by calculating the cross-sectional values (area A, section moduli W_y or W_z) of the "effective" sections and multiplying with the yield strength.

When thin walled elements are used as members under pure compression, global buckling must also be accounted for. This is done in EC3 by applying buckling reduction factors χ to the cross-sectional capacity:

$$\chi = \frac{1}{\Phi + \sqrt{\Phi^2 - \bar{\lambda}^2}} \le 1{,}0 \qquad (2)$$

with

$$\Phi = 0{,}5 \cdot \left(1 + \alpha\left(\bar{\lambda} - 0{,}2\right) + \bar{\lambda}^2\right) \qquad (3)$$

In the above equations, α is an "imperfection" factor accounting for the different buckling behaviour of different section shapes (and inherent geometric and structural imperfections), leadinf to the different so-called "European buckling curves", while the global column slenderness $\bar{\lambda}$ is calculated as the square root of the ratio between the section capacity for axial force and the Euler bifurcation load N_{cr}. For thin-walled sections, it takes on the following values:

$$\bar{\lambda} = \sqrt{\frac{A_{eff} \cdot f_y}{N_{cr}}} \qquad (4)$$

The buckling strength for axial compression $N_{b,Rd}$ is finally calculated as:

$$N_{b,Rd} = \chi \cdot A_{eff} \cdot f_y / \gamma_{M1} \qquad (5)$$

whereby γ_{M1} represents a safety factor.

If a compression member is also subjected to bending moments M_y or M_z (making it a "beam-column"), second-order effects may cause a further deterioration of the (in-plane) buckling strength. In EC3, this is taken into account (among a number of methods) by using so-called "beam-column interaction formulae". For the cases studied in this paper, with thin-walled sections and mono-axial bending, they take in the following shape:

$$\frac{N}{N_{b,Rd}} + k_{yy} \cdot \frac{N}{M_{y,eff,Rd,el}} \le 1{,}0 \qquad (6)$$

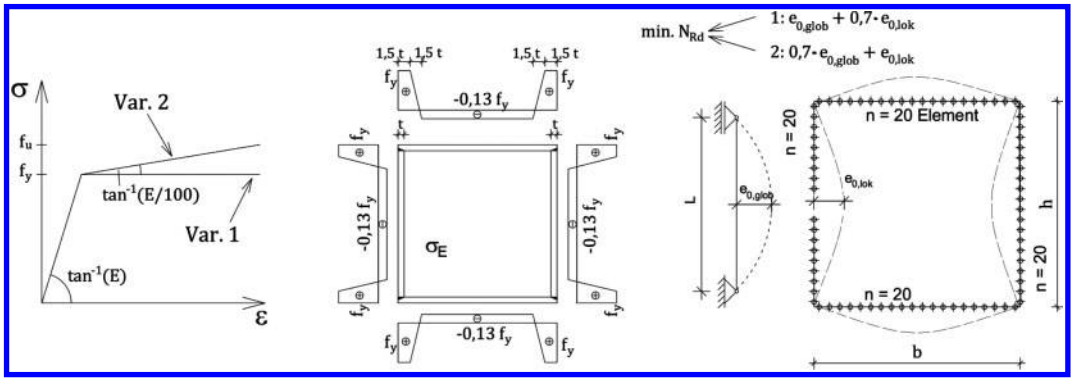

Figure 3. Numerical modelling for GMNIA calculations; stress-strain relationships; assumed residual stresses and geometric (local and global) imperfections and their combination rules; FEM discretization.

Note that the bending strength $M_{y,eff,Rd,el}$ is calculated on the basis of the effective cross-section for bending shown in Figure 2b) and an elastic cross-sectional utilization (yield in only one fibre). The interaction coefficient k_{yy} is a term that depends on both the slenderness $\bar{\lambda}$ and the bending moment diagram (factor C_m) but cannot be treated in detail here.

2.2 *Realistic strength – Numerical study*

As stated in the interaction, design procedures to determine the cross-sectional or member strength as the one described in section 2.1 assume a rather "strong" coupling between the local (plate) and gobal (flexural) buckling modes.

In order to study the realistic behavior and assess the accuracy of the EC3 design rules, a large numerical study was conducted within the scope of a graduate thesis at Graz University of Technology (Hafner, 2012). The numerical part of this work was carried out using the Finite Element Method (FEM) and the dedicated software Abaqus (Dassault Systems, 2010). The input parameters (material, geometry, imperfections) are shown in a schematic way in Figure 3 and can be described as follows:

i. A bi-linear elastic-plastic material characteristic (stress-strain relationship) was used, with and without linear strain hardening. The results shown in this paper refer to "Var. 1" above, and only to the steel grade S355.
ii. The cross-sections were discretized using 3D shell elements of type "S4R", with 4 nodes, linear isoparametric shape functions and reduced integration. 20 elements were used per each face/plate of the box sections.
iii. Imperfections of two types were considered: residual stresses σ_E as shown in the figure above and recommended by ECCS (1984), and geometric imperfections of both local and global type. The imperfection amplitude for the global buckling modes were assumed to be equal to 1/1000 of the member length, which is consistent with assumptions underlying the European column buckling curves (Beer & Schulz, 1970), while the local imperfection amplitude was calibrated – in a preliminary study – to match the Winter curve with sufficient accuracy; this led to a value of b/400, see also Rusch & Lindner (2001). Eigenmode-affine shapes were chosen for the different geometric imperfection types.

Since it is unlikely that both geometric amplitudes occur with their full magnitude at the same time, a case distinction was made, which follows rules also found in EC3. In one case, the full global imperfection was considered, in combination with 70% of the local imperfection, while in the other case the 70%/100% proportions were reversed. The lower of the two buckling resistances was considered to be relevant in the comparisons.

In summary, the chosen procedure is a Geometrically and Materially Non-linear Analysis which considers Imperfections, and is referred to as "GMNIA" in the steel structures literature and in the following figures.

3 MEMBERS IN PURE COMPRESSION – COLUMNS

The first comparison of GMNIA results with the EC3 regulations is performed for the basic case of a simply supported (hinged ends) column, under pure compression. Figure 4 shows plots representing the buckling strengths (as fraction of the EC3 cross-sectional capacity $A_{eff} \cdot f_y =$ "$N_{pl,eff,k}$") according to the GMNIA calculations, the appropriate EC3 buckling curve "b", a higher EC3 curve "a", and the Euler hyperbola. The difference between the two graphs a) and b) is given by the plate (i.e. local) slenderness $\bar{\lambda}_p$, which is 1,1 and 1,5 respectively.

The plots highlight the degree of conservatism to be found in the EC3 rules for thin-walled columns of this type. The following observations can be made:

i. Strength reserves of more than 20% were observed for the box section with $\bar{\lambda}_p$ equal to 1,1, see Figure 4a. These reserves are most visible

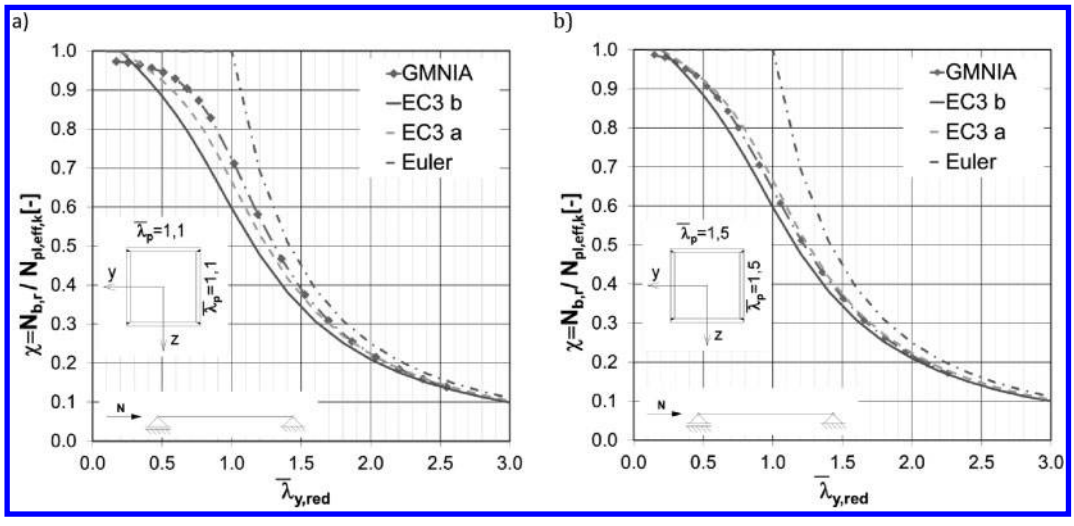

Figure 4. Buckling reduction coefficients χ for thin-walled compression members, based on the strength of the (reduced) effective cross-section, according to Eurocode 3 and the numerical GMNIA calculations.

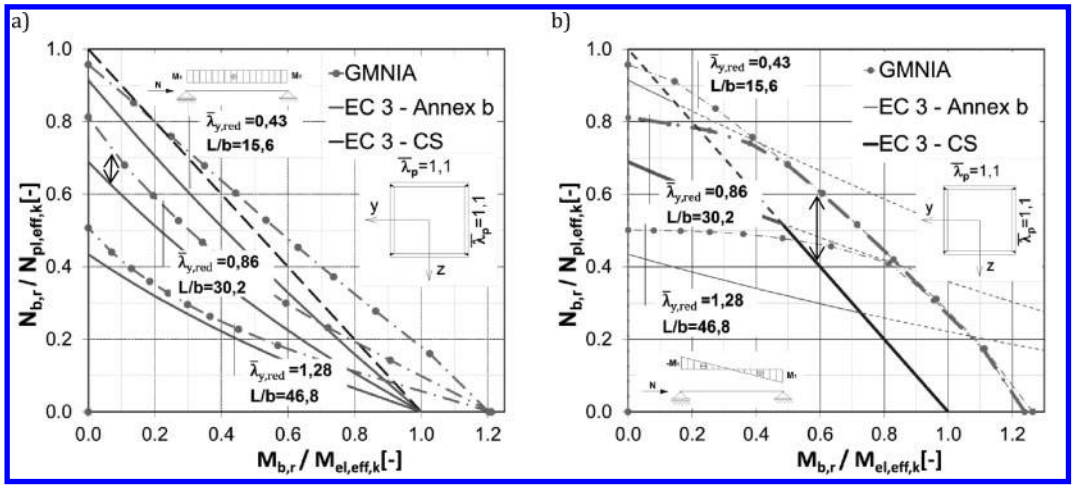

Figure 5. Buckling strengths (N-M interaction curves) for thin-walled beam-columns, according to Eurocode 3 and GMNIA calculations. a) for a uniform bending moment; b) for end moments of opposite sign.

around the "intermediate" (global) slenderness range of $\bar{\lambda}$ ($=\bar{\lambda}_{y,red}$ in the figure) of 1,0, which is the slenderness range where the combination of plasticity and elastic buckling is most felt. This is also the range where the EC3 rules most strongly assume an interaction between local and global buckling.

ii. For the member with a local plate slenderness of $\bar{\lambda}_p$ equal to 1,5 in Figure 4b, the GMNIA results fall closer to EC3 buckling curve, even though the "better" curve "a" would still describe the results better.

iii. Detzel (2006) also studied welded box sections in pure compression; she observed similar results and suggested the adoption of buckling curve "a" for the design of these sections. She attributed the inaccuracy to a combination of the "double counting" of imperfections inherent in the EC3 design process (residual stresses are included in the reduction factors for both local and global buckling and are thus counted twice) and an inaccuracy in the definition of the slenderness, which accounts for the reduced cross-section in terms of area, but not inertia.

iv. An additional explanation is given here: for columns failing in flexural buckling, the failure cross-section at the ultimate limit state is – as the name says - subjected to a lot of flexion. This bending action reduces compression in the webs and the tension-side flange, making the quantity to which the reduction is applied, i.e. the effective cross-section (for which every plate's effective

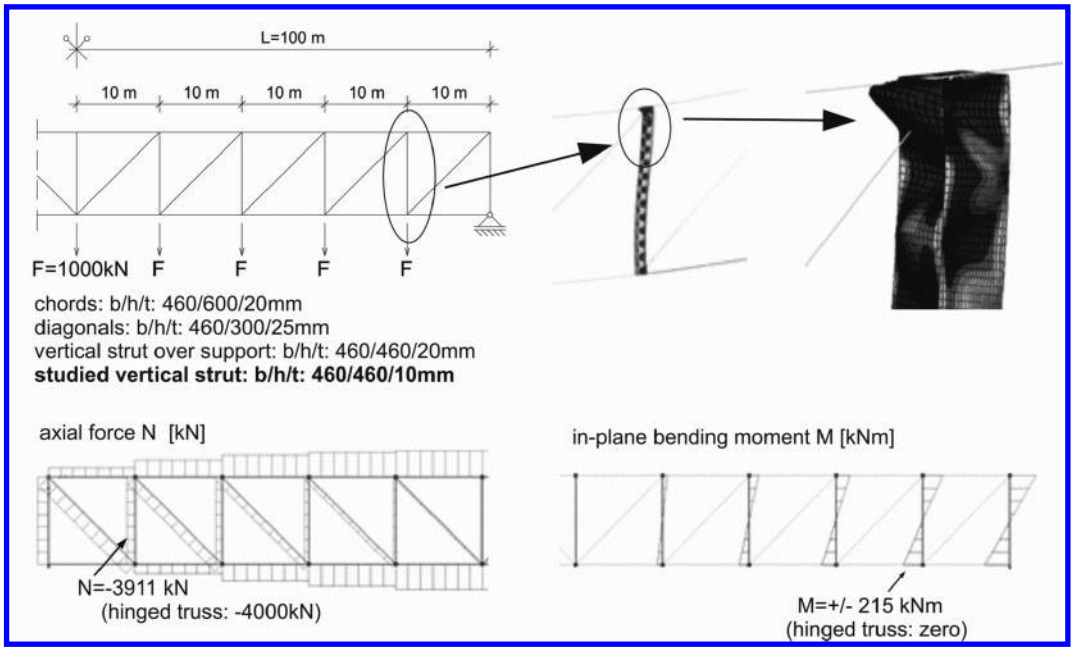

Figure 6. Case study: member in a truss; second-to-last vertical strut, subjected to compression and bending due to restraint.

width is equally reduced in a square box section) less relevant and accurate. In other words: the basis value $N_{pl,eff,k}$ is "too low" and must therefore be reduced less.

4 BEAM-COLUMNS

Members subjected to axial compression and bending were the main focus of the study presented in this paper. Among the multitude of possible bending moment diagrams and boundary conditions that can be considered for this case, Figure 5 shows two cases with linear bending moment diagrams (equal and unequal and moments of the same magnitude) and the basic case of a simply-supported beam-column.

In this case, the EC3 rules represent the interaction formulae briefly introduced in section 2.1. Again, a number of observations can be made:

i. The conservatism found to be present in the design rules for columns is obviously "carried on" in the interaction formulae design rules for beam-columns; this means that the values on the Y-axis of the plots in Figure 5 are equal to the values of χ in Figure 4a, both for the EC3 and the GMNIA curves, which makes the GMNIA N-M interaction curves plotted in Figure 5 start at a higher point than the code curves.

ii. The additional degree of conservatism that is observed in the plots of Figure 5 is given by the inaccuracy of the code rules for the bending strength (for zero axial force) of the studied square box sections.As shown in Figure 2b this bending strength is calculated on the basis of an elastic stress distribution and the EC3 effective cross-section. For the studied sections, in bending only the top flange requires the consideration of an effective width. While this reduction might be appropriate, it is obvious from the above results that the implied reduction of rotation capacity for this "class 4" section is too pessimistic: a strength approaching the plastic bending capacity was observed for the shown section with $\overline{\lambda}_p$ equal to 1,1.

iii. In order to further explain the source of this additional strength, one can use the simple model shown in Figure 2b, on the right: if the bending capacity were calculated using an effective cross-section, but with plastic utilization of the plates that are not class 4, a more realistic strength value would be calculated.

iv. Regarding the effect of the different bending moment diagrams, the example shows that the opposite-sign bending moments lead to an even higher degree of conservatism of the design rules, which can be explained by conservatism of both the interaction coefficient k_{yy} itself and the plate buckling reduction factor ρ for non-uniform compression along the plate.

5 EXAMPLE: MEMBER IN A TRUSS

To conclude this study on the behavior of thin-walled welded box sections, a case study for a "realistic" configuration of a member of this type is carried out, see Figure 6. One member in a truss (representative e.g. for a large bridge superstructure) is studied in detail,

	Method 1	Method 2	Method 3	GMNIA
	 "hinged truss", N alone	 k_y=0,454 / c_{my}=0,4	 k_y=0,523 / c_{my}=0,4	Obtained Load Proportionality Factor: LPF 1,14
Utilization Buckling	**0,909**	0,896	**1,024**	Util.≈$\frac{1}{1,14}$=**0,88**
Utilization Cross-Section	0,777	**1,013**	1,013	

Figure 7. Results of the case study of Figure 6, expressed in utilizations.

using three different analysis and design methods plus a GMNIA calculation of the full truss (with the studied member sub-modeled as described in section 2.2, the rest as beam elements) for comparison. The results are summarized (in terms of utilization) in Figure 7. Briefly, the main findings are:

i The most conservative approach would be what the EC3 currently recommends: isolating the member, with its axial force and end moments, and considering it a hinged-end beam-column with its system length as buckling length.

ii However, also the use of the "real" buckling length, which is L/2 in the studied case due to the stiffness of the chords of the truss, would not significantly improve the design for this particular member, because in this case the cross-sectional resistance is dominant.

iii The most accurate design procedure for the studied case would be the "forbidden" one for trusses made of class 4 sections: an analysis and design based on a classic "hinged truss" model, i.e. neglecting the moments but considering system and buckling length to be equal.

6 CONCLUSIONS AND OUTLOOK

The study performed for this paper showed that significant strength reserves are present in the current (Eurocode) buckling design checks for thin-walled and globally slender welded box sections. Due to the increased use of sections with this characteristic of a "double slenderness", it is certainly worthwhile to expand and improve the knowledge on the actual ultimate load capacity of these sections. The plastic reserves of class 4 sections are totally unexploited at the moment, which is clearly not accurate for a variety of applications that do not require the full rotational capacity implied by the class 4 definition. Members in trusses with cross-sections of the type studied here are one clear example where increased knowledge would lead to great design economy.

Performance of reinforced web openings of cold-formed steel joists

K.S. Sivakumaran
Department of Civil Engineering, McMaster University, Hamilton, Ontario, Canada

ABSTRACT: The floor joists of Cold-Formed Steel (CFS) structures frequently require large web cut-outs, through which building services may be efficiently located. Presence of a large web opening, however, causes localized redistribution of stresses, and loss of member stiffness and cross-sectional capacities. Providing appropriate reinforcements for such openings may alleviate the adverse effects of such large web openings. The experimental investigation presented in this paper considered the flexural and shear capacities of galvanized lipped channel steel sections having circular and square web openings, and three associated reinforcement schemes. Two lipped channel sections were set face-to-face to form the test specimens. The test specimens were simply supported at their ends, and were subjected to appropriate loads. The plate reinforcement and the stud reinforcement schemes considered in the study are those recommended in the Standard for Cold-Formed Steel Framing- Prescriptive Method for One and Two Family Dwellings. This investigation shows that such reinforcement schemes are ineffective for the joists experiencing high shear. New reinforcement schemes, utilizing bridging channels, were developed for moment regions and for shear regions, and the corresponding responses were experimentally established. The new reinforcement schemes can restore the original flexural capacities and the shear capacities of such sections having large circular or square openings. Overall, it is evident from the test results that it is possible to establish cost-effective reinforcement schemes for cold-formed steel sections having large web openings. Based on this investigation, construction guidelines for web openings reinforcements for cold-formed steel joists have been proposed.

1 INTRODUCTION

The Cold-Formed Steel (CFS) members are widely used in small to medium size building construction, including family dwellings, perhaps because they are structurally efficient compared to other traditional construction materials such as reinforced concrete, masonry, and wood. The floor system of detached one- and two-family dwellings, townhouses and other attached single-family dwellings is often constructed using CFS floor joists. Typical cross section of such joists is a lipped channel shape. Large web openings may be cut-out on these floor joists in order to provide the necessary pass through space for ductwork, piping, drainage and other similar systems, while keeping the floor height to a minimum. Appropriate use of circular or non-circular web openings can enhance the aesthetic appeal and can result in cost effective construction of CFS floor systems. The depth of these large web openings, however, can be a substantial proportion of the beam depth, and introduction of such a large web opening, however, causes localized redistribution of stresses, and loss of member stiffness and loss of cross-sectional capacities. Various studies (Shanmugam & Dhanalakshmi 2001, Keerthan & Mahendran 2012, LaBoube et al. 1999) exist on the flexural, shear, web crippling strengths of CFS sections having a large web opening. The current North American cold-formed steel design standard (AISI 2007a) also provides guidelines to account for the effects of such openings. However, a cost effective way to mitigate the negative effects of a large web opening is to screw fasten appropriate reinforcements around the opening regions, so as to restore the original strength and stiffness of the member. Strategically positioned reinforcements for such openings can reestablish the overall capacity of such cold-formed steel members, and can mitigate the detrimental effects of such large web openings. Objectives of this investigation are to establish the effects of a large web opening on [a] the flexural capacity and [b] the shear capacity of cold-formed steel lipped channel shaped floor joists, and to establish constructionally effective and economical reinforcement schemes for large web openings in order to restore the original flexural and the shear capacities.

2 THE TEST SPECIMENS

This investigation focused on 203.20 mm (8″) deep 1.146 mm (43 mils) thick galvanized lipped channel cold-formed steel (CFS) joists, primarily because it is one of most widely used joists in one and two family dwellings construction in North America. The nominal

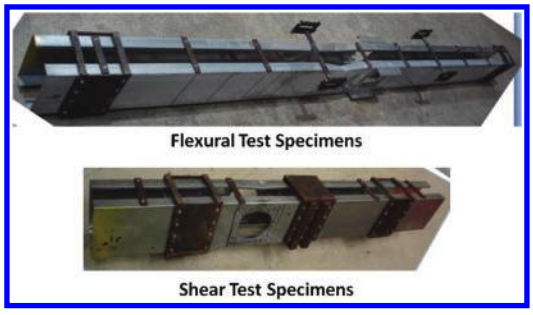

Figure 1. The test specimens.

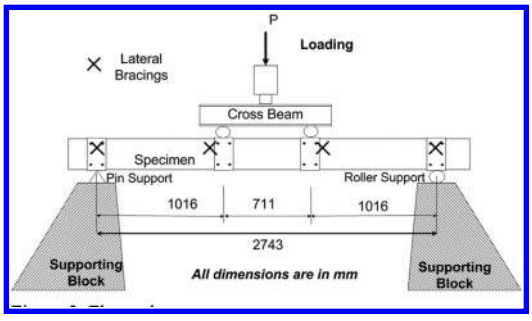
dimensions of the section are web 203.2 mm, flanges 41.275 mm, lips 12.7 mm and thickness 1.146 mm, and these dimensions were confirmed by taking measurements at several random cross-section locations. The specified minimum yield strength of 230 MPa, whereas, the average mechanical properties based on the nine tension coupon test results are; yield stress 311 MPa, tensile strength 401 MPa, and the strain at rupture 21%. The sectional flexural strength of a fully braced section and the shear strength of the section can be established based North American cold-formed steel design standard (AISI, 2007a) and found to be 4.35 kN·m, and 8.81 kN (aspect ratio = 1.5), respectively.

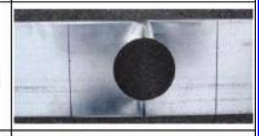
The lipped channel shaped joist under consideration is a mono-symmetric section, which would experience torsional moments unless otherwise the transverse load is applied through the shear center, which is not easy to do in a single channel section as its shear center is outside of the section and does not coincide with the centroid of the section. Besides, in a joist floor system the floor loads are transmitted to the joist through its top flange. Furthermore, the top flange of the joist associated with a floor system often experience compression which may require bracing to prevent lateral torsional buckling. In a joist floor system the floor sheathing might provide such a bracing, however, the test specimens under consideration may require discrete braces. In order to alleviate such issues in this investigation two lipped channel sections were positioned face-to-face to form the test specimen assembly. Figure 1 shows such test specimens. Steel plate strips (130 × 20 × 6.4 mm) were used to tie together the compression flanges of the two sections at about 305 mm interval, and the tension flanges at every 606 mm spacing. The concentrated loads at the load point and at the supports may potentially web-cripple the cold-formed sections, prior to the projected flexural/shear failure. To prevent such a premature failure the machine load was transmitted to the test specimen through a steel bracket, as shown in Figure 1. The vertical planes of the steel brackets were fastened to the webs of the test specimens using self-drilling screws, which created gradual transfer of the concentrated loads into the web. The ends of the tests specimens were supported on similar steel brackets, which also acted as bearing plates, thereby distributing the concentrated reactions to the webs of the test specimens. In order to improve the web crippling capacities of the ends, each end of the test specimen had an overhang of more than 152 mm. With this arrangement the torsional effects are expected to be counterbalanced by each other section due to the torsional restraints that were provided at several locations namely, steel brackets at the load and the support locations and the steel plate strips in the compression flanges and at the non-bearing flanges at the load and at the support locations.

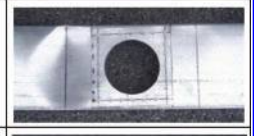
This study considered the performance of reinforced web opening in high moment zones and in high shear zones. In each case, the first part of the investigation considered the corresponding strengths of [a] sections with no openings, [b] sections with a large circular opening, and [c] sections with a large square opening. Circular opening with 127 mm diameter, and square openings with 127 mm sides were considered for the study. The size of the opening for use was determined on the basis of the space requirement for reinforcements. The opening depth considered herein is about 65% of the flat width of the web, and these openings were located at the centre of the test specimen span. Water-jet cutting was used to cut-out these large web openings. Three identical tests were done for each case. The second part of the investigation considered reinforced web openings. Three different reinforcement schemes were considered. Reinforcement Scheme – A is the AISI (2007b) specified patching scheme, where the web openings were reinforced with a solid steel plate having the same size and the shape of openings. The thickness of the steel plate was equal to the thickness of receiving section of 1.146 mm and extended 25.4 mm beyond all edges of the hole. In Reinforcement Scheme – B the web openings were patched with a CFS joist section having same size and shape of openings. The thickness of the reinforcement was equal to the thickness of receiving section of 1.146 mm and extended 25.4 mm beyond all edges of the hole. The joist reinforcement was fastened to the web of the section with No. 8 screws spaced 25.4 mm center-to-center along the edges of the patch with an outer edge distance of 12.7 mm. The reinforcement scheme C is our proposed scheme which utilizes the bridging channels. The reinforcement arrangements for high moment and high shear regions are different, and thus, the details are presented in the following sections.

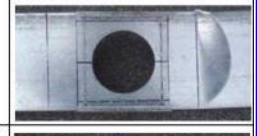
3 FLEXURAL RESISTANCE OF REINFORCED WEB OPENINGS

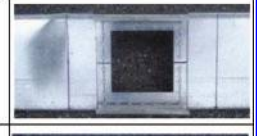
This section discusses the flexural strength of CFS joists having a large reinforced web opening. A total of twenty seven CFS joist specimens were subjected to flexural tests. The objective of this part of the experimental investigation was to assess the effectiveness of three different reinforcement schemes for high moment zones. The flexural tests were carried











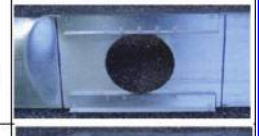


Figure 2. Flexural test setup.

out on 2,743 mm (9′) long specimens, which were simply supported at their ends, and were subjected to two equal point loads acting at equal distances from the supports. One end of the test specimens was pin-supported, whereas the other end was roller-supported. Figure 2 shows the test setup. The ends of the test specimen were laterally supported by smooth vertical rods to prevent lateral movement of the ends. Furthermore, in order to prevent lateral torsional buckling of the test specimens, lateral braces were provided at one-third span locations. A hydraulic jack having 152.4 mm stroke was used to apply a vertical downward load. A load cell having 200 kN load capacity was attached at the end of the jack to measure the total applied load. However, as shown in Figure 2 a transfer beam was used to subdivide the applied load into two equal point loads. Clear span-to-shear span ratio determines the relations between the applied shear force and the bending moments. For flexural tests such as this a clear span-to-shear span ratio within a range of 2.5 to 3.0 is recommended (Li 2002). A clear span of 2743 mm, and a shear span of 1016 mm used in the investigation give such a ratio of 2.7. For a shear span of 'a', this loading arrangement produces a uniform moment of '(P/2).a'. In the above test setup, however, load 'P/2' are applied to the specimens at the load locations, as well as at the support locations.

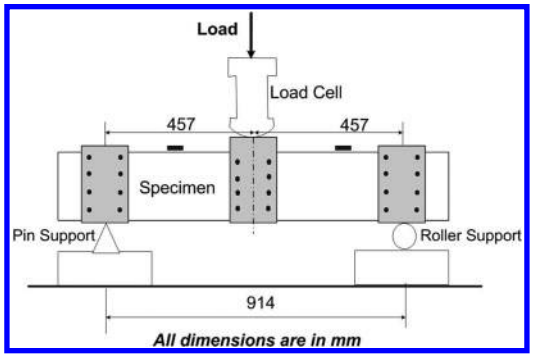
Table 1 summarizes the test results, which includes the moment resistances of the CFS sections with and without the reinforcements. The reduction in the flexural strength of a CFS joist section due to a large web opening (up to 65% of web height) is less than 15%. All the specimens containing reinforcement Scheme-A failed at locations other than the opening locations. Furthermore, the reinforced sections carried about 4% higher moments at the reinforced opening locations. This indicates that the steel plate reinforcement Scheme-A is capable of restoring the flexural strengths with a large web opening. Similar observations can be made on the reinforcement Scheme-B.

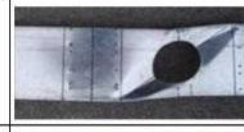
The investigation considered a much simpler reinforcement scheme identified herein as Scheme C, which involves screw fastening (No. 8 self-drilling screws) of bridging channels (depth 38 mm, thickness 1.146 mm) of length determined by width of the opening plus one half of the depth of the opening on either side and plus a minimum edge distance for

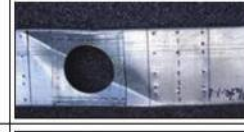
Table 1. Flexural resistance of reinforced web openings.

Test Series: F-N Average Moment Resistance = 4.40 kN.m (Reference Resistance)	
Test Series: F-C Average Moment Resistance = 4.13 kN.m (% Change = - 6.1%)	
Test Series: F-S Average Moment Resistance = 3.78 kN.m (% Change = - 14.1%)	
Test Series: F-CR$_A$ Average Moment Resistance = 4.59 kN.m (% Change = + 4.3%)	
Test Series: F-SR$_A$ Average Moment Resistance = 4.61 kN.m (% Change = + 4.8%)	
Test Series: F-CR$_B$ Average Moment Resistance = 4.58 kN.m (% Change = + 4.1%)	
Test Series: F-SR$_B$ Average Moment Resistance = 4.53 kN.m (% Change = + 3.0%)	
Test Series: F-CR$_C$ Average Moment Resistance = 4.62 kN.m (% Change = + 5.0%)	
Test Series: F-SR$_C$ Average Moment Resistance = 4.54 kN.m (% Change = + 3.2%)	

screws (10 mm). As a result, the total length of the reinforcements was 274 mm. The scheme-C consisted of two bridging channels, one along the top edge of the opening, and the other along the bottom edge of the opening. The bridging channels were screw fastened along the edges of the opening (12.7 mm) from the edge) at a spacing of 31.75 mm (d/4, where d is depth of the openings). The r/f scheme "C" specimens also failed outside the opening and the reinforcement. The circular and square openings with scheme "C" resisted 5% and 3% more moment, respectively, than the solid sections. Thus, the reinforcement scheme "C" is capable of restoring the original flexural strength of a CFS joist.







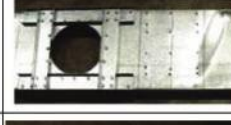


Figure 3. Shear test setup.

4 SHEAR RESISTANCE OF REINFORCED WEB OPENINGS

It is impossible to create a pure shear zone for "shear testing" because of the presence of a moment whenever there is a shear force. In practice though, a shear test is performed by creating a high shear and low moment region. Here, a 914 mm short span, with mid-span point load was considered as an appropriate test setup to achieve high uniform shear and low moments. One end of the test specimen was pin-supported, whereas the other end was roller-supported. Figure 3 shows the shear test setup. The overall load was applied at the centre of the span using the 600 kN capacity Tinius Olsen test. The test arrangement used herein results in uniform shear forces and increasing moments between the support and the load point. In reality though, short span specimen subjected to single mid-span load experiences high shear as well as high moment at the load location. Thus, this test setup simulates the high shear zones, as well as high shear-high moment conditions that exist at the over-the-support location in a continuous span joist.

Since the section is mono-symmetric, in this investigation two lipped channel sections with a length of about 1220 mm (48″) were set face-to-face to form the test specimen. Three identical tests were done for each case, thus, this part included twenty seven tests. Table 2 summarizes the test results. The reduction in the shear strength of a cold-formed steel joist section due to the presence of a large web opening (up to 65% of web height), and in the presence of high moments, may be as high as 60%. In other words, the residual shear strength of a joist with a large opening may be as low as 40%. Once agin, three types of reinforcement schemes namely, Scheme-A, Scheme-B and Scheme-C, were considered for shear tests. These reinforcements were used for both circular and square openings. The shear r/f Scheme-C is different from the flexural reinforcement Scheme-C, and it involves screw fastening (No. 8 self-drilling screws) of bridging channels [depth 38 mm, thickness 1.438 mm (54 mils)] along all four edges of the opening. Note that the bridging channels are 1.438 mm (54 mils) thick whereas the main joist section is of 1.146 mm (43 mil) thick. The shear reinforcements consisted of horizontal and vertical reinforcements. Horizontal reinforcements consisted of two bridging channels of length determined by width of the opening plus one half of the depth of the opening on both sides and a minimum edge distance for screws (10 mm). Therefore, the total length of the horizontal reinforcements was 274 mm. Vertical reinforcements included two bridging channels of length equal to the depth of the web of receiving channel 203 mm. One horizontal reinforcement was fastened along the top edge of the opening, and the other one was placed along the bottom edge of the opening. The channels were

Table 2. Shear resistance of reinforced web openings.

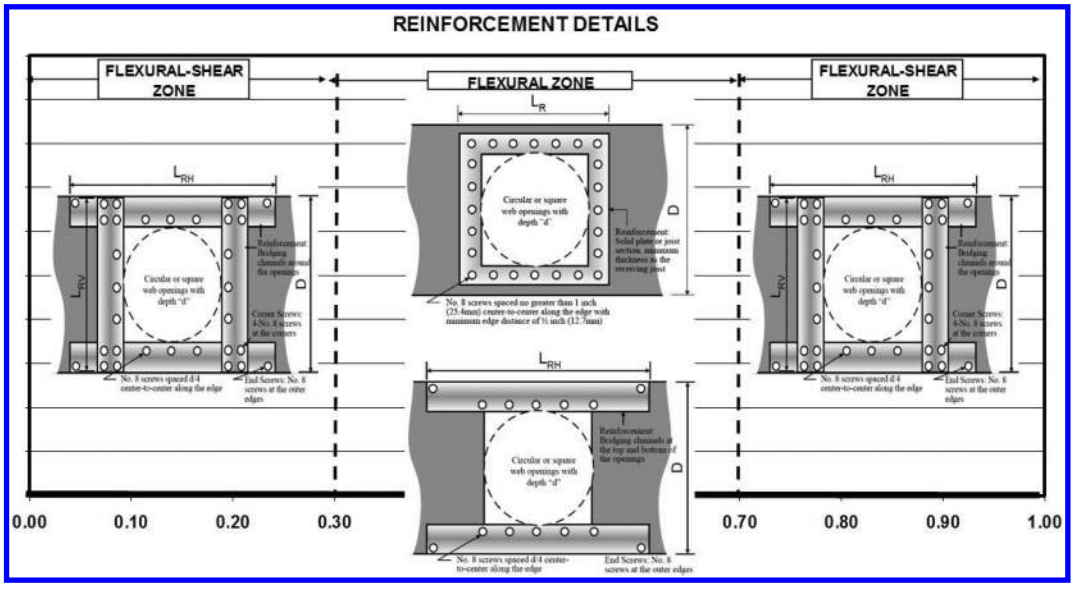

Figure 4. Recommended reinforcements details for joists with large web opening.

screw fastened at a spacing of 31.75 mm (d/4, where d is depth of the openings) close to the opening edges within the opening region, starting from the central screw. Vertical reinforcements were placed closer to the vertical edges of the openings. Four screws were fastened at the corner of horizontal and vertical reinforcements to create a joint. This system produces a Virendeel type reinforcement system.

It is evident from the test results, as presented in Table 2, the reinforcement schemes "A", and "B", established as per AISI (2007a) patching requirements, are not adequate to restore the shear strengths of joist sections with opening. It is clearly evident that the specimens with reinforcement scheme "C" failed at locations outside the reinforced opening location. Thus it may be concluded that reinforcement scheme "C", Virendeel type reinforcement system, for web opening is capable of restoring the original shear strength of a cold-formed steel joist section.

5 DISCUSSION AND RECOMMENDATIONS

Sections 3 and 4 presented the experimental flexural strength and the shear strength of cold formed steel (CFS) joist having web opening. These tests established the impact of such web opening, and they also determined the reinforcement schemes which restored the flexural strength and the shear strength, respectively. It was noted in section 3 that web opening depth up to 65 percent of web depth would reduce the flexural strength of cold-formed joist by 15 percent or in another words, CFS web with a large openings still retains a residual moment resistance of 85% of the moment resistance of the original joist. Thus, flexural reinforcement is required only when the moment at the opening location is greater than 85% of the moment resistance. Similarly, it was noted in section 4 that web opening depth up to 65 percent of web depth would reduce the shear strength of cold-formed joist by 60 % or in another words, CFS web with a large openings still retains 40% shear capacity of the original joist, thus, shear reinforcement is required when shear load at the opening location is greater than 40 percent of shear capacity.

In the experimental program, the moment and shear resistances were investigated separately and the high moment zone and the high shear zone were not defined. These zones for a joist member depend on the structural arrangement and the loading. This section establishes a definition for high moment zone and high shear zone for CFS joists. In general, the Cold-formed steel (CFS) floor joists are expected to carry uniformly distributed load imposed by the floor deck. Therefore, in the analysis and design of CFS floor joists for housing construction, it is reasonable to assume that the floor joist is subjected to uniformly distributed loads. Shear and moment variations in a floor joist having three different structural arrangements, namely, simple support, continuous support and moment optimized two-span joist were investigated. For a simply supported case the maximum shear (Vmax) occurs at the supports, and the shear forces in the mid-span region defined by 0.30 L and 0.70 L, where L is the span length, are less than 0.40Vmax. If the joist is continuous over two or more spans, then the shear forces in the mid-span region defined by 0.125 L and 0.625 L are less than 0.40Vmax, where Vmax is the corresponding maximum shear, which is higher than that for a simply supported joist. For all other structural arrangements the range under discussion is within the above two regions (example: If the joist has

an over-hang and the joist had been designed such that the moment over the support is equal to the moment at the mid-span (moment optimized two-span joist), then shear is less than 0.40Vmax in the mid-region defined by 0.18L and 0.65L). Considering these three possible structural arrangements, and considering the fact that often the shear resistance of the joist is higher than shear force, since often deflection or bending moment governs the design of such joist, it can be concluded that shear reinforcement scheme C discussed in section 4 must be provided for large openings located within 0.30L from the support. Thus, high shear zone can be defined as distance 0.3L from the supports.

Similarly, considering the moment variations in a floor joist subjected to a uniformly distributed load, if the joist is simply supported, then the maximum moment Mmax occurs at the mid-span. Focusing on the mid-span region, moments between 0.3L and 0.7L exceed 0.85Mmax. If the joist is continuous over two or more spans, then the maximum moment Mmax occurs over the support, mid-span region does not experience moments greater than 0.85Mmax. If the joist has an over-hang and the joist had been designed such that the moment over the support is equal to moment at the mid-span (moment optimized two-span joist), then the maximum moment Mmax occurs over the support and at the mid-span region at 0.41L. Focusing on the mid-span region, moments between 0.255L and 0.575L are greater than 0.85Mmax. Considering these three possible loading and structural arrangements, the mid-region between 0.3L and 0.7L, where shear force was shown to be less than 0.4Vmax, may experience moments greater than 0.85Mmax. Thus, it will suffice to provide the flexural reinforcements discussed in section 2 for large openings located in this mid-region between 0.3L and 0.7L. Figure 4 summarizes these recommendations.

A linear one-dimensional model for the flexural-torsional vibrations of tapered thin-walled bars with open cross-sections

A. Andrade & P. Providência

D. Camotim
Civil Engineering Department, ICIST, Instituto Superior Técnico, Technical University of Lisbon, Portugal

ABSTRACT: The physical significance of a newly developed one-dimensional model for tapered thin-walled bars with open cross-sections is discussed by means of an illustrative example – the (undamped) free torsional motion of a family of doubly symmetric and linearly web-tapered I-section cantilevers. The shortcomings of stepped (piecewise prismatic) models, which become particularly noticeable when restrained warping plays an important part in the torsional behaviour, are highlighted. It is also shown that the approach to non-uniform torsion pioneered by Timoshenko – *i.e.*, regarding each plated component of the bar as an Euler-Bernoulli member undergoing stretching and bending –, when correctly applied to the tapered case, leads to identical results.

1 INTRODUCTION

The authors have recently developed a Vlasov-type one-dimensional (1D) model for the linear dynamic analysis of tapered thin-walled bars with open cross-sections under general monogenic loads (Andrade 2012). This paper presents, in considerable detail, a specific application of this model. The selected illustrative example, namely the (undamped) free torsional motion of a family of doubly symmetric and linearly web-tapered I-section cantilevers, serves a threefold purpose:

(i) To provide a tangible meaning for the non-standard quantities appearing in the 1D model.
(ii) To show that the approach to non-uniform torsion pioneered by Timoshenko (*i.e.*, regarding each plated component of the bar as an Euler-Bernoulli member undergoing stretching and bending), when correctly applied to the tapered case, is entirely compatible with ours.
(iii) To underscore the differences between tapered and stepped (*i.e.*, piecewise prismatic) models, regardless of the number of segments considered in the latter. In fact, stepped models exhibit a number of significant mechanical shortcomings, which are clearly pointed out.

2 A BIRD'S-EYE VIEW OF THE 1D MODEL

The most distinctive features of the developed 1D model may be summarised as follows:

(i) Thin-walled bars are basically regarded as internally constrained membrane shells.
(ii) The internal constraints extend to the tapered case the classical assumptions of Vlasov's prismatic bar theory (Vlasov 1961).
(iii) The internal constraints are treated consistently as *a priori* restrictions, of a constitutive nature, on the possible deformations of the middle surface of the bar (Podio-Guidugli 1989). The membrane forces are split additively into active and reactive parts. The reactive forces perform no work in any admissible deformation. Moreover, the constitutive dependence of the active membrane forces on the membrane strains reflects the maximal symmetry compatible with the assumed internal constraints (a special case of curvilinear anisotropy). Stress resultants are likewise split into active and reactive categories.
(iv) In tapered bars, and from the point of view of kinematics, the constraints give rise to an additional (*i.e.*, non-standard) basic membrane strain mode, which is absent in prismatic bars – its amplitude is the rate of twist. As a consequence, the model features additional stiffness terms associated with the torsional behaviour.
(v) From the point of view of statics, the counterpart of the preceding item is the contribution of the active membrane forces to the total torque, which is absent in prismatic bars.
(vi) There are exceptions to the statements in items (iv) and (v) – for instance, the additional basic strain mode and the contribution of the membrane forces to the total torque vanish in tapered bars whose middle surface is cut out from a cylindrical one.

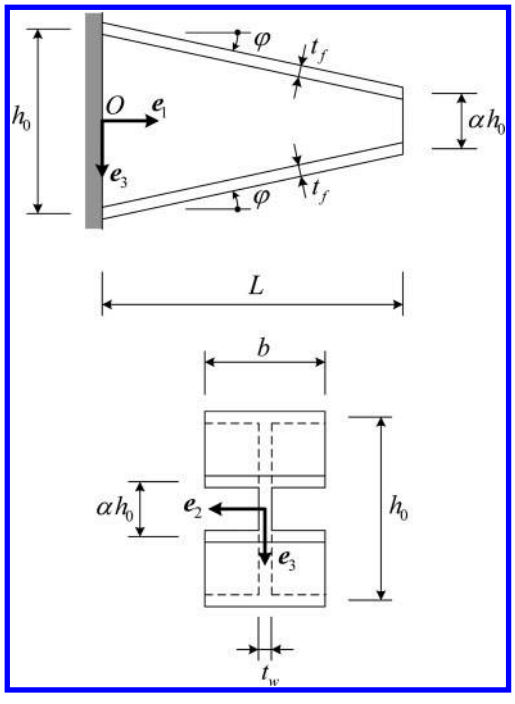

Figure 1. Illustrative example – Reference shape and support conditions.

(vii) The classical model of Vlasov for prismatic bars is obtained as a special case.

3 THE ILLUSTRATIVE EXAMPLE

To illustrate the application of the 1D model, we investigate the undamped free torsional motion of the family of doubly symmetric web-tapered I-section cantilevers whose reference shape is shown in Figure 1. The chosen inertial frame, also shown in this figure, is such that the planes containing the origin O and spanned by $\{\boldsymbol{e}_1, \boldsymbol{e}_2\}$ and by $\{\boldsymbol{e}_1, \boldsymbol{e}_3\}$ are the longitudinal planes of symmetry of the reference shape. The depth h of the web, measured between flange middle lines, varies according to the affine law

$$h(x_1) = \left[1 - (1-\alpha)\frac{x_1}{L}\right] h_0 \ , \tag{1}$$

with $0 < \alpha \leq 1$. The parameter α is referred to as the (web) taper ratio. The bar is clamped at its larger end and free at the smaller end.

4 THE MATHEMATICAL MODEL AND ITS PHYSICAL SIGNIFICANCE

4.1 *The initial-boundary value problem*

From a mathematical point of view, we will be dealing with the following initial-boundary value problem (the symbol τ denotes time, a prime denotes differentiation with respect to the longitudinal coordinate x_1 and a superposed dot represents differentiation with respect to time):

Find $\Phi_1 \in C^{4,2}[0, L] \times [0, \tau_0]$, *satisfying the partial differential equation*

$$\begin{aligned} &-\left(\tilde{E}I^*_{\omega}\,\Phi_1'' + \tilde{E}I^*_{\omega\psi}\,\Phi_1'\right)'' + \left[\tilde{E}I^*_{\omega\psi}\,\Phi_1'' + \left(GJ + \tilde{E}I^*_{\psi}\right)\Phi_1'\right]' \\ &\quad + \rho\left(I_{\omega}\ddot{\Phi}_1'\right)' - \varrho\left(I_2 + I_3\right)\ddot{\Phi}_1 = 0 \end{aligned} \tag{2}$$

on $(0, L) \times (0, \tau_0)$, *together with the boundary conditions*

$$\Phi_1(0,\tau) = 0 \qquad \Phi_1'(0,\tau) = 0 \tag{3}$$

$$\begin{aligned} &-\left(\tilde{E}I^*_{\omega}\,\Phi_1'' + \tilde{E}I^*_{\omega\psi}\,\Phi_1'\right)'(L,\tau) - \tilde{E}I^*_{\omega\psi}(L)\,\Phi_1''(L,\tau) \\ &\quad + \left(GJ(L) + \tilde{E}I^*_{\psi}(L)\right)\Phi_1'(L,\tau) \\ &\quad + \rho\, I_{\omega}(L)\ddot{\Phi}_1'(L,\tau) = 0 \end{aligned} \tag{4}$$

$$-\tilde{E}I^*_{\omega}(L)\,\Phi_1''(L,\tau) - \tilde{E}I^*_{\omega\psi}(L)\,\Phi_1'(L,\tau) = 0 \ , \tag{5}$$

$0 \leq \tau \leq \tau_0$, *and the initial conditions*

$$\Phi_1(x_1,0) = \Phi_{1.0}(x_1) \qquad \dot{\Phi}_1(x_1,0) = \dot{\Phi}_{1.0}(x_1) \ , \tag{6}$$

$0 \leq x_1 \leq L$. *In these equations,* ρ *is the (constant) mass density over the reference shape,*

$$\tilde{E} = \frac{E_1}{1 - \nu_{\text{I-II}}\,\nu_{\text{II-I}}} \tag{7}$$

is the ratio between the sole active stress component $n_{1\text{-}1}/t$ *and the corresponding membrane strain* $\gamma_{1\text{-}1}$ *for the internally constrained orthotropic membrane, and*

$$I_2 = \frac{h^3 t_w}{12} + \frac{b\,h^2}{2}\frac{t_f}{\cos\varphi} \qquad I_3 = \frac{b^3 t_f}{6\cos\varphi} \tag{8}$$

$$J = \frac{2b}{3}\left(\frac{t_f}{\cos\varphi}\right)^3 + \frac{h t_w^3}{3} \qquad I_{\omega} = \frac{b^3 h^2}{24}\frac{t_f}{\cos\varphi} \tag{9}$$

$$I^*_{\omega} = \frac{1}{24} b^3 h^2 t_f \cos^3\varphi \tag{10}$$

$$I^*_{\omega\psi} = -\frac{1}{6} b^3 h \tan\varphi\, t_f \cos^3\varphi \tag{11}$$

$$I^*_{\psi} = \frac{2}{3} b^3 \tan^2\varphi\, t_f \cos^3\varphi \tag{12}$$

are geometrical properties.■

It should be noticed that

$$I^*_{\omega\psi} = I^{*\prime}_{\omega} \qquad I^*_{\psi} = 2I^{*\prime\prime}_{\omega} = 2I^{*\prime}_{\omega\psi} \tag{13}$$

but the validity of these identities is, of course, restricted to the particular bar shape considered in this illustrative example.

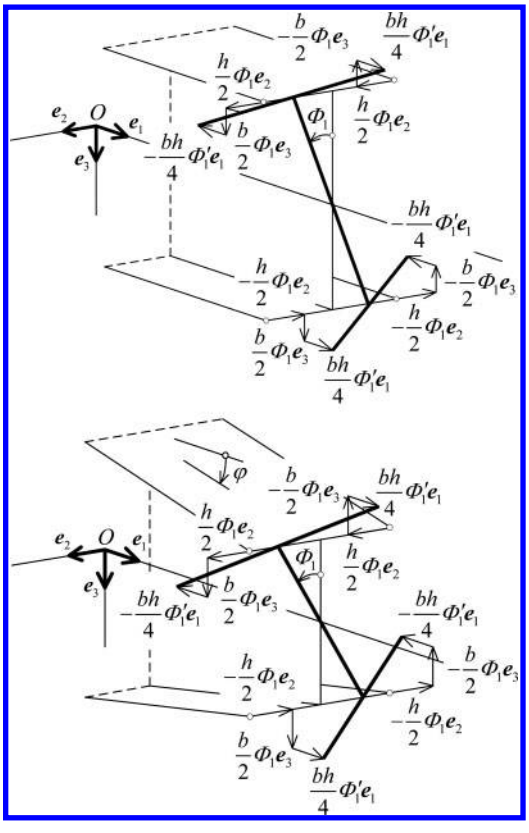

Figure 2. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Motion of cross-section middle line.

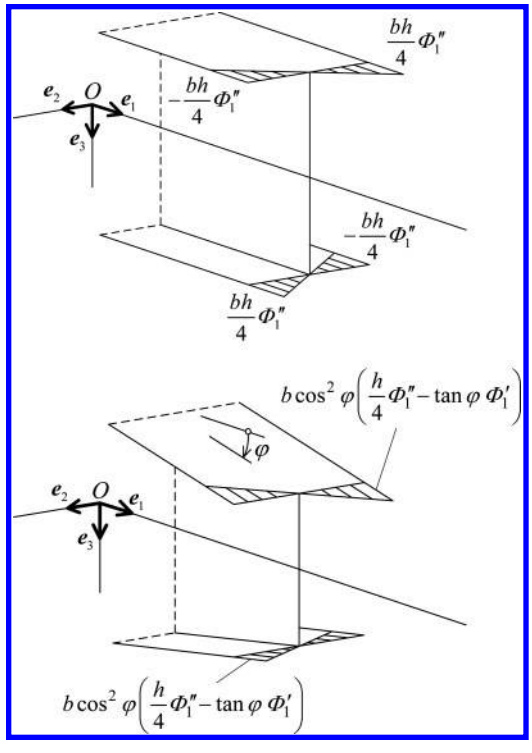

Figure 3. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Membrane strains $\gamma_{\mathrm{I}\cdot\mathrm{I}}$.

4.2 *On the physical significance of the stiffness terms*

In an effort to gain a firm understanding of the nature of the (non-standard) stiffness terms appearing in the initial-boundary value problem 2–6, the warping-torsion behaviours of prismatic ($\alpha = 1$) and linearly depth-tapered ($0 < \alpha < 1$) doubly symmetric I-section bars is contrasted in Figures 2–7. The following facts are worthy of notice:

(i) In both cases, the Vlasov-type internal constraints, together with symmetry considerations, imply qualitatively similar motions for any given cross-section middle line (Fig. 2). However, one must not forget that in the web-tapered case the displacements along $\boldsymbol{e}_3$ are obviously *not* orthogonal to the middle planes of the flanges.

(ii) The membrane strains $\gamma_{\mathrm{I}\cdot\mathrm{I}}$ in the flanges can now be found by direct computation (Fig. 3). Comparing the ensuing strain-displacement relation for prismatic and web-tapered bars, one readily sees that the latter contains an additional term $(-\tan\varphi\,\Phi_1')$ and a common scaling factor $(\cos^2\varphi)$. These remarks also apply to the (active) membrane forces $n_{\mathrm{I}\cdot\mathrm{I}}$ in the flanges, as shown in Figure 4.

(iii) The membrane forces $n_{\mathrm{I}\cdot\mathrm{II}}$ shown in Figure 5, which have a reactive character, may be found by considering the equilibrium of a "flange slice" acted by the previously obtained membrane forces $n_{\mathrm{I}\cdot\mathrm{I}}$, as ordinarily done in standard textbooks on Strength of Materials.

(iv) The membrane forces $n_{\mathrm{I}\cdot\mathrm{I}}$ (resp. $n_{\mathrm{I}\cdot\mathrm{II}}$) are statically equivalent to a bending moment M_f (resp. shear force V_f) in each flange (Figs. 6–7). In the web-tapered case, the modified warping stiffness $\tilde{E}I_\omega^*$, calculated with the reduced flange thickness $t_f^* = t_f\cos^3\varphi$, and the non-standard mechanical property $\tilde{E}I_{\omega\psi}^*$ arise naturally in this process, thus acquiring a tangible meaning:

$$M_f = \frac{1}{6}\tilde{E}\,b^3 t_f\cos^2\varphi\left(\frac{h}{4}\Phi_1'' - \tan\varphi\,\Phi_1'\right) = \frac{1}{h\cos\varphi}\left(\tilde{E}I_\omega^*\,\Phi_1'' + \tilde{E}I_{\omega\psi}^*\,\Phi_1'\right) \tag{14}$$

$$V_f = -\frac{1}{12}\tilde{E}\,b^3 t_f\cos^3\varphi\left(\frac{h}{2}\Phi_1''' - 3\tan\varphi\,\Phi_1''\right) = -\frac{1}{h}\left(\tilde{E}I_\omega^*\,\Phi_1''' + \frac{3}{2}\tilde{E}I_{\omega\psi}^*\,\Phi_1''\right). \tag{15}$$

Observe that

$$M_f = \tilde{E}\frac{b^3 t_f}{12}\cos^2\varphi\left(\frac{h}{2}\Phi_1\right)'' \tag{16}$$

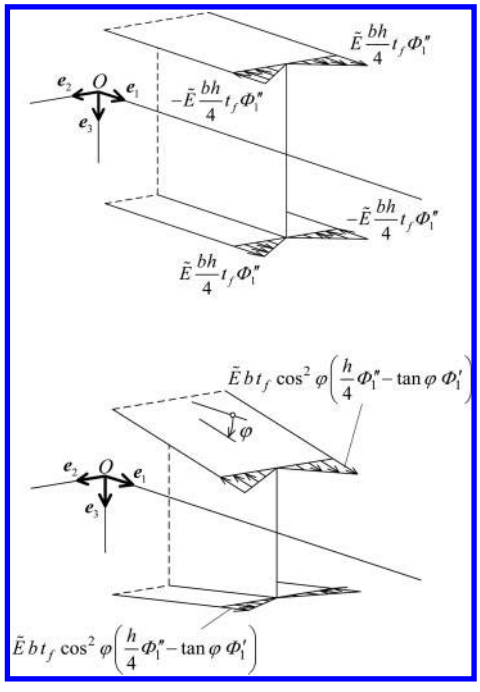

Figure 4. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Membrane forces $n_{\mathrm{I}\cdot\mathrm{I}}$ (active).

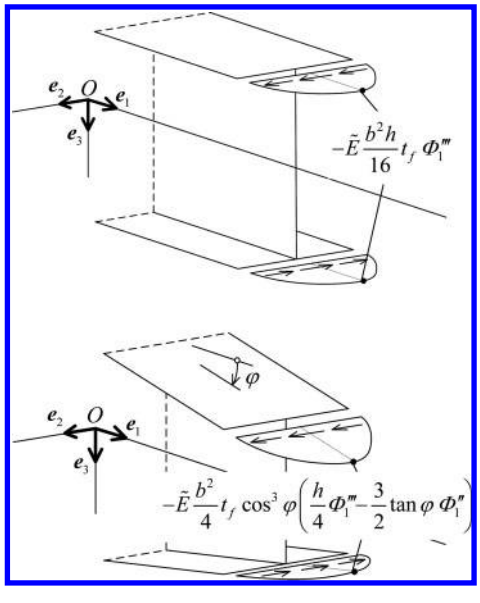

Figure 5. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Membrane forces $n_{\mathrm{I}\cdot\mathrm{II}}$ (reactive).

$$V_f=-\cos\varphi\,M_f'\ . \tag{17}$$

We can thus look at each flange as an Euler-Bernoulli beam undergoing deflections $\pm h\,\Phi_1/2$. However, a word of caution is in order:

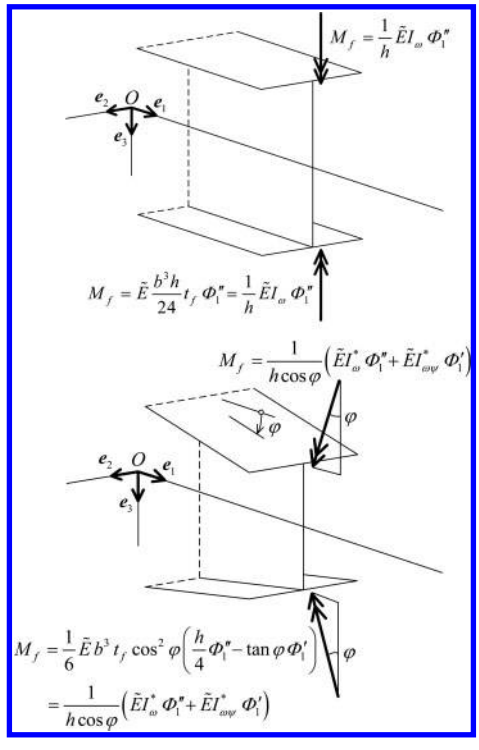

Figure 6. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Bending moments in the flanges.

when dealing with web-tapered bars, a careful distinction must be made between derivatives with respect to x_1 and derivatives with respect to the arc length of the flange centroidal lines, whence the appearance of $\cos\varphi$ in Equations 16–17. Clearly, a stepped model, regardless of the number of prismatic segments it comprises, cannot capture the second term on the right-hand side of

$$\frac{1}{2}\left(h\Phi_1\right)''=\frac{1}{2}h\Phi_1''+h'\Phi_1'\ , \tag{18}$$

nor can it capture the factor $\cos\varphi$.

(v) In web-tapered bars, the flange bending moments have an axial component (see Fig. 6), featuring $\tilde{E}I_{\omega\psi}^*$ and $\tilde{E}I_\psi^*$, which totals

$$\begin{aligned}-2\sin\varphi\,M_f\,\boldsymbol{e}_1&=-\frac{2\tan\varphi}{h}\left(\tilde{E}I_\omega^*\Phi_1''+\tilde{E}I_{\omega\psi}^*\Phi_1'\right)\boldsymbol{e}_1\\&=\frac{1}{2}\left(\tilde{E}I_{\omega\psi}^*\Phi_1''+\tilde{E}I_\psi^*\Phi_1'\right)\boldsymbol{e}_1\ .\end{aligned} \tag{19}$$

The torque is thus given by

$$\begin{aligned}M_1&=-2\sin\varphi\,M_f+V_f\,h+GJ\,\Phi_1'\\&=-\tilde{E}I_\omega^*\Phi_1'''-\tilde{E}I_{\omega\psi}^*\Phi_1''+\left(GJ+\frac{1}{2}\tilde{E}I_\psi^*\right)\Phi_1'\ .\end{aligned} \tag{20}$$

Obviously, the contribution of the flange bending moments to the torque, absent in prismatic bars,

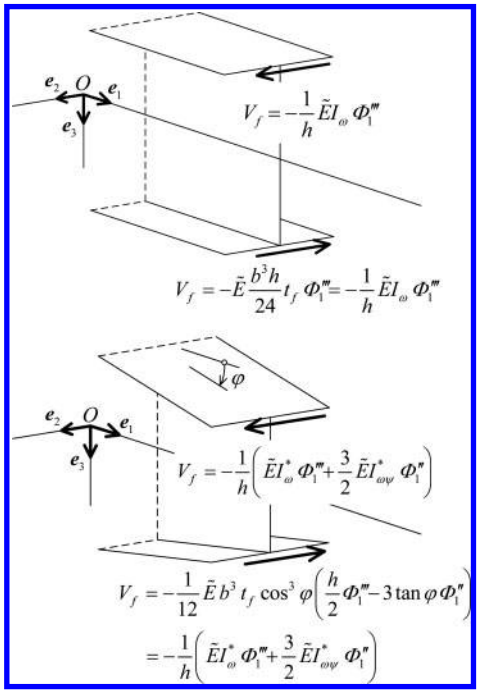

Figure 7. Contrasting the warping-torsion behaviours of prismatic and web-tapered bars – Shear forces in the flanges.

cannot be captured by stepped models. Finally, notice that

$$\cos\varphi\, M_f = \frac{1}{h}\left(\tilde{E} I_\omega^* \Phi_1'' + \tilde{E} I_{\omega\psi}^* \Phi_1'\right) = -\frac{B}{h}\,, \qquad (21)$$

where B denotes the bimoment.

4.3 *On the physical significance of the inertial terms*

The physical significance of the inertial terms $\rho I_\omega \ddot{\Phi}'_1$ and $-\rho(I_2 + I_3)\ddot{\Phi}_1$ in Equation 2 – distributed bimoment and torque, both defined per unit length of the line segment $\{O + x_1 e_1,\ 0 \le x_1 \le L\}$ – is schematically shown in Figure 8.

4.4 *The eigenproblem*

We now ignore the initial conditions and look for a very specific type of (non-trivial) solution, namely a product of two functions, one depending only on x_1 and four times continuously differentiable, and the other depending only on τ and twice continuously differentiable:

$$\Phi_1(x_1, \tau) = \phi(x_1)\, f(\tau)\ ,\quad 0 \le x_1 \le L\ ,\quad 0 \le \tau \le \tau_0\ . \qquad (22)$$

(In other words, we apply the technique of separation of variables.) The physical implication of Equation 22 is that the bar undergoes a synchronous motion. It turns out that the time dependency is harmonic, with the torsional natural frequencies k and the associated mode shapes ϕ being given by the following eigenproblem:

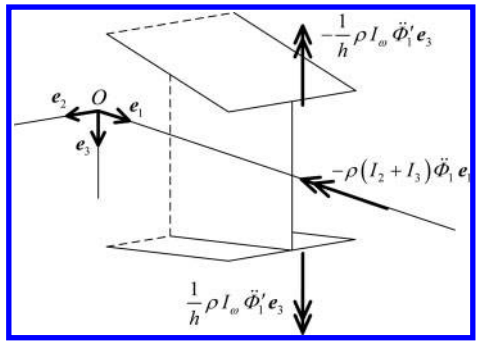

Figure 8. Resultants of the inertial forces, defined per unit length of the line segment $\{O + x_1 e_1,\ 0 \le x_1 \le L\}$.

Find $\lambda = k^2 > 0$ and $\phi \in C^4[0, L]$, with $\varphi \neq 0$, satisfying the ordinary differential equation

$$\tilde{E} I_\omega^* \phi^{(4)} + 2\tilde{E} I_\omega^{*\prime} \phi''' - GJ\,\phi'' - GJ'\,\phi' + \lambda\,\rho\left[I_\omega \phi'' + I'_\omega \phi'(\theta^1) - (I_2 + I_3)\phi\right] = 0 \qquad (23)$$

on $(0, L)$, together with the boundary conditions

$$\phi(0) = 0 \qquad \phi'(0) = 0 \qquad (24)$$

$$-\tilde{E} I_\omega^*(L)\phi'''(L) - \tilde{E} I_\omega^{*\prime}(L)\phi''(L) - \left(GJ(L) + \frac{1}{2}\tilde{E} I_\psi^*(L) - k^2\,\rho\, I_\omega(L)\right)\phi'(L) = 0 \qquad (25)$$

$$-\tilde{E} I_\omega^*(L)\phi''(L) - \tilde{E} I_{\omega\psi}^*(L)\phi'(L) = 0\ . \blacksquare \qquad (26)$$

5 SOME NUMERICAL RESULTS

Numerical results were obtained for the fundamental (lowest) torsional frequency and the corresponding normalised vibration mode of two series of cantilevers that share the geometrical and material properties

$L = 4572\,\text{mm}$	$h_0 = 554.2\,\text{mm}$	
$t_w = 11.4\,\text{mm}$	$t_f = 17.8\,\text{mm}$	
$\tilde{E} = 206.8\,\text{GPa}$	$G = 79.5\,\text{GPa}$	$\rho = 7997.4\,\text{kg/m}^3$

and differ in the width of the flanges: the cantilevers in the first series exhibit $b = 203\,\text{mm}$ (narrow flanges), while those in the second series exhibit $b = 350\,\text{mm}$ (wide flanges). In both series, the web taper ratio α varies between 0.2 and 1.0. It is worth pointing out that the non-dimensional ratio

$$\kappa_{\omega 0} = \frac{\pi}{L}\sqrt{\frac{\tilde{E} I_\omega^*(0)}{GJ(0)}} \qquad (27)$$

takes on the approximate values 1.1 and 2.0 for the cantilevers in the first and second series, respectively.

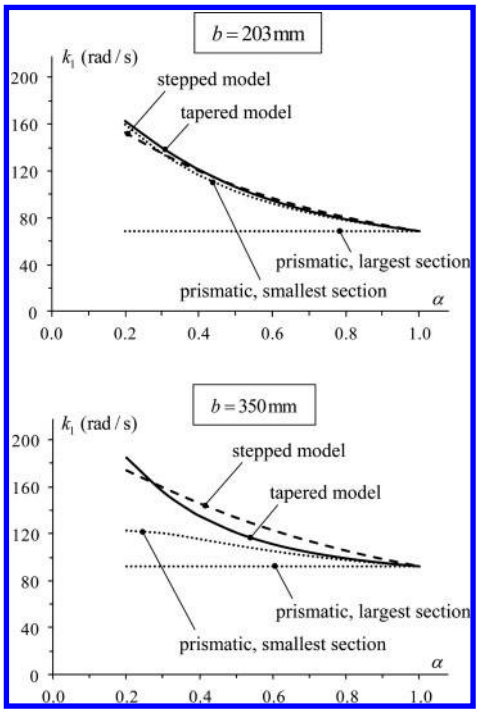

Figure 9. Illustrative example – Fundamental torsional frequency k_1 *versus* the taper ratio α.

The fundamental torsional frequency, denoted k_1, is shown in Figure 9 as a function of α (solid lines, labelled "tapered model"). The result for $b = 203$ mm and $\alpha = 0.378$, namely $k_1 = 125.1$ rad/s, is in perfect agreement with the one reported by Wekezer (1989) – Rajasekaran (1994) obtained the slightly lower value of 120.3 rad/s, which amounts to a -3.8% relative difference. If one represents the tapered cantilevers by an assembly of prismatic segments obeying Vlasov's theory and then makes the length of the segments tend to zero, one obtains the dashed lines shown in Figure 9 with the label "stepped model". For the first series ($b = 203$ mm), the solid and dashed lines are close to each other. In contrast, the two lines deviate considerably from each other in the second series ($b = 350$ mm), with the stepped model delivering higher frequencies for $0.3 < \alpha < 1.0$. Indeed, tapered and stepped models share the same inertial characteristics but exhibit different stiffnesses, as discussed in Section 4.2, and the differences in stiffness increase with $\kappa_{\omega 0}$ (*i.e.*, with the relevance of restrained warping – Andrade 2012). For reference purposes, Figure 9 also presents the fundamental torsional frequencies of prismatic cantilevers with the same length and material properties and with the largest or smallest cross-sectional dimensions, *i.e.*, with constant web depth $h_0 = 554.2$ mm or αh_0, respectively (dotted lines, labelled "prismatic, largest section" and "prismatic, smallest section"). It can be observed that the frequencies k_1 of tapered cantilevers fall outside the envelope defined by the dotted lines. According to Cywinski (2001), this fact "goes against the conventional engineering intuition, thus becoming a «paradox»". However, it must be observed that the frequencies yielded by the stepped model also fall outside that envelope (except for $\alpha < 0.3$ in the first series). In fact, since the natural frequencies depend on the relation between stiffness and inertia, it cannot be anticipated that the frequency k_1 of a tapered cantilever will always be in-between the values obtained for similar prismatic cantilevers with the largest and smallest cross-sectional dimensions. If sometimes it does not, there is nothing necessarily "paradoxical" about it.

6 CONCLUSIONS

This paper illustrated the application of the Vlasov-type 1D model developed by the authors for the linear dynamic analysis of tapered thin-walled bars with open cross-sections under monogenic loads. The selected illustrative example – (undamped) free torsional motion of a family of doubly symmetric and linearly web-tapered I-section cantilevers – allowed us (i) to offer physical explanations for the non-standard quantities appearing in the 1D model, (ii) to show that the approach to non-uniform torsion pioneered by Timoshenko (*i.e.*, regarding each plated component of the bar as an Euler-Bernoulli member undergoing stretching and bending) is entirely compatible with ours, and (iii) to point out the shortcomings of stepped (piecewise prismatic) models, which become particularly noticeable when restrained warping plays an important part in the torsional behaviour.

Romanian Academy, Timisoara, Branch, Romania

P. Perneş
Technical University of Cluj-Napoca, Romania

ABSTRACT: Pitched roof cold-formed steel portal frames of back-to-back built-up lipped channel sections and bolted joints are analysed in this paper. Usually, the beam-to-column and apex joints of such frames are made of gusset bracket bolted connections. Such joints, for which the bolts are installed into the webs of the C-sections trough the gusset, are partial-strength and semi-rigid. An advanced non-linear FE model has been calibrated based on relevant tests on such type of joints carried out at the CEMSIG Research Centre of the PU Timisoara. Numerical models were applied to undertake an extended parametrical study on such joints. Using these results and applying a genetic algorithm, some analytical formulas have been proposed to predict the capacity and rigidity of the joints. A portal frame was numerical tested and compared with the results obtained considering the capacity and rigidity of joints estimated with those formulas, in order to prove its effectiveness. Present paper summarizes the main phases of the study as well as the significant results.

1 INTRODUCTION

The global behaviour of cold-formed steel portal frames of bolted joints was studied experimentally by Lim (2001), Dundu & Kemp (2006), and Kwon et al. (2006). All these studies provided evidences of the crucial importance of joints performance on the global response of frames, which are semi-rigid and in almost all cases partial-strength (Lim, 2001).

An extensive experimental program on ridge (apex) and eaves knee joints of pitched roof cold-formed steel portal frames of back-to-back lipped channel sections and bolted joints was carried out at the "Politehnica" University of Timisoara. Three alternatives of joints configuration, using welded bracket elements and bolts, installed either on webs only or both on webs and flanges have been tested. Detailed results are reported by Dubina et al. (2004).

The behaviour and failure mechanisms of joints were recorded in order to evaluate their rigidity, strength and ductility. Based on experimental results, a calculation procedure, using the *component method* of EN1993-1-8:2005, was adapted to cold-formed steel joints with bolts installed both on webs and flanges (Nagy et al. 2006). Joint stiffness and moment capacity, obtained using the *component method*, were used to develop a joint model for global structural analysis.

In a second phase, two full-scale tests on cold-formed pitched-roof portal frames with bolted joints were performed (Dubina et al. 2007), with the primary objective to assess their performance under horizontal (seismic) loading, i.e. (1) horizontal load, and (2) horizontal and gravity loadings. The objective of the full-scale tests was to assess performance of pitched-roof cold-formed portal frames with moment-resisting joints under lateral loading, with particular emphasis on earthquake loading. A procedure to evaluate the ultimate design capacity of these frames, for joints with bolts both on the web and the flanges was proposed by Dubina et al. (2008).

Present paper, starting from the initial experimental results on joints with bolts on webs only, extend the investigation by numerical FEM simulations in order to calibrate analytical formulas to predict both moment capacity and stiffness of such a type of joints. At the end, *component method* design procedure is proposed and validated using the experimental results (Pernes 2012).

2 SUMMARY OF TESTING PROGRAM

In order to build realistic joint specimens, a simple pitched roof portal frame was previously designed having the following dimensions: span 12 m, bay 5 m, eaves height 4 m and roof angle 10°. The frame was subjected to loads common in Romanian, totalling approximately 10 kN/m uniformly distributed load on the rafter. The frame was analysed and designed according to EN1993-1-3:2006 provisions.

Detailed results on the behaviour of tested joints were reported by Dubina et al. (2004). The frame members are built-up sections, made of back-to-back C350/3.0 lipped-channel profiles, with the yield

	KIP-FB-C*	Cyclic: modified ECCS

* Specimens with supplementary bolts on the flanges (FB).

strength $f_y = 350\,\mathrm{N/mm^2}$. Three joint typologies were designed, using welded bracket elements (S235, $f_y = 235\,\mathrm{N/mm^2}$) and M20 class 6.6 bolts (see Fig. 1).

The joint specimens have been tested under monotonic and cyclic loading (see Table 1).

One group of specimens (RSG and KSG) used spaced built-up gussets. In this case, bolts were provided on the webs of the C350 profile only. In the other cases, where two different details were used for connecting brackets (i.e. welded I-sections for KIS and RIS, and welded I-section with plate bisector for KIP and RIP), bolts were provided on the web only, or both on the web and the flanges. Joints where bolts were provided both on the webs and flanges were denoted by FB, as shown in Table 1.

3 CALIBRATION OF NUMERICAL MODELS. PARAMETRIC STUDY

Numerical models applied to simulate the behaviour of members experimentally tested have been created using the commercial FE program ABAQUS/CAE v.6.7.1 (Pernes 2012).

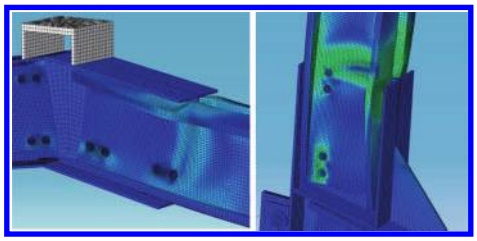

Figure 4. Failure modes obtained via numerical models: (a) RIS-M specimen; (b) KIS-M specimen.

Different element types and mesh sizes were tested in order to find the optimum number of elements from the point of view of ultimate force accuracy and, in the same time, to reduce the computational time. Rectangular 4-noded shell elements with reduced integration (S4R) were used to model the thin-walled components. For the welded brackets, bolts and nuts, 8-noded hexahedral elements with reduced integration (C3D8R) have been used. In order to create a reliable mesh, a mesh size of 8 × 8 mm for C-profiles and 12 × 12 mm for the bracket were considered to provide enough accuracy. The elements were constrained to a rectangular form using structured mesh, excepting the ones around holes for which were free mash was used. Pre-tensioning force to model the effect of bolt tightening has been introduced. A measured thickness minus zinc coating, of 2.90 mm, was considered for lipped channel profiles.

The material behaviour used for numerical modelling was in accordance with the recorded curves from tensile tests from coupons cut over the cross-section of C350/3 elements, with the following mean values for yield strength $f_y = 452.9$ N/mm^2 and $f_u = 518.16$ N/mm^2 for ultimate strength.

General contact with the following parameters have been used, i.e. (1) *normal direction* – Hard Contact; (2) *transversal direction* – a friction coefficient of $\mu = 0.3$. The load introduction and the supports were modelled to reproduce the real tests.

Some imperfections have been introduced in the models at the level of holes according to EN1090-2:2008. Nonlinear analyses were performed, using dynamic explicit steps as quasi-static, obtained by choosing time parameter so that the inertial effects on the system to be insignificant (takes into account stiffness loss due to local buckling).

The calibrated FE models reproduce the same failure mechanism in case of experimental tests, as shown in Figure 4.

Figure 5 presents the force-displacement and moment-rotation curves obtained both experimentally and numerically, for some of the joints. A good agreement can be observed between the experimental and numerical curves.

Table 2 presents the synthetically the experimental and numerical results obtained with ABAQUS computer code for three types of joints.

Based on the results obtained via numerical simulations, it can be noted that the behaviour and maximum

load accurately replicate the experimental tests. On the following, a parametric study has been conducted on RIS-M joints with bolts on webs only. A set of 35 numerical models have been created considering the following parameters: (1) three types of thicknesses, i.e. 2.9 mm, 2.4 mm and 1.91 mm; (2) the number and distribution of bolts (see Fig. 6).

The outputs of the parametric study are:

- long distances between the columns of bolts do not influence the maximum moment more than 2%, confirmed also by Dundu & Kemp (2006);
- if the distance between the external columns of bolts decreases, a sensitivity related to the number of bolts was recorded;
- compact columns of bolts lead to significant variation in terms of moment resistance if the number of bolts changes and, the failure is influenced by the components of the connection;
- similar conclusions can be drawn for the stiffness of joints too.

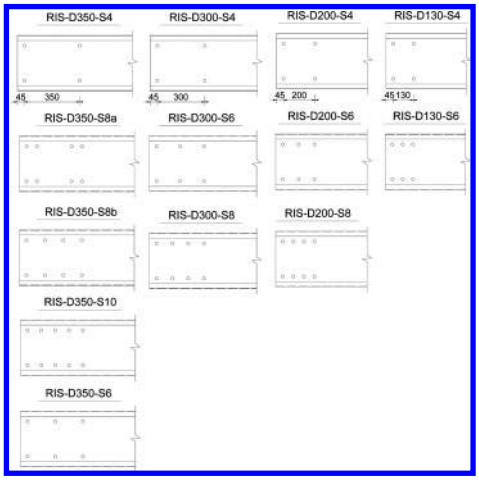

Figure 6. Number and distribution of bolts for the parametric study of RIS-M joints.

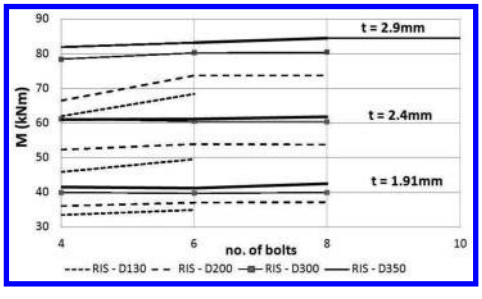

Figure 7. The influence of number of bolts on the moment resistance of joints.

Figure 7 presents the influence of number of bolts and the thicknesses of the profiles on the moment resistance of the joints, with the configurations presented in Figure 6.

According to the joints classification in terms of strength and stiffens (see EN1993-1.8:2005), the RIS joints, with bolts on webs only, are semi-rigid and partial-strength. Therefore design of light-gauge steel portal frames of the type analysed in the present paper need to account for connections flexibility.

4 THE COMPONENT METHOD

The *component method* is a general procedure for designing strength and stiffness of joints in building frames, and is implemented in EN1993-1-8:2005.

Application of the component method requires the following steps: (1) identification of the active components within the joint; (2) evaluation of the stiffness and strength of individual components; (3) = assembly of the components in order to evaluate stiffness and strength of the whole joint.

The present study investigates joints with bolts on webs (i.e. RIS-M) only, based on the conclusions of experimental and numerical program (Pernes 2012).

Figure 8. Parameters to characterise the $M^s_{j,Rd}$ component.

It was observed that bolts on the web only introduce stress concentration in the web, which causes premature local buckling failure. The following components were identified and used to model the connection strength and stiffness: (1) cold-formed steel member in bending; (2) bracket in bending; (2) local component of the beam due to stress concentration in the web around holes; (4) bolts in shear; (5) bolts in bearing with the cold-formed member; (6) bolts in bearing with the bracket.

The joint moment resistance was obtained as the minimum of moment resistance of the components:

$$M_{j,Rd} = \min\left(M^g_{j,Rd}, M^b_{j,Rd}, M^i_{j,Rd}, M^s_{j,Rd}\right) \qquad (1)$$

where: $M^g_{j,Rd}$ is the moment resistance of the bracket, $M^b_{j,Rd}$ is the moment resistance of the cold-formed steel member and was determined using measured geometrical, mechanical characteristics and effective cross-section modulus, $M^i_{j,Rd}$ is the moment resistance of the bolted connection and $M^s_{j,Rd}$ is the local component of the beam due to stress concentration in the web around holes.

It was observed that, due to the dimensions of the bracket and lipped channel profiles chosen for the experimental specimens, the moment resistance of the bracket, $M^g_{j,Rd}$, is higher than the moment resistance of the cold-formed steel member in bending, $M^b_{j,Rd}$, and both components are higher than the moment resistance of the joint obtained experimentally. Consequently, Eq. (1) becomes:

$$M_{j,Rd} = \min\left(M^i_{j,Rd}, M^s_{j,Rd}\right) \qquad (2)$$

The only major problem is to determine correctly the local component of the beam due to stress concentration in the web around holes, $M^s_{j,Rd}$.

425 numerical simulations have been done, in order to determine the influence of parameters which govern the behaviour of this component. Figure 8 presents the parameters considered in the analysis.

Based on genetic programming using Eureka Formulize software the following equation has been obtained for the component $M^s_{j,Rd}$, considering the parameters from above, i.e.:

$$M^s_{j,Rd} = \left(20t^2\left(b_c + h_c + \frac{l_c}{20}\right) + t\left(c^2 + \frac{4h^2}{125} + \frac{(h-h_c)^2}{7}\right)\right)\cdot c_n\sqrt{\frac{f_{ya}}{450}}450 \qquad (3)$$

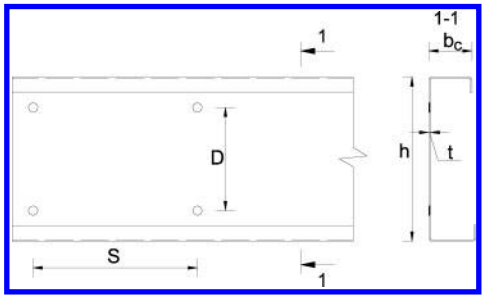

Figure 9. Details for $M^s_{j,Rd}$ component.

where
$c_n = 1 + \left(\frac{n_{b,r}}{0.17+n_{b,r}} - 0.925\right)\frac{D}{h}$ is correction coefficient
t is the thickness of the profile;
b_c is the width of the flange in compression;
h is the height of the profile;
c is the lip of the profile;
h_c is the horizontal distance between bolts, i.e. $h_c = S + 2d$ (see Fig. 9);
l_c is the vertical distance between bolts, i.e. $l_c = D + 2d$ (see Fig. 9);
d is the diameter of the of the bolt;
$n_{b,r}$ is the number of bolts on a row.

The limits of this calibrated formula are:

– cross-section (see Fig. 9):
  - $h = (250, 300, 350\,\text{mm})$
  - $0.22\,h < b < 0.35\,h$
  - $0.13\,b < c < 0.33\,b$
– connection (see Fig. 9):
  - $0.4\,h < D < h$
  - $0.4\,h < S < 0.7\,h$
– $f_y = 450\,\text{N/mm}^2$

In terms of stiffness, four components were considered to contribute to the stiffness of the connection: the bracket in bending, k_g, the cold-formed steel member in bending, k_b, the bolts on cold-formed member (shear or bearing denoted k_{br}), and bolts on the bracket (shear or bearing denoted k_{bg}), as shown in Figure 10.

Finally, the initial connection stiffness is determined as:

$$S_{j,ini} = \frac{1}{\frac{1}{k_g} + \frac{1}{k_b} + \frac{1}{k_{br}} + \frac{1}{k_{bg}}} \quad (4)$$

5 DESIGN OF PORTAL FRAMES WITH SEMI-RIGID AND PARTIAL-STRENGTH JOINTS

This chapter proposes to compare the results obtained for a full frame, using an advanced FEM model with ABAQUS and the limits obtained using beam elements

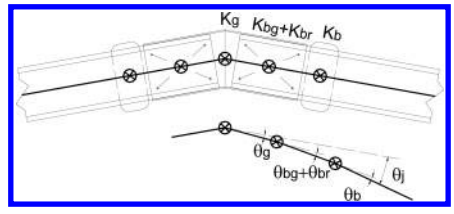

Figure 10. The components contributing to the joint stiffness.

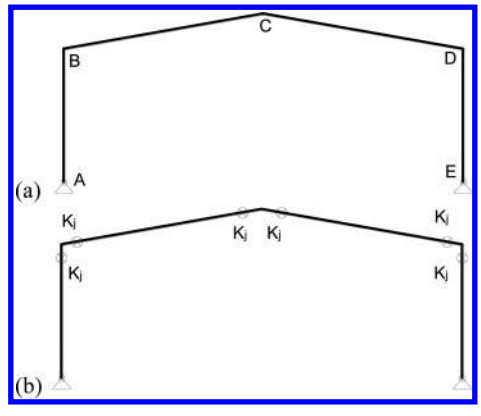

Figure 11. Beam model for (a) frame with rigid joints; (b) semi-rigid joints.

via SAP2000 computed code (elastic analyses), considering firstly the joints behaviour as rigid and full strength and secondly semi-rigid and partial-strength estimated with the formulas based on *component method* described previously (see Fig. 11). The frame was subjected to: (1) vertical loads only and (2) horizontal load only (Pernes 2012).

The stiffnesses of the joints presented in Figure 11(b) are calculated in Table 3, applying the formulas based on *component method* described above.

Figure 12 presents the failure mode of the frame obtained with ABAQUS software, while Figure 13 shows the force-displacement curve considering the vertical loads only.

Figure 13 presents comparatively the result obtained using ABAQUS and the ones using beam elements via SAP2000 computed code (elastic analyses), considering or not the semi-rigidity of joints. It is easy to observe that, in terms of vertical displacements the frame with continuous joints gives a vertical displacement of 66 mm, very low compared with 219 mm obtained via ABAQUS, while the frame

Figure 12. Failure mode obtained via an advanced FEM model.

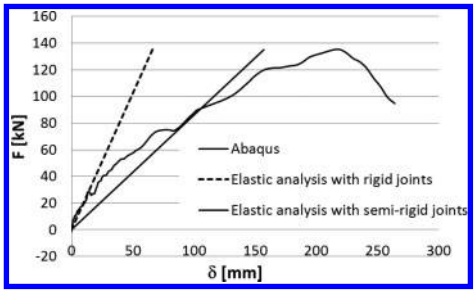

Figure 13. Force-displacement curve for vertical loads.

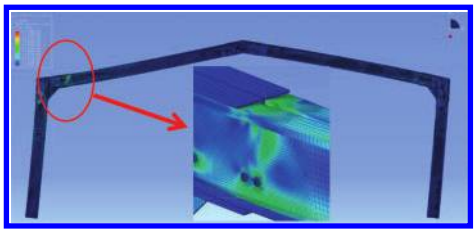

Figure 14. Failure mode obtained via an advanced FEM model.

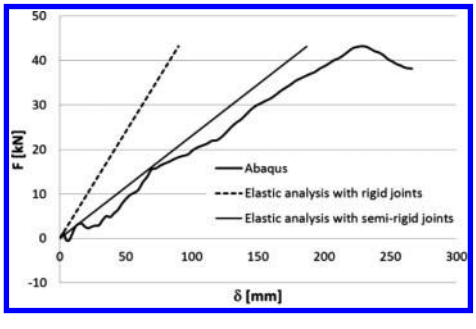

Figure 15. Force-displacement curve for horizontal loads.

with semi-rigid joints gives a vertical displacement of 157 mm.

In case of horizontal load, Figure 14 presents the failure mode for the frame obtained with ABAQUS software, while Figure 15 presents the force-displacement curve considering the horizontal load only. Figure 15 presents comparatively the result obtained using ABAQUS and the ones using beam elements via SAP2000 computed code (elastic analyses), considering or not the semi-rigidity of joints, under horizontal load only.

It is easy to observe that, in terms of horizontal displacements the frame with continuous joints gives a horizontal displacement of 90 mm, very low compared with 225 mm obtained via ABAQUS, while the frame with semi-rigid joints gives a horizontal displacement of 187 mm.

6 CONCLUSIONS

The influence of joints detailing, e.g. typology, position and number of bolts on the capacity and stiffness of cold-formed pitched roof portal frames was numerically investigated. On this purpose an advanced FEM model was experimentally calibrated and applied. Bolted joints, with bolts on web only, were parametrically studied in order to identify the active components for both moment capacity and stiffness. On this basis, *component method* design formulas have been proposed and validated.

It was confirm0ed that such type of joints are partial-strength and semi-rigid. In what concerns the influence of joints properties on the response of the frames, the semi-rigidity is more significant than partial-strength, making the frame sensitive to 2nd order effects.

Tests of cold-formed steel lipped channel columns undergoing local-distortional-global interaction

B. Young
Department of Civil Engineering, The University of Hong Kong, Hong Kong, China

D. Camotim & P.B. Dinis
Civil Engineering Department, ICIST, Instituto Superior Técnico, Technical University of Lisbon, Portugal

ABSTRACT: The paper presents a test program on cold-formed steel lipped channel columns with geometries (cross-section dimensions and lengths) selected to ensure that they undergo interaction between local, distortional and global (flexural-torsional) buckling modes. The columns were compressed between fixed-ended conditions. The column ultimate loads, failure modes and load-axial shortening equilibrium path are reported. The test results obtained from this study provide clear experimental evidence of column interactive failures involving local, distortional and flexural-torsional deformations. Moreover, these test results also provide useful information for development of design rules aimed at predicting the ultimate strength of columns experiencing the triple interaction under consideration.

1 INTRODUCTION

Thin-walled cold-formed steel lipped channel columns are well known to be highly susceptible to local (L), distortional (D) and global (G – flexural or flexural-torsional) buckling. Depending on the column geometry (cross-section dimensions and length) and end support conditions, its post-buckling behaviour and ultimate strength may be significantly affected (eroded) by interactions involving the above three buckling mode types. Therefore, design codes must include procedures to adequately take into account such interaction phenomena. Out of them, local-global (LG) interaction is now quite well understood, which explains why the current specifications are able to handle it, using either the traditional Effective Width Method or the more recent Direct Strength Method (DSM). In the last decade, considerable research work was devoted to local-distortional (LD) interaction, including experimental investigations, numerical simulations and the proposal of DSM-based design approaches (Yang and Hancock 2004, Dinis et al. 2007, Silvestre et al. 2009, 2012, Kwon et al. 2009 and Young et al. 2013).

Concerning the mode interaction involving distortional and global buckling modes, namely distortional-global (DG) and local-distortional-global (LDG) interaction, the available literature is much scarcer. In the first case, there exist only a few recent numerical and experimental studies (e.g., Dinis and Camotim 2011a) and a suitable design approach is still lacking. In the case of LDG coupling, the existing research work is similarly scarce and (experimental and numerical) research work on this triple interaction was only reported in the last year (Dinis and Camotim 2011b, Dinis et al. 2011, 2012, Santos et al. 2012) and only incipient design considerations are available. One interesting preliminary conclusion from this research work was the very minor (almost inexistent) role played by the local deformations, which amounts to arguing that the DG and LDG interaction effects are qualitatively and quantitatively similar.

The objective of this work is to report the results of a well-planned experimental investigation carried out at The University of Hong Kong, aimed at assessing the non-linear (post-buckling) behaviour and ultimate strength of fixed-ended cold-formed steel lipped channel columns, affected by LDG interaction. The specimens with selected lipped channel geometries were carefully fabricated and measured (in order to acquire information on the real dimensions and initial imperfections) and then tested under uniform compression. The experimental results presented consist of initial imperfection measurements, non-linear equilibrium path (applied load vs. relevant displacements) and ultimate strengths – particular attention is paid to the characterisation of the column collapse modes, namely in order to detect the presence of local deformations. The experimental results reported are ideally suited (i) to provide evidence of the interaction effects under consideration and (ii) to provide ultimate strength data to develop and calibrate a DSM design approach for lipped channel columns experiencing LDG interaction. The future performance of a similar study involving columns displaying only DG interaction will make it possible to assess the ultimate

strength differences between the two column sets and, therefore, confirm or refute the above preliminary conclusion on the minor role played by the local deformations, an important issue for the development of rational design models.

2 TEST SPECIMENS

A series of cold-formed steel lipped channel columns was conducted. A total of seventeen specimens with two of the repeated specimens was tested. The column specimens were compressed between fixed ends condition. The column test specimens were brake-pressed from high strength zinc-coated grades G500 and G550 structural steel sheets having nominal 0.2% proof stresses (yield stresses) of 500 and 550 MPa, respectively. These structural steel sheets conformed to the Australian Standard AS 1397 (1993). The nominal column length ranged from 1400 to 2750 mm. The ends of the column specimens were welded to 25 mm thick steel end plates to ensure full contact between the specimen and end bearings. The test specimens had the nominal web width (b_w) ranged from 53 to 88 mm, flange width (b_f) ranged from 48 to 88 mm and a constant lip width (b_l) of 12 mm. The nominal plate thicknesses of the specimens were 1.0 and 1.2 mm. The base metal thickness (t^*) was measured by removing the zinc coating by acid-etching. The thickness of the zinc coating on one side of the section was measured as 32 μm for 1.0 mm plate thickness and 29.5 μm for 1.2 mm plate thickness. The measured inside corner radius (r_i) was 2.0 mm for all specimens. The measured cross-section dimensions and column length for each test specimen are shown in Table 1 using the nomenclature defined in Fig. 1. Furthermore, the critical local ($\sigma_{cr.L}$), distortional ($\sigma_{cr.D}$) and global ($\sigma_{cr.G}$) buckling

stresses are also shown in Table 2. There are nine specimens having a nominal plate thickness of 1.0 mm and labelled as LC-1, LC-2-1, LC-2-2, LC-3, LC-4, LC-9, LC-10, LC-11 and LC-12. There are eight specimens having a nominal plate thickness of 1.2 mm and labelled as LC-5, LC-6, LC-7, LC-8, LC-13, LC-14, LC-15 and LC-16.

3 MATERIAL PROPERTIES

The material properties of the column test specimens were determined by tensile coupon tests. The coupons were extracted from the centre of the flange and web in the longitudinal direction of specimens LC-1 and LC-5. The cold-formed lipped channel column specimens were fabricated from the same batch of steel for each plate thickness. Therefore, the material properties obtained from specimens LC-1 and LC-5 are expected having the same material properties for those specimens having the same nominal plate thickness.

The coupon dimensions conformed to the Australian Standard AS 1391 (2007) for the tensile testing of metals using 12.5 mm wide coupons of gauge length 50 mm. An MTS displacement controlled testing machine using friction grips was used to conduct

Table 3. Nominal and measured material properties of cold-formed steel lipped channels

Test Series	Nominal		Measured			
	t (mm)	$\sigma_{0.2}$ (MPa)	E (GPa)	$\sigma_{0.2}$ (MPa)	σ_u (MPa)	ε_f (%)
LC-1 (Flange)	1.0	550	211	597	598	10.2
LC-1 (Web)	1.0	550	216	612	619	8.7
LC-5 (Flange)	1.2	500	213	594	610	8.9
LC-5 (Web)	1.2	500	215	598	611	8.5

Note: 1 in. = 25.4 mm; 1 ksi = 6.89 MPa.

Figure 3. Column test set-up.

the coupon tests. The coupons were also tested according to the Australian Standard AS 1391 (2007). A calibrated extensometer of 50 mm gauge length was used to measure the longitudinal strain of the coupon specimens. A data acquisition system was used to record the load and the strain readings at regular intervals during the tests. The static load was obtained by pausing the applied straining for 1.5 minutes near the 0.2% proof stress and the ultimate tensile strength. This allowed the stress relaxation associated with plastic straining to take place. The nominal and measured material properties obtained from the coupon tests are summarized in Table 3. The measured values of Young's modulus (E), static 0.2% proof stress ($\sigma_{0.2}$), static tensile strength (σ_u) and elongation after fracture (ε_f) based on a gauge length of 50 mm are shown in Table 3. A stress-strain curve obtained from the coupon test for specimen LC-5 in the web is shown in Fig. 2. Both test curve and static curve are shown in the figure.

4 TEST RIG AND TEST PROCEDURE

Figure 3 shows a typical column test as well as the test rig and test set-up. A servo-controlled hydraulic testing machine was used to apply compressive axial force to the column specimens. Two steel end plates were welded to the ends of the specimen. The top end plate of the specimen was bolted to the rigid flat bearing plate, which was restrained against the minor and major axis rotations as well as twist rotations and warping. Hence, the top end of the column was fixed in position. A special bearing was used at the lower end support. Initially, the special bearing was free to rotate in any direction. The ram of the actuator was moved slowly until the bottom end plate of the specimen in full contact with the special bearing having a small initial load of approximately 1 kN. This procedure eliminated any possible gaps between the special bearing and the bottom end plate of the specimen. The bottom end plate of the specimen was bolted to the special bearing, and the bearing was then restrained from rotations and twisting by using vertical and horizontal bolts, respectively. The vertical and horizontal bolts of the special bearing were used to lock the bearing in position after full contact was achieved. Hence, the special bearing became a fixed-ended bearing. The fixed-ended bearing was considered to restrain both minor and major axis rotations as well as twist rotations and warping.

Three displacement transducers were used to measure the axial shortening of the column. Displacement control was used to drive the hydraulic actuator at a constant speed of 0.2 mm/min for all column specimens. The use of displacement control allowed the tests to be continued into the post-ultimate range. In addition, seven transducers were used to measure the deformation of the cross-section at mid-length of the column. Figure 4(a) shows the arrangement of the seven transducers. Three transducers were located in the web, where two of them located 10 mm away from the web-flange junctions and one of them located in the middle of the web. The transducer located in the middle of the web was shifted 60 mm from the mid-length of the column, as shown in Fig. 4(b). This is due to the

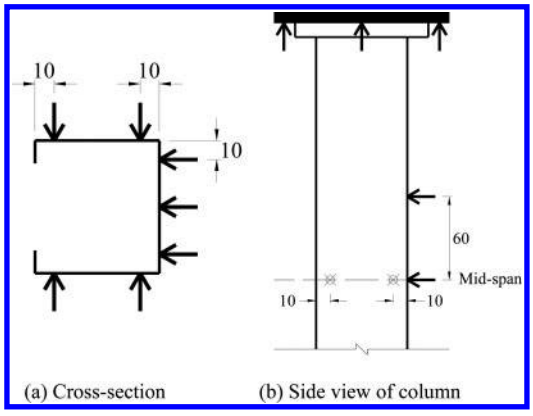

Figure 4. Location of transducers.

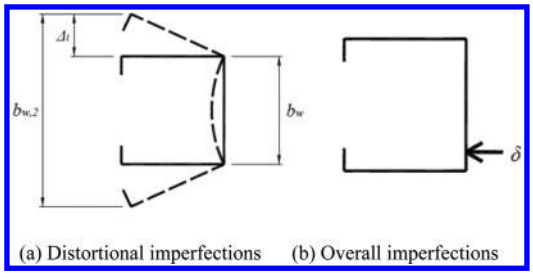

Figure 5. Initial geometric imperfection measurements.

limitation of space in the web. Local and overall buckling can be determined from these three transducers in the web. Two transducers were located 10 mm away from the web-flange junctions in the flanges. Major axis bending of the column can be determined from these two transducers. Furthermore, two transducers were located 10 mm away from the lip-flange junctions in the flanges, where distortional buckling can be identify from these two transducers. A data acquisition system was used to record the applied load and the readings of the displacement transducers at regular intervals during the tests.

5 INITIAL GEOMETRIC IMPERFECTIONS

The initial distortional and overall geometric imperfections of the column specimens were measured prior to testing. The distortional imperfections (Δ_l) were obtained by measuring the cross-section in the web width (b_w) between the web-flange junctions and also the web width ($b_{w,2}$) between the lip-flange junctions, as shown in Fig. 5(a). The measured values (Δ_l) on one side of the flange at mid-length of the columns are shown in Table 4, where positive value of Δ_l indicates outward deformations. The maximum distortional geometric imperfection was 1.78 mm inward deformation for specimen LC-8. In addition, the minor axis flexural initial overall geometric imperfections were also measured in all specimens along the web-flange longitudinal edges, as shown in Fig. 5(b).

Table 4. Measured initial distortional and overall geometric imperfections at mid-length

Specimen	Distortional imperfection $\Delta_l = (b_{w,2} - b_w)/2$ (mm)	Overall imperfection δ/L
LC-1	0.95	1/4394
LC-2-1	0.58	−1/32503
LC-2-2	0.57	−1/66891
LC-3	0.38	−1/4043
LC-4	0.81	−1/12075
LC-5	−0.17	1/29860
LC-6	0.11	−1/3586
LC-7	−0.87	−1/1888
LC-8	−1.78	−1/2927
LC-9	0.26	−1/4596
LC-10	0.10	1/15769
LC-11	0.47	−1/66891
LC-12	−0.05	−1/6501
LC-13	−0.21	−1/2974
LC-14	−1.24	−1/2756
LC-15	0.73	−1/4202
LC-16	−0.73	−1/10826

A theodolite was used to obtain readings at mid-height and near both ends of each column. The measured values at mid-height (δ), normalised with respect to the column length L, are also given in Table 4, where positive value of δ/L indicates a column curved towards the lips. The maximum overall geometric imperfection at mid-height was 1/1888 of the column length for specimen LC-7.

6 COLUMN TEST RESULTS

The experimental ultimate loads (P_{Exp}) are given in Table 5, which also provides the nature of the column failure modes – note that one test was repeated (specimen LC-2-2 is identical to the LC-2-1 one). The analysis of the experimental results presented prompts the following remarks:

(i) All specimens were found to fail in local-distortional-global interactive modes ("L + D + FT") – Figures 6 and 7 show the deformed configurations near collapse of specimens LC-4 and LC-8, respectively, providing very clear evidence of the simultaneous occurrence of local, distortional and flexural-torsion deformations.

(ii) The LDG interaction observed does not stem from the near coincidence of the local, distortional and global column critical buckling loads – Table 2 shows that the ratio between the higher and lower of the three column buckling stresses varies between 1.16 and 1.39. Instead, the interaction occurs because (ii_1) the yield stress $\sigma_{0.2}$ is "sufficiently larger" than the higher column buckling stress (it varies between 1.61 and 3.37) and (ii_2) the global buckling is never critical –

Figure 6. Interaction of local, distortional and flexural-torsional buckling for column specimen LC-4.

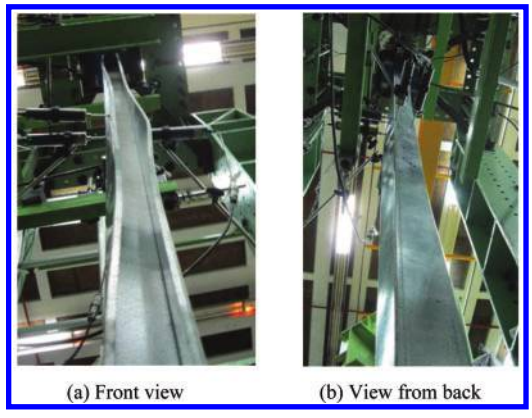

Figure 7. Interaction of local, distortional and flexural-torsional buckling for column specimen LD-8.

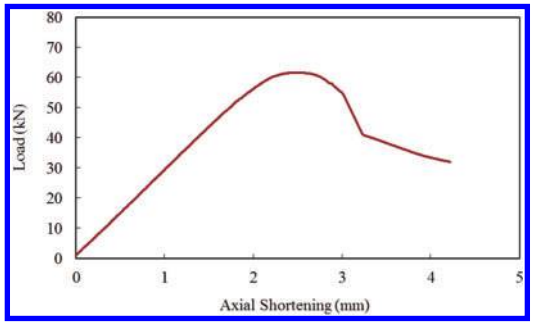

Figure 8. Load versus axial shortening curve for column specimen LC-5.

numerical studies showed that a significant ultimate strength erosion takes place when global buckling is critical (Dinis et al. 2012).

(iii) The ultimate strengths corresponding to the repeated tests with LDG interaction (specimens LC-2-1 and LC-2-2) differed by 1.3%, thus evidencing the test repeatability.

(iv) Regardless of the half-wave number exhibited by the critical distortional buckling mode, the LDG interaction involves always distortional deformation with odd-numbered half-waves – they are brought about "attracted" by the global deformations, as was already observed by Dinis et al. (2012).

Figure 8 depicts the applied load vs. axial shortening equilibrium path of specimen LC-5 – many other equilibrium paths, corresponding to various specimens and transducer measurements, were recorded and will be reported elsewhere in the near future.

7 CONCLUSIONS

An experimental investigation of cold-formed steel lipped channel columns has been presented. The columns were clearly failed by interaction of local, distortional and global buckling. Material properties of the column specimens were determined by coupon tests. The measured 0.2% proof stress of the material ranged from 594 to 612 MPa, which is considered to be high strength steel material. Initial geometric imperfections of the columns were also reported. The ultimate loads, failure modes and load-axial shortening equilibrium path of the columns provide useful

Table 5. Experimental ultimate loads and failure modes

Specimen	Experimental ultimate load P_{Exp} (kN)	Failure mode
LC-1	46.15	L + D + FT
LC-2-1	44.78	L + D + FT
LC-2-2	44.20	L + D + FT
LC-3	39.83	L + D + FT
LC-4	39.68	L + D + FT

Shear design of cold-formed steel beams using direct strength method

P. Keerthan & M. Mahendran
Queensland University of Technology, Brisbane, Queensland, Australia

ABSTRACT: This paper presents the Direct Strength Method (DSM) equations for cold-formed steel beams subject to shear. Light gauge cold-formed steel sections have been developed as more economical building solutions to the alternative heavier hot-rolled sections in the commercial and residential markets. Cold-formed Lipped Channel Beams (LCB), LiteSteel Beams (LSB) and Hollow Flange Beams (HFB) are commonly used as flexural members such as floor joists and bearers. However, their shear capacities are determined based on conservative design rules. For the shear design of cold-formed web panels, their elastic shear buckling strength must be determined accurately including the potential post-buckling strength. Currently the elastic shear buckling coefficients of web panels are determined by assuming conservatively that the web panels are simply supported at the junction between the flange and web elements and ignore the post-buckling strength. Hence experimental and numerical studies were conducted to investigate the shear behaviour and strength of LSBs, LCBs and HFBs. New Direct Strength Method (DSM) based design equations were proposed to determine the ultimate shear capacities of cold-formed steel beams. An improved equation for the higher elastic shear buckling coefficient of cold-formed steel beams was proposed based on finite element analysis results and included in the DSM design equations. A new post-buckling coefficient was also introduced in the DSM equation to include the available post-buckling strength of cold-formed steel beams.

1 INTRODUCTION

In recent times cold-formed steel members have become an increasingly integral part of the construction and building industries (see Figure 1). They have many advantages over other materials including their light weight, high strength, high quality, protection, cost-effective fabrication, accurate detailing, resistance, and non-combustibility. They are used in applications such as building frames, roof trusses, purlins and girts, floor framing and many other load bearing components.

In steel building systems, lipped channel beam (LCB), LiteSteel beam (LSB) (OATM, 2008), dogbone hollow flange beams (DHFB) and rectangular hollow flange beams (RHFB) are commonly used as flexural members, for example, floor joists, bearer and purlins. For these cold-formed steel beams to be used as flexural members, their flexural and shear capacities must be known. In this research the elastic shear buckling behaviour of such LCBs, LSBs, DHFBs and RHFBs was investigated using finite element analyses (FEA) including the effect of true support conditions at the junction between their flange and web elements. For comparison purposes, a plate girder (PG) was also considered in FEA. The results were then used to develop an equation for the elastic shear buckling coefficient of these beams and determine the corresponding ultimate shear capacity improvement based on the proposed shear capacity equations (Keerthan and Mahendran, 2010).

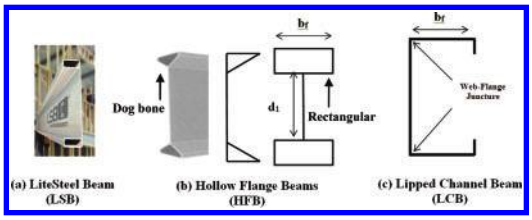

Figure 1. Hollow flange and open cold-formed steel members.

In the traditional shear design method of cold-formed steel beams, the web shear buckling performance is considered without the effect of flange rigidity. The shear strength of cold-formed steel lipped channel beams was studied by LaBoube and Yu (1978). They determined the ultimate strengths of LCBs by assuming that the web-flange juncture of LCBs was simply supported. Pham and Hancock (2009) investigated the elastic buckling behavior of unlipped and lipped channel section members subject to shear using an isoparametric spline finite strip method. They found that the flanges can have a significant influence on the shear buckling capacity of thin-walled channel sections and that lack of lateral restraint for sections with narrow flanges can lead to premature buckling of the section in a twisting and lateral buckling mode. However, they did not propose a simple equation to determine the shear buckling coefficients of lipped channel beams.

In this research, elastic buckling analyses were undertaken using suitable finite element models of LCBs, LSBs, DHFBs, RHFBs and plate girders (PG) developed based on ABAQUS. These finite element models included idealized simply supported boundary conditions and a shear flow based loading to prevent any torsional effect. Their shear buckling modes and shear buckling coefficients are presented in this paper. An improved equation for the higher elastic shear buckling coefficients of cold-formed steel beams was determined and included in the direct strength method (DSM) based design equations (Keerthan and Mahendran, 2010).

2 ELASTIC SHEAR BUCKLING ANALYSES OF HOLLOW FLANGE AND OPEN STEEL BEAMS

2.1 *Model Description*

This section presents the development of finite element models to investigate the shear behaviour of hollow flange (LSBs, DHFBs and RHFBs) and open (LCBs and PG) steel beams including their elastic shear buckling characteristics. For this purpose, a general purpose finite element program ABAQUS (HKS, 2007), which has the capability of undertaking geometric and material non-linear analyses of three dimensional structures, was used. Idealized simply supported boundary conditions were implemented in cold-formed steel beams under a three–point loading arrangement. Figure 2 shows the schematic diagram of the loading set-up used in this research. ABAQUS has several element types to simulate the shear behaviour of beams. But among those, shell element was selected for the ideal model as it has the capability to simulate the shear buckling behaviour of LiteSteel beams (LSB), lipped channel beams (LCB), dog bone hollow flange beams (DHFB), rectangular hollow flange beams (RHFB) and plate girders (PG). The shell element available in ABAQUS called S4R5 was used to model the shear behaviour of the chosen beams. This element is thin, shear flexible, isometric quadrilateral shell with four nodes and five degree of freedom per node, utilizing reduced integration and bilinear interpolation scheme. The finite element models were developed using their centreline dimensions based on the nominal external dimensions. Keerthan and Mahendran (2010) found that the effect of corners on the shear buckling behaviour of LiteSteel beam is negligible (less than 1%). Therefore in the finite element models used here, the corner radius was not included. Finite element models were created using MD PATRAN R 2.1 preprocessing facilities and then submitted to ABAQUS for the analysis. The results were also viewed using MD PATRAN R 2.1 post-processing facilities.

In the elastic buckling analyses undertaken in this study the elastic modulus (E) and Poisson's ratio (ν) were taken as 200,000 MPa and 0.3, respectively. To provide simply supported conditions for the shear

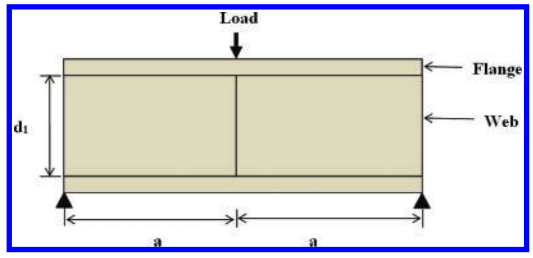

Figure 2. Schematic diagram of shear loading set-up (RHFB).

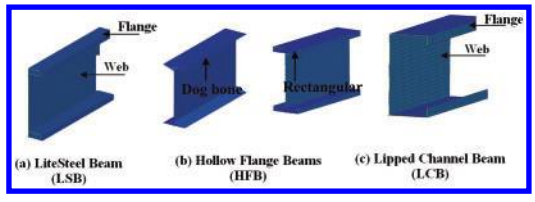

Figure 3. Geometry and finite element mesh of cold-formed steel beams.

panels of LSB, LCB, DHFB, RHFB and PG, simply supported boundary conditions were applied at the supports and the loading point (middle point).

Applied loading was based on the shear flows and forces in LCBs and LSBs to eliminate any torsional loading effects. The loading and boundary conditions used in the finite element model used in this research are similar to those used by Keerthan and Mahendran (2010, 2012) in their research on the shear buckling behaviour of LSBs and LCBs.

Figure 3 shows the geometry and finite element mesh of a cold-formed steel beam while Figure 4 shows the finite element models of LSB and plate girder (PG).

2.2 *Elastic Shear Buckling*

2.2.1 *General*

Timoshenko and Gere (1961) and Stein (1985) investigated the shear buckling stress of flat rectangular plates. Elastic shear buckling stress of a rectangular plate is given by Timoshenko and Gere (1961) as follows.

$$\tau_{cr} = \frac{k_v \pi^2 E}{12(1-\nu^2)}\left(\frac{t_w}{d_1}\right)^2 \quad (1)$$

where

d_1, t_w = Clear height and thickness of web

k_v = Shear buckling coefficient (5.34)

The shear buckling coefficient (k_v) of a plate simply supported on all four edges varies from 5.34 for a very long plate to 9.34 for a square plate. For a web element with a large depth to thickness ratio, its shear capacity is governed by its elastic shear buckling stress. The elastic critical shear buckling stress can be computed

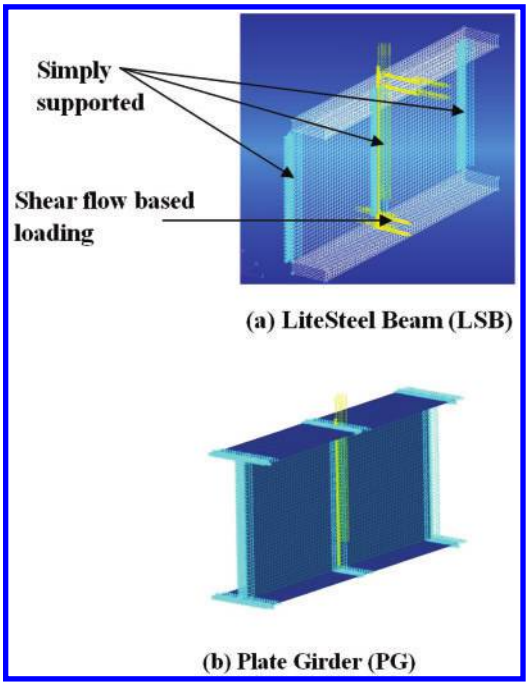

Figure 4. Ideal finite element models of steel beams.

using Equation 1 if the relevant elastic shear buckling coefficient (k_v) is known.

In the early days the web-flange juncture of cold-formed steel beams was assumed as simply supported due to lack of means to evaluate it in a rational manner. Basler (1961) assumed that the web panel of plate girders was simply supported at the web-flange juncture while LaBoube and Yu (1978) also assumed that the web panel of lipped channel beam was simply supported at the web-flange juncture. Recent research by Lee et al. (1996) has shown that the boundary condition at the flange-web juncture in practical designs is much closer to fixity for plate girders. They showed that the assumption that the web panel is simply supported at the web-flange juncture leads to a significant underestimation of the ultimate shear strength because of the underestimation of the elastic shear buckling strength of plate girders. Keerthan and Mahendran (2010) have also shown that the boundary condition at the flange-web juncture of LiteSteel beams is much closer to a fixed condition.

Keerthan and Mahendran (2010 and 2012) proposed the following simple equations based on FEA results for the determination of shear buckling coefficients of LiteSteel beams (k_{LSB}) and lipped channel beam (k_{LCB}) in terms of the shear buckling coefficients of web plates with simple-simple (k_{ss}) and simple-fixed (k_{sf}) boundary conditions. The latter case refers to web panels that have fixed conditions at the web-flange juncture and simply supported along the other two edges.

$$k_{LCB} = k_{ss} + 0.23(k_{sf} - k_{ss}) \quad (2)$$

Table 1. Comparison of shear buckling coefficients of dogbone hollow flange beams (DHFB) (Aspect ratio = 1.0 & $t_f/t_w = 1$).

No.	Section	Type	t_w	k_v
1	150 × 90 × 15 × 1.6 × 1.6	Symmetric	1.6	12.58
2	150 × 90 × 15 × 2.0 × 2.0	Symmetric	2.0	12.58
3	200 × 90 × 15 × 1.6 × 1.6	Symmetric	1.6	12.30
4	300 × 120 × 20 × 2.0 × 2.0	Symmetric	2.0	12.53
5	300 × 120 × 20 × 2.5 × 2.5	Symmetric	2.5	12.49
6	300 × 120 × 20 × 3.0 × 3.0	Symmetric	3.0	12.45
7	150 × 45 × 15 × 1.6 × 1.6	Mono Symmetric	1.6	12.57
8	150 × 45 × 15 × 2.0 × 2.0	Mono Symmetric	2.0	12.58
9	200 × 45 × 15 × 1.6 × 1.6	Mono Symmetric	1.6	12.22
10	200 × 45 × 15 × 2.0 × 2.0	Mono Symmetric	2.0	12.23

Note: $k_{ss} = 9.34$ and $k_{sf} = 12.60$ for aspect ratio of 1.0.

$$k_{LSB} = k_{ss} + 0.87(k_{sf} - k_{ss}) \quad (3)$$

$$k_{ss} = 4 + \frac{5.34}{(a/d_1)^2} \qquad \frac{a}{d_1} < 1 \quad (4a)$$

$$k_{ss} = 5.34 + \frac{4}{(a/d_1)^2} \qquad \frac{a}{d_1} \geq 1 \quad (4b)$$

$$k_{sf} = \frac{5.34}{(a/d_1)^2} + \frac{2.31}{(a/d_1)} - 3.44 + 8.39(a/d_1) \qquad \frac{a}{d_1} < 1 \quad (5a)$$

$$k_{sf} = 8.98 + \frac{5.61}{(a/d^1)^2} - \frac{1.99}{(a/d_1)^3} \qquad \frac{a}{d_1} \geq 1 \quad (5b)$$

where a = Shear span of web panel, d_1 = Clear web height and a/d_1 = Aspect ratio.

Equation 2 shows that the shear buckling coefficient of Lipped Channel beams (k_{LCB}) is closer to k_{ss} while Equation 3 shows that the shear buckling coefficient of LiteSteel beams (k_{LSB}) is closer to k_{sf}. Hence the realistic support condition of LCB at the web-flange juncture is considered to be closer to a simply supported condition while realistic support condition of LSB at the web-flange juncture is considered to be closer to a fixed supported condition.

2.2.2 *Elastic Buckling Analyses*

In order to obtain the shear buckling coefficients of both hollow flange and open steel beams, elastic buckling analyses were conducted based on the developed finite element models of DHFB, RHFB and PG with an aspect ratio (a/d_1) of 1.0 (see Figure 4). S4R5 shell elements were used with a suitable mesh size of 5 mm × 5 mm for the entire cross-section and length of steel beam sections. ABAQUS uses the subspace iteration Eigenslover in its buckling analyses. In the buckling analysis, four buckling mode shapes were considered.

Figures 5 (a) to (d) show the typical shear buckling modes of LSB, LCB, DHFB, RHFB and PG. In all the analyses here, a flange width (b_f) to clear web height (d_1) ratio more than 0.4 was used. This is because most

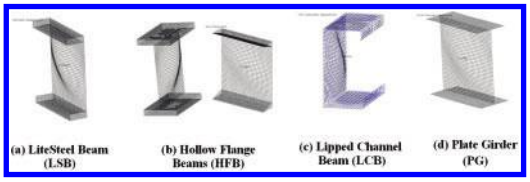

Figure 5. Shear buckling modes of steel beams (Aspect Ratio = 1.0).

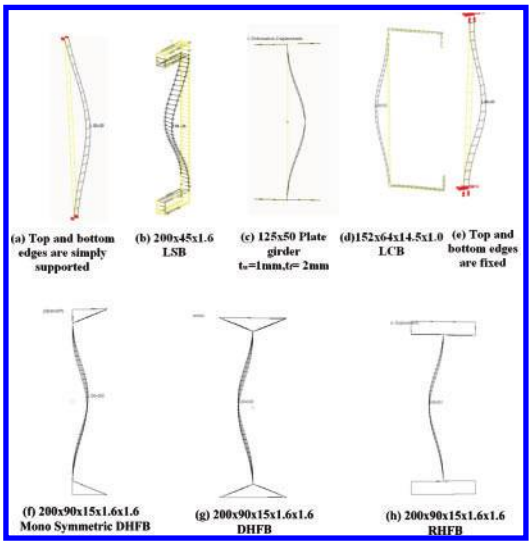

Figure 6. Shear buckling shapes (Aspect ratio = 1.0).

of the available steel sections have a b_f/d_1 ratio greater than about 0.4. Table 1 compares the shear buckling coefficients (k_v) determined from the elastic buckling analyses of dogbone hollow flange beam (DHFB) for an aspect ratio of 1.0. The web and flange thicknesses were assumed to be the same for DHFBs. The reference buckling coefficients, k_{ss} and k_{sf}, were determined by using Equations 4 and 5, respectively. Table 1 indicates that k_{DHFB} is close to k_{sf} (12.60). Hence the realistic support condition of DHFB at the web-flange juncture is considered to be closer to a fixed supported condition. Since k_{DHFB} is close to k_{sf} (12.60) with even a t_f/t_w ratio (ratio of flange to web thickness) of 1, higher t_f/t_w ratios were not considered in the analyses of DHFBs. Similar observation was also made for LSBs for which also a t_f/t_w ratio of 1 was used.

Keerthan and Mahendran (2010 and 2012) investigated the shear buckling behaviour of LSBs and LCBs using numerical studies. Shear buckling coefficient of LSBs and LCBs are given in Keerthan and Mahendran (2010 and 2012).

Figures 6 (a) to (h) show typical deformed cross-sections of buckled LSB, DHFB, RHFB, PG and LCB. This can be compared with the deformation shapes of plates with simply supported and fixed edges as shown in Figures 6 (a) and (e), respectively. This observation shows that the boundary condition at the web-flange juncture of LCBs is close to a simply supported condition while that of LSB, DHFB, RHFB and plate girder ($t_f/t_w > 2$) at the web-flange juncture is considered to be closer to a fixed supported condition.

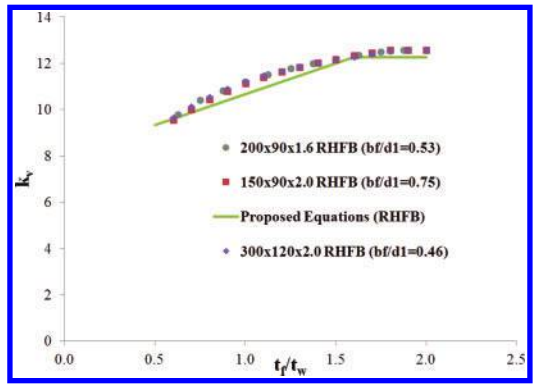

Figure 7. Shear buckling coefficients of rectangular hollow flange beams (RHFB) (Aspect ratio = 1.0).

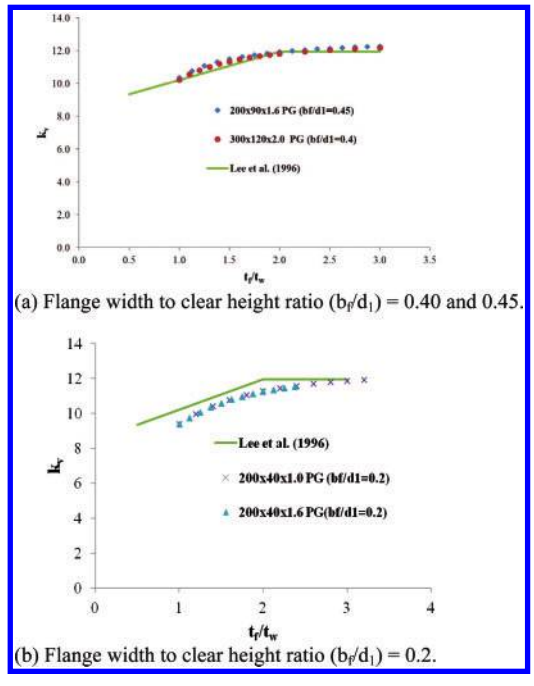

Figure 8. Shear buckling coefficients of plate girders (Aspect ratio = 1.0, Flange width to clear height ratio (b_f/d_1) = 0.20, 0.40 and 0.45.

Unlike for LCBs, LSBs and DHFBs, the effect of t_f/t_w ratio was investigated. Figure 7 shows that the elastic shear buckling coefficient of RHFB rapidly increases when this ratio increases up to 1.6. However, it did not increase much after it has exceeded 1.6. Hence it can be concluded that t_f/t_w ratio should be increased to 1.6 in order to gain about 90% fixity level for RHFBs.

Figure 8 shows that the elastic shear buckling coefficient of plate girders rapidly increases when the t_f/t_w

Table 2. Coefficient of k_n for hollow flange and open steel beams.

Section	k_n
Plate Girder (PG)	$0.8\left(1-\frac{2}{3}(2-\frac{t_f}{t_w})\right)$ $0.5<\frac{t_f}{t_w}<2.0$ $\frac{b_f}{d_1}>0.4$
Plate Girder (PG)	0.8 $\frac{t_f}{t_w}\geq 2.0$ $\frac{b_f}{d_1}>0.4$
Rectangular Hollow Flange Beam (RHFB)	$\left(0.82\frac{t_f}{t_w}-0.41\right)$ $0.5<\frac{t_f}{t_w}<1.6$ $\frac{b_f}{d_1}>0.4$
Rectangular Hollow Flange Beam (RHFB)	0.90 $\frac{t_f}{t_w}\geq 1.6$ $\frac{b_f}{d_1}>0.4$
Lipped Channel Beam (LCB)	0.23
LiteSteel Beam (LSB)	0.87
Dog Bone Hollow Flange Beam DHFB (Symmetric and Mono Symmetric)	0.90

ratio increases up to 2.0. However, it did not increase much after it has exceeded 2.0. Hence it can be concluded that the t_f/t_w ratio should be increased to 2.0 in order to gain about 80% fixity level for plate girders. Figure 8 (a) shows that the shear buckling coefficients of plate girders were similar to Lee et al.'s (1996) findings when the flange width to clear height ratio (b_f/d_1) exceeded 0.4. However, the shear buckling coefficients of plate girders were slightly different to Lee et al.'s (1996) values when the flange width to clear height ratio (b_f/d_1) was less than 0.4 (see Figure 8 (b)).

2.2.3 *Shear Buckling Coefficients*

Based on the elastic buckling analysis results, the following simple equation (Equation 6) was developed for the determination of the elastic shear buckling coefficients of both hollow flange and open steel beams. For this purpose the minimum shear buckling coefficient of LCB, LSB, DHFB, RHFB and PG from finite element analyses were used. Shear buckling coefficient equations included the effect of flange thickness to web thickness ratio (t_f/t_w) for rectangular hollow flange beams (RHFB) and plate girders (PG). The values of k_{ss} and k_{sf} for a given aspect ratio were determined from Equations 4 and 5, respectively.

$$k_v = k_{ss} + k_n(k_{sf} - k_{ss}) \tag{6}$$

where

k_v = Shear buckling coefficient of cold-formed steel beam and k_{ss}, k_{sf} = Shear buckling coefficients of plates with simple-simple and simple-fixed boundary conditions.

k_n can be obtained from Table 2 (k_n depends on the type of steel beam section).

The proposed shear buckling coefficient equation for steel beams (Equation 6) shows that the boundary condition at the flange-web juncture of LCBs is equivalent to 23% fixed condition while it shows that boundary condition at the flange-web juncture of LSBs is equivalent to 87% fixed condition. Since the level of fixity at the web-flange juncture of hollow flange and open steel beam is the same for the available steel beams, Equation 6 is applicable for all the aspect ratios. It was found that clear height to thickness ratio (d_1/t_w) does not affect the buckling coefficient of steel beams.

3 DIRECT STREGTH METHOD (DSM)

The direct strength method provides simple design procedures to determine the ultimate capacities of cold-formed steel members. Following the elastic buckling analyses and the resulting elastic buckling coefficients for the chosen hollow flange and open beams, new direct strength method equations (Equations 7 to 12) were proposed for the ultimate shear capacities of these hollow flange and open cold-formed steel beams. These equations include the accurate shear buckling coefficient that takes into account the effects of web-flange fixity. The slenderness was calculated using Equation 12.

A new post-buckling coefficient (p_n) was also introduced in the DSM equations to include the available post-buckling strength of cold-formed steel beams.

$$\frac{V_v}{V_{yw}} = 1 \qquad \lambda \leq 0.815 \tag{7}$$

$$\frac{V_v}{V_{yw}} = \frac{0.815}{\lambda} + p_n\left(1-\frac{0.815}{\lambda}\right) \qquad 0.815 < \lambda \leq 1.23 \tag{8}$$

$$\frac{V_v}{V_{yw}} = \frac{1}{\lambda^2} + p_n\left(1-\frac{1}{\lambda^2}\right) \qquad \lambda > 1.23 \tag{9}$$

where

$$V_{yw} = 0.6 f_{yw} d_1 t_w \tag{10}$$

$$V_{cr} = \frac{k_v \pi^2 E}{12(1-\nu^2)}\left(\frac{t_w}{d_1}\right)^2 d_1 t_w \tag{11}$$

$$\lambda = \sqrt{\left(\frac{V_{yw}}{V_{cr}}\right)} = 0.815\left(\frac{d_1}{t_w}\right)\sqrt{\left(\frac{f_{yw}}{E k_v}\right)} \tag{12}$$

p_n = post-buckling coefficient, For LSB, DHFB, RHFB, p_n = 0.25 and For LCB, p_n = 0.2.

Figure 9 compares the shear design curve based on the proposed DSM based shear strength equations with FEA and available experimental results of LCBs and LSBs. Both experimental and numerical analyses show that there is considerable amount of post-buckling strength for LSBs and LCBs subjected to shear, in particular for LSBs and LCBs with large clear web height to thickness (d_1/t_w) ratios. Hence post-buckling shear strength can be taken into account in the design of LSBs, LCBs, DHFB, RHFB and other cold-formed steel beams. It is clear from Figure 9 that the new shear strength equations (Eqs. 7 to 9) that include post-buckling are able to predict the shear strengths of LSBs and LCBs more accurately. Keerthan and Mahendran (2010 and 2012) found that

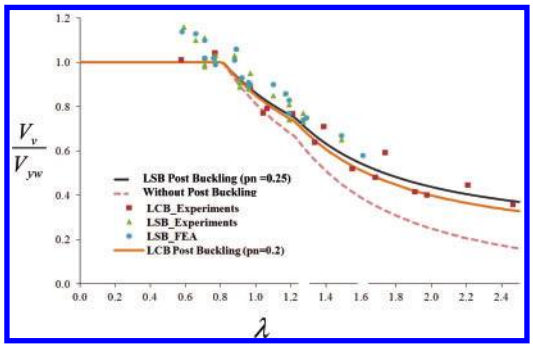

Figure 9. Comparison of shear strengths of LSBs and LCBs with DSM based design equations.

post-buckling coefficients (p_n) of LSBs and LCBs are 0.25 and 0.20, respectively based on their test and FEA results. Since the level of fixity at the web-flange juncture is the same for LSBs (87%), DHFBs (90%), and RHFBs (90%), the same post-buckling coefficient (p_n) of 0.25 can be used for LSBs, DHFBs and RHFBs.

The ultimate shear capacities of LCB, LSB, DHFB and RHFB predicted by the current design rules are very conservative as the potential post-buckling strength has also not been included while also assuming that web panels are simply supported at the web-flange juncture.

This research has shown that the currently available design guidelines in AISI (2007) and AS/NZS 4600 (SA, 2005) for the shear capacity of LCBs, LSBs, DHFBs and RHFBs can be modified to take into the effect of web to flange fixity and post-buckling strength.

4 CONCLUSIONS

This paper has presented the details of an investigation into the shear behavior and strength of hollow flange and open steel beams. Numerical analyses were conducted to investigate the shear buckling behaviour of different hollow flange (LSBs, DHFBs and RHFBs) and open (LCBs and PGs) steel beams. Currently the elastic shear buckling coefficients and strengths of web panels are determined by assuming conservatively that the web panels are simply supported at the web-flange juncture. However, it was found that the web-flange juncture in LSB, DHFB, RHFB and plate girder (PG) has some fixity. A simple equation was therefore proposed for the higher elastic shear buckling coefficient of steel beams based on finite element analysis results, and was included in the proposed ultimate shear capacity equations. The presence of post-buckling strength was also included in the proposed equations and hence they were able to predict the ultimate shear capacities of hollow flange and open cold-formed steel beams more accurately than the current design rules.

ACKNOWLEDGEMENTS

The authors would like to thank Australian Research Council for their financial support and Queensland University of Technology for providing the necessary facilities and support to conduct this research.

ABSTRACT: This paper reports the available results of an ongoing numerical research effort and whose final goal is to assess and mechanically interpret the influence of the cross-section geometry and end support conditions on the elastic distortional post-buckling behavior and strength of cold-formed steel columns. This work deals only with simply supported columns exhibiting lipped channel, hat and zed cross-sections, which share common critical distortional buckling loads. Taking advantage of the GBT modal decomposition features, the buckling analyses are used to mechanically characterize the various column critical bucking modes. The paper presents and discusses results concerning the elastic post-critical strength of the selected column triplets, obtained from Ansys shell finite element analysis. The post-critical strength data are used to attempt identifying key parameters, in the sense that they play a pivotal role in influencing the features exhibited by the column distortional post-buckling behavior and strength.

1 INTRODUCTION

In the course of a numerical investigation on the Direct Strength Method (DSM) design, against distortional failures, of pin-ended and fixed-ended lipped channel and rack-section columns, the authors (Landesmann & Camotim 2010) literally "stumbled" on a rather unexpected finding: the current DSM design curve clearly overestimated the column ultimate strength *at room temperature* (this did not happen at all for the fixed-ended columns). This finding prompted an investigation on how the column end support condition influenced the quality of the DSM prediction of their distortional failure loads (Landesmann & Camotim 2011, 2013) – this involved (i) four end support conditions (fixed, fixed-pinned, pinned and fixed-free end sections), (ii) four cross-section shapes (lipped channels, hats, zeds and racks), (iii) a few (six or seven) mid-line dimensions per cross-section shape, selected to ensure pure buckling and failure modes, and (iv) various yield stresses, selected in order to cover a wide distortional slenderness range. The chief conclusion of the above investigation consisted of the fact that, regardless of the cross-section shape, the current DSM distortional strength curve only predicts adequately the ultimate strength of fixed columns – all the remaining column ultimate strengths were found to be more or less overestimated, a surprising feature that was (rightly) attributed to the relevant stiffening role played by the end cross-section wall bending and (mostly) warping fixity. However, another behavioral feature emerged from the this study: the wide variety of elastic post-buckling behaviors exhibited by the columns analyzed, even amongst those sharing the same cross-section shape and end support conditions – this led the authors to "pledge" that they would investigate this issue in the near future. The fulfillment of this "promise" provided the motivation for the research effort currently under way (Landesmann *et al.* 2013) and whose first fruits are reported in this paper.

The objective of this paper is two-fold. First of all, to identify and mechanically characterize a significant number of simply supported (pinned end sections that can warp freely) columns exhibiting lipped channel, zed and hat cross-sections and buckling in "pure" distortional modes, in the sense that their critical distortional buckling loads are well below their local and global counterparts, thus precluding the occurrence of relevant mode interaction effects, *i.e.*, ensuring "truly distortional" post-buckling behaviors. Taking advantage of the fact that lipped channel, hat-section and zed-section columns share the same distortional (and local) buckling behavior, each set of cross-section dimensions and length identified defines a column triplet that is eligible for the present investigation. Then, the paper addresses the elastic (distortional) post-buckling behavior and strength of the various columns identified: a representative sample of the corresponding non-linear equilibrium paths are presented, analyzed, compared and, whenever possible,

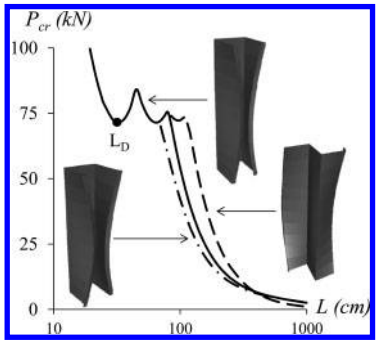

Figure 1. Curves P_{cr} vs. L concerning C-H-Z 60(6) columns with the indication of the selected lengths (L_D) and associated distortional buckling mode shapes.

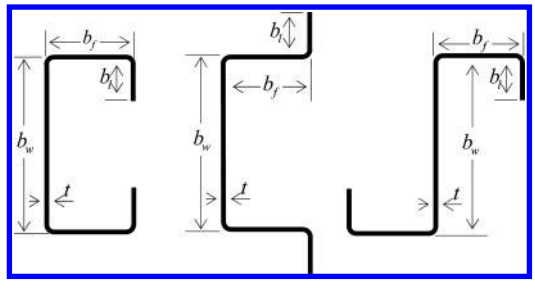

related to the buckling mode mechanical characteristics determined previously. The goal is to make an attempt to pin down key parameters (*e.g.*, cross-section dimension ratios or critical buckling mode mechanical characteristics), in the sense that they play a pivotal role in influencing the features exhibited by the column distortional post-buckling behavior and strength.

2 COLUMN GEOMETRY SELECTION

The first step consists of selecting the cross-section dimensions and lengths of the simply supported lipped channel (C), hat-section (H) and zed-section (Z) columns to be analyzed. At this stage, recall that the end cross-sections of such columns exhibit (i) null in-plane local/global displacements and torsional rotations, and (ii) free local/global rotations and warping displacements. The selection procedure involved time-consuming sequences of "trial-and-error" buckling analyses, performed with the GBT-based code GBTUL (Bebiano *et al.* 2008ab) and aimed at satisfying the following requirements: (i) columns buckling in "pure" symmetric distortional modes, this goal is achieved by ensuring, as much as possible, that the critical buckling stress (i_1) is clearly distortional and (i_2) falls considerably below the lowest local and global bifurcation stresses, (ii) cross-section dimensions not "too extreme" and involving wall proportions (*e.g.*, the web-to-flange width ratio b_w/b_f ratio) covering ranges as wide as possible and, (iii) columns lengths (iii_1) corresponding to single half-wave buckling modes and (iii_2) as close as possible to the values associated with the minimum distortional critical buckling stress, as illustrated in Figure 1 for the columns C-H-Z 60(6). Fortunately, it was possible to fulfill all the above requirements and the end product of the "trial-and-error" selection procedure are the 44 column triplets (Cs, Hs and Zs) with identical cross-section dimensions and distortional buckling lengths L_D – they are given in Table 1, where it is worth noting that (i) the columns are ordered according to the web width b_w (indicated with parenthesis) (ii) several columns share

the same b_w value and (iii) the b_w/b_f, b_w/t and b_f/b_l ratios range from 1.0 to 2.0,27.3 to 61.1 and 3.8 to 15, respectively. Table 1 also provides the (i) critical (distortional) buckling load $P_{cr.D} \equiv P_{cr}$, all obtained for $E = 210\ GPa$ (Young's modulus) and $\nu = 0.3$ (Poisson's ratio), and (ii) elastic post-critical strengthP_{10t} (this will be specifically addressed ahead in the paper).

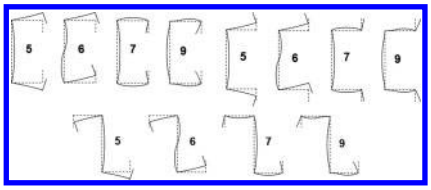

Figure 2. Configurations of the C-H-Z 110(5) column GBT deformation modes (i) **5** (symmetric distortional), (ii) **6** (anti-symmetric distortional) and (iii) **7** + **9** (web-triggered local).

3 BUCKLING MODE MECHANICAL CHARACTERIZATION

This section addresses the mechanical characterization of the critical buckling modes of the selected column triplets – the objective is to assess and quantify the natures of the deformations involved in the various column critical distortional buckling modes. This is straightforwardly done by means of GBT, taking advantage of (i) its rather unique modal features and (ii) the fact that the selected column geometries were obtained from buckling analyses carried out in the code GBTUL, which automatically provides the GBT modal decomposition of the column buckling modes (*e.g.*, Silvestre & Camotim 2002ab, Camotim *et al.* 2004, Dinis *et al.* 2006). Figure 2 displays the in-plane configurations of the C-H-Z 110(5) column GBT deformation modes that are most relevant for the present investigation, namely the (i) symmetric (**5**) and anti-symmetric (**6**) distortional modes, and (ii) two local (**7** and **9**) modes – all the remaining columns exhibit qualitatively similar deformation modes.

Figure 3 illustrates the buckled mid-span cross-section of the C 110(5) column, providing the typical contributions (percentage participation) of the GBT deformation modes (modal decomposition) to the critical buckling mode. The following conclusions can be drawn from the observation of obtained results:

(i) All critical buckling modes combine a highly dominant participation from symmetric distortion (p_5) with minor (but non negligible) contributions from web-triggered local deformations (p_7 and p_9) – p_n stands for the percentage participation of GBT deformation mode n. While the former varies in the ranges *86.0–95.4* (Cs), *87.0–97.0* (Hs) and *86.4–93.6* (Zs), the joint contribution of the latter (p_{7+9}) amounts to *3.5–12.9* (Cs), *4.3–12.2* (Hs) and 3.6 – 13.1 (Zs) – results are summarized in Landesmann *et al.* (2013). The participation of the other deformation modes never exceeds *4.5%* and is below *1.0%* in most cases.

(ii) Figure 4, which plots p_5, p_7 and p_9 against the b_w/b_f ratio for lipped channel column (which are also typical for H and Z sections), shows that there are clear (and opposite) trends concerning the variation of both p_5 and p_7 withb_w/b_f. Indeed, it is observed that p_5 (p_7) decreases (increases) as b_w/b_f grows a bit more than linearly (almost parabolic variation), which probably stems from the higher vulnerability of wider webs to local deformations. Conversely, no tendency is detected in the p_9 vs. b_w/b_f plot.

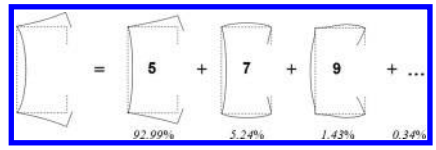

Figure 3. Illustrative GBT modal decomposition: distortionally buckled mid-span cross-section of the C 110(5) column.

4 ELASTIC POST-BUCKLING BEHAVIOR AND STRENGTH

4.1 *Numerical Model*

The column distortional post-buckling equilibrium paths were determined through geometrically nonlinear SFEA carried out in the code ANSYS (SAS 2009). The columns were discretized into SHELL181 elements (4-node shear deformable thin-shell elements with six degrees of freedom per node and full integration) – previous convergence studies showed that *5 mm* × *5 mm*

meshes provide quite accurate results, even if at the cost of a fairly high computational effort. The analyses were performed by means of an incremental-iterative technique combining Newton-Raphson's method with an arc-length control strategy. All columns exhibited (i) a linear elastic material behavior ($E = 210\,GPa$ and $\nu = 0.3$) and (ii) critical-mode (distortional) initial geometrical imperfections with small amplitudes (*10%* of the wall thickness t). Their incorporation in the columns was made automatically by means of the following procedure (*e.g.*, Dinis & Camotim 2013): (i) determination of the critical buckling mode shape, through an ANSYS SFE buckling analysis adopting exactly the same discretization/mesh employed to carry out the subsequent post-buckling analysis, which was then (ii) scaled to exhibit maximum vertical displacements along the flange-stiffener longitudinal edges equal to $0.1t$ – this buckling analysis output is then "transformed" into an input of the non-linear analysis. Following the column distortional post-buckling asymmetry first unveiled by Prola & Camotim (2002) and later also studied by Silvestre & Camotim (2006), these initial imperfections involve outward (Cs) and inward (Hs) flange-stiffener motions (those shown to lead to the lower post-buckling strengths) – obviously, this distinction makes no sense in the Z columns, since their flange-stiffener motions are always opposite (one outward and the other inward).

Concerning the modeling of the end support conditions, the membrane and bending transverse displacements were prevented at all end section nodes, while keeping the axial (warping) displacements and all the bending rotations free. To enable the load application, the rigid-body axial translation is free at both end sections – the axial compression is applied by means of a set of point loads acting on both end section nodes and increased in small increments, through the ANSYS automatic load stepping procedure.

4.2 *Results and Discussion*

These results presented and discussed consist of elastic post-buckling equilibrium paths that are then used to make a comparative assessment of the post-critical strength exhibited by the various columns. In order to illustrate the results obtained and also address the qualitative and quantitative assessment of how the column elastic distortional post-critical strength is influenced by the cross-section shape and dimensions, Figure 6 depicts the equilibrium paths of the C-H-Z 60(6) and C-H-Z 100 columns, plotting the applied load P, normalized w.r.t. P_{cr}, against $|\delta|/t$, where $|\delta|$ is the absolute value of the mid-span (maximum) flange-stiffener corner vertical displacement and t is the wall thickness (note that in the Z-section columns, $|\delta|$ always concern the flange-stiffener moving inwards). In order to achieve a more rational and meaningful comparison between the various equilibrium paths and post-critical strengths, it was decided to focus on strength values associated with $|\delta|/t = 10$, hereafter designated as P_{10t} and corresponding to the black dots drawn on the P/P_{cr} *vs.*$|\delta|/t$ curves in Figure 6.

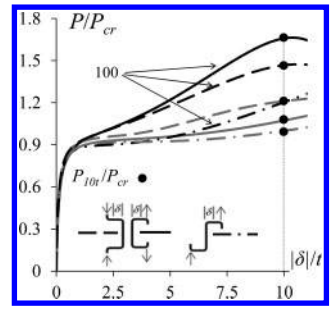

Figure 5. Elastic post-buckling equilibrium paths P/P_{cr} *vs.*$|\delta|/t$ concerning the C-H-Z 60(6)/100 columns.

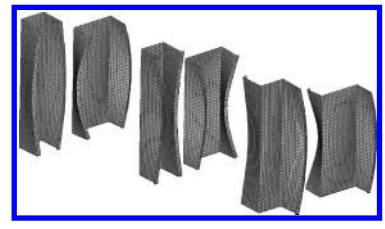

Figure 6. Post-buckling deformed configurations at $P = P_{10t}$ concerning the C-H-Z 60(6)/100 columns.

Finally, Figure 7(a) depicts the C-H-Z 60(6)/100 column deformed configurations occurring for P_{10t} on each equilibrium path displayed in Figure 6.

In order to assess the variation of P_{10t} with the columns cross-section shape and dimension concerning, Figure 8 plots P_{10t}/P_{cr} against b_w/b_f, b_w/t and b_f/b_l concerning the lipped channel columns. The close observation of the results presented in Table 1 and Figs 6 to 8 prompts the following remarks:

(i) First of all, it is worth recalling the quite visible differences between the elastic equilibrium paths P/P_{cr} *vs.*$|\delta|/t$ displayed Figure 6: the 100 columns ($b_w/b_f = 2$) exhibit considerably higher post-critical strengths than their 60(6) counterparts ($b_w/b_f = 1$).

(ii) Regardless the cross-section dimensions, the lipped channel and zed-section columns exhibit higher post-critical strengths than their hat-section counterparts (this difference is clearly visible in Figure 5).

(iii) Figure 8(a) shows that there is substantial scatter in the plots showing the variation of P_{10t}/P_{cr} with b_w/b_f, b_w/t and b_f/b_l. Indeed, these values vary between (iii_1)1.02 and 1.81 (Cs), (iii_2)0.86 and 1.63 (Hs), and (iii_3)1.01 and 1.75 (Zs) – these values confirm the assertion made in the previous item (full results are given in Landesmann *et al.*, 2013).

(iv) The comparison between the plots in Figure 8(a) provides clear evidence that, unlike their b_w/t and b_f/b_l counterparts, the b_w/b_f ratios show some correlation with the normalized column post-critical strengths P_{10t}/P_{cr}. In fact, it is observed that P_{10t}/P_{cr} generally increases with b_w/b_f.

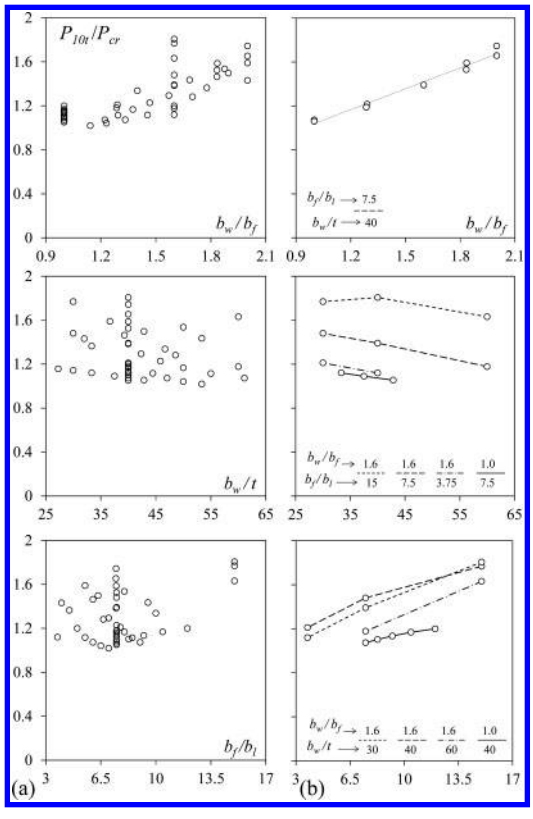

Figure 7. Variation of P_{10t}/P_{cr} with: (a) b_w/b_f, b_w/t and b_f/b_l and (b) each individual width ratio b_w/b_f, b_w/t and b_f/b_l (the remaining two are kept constant), concerning the lipped channel columns.

(v) Since the C 60(1-10) and 120(1-7) columns share the same web-to-flange width ratio (b_w/b_f equal to 1.0 and 1.60, respectively), their P_{10t}/P_{cr} values are located on the same vertical line in the P_{10t}/P_{cr} *vs.* b_w/b_f plots. The vertical dispersions exhibited by these values provide an indication of the combined influence of the b_w/t and b_f/b_l ratios, which vary within each column set. Because these vertical dispersions are much higher for $b_w/b_f = 1.6$ than for $b_w/b_f = 1.0$, it seems fair to conclude that the combined influence of b_w/t and b_f/b_l on P_{10t}/P_{cr} increases with b_w/b_f.

In an attempt to capture the influence of each individual width ratio on the column elastic distortional post-critical strength, Figure 8(b) depicts the variations of P_{10t}/P_{cr} with each of the b_w/b_f, b_w/t and b_f/b_l width ratios, while keeping the remaining two constant. The analysis of this limited amount of results suggests that:

(i) By far the best documented P_{10t}/P_{cr} variations are those associated with the b_w/b_f ratio, which involve the C 60(6)/75/80(6)/90/100/110(2)/116/118/120(7)/ 130 columns – b_w/b_f varies between 1.0 and 2.0, while $b_w/t = 40$ and $b_f/b_l = 7.50$ are kept constant (results concerning other shapes are given in Landesmann *et al.*, 2013). The variation of P_{10t}/P_{cr} with b_w/b_f follow roughly ascending straight line.

(ii) Although the variation of P_{10t}/P_{cr} with the b_w/t is poorly documented (no more than three columns sharing the same b_w/b_f and b_f/b_l combination), it seems possible to conclude that a b_w/t increase tends to slightly lower the column post-critical strength.

(iii) Lastly, the variation of P_{10t}/P_{cr} with b_f/b_l falls somewhere in between the previous two, as far as the quality of the documentation is concerned (there are five columns sharing the same b_w/b_f and b_w/t combination), the P_{10t}/P_{cr} value increases steeply with b_f/b_l.

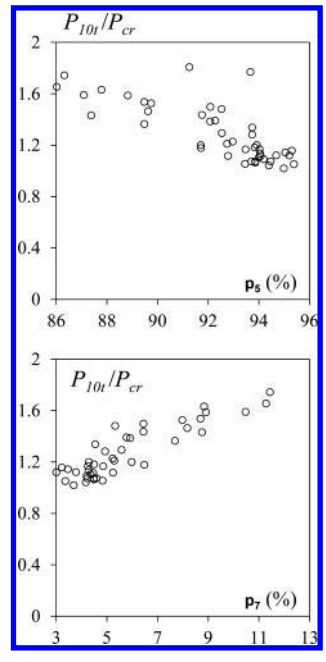

Figure 8. Variation of P_{10t}/P_{cr} with the GBT modal participations p_5 and p_7 (in the column critical buckling mode).

Finally, Figure 9 plots the P_{10t}/P_{cr} values against p_5 and p_7, *i.e.*, the participations of the GBT deformation modes **5** (symmetric distortion) and **7** (web-triggered local) on the column (distortional) critical buckling modes – recall that these modal participations were shown to exhibit some correlation with the b_w/b_f ratio. The observation of these results prompts the following remarks:

(i) There is a considerable scatter of the P_{10t}/P_{cr} values for the GBT modal participation considered. However, the least of such scatters clearly concerns local mode participations (p_7) – moreover, the corresponding P_{10t}/P_{cr} *vs.* p_7 plot shows that the presence of the local mode **7** entails a visible column post-critical strength increase (which is logical).

(ii) Naturally, the trends of the P_{10t}/P_{cr} *vs.* p_5 plots are practically the "inverse" of those exhibited by their P_{10t}/P_{cr} *vs.* p_7 counterparts, which means that now an increase in the participation of mode **5** causes a column post-critical strength drop (downward trend). Quantitatively speaking, the scatter of the P_{10t}/P_{cr} values is either (ii_1) very similar to that observed for the variation with p_7 or (ii_2) slightly above it (Cs) – in any case, the lipped channel column results still exhibit the lower scatter.

(iii) It may be safely argued that the modal participations p_5 and p_7 provide fairly good indicators of the lipped channel column post-critical strength level (p_7 slightly outperforms p_5).

5 CONCLUDING REMARKS

This paper reported the available results of a numerical research effort currently under way that aims at assessing and mechanically interpreting the influence of the cross-section geometry and end support conditions on the elastic distortional post-buckling behavior and strength of cold-formed steel columns. Regardless of the cross-section shape, it was found that, in fact, the so-called "pure distortional buckling modes" exhibit not only anti-symmetric distortional deformations (the predominant ones), but also web-triggered local deformations – moreover, the relative contribution of these deformations depends on the column cross-section shape and dimensions in a non-negligible fashion. It was observed that, generally, an increase in the presence of local deformations in the column critical (distortional) buckling mode leads to a higher post-critical strength (which seems logical, in view of the high post-critical strength reserve associated with local buckling). Finally, it was also found that more significant local deformations occur in columns exhibiting large web-to-flange width ratios, which is perfectly in line with the well-known higher vulnerability of wider webs to local buckling effects.

Concerning the correlation of the column post-critical strength with its cross-section dimension ratios and buckling mode GBT modal participations, it was found that, in the case of lipped channel columns, the variations of the (i) web-to-flange width ratio and (ii) percentage participation of the web-triggered local mode **7** provide the reasonable well the means to predict the post-critical strength change. No similar trait could be found for the hat-section and zed-section columns, for which the above correlation is visibly weaker (even if qualitatively similar). Although these preliminary findings are quite encouraging, it is undeniable that considerable further research is required before more solid conclusions can be drawn.

Finally, it is worth mentioning that the authors plan to complement the investigation reported in this paper with the performance of GBT-based elastic post-buckling analyses of several columns (*e.g.*, Silvestre & Camotim 2003, 2006 or Basaglia *et al.* 2011).

Cold-formed steel beams of corrugated web

D. Dubina & V. Ungureanu
"Politehnica" University of Timisoara, Romania Romanian Academy, Timisoara, Branch, Romania

L. Gîlia
Technical University of Cluj-Napoca, Romania

ABSTRACT: The steel beams of corrugated web represent a relatively new structural system which emerged in the past two decades. The thin corrugated web, affords a significant weight reduction of these beams, compared with hot-rolled or welded ones. In the initial solutions, the flanges are made of flat plates, welded to the sinusoidal web sheet, requiring a specific welding technology. A new solution is proposed in this paper, in which the beam is composed by a web of trapezoidal cold-formed steel sheet and flanges of built-up cold-formed steel members (e.g. back-to-back lipped channel sections or angles with turn lips). The connections between flanges and web can be done by self-drilling screws or by spot welding. The paper summarizes the experimental and numerical investigations carried out at the CEMSIG Research Centre of the "Politehnica" University of Timisoara, in order to evaluate and validate a new technological solution.

1 INTRODUCTION

Corrugated web girders represent a relatively new structural system emerged in the past two decades especially in Germany and Austria. Increased interest of this solution was observed for the main frames of single-storey steel buildings and in steel bridges.

The main benefits of this type of elements are that the corrugated webs increase the beam's stability against buckling, which may result in a very economical design via the reduction of web stiffeners. Furthermore, the use of thinner webs results in lower material cost, with an estimated cost savings of 10–30% in comparison with conventional fabricated sections and more than 30% compared with standard hot-rolled beams. The buckling resistance of used sinusoidal corrugated sheet used for webs is comparable with plane webs of 12 mm thickness or more.

In the previously developed solutions the flanges are flat plates, welded to the sinusoidal web sheet, requiring a specific welding technology. The flanges mainly provide flexural strength to the beam with low contribution from the corrugated web, which provides the shear capacity. Failure of the web occurs by steel yielding or web buckling. Lateral-torsional buckling of the girder and local flange buckling represents other possible failure modes.

The paper presents a new technological solution of such a system, composed by webs made of trapezoidal cold-formed steel sheet and flanges of built-up cold-formed steel members (e.g. back-to-back lipped channel sections or angles with turn lips). The connections between flanges and web are made with self-drilling screws or by spot welding. It is easy to be observed that the new solution, as a whole, is 100% composed by cold-formed steel elements, avoiding the combination of two types of products, i.e. cold-formed for webs and hot-rolled for flanges. High protection to corrosion due to the fact that all components are galvanized is a major advantage. On the other hand, if the fabrication might adopt an automotive fastening technology such as cold metal transfer (CMT) welding, the production of some standardised beam series can be highly automated.

2 LITERATURE REVIEW

Significant work on girders with corrugated web was devoted to study the shear capacity. A summary of the research and development in beams with corrugated webs was reported by Elgaaly & Dagher (1990). Smith (1992) performed four tests on two girders with corrugated webs, which were welded to the flanges using intermittent welding. He found that the connection between the flange and the web is critical for the shear strength as the weld used in the test was subjected to high strength and web was easily ruptured at this point before it reached its buckling strength. He suggested that intermittent welding of the corrugated webs to the flange is not advisable.

Hamilton (1993) performed 42 tests on 21 beams, which used four different corrugation configurations and two thicknesses. Unlike Smith's (1992) specimens, the webs were continuously welded to the flanges from one side. It was found that the failure of all specimens was initiated by local buckling of one of the corrugation folds. Another conclusion was that dense corrugation profiles are more likely to fail in global shear buckling. Elgaaly et al. (1996) verified the test

results done by Smith (1992) and Hamilton (1993) using nonlinear FEM and found that the results of FEA were very close to the test results.

Luo & Edlund (1995) used non-linear finite element analysis to perform a geometrical parametric study and compared the numerical results with existing empirical and analytical formulae. They have found that the ultimate shear capacity increases proportionally with the girder depth and does not seem to be dependent on the ratio of girder length over girder depth, while the post-buckling shear capacity not only increases with the girder depth, but also appears to be dependent on the ratio of girder length over girder depth. They have also found that the corrugation depth did not seem to have much effect on the ultimate shear capacity but affected the degree of the localization of the buckling mode.

A lot of work has been done on the bending behaviour of steel girders with corrugated web. It was observed that the contribution of the web to the ultimate moment capacity of a beam with corrugated web is negligible, and the ultimate moment capacity will be based on the flange yield stress. Elgaaly et al. (1997) have performed a series of experimental and analytical studies. They have experimentally tested six specimens that had corrugated webs in the centre panel and flat panels adjacent to the support. All the specimens failed due to flange yielding followed by vertical buckling of the compression flange into the web. They found that the web did not contribute much to the bending capacity of the beam and its contribution could be neglected.

Chan et al. (2002) studied the effect of web corrugation on the bending capacity of the beam using FEM. Webs with horizontal and vertical corrugations were studied. They found that the vertically corrugated web provides a stronger support against the flange buckling than those with horizontally corrugated and flat webs. Also, the corrugation radius was investigated and found that larger corrugation radius could sustain higher bending moment.

Johnson & Cafolla (1997) have studied the effect of the vertically corrugated webs on the local buckling of the compressive flange and the flexural behaviour of beams with corrugated webs via numerically and in experimental tests. They found that the contribution of the web to flexural capacity is small.

Lindner (1990) studied by experimental tests the lateral-torsional behaviour of steel girders with corrugated webs and found that the torsional section constant I_t for a beam with corrugated web doesn't differ from that of a beam with flat web, but the warping section constant I_w is different.

The effect of the corrugation profiles of the web on the lateral-torsional buckling strength of the inelastic I-girder was also studied. Pasternak et al. (2010) presented a new proposal for Annex D of EN 1993-1-5:2006.

Moon et al. (2009, 2013) investigated the lateral–torsional buckling strength of an I-girder with corrugated steel webs under linear moment gradient by using finite element analysis. It was found that the buckling behaviour of the I-girder with corrugated steel webs differed depending on the number of periods of the corrugation. Simple equation for the moment gradient correction factor for these types of beams was suggested.

Elgaaly & Seshadri (1997) performed five tests on four different corrugation profiles. Two distinct modes of failure were observed: web crippling and web yielding. They also studied, using FEM, the interaction between partial compressive edge loading and bending or shear.

Luo & Edlund (2006) performed nonlinear finite element analysis to study the effect of four factors that influence the buckling strength of the beams, i.e.: (1) strain hardening model; (2) corner effect; (3) initial imperfections; (4) loading position. They used elastic-perfectly plastic and Ramberg-Osgood's models and found that with a Ramberg-Osgood strain-hardening model for webs, the ultimate strength of the girder is about 8-12% higher than using an elastic-perfectly plastic model. Also, the effect of the corners due to cold-forming does not have any significant effect on the ultimate strength.

Nguyen et al. (2012) investigate the moment modification factors of I-girder with trapezoidal web corrugations under moment gradient and various end restraint conditions and proposed closed-form expressions for the moment modification factors.

Another important aspect is the investigation of the stress distribution in the flange of the girders with corrugated webs (Kövesdi et al. 2012). During the experimental tests the stress distributions on different locations (i.e. flanges and web) were measured as a basis for parametric analyses.

As a final remark, a beam with corrugated web behaves similarly to a lattice girder, in which the bending moments and applied forces are transferred via flanges only, while the transverse forces are transferred through the diagonals and verticals of the lattice girder, in this case the corrugated web. The dimensioning of corrugated web beams is ruled by Annex D of the EN 1993-1-5:2006, together with specific aspects of EN 1993-1-1 and EN 1993-1-3. At the end, on the purpose of finding an analytical approach for designing such beams with corrugated web intermittently connected to the flanges, the procedure used for calculation sheathing acting as a diaphragm could be adapted (ECCS 1995). The experience, in this case, has shown the most contributing factors, both to strength and stiffness are the distortion of sheeting corrugations and seem fasteners (Fülöp & Dubina 2006).

3 EXPERIMENTAL TESTS

3.1 *Specimens and test procedure*

The experimental program was carried out at the CEMSIG Research Centre (http://cemsig.ct.upt.ro) of the "Politehnica" University of Timisoara. Five beams

Table 1. Types of specimens.

CWB-1	Standard solution: flange-to-web connection in every corrugations and uniformly distributed seam fasteners
CWB-2	Standard solution + supplementary lipped channel sections under the load application points
CWB-3	Optimized solution by adapting the flange-to-web connections according to the distribution of shear stresses (connections at each second corrugations where the shear force decreases)
CWB-4	Optimized solution by eliminating shear panels and doubling of corrugated webs in the zones with high shear forces
CWB-5	Optimized solution by adapting both the flange-to-web connections and seam fasteners to the distribution of shear stresses

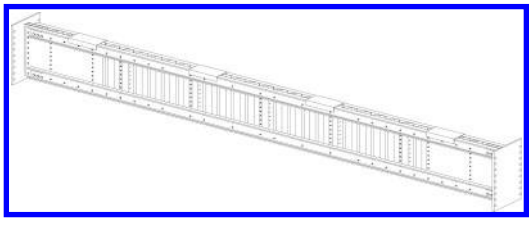

Figure 1. Configuration of the specimens.

with corrugated webs with a span of 5157 mm and a height of 600 mm have been tested (see Table 1), considering different arrangements for self-drilling screws and shear panels (Gilia 2012, Dubina et al. 2012).

Figure 1 presents the components of the CWB-1 beam with corrugated web (standard solution), i.e.:

- back-to-back lipped channel sections for flanges – 2 × C120/2.0;
- corrugated web with the corrugation depth of 43 mm and the thickness of 0.7 mm – A45/0.7;
- reinforcing shear panels – plates of 1 mm thickness and 830 mm length, at the beam ends where the shear force is maximum;
- reinforcing U150/2.0 profiles used under the load application points, to avoid excessive local deformations;
- self-drilling screws for flange-to-web connection – STP-6.3 × 25;
- self-drilling screws for shear plates to end support with a nominal diameter – STP-5.5 × 25;
- self-drilling screws as seam fasteners for corrugated webs with a nominal diameter– STT-4.8 × 20;
- bolts M12 class 8.8 for flanges to the end support connection.

Figure 2 presents the experimental arrangement. Six points bending tests, monotonically conducted, were applied for each specimen with a loading velocity of 2 mm/min.

The full-scale testing program was completed with tensile tests to determine both the material properties for beam components and the behaviour of connections.

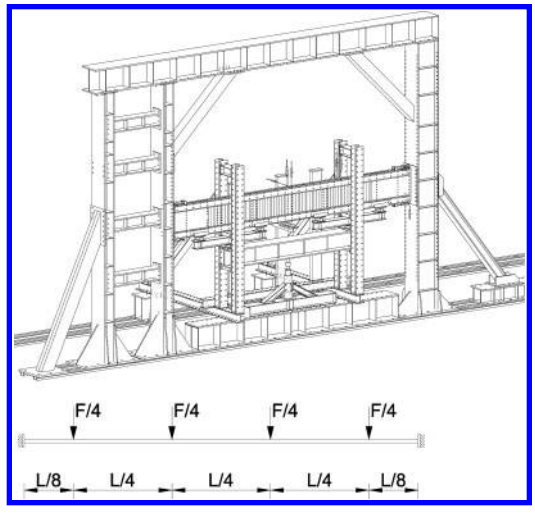

Figure 2. Experimental arrangement.

Figure 3. Deformed shape of CWB-1 beam at failure.

Figure 4. Deformed shape of the beam end shear panel.

3.2 *Test results*

3.2.1 *Beam CWB-1*

In case of the CWB-1 beam, the first deformation, which corresponds to the buckling of shear panel, appears for a displacement of 10 mm. The behaviour is ductile, with an initial stiffness of $K_{0\text{-}Exp} = 6862.2 N/mm$ and the maximum load is reached at $F_{max} = 218.9\,kN$. The collapse appears for a displacement of 58 mm. Figure 3 presents the deformed shape of the beam at collapse, while Figure 4 shows a detail of the shear panel at failure.

3.2.2 *Beam CWB-2*

In this case, the first deformation, which corresponds to the buckling of shear panel, appears for a displacement of 10 mm. The behaviour is ductile, with an

Figure 5. Deformed shape of CWB-2 beam at failure.

initial stiffness of $K_{0\text{-}Exp} = 7831.5$ N/mm and the maximum load is reached at $F_{max} = 231.3$ kN. The collapse appears for a displacement of 54 mm. Figure 5 presents the deformed shape of the beam at collapse, while Figure 6 shows a detail of the shear panel at failure.

3.2.3 *Beam CWB-3*

For CWB-3 beam, the first deformation appears for a displacement of 15 mm, which corresponds to the buckling of shear panel and distortion of the corrugated web. The behaviour is ductile, with an initial stiffness of $K_{0\text{-}Exp} = 7184.9$ N/mm and the maximum load is reached at $F_{max} = 209.5$ kN. The collapse appears for a displacement of 62 mm. Figure 7 presents the deformed shape of the beam at collapse, while Figure 8 shows the distortion of the web corrugation.

3.2.4 Beam CWB-4

In case of this beam, the first deformation, which corresponds to the distortion of the corrugated web, appears for a displacement of 21 mm. The behaviour is ductile, with an initial stiffness of $K_{0\text{-}Exp} = 3985$ N/mm and the maximum load is reached at $F_{max} = 181.9$ kN. The collapse appears for a displacement of 164 mm. Figure 9 presents the deformed shape of the beam at collapse, while Figure 10 shows the distortion of the web corrugation.

Figure 9. Deformed shape of CWB-4 beam at failure.

Figure 10. Distortion of the web corrugation.

Figure 11. Deformed shape of CWB-5 beam at failure.

Figure 12. Distortion of the web corrugation.

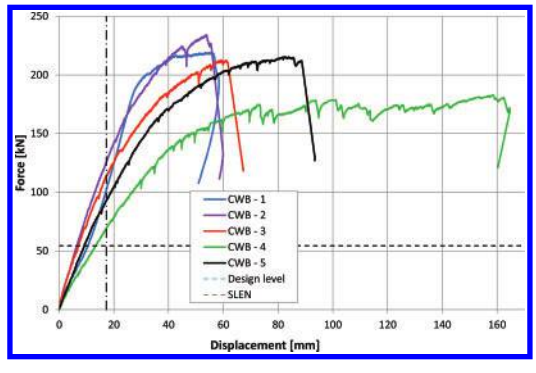

Figure 13. Load-displacement curves for the tested specimens.

3.2.5 Beam CWB-5

The first deformation corresponds to the buckling of shear panel, which appears for a displacement of 21 mm. The behaviour is ductile, with an initial stiffness of $K_{0\text{-}Exp} = 5516.2$ N/mm and the maximum load is reached at $F_{max} = 214.6$ kN. The collapse appears for a displacement of 88 mm. Figure 11 presents the deformed shape of the beam at collapse, while Figure 12 shows the distortion of the web corrugation in the region with the reduced number of screws.

Figure 13 shows comparatively, for all the five tested specimens, the load-displacement curves.

3.3 *Material properties and connections behaviour*

In order to determine the mechanical properties, a set of samples were cut out from the lipped channels of the flanges and corrugated web, both from the flat regions and corners, according to EN10002-1:2001 specifications, as shown in Figure 14.

Table 2 presents the mean values, standard deviations and the characteristic values for yield and ultimate strengths for the above samples.

Six types of connections were tested according to ECCS (2008), at a loading velocity of 1 mm/min, i.e. (1) T1-1.4 seam fasteners for corrugated sheets; (2) T2-1.7, seam fasteners for shear plates and corrugated sheets; (3) T3-3.7, self-drilling screws for shear plates and flanges; (4) T4-9.0, self-drilling screws for shear plates and end supports; (5) T5-11.0, bolts for flanges to end-supports; (6) T6-2.7, self-drilling screws for flanges to corrugated webs at mid-span, in order to determine the behaviour of all types of connections found in the beam (see Table 3).

4 NUMERICAL MODEL CALIBRATION AND VALIDATION

Numerical models applied to simulate the behaviour of members experimentally tested have been created using the commercial FE program ABAQUS/CAE v.6.7.1.

Rectangular 4-noded shell elements with reduced integration (S4R) were used to model the thin-walled components. CONN3D2 element types, with 2 nodes and 6 DOF per node, have been used to model the self-drilling screws and bolts. RB3D2 elements were used as rigid body for load transfer and multi-point constrain beam (MPC-Beam) for DOF coupling between groups of specified nodes.

The material behaviour used for numerical modelling was in accordance with the recorded curves from tensile tests from coupons cut over the cross-section of component elements. Self-drilling screws and bolts were introduced using CONN3D2 element type according to the mean values recorded from tests of each type of connection.

General contact with the following parameters have been used, i.e.

– Normal direction – Hard Contact;
– Transversal direction – a friction coefficient of $\mu = 0.1$.

Finally, initial imperfections according to first 3 eigen modes from a linear bucking analysis have been used.

Figure 15 presents comparatively the FEM and experimental load-displacement curves for the beam CWB-2, while Table 4 shows the initial stiffness and ultimate load obtained via numerical simulations compared to experimental results for each specimen.

Based on the results obtained via numerical simulations, it can be noted that the behaviour and maximum load accurately replicate the experimental tests.

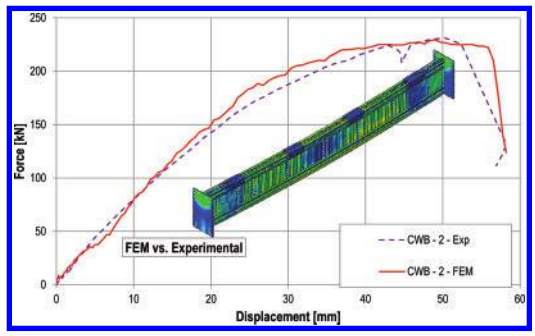

Figure 15. FEM/experimental load-displacement curves for CWB-2 beam.

Table 4. Initial stiffness and ultimate load: FEM vs. experimental results.

Beam type	$K_{0\text{-}Exp}$ (N/mm)	$K_{0\text{-}FEM}$ (N/mm)	$F_{max-Exp}$ (kN)	$F_{max-FEM}$ (kN)
CWB-1	6862.2	7721.1	218.9	225.9
CWB-2	7831.5	7834.6	231.3	229.5
CWB-3	7184.9	6819.3	209.5	205.8
CWB-4	3985.0	4932.0	181.9	223.5
CWB-5	5516.2	6594.9	214.6	216.0

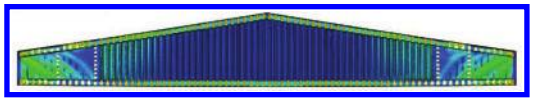

Figure 16. Stress distribution for a 12 m span beam.

On the next step, a beam of 12 m span with trapezoidal shape for the top flange has been investigated (see Fig. 16). The lateral-torsional bucking has been prevented. Similar failure modes have been obtained as in case of the tested beams, both experimentally and numerically.

5 CONCLUSIONS

A large experimental program carried out at the CEMSIG Research Centre (http://cemsig.ct.upt.ro) of the "Politehnica" University of Timisoara on five beams with corrugated webs with different arrangements for self-drilling screws and shear panels was presented.

Very good agreement can be found between beams CWB-1 and CWB-3, both in terms of initial stiffness and ultimate force. A slightly increase in stiffness can be observed in case of CWB-2 beam, due to the supplementary lipped channel sections added locally at the load application points. CWB-4 beam is the most flexible solution compared to the other four and has half initial stiffness compared to CWB-2 beam. At this level, CWB-5 beam represents the best solution in terms of optimisation.

Also, it can be underline that a very good agreement between numerical models and experimental ones have been obtained, in both failure modes and load-displacement curves.

Finally, even the results looks promising, significant work has to be done in order to investigate, validate and optimise such a solution for mass production, i.e.:

- to optimise the number of self-drilling screws used for connections;
- tests using spot welding are the next step of research; there are no differences expected at the level of global behaviour, but some are estimated in terms of strength and stiffness;
- numerical simulation of larger span beams in order to study the sensitivity to lateral-torsional buckling of such elements.

Post-buckling behaviour and strength of cold-formed steel lipped channel columns: when is local-distortional interaction relevant?

P.B. Dinis, D. Camotim & A.D. Martins
Civil Engineering Department, ICIST, Instituto Superior Técnico, Technical University of Lisbon, Portugal

ABSTRACT: The results of a numerical (ABAQUS shell finite element analysis) investigation concerning the relevance of Local-Distortional (L-D) interaction effects on the ultimate strength of fixed-ended lipped channel columns are presented and discussed. The columns analysed exhibit various geometries (cross-section dimensions and length) and yield stresses, selected to ensure a wide variety of combinations of the ratios between the (i) distortional and local critical buckling stresses (R), and (ii) yield and critical buckling stresses (R_y). The aim of the work is to identify the R and R_y range combinations for which the L-D interaction effects are relevant, in the sense of eroding visibly the lipped channel column ultimate strength and altering its failure mechanism. The ultimate strength erosion due to L-D interaction is assessed by comparing the numerical column failure loads with their estimates provided by the current Direct Strength Method (DSM) local and distortional strength curves – an overestimation by both curves implies the occurrence of erosion. Finally, the paper closes with some considerations on how the findings of this work may impact the DSM design of lipped channel columns undergoing different levels of L-D interaction.

1 INTRODUCTION

Most cold-formed steel members exhibit slender thin-walled open cross-sections, a feature making them highly susceptible to several instability phenomena, namely local and distortional buckling. Moreover, since several common member geometries (unrestrained length and cross-section shape/dimensions) are associated local (L) and distortional (D) buckling stresses that are not too far apart, the corresponding post-buckling behaviour (elastic or elastic-plastic), ultimate strength and failure mechanism are likely to be affected, to a larger or smaller extent, by interaction effects involving these two instability phenomena – local-distortional (L-D) interaction.

A considerable amount of research work has been recently devoted to L-D interaction, involving mostly lipped channel columns and including experimental investigations, numerical simulations and design proposals (*e.g.*, Yang & Hancock 2004, Dinis *et al*. 2007, Yap & Hancock 2011, Kwon *et al*. 2009, Silvestre *et al*. 2012, Young *et al*. 2013, Camotim *et al.* 2013). It was found that these interaction effects are relevant if the ratio between the critical distortional and local buckling stresses, denoted as $R = f_{crd}/f_{crl}$, is either (i) in the close vicinity of 1.0 (between 0.9 and 1.1) or (ii) well above 1.0, provided that the yield stress f_y is "high enough" to allow for the development of L-D interaction prior to collapse – this means that the yield-to-critical stress ratio plays a crucial role in the relevance of L-D interaction effects. However, a systematic investigation aimed at identifying the combinations of f_{crd}, f_{crl} and f_y stresses associated with non-negligible L-D coupling effects is still lacking – the only available work that addresses (partially) this issue has been reported by Dinis *et al*. (2009).

This paper presents and discusses the results of a numerical (ABAQUS shell finite element analysis – SFEA) investigation comprising 416 fixed-ended lipped channel columns that exhibit different cross-section dimensions and yield stresses, thus ensuring a wide variety of combinations concerning the stress ratios (i) $R = f_{crd}/f_{crl}$, relating the distortional and local critical buckling stresses and (ii) $R_y = f_y/f_{crmax}$, quantifying the difference between the yield stress and the non-critical of the above column buckling stresses, *i.e.*, $f_{crmax} = max\,(f_{crl}; f_{crd})$ – when f_{crd} and f_{crl} are not very close, the development of L-D interaction effects is also governed by the closeness between f_y and f_{crmax}. The aim is to identify the $R - R_y$ range combinations for which the L-D interaction effects are relevant, in the sense of eroding visibly the lipped channel column ultimate strength and altering its failure mechanism. The ultimate strength erosion due to L-D interaction is assessed by comparing the numerical column failure loads with their estimates provided by the current Direct Strength Method (DSM – Schafer 2008) local and distortional strength/design curves – an overestimation by both curves implies that erosion has occurred. Finally, the paper closes with some considerations concerning the impact of the findings reported in this work on the DSM design (ultimate strength prediction) of lipped channel columns undergoing different levels of L-D interaction.

2 BUCKLING ANALYSIS – COLUMN SELECTION

The column geometry (cross-section dimensions and length) selection to ensure the occurrence of various levels of L-D interaction was made by means of trial-and-error procedure involving the performance of buckling analysis sequences carried out in GBTUL (Bebiano *et al.* 2008), mainly due to its computational efficiency and modal nature. The selection procedure led to the cross-section dimensions (b_w, b_f, b_l, t–web/flange/lip widths and wall thickness) and lengths (L) provided in Table 1. The half-wave numbers exhibited by the critical distortional (n_d) and local (n_l) buckling modes are also included – the

latter only when $f_{crl} < f_{crl}$. It is worth noting that the 24 fixed-ended columns ($E = 210GPa$,v $= 0.3$) (i) exhibit R values such that $0.33 < R < 2.39$ and (ii) have global critical buckling stresses much higher than their local and distortional counterparts ($f_{crg}/f_{crmax} > 7.9$), thus meaning that no interaction with flexural-torsional buckling occurs.

3 RELEVANCE OF L-D INTERACTION

This section presents and discusses the main results of the numerical investigation aimed at identifying the relevance of the L-D coupling effects. All these results were obtained by means of ABAQUS SFEA and using the elastic-perfectly plastic model adopted earlier by Dinis *et al.* 2007, 2009): (i) columns discretised into fine meshes of 4-node isoparametric shell (S4) elements with length-to-width roughly equal to 1, (ii) fixed-ended supports modelled by attaching rigid plates to the column end sections, and (iii) steel material behaviour modelled by means of Prandtl-Reuss's classical plasticity model.

It is well known that the initial geometrical imperfection shape plays a crucial role in mode interaction studies (*e.g.*, Dinis *et al.* 2007). In this work, and regardless of the stress ratio R value, all columns contained distortional initial geometrical imperfections (i) with small amplitudes (the maximum lip free edge vertical displacement is equal to 10% of the wall thickness t) and (ii) involving central half-wave outward or inward flange-lip motions - previous studies showed that outward motions are the most detrimental: they lead to the lower lipped-channel column

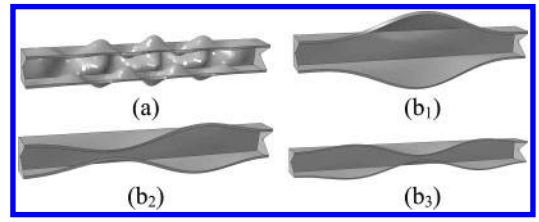

Figure 1. Initial geometrical imperfections: (a) local (multiple half-waves) and (b) distortional – (b_1) 1, (b_2) 2 and (b_3) 3 half-waves.

ultimate strengths (Dinis *et al.* 2007). Thus, when the critical buckling mode half-wave number is odd (*e.g.*, see Figs. 1(b_1) and 1(b_3)), the most detrimental imperfection corresponds to the largest number of half-wave outward flange-lip motions – when the number is even (*e.g.*, see Fig. 1(b_2)), the outward or inward shapes lead to identical ultimate strengths. Moreover, when $R > 1$ (critical local buckling) a local initial imperfection shape is also considered: its amplitude is such that the maximum mid-web flexural displacement equals 10% of wall thickness t – this imperfection "sign" is not relevant, due to symmetric nature of the column local post-buckling behaviour.

In order to cover a wide critical (L or D) slenderness range [$\lambda = (f_y/f_{cr})^{0.5}$ varying from 1.0 to 4.0 in 0.25 intervals], eleven yield stresses were considered for each imperfect column. Their maximum values ranged from 315 to 2895 MPa and involving f_{crg}/f_y always larger than 1.12. A total of 416 columns were analysed through ABAQUS SFEA (both residual stresses and corner strength effects were neglected, as they have been shown to have little impact on the column response), in order to determine their failure loads and collapse mechanisms.

The numerical ultimate strength data determined are used next to relate the R and R_y values with the relevance of the L-D interactions effects. Due to space limitations, only a representative fraction of the results obtained are presented, discussed and interpreted here – the full set of results can be found in Martins *et al.* (2013). The presentation addresses separately the identification of (i) the R limit values (closeness to 1.0) associated with "true L-D interaction", in which coupling effects gradually evolve as loading progresses (and occur regardless of the yield stress value), and (ii) the R_y limit values (large enough yield stress) required to allow the development of L-D interaction effects caused by a "secondary bifurcation" – these effects only emerge and grow as the loading nears the f_{crmax} applied stress level. The illustrative numerical results concern columns (i) C12 ($R = 1.13$), and (ii) C24 ($R = 2.39$) – no column with $R < 1.0$ is addressed in detail.

3.1 *True L-D interaction – R upper and lower limits*

After briefly presenting column C12 ($R = 1.13$ – critical local buckling) post-buckling behaviour, the relevance of the L-D interactions effects in columns with different yield stresses (R_y values) is addressed.

Figure 2(a) shows the upper portions ($P/P_{cr} > 0.5$) of the elastic-plastic P/P_{cr} vs v/t equilibrium paths (v : mid-span flange-lip corner vertical displacement) of C12 columns exhibiting (i) D or L initial imperfections and (ii) six R_y values (1.4, 2.0, 3.5, 5.5, 8.0 and ∞ – the latter corresponds to elastic behaviour). Figures 2(b), they show the deformed configurations and plastic strain distributions near collapse of columns with (i) $R_y = 2.0$ and

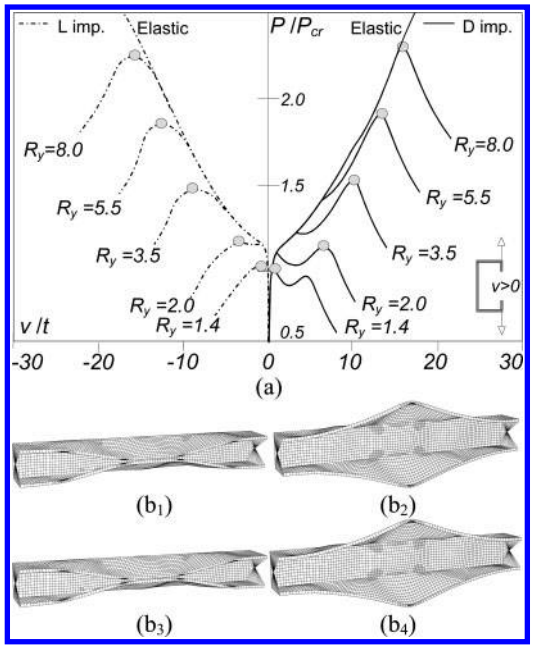

Figure 2. (a) P/P_{cr} vs v/t paths of column C12 ($R = 1.13$) with D and L imperfections, and (b) failure modes and plastic strain diagrams of the (b_1)-(b_4) $R_y = 2.0 + L$, $R_y = 2.0 + D$, $R_y = 5.5 + L$ and $R_y = 5.5 + D$ columns.

L (Fig. 2(b_1)) or D (Fig. 2(b_2)) imperfections, and (ii) $R_y = 5.5$ with L (Fig. 2(b_3)) or D (Fig. 2(b_4)) imperfections – note that the deformed configurations are amplified 10 or 2.5 times (D or L imperfections). The observation of these results prompts the following remarks:

(i) Unlike the D imperfection columns, which exhibit mid-span outward flange-lip motions, all L imperfection columns display mid-span inward flange-lip motions. This feature is due to the presence of a small amount of minor-axis bending, caused by the occurrence of effective centroid shifts towards the web (in spite of the fixed ends – Young & Rasmussen 1999). The corresponding outward web curvature "attracts" mid-span inward distortional deformations, which explains the failure modes of Figures 2(b_1) and 2(b_3).

(ii) In the columns with R_y closest to 1.0 ($R_y = 1.4$), yielding starts when the normal stress distribution is still "not too far from uniform" and, thus, precipitates a rather abrupt (imperfection-dependent) collapse.

(iii) On the other hand, in the columns with $R_y > 1.4$, first yielding occurs when normal stress distribution is already "highly non-uniform" and, thus, does not lead to an immediate failure – collapse takes place after a snap-through phenomenon and subsequent strength increase up to a limit point. As R_y increases, the snap-through becomes less pronounced (eventually barely visible) and the strength increase grows considerable-this can be confirmed by comparing the $R_y = 2.0 + D$ path with the remaining ones.

(iv) Regardless of the initial imperfections shape and R_y value, all columns with $R_y \geq 2.0$ exhibit visible L-D interaction. Moreover, note that the failure mode does not depend on R_y – *e.g.*, compare Figures 2(b_2) and 2(b_4), showing the collapse mechanisms of the $R_y = 2.0 + D$ and $R_y = 5.5 + D$ columns.

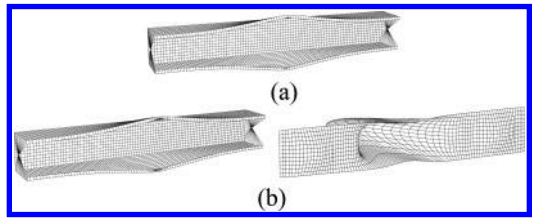

Figure 3. (a) $R = 0.78 + R_y = 1.2$ column and (b) $R = 0.86 + R_y = 1.3$ column and web deformed shapes and plastic strain diagrams at collapse.

Since L-D interaction always occurs in columns with R close to 1.0 (even if it only causes significant ultimate strength erosion for $R_y \geq 2.0$), it is important to identify when does "true L-D interaction" cease to occur, *i.e.*, the corresponding R upper and lower limits. Such limits are identified through a procedure that involves the performance of the following tasks:

(i) Select column sets with increasing and decreasing R value sequences, starting as near to 1.0 as possible, and exhibiting similar R_y values that are not too far from 1.0 (to avoid the yield stress influence).

(ii) Analyse all the columns within a set and, for each of them, observe and record the failure mode characteristics and location of the plastic strains at collapse. Only D initial imperfections are considered.

(iii) Compare the failure mode characteristics and/or collapse plastic strain patterns of the columns with similar R_y values and identify the pairs of successive R values that are associated with a change in them.

The above procedure was first adopted to identify the R lower limit associated with the presence of L-D interaction when the column critical buckling is distortional ($R < 1.0$). Figures 3(a)-(b) display the collapse modes and plastic strains of the $R = 0.78 + R_y = 1.2$ and $R = 0.86 + R_y = 1.3$ columns – note that the two column deformed shapes are amplified 3 times and the latter has its web magnified 150 times. The following conclusions can be drawn from the observation of these figures:

(i) The $R = 0.78 + R_y = 1.2$ column failure mode exhibits a perfect single-wave sinusoidal shape – there is no trace of local deformations (*i.e.*, L-D interaction).

(ii) Although barely perceptible, L-D interaction occurs near the collapse for the $R = 0.86 + R_y = 1.3$ column – the magnified deformed web shown in Figure 3(b) evidences the presence of a minute local component.

(iii) Therefore, it seems fair to argue that the emergence of L-D interaction effects takes place somewhere in between the $R = 0.78$ and $R = 0.86$ values.

A similar procedure was adopted to identify the R upper limit, which concerns columns for which critical buckling is local ($R > 1.0$). Figures 4(a)–(b) display the deformed shapes (amplified 20 times) and plastic strain diagrams of the $R = 1.41 + R_y = 1.1$ and $R = 1.35 + R_y = 1.2$ columns at the onset of collapse – note that these figures include also detailed views of the

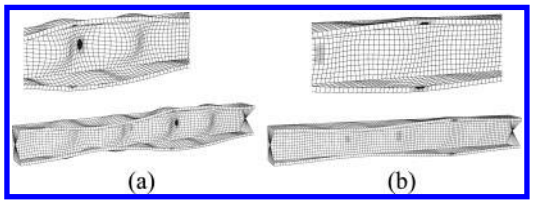

Figure 4. (a) $R = 1.41 + R_y = 1.1$ and (b) $R = 1.35 + R_y = 1.2$ column deformed shapes (with details) and plastic strain diagrams at collapse.

column region with larger outward distortional deformations. The observation of these results prompts the following remarks:

(i) Although the two failure mode configurations share the same qualitative features, namely the combination of 2 D and several L half-waves, they are quantitatively quite different. Indeed, it is very clear that the L half-waves prevail in the $R = 1.41 + R_y = 1.1$ column failure mode, while the D ones are dominant in the $R = 1.35 + R_y = 1.2$ column collapse. Since both columns have L critical buckling modes and D initial imperfections, the dominance of the L (D) deformations in the failure mode may then be attributed to the absence (presence) of L-D interaction.

(ii) The above assertion is confirmed by the plastic strain diagrams of the two columns at the onset of collapse. In the $R = 1.41 + R_y = 1.1$ column, yielding starts at the web and flange crests (*i.e.*, central areas) of the most deformed L half-wave (see detail in Fig. 4(a)), which is a clear indication of a local failure (no visible L-D interaction occurs). In the $R = 1.35 + R_y = 1.2$ column, on the other hand, yielding starts at the lip free edge regions of the mid-span cross-section (see detail in Fig. 4(b)), which is the trademark of a distortional failure – thus, L-D interaction takes place.

(iii) Thus, it may be argued that L-D interaction effects wane somewhere in between $R = 1.35$ and $R = 1.41$.

Finally, it is worth noting that (i) the above R limits are in agreement with the findings of Dinis *et al*. (2009) and (ii) Silvestre *et al*. (2012) investigated the detrimental L-D interaction effects in columns with nearly coincident L and D critical buckling stresses ($0.9 < R < 1.1$).

3.2 *Secondary bifurcation – R_y lower limits*

As mentioned earlier, L-D interaction may occur even when the L and D critical buckling stresses are far apart, *i.e.*, when R not close to 1.0. This interaction, associated with a secondary bifurcation, takes place if R_y (*i.e.*, the yield stress) is "large enough" to allow for the emergence and development of coupling before plasticity precipitates failure. Although this type of interaction may occur when $R > 1.0$ (L buckling is critical) or $R < 1.0$ (D buckling is critical), the first case is clearly more relevant, due to the higher L post-critical strength – due to space limitations, only this case is dealt with here (columns with R < 1.0 are addressed in Martins *et al.* 2013).

To illustrate the L-D interaction R_y-dependence, Figure 5(a) depicts the upper portions ($P/P_{cr} > 0.75$) of the column C24 ($R = 2.39$) elastic-plastic P/P_{cr} vs v/t equilibrium paths associated with (i) D or L initial imperfections and (ii) $R_y = 0.9,\ 1.7,\ 2.6,\ 3.8,\ \infty$. Figures

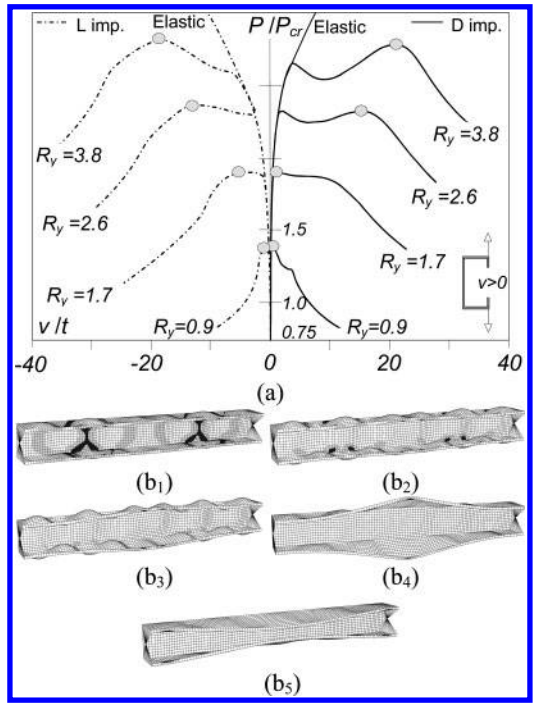

Figure 5. (a) P/P_{cr} vs v/t paths of column C24 ($R = 2.39$) with D and L imperfections, and (b) failure modes and plastic strains of the (b_1)-(b_5) R_y =0.9+D, R_y =1.7+D, $R_y = 2.6 + \mathrm{D}$, $R_y = 3.8 + \mathrm{D}$ and $R_y = 3.8 + \mathrm{L}$ columns.

5(b_1)–(b_5) show the plastic strains diagrams at the onset of collapse of columns exhibiting (i) D imperfections and $R_y = 0.9$, $R_y = 1.7$, $R_y = 2.6$ or $R_y = 3.8$, and (ii) L imperfections and $R_y = 3.8$ – the first 4 deformed shapes are amplified 20 times, and the fifth only 3 times. The observation of all these figures leads to the following comments:

(i) The $R_y = 0.9$ columns collapse abruptly with no trace of L-D interaction (see Fig. 5(b_1)).

(ii) The$R_y = 1.7$ and $R_y = 2.6$ columns exhibit local failures even in the presence of D initial imperfections (see Figs. 5(b_2)–(b_3) – no L-D interaction occurs).

(iii) Both the $R_y = 3.8$ columns with D and L imperfections exhibit L-D interaction (see Figs. 5(b_4)-(b_5)) and fail after a snap-through and subsequent applied load increase (see Fig. 5(a)). Moreover, note that, similarly to what was observed in Figures 2(a)–(b), the column with D (L) imperfections exhibits mid-span outward (inward) flange-lip motions – in the latter case, due to global bending caused by the effective centroid shift effects.

(iv) Thus, for this particular column (R value), it can be said that L-D interaction only develops if R_y is larger than a value comprised between 2.6 and 3.8. Similar investigations for columns C16 ($R = 1.45$) and C17 ($R = 1.60$) led to the determination of the following R_y lower limits for the occurrence of visible L-D interaction effects: 1.10-1.60 and 1.40-1.90. In the future, these intervals will be refined and additional ones will be obtained for other columns.

4 DIRECT STRENGTH METHOD (DSM) DESIGN

The current DSM design curves for cold-formed steel columns, defined by "Winter-type" expressions, provide mostly safe and accurate ultimate strength estimates associated with local, distortional, global and local-global interactive failures on the basis of elastic critical buckling and yield stresses – the expressions for the DSM nominal local (f_{nl}) and distortional (f_{nd}) strengths can be found, for instance, in Schafer's state-of-the-art report (2008).

The numerical ultimate strengths (f_u) obtained in the investigations reported in the previous section are now compared with the estimates provided by the current DSM local and distortional strength curves. The aim of this comparison is to assess how the combined values of R and R_y affect the ultimate strength erosion stemming from the L-D interation effects and, in particular, to provide preliminary guidelines on the relevance of such effects – due to space limitations, the results presented concern only a representative sample of the columns analysed, selected to cover the whole R range considered: columns C5-9-11-14-18-20-22-24, corresponding to $R = 0.58$-0.86-1.07-1.35-1.66-1.86-2.15-2.39. Each column was analysed with 11 distinct yield stresses, thus making it possible to cover a quite wide critical (distortional or local) slenderness range.

Figures 6(a)-(h) show the variations of f_u/f_y with λ_l or λ_d for the 8 columns listed in the previous paragraph. While for the columns buckling distortionally ($R < 1.0$) only D initial imperfections were considered, all the columns buckling locally ($R > 1.0$) were analysed with L (white circles) and D (grey circles) initial imperfections – the numerical f_u/f_y values are compared, separately, with their estimates provided the current DSM L and D strength curves. The comparative analysis of all these ultimate strength results prompts the following remarks:

(i) First of all, note that all the numerical f_u/f_y values are well aligned along "Winter-type" curves.

(ii) The DSM D curve predicts very well all the $R = 0.58$ column ultimate strengths, thus evidencing the absence of erosion due to L-D interaction effects.

(iii) The quality of the DSM D curve estimates decreases a bit for the $R = 0.86$ columns: a few overestimates in the intermediate slenderness range and practically no overestimations, reflecting the presence of just mild L-D interaction effects.

(iv) For the columns with $R > 1.0$, the first remark concerns the fact that the vast majority of the f_u values associated with L and D initial imperfections are virtually coincident, even if critical buckling is local. The few exceptions are stocky columns whose ultimate strengths are generally very well predicted by the DSM L curve, which means that they are not affected by L-D interaction (low R_y values).

(v) Secondly, practically all the most slender columns with $R > 1.0$ have failure loads clearly overestimated by the DSM L and D curves – an undeniable sign of significant L-D interaction (high enough R_y values).

(vi) Lastly, it may be concluded that, generally speaking, the ultimate strengths of the columns with $R > 1.0$ tend to be less overestimated by the DSM L curve as R increases (switch from "true L-D interaction" to "secondary bifurcation) and λ_l decreases (lower R_y values), which corresponds to less relevant L-D interaction effects (as assessed earlier) – the number of fairly accurate estimates, indicating local failures,

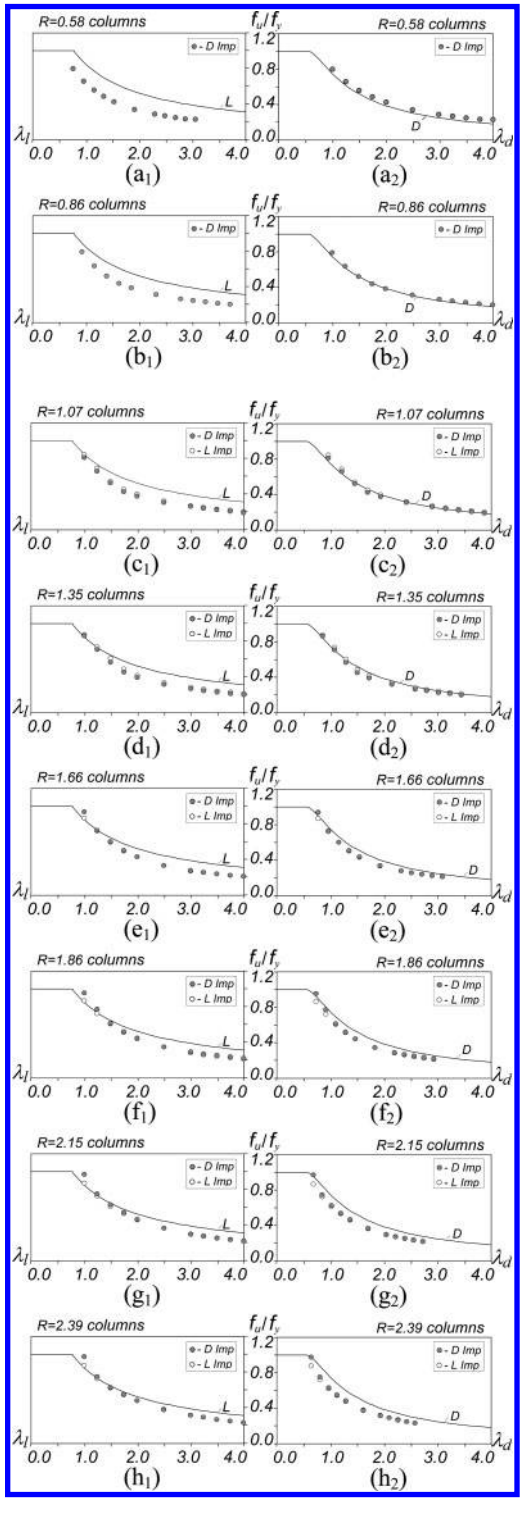

Figure 6. Variation of f_u/f_y with $(_1)\,\lambda_l$ or $(_2)\,\lambda_d$ for the (a)-(h) $R = 0.58$, $R = 0.86$, $R = 1.07$, $R = 1.35$, $R = 1.66$, $R = 1.86$, $R = 2.15$, $R = 2.39$ columns.

grows with R. Conversely, the DSM D curve provides overestimates that increase as R increases and λ_l decreases – for $R \leq 1.35$, these overestimations are invariably quite small and only become "visible" for columns with intermediate slenderness values.

5 CONCLUDING REMARKS

A numerical investigation about the relevance of L-D interaction effects on the post-buckling behaviour, ultimate strength and DSM design of fixed-ended cold-formed lipped channel columns was reported. The 416 columns analysed had cross-section dimensions, lengths and yield stresses selected to ensure a wide variety of ratios between the (i) D and L critical buckling stresses, and (ii) yield and critical buckling stresses. The ensuing results made it possible to reach preliminary (and limited) conclusions on the identification of the combinations of these ratios for which L-D interaction is relevant, *i.e.*, erodes visibly the ultimate strength of lipped channel columns and alters their failure modes. After providing numerical evidence about the presence or absence of L-D interaction, its influence on the ultimate strength erosion was assessed by comparing the numerical column failure loads with their estimates provided by the current DSM local and distortional strength curves – an overestimation by the two curves naturally implies the occurrence of more or less ultimate strength erosion.

The numerical results presented and discussed in this work, concerning lipped channel columns, provided clear evidence that cold-formed steel columns may be affected by two types of L-D interaction: (i) one associated with relatively close L and D critical buckling stresses, characterised by the simultaneous occurrence of L and D deformations since the early loading stages and denoted as "true L-D interaction", and (ii) the other stemming from a "secondary bifurcation", which occurs when the not so close L and D critical buckling stresses are well below the yield stress. However, further research is still required before it is possible to quantify adequately the relevance of the L-D interaction effects – moreover, it is also necessary to consider additional cross-section shapes.

The fruits of this ongoing investigation will help to (i) define the field of application and (ii) asses the merits of the existing DSM design methods to account for L-D interaction, proposed in quite specific/limited contexts.

Design of Z-section purlins under combined axial compression and bending

J. Becque
The University of Sheffield, Sheffield, South Yorkshire, UK

K.J.R. Rasmussen
The University of Sydney, Sydney, New South Wales, Australia

ABSTRACT: The paper presents a design methodology for Z-section purlins subject to combined axial compression and bending. A specific application arises when Z roof purlins are used as temporary struts in between portal frames during construction and are thus subject to compression resulting from wind loading on the frames in combination with their self-weight. In order to arrive at an economic design, the rotational restraint provided by the purlin end connections, as determined from an experimental program, is taken into account through a rational column buckling analysis. Simple span purlins, as well as purlins lapped with an adjacent span, are considered. The effects of fly-bracing and bridging are also studied.

1 BACKGROUND

As part of a fast and economical way to construct steel framed buildings, roof purlins are often counted upon during the construction phase to act as struts in between the main frames (Fig. 1).

In this situation, before the attachment of roof and wall sheeting, the purlins are subjected to an axial compressive load as a result of wind loading perpendicular to the frames (which accumulates over consecutive bays), in combination with bending moments resulting from the self-weight. Since the principal axes of a Z-section are inclined relative to the vertical, the self-weight results in biaxial bending.

Despite the fact that this only constitutes a temporary situation, it is paramount that the proposed design process is at the same time safe and economical. The latter can be achieved by incorporating the beneficial effect of the rotational end restraints provided by the connections. Three types of purlin-to-rafter connections were considered in this research (Fig. 2):

a. a purlin connected to the rafter through a cleat plate with two bolts (in what follows referred to as a 'simple connection')
b. a purlin connected to a cleat plate and lapped with an adjacent (unloaded) span (a 'continuous connection')
c. a purlin connected to a cleat plate, without lapping, but connected to the rafter by additional fly-bracing. The primary purpose of the fly-bracing is to stabilize the bottom flange of the rafter under uplift wind loading.

Single purlins as well as purlin pairs connected by bridging were considered in this research. Three different cross-sections were part of the investigation: Z200-15, Z200-19 and Z200-24. Their (nominal) geometry is detailed in Figure 3 and Table 1. All purlins were made of G450 steel to AS 1397 (2011) with a nominal yield stress of 450 MPa.

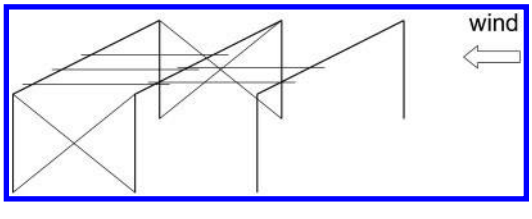

Figure 1. Purlins temporarily used as struts during construction.

2 EXPERIMENTAL PROGRAM

An experimental program was set up to measure the amount of rotational restraint provided by the three different connections previously mentioned.

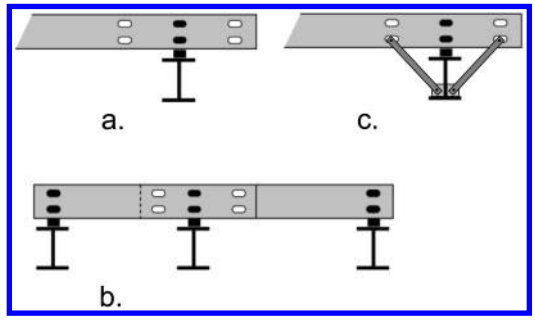

Figure 2. Purlin-to-rafter connections.

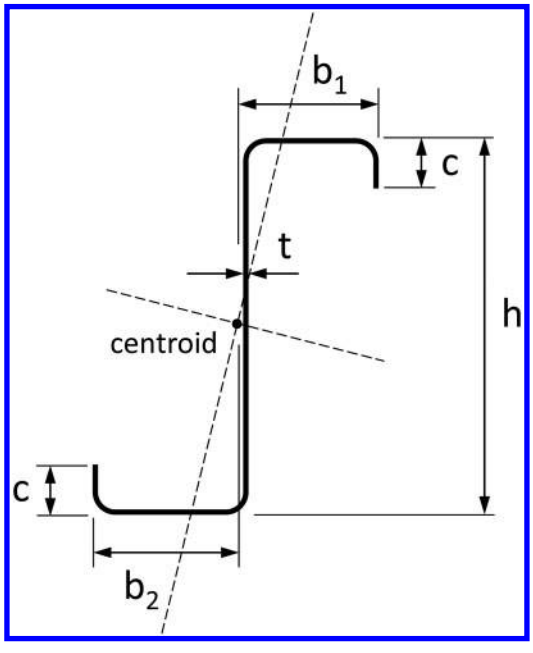

Figure 3. Cross-section geometry.

Table 1. Cross-sectional dimensions.

	h mm	t mm	c mm	b_1 mm	b_2 mm
Z200-15	203.0	1.5	16.0	74.0	79.0
Z200-19	203.0	1.9	19.5	74.0	79.0
Z200-24	203.0	2.4	21.0	74.0	79.0

The restraint was measured about both a horizontal and a vertical axis of bending. Figure 4 shows a typical test set-up. A purlin segment was bolted to a cleat plate, welded to a 360UB45 rafter stub, using two M12 grade 4.6 bolts. A 32 kN jack, placed at a distance of 0.5 m from the centerline of the connection, was then used to apply an increasing moment while maintaining the displacement rate at 0.2 mm/s.

All tests were carried out on Z200-15 purlins. Since this cross-section featured the thinnest web out of the three cross-sections considered, the tests yielded conservative values for the rotational stiffness of the connections. Three identical tests were carried out for each connection type and for each axis of rotation. Figure 5 shows the set-up used for a continuous connection, where the load was applied on a cantilever purlin, lapped over a distance of 2.2 m with an adjacent 11.5 m span. A span length of 11.5 m is the maximum length used in practical applications and therefore conservative test results were obtained for the rotational restraint of a continuous connection. Significant sagging and twisting of the purlin at mid-span was observed, even before applying any load.

Figure 4. Experimental set-up: simple connection.

Figure 5. Experimental set-up: continuous connection.

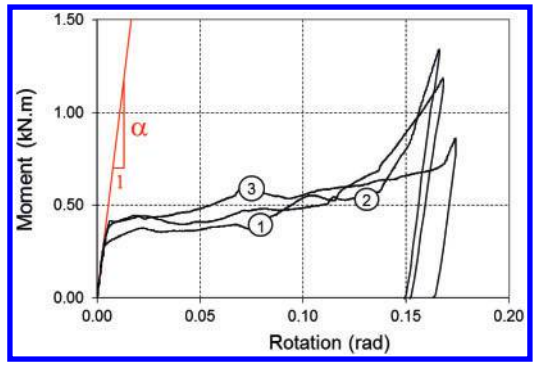

Figure 6. Moment-rotation diagram (simple connection rotating about horizontal axis).

By way of an example, Figure 6 shows the moment-rotation diagram of a simple connection about the horizontal X-axis. The initial rotational stiffness values α before slip occurred are listed in Table 2 for all tests. The standard deviations σ and the coefficients of variation V over each set of three tests are also listed. Average stiffness values are indicated by

Table 2. Calculation of (α_{Xc}, α_{Yc}); α and σ in kNm/rad.

	simple		continuous		simple + fly-brace	
	α_Y	α_X	α_Y	α_X	α_Y	α_X
Test 1	-	81.2	24.2	221	8.77	1850
Test 2	1.84	90.5	22.9	242	5.87	2823
Test 3	1.94	87.9	23.7	352	6.12	3292
α_{Xm}, α_{Ym}	1.89	86.5	23.6	272	6.92	2655
σ_α	0.071	4.80	0.66	70	1.61	736
V_α	0.037	0.055	0.028	0.26	0.23	0.28
α_{Xc}, α_{Yc}	1.33	60.9	16.6	191	4.87	1868

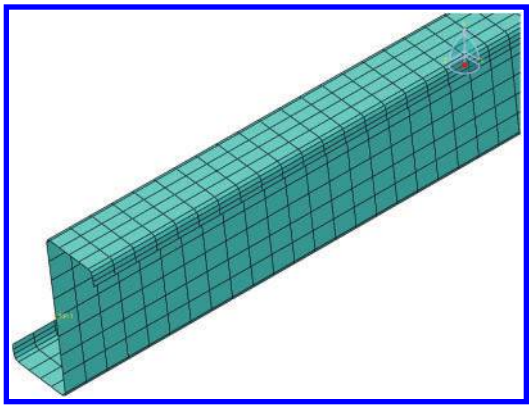

Figure 7. FE mesh.

α_{Xm} and α_{Ym}, while α_{Xc} and α_{Yc} stand for characteristic values, obtained by subtracting twice the standard deviation σ from the average.

It is seen from Table 2 that the restraint provided about the vertical Y-axis by any type of connection is rather small. Lapping the purlin with an adjacent span significantly increases the rotational restraint about a horizontal axis, while adding fly-bracing results in the most pronounced increase.

3 NUMERICAL SIMULATIONS

The finite element (FE) software package ABAQUS/CAE v6.5 was used to study (i) single purlins, and (ii) a pair of purlins with one, two or three lines of bridging, under a combination of self-weight and axial compression. Since practical span lengths range from 8.5 m to 11 m, simulations were carried out for lengths of 8.5 m, 10 m and 11.5 m, while Z200-15, Z200-19 and Z200-24 cross-sections were included.

The S4R element, a 4-node shell element with reduced integration, was used in the simulations. This element accounts for finite membrane strains and arbitrarily large rotations and is therefore suitable for large-strain geometrically non-linear analyses. A convergence study was carried out to determine a suitable mesh size. The mesh is shown in Figure 7.

Table 3. Z200-15 purlin ultimate strength axial capacities.

	Number of lines of bridging			
	0	1	2	3
L	N_u	N_u	N_u	N_u
m	kN	kN	kN	kN
8.5	6.77	6.82	6.82	6.82
10.0	4.56	5.21	5.32	5.36
11.5	3.11	4.42	4.79	4.88

The rotational end restraint provided by the connections was modeled using non-linear rotational springs with the actual moment-rotation behavior determined from the experimental program.

Geometrically non-linear analyses were carried out in two steps. In a first step, only the self-weight of the purlin was applied. In a second step, the purlin was compressed, in the presence of the self-weight, by imposing a displacement in the axial direction at one of the supports.

For purlins with bridging, the bridging was modeled as a 65 mm deep channel with 30 mm wide flanges, in accordance with typical industry practice. At both ends of the bridging channel the webs were allowed to rotate about the connecting line with the purlin web, while the flanges were left unconnected. The effect of installing bridging is illustrated in Table 3, which lists the ultimate capacities in compression in the presence of self-weight for single Z200-15 purlins and Z200-15 purlins with one, two and three lines of bridging. Not surprisingly, the effect of the bridging appears to be most beneficial for the longer 10 m and 11.5 m span purlins.

The main purpose of these FE studies was to numerically confirm the validity of the design equations proposed in Section 5 of this paper.

4 RATIONAL COLUMN ANALYSIS

In a first step towards the development of a design methodology, the stability of a Z-purlin under axial compression only, but taking into account rotational end restraints, was investigated. The problem is complicated by the fact that the rotational end restraints act about horizontal and vertical axes, while the principal bending axes of the section are inclined. In a general case, this leads to a coupling of the buckling displacements through the boundary conditions, resulting in simultaneous buckling about both principal axes, as demonstrated by Rasmussen and Trahair (2005). In order to be applicable to the problem under consideration, where different amounts of restraint may be encountered at both ends (e.g. a simple connection at one end and a lapped connection at the other end), the theory by Rasmussen and Trahair (2005) first needed modification.

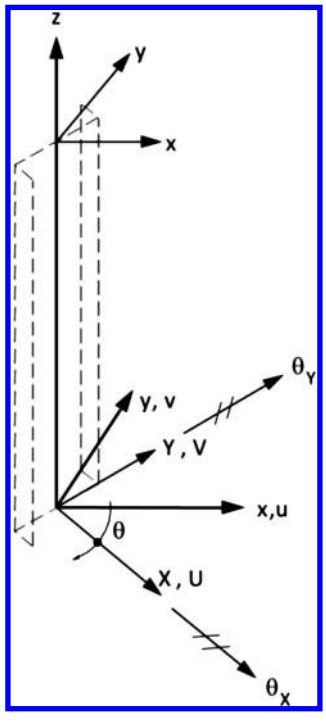

Figure 8. Coordinate systems.

Figure 8 depicts a column which is elastically restrained against rotations about oblique (X, Y)-axes, rotated over an angle θ from the principal (x, y)-axes.

At $z = 0$, the elastic external restraining moments about the X and Y axes are

$$\overline{M}_{X0} = \alpha_{X0}\theta_{X0} \qquad \overline{M}_{Y0} = \alpha_{Y0}\theta_{Y0} \tag{1}$$

where $(\alpha_{X0}, \alpha_{Y0})$ are the rotational rigidities of the supports at $z = 0$ and $(\theta_{X0}, \theta_{Y0})$ are the rotations about the X and Y axes at $z = 0$:

$$\theta_{X0} = -\left.\frac{dV}{dz}\right|_{z=0} \qquad \theta_{Y0} = \left.\frac{dU}{dz}\right|_{z=0} \tag{2}$$

Similarly, at the opposite end, $z = L$, external restraining moments about the X and Y axes are:

$$\overline{M}_{XL} = \alpha_{XL}\theta_{XL} \qquad \overline{M}_{YL} = \alpha_{YL}\theta_{YL} \tag{3}$$

where $(\alpha_{XL}, \alpha_{YL})$ are the rotational rigidities of the supports at $z = L$ and $(\theta_{XL}, \theta_{YL})$ are the rotations about the X and Y axes:

$$\theta_{XL} = -\left.\frac{dV}{dz}\right|_{z=L} \qquad \theta_{YL} = \left.\frac{dU}{dz}\right|_{z=L}. \tag{4}$$

The governing differential equations (DEs) for flexural buckling are (Timoshenko & Gere 1961; Trahair 1993):

$$(EI_y u'')'' + (Nu')' = 0 \tag{5}$$

$$(EI_x v'')'' + (Nv')' = 0 \tag{6}$$

where EI_x and EI_y are the flexural rigidities for bending about the principal x and y axes respectively and (u, v) are the principal axis displacements as shown in Figure 7. It is assumed that $EI_x \geq EI_y$.

Assuming the flexural rigidities and the internal compressive force (N) are constant along the column, the exact solution to the DEs is:

$$u = C_1 \sin\left(\frac{\sqrt{n}\pi z}{L}\right) + C_2 \cos\left(\frac{\sqrt{n}\pi z}{L}\right) + C_3 \frac{z}{L} + C_4 \tag{7}$$

$$v = C_5 \sin\left(\frac{\sqrt{en}\pi z}{L}\right) + C_6 \cos\left(\frac{\sqrt{en}\pi z}{L}\right) + C_7 \frac{z}{L} + C_8 \tag{8}$$

where and $C_1 \ldots C_8$ are arbitrary constants, and n and e are non-dimensional measures of the buckling load and the flexural rigidity (EI_x):

$$n = \frac{N_E}{N_{Ey}} \tag{9}$$

$$e = \frac{EI_x}{EI_y}. \tag{10}$$

In Eq.(9), N_E is the buckling load and N_{Ey} is the Euler load for flexural buckling about the minor y-axis without the presence of restraints:

$$N_{Ey} = \frac{\pi^2 EI_y}{L^2}. \tag{11}$$

The boundary conditions (BCs) are:

$$u = v = 0 \qquad \text{at } z = 0, L \tag{12}$$

$$\overline{M}_{X0} = M_{X0} \qquad \overline{M}_{Y0} = M_{Y0} \qquad \text{at } z = 0 \tag{13}$$

$$\overline{M}_{XL} = -M_{XL} \qquad \overline{M}_{YL} = -M_{YL} \qquad \text{at } z = L. \tag{14}$$

where (M_X, M_Y) are the bending moments about the oblique $X-$ and Y-axes.

To determine the rotations (θ_X, θ_Y), we obtain the displacements in the oblique axis directions:

$$U = u\cos(\theta) + v\sin(\theta) \tag{15}$$

$$V = v\cos(\theta) - u\sin(\theta) \tag{16}$$

and utilize:

$$\theta_X = -\frac{dV}{dz} \tag{17}$$

$$\theta_Y = \frac{dU}{dz}. \tag{18}$$

To determine the bending moments (M_X, M_Y) we obtain the bending moments (M_x, M_y) about the principal (x, y)-axes:

$$M_x = -EI_x v'' \tag{19}$$

$$M_y = EI_y u'' \tag{20}$$

and utilize:

$$M_X = M_x \cos(\theta) + M_y \sin(\theta) \tag{21}$$

$$M_Y = M_y \cos(\theta) - M_x \sin(\theta). \tag{22}$$

Equations (13, 14) can be expressed in terms of the displacements (u, v) by combining Eqs. (1–4, 19–22), where the displacement functions satisfying the DEs are given by Eqs. (7–8). On making the substitutions, the boundary conditions yield eight homogeneous equations in $C_1 \ldots C_8$ which may be arranged as:

$$[K]\{C\} = \{0\} \tag{23}$$

Non-trivial solutions are obtained by requiring:

$$\det([K]) = 0 \tag{24}$$

which produces an implicit equation in the non-dimensional buckling load n.

5 DESIGN EQUATIONS

5.1 *Single Z purlins without bridging*

It is proposed that the capacity of a single Z purlin subject to combined axial load N* and self-weight is determined from the following equation:

$$\frac{N^*}{\phi_c N_c} + \frac{M^*}{\phi_b M_{cy} \alpha_m} \le 1.0 \tag{25}$$

where ϕ_c and ϕ_b are the resistance factors applied to the ultimate capacity of the member in compression and bending, respectively. In the context of AS/NZS4600 (2005) (concurrent with the AISI (2007) guidelines for cold-formed steel): $\phi_c = 0.85$ and $\phi_b = 0.95$. N* and M* are the design values of the axial force and the mid-span (self-weight) moment, respectively. When calculating N_c, the capacity of the purlin under pure axial compression, the effect of the purlin end restraints may be brought into account by calculating the elastic Euler buckling load N_E according to the rational analysis explained in the previous paragraph.

M_{cy} is the section moment capacity about the minor principal axis. The Z200-15, Z200-19 and Z200-24 sections are thereby fully effective with respect to local buckling.

The moment amplification factor α_m in Eq. (25) is determined as:

$$\alpha_m = 1 - \frac{N^*}{N_E} \tag{26}$$

Figure 9. Z purlin in unrestrained bending.

where the Euler buckling load N_E may again be determined from a rational buckling analysis.

The proposed design equation (25) originates from the experimental observation that, in the presence of a bending moment, the cross-sections of the purlin near mid-span tend to rotate until, eventually, the minor principal axis is nearly aligned with the horizontal (Fig. 9).

The ultimate capacities obtained in the finite element models were compared to the predictions of Eq. (25) with the resistance factors set equal to 1.0. It was concluded that the proposed equation (25) results in safe predictions for all cases studied. The error is within the range of 15%–19% for the simple span purlins and within 11-18% for the purlins with one simple connection and one lapped connection. Load tables can be derived from Eq. (25) for relevant span lengths, cross-sections and end conditions and are provided in Becque & Rasmussen (2012).

5.2 *Z Purlins with bridging*

It was found that Z purlins with bridging, subject to combined self-weight and axial load, may safely be designed using the existing interaction equation of AS/NZS4600 (2005) (or AISI 2007):

$$\frac{N^*}{\phi_c N_c} + \frac{C_{mx} M_x^*}{\phi_b M_{cx} \alpha_{mx}} + \frac{C_{my} M_y^*}{\phi_b M_{cy} \alpha_{my}} \le 1.0 \tag{27}$$

The axial load capacity as determined from Eq. (27), however, should not be less than the capacity determined from Eq. (25) in the absence of bridging. M_x^* and M_y^* are obtained by projecting the design self-weight moment M* onto the principal axes x and y of the cross-section. M_{cy}, N*, N_c, ϕ_c and ϕ_b are as previously defined under Section 5.1, and C_{mx} and C_{my} may be taken as 0.85, as per AS/NZS 4600.

The effect of the rotational end restraint may be taken into account by calculating the buckling load

N_E, used to determine N_c, from the rational analysis in Section 4. The moment amplification factors α_{mx} and α_{my} are determined from Eq. (26), where N_E is taken as the Euler buckling load about the x- or the y-axis, respectively, taking into account the effect of the rotational end restraints.

In Eq. (27), M_{cx} is the member moment capacity about the major principal axis. When applying AS/NZS4600 (2005), M_{cx} is the minimum of the flexural-torsional buckling capacity, taking into account local buckling, and the distortional moment capacity M_d. M_d was calculated based on a distortional slenderness value λ_d obtained from the software package ThinWall (Papangelis & Hancock 1995) and found to be equal to 8.75 kNm for the Z200-15 section, 12.90 kNm for the Z200-19 section and 18.01 kNm for the Z200-24 section.

Eq. (27) (with $\phi_b = \phi_c = 1.0$) matches the results of the FE simulations within 0%-34%, while consistently erring on the safe side. Load tables based on Eq. (27) for Z200-15, Z200-19 and Z200-24 purlins with one, two or three lines of bridging and various span lengths and end conditions are provided in Becque & Rasmussen (2012).

6 CONCLUSIONS

This paper presents practical design equations which cover the stability of Z-section purlins under combined axial force and self-weight bending. Single purlins, as well as purlins with one or more lines of bridging were considered. The results of an experimental program are presented which aimed to measure the degree of rotational end restraint of three different connections: a simple cleat plate connection, a connection with fly-bracing and a lapped connection. It is shown how the beneficial effect of these end restraints on the purlin stability can be taken into account through a rational column buckling analysis. It is seen that significant gains in the elastic column buckling capacity can thus be obtained, ranging from 34% on average for a simply supported Z-purlin to 69% for a Z-purlin lapped at one end and more than 100% for a Z-purlin with fly-bracing at one end. When compared to detailed FE analyses, the proposed design equations are consistently safe with an average difference in ultimate capacity of 15%.

Buckling of cold-formed lipped-channel stub columns

M. Dundu
University of Johannesburg, Johannesburg, South Africa

J. Lim
Queen's University Belfast, Belfast, UK

ABSTRACT: This paper presents an experimental investigation of short cold-formed lipped-channel columns compressed between pinned ends. The short columns are subjected to pure axial compressive loading. A total of 12 column specimens are tested and the columns are categorised into three groups depending on the length and thickness. The buckling modes of failure that occurred include local buckling and distortional buckling. A comparison of the experimental results with the loads predicted by the South African standard for the design of cold-formed steelwork code (SANS 10162-2) shows that the code is not conservative enough to cater for these columns.

1 INTRODUCTION

Cold-formed lipped short columns are vulnerable to local or distortional buckling or both, because of the high width-to-thickness ratios of the web and/or flange. Local buckling (LB) occurs when the line junction of both corners do not change, with the adjoining lip, flange and web elements failing by plate flexure alone (Fig. 1(a)). Distortional buckling occurs in thin-walled channel sections when the lip-stiffened flange of the section rotates about the flange-web junction. This usually occurs if the lip stiffener does not have enough stiffness to prevent the flange from rotating. The rotation can cause the flange to either move outward (Outward distortional buckling (ODB)) or inward (Inward distortional buckling (ODB)) depending on the nature of the load, supporting system or imperfections. At ultimate failure, both rotations can be accompanied by the bending of the web (Figure 1 (b) and (c)). The wavelength of this mode of failure is in most cases between that of local and overall member buckling, which makes it a practical member length.

The aims of this paper are to investigate the behaviour (buckling failure modes) and the strength (compressive resistance) of short cold-formed lipped channel sections. According to Ziemian (2010), a short column is defined as a member that is sufficiently short so as to preclude member buckling when compressed, but sufficiently long to contain the same initial residual stress pattern as a much longer member cut from the same stock. For cold-formed steel sections, the stub-column length should be sufficiently long to exhibit local buckling as well as the effect of cold-forming on the column performance. The length of cold-formed stub columns should not be less than three times the largest dimension of the cross-section and no more than 20 times the least radius-of-gyration.

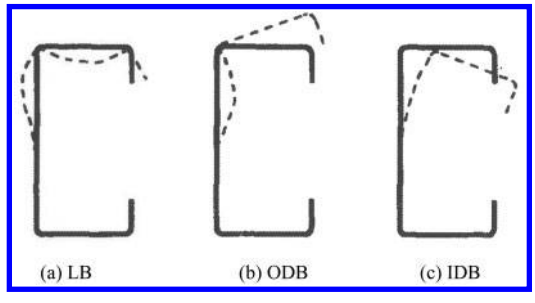

Figure 1. Local and distortional buckling modes.

Table 1. Dimensions of the columns.

	1250	4.50	25.1	900	502

The cold-formed lipped sections tested are given in Table 1, and do not comply with the length provisions for a short column, determined by Ziemian (2010). In this table L is the length of the stub

Table 2. Average material properties.

Specimen	f_y (MPa)	f_u (MPa)	ε_u (%)	E (MPa)
300 × 75 × 20 × 2.0	242.79	344.88	20.37	200 766
300 × 75 × 20 × 2.5	282.26	372.20	16.86	203 058
300 × 75 × 20 × 3.0	258.94	350.42	20.35	206 308

column, h is the depth, b is the width, c is the size of the lip, t is the thickness, r_i is the internal radius and r_y is the radius of gyration of the section. To cover a wider range of lengths it was decided to test three specimens of each section size (Table 1). The 300 × 75 × 20 × 2.0, 300 × 75 × 20 × 2.5 and 300 × 75 × 20 × 3.0 are abbreviated as C2.0, C2.5 and C3.0 in Table 3, respectively.

2 MATERIAL PROPERTIES

The material properties of the cold-formed column sections were determined from coupon tests. Three longitudinal coupons were cut from the web to establish the yield stress, ultimate stress, elastic modulus and the elongation of the material. The coupons were prepared and tested according to the British Standard, BS 18. A 1195 Instron testing machine with an ultimate capacity of 100 kN was utilized to test the coupons. The tensile load was applied at a low rate of 3 mm/min. A calibrated extensometer was utilized to measure the strain. The average material properties are shown in Tables 2. In this table, f_y is the 0.2% proof yield strength, f_u is the ultimate strength, E is the elastic modulus and ε_u is the strain at fracture based on a gauge length of 50 mm. These values were established from stress – strain curves obtained from coupon tests. The 0.2% yield strengths were used to calculate the theoretical strengths of the columns.

3 TEST PROCEDURE

A total of 12 short columns were tested under pure axial compressive loading. The specimens were delivered by the manufacturer in lengths of 6 m. Each specimen was cut to a specified column length. The ends of the columns were machined flat and the load was applied at the centroid to ensure a uniform distribution of the load throughout the entire cross-sectional area of the column. The load was applied through 2 thick plates with grooves at the centre to accommodate a spherical ball, so as to simulate a pin. A Moog testing machine with an ultimate capacity of 2000 kN was used for the experimental test. To allow gradual failure of the columns, the load was applied at a rate of 2 mm/min. A schematic experimental set-up is shown in Figure 2. The testing machine measured the axial compressive load and displacement.

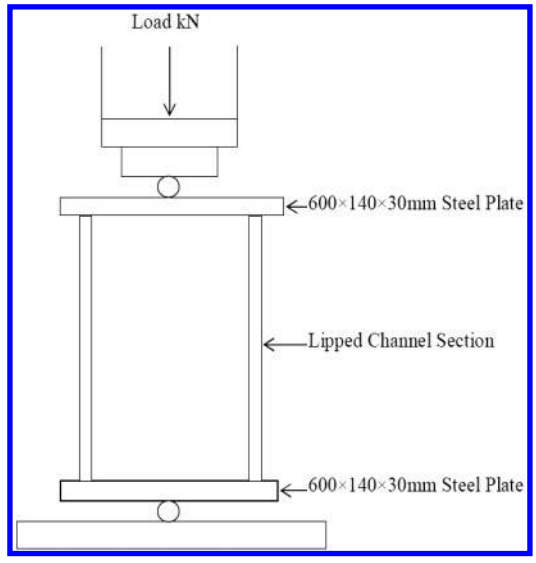

Figure 2. Schematic test setup.

4 TEST RESULTS

The experimental compressive resistance (P_{EX}), gross squash load ($P_Y = A_g f_y$), effective squash load ($P_{EY} = A_{ef} f_y$) and the buckling compressive resistance ($P_C = A_{ef} f_c$) are given in Table 3. The effective area (A_{ef}) is determined using the effective width method, where the channel lips area, the flanges area and the web area of the column are analysed separately, and P_Y and P_C are calculated using the stress conditions of $f = f_y$ and $f = f_c$, respectively. The predicted resistance values are obtained using the South African code, SANS10162-2. This code is based on the Canadian code, CAN/CSAS16.1-M01 and the North American Specification, AISI S100-07.

Table 3 shows that there is not much difference between the experimental compressive resistances of the chosen lengths of each specimen. This implies that

both lengths of columns can be classified as short. If this is the case then it is not appropriate to use the length suggested by Ziemian (2010), for these cold formed sections. In order to classify the length of these sections it is proposed to adopt the length classification for hot-rolled stub columns. According to this classification, the length of hot-rolled stub columns should not be less than $(2d + 250\,\text{mm})$ or $3d$, whichever is smaller, and not greater than $20r_y$ or $5d$, whichever is larger, where d is the depth of the shape and r_y is radius-of-gyration about the minor axis. This classification is wide enough to accommodate these sections.

Table 3 also shows the experimental buckling resistance to be almost 50% of the gross-sectional yield resistance for the $300 \times 75 \times 20 \times 2.0$ and $300 \times 75 \times 20 \times 2.5$ specimens. This percentage reduces to about 45% for the $300 \times 75 \times 20 \times 3.0$ specimens. This huge decrease in resistance clearly shows the importance of considering local and distortional buckling in such members. The effect is also seen in the corresponding effective yield and the buckling resistances. The difference in column strength between the sections tested is as a result of the different thickness, yield strengths and the magnitude of the residual stresses.

A clear trend can be seen here; the ratio of the experimental strength to the predicted strength decreases with increase in thickness of the specimen. Residual stresses tend to affect thicker sections and are responsible for the lower strength ratio of the $300 \times 75 \times 20 \times 3.0$. One other confirmation that the tested columns are actual short is that the effective yield resistance and the buckling resistance are almost the same.

A comparison of the tests results and calculated unfactored resistances shows that the SANS 10162-2 specification and its related specifications (CAN/CSA S16.1-M01 and AISI S100-07) overestimates the compressive strengths of short cold-formed lipped channel columns. On average the tests loads for the $300 \times 75 \times 20 \times 2.0$, $300 \times 75 \times 20 \times 2.5$, $300 \times 75 \times 20 \times 3.0$ specimens are 87%, 81% and 66% of the effective squash or buckling loads predicted by SANS 10162-2, respectively. For the $300 \times 75 \times 20 \times 3$, the average difference between the test results and the code predicted strength is 34%. The largest cause of this low resistance is local buckling and distortional buckling. Local buckling occurred at the end of the column in the 500 mm, 750 mm, and 1000 mm length columns and may have been initiated by the cutting process. Lam Wang and Chung (2006), and Wang, Lam and Chung (2006) found that the cutting process causes cross-section distortion and initial geometric imperfection, which in turn influences the buckling capacities of the short columns. In this investigation, Lam, Wang and Chung (2006) found the test compressive resistances of fixed ended steel stub columns, made out of $150 \times 65 \times 13 \times 1.6$ mm and $100 \times 50 \times 10 \times 1.6$ mm cold-formed lipped channels, to be 75% and 77% of the predicted resistance, calculated using the British code (BS 5950),

Figure 3. Bucking failure modes.

respectively. A similar investigation by Young and Rasmussen (1998) illustrated that design codes overestimated the strength of short cold-formed column lengths. Kwon and Hancock (1992) also found the maximum stresses in small sized lipped channel sections to range from 25% to 34% of the yield stress.

Another possible cause of the substantial low ratios of test versus predicted strengths might be the size of the lip. Specimens with a smaller effective lip size resist less load than those with a larger lip size (Known and Hancock, 1992).

5 FAILURE MODES

Two buckling modes of failure were observed from the experimental tests, namely local, and distortional buckling. Local buckling occurs when parts or portions of the section elements yield before the actual yielding of the member is achieved, and was observed in very short columns, in lengths ranging from 500 mm to 1000 mm (Figure 9(a)-(c)). The local buckling failure mode of these columns was more excessive at the ends of the columns and caused the web to buckle outwards. This failure mode is more distinct in thinner sections and the buckle of these sections seems to affect a larger area of the web than thicker sections. As indicated above the process of cutting cold-formed steel sections to form a stub column may have led to cross section distortion and initial geometric imperfection.

Distortional buckling or stiffener buckling is a mode characterized by rotation of the flange at the flange/web junction in members with edge stiffened elements (Schafer and Pekoz, 1998). Distortional buckling was observed in 1250 mm length columns. Figs. 3(d) show evidence of distortional buckling. In this figure distortional buckling is characterized by the closing up of the two flanges. This mode of failure is probably unsymmetrical because the section was distorted during the cutting process (Lam, Chung and Wang, 2006).

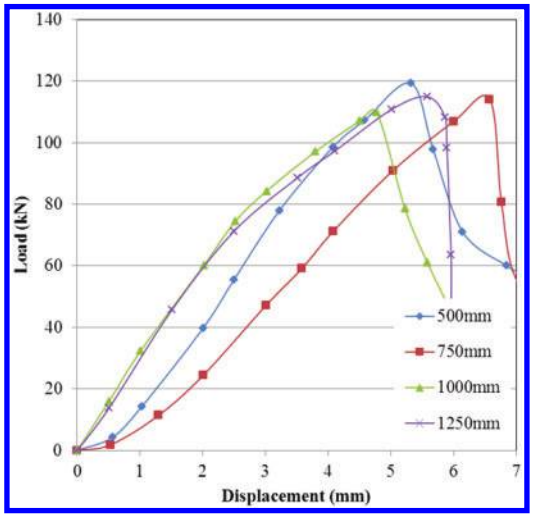

Figure 4. 300 × 75 × 20 × 2 short columns.

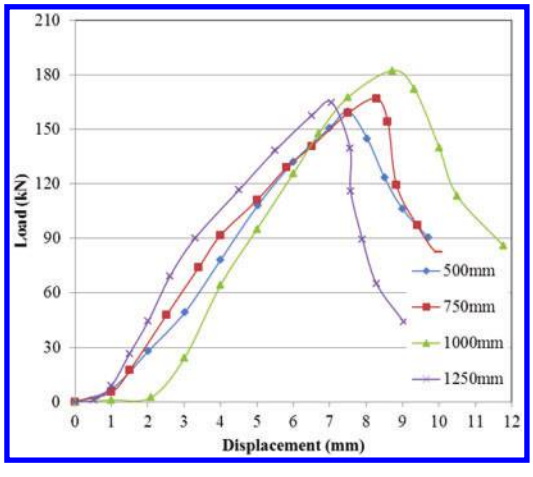

Figure 5. 300 × 75 × 20 × 2.5 short columns.

6 LOAD-AXIAL SHORTENING

The experimental load-displacement graphs for the three different sections are shown in Figure 4. The graphs are linear elastic up to the maximum load and there is little or no evidence of inelastic behaviour. For the 300 × 75 × 20 × 2 specimens, the load–axial shortening curves experience abrupt drops immediately after the ultimate loads, while for specimens 300 × 75 × 20 × 2.5 and 300 × 75 × 20 × 3.0 the load–axial shortening curve shows a smooth decrease of loads at the post-ultimate range (Figures 4-5). The abrupt drops correspond to the sudden collapse of the columns in the tests. Generally, columns with larger thickness experience less abrupt drops in load immediately after the ultimate load compared with thinner sections.

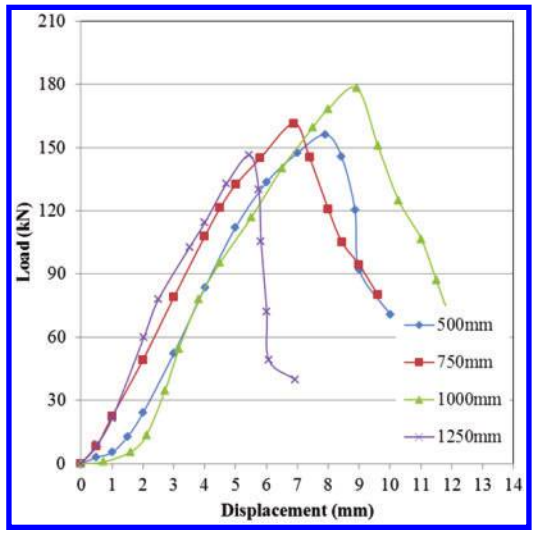

Figure 6. 300 × 75 × 20 × 3 short columns.

7 CONCLUSION

Ziemian's (2010) suggested length for short columns do not apply to these sections, however, the sections can be classified as short considering that there is little or no variation in the test strength achieved. Columns with length ranging from 500 mm to 1000 mm failed by local buckling of the web, whilst the 1250 mm column length failed by distortional buckling. The ultimate compressive resistance obtained from the test results ranged from 66–87% of the compressive resistance calculated based on SANS10162-2 and its related specifications. This implies that the design predicted strengths by the SANS10162-2 specification generally overestimated (not conservative) the design compressive strengths of the short cold-formed lipped channel columns. The predicted strengths for the 300 × 75 × 20 × 3 mm columns are much larger than the test strength. This huge difference is caused by the fact that the lips for these sections are all fully effective in resisting local buckling. Local buckling reduced the effectiveness of the lips of the 300 × 75 × 20 × 2 mm and 300 × 75 × 20 × 2.5 mm column sections.

8 ACKNOWLEDGEMENTS

The author wishes to acknowledge Nhlanhla Tshabalala, a final year Civil Engineering student, who assisted in carrying out the tests, reported in this paper and the University of Johannesburg Research Committee (URC) for sponsoring this research.

Continuous beam tests on aluminium alloy SHS and RHS with internal stiffeners

M. Su & B. Young
Department of Civil Engineering, The University of Hong Kong, Hong Kong, China

L. Gardner
Department of Civil Engineering, Imperial College London, London, UK

ABSTRACT: The aims of this study are to generate experimental data on aluminium alloy continuous beams of square and rectangular hollow section (SHS and RHS) with internal stiffeners, as well as to assess the current design approaches for indeterminate structures using this new cross-section shape. The experimental programme comprised material tests and five-point bending tests (i.e. continuous beams over three supports) with three different loading configurations. Generally, the specimens failed by the formation of a collapse mechanism comprising three plastic hinges. Comparisons of the test results with design strengths were also carried out. The design strengths predicted by the American (2010), Australian/New Zealand(1997) and European (2007) specifications are found to be rather conservative. The plastic hinge method in Annex H of Eurocode 9 (2007) provides improved results, while the Continuous Strength Method (CSM) for indeterminate structures gives the most accurate and consistent predictions. The results reveal that both strain hardening at the cross-sectional level and moment redistribution at the global system level have significant influence on the structural performance of stocky aluminium alloy structures.

1 INTRODUCTION

Aluminium alloy structural members are being used increasingly widely nowadays owing to a range of advantageous characteristics. Ease of fabrication is one of the key benefits of aluminium alloys over steel, and should be taken into account in an economic comparison of aluminium and other metals (Mazzolani, 1994). The benefits arise from the extrusion procedure, which allows increasingly creative cross-sectional shapes to be formed.Square and rectangular hollow sections (SHS/RHS) have been widely used in a range of engineering applications, butthin-walledhollow sections are significantly affected by local buckling. In order to inhibit local buckling and utilize the cross-section more efficiently, internal cross stiffeners can be added to SHS/RHS. However, there are currently no available experimental data on either the bending or compression behaviour on this type of section.

Determination of the internal forces and moments in statically indeterminate structures cannot be achieved by statics alone, but requires knowledge of the stiffness of the structural elements, which may change during loading(e.g. through plastification).Design approaches for indeterminate structures often consider moment redistribution at the global system level, which can be addressed by means of global plastic design. Although some tests on aluminium alloy structural members subjected to bending (Langseth & Hopperstad, 1997; Faella et al., 2000; Mennink, 2002 and Su et al., 2012a) and compression (Lai & Nethercot, 1992; Moen et al., 1999; Zhu & Young, 2006; Zhu & Young 2009 and Su et al., 2012b) have been conducted, few tests on indeterminate aluminium alloy structures exist in the literature;thus a series of continuous beam tests was conducted in this study.

In the field of aluminium alloy structural member design, the design specifications of the American Aluminium Design Manual (AA, 2010), the Australian/New Zealand Standard (AS/NZS, 1997) and Eurocode 9 (EC9, 2007) are widely used. However, these specifications may lead to inaccurate capacity predictions for indeterminate structures comprising SHS/RHS with internal stiffeners due to the fact that the current design methods are (1) proposed based on traditional cross-section shapes; (2) not considering strain hardening (except Annex E in EC9) and (3) not accounting for moment redistribution(except Annex H in EC9).The continuous strength method (CSM) for indeterminate structures (Gardner et al., 2011) accounts for these factors and is described herein.

The aims of this study are to generate experimental data for aluminium alloy continuous beams of square and rectangular hollow section (SHS and RHS) with internal stiffeners, and to assess the current design approaches for indeterminate structures of this new cross-section shape.

2 EXPERIMENTAL INVESTIGATION

2.1 *Test specimens and specimen labelling*

A total of 20 continuous beam specimens of different cross-sectional geometry, defined using the symbols illustrated in Figure 1, was tested. The cross-sectional dimensions shown in Table 1 are the average measured values for each test specimen in this study. The measured material properties are also provided, which were determined by means of longitudinal tensile coupon tests. The symbols employed in Table 1 are defined as follows: E is the Young's Modulus, f_y is the material yield stress (taken as the 0.2% proof stress), f_u is the material ultimate stress, ε_u is the strain corresponding to the ultimate tensile stress of the material and F_{exp} is the total experimental ultimate load.

The specimens were labelled according to the type of material, cross-sectional dimensions and the test configuration. For example, the label "$+H50 \times 95 \times 10.5$B5I" defines a specimen of high strength aluminium alloy6061-T6, with cross-sectional dimensions of width B(50 mm) × height H(95 mm) × thickness t(10.5 mm). If the label starts with "N", it signifies that the specimen is of normal strength aluminium alloy 6063-T5. The symbol "B5I" following the dimensions refers to the five-point loading configuration, as shown in Figure 2. If a test is repeated, a letter "R" is shown in the suffix of the label. The arrangement of the cross-sectional dimensions also refers to the bending axis. In this case, the specimen $+H50 \times 95 \times 10.5$B5I was bent about the major axis, while the specimen "$+H95 \times 50 \times 10.5$B5I" was bent about the minor axis.

Figure 3. Experimental setup for five-point bending tests.

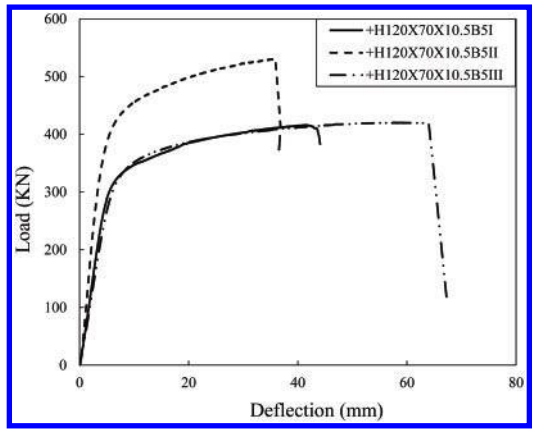

Figure 4. Typical Load-deflection curves for five-point bending tests.

2.2 *Testing procedure*

Three symmetrical five-point bending configurations (Figure 2) were employed in this study. The overall nominal length of continuous beams was 1690 mm. In loading configuration B5I, the distance between the loading points and the supports were all equal to 400 mm (L1 = $L2 = 400$ mm), while in the configurations B5II and B5III, the loads were applied at one third of the half span (L2 = 266.7 mm) and two thirds of the half span (L2 = 533.3 mm),respectively.

A 1000 kN capacity servo-controlled hydraulic testing machine was used to apply compressive force by displacement control at a constant rate of 0.8 mm/min for all tests. The specimens were loaded symmetrically at two points using a spreader beam, as shown in Figures 2 and 3.Steel rollers and a half round were employed to achieve rotationally free conditions. Steel bearing plates were placed between the specimen and loading/support points for the purpose of spreading the concentrated load. Transducers were used to measure the specimen deflection and end rotation.

2.3 *Test results and failure modes*

Generally, the specimens failed by material yielding and the formation of a collapse mechanism comprising three plastic hinges. In the case of configurations I and II, the first hinge formed at the central support and the latter two hinges formed at the loading points. Plastic hinges in the configuration III formed in a reverse sequence. Eventually all specimens fractured at the tensile flange, though in some cases, this was after the peak load, attributed to inelastic local buckling, had been attained. It should be noted that significant visual local buckling was not observed in the tests. In all cases, the ultimate loads attained in the tests were beyond the calculated loads corresponding to the occurrence of the first hinge as well as the calculated loads corresponding to the formation of the plastic collapse mechanism. Three typical load-deflection curves for the five-point bending tests, shown for specimens $+H120 \times 70 \times 10.5$B5I, $+H120 \times 70 \times 10.5$B5II and $+H120 \times 70 \times 10.5$ B5III,are given in Figure 4, while a deformed tested specimen from each loading configuration exhibiting three distinct plastic hinges is shown in Figure 5. The test results are presented in Table 1.

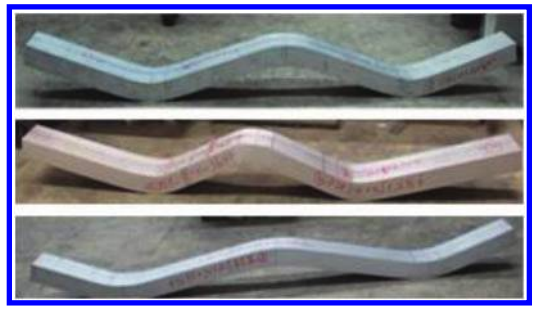

Figure 5. Tested specimens ($+N95 \times 50 \times 10.5$B5I, $+N95 \times 50 \times 10.5$B5II and $+$N$95 \times 50 \times 10.5$B5III) subjected to five-point bending.

3 COMPARISON OF TEST STRENGTHS WITH DESIGN PREDICTIONS

The experimental ultimate loads (F_{exp}) obtained from this study are compared with the design strengths predicted by the American (F_{AA}), Australian/New Zealand ($F_{AS/NZS}$) and European (F_{EC9} and F_{EC9-H}) specifications for aluminium structures. In addition, the Capacities calculated based on the CSM for indeterminate structures (F_{csm}) are also compared with the experimental ultimate loads. The predictions are all based on the measured dimensions and material properties in Table 1, while the calculation concepts for each method are summarised in Table 2, where the following symbols are used: c_{cf} and c_{cw} are the distances from the centerline of the compression flange/web group's extreme compression fibre to the cross section's neutral axis, c_{tf} and c_{tw} are the distances from the extreme tension fibre/web group's extreme tension fibre to the cross section's neutral axis, $F_c$is the local buckling stress of the flat elements in uniform

Table 2. Summary table of cross-section moment capacities and analysis methods for different approaches.

Design approach	Section capacity and analysis type	Class 1	Class 2	Class 3	Class 4
AA	Cross-section capacity	Lesser of ($M_{nc} = \mathrm{F}_c I_f/\mathrm{c}_{cf} + \mathrm{F}_b I_w/\mathrm{c}_{cw}$, $M_{nt} = \mathrm{F}_t I_f/\mathrm{c}_{tf} + \mathrm{F}_b I_w/\mathrm{c}_{tw}$), where F_c, F_b and F_t are slenderness dependent.			
	Global analysis	Elastic			
AS/NZS	Cross-section capacity	Lesser of ($W_{el}F_{bc}$, $W_{el}F_{bt}$), where F_{bc} and F_{bt} are slenderness dependent			
	Global analysis	Elastic			
EC9	Cross-section capacity	$W_{pl}f_y$	$W_{pl}f_y$	$W_{el}f_y$	$W_{eff}f_y$
	Global analysis	Elastic			
EC9- Annex H	Cross-section capacity	$\alpha\eta W_{el}f_y$	$W_{pl}f_y$	$W_{el}f_y$	$W_{eff}f_y$
	Global analysis	Plastic		Elastic	
CSM	Cross-section capacity	M_{csm} for cross-section			
	Global analysis	Plastic, but with allowance for ratio of hinge rotations. (for $\varepsilon_{csm}/\varepsilon_y < 3.6$: elastic)			

compression, F_t is the yield stress in tension, F_b is the local buckling/tensile stress of the flat elements in flexure, F_{bc} and F_{bt} are the weighted average factored limit state compressive/tensile stress in accordance with the ratio of the area of each elements, I_f and I_w are the moments of inertia of the flange/web group about the cross section's neutral axis, M_{nc} and M_{nt} are the weighted average compression/tension flexural strength, W_{pl}, W_{el} and W_{eff} are the plastic section modulus of the gross section, elastic section modulus of the gross section and elastic section modulus of the effective section, α is the shape factorη is the correction factor and ε_{csm} is the CSM strain.

The AA,AS/NZS and EC9specificationshave similar approaches for continuous beam design. The predicted failure loads are defined as when the maximum moment reaches the cross-section capacity, (i.e. the first hinge formed), following the concept of global elastic design. The mean values of the tested-to-predicted failure load ratios F_{exp}/F_{AA}, $F_{exp}/F_{AS/NZS}$ and F_{exp}/F_{EC9} are 1.80, 2.27 and 1.69,with corresponding coefficients of variation (COV) of 0.152, 0.185 and 0.153, respectively.

EC9 also gives the possibility to implement global plastic analysis as an alternative for Class 1 sections by using the plastic hinge method in Annex H (F_{EC9-H}). Besides moment redistribution, this method also takes into account strain hardening for Class 1sections. The Plastic Hinge Method in EC9 provides better agreement with the test results (mean value of $F_{exp}/F_{EC9-H} = 1.48$) and the least scatter of the predictions (COV = 0.082).

The continuous strength method (CSM) for indeterminate structures combines the merits of the traditional plastic analysis(i.e. allowing moment redistribution) and an accurate assessment of cross-section moment capacity through a deformation based approach that allows for strain hardening. In the calculation of F_{csm}, the cross-section slenderness ($\overline{\lambda}_p$) was determined by CUFSM (Li & Schafer, 2010). The material model is an elastic, linear hardening relationship where the strain hardening region is defined by the strain hardening slope (E_{sh}), given by Eq. 1. Notethat the measured ultimate strain (ε_u) from the tensile coupon tests for the comparisons made in this section. The bi-linear model has been verified by the authors against all the available coupon test material data, and it is found that the over-predictions of stress never exceed 5%. The comparison of the CSM with the results of continuous beam tests shows a mean value of 1.31 with a corresponding COV of 0.082.

$$E_{\mathrm{sh}} = \frac{f_u - f_y}{0.5\varepsilon_u - \varepsilon_y} \tag{1}$$

where $\varepsilon_y = f_y/E$ is the yield strain.

Figure 6 shows the test divided by predicted ultimate loads against section slenderness for the various design methods. The predictions of the AA, AS/NZS and EC9 specifications may be seen to be rather conservative, especially for the more stocky sections. Among the three specifications, EC9 is the least conservative while the AS/NZS specification is the most conservative. On the other hand, by allowing for moment redistribution at the global system level and accounting for strain hardening at the cross-sectional level, the two other design approaches, the plastic hinge method in Annex H of EC9 and the CSM for indeterminate structures, provide better predictions and less scatter. It can be observed in Figure 6 that the CSM offers the most accurate mean resistance, attributed to a rational exploitation of strain hardening.

4 CONCLUSIONS

A series of experiments on aluminium alloy square and rectangular hollow sections with internal stiffeners subjected to five-point bending has been presented. The specimens were of Class 1 proportions according to Eurocode 9 (2007). The experimental results were used to assess the accuracy of five design approaches: namely the American Aluminium Design Manual (2010), the Australian/New Zealand Standard(1997), Eurocode 9 (2007), the plastic hinge

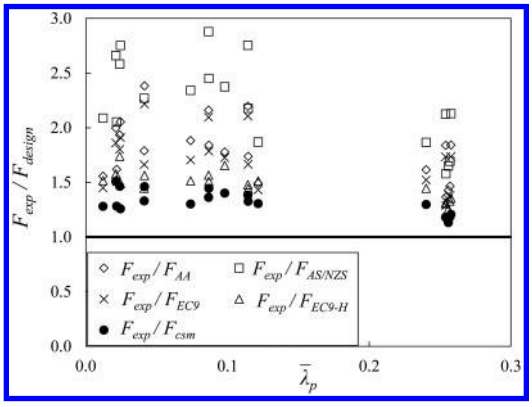

Figure 6. Comparison between the five-point bending test results and design strengths.

method in Eurocode 9and the Continuous Strength Method (CSM) for indeterminate structures. The results generally revealed that the AA, the AS/NZS and EC9standards considerably underestimate the strength of continuous beams, especially for stocky sections. As expected, the ultimate loads of the continuous beams are better predicted by the plastic hinge method (EC9)and the CSM for indeterminate structures; this is attributed to the consideration of both moment redistribution at the system level and strain hardening in the calculation of cross-section resistance. Comparing all five design approaches used in this study, the CSM for indeterminate structures yields the most accurate predictions. It should be noted that there are different configurations for indeterminate structures, but at the moment, the conclusions are only drawn based on five-point bending tests. Investigations into other indeterminate configurations are needed before reaching more general conclusions in the future.

ACKNOWLEDGEMENTS

The research work in this paper was supported by a grant from The University of Hong Kong under the seed funding program for basic research. The authors are also grateful to MrYi-Ran Li for his assistance in the experimental program as part of his final year undergraduate research project at The University of Hong Kong.

Rational DSM design of thin-walled cruciform and angle columns

P.B. Dinis & D. Camotim
Civil Engineering Department, ICIST, Instituto Superior Técnico, Technical University of Lisbon, Portugal

ABSTRACT: This paper presents the output of an investigation on the development of more rational approaches to design pin-ended and fixed-ended equal-leg cruciform and angle columns by means of the Direct Strength Method (DSM). The key feature of these approaches consists of replacing the currently used local strength curve by genuine (i) torsional (cruciforms) or (ii) flexural-torsional (angles) ones, specifically developed for the columns under consideration and, therefore, accounting for the structural peculiarities of their cross-section shapes, formed by just four or two outstands. Moreover, the effective centroid shift effects, which have a strong impact on the pin-ended angle column ultimate strength, are also incorporated into the design approach. The merits of the developed DSM design approaches are assessed through the comparison with numerical and experimental column failure load data reported in the literature.

1 INTRODUCTION

The post-buckling behaviour and strength of cruciform and (mostly) angle columns has attracted the attention of several researchers in the past – *e.g.*, Popovic *et al* (1999), Young (2004), Ellobody & Young (2005), Rasmussen (2005, 2006), Dinis *et al.* (2010), Shifferaw & Schafer (2011), Silvestre *et al.* (2013), Trahair (2012). Some of them devoted a fair amount of work to develop rules and procedures aimed at predicting the failure loads of short-to-intermediate columns, adopting mostly local buckling concepts. Nevertheless, numerical simulations recently carried out by the authors (Dinis *et al* 2012, 2013a,b), on pin-ended and fixed-ended short-to-intermediate equal-leg cruciform and angle columns, unveiled some surprising behavioural features. It was then concluded that the column design should be based on genuine torsional (cruciforms) or flexural-torsional (angles) buckling concepts, instead of local ones. Moreover, it became clear that (i) specific design procedures, able to capture the angle column post-critical strength reserve length-dependence, were needed and (ii) that a single design approach cannot handle properly both pin and fixed-ended angle columns, due to the effective centroid shift effects.

The aim of this work is to present the output of a recent investigation on the development of more rational approaches to the Direct Strength Method (DSM – Schafer 2008) design of pin-ended (P) and fixed-ended (F) equal-leg angle and cruciform columns (Dinis *et al* 2013a,b). After briefly reviewing the most efficient DSM methodologies available to estimate these column failure loads (against "local"-global failures), namely those proposed for equal-leg angle columns by Young (2004), Rasmussen (2006) and Silvestre *et al.* (2013), the paper presents new DSM-based design approaches that take account for the structural peculiarities of the cruciform and angle cross-section shapes, formed by just four and two outstands. The key feature of the new proposals consists of replacing the current local design curves by genuine (i) torsional (cruciforms) or (ii) flexural-torsional (angles) ones, both specifically developed for the columns under consideration. The merits of these DSM design approaches are assessed through the comparison with (i) experimental load data reported in the literature and (ii) numerical failure loads obtained through ABAQUS shell finite element analyses (SFEA).

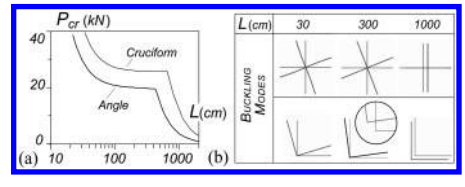

Figure 1. (a) Cruciform and angle critical buckling curve and (b) six column buckling mode shapes.

1.1 *Cruciform and angle column structural behaviour*

The peculiar behavioural features exhibited by the cruciform and angle columns are briefly addressed next – further information can be found in Dinis *et al.* (2013a,b). Particular attention is paid to the issues having higher impact on the development of the design approaches dealt with in this work.

(i) Due to the secondary warping resistance, local and torsional deformations cannot be handles similarly in cruciform columns (even if they are akin).
(ii) The ultimate strengths of P and F cruciform columns with lengths within the P_{cr} (L) curve plateau (see Fig. 1(a)) and containing torsional initial imperfections are virtually the same.
(iii) The angle column post-buckling is strongly length-dependent within the P_{cr} (L) curve plateau (see Fig. 1(a)). The shorter columns exhibit substantial

post-critical strength and little minor-axis flexure. Conversely, the longer columns exhibit minute post-buckling strength and substantial minor-axis flexure. The amount of major-axis flexure appearing in the column buckling mode (see Fig. 1(b)) was found to increase along the P_{cr} (L) curve plateau and correlate quite well with its post-buckling strength.

(iv) The angle column failure loads decrease with the length, due to lower flexural-torsional post-critical strength and higher interaction with minor-axis flexure – in the P columns, these interaction effects are further enhanced by the effective centroid shifts.

2 DIRECT STRENGTH METHOD (DSM) DESIGN

The current DSM strength/design curves for cold-formed steel columns are defined by "Winter-type" expressions that (i) were calibrated against fairly large numbers of experimental and/or numerical results and (ii) provide safe and accurate ultimate strength estimates associated with local, distortional, global and local-global interactive failures on the sole basis of elastic critical buckling (f_{crl}, f_{crd}, f_{cre}) and yield stresses. In the context of this investigation on cruciform and angle columns, the latter of which are not (yet) pre-qualified for the DSM design, the relevant nominal strengths are f_{nl} (local), f_{ne} (global) and f_{nle} (local-global) – the DSM expressions providing them can be found in Schafer (2008).

Since local and torsional deformations are akin in cruciform and angle columns, (i) both designations are often used indistinctly in the context of these columns and (ii) f_{nle} expressions are commonly used to estimate their "local"-global failure loads. However, such an approach neglects the fact that (i) torsional deformations are affected by secondary warping resistance (under warping-fixity) and (ii) angle columns buckle in flexural-torsional modes.

The most relevant design proposals for angle columns were recently revised by Silvestre *et al.* (2013), namely those proposed by Young (2004) and Rasmussen (2006). The latter developed a DSM-based approach for the design of P angle columns that incorporates explicitly the eccentricity stemming from the effective centroid shift – the strength curve depends on $\lambda_l = (f_y/f_{crl})^{0.5}$ and reads

$$f_{nl} = \rho \cdot \beta \cdot f_y \tag{1a}$$

$$\rho = \frac{A_e}{A} = \begin{cases} 1 & \text{if} \quad \lambda_l \le 0.673 \\ \dfrac{\lambda_l - 0.22}{\lambda_l^2} & \text{if} \quad \lambda_l > 0.673 \end{cases} \tag{1b}$$

$$\beta = \begin{cases} 1 & \text{if} \quad \lambda_l \le 1.22 \\ \dfrac{0.68}{(\lambda_l - 1)^{0.25}} & \text{if} \quad \lambda_l > 1.22 \end{cases} \tag{1c}$$

and accounts simultaneously for both the (i) bending effects due to the effective centroid shift, through parameter β, and (ii) "local" (flexural-torsional) buckling effects, through the effective area reduction factor ρ. Moreover, Silvestre *et al* (2013) proposed different DSM-based design approaches for P and F columns, which combine (i) Young's (2004) experimentally-based global design curve with (ii) either the current DSM local strength curve (F columns) or an empirically modified/lowered alternative curve (P columns) – these curves are expressed by

$$f_{ne} = \begin{cases} f_y \left(0.5^{\lambda_c^2}\right) & \text{if} \quad \lambda_c \le 1.4 \\ f_y \left(\dfrac{0.5}{\lambda_c^2}\right) & \text{if} \quad \lambda_c > 1.4 \end{cases} \tag{2}$$

$$f_{nl} = \begin{cases} f_y & \text{if} \quad \lambda_l \le 0.71 \\ f_y \left(\dfrac{f_{crl}}{f_y}\right)\left[1 - 0.25\left(\dfrac{f_{crl}}{f_y}\right)\right] & \text{if} \quad \lambda_l > 0.71 \end{cases} \tag{3}$$

with $\lambda_c = (f_y/f_{cre})^{0.5}$. These DSM-based design approaches were shown (i) to provide safe, accurate and reliable estimates of the available experimental and numerical failure loads, and, moreover, (ii) to outperform their most efficient predecessors: those developed by Young (2004) and Rasmussen (2006), for F and P columns. However, in spite of the quite positive performance indicators, one negative feature subsisted: the lack of a rational structural model, reflected in (i) the almost fully empirical roots of the strength curves given in Eqs. (2) and (3), and (ii) the inadequate nature of the current local DSM design curve involved in the approaches. The proposals developed in the next section aim at eradicating this negative feature.

3 NOVEL DSM-BASED DESIGN APPROACHES

Rational DSM-based design approaches for cruciform and angle columns must reflect the peculiarities of their behaviour, fully reported by Dinis *et al.* (2012, 2013a,b) and outlined in section 1.1. Thus, it may be established at the outset that the sought DSM-based design approaches must exhibit the following characteristics:

(i) Since the intermediate cruciform and angle columns fail mostly in interactive modes combining flexural (minor-axis) and torsional or flexural-torsional instability, the strength curves involved must be (i_1) the current DSM global curve and (i_2) torsional (cruciforms) or flexural-torsional (angles) strength curves, which need to be specifically developed and replace the single local strength curve in the current DSM design against local-global interactive failures.

(ii) The cruciform column torsional strength curve must take into account (ii_1) the secondary warping resistance and (ii_2) the fact that the failure loads of P and F column with initial torsional imperfections remain practically constant as the (short-to-intermediate) length grows and are unaffected by the end-support conditions – then, a single common torsional strength curve suffices for both P and F cruciform columns.

(iii) However, several flexural-torsional curves must be developed for angle columns, in order to enable capturing the progressive erosion of the column post-critical strength as its length increases within the P_{cr} (L) curve plateau – see Figure 1(a).

(iv) The effective centroid shift effects, strongly influencing the P angle column failure loads (not the F column ones), must be incorporated into

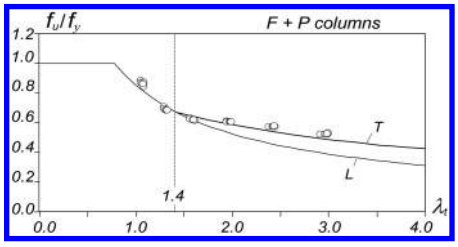

Figure 2. Variation of f_u/f_y with λ_t for F and P cruciform columns.

the design approach through a procedure or parameter that only comes into play for the P columns – exactly the idea of Rasmussen (2006) (see parameter β in Eq. (1c)). However, such procedure/parameter must reflect, as closely as possible, the length-dependence of the column flexural-torsional behaviour – Rasmussen based his parameter β on local buckling concepts.

The new DSM-based design proposals for cruciform and angle columns are presented separately and their merits will be assessed trough the comparison with (i) experimental load data reported in the literature and (ii) numerical failure loads obtained through ABAQUS SFEA, based on an existing elastic-perfectly plastic model: (ii_1) columns discretised into fine 4-node isoparametric element meshes (length-to-width ≈1.0), (ii_2) P and F support conditions modelled through rigid plates attached to the column end sections (end section secondary warping and one or both flexural rotations prevented) and (ii_3) steel constitutive law described by Prandtl-Reuss's model. Details concerning the experimental tests and numerical simulations can be found in Dinis *et al.* (2012, 2013a,b).

3.1 *Cruciform columns*

The first step involved in the proposed DSM design approach for cruciform columns consists of using the numerical failure load data concerning P and F cruciform columns with torsional initial imperfections, which fail in pure torsional modes, to search for a "Winter-type" torsional strength curve to estimate them as accurately as possible. This search was made by "trial-and-error" and, taking into account that the current DSM local strength curve provides accurate estimates for slenderness values up to about 1.4, led to

$$f_{nt} = \begin{cases} f_y & \text{if} \quad \lambda_t \le 0.776 \\ f_y \left(\frac{f_{crt}}{f_y}\right)^{0.4} \left[1 - 0.15\left(\frac{f_{crt}}{f_y}\right)^{0.4}\right] & \text{if} \quad 0.776 < \lambda_t < 1.4 \\ f_y \left(\frac{f_{crt}}{f_y}\right)^{0.2} \left[1 - 0.22\left(\frac{f_{crt}}{f_y}\right)^{0.26}\right] & \text{if} \quad \lambda_t \ge 1.4 \end{cases}, \quad (4)$$

with $\lambda_t = (f_y/f_{crt})^{0.5}$. Figure 2 compares the proposed curve with (i) the current DSM local curve and (ii) the numerical torsional failure loads. The proposed curve clearly (i) lies well above the DSM local curve in the moderate-to-high slenderness range and (ii) fits nicely the numerical torsional failure loads (differences below 3.5%).

Next, Eq. (4) is combined with the current DSM global strength curve: f_y replaced by f_{ne} in Eq. (4) to yield f_{nte} ultimate strength estimates. The merits of this DSM design approach can be assessed by looking at Figures 3(a)-(b), comparing the variations of f_u/f_{nle} and f_u/f_{nte} with λ_t, concerning the numerical (white circles – 252 simulations) and experimental (black circles- 31 tests) failure loads – also shown are the associated averages, standard deviations and maximum/minimum values. The observation of these results leads to the following conclusions:

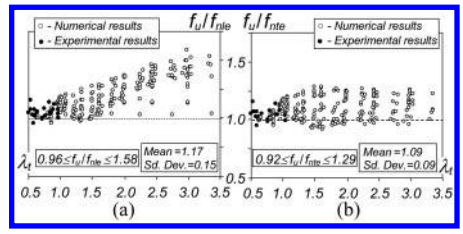

Figure 3. Variation of (a) f_u/f_{nle} and (b) f_u/f_{nte} with λ_t, for the whole set of numerical and tests results concerning the F and P columns.

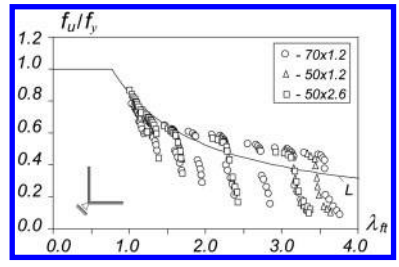

Figure 4. Variation of f_u/f_y with λ_{ft} (flexural-torsional failures).

(i) As anticipated, the f_{nte} estimates exhibit higher quality than the f_{nle} ones: ultimate-to-predicted stress ratios with (i_1) an average closer to 1.0 (1.09 *vs.* 1.17), (i_2) a smaller standard deviation (0.09 *vs.* 0.15), and (i_3) lower maximum values (1.29 *vs.* 1.58) – the obvious "trade off" was the appearance of slightly larger underestimations (0.92 *vs.* 0.96).

(ii) There are virtually no differences between the numerical ultimate-to-predicted stress ratios of the F and P columns, thus indicating that the above remarks apply to both of them.

(iii) Since the available experimental failure loads concern only quite stocky columns ($\lambda_t < 1.05$), they are equally well predicted by both DSM approaches (averages and standard deviations of 1.07/0.06).

(iv) The main differences between the f_{nte} and f_{nle} predictions concern the most slender columns, excessively underestimated by the latter. Unfortunately, there are no test results available for this slenderness range.

3.2 *Angle columns*

3.2.1 *Flexural-torsional strength curves*

A fully numerical approach is adopted to obtain "Winter-type" strength curves to predict "pure flexural-torsional failures" of equal-leg angle columns buckling in flexural-torsional modes – the failure loads of 170 columns continuously restrained against

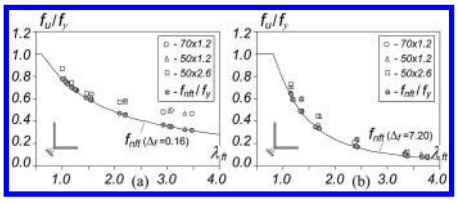

Figure 5. Proposed f_{nft} strength curves for (a) $\Delta_f = 0.16$, (b) 7.20 and numerical failure loads predicted by them.

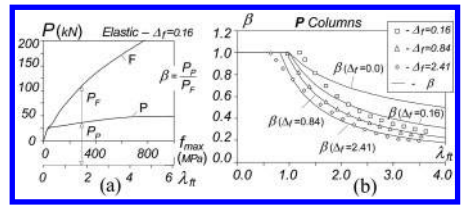

Figure 6. (a) F and P column P *vs.* f_{max} curves ($\Delta_f = 0.16$), and (b) proposed $\beta(\lambda_{ft})$ ($\Delta_f = 0.0; 0.16; 0.84; 2.41$) and fitted β values.

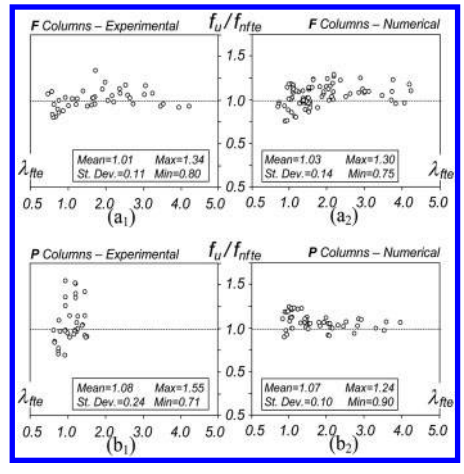

Figure 7. Variation of f_u/f_{nfte} with λ_{fte} for (a) F and (b) P angle columns: ($_1$) experimental and ($_2$) numerical results.

minor-axis flexure (forced to fail in modes combining major-axis flexure and torsion) are considered. Figure 4 shows the variation of the ultimate strength ratio f_u/f_y with λ_{ft} – also shown is the current DSM local strength curve. The huge "vertical dispersion" of the f_u/f_y values makes it easy to conclude that no single Winter-type curve can predict satisfactorily all of them. Since the "vertical dispersion" is linked to the column length, it was decided:

(i) To group the columns according to the ratio between their pure torsional (f_{bt}) and flexural-torsional (f_{crft} – critical) buckling loads – Figures 5(a)-(b) provide the variation of f_u/f_y with λ_{ft} for the columns analysed earlier sharing similar f_{bt}/f_{crft} ratios, namely 1.0016 (Fig. 5(a)) and 1.070 (Fig. 5(b)).

(ii) To propose curves to estimate flexural-torsional strengths (f_{nft}) that adopt "Winter-type" expressions and depend on a parameter a, included to capture the strength curve length-dependence – see Eq. (4). This parameter is expressed in terms of the percentage ratio Δ_f, quantifying the weakening effect of major-axis flexure on the column post-critical strength and given by $\Delta_f = [(f_{bt} - f_{crft})/f_{crft}] \times 100$.

(iii) To obtain, through a "trial-and-error curve-fitting procedure" based on the numerical failure load data, an expression for parameter a (see Eq. (5)).

3.2.2 *Effective centroid shift effects*

The strength differences between P and F columns stem from the effective centroid shift effects. Thus, a rational procedure must be found to account for them before proposing a DSM-based approach to design P columns. The procedure adopted follows Rasmussen's (2006) idea: effective centroid shift incorporated through a multiplicative parameter β that depends also on the column slenderness – the P column ultimate strength estimate is obtained by multiplying its F column counterpart (f_{nfte}) by parameter β – f_{nfte} is obtained replacing f_y with f_{ne} in the f_{nft} curves.

The search for an expression providing parameter β is based on an "elastic reduction factor" concept that accounts for the fact that both the post-buckling strength and effective centroid shift effects vary substantially with the column length. It involves the following steps:

(i) Perform elastic post-buckling analyses of geometrically identical F and P columns (same f_{bt}/f_{crft} ratio and critical-mode initial geometrical imperfections with amplitude $L/1000$) and record the evolution, as the applied load P increases, of the maximum mid-span cross-section longitudinal normal stress f_{max}. For illustration, Figure 6(a) shows the P *vs.* f_{max} curves for the F and P columns with $\Delta_f = 0.16$.

(ii) Assume that, for a given f_{max}, the difference between the F and P column applied loads (P_F and P_P) stems from the effective centroid shift effects – then, the ratio P_P/P_F provides a good approximation for the parameter β, i.e., $\beta \approx P_P/P_F$.

(iii) Relate f_{max} with the column slenderness by means of $\lambda_{ft} = (f_{max}/f_{crft})^{0.5}$, which amounts to assuming that β is the strength reduction due to the effective centroid shift effects at the "limit elastic applied load". Then, it becomes possible to develop $\beta(\lambda_{ft})$ curves, one for each Δ_f value.

(iv) Through a second "trial-and-error curve-fitting procedure", look for "Winter-type" expressions relating parameter β with λ_{ft} (see Eq. (6)). Figure 6(b) shows (iv$_1$) the β *vs.* λ_{ft} curves for $\Delta_f = 0.0$; 0.16; 0.84; 2.41, and (iv$_2$) the fitted β values (for $\Delta_f \neq 0.0$).

3.2.3 *Proposed DSM design approaches*

The proposed DSM-based approaches for the design of F and P angle columns can be cast in a unified form,

$$f_{nfte} = \begin{cases} \beta \cdot f_{ne} & \text{if} \quad \lambda_{fte} \le 0.641^{\frac{1}{a}} \\ \beta \cdot f_{ne} \left(\frac{f_{crft}}{f_{ne}}\right)^a \left[1 - 0.23\left(\frac{f_{crft}}{f_{ne}}\right)^a\right] & \text{if} \quad \lambda_{fte} > 0.641^{\frac{1}{a}} \end{cases}, \quad (4)$$

with $\lambda_{fte} = (f_{ne}/f_{crft})^{0.5}$ and

$$a = \begin{cases} 0.003\,\Delta_f^3 - 0.030\,\Delta_f^2 + 0.230\,\Delta_f + 0.400 & \Delta_f \le 4.0 \\ 1 & \Delta_f > 4.0 \end{cases}, \quad (5)$$

$$\beta = \begin{cases} 1 & \text{for } F \text{ columns} \\ (1-b)\left(\frac{1}{\lambda_{fte}^2}\right)^c \le 1 & \text{for } P \text{ columns} \end{cases}, \quad (6)$$

with

$$b = \begin{cases} 0 & \Delta_f \le 0.3 \\ 0.091\,\Delta_f - 0.027 & 0.3 < \Delta_f < 2.5 \\ 0.2 & \Delta_f \ge 2.5 \end{cases}, \quad (7)$$

$$c = \begin{cases} 0.833\,\Delta_f + 0.25 & \Delta_f < 0.3 \\ -0.009\,\Delta_f^2 + 0.047\,\Delta_f + 0.487 & 0.3 \le \Delta_f < 2.5 \\ 0.55 & \Delta_f \ge 2.5 \end{cases}, \quad (8)$$

where it is recalled that $\Delta_f = [(f_{bt} - f_{crft})/f_{crft}] \times 100$.

3.2.4 *Assessment of the proposed DSM design approaches*

Attention is now turned to assessing the performance of the proposed two DSM-based design procedures (f_{nfte} estimates), namely the DSM-F and DSM-P approaches. Figures 7(a)-(b) provide the variation of f_u/f_{nfte} (failure-to-predicted strength ratio) with λ_{fte}, for the whole set of experimentally tested and numerically analysed F and P columns – the associated averages, standard deviations, maximum and minimum values are given in Table 1, together with those concerning the proposals of Young (2004) (F columns), Rasmussen (2006) (P columns) and Silvestre *et al* (2013) (F and P columns). The observation of the results presented prompts the following remarks:

(i) The DSM-F and DSM-P procedures leads to quite accurate predictions of the experimental and numerical ultimate strengths – the f_u/f_{nfte} averages and standard deviations are (i_1) 1.04/0.12 (experimental + numerical F columns) and (i_2) 1.06/0.16 (experimental + numerical P columns).

(ii) The quality of the above performance indicators (ii_1) provides solid evidence concerning the adequacy of the reasoning behind the development of the flexural-torsional strength (F and P columns) and β *vs.* λ_{fte} (P columns) curves, and (ii_2) also indicates that the outputs of these curves reflect quite accurately the underlying structural concepts.

(iii) The comparison between the values given in Table 1 makes it possible to conclude that the proposed design approaches have performance indicators similar to those exhibited by the proposals due to Young (2004), Rasmussen (2006) and Silvestre *et al* (2013). However, it has the very important advantage of being clearly more rational – they reflect quite closely the angle column structural behaviour and, moreover, retain the current DSM global strength curve.

3.3 *Load and Resistance Factor Design (LRFD)*

The evaluation of the LRFD resistance factor ϕ associated with the proposed DSM-based approaches for angle and cruciform columns is addressed next. According to the current North American cold-formed steel specification (AISI 2007), ϕ can be calculated using the formula given in section F.1.1 of chapter F,

$$\phi = C_\phi (M_m F_m P_m)\, e^{-\beta_0 \sqrt{V_M^2 + V_F^2 + C_P V_P^2 + V_Q^2}}, \quad C_P = \left(1 + \frac{1}{n}\right)\frac{m}{m-2}, \quad (9)$$

where (i) C_ϕ is a calibration coefficient ($C_\phi = 1.52$ for LRFD), (ii) $M_m = 1.0$ and $F_m = 1.00$ are the mean values of the material and fabrication factor, respectively, (iii) β_0 is the target reliability index ($\beta_0 = 2.5$ for structural members in LRFD), (iv) $V_M = 0.10$, $V_F = 0.05$ and $V_Q = 0.21$ are the coefficients of variation of the material factor, fabrication factor and load effect, respectively, and (v) C_P is a correction factor depending on the numbers of tests (n) and degrees of freedom ($m = n - 1$). In order to evaluate ϕ for each propose procedure (DSM-F and DSM-P), it is necessary to calculate P_m and V_P (mean and standard deviation of the failure-to-predicted strength ratios f_u/f_{nfte} – the f_u values are either experimental or/and numerical.

Table 2 shows the n and ϕ values obtained for the angle column ultimate strength predictions provided by the DSM-F and DSM-P procedures applied to the total failure load data (experimental and numerical – the mean P_m and standard deviation V_P values are also given in Table 1) – also indicated are the values (i) reported by Silvestre *et al* (2013) and (ii) determined with the proposals of Young (2004) and Rasmussen (2006). It is observed that:

(i) When the whole (experimental and numerical) failure load data are considered, the resistance factors associated with each proposed DSM-based procedure are $\phi = 0.87$ for both the F and P columns. These values are almost perfectly in line with the recommendations of the North American specification for cold-formed steel compression

Table 1. Means, standard deviations and maximum/minimum values of the DSM-F and DSM-P procedures and available proposals.

	F Columns			P Columns		
	DSM-F approach	Silvestre *et al.* (2013)	Young (2004)	DSM-P approach	Silvestre *et al.* (2013)	Rasmussen (2006)
Mean	1.02	1.01	1.14	1.07	1.11	1.06
Sd. Dev.	0.13	0.12	0.17	0.16	0.20	0.21
Max	1.34	1.40	1.70	1.55	1.89	1.81
Min	0.75	0.73	0.83	0.71	0.88	0.72

Table 2. LRFD resistance factors ϕ – DSM-F and DSM-P procedures and available proposals.

	F Columns			P Columns		
	DSM-F approach	Silvestre *et al.* (2013)	Young (2004)	DSM-P approach	Silvestre *et al.* (2013)	Rasmussen (2006)
n	133	130	130	99	63	63
ϕ	0.87	0.87	0.92	0.87	0.85	0.80

members (AISI 2007 – $\phi = 0.85$) – currently not applicable to angles.

(ii) The ϕ values obtained are very similar to those reported by Silvestre *et al.* (2013) and are slightly below and above those provided by Young (2004), for F columns, and by Rasmussen (2006), for P columns.

(iii) There is solid evidence that $\phi = 0.85$ can be also recommended for cold-formed steel angle columns designed with the DSM-F and DSM-P procedures. Although this feature is shared by the proposals developed by Young (2004) and Silvestre *e t al* (2013), the structural clarity and rationality of the approaches proposed in this work is definitely an advantage.

Finally, the resistance factors associated with the proposed DSM-based procedure for cruciform columns (f_{nte}) are $\phi = 0.96$ (experimental and numerical data – $n = 283$, $P_m = 1.09$, $V_P = 0.09$). The corresponding f_{nle} value is practically the same ($\phi = 0.97$), but the f_u/f_{nle} estimates exhibit involve fairly higher average, standard deviation and maximum values (1.17-0.15-1.58 *vs.* 1.09-0.09-1.29), mostly because of the considerable overestimations in the high slenderness range.

4 CONCLUSION

This work presented the output of an investigation on the development of more rational approaches to the DSM design of P and F equal-leg cruciform and angle columns with short-to-intermediate lengths, i.e., buckling in torsional or flexural-torsional modes. After reviewing the most efficient available methods to estimate the failure loads of such members, the paper addressed the key feature of the more rational DSM approaches, i.e., the mechanical reasoning behind these proposed procedures. It is based on the fact that (i) both the F and P columns fail in interactive modes, combining minor-axis flexural and (i_1) torsional (cruciforms) or (i_2) major-axis flexural-torsional (angles) deformations, and that (ii) the above interaction is much stronger in the P angle columns, due to the effective centroid shift effects. In order to incorporate these behavioural features into the DSM design approaches, it was necessary to find efficient/accurate ways to quantify (i) the F and P column torsional (cruciforms) and flexural-torsional (angles) strength, and (ii) the P angle columns effective centroid shift effects. These tasks were performed numerically and led to the development of genuine torsional (cruciforms) and flexural-torsional (angles) strength curves, which replace the local strength curve in the traditional design against local-global interactive failure. Moreover, the numerical investigation led also to the development of curves providing a parameter able to capture the angle P column ultimate strength erosion stemming from the effective centroid shifts. Since the flexural-torsional strength curves and the new parameter were found to be heavily length-dependent, their definition included the percentage ratio between the angle column torsional and flexural-torsional buckling loads, which is able to capture the above length-dependence, essentially linked to the amount of minor-axis flexural deformations in the angle column failure modes.

The merits of the developed DSM-based design approaches were assessed trough the comparison with experimental tests results reported in the literature and numerical (Abaqus SFEA) column failure loads obtained by the authors. Both the quality and reliability of the predictions provided by the proposed design procedures were found to be very good – in particular, it was shown that the LRFD resistance factor $\phi = 0.85$, presently prescribed for member design, can also be safely adopted for the cruciform and angle columns – the latter are currently explicitly excluded from the above prescription.

Flexural-torsional analysis of shear-deformable monosymmetric thin-walled open members – I. Closed-form solution

Mohammed Ali Hjaji
Department of Mechanical and Industrial Engineering, University of Tripoli, Tripoli, Libya

Magdi Mohareb
Department of Civil Engineering, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT: The governing field equations and boundary conditions based on a generalized Vlasov-Timoshenko beam theory are formulated using the principle of the stationary total potential energy. The formulation incorporates shear deformation effects due flexure and warping, and captures the flexural-torsional coupling in monosymmetric cross-sections. General closed-form solutions are obtained for cantilever boundary conditions. Numerical examples for the flexural-torsional coupled analysis are presented and compared with Abaqus finite element solutions. Additional comparisons are performed against non-shear deformable beam theories and the effect of transverse shear deformation is illustrated.

1 INTRODUCTION AND OBJECTIVES

Several studies investigated the coupled bending-torsional buckling of thin-walled beams. Based on the Vlasov beam theory, Friberg (1983), Leung (1991, 1992), Banerjee et al (1996), Kim et al (2007) developed the dynamic stiffness matrix in which shear deformation effects are neglected. Kollar and Pluzsik (2002) formulated the stiffness matrix for composite beams of open thin-walled sections. Kabir and Sherbourne (1999) derived a solution of thin-walled beams made from symmetric composite laminates. In their study, they neglected the effects of shear deformation and restrained torsional warping. Several studies on shear deformable beam theories have been conducted. Among them, Li et al (2004) developed the dynamic transfer matrix to formulate a solution for determining the coupled bending-torsional response of thin-walled beam under random excitations by considering the effects of warping stiffness and rotary inertia. Prokic (2006) formulated the governing equations for the coupled bending-torsional vibrations of thin-walled beams. Vo and Lee (2009) presented a general analytical solution for the study of flexural-torsional buckling and vibration analysis of open thin-walled composite beams. Jung and Lee (2003) derived a closed-form solution for both symmetric and anti-symmetric lay-up I-beam. Their solution included the effects of torsional warping and constrained warping. Kim et al. (2004) derived the exact stiffness matrices for the buckling and the elastic analysis of thin-walled beam with nonsymmetric cross-sections. Lee (2005) developed an analytical model to study the flexural behavior of thin-walled composite beams with doubly symmetric I-section subjected to distributed vertical load. The governing equations were derived from the principle of stationary potential energy are account for the ?exural response of the thin-walled composites beams. Kim and Shin (2009) derived a solution for thin-walled composite beams with monosymmetric cross-sections. Recently, Kim (2011) developed a shear deformable beam element for the coupled flexural and torsional analyses of thin-walled composite I-beams with doubly and monosymmetric cross-sections. He derived the governing equations and force–displacement relations using the principle of minimum total potential energy. His formulation captures restrained warping effects. More recently, using power series, Kim (2012) presented an explicit analytical expression for the coupled flexural-torsional analysis of thin-walled composite beams with channel section resting on elastic foundations.

To the best of author's knowledge, no study in the literature reported an analytical closed-form solution for the static transverse-torsional coupled response of thin-walled monosymmetric beams which captures shear deformation effects. Thus, the aim of the present study is to develop such a solution.

2 BASIC ASSUMPTIONS

The basic assumptions of the formulation are

1. The formulation is restricted to prismatic open thin-walled monosymmetric members,
2. Cross-section is assumed to remain undistorted (rigid) in its own plane but free to undergo warping in the longitudinal direction (Vlasov assumption),

3. The cross-section remains planar but does not remain perpendicular to the neutral axis after deformation, i.e., the transverse shear deformation of the mid-surface of the cross-section is incorporated in the formulation (Timoshenko beam assumption),
4. The deformations are assumed to remain within the elastic range of the material, and
5. Strains and rotations are assumed small.

3 KINEMATICS RELATIONS

Based on the above assumptions, the longitudinal displacement $w_p(z,s)$ and the in-plane displacements $u_p(z,s)$ and $v_p(z,s)$ of an arbitrary point $p[x(z), y(z)]$ on the mid-surface are, respectively, given by [e.g., Back and Will 1998]

$$\begin{aligned} w_p(z,s) &= w(z) + y(s)\theta_x(z) - x(s)\theta_y(z) - \omega(s)\psi(z) \\ u_p(z,s) &= u(z) - y(s)\theta_z(z) \text{ , and} \\ v_p(z,s) &= v(z) + [x(s) - x_s]\theta_z(z) \end{aligned} \tag{1-3}$$

where $w(z)$ is the average longitudinal displacement along the Z direction, $u(z)$ and $v(z)$ are the shear centre displacements along the principal X and Y axes, respectively, $\theta_x(z)$ and $\theta_y(z)$ are the rotations of the section about X and Y axes, $\theta_z(z)$ is the angle of twist of the cross-section, $\psi(z)$ is a function which characterizes the magnitude of the warping deformation, and $\omega(z)$ is the warping function of the section defined by $\omega(z) = \int_A h(z)\,dA$, where $h(s) = [x(s) - x_s]sin\alpha(s) - y(s)cos\alpha(s)$, $\sin\alpha(s) = dy(s)/ds$, $\cos\alpha(s) = dx(s)/ds$ and $\alpha(s)$ is the angle between the tangent of point p and the axis (Figure 1), $x(s)$ and $y(s)$ are the coordinates of point p, s is a curvilinear coordinate, and x_s is the coordinate of the shear center S_c along the axis of symmetry X. The tangential displacement component $\xi(z,s)$ of general point p on the mid-surface can be expressed in terms of the shear centre displacements and the rotation of the section as

$$\xi_p(z,s) = u(z)\frac{dx(s)}{ds} + v(z)\frac{dy(s)}{ds} + h(s)\theta_z(z) \tag{4}$$

4 VARIATIONAL FORMULATION

The total potential energy Π of the member is the sum of the internal strain energy U and the potential energy V of the applied forces, i.e., $\Pi = U + V$. Taking the first variation of Π and setting it equal to zero, one obtains

$$\delta\Pi = \delta U + \delta V = 0 \tag{5}$$

in which δU is the internal strain energy defined by

$$\delta U = \int_0^\ell \int_A \left[E\varepsilon_{zz}\delta\varepsilon_{zz} + G\gamma_{zs}\delta\gamma_{zs}\right]dA\,dz + \int_0^\ell GJ\theta_z'\delta\theta_z'\,dz \tag{6}$$

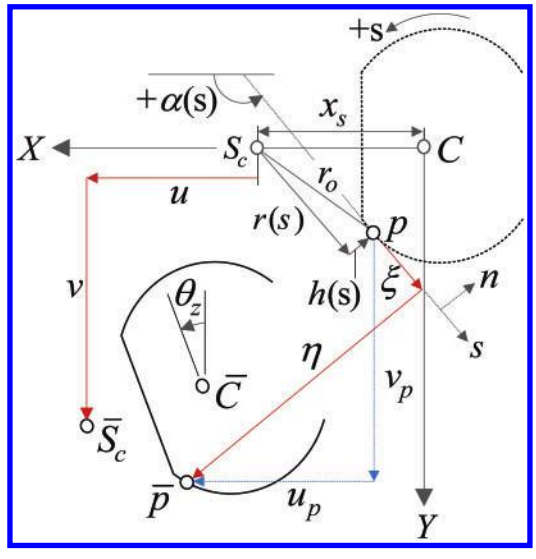

Figure 1. Coordinate systems and displacement components.

where E is the Young's modulus, G is the shear modulus, J is the St. Venant torsional constant, A is the cross-sectional area, $\varepsilon_{zz} = \partial w_p/\partial_z$ is the longitudinal strain and $\gamma_{zs} = \partial w_p/\partial_s + \partial\xi/\partial_z$ is the shear strain. All primes denote derivatives with respect to coordinate z. The potential of the applied forces δV is given by

$$\begin{aligned} \delta V = \int_0^\ell \Big[& q_z\delta w + q_x\delta u + q_y\delta v + m_z\delta\theta_z \\ & + m_x\delta\theta_x + m_y\delta\theta_y + m_w\delta\psi\Big]dz \\ & + \left[N_z\delta w\right]_0^\ell + \left[V_x\delta u\right]_0^\ell + \left[V_y\delta v\right]_0^\ell \\ & + \left[M_x\delta\theta_x\right]_0^\ell + \left[M_y\delta\theta_y\right]_0^\ell + \left[M_z\delta\theta_z\right]_0^\ell + \left[M_w\delta\psi\right]_0^\ell \end{aligned} \tag{7}$$

5 GOVERNING EQUATIONS

From Equations (1) to (4) and by substituting into energy Equations (6) and (7), and the resulting expressions into Equation (5), performing integration by parts and enforcing the orthogonality conditions; $\langle \int_A [x, y, xy, x\omega, y\omega, \omega]dA\rangle^T = \langle 0\rangle^T$, the governing field equations are given as

$$\begin{aligned} & EAw'' = -q_z\,, \\ & GD_{xx}\left(u'' - \theta_y'\right) = -q_x\,, \\ & GI_{yy}\theta_y'' + GD_{xx}\left(u' - \theta_y\right) = -m_y \\ & GD_{yy}\left(v'' + \theta_x'\right) + GD_{hy}\left(\theta_z'' + \psi'\right) = -q_y\,, \\ & -EI_{xx}\theta_x'' + GD_{yy}\left(v' + \theta_x\right) + GD_{hy}\left(\theta_z' + \psi\right) = m_x \\ & GJ\theta_z'' + GD_{hy}\left(v'' + \theta_x'\right) + GD_{\omega\omega}\left(\theta_z'' + \psi'\right) = -m_z\,, \\ & -EC_w\psi'' + GD_{hy}\left(v' + \theta_x\right) + GD_{\omega\omega}\left(\theta_z' + \psi\right) = m_w \end{aligned} \tag{9-15}$$

The relevant boundary conditions are obtained as

$$
\begin{aligned}
&\left[EAw'-N_z\right]\delta w_0^{\ell}=0,\\
&\left[GD_{xx}\left(u'-\theta_y\right)-V_x\right]\delta u\big|_0^{\ell}=0,\\
&\left[EI_{yy}\theta_y'-M_y\right]\delta\theta_y\big|_0^{\ell}=0,\\
&\left[GD_{yy}\left(v'+\theta_x\right)+GD_{hy}\left(\theta_z'+\psi\right)-V_y\right]\delta v\big|_0^{\ell}=0,\\
&\left[EI_{xx}\theta_x'+M_x\right]\delta\theta_x\big|_0^{\ell}=0,\\
&\left[GJ\theta_z'+GD_{hy}\left(v'+\theta_x\right)+GD_{\omega\omega}\left(\theta_z'+\psi\right)-M_z\right]\delta\theta_z\big|_0^{\ell}=0,\\
&\text{and }\left[EC_w\psi'+M_w\right]\delta\psi\big|_0^{\ell}=0
\end{aligned}
\tag{16-22}
$$

In the above Equations, the cross-sectional properties are defined as

$$
A, I_{xx}, I_{yy}, D_{xx}, D_{yy}, D_{hy}, D_{\omega\omega}
=\int_A\left[1, y^2, x^2, \left(\frac{dx}{ds}\right)^2, \left(\frac{dy}{ds}\right)^2, \left(\frac{dy}{ds}\right)\left(\frac{d\omega}{ds}\right), \left(\frac{d\omega}{ds}\right)^2\right]dA
$$

Equation (9) governs the longitudinal deformation of the member which is uncoupled from the remaining field equations and can be solved independently. Equations (10-11) provide the lateral deflection and related rotation, while Equations (12-15) govern the coupled transverse-torsional behaviour and associated warping deformation. The present study is focused on the closed-form solution for the response governed by the coupled transverse-torsional equations.

6 HOMOGENEOUS SOLUTION FOR COUPLED TRANSVERSE-TORSIONAL RESPONSE

The homogeneous solution of the coupled transverse-torsional equations (12-15) is obtained by setting the right-hand side of the equations to zero, i.e. $q_y(z)=m_x(z)=m_z(z)=m_w(z)=0$. The solution of the displacement functions is then assumed to take the form

$$
\begin{aligned}
\left\langle \bar{U}(z)\right\rangle_{1\times4}^{T}&=\left\langle v_h(z)\quad \theta_{xh}(z)\quad \theta_{zh}(z)\quad \psi_h(z)\right\rangle_{1\times4}^{T}\\
&=\left\langle C\right\rangle_{1\times4}^{T}e^{m_i z}\ ,\ \text{for } i=1,2,3,4
\end{aligned}
\tag{23}
$$

in which $\langle\bar{U}(z)\rangle_{1\times4}^{T}=\langle v_h(z)\ \theta_{xh}(z)\ \theta_{zh}(z)\ \psi_h(z)\rangle_{1\times4}^{T}$ is the vector of transverse and torsional displacements, and $\langle C\rangle_{i,1\times4}^{T}=\langle c_1 c_2 c_3 c_4\rangle_i$ is the vector of unknown integration constants.

From Equation (23), by substituting into Equations (12-15), rewritten in matrix form yielding

$$
\begin{bmatrix}
GD_{yy}m_i^2 & GD_{yy}m_i & GD_{hy}m_i^2 & GD_{hy}m_i\\
 & \left(GD_{yy}\right. & GD_{hy}m_i & GD_{hy}\\
 & \left.-EI_{xx}m_i^2\right) & & \\
 & Symm & G(D_{\omega\omega}+J)m_i^2 & GD_{\omega\omega}m_i\\
 & & & \left(GD_{\omega\omega}\right.\\
 & & & \left.-EC_w m_i^2\right)
\end{bmatrix}_{i,4\times4}
\times
\begin{bmatrix}
e^{m_1 z} & 0 & 0 & 0\\
0 & e^{m_2 z} & 0 & 0\\
0 & 0 & e^{m_3 z} & 0\\
0 & 0 & 0 & e^{m_4 z}
\end{bmatrix}
\begin{Bmatrix}c_1\\c_2\\c_3\\c_4\end{Bmatrix}_{i,4\times1}
=\left\{0\right\}_{4\times1}
\tag{24}
$$

A nontrivial solution is given by setting the determinant of the matrix to zero. The resulting quadratic eigen value problem is solved for the eight eigen pairs $(m_i, \{C\}_i)$. The solution of the coupled system of equation is

$$
\left\{\bar{U}(z)\right\}_{4\times1}=\left[\bar{C}\right]_{4\times8}\left[X(z)\right]_{8\times8}\left\{\bar{A}\right\}_{8\times1}
\tag{25}
$$

where $\left[\bar{C}\right]_{4\times8}=\left[\{C\}_1\ \{C\}_2\ \{C\}_3\ \{C\}_4\ \ldots.\ \{C\}_8\right]_{4\times8}$ is

where $[\bar{C}]_{4\times8}=[\{C\}_1\ \{C\}_2\ \{C\}_3\ \{C\}_4\ \ldots.\ \{C\}_8]_{4\times8}$ is the matrix of eigen vectors, $[X(z)]_{8\times8}=Diag[e^{m_1 z}\ e^{m_2 z}\ e^{m_3 z}\ e^{m_4 z}\ \ldots..\ e^{m_8 z}]_{8\times8}$ is a diagonal matrix of exponential functions, and $\{\bar{A}\}_{8\times1}$ is a vector of integration constants to be determined from the boundary conditions.

7 SOLUTION FOR CANTILEVER BEAM UNDER ENF FORCES

For a cantilever beam under tip loads $P_y(\ell)$, $M_x(\ell)$, $M_z(\ell)$ and $M_w(\ell)$, the unknown constants $\{\bar{A}\}_{4\times1}$ are determined from the boundary conditions at both ends, $z=0, \ell$

$$
\begin{aligned}
&v(0)=\theta_x(0)=\theta_z(0)=\psi(0)=0,\\
&GD_{yy}\left[v'(\ell)+\theta_x(\ell)\right]+GD_{hy}\left[\theta_z'(\ell)+\psi(\ell)\right]=P_y(\ell),\\
&EI_{xx}\theta_x'(\ell)=-M_x(\ell),\\
&GJ\theta_z'(\ell)+GD_{hy}\left[v'(\ell)+\theta_x(\ell)\right]\\
&\qquad+GD_{\omega\omega}\left[\theta_z'(\ell)+\psi(\ell)\right]=M_z(\ell)\ ,\ \text{and}\\
&EC_w\psi'(\ell)=-M_w(\ell).
\end{aligned}
$$

By substituting into the displacement fields in Equation (23), one obtains $\{\bar{A}\}_{4\times1}$ in terms of the tip loads $P_y(\ell)$, $M_x(\ell)$, $M_z(\ell)$ and $M_w(\ell)$.

Table 1. Static results for coupled lateral-torsional responses of monosymmetric cantilever.

Variable	Abaqus Beam [1]	Present Solution [2]	Vlasov Solution [3]	Diff = [1–2]/1	Diff = [1–3]/1

8 NUMERICAL EXAMPLES

Two examples are investigated in order to demonstrate the validity and accuracy of the present solution. In both examples, the material is assumed to be steel with $E = 200\,\text{GPa}$ and $G = 70\text{GPa}$. The analytical closed-form solution developed in the present study is applied.

8.1 *Example 1: Cantilever beam under Torsion - Coupled Lateral-Torsional Response*

A cantilever beam with monosymmetric I-section is subjected to concentrated twisting moment $M_z(\ell) = 8.0\,\text{kNm}$ applied at the cantilever free end. The dimensions of the cross-section are: flange thickness $t_f = 20\,\text{mm}$, web thickness $t_w = 15\,\text{mm}$, upper flange width $b_u = 100\,\text{mm}$, lower flange width $b_\ell = 200\,\text{mm}$ and a mid-surface height $H = 200\,\text{mm}$. The coordinate of the centroid in the direction of the principal axis of symmetry is $C_x = 77.78\,\text{mm}$ and the shear centre coordinate along the symmetry axis is $x_s = -55.56\,\text{mm}$. Section properties are;

$$A = 0.56\times10^4\,mm^2,\ I_{xx} = 15.0\times10^6\,mm^4,$$
$$J = 1.025\times10^6\,mm^4,\ C_w = 59.26\times10^9\,mm^6,$$
$$D_{xx} = 0.30\times10^4\,mm^2,\ D_{yy} = 0.60\times10^4\,mm^2,$$
$$D_{hy} = 2.667\times10^4\,mm^3 \text{ and } D_{\omega\omega} = 65.19\times10^6\,mm^4.$$

The analysis results for maximum lateral displacement v_A (point A is located at the intersection of the web and upper flange center-lines), twist angle θ_z and the warping deformation function ψ are given in Table (1) and Figure (2). Results are based on (a) the analytical closed-form solution developed in the present study, (b) Vlasov beam theory and (c) Abaqus beam solution using one-hundred B31OS beam element (≈700 dofs). Due to the mono-symmetry of the cross-section, the lateral response is fully coupled with torsional-warping response, but it is observed that the bending rotation θ_x vanishes in all three solutions. Results based on the present study are observed to exactly match those based on Vlasov theory and Abaqus beam model. It is also observed that, under the applied twisting moment, the bending rotation vanishes in all three solutions.

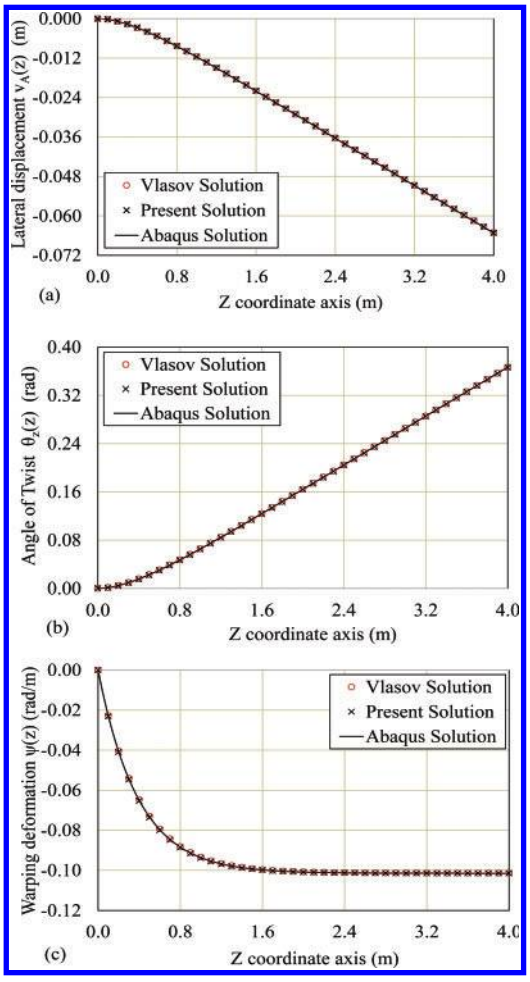

Figure 2. Static results for coupled lateral-torsional response of cantilever C-beam.

8.2 *Cantilever beam under End Transverse Forces-Shear Deformation Effect*

The purpose of this example is to demonstrate the ability of the present formulation to capture the shear deformation effects on the coupled transverse-torsional behavior of long span ($\ell = 4.8\,\text{m}$) and short span ($\ell = 1.0\,m$) cantilevers with monosymmetric channel-sections. The long cantilever is subjected to transverse force $P_y(\ell) = 4.0\,\text{kN}$ while the short cantilever is subjected to $P_y(\ell) = 80.0\,\text{kN}$ acting at the corner point A at the tip. The dimensions of the C-section are; flange thickness $t_f = 12\,\text{mm}$, web thickness $t_w = 8.0\,\text{mm}$, flange width $b = 80\,\text{mm}$ and mid-surface height $H = 200\,\text{mm}$. The coordinates of the centroid are $C_x = 21.82\,\text{mm}$, $C_y = 100\,\text{mm}$ and the coordinate of the shear centre along the axis of

Table 2. Tip deformations of cantilever C-section under transverse load.

Beam span	Variable	Abaqus Beam	Present Solution	Vlasov Solution
	v_A (mm)	−3.590	−3.787	−3.333
Short	θ_x (10_3 rad)	5.000	5.001	4.999
$\ell = 1.0\,m$	θ_z (10_3 rad)	−38.95	−39.89	−36.87
	ψ (10_6 rad/mm)	54.47	54.59	51.97
	v_A (mm)	18.50	18.54	18.43
Long	θ_x (10_3 rad)	−5.760	−5.760	−5.760
$\ell = 4.8\,m$	θ_z (10_3 rad)	13.61	13.62	13.61
	ψ (10_6 rad/mm)	−3.131	−3.124	−3.068

symmetry is $x_s = -53.12$ mm. The channel section properties are;

$$A = 35.2\times10^6\,mm^2,\ I_{xx} = 24.53\times10^6\,mm^4,$$
$$J = 0.126\times10^6\,mm^4,\ C_w = 16.92\times10^9\,mm^6,$$
$$D_{xx} = 0.192\times10^4\,mm^2, D_{yy} = 0.16\times10^4\,mm^2,$$

$$D_{hy} = 5.10\times10^4\,mm^3 \text{ and } D_{\omega\omega} = 20.77\times10^6\,mm^4.$$

Three solutions were provided based on; (i) present solution, (ii) Vlasov beam theory and (iii) Abaqus beam element model for long and short cantilever beams (Table 2). For longer span, the maximum transverse displacement $v_{\max}$, related rotation $\theta_{x\max}$, twist angle $\theta_{z\max}$ and warping deformation $\psi_{\max}$ obtained from the analytical solution developed in the present study are in excellent agreement with those based on Vlasov solution and Abaqus beam element model using 60 B31OS beam elements. For short cantilever, the present solution which captures the shear deformation effects due to bending and restraint warping predicts the transverse displacement, bending rotation, twist angle and warping deformation (a) are respectively 5.49%, 0.02%, 2.41%, and 0.22% greater than those based on the Abaqus beam element model which captured only the shear deformation due to bending. While due to the ignorance of shear deformation effects on the coupled transverse-torsional deformation, results obtained from the Vlasov theory (which ignores the shear deformation effects) are 7.16%, 0.02%, 5.34% and 4.59% lower than the corresponding results based on Abaqus beam solution.

The generalized displacements are plotted in Figure (3a-d). The transverse displacement, angle of twist and warping deformation based on the present solution demonstrate a significantly more flexible response than those obtained from the Vlasov solution but the bending rotation exactly coincided. The results based on excluding shear deformations underestimate the coupled transverse-torsional-warping response the thin-walled monosymmetric beam. Also, shear deformation effects are more significant for short beams.

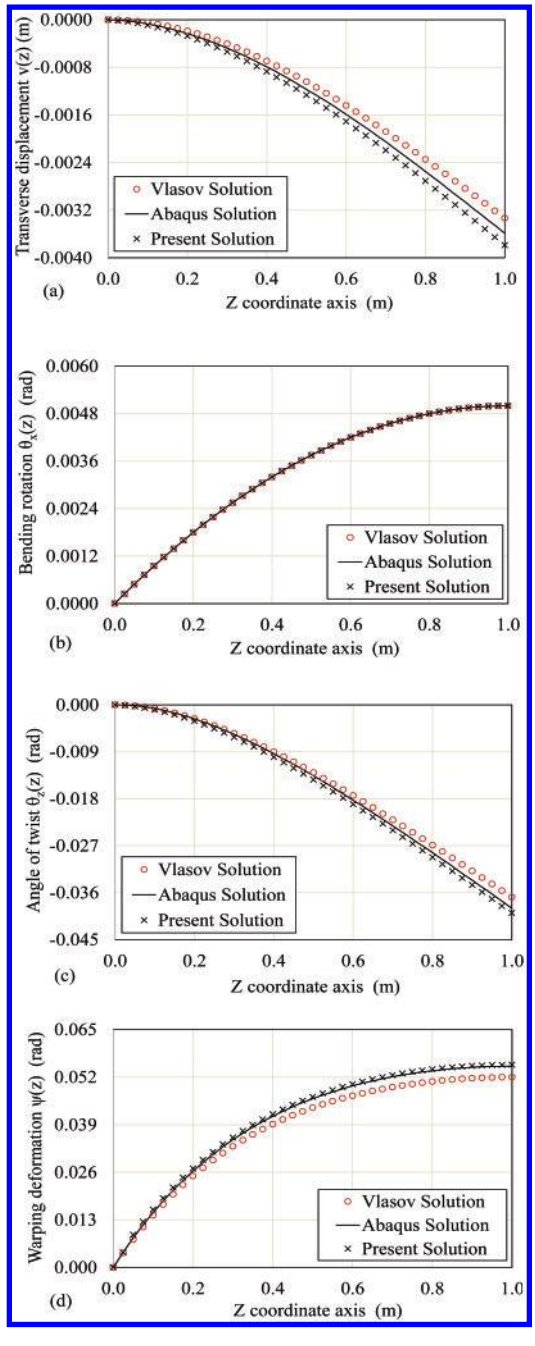

Figure 3. Response of short cantilever with a C-section under end transverse force.

9 SUMMARY AND CONCLUSIONS

1. The governing field equations and related boundary conditions were formulated for thin-walled beams of monosymmetric open cross-sections.
2. Closed-form solutions of coupled were obtained for cantilever as an example.

3. The formulation successfully captures the coupled flexural-torsional static response of monosymmetric cross-sections.
4. Numerical examples validated the accuracy of the present theory and to illustrated the shear deformation effects
5. The model provides superior predictions compared to Abaqus beam and Vlasov solutions.
6. Results show that shear deformation effects are more significant than short span beams.

Flexural-torsional analysis of shear-deformable monosymmetric thin-walled open members – II. Finite element formulation

Mohammed Ali Hjaji
Department of Mechanical and Industrial Engineering, University of Tripoli, Tripoli, Libya

Magdi Mohareb
Department of Civil Engineering, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT: A finite element formulation is developed for the coupled flexural-torsional analysis of thin-walled open members under general forces. Based on a generalized Timoshenko-Vlasov thin-walled beam theory, and the principle of minimum total potential energy, a two-node finite element is developed with four degrees of freedom per node. The element fully captures the effects of warping stiffness, shear deformation, and the torsional-flexural coupling and is based on shape functions which exactly satisfy the homogeneous form of the equilibrium conditions. The element is demonstrated to be free from shear locking and discretization errors occurring in conventional finite element solutions. The applicability of the finite beam element is illustrated through examples. The results based on the present formulation are compared against established analytical and finite element solutions and demonstrate the accuracy and efficiency of the solution.

1 INTRODUCTION AND OBJECTIVES

Several finite element solutions investigated the coupled torsional-flexural response of thin-walled open beams. Two types of shape functions have been used; (1) approximate polynomial functions, and (2) functions based on the exact solution of the governing equilibrium equations. Most finite element formulations lie within the first type, including the work of Chen and Tamma (1994), Lee and Kim (2002a, b), Kim and Kim (2005), Voros (2008, 2009), Vo and Lee (2010) and Vo et al. (2011). Among them, Chen and Tamma (1994) used the finite element method in conjunction with an implicit-starting unconditionally stable methodology for the dynamic analysis of thin-walled open members under deterministic loads. By using linear and cubic Hermitian shape functions, Lee and Kim (2002a, 2002b) investigated the coupled free vibration of thin-walled composite beams with doubly symmetric and channel-shaped cross-sections. Lee and Lee (2004) developed a finite element model to investigate the flexural and torsional behaviour of thin-walled composite I-beams with arbitrary laminate stacking sequence using a linear combination of the one-dimensional Lagrangian interpolation function for axial displacement and the Hermite-cubic interpolation function for lateral displacements and twist angle. In their formulation, the shear deformation effects were not considered. Kim and Kim (2005) derived the coupled flexural-torsional free vibration of asymmetric thin-walled shear deformable beam using an isoparametric finite beam element.

The influence of lateral forces on the coupled flexural-torsional free vibration of thin-walled open members was studied by Voros (2008, 2009) who developed a two-noded beam element with fourteen degrees of freedom. Vo and Lee (2010) and Vo et al. (2011) studied the coupled flexural-torsional free vibration of thin-walled composite beams under constant axial forces and end moments by developing a displacement-based one dimensional finite element model. Recently, Kim (2011) developed a shear deformable beam element for the coupled flexural and torsional analyses of thin-walled composite I-beams based on an isoparametric Lagrangian interpolation formulation. More recently, Kim (2012) extended his work (Kim 2011) to investigate the coupled flexural-torsional static analysis for thin-walled channel composite beams resting on elastic foundations. Finite element solutions based on exact homogeneous solution of the dynamic equations of motion include the work of Hjaji and Mohareb (2011) and offer two advantages: (1) it eliminates the discretization errors encountered in other finite element formulations, and thus it converges to the solution using a minimum number of degrees of freedom, and (2) it leads to elements that are free from shear locking normally arising in formulations based on approximate interpolation functions. To the best of the author's knowledge, such a finite element solution not been reported for monosymmetric sections and is thus the object of this paper. The reader is referred to the companion paper for the assumptions of the formulation and a description of the kinematics of the problem.

2 VARIATIONAL FORMULATION

The total potential energy Π of the member is the sum of the internal strain energy U and potential energy V gained by the applied forces. The first variation of $\delta\Pi$ must vanish to satisfy the equilibrium condition yielding

$$\delta\Pi = \delta U + \delta V = 0 \tag{1}$$

in which the expressions for the first variation of strain energy is given by:

$$\begin{aligned}\delta U &= \int_0^\ell \int_A \left[E\varepsilon_{zz}\delta\varepsilon_{zz} + G\gamma_{zs}\delta\gamma_{zs}\right] dA\,dz + \int_0^\ell GJ\theta_z'\delta\theta_z'\,dz \\ &= \int_0^\ell \Big[\left\langle \delta\bar{U}' \right\rangle_{1\times4}^T [Y_a]_{4\times4} \left\{\bar{U}'\right\}_{4\times1} \\ &\quad + \left\langle \delta\bar{U}_s \right\rangle_{1\times4}^T [Y_s]_{4\times4} \left\{\bar{U}_s\right\}_{4\times1} \Big] dz\end{aligned} \tag{2}$$

where E is the Young's modulus, G is the shear modulus, J is the St. Venant torsional constant, A is the cross-sectional area. The primes denote derivatives with respect to coordinate z. The longitudinal strain is

$$\varepsilon_{zz} = \partial w_p/\partial z = \left\langle X_a \right\rangle_{1\times4}^T \left\{\bar{U}'\right\}_{4\times1},$$

the vector of displacement derivatives is

$$\left\langle \bar{U}' \right\rangle^T = \left\langle\, v'(z) \quad \theta_x'(z) \quad \theta_z'(z) \quad \psi'(z) \right\rangle^T,$$

the shear strain is

$$\gamma_{zs} = \partial w_p/\partial s + \partial \xi_p/\partial s = \left\langle X_s \right\rangle_{1\times4}^T \left\{\bar{U}_s\right\}_{4\times1}, \text{ and}$$

$$\left\langle \bar{U}_s \right\rangle_{1\times4}^T = \left\langle v'(z) \;\; \theta_x(z) \;\; \theta_z'(z) \;\; \psi(z) \right\rangle_{1\times4}^T.$$

in which $v(z)$, $\theta_x(z)$, $\theta_z(z)$, $\psi(z)$ are the transverse displacement, related bending rotation, twist angle and warping deformation functions, respectively.

In Equation (2),

$$[Y_s]_{4\times4} = G\int_A \left\langle X_s \right\rangle_{1\times4}^T \left\{X_s\right\}_{4\times1} dA = \begin{bmatrix} GD_{yy} & GD_{yy} & GD_{hy} & -GD_{hy} \\ & GD_{yy} & GD_{hy} & -GD_{hy} \\ & & GD_{\omega\omega} & -GD_{\omega\omega} \\ Symm & & & GD_{\omega\omega} \end{bmatrix}_{4\times4}, \text{ and}$$

$$[Y_a]_{4\times4} = E\int_A \left\langle X_a \right\rangle_{1\times4}^T \left\{X_a\right\}_{4\times1} dA + GJ = diag\left[0 \;\; EI_{xx} \;\; GJ \;\; EC_w\right]_{4\times4},$$

where I_{xx} is a moment of inertia about X axis and C_w is the warping constant.

The section properties are defined by

$$D_{yy}, D_{hy}, D_{\omega\omega} = \int_A \left[\left(\frac{dy}{ds}\right)^2, \left(\frac{dy}{ds}\right)\left(\frac{d\omega}{ds}\right), \left(\frac{d\omega}{ds}\right)^2 \right] dA,$$

where $\omega(s)$ is the warping coordinate,

$$\left\langle X_a \right\rangle_{1\times4}^T = \left\langle 0 \;\; y \;\; 0 \;\; -\omega \right\rangle_{1\times4}^T, \text{ and}$$

$$\left\langle X_s \right\rangle_{1\times4}^T = \left\langle dy/ds \;\; dy/ds \;\; d\omega/ds \;\; -d\omega/ds \right\rangle_{1\times4}^T.$$

The first variation of the potential energy δV of the applied forces is

$$\begin{aligned}\delta V &= -\int_0^\ell \left[q_y\delta v + m_x\delta\theta_x + m_z\delta\theta_z + m_w\delta\psi \right] dz \\ &\quad + \left[V_y\delta v\right]_0^\ell + \left[M_x\delta\theta_x\right]_0^\ell + \left[M_z\delta\theta_z\right]_0^\ell + \left[M_w\delta\psi\right]_0^\ell \\ &= -\left[\left\langle \delta\bar{U} \right\rangle_{1\times4}^T \{F\}_{4\times1} \right]_0^\ell - \int_0^\ell \left\langle \delta\bar{U} \right\rangle_{1\times4}^T \{Q_s\}_{4\times1} dz\end{aligned} \tag{3}$$

Equations (2–3) are obtained by; (a) substituting the displacement fields given in companion paper [Hjaji and Mohareb 2013] into first energy expressions presented in Equations (2–3), and (b) enforcing the orthogonality conditions; $\int_A [x, y, xy, x\omega, y\omega, \omega] dA = 0$. In Equation (3), $q_y(z)$ is the distributed transverse force, $m_i(z)$ for are the distributed moments about X and Z axes, $m_w(z)$ is the distributed bimoment, $V_y(z_e)$ are the transverse end forces, $M_i(z_e)$ for $i = x, z$ are the end moments about X and Z, and $M_w(z_e)$ are the end bimoments. All forces and moments are applied at beam ends ($z_e = 0, \ell$). The sign conventions of the applied forces are identical to those introduced for the end displacement fields [Hjaji and Mohareb 2013].

In line with the objective of the present paper, the present study focuses on the coupled transverse-torsional-warping response of thin-walled monosymmetric cross-sections. Consequently, neglected are the terms associated with the longitudinal response and pure flexural response along the direction of symmetry axis.

3 FORMULATION OF EXACT SHAPE FUNCTIONS

Expressions for displacement fields for the coupled field equations were derived in the companion paper [Hjaji and Mohareb 2013] as

$$\left\{\bar{U}(z)\right\}_{4\times1} = \left[\bar{C}\right]_{4\times8} \left[X(z)\right]_{8\times8} \left\{\bar{A}\right\}_{8\times1} = \left[\chi(z)\right]_{4\times8} \left\{\bar{A}\right\}_{8\times1} \tag{4}$$

in which we recall that $[\chi(z)]_{4\times8} = [\bar{C}]_{4\times8}[X(z)]_{8\times8}$, matrix $[\bar{C}]_{4\times8}$ contains the eigenvectors of the

quadratic eigenvalue problem arising from the coupled system of equilibrium equations, $[X(z)]_{8\times 8} = Diag[e^{m_1 z}\ e^{m_2 z}\ e^{m_3 z}\ \ldots\ldots\ e^{m_8 z}]_{8\times 8}$ is a diagonal matrix of the exponential functions $e^{m_i z}$ (m_i being the eigen values of corresponding eigen values), and $\{\bar{A}\}_{8\times 1}$ is a vector of integration constants to be determine from the boundary conditions of the problem., In the present treatment, the constants in $\{\bar{A}\}_{8\times 1}$ are related to the nodal displacements $\{U_N\}_{8\times 1}$ through

$$\{U_N\}_{8\times 1} = \begin{Bmatrix} \{\bar{U}(0)\}_{4\times 1} \\ \{\bar{U}(\ell)\}_{4\times 1} \end{Bmatrix}_{8\times 1} = \begin{bmatrix} [\chi(0)]_{4\times 8} \\ [\chi(\ell)]_{4\times 8} \end{bmatrix}_{8\times 8} \{\bar{A}\}_{8\times 1} = [T]_{8\times 8}\{\bar{A}\}_{8\times 1} \tag{5}$$

From Equation (9), by substituting into Equation (8), one obtains:

$$\{\bar{U}(z)\}_{4\times 1} = [\chi(z)]_{4\times 8}[T]^{-1}_{8\times 8}\{U_N\}_{8\times 1} = [H(z)]_{4\times 8}\{U_N\}_{8\times 1} \tag{6}$$

where

$$[H(z)]_{4\times 8} = [\chi(z)]_{4\times 8}[T]^{-1}_{8\times 8} = \left[\{H_{1,j}(z)\}_{8\times 1}\ \{H_{2,j}(z)\}_{8\times 1}\ \{H_{3,j}(z)\}_{8\times 1}\ \{H_{4,j}(z)\}_{8\times 1}\right]_{4\times 8}$$

is the matrix of the shape functions which exactly satisfy the homogeneous form of the coupled governing field equations.

4 FINITE ELEMENT FORMULATION

From Equation (6), by substituting into energy expressions in Equations (2) and (3), and then substituted in Equation (1), one recovers

$$[K_e]_{8\times 8}\{U_N\}_{8\times 1} = \{F_e\}_{8\times 1} \tag{7}$$

In Equation (7),

$$[K_e]_{8\times 8} = \int_0^{\ell}\left[[H'(z)]^T_{8\times 4}[Y_a]_{4\times 4}[H'(z)]_{4\times 8} + [H_s(z)]^T_{8\times 4}[Y_s]_{4\times 4}[H_s(z)]_{4\times 8}\right]dz$$

is the element stiffness matrix, and

$$\{F_e\}_{8\times 1} = \int_0^{\ell}\left[[H(z)]^T_{8\times 4}\{Q_s\}_{4\times 1}\right]dz + \left[[H(z)]^T_{8\times 4}\{Q_c(z)\}_{4\times 1}\right]_0^{\ell}$$

is the element load vector, where

$$[H_S(z)]_{4\times 8} = \left[\{H'_{1,j}(z)\}_{8\times 1}\ \{H_{2,j}(z)\}_{8\times 1}\ \{H'_{3,j}(z)\}_{8\times 1}\ \{H_{4,j}(z)\}_{8\times 1}\right]_{4\times 8}.$$

5 NUMERICAL EXAMPLES AND DISCUSSION

In the following examples, material is steel are $E = 200$GPa and $G = 70$GPa. As a result of the exact shape functions derived, the present treatment eliminated mesh discretization errors is compared with additional solutions; (1) An analytical solution based on Vlasov beam theory and (2) An Abaqus B31OS beam element solution.

5.1 *Example 1: Cantilever C-beam under Torsion*

A cantilever thin-walled monosymmetric channel-section subjected to; (i) concentrated transverse force $P_y(\ell) = 4.80$ kNm applied at the cantilever free end, and (ii) uniformly distributed transverse force is considered as illustrated in Fig. (1). Section dimensions are; $t_f = 12$ mm, $t_w = 8$ mm, $b = 80$ mm, $H = 200$ mm. The coordinates of the centroid are $C_x = 21.82$ mm, $C_y = 100$ mm and the coordinate of the shear centre along the axis of symmetry is $x_s = -53.12$ mm. The section properties are; $D_{yy} = 0.16 \times 10^4$ mm^2, $D_{hy} = 5.1 \times 10^4$ mm^3 and $D_{\omega\omega} = 20.8 \times 10^6$ mm^4.

The results of nodal displacements obtained from the present finite element formulation using a single beam element are compared with Vlasov beam solution and Abaqus beam element model using one-hundred B31OS element with 700 degrees of freedom in order to achieve the solution accuracy. Table (1) provides the shows that the nodal degrees of freedom

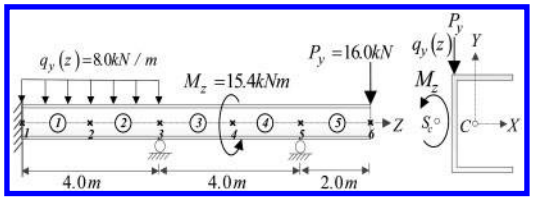

Figure 2. Continuous beam with channel-section under transverse and torsional loads.

results predicted from the present finite element using a single beam element with 8 dof are found exactly identical to the analytical closed-form solution developed in the companion paper. It is observed that the present formulations (which captures the shear deformation due to bending and warping torsion) are in excellent agreement with the results based on Vlasov beam theory (which discounts the shear deformation effects) and Abaqus beam element solution (which captures only the shear deformation due to bending) using 100 B31OS beam elements (700 dofs). Even though shear deformation effects are neglected fully in the Vlasov solution and partially in Abaqus beam solution, both solutions predict results in close agreement with the present formulation. This indicates that shear deformation effects are not significant for the present long-span beam problem.

5.2 *Example 2: Continuous Three-Span beam - Finite element formulation*

A three-span beam with the cross-section in Example 1 is subjected to three forces; concentrated transverse force $P_y(\ell) = 16.0\,kN$, concentrated twisting moment $M_z = 15.4$ kNm and uniformly distributed transverse force $q_y = 8.0\,kN/m$ is considered (Figure 3). It is required to compare the response of the continuous beam based on the finite element formulation with those based on the Abaqus beam element.

The problem is solved based on five beam elements (20 dofs). Results based on the present formulation are compared with the Abaqus solution which was able to achieve convergence based on 200 B31OS beam elements (1400 dofs). The analysis results for the nodal transverse displacement, related rotation, twist angle and warping deformation plotted against the beam axis Z are displayed in Figure (4a–d). The present solution based on five elements is in excellent agreement with that based on the Abaqus solution.

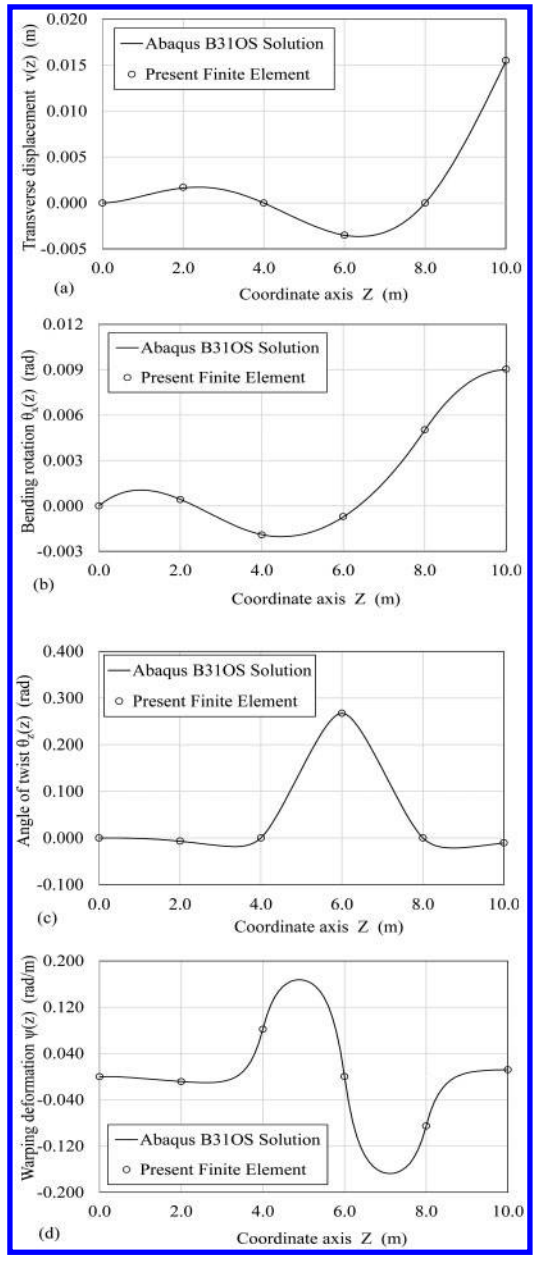

Figure 3. Static analysis for three-span monosymmetric C-beam under transverse and torsional forces.

6 SUMMARY AND CONCLUSIONS

(1) A super-convergent finite element was developed for the analysis of thin-walled members with monosymmetric sections.
(2) The element is based on a generalized Vlasov-Timoshenko beam theory which accounts for shear deformation effects due to bending and non-uniform torsion.
(3) The finite element formulation developed successfully captures the coupled flexural-torsional response of monosymmetric cross-sections.
(4) Results are in excellent agreement with Abaqus beam element at a small fraction of the computational and modeling cost.
(5) Since integration within the element is explicit, shear locking problems do not arise in the formulation.

Flexural strength of single channels restrained by angle cleats

G.M. Bukasa & M. Dundu
University of Johannesburg, Johannesburg, South Africa

ABSTRACT: It is common practice to restrain members in flexure using fly-bracings. In this investigation a series of channels are restrained by a purlin–angle cleat connection. The channels are subjected to a two point loading system in order to simulate a distributed load. Variable in the tests include the unbraced length between the two-point loads and the size of the channels. Failure of the channels occurred by local buckling of the compression zone of the flange and web and lateral torsional buckling of the channels between points of lateral support. The capacity reached by the channels shows that the purlin-cleat restraining system is able to resist lateral torsional buckling of the channels, and that this system can be used without including any fly bracing.

1 INTRODUCTION

Cold-formed steel channels are widely used as structural elements, especially in residential, industrial and commercial buildings. In these structures, the smaller sections are normally used as purlins and diagonal bracing elements, and the larger sections are used as the main frame. When cold-formed steel lipped channels are used as the main frame members, for example in portal frames, the channels are usually restrained against lateral torsional buckling from the top flange through an angle cleat-purlin connection. Torsional restraint is usually provided by fly bracings. This restraining system is complicated and has the disadvantages of tearing the bolted area of the top flange of the main frames if it is in tension or weakening the bearing area of the top flange, if the purlin is subjected to large downward loads.

For this reason, this study investigates a restraint that avoids the use of fly bracing and bolt-holes in the top flange of the rafter. Restraint of the beam rafter or main frame is still provided by a purlin-angle cleat connection; however the angle is long enough to connect the web of the main beam or rafter. This restraint has also the advantage of preventing the rafter and purlin's web from crippling at loading points, since it connects both elements in the web, and no drilling or welding is performed in the top flange. In addition, the moment capacities that can be achieved by these beams, with the proposed bracing, are also determined.

In all the tests carried out, the sections used are all cold-formed steel sections in order to make the structure light and all the elements of the structure are connected together by bolts only. The size of the beams investigated in this paper are $300 \times 75 \times 20 \times 2.0$ mm, $300 \times 75 \times 20 \times 2.5$ mm and $300 \times 75 \times 20 \times 3.0$ mm, and the purlin and angle cleat section are $100 \times 50 \times 20 \times 2$ mm and $100 \times 75 \times 20 \times 3$ mm, respectively. The support systems were designed to achieve simply supported end conditions in both the vertical and horizontal planes. Restraints were provided at the loading points and the beams were subjected to a two-point loading system in order to experience uniform bending in the internal span. The objectives of the tests are to examine the ability of thin cold-formed angle cleat to restrict lateral-torsional buckling and to compare the test results with unfactored resistances from the South African cold-formed steel code, SANS10162-2 (2005). This code is based on the Canadian code (CAN/CSA S16.1-M01) and the North American Specification (AISI S100-07).

2 MATERIAL PROPERTIES

The material properties were determined from the web coupons, which were cut from the $300 \times 75 \times 20 \times 2$ mm, $300 \times 75 \times 20 \times 2.5$ mm, and $300 \times 75 \times 20 \times 3$ mm sections Coupon tests from the web represent material properties of virgin steel sheet. The coupons were prepared and tested in a 100 kN capacity displacement controlled testing machine according to the guidelines provided by the British Standard, BS 18. The tensile load was applied to coupon test at a rate of 3.0 mm/min until failure.

Stress-strain relationships of the coupons were derived from the load-elongation relationship using its original cross-sectional area and the gauge length. The average yield stress (f_y), ultimate stress (f_u) and modulus of elasticity (E) of the steel in Table 1 were determined from these stress-strain curves. In compliance with SANS-10162-1 (2005), the material properties of the channels achieved the recommended ductility requirements, that is, the percentage elongation at failure exceeded 10% for a 50 mm gauge length

Table 1. Average material properties.

Specimen	f_y (MPa)	f_u (MPa)	E (GPa)
300 × 75 × 20 × 2.0	246.60	346.05	206.35
300 × 75 × 20 × 2.5	287.30	364.05	201.61
300 × 75 × 20 × 3.0	265.70	351.55	205.58

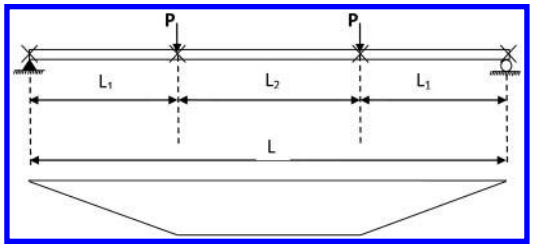

Figure 1. Restraints and support system.

Table 2. Length of tested beams.

Specimen	L (mm)	L_2 (mm)	L_1 (mm)	r_y (mm)	KL_2/r
300 × 75 × 20 × 2.0	5900	2200	1800	25.7	85.60
300 × 75 × 20 × 2.5	5900	1800	2000	25.4	70.87
300 × 75 × 20 × 2.5	5900	2000	1900	25.4	78.74
300 × 75 × 20 × 2.5	6000	2400	1750	25.4	94.49
300 × 75 × 20 × 3.0	4600	1800	1350	25.1	71.71
300 × 75 × 20 × 3.0	5900	2200	1800	25.1	87.65
300 × 75 × 20 × 3.0	6000	2400	1750	25.1	95.62

and the ratio of the specified ultimate tensile strength (f_u) to the specified yield strength (f_y) exceeded 1.08.

3 TEST PROGRAMME

3.1 *Test set-up*

A set-up was prepared to test the ability of thin cold-formed steel angle-cleats to restrain the beams from failing due to lateral-torsional buckling. The beams consisted of three different sections, namely; 300 × 75 × 20 × 2 mm, 300 × 75 × 20 × 2.5 mm and 300 × 75 × 20 × 3 mm, in order to vary the slenderness ratios, and were tested under two point loading as illustrated by the schematic diagram in Figure 1. Two-point loading provides a constant moment between the applied loads so that pure bending failure only is experienced. This loading arrangement simulates a distributed load over the entire span of the beam. The support system was designed to ensure that the beam test is simply supported, and that only lateral deflection is prevented at the ends. Lateral and torsional restraints were provided by the angle cleats at the loading points. Details of the span and points of bracing are shown in Table 2.

The middle unbraced lengths were selected based on the recommendation by Schuster (1991) on maximum unbraced length. According to this recommendation, the internal length should be greater than the maximum laterally unbraced length (L_u) for lateral-torsional buckling to occur. For a channel section the maximum unbraced length (L_u) is given by:

$$L_u = \left\{ \frac{GJ}{2C_1} + \left[\frac{C_2}{C_1} + \left(\frac{GJ}{2C_1} \right)^2 \right]^{1/2} \right\}^{1/2} \quad (1)$$

where,

$$C_1 = \frac{11.3 f_y^2 K_y^2 S_{xc}^2}{C_b^2 A \pi^2 r_y^2 E} \quad \text{and} \quad C_2 = \frac{\pi^2 E C_w}{K_t^2}$$

In Equation (1), G is the shear modulus, J is the St. Venant torsional constant, K_y is the effective length factor for bending about the minor axis, K_t is the effective length factor for torsional buckling, S_{xc} is the effective section modulus about the x-axis, the bending coefficient $C_b = 1/\omega \leq 2.5$, where, $\omega = 0.6 + 0.4\kappa$ (κ is the ratio of the smaller to the larger moment at opposite ends of the unbraced portion/segment, positive for double curvature and negative for single curvature), A is the area and C_w is the warping constant. The maximum unbraced length was derived by equating the critical elastic lateral-torsional buckling stress to the yield stress of the material.

A pair of channels was used in the test to allow interaction between the beams to occur, and to provide stability to the test set-up. This idea was selected based on previous research (Kavanagh and Ellifritt (1994), Goncalves, Malite and Javaroni (2000), and Dundu and Kemp (2006a,b)). The present investigation adopted spacing between two beams of 1.84 m from a study conducted by Dundu and Kemp (2006a, b). Two purlins, size 100 × 50 × 20 × 2 mm cold-formed sections, were used in all the tests to connect the two beams. The channels are oriented in the same direction as this offers greater stiffness than having the channels oriented in different directions (Dundu and Kemp 2006a, b).

To make the frame light-weight all members including the angle cleat are cold-formed steel members. The connection configuration of the angle cleat is shown in Figure 2. As indicated in the figure, M20 and M12 high strength bolts were used to connect the 100 × 75 × 20 × 3 mm cold-formed angle-cleat to the 300 × 75 × 20 × 3 beam channel and 100 × 50 × 20 × 2 mm purlin, respectively. The bolts used to attach angle cleat to purlin were aligned diagonally in order to generate enough rotational moment of resistance. To prevent premature local buckling failure of the beams, at the point where the load was applied, the web and the flange was stiffened using a hot-rolled steel angle, as shown in Figure 3.

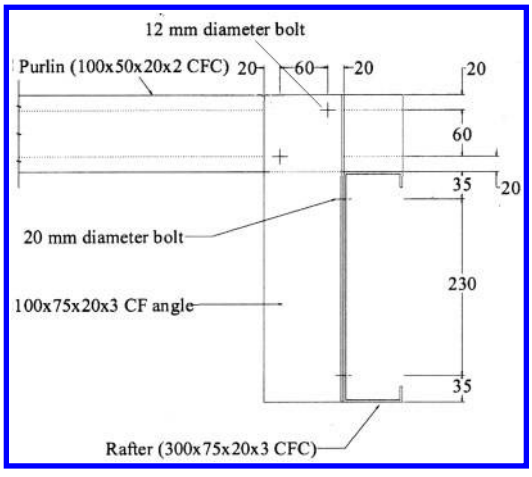

Figure 2. Angle-cleat connection.

Figure 3. Web and flange stiffener.

Figure 4. Test set-up.

3.2 *Instrumentation*

The beams were fully instrumented so that in-plane and out-of-plane deflection, strains and rotation could be measured. The measurements were recorded at the mid-span of the beams by means of a data-logging system. Two computers were used during the tests; one was used to initiate the application of the load by the Instron to the test beams, and another one to collect the readings from the data logger. In-plane and out-of-plane deflections of a beam were monitored using three linear variable differential transducers, commonly known as LVDTs. The LVDTs were installed at mid-span, since the maximum vertical and lateral deflections were expected to occur at this point.

In addition to the LVDTs in the web, a rotation gauge (also known as an AccuStar Electronic Clinometer) was installed at the centre of the web located at mid-span of the beam to monitor the rotation. Figure 5 shows the rotation gauge. The two holes of the clinometer were aligned vertically so that the output from the multimeter could read zero in the unloaded condition.

Longitudinal strains at mid-span were recorded by means of strain gauges. This was done in order to determine the moment-curvature behaviour of the beam. Two strain gauges were used for each channel; one placed inside the top flange (compression zone), and another one placed inside the bottom flange (tension zone).

3.3 *Test procedure*

Once all devices were set and calibrated, the loading procedure began. Great care was taken so that both computers start recording data at the same time. A 250 kN hydraulic Instron was used to apply a downward load to the test beam through spreader beam until its failure. The channels were subjected to equal loads. Each beam was incrementally loaded at the rate of 0.5 mm/min, so that the behaviour and failure patterns of the beam could be well observed during the test. The readings were taken after each load increment until the beams collapsed. The test was stopped once the load started falling off.

4 FAILURE MODES

The governing failure mode for all the beams tested was lateral-torsional buckling. Lateral-torsional buckling is shown in Figure 5, and was largely influenced by the length of the internal segment. In both beams the outside segments and the restraining angle cleats remained vertical. This is clear evidence that the angle cleats were able to restrain the channels. In all the $300 \times 75 \times 20 \times 3$ mm and $300 \times 75 \times 20 \times 2.5$ mm beams tested lateral-torsional buckling of the internal segment was accompanied by distortional buckling of the web, which deflected inward towards the centroid (Figure 6(a)) followed by distortional buckling of the top compression flange, which deflected upwards (Figure 6(b)). In contrast to the $300 \times 75 \times 20 \times 3$ mm and $300 \times 75 \times 20 \times 2.5$ mm channels, distortional buckling of the $300 \times 75 \times 20 \times 2$ mm caused the web to deflect outward towards the shear centre and the top compression flange to deflect inward towards the neutral axis. This behavior can be attributed to the small

Figure 5. Lateral-torsional buckling.

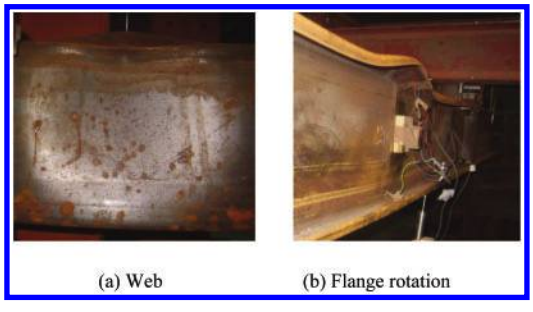

Figure 6. Distortional buckling.

thickness exhibited by the section. Considerable more distortional buckling failure of both the web and top flange were experienced in the 300 × 75 × 20 × 2 mm section because of the smaller thickness.

5 TEST RESULTS

The results of the flexural tests are shown in Table 3 In this table M_t is the maximum moment applied to the tested specimens and M_r is the buckling moment resistance, determined using the South African structural steel code, SANS 10162-2 (2005). As indicated in the introduction of this paper, this code is based on the Canadian cold-formed structural steel code, CAN-S16.1-M01, and the North American Specification, AISI S100-07. The buckling moment of resistance of the middle unbraced length is determined, based on modified section properties (effective width of compression elements) to control local buckling. The effective width concept was first proposed by Von Karman (1932) and calibrated for use by Winter (1947). An effective length factor of 1 is assumed for bending about the minor axis and a moment-gradient factor of 1 is used because of the uniform bending moment diagram.

As expected the moment capacities of all beams in Table 3 decrease with increase of the middle segment length. A comparison of the test moments and the buckling moment resistances shows the test moments of all the sections, except the 300 × 75 × 20 × 2.5 of 2.4 m length, to be larger than the buckling resistance. Significantly larger test moments are achieved by 1.8 m length of the 300 × 75 × 20 × 2.5 and 300 × 75 × 20 × 3.0 sections. In these two cases the test-to-predicted moments are 32% and 28% respectively. On average the tests moments are 16% greater than the moments predicted by SANS 10162-2 (2005). Table 3 also shows that the ratio of the test-to-predicted moments tends to be larger for sections of shorter length, and decrease as the length of the channels increases.

Table 3. Test results.

Specimen (h × b × c × t)	L_u (m)	f_y (MPa)	M_t (kNm)	M_r (kNm)	M_t/M_r
300 × 75 × 20 × 2.0	2.2	246.60	20.98	18.05	1.16
300 × 75 × 20 × 2.5	1.8	287.30	34.66	26.18	1.32
300 × 75 × 20 × 2.5	2.0	287.30	27.18	24.82	1.10
300 × 75 × 20 × 2.5	2.4	287.30	22.00	22.14	0.99
300 × 75 × 20 × 3.0	1.8	265.70	39.51	30.82	1.28
300 × 75 × 20 × 3.0	2.2	265.70	32.38	30.32	1.07
300 × 75 × 20 × 3.0	2.4	265.70	31.25	29.67	1.05

In general the test moments obtained compares favourably well of with the prediction of the South African code, SANS10161-2 (2005). The fact that the tests moments are larger than the code-predicted moments shows that the angle cleats are able to restrain lateral-torsional buckling. Even at the stage where the internal segment of the beam buckled, the angle cleat configuration remained vertical. Lateral-torsional buckling did not contribute to a significant loss of moment of resistance until distortional kicked in or took effect.

6 CONCLUSION

This paper has described tests on the lateral-torsional buckling behaviour of cold-formed channels beams, subjected to two- point loading and restrained by angle cleats. From the tests the following conclusions are made:

- The lateral-buckling strength values obtained from the tests are in all cases larger than the values predicted by the Canadian/South-Africa code of practice. The fact that the tests moments are larger than the code-predicted moments shows that the angle cleats are able to restrain lateral-torsional buckling. Even at the stage where the internal segment of the beam was buckling, the angle cleat configuration remained vertical.
- In all cases, failure of the channels occurred by a combination lateral-torsional buckling of the internal segment and distortional buckling of the web and the flange. The capacity reached by the channels shows that an angle-cleat restraining system is

able to resist lateral-torsional buckling. This means that such a system can be used without the need of fly-bracings, as is normally done in practice to restrain torsion instability.

- The connection configuration investigated is found to be better, not only because it restrains both lateral and torsional movements of the member, but, it is also acting as web stiffeners for both purlin and rafter.

Single shear screwed connection tests of thin sheet steel at elevated temperatures

S. Yan
Ove Arup & Partners Hong Kong Ltd., Kowloon Tong, Hong Kong, China

B. Young
Department of Civil Engineering, The University of Hong Kong, Hong Kong, China

ABSTRACT: The design rules on screwed connections of thin sheet steel in the current International specifications for cold-formed steel structures are only applicable for ambient temperature. Up-to-date, investigation of screwed connections at elevated temperatures is quite limited. In this study, a total of 24 single shear screwed connection specimens fabricated from G550 0.42 mm, G500 1.20 mm and G450 1.90 mm thin sheet steels were conducted by transient state test method. The tests were performed at three different load levels of 25%, 50% and 75% of the failure load at ambient temperature. The critical temperature and the corresponding displacement of screwed connections were obtained from the transient state test curves. The connection strength deterioration obtained from the transient state tests was compared with that obtained from steady state tests. The critical temperatures determined by the transient state test results are slightly higher compared with those deduced from the steady state test results at similar load levels, and even higher than those from the coupon test results. Different failure modes, such as bearing, tear out, material failure and several combined failure modes were observed in the transient tests. It is found that the failure mode of the screwed connections may change as the load level increases.

1 INTRODUCTION

The use of high strength cold-formed steel structural members has increased rapidly in recent years. Cold-formed steel can provide a substantial increase in strength to weight ratio compared with thicker hot-rolled steel members (Young & Rasmussen 2000). Self-tapping screws are convenient to provide an effective means to fasten sheet metal roofing to frame members as well as connecting light gauge steel structural members together. The pull-through failures of screws in crest-fixed trapezoidal steel claddings has been numerically studied by Mahaarachchi and Mahendran (2004). Furthermore, screws can also be used as connectors in timber structures (Fragiacomo et al. 2011) and timber lightweight concrete composite floors (Jorge et al. 2010).

Screwed connection specimen tests have been conducted by Rogers and Hancock (1998 and 1999)that mainly focused on the bearing failure. Based on their test results, the Australian/New Zealand Standard (AS/NZS 2005) for cold-formed steel structures has modified the bearing factors in the design equations for tilting and bearing failure of screwed connections. However, the design rules of screwed connections in the current specifications (AS/NZS 2005; AISI 2007; EC3 2006) of cold-formed steel structures are based on investigation at ambient temperature, which means that they are not applicable to connections under elevated temperatures condition. Lu et al.(2009a and 2009b) investigated single lapped screwed connections in the temperature range from 20°C to 600°C. The reduction in screwed connection strengths and the failure modes were reported. Chen and Young (2006a and 2007) investigated the material properties of cold-formed steel at elevated temperatures. Yan and Young (2012) conducted more than one hundred screwed connections of thin sheet steels at elevated temperatures using steady state test method. It is shown that the current design rules are conservative when the reduced material properties were used to calculate the connection strengths.

The testing of a loaded structure under fire conditions can be carried out in two generic ways: (1) transient state testing; or (2) steady state testing (Wang 2002). In the transient state tests, the specimen is under a constant stress level while the temperature raise until the failure take place (Chen & Young 2006b). The transient state test method is some how closer to real fire situation compared with the steady state test method. The transient state test method has been used in experimental (Tan et al. 2007) and numerical (Young & Ellobody 2011) investigation on structural behaviour of steel and composite columns at elevated temperatures. However, the experimental investigation on the screwed connections of thin sheet steels in transient state is limited.

This paper reported a test program on single shear Screwed connections fabricated from three different thicknesses of steels tested under transient state test method. The screwed connections were investigated by varied the screw size, steel plate thickness, number and arrangement of the screws in five test series. The transient state tests were conducted at three different load levels, namely 0.25, 0.50 and 0.75 of the failure load at ambient temperature. The critical temperature is defined as the temperature that caused the failure of the specimen. The strength reduction and the failure modes of the screwed connections observed in the transient state tests were also compared with the steady state test results.

2 TRANSIENT STATE TESTS OF SCREWED CONNECTIONS

A total of 24 single shear screwed connection specimens were tested using transient state test method. The specimen design and specimen labeling are identical to those of the steady state tests conducted by Yan and Young (2012). All the screwed connection tests were conducted using the same MTS machine and test rig as those of the bolted connection tests conducted by Yan and Young (2011a). In this study, the screwed connection specimens were fabricated from the same batch of thin sheet steels as those specimens tested using the steady state test method, namely G550 0.42 mm, G500 1.20 mm, and G450 1.90 mm sheet steels. The material properties, including the 0.2% proof stresses($f_{0.2,normal}$ and $f_{0.2,T}$), tensile strengths ($f_{u,normal}$ and $f_{u,T}$), elastic moduli (E_{normal} and E_T) and ultimate strains ($\varepsilon_{u,normal}$ and $\varepsilon_{u,T}$), were obtained from normal room (ambient) temperature of 22°C to 900°C for each sheet steel. The details of the tensile coupon tests and the test results of the material properties are reported in Yan and Young (2011a).

2.1 *Load levels and heating rate*

Three different load levels were adopted in the transient state tests, namely 0.25, 0.50 and 0.75 of the failure load at ambient temperature ($P_{u,normal}$) which was obtained from the steady state tests conducted by Yan and Young (2012). As a result, the loading on each connection specimen was chosen as $0.25P_{u,normal}$, $0.50P_{u,normal}$, and $0.75P_{u,normal}$. The single shear screwed connection specimens were aiming to heat up according to the ISO Standard fire curve (EC1 2002). However, in this study, the ISO standard fire curve was not able to obtain in the first 5 – 6 minutes of the heating process due to the limitation of the heating rate on the MTS model 653.04 high temperature furnace. Therefore, the heating rate used in this study is follows: (a) The maximum heating rate of 100°C/min of the furnace was used in the first 5 minutes, and raised the temperature from 20°C to 520°C; (b) The heating rate was adjusted lower than 100°C/min in every minute, depending on the required temperature. The tests were able to follow the ISO fire curve after 5 – 6 minutes of heating.

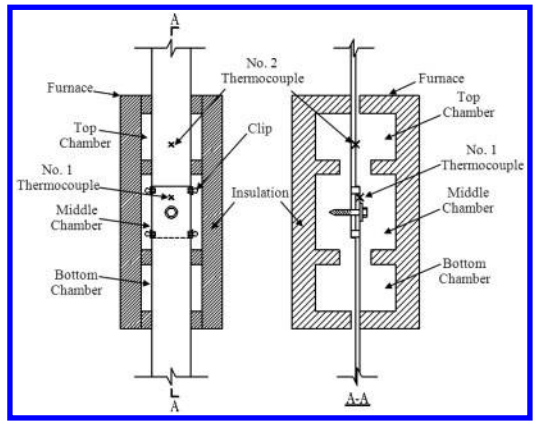

Figure 1. Position of the thermocouples.

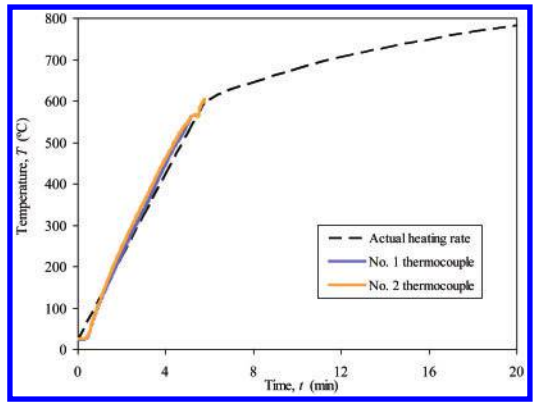

Figure 2. Measured temperature for specimen 042-190-S2-P-14.

2.2 *Transient state test procedure*

The specimens tested in the transient state were subjected to constant load while the temperature rises. The force control was used during the tests in order to maintain the load constant. The screwed connection specimen was firstly loaded to a pre-selected load level within 1 or 2 minutes. The pre-selected constant load was maintained for approximately 1 minute to ensure the load level stabilized. The temperature was then increased according to the heating rate as discussed earlier until the specimen failed or until the stroke of the hydraulic actuator reached 20 mm movement.

The temperature of the test specimen was recorded using two external thermocouples, as shown in Figure1. The thermocouple No. 1 contacted on the surface of sheet steel in the vicinity of the screws, while thermocouple No. 2 is located on the sheet steel beyond the connection overlapped region. The measured temperatures on specimen 042-190-S2-P-14 at the load level of $0.50P_{u,normal}$ recorded by these two thermocouples are shown in Figure 2, which plotted the testing time

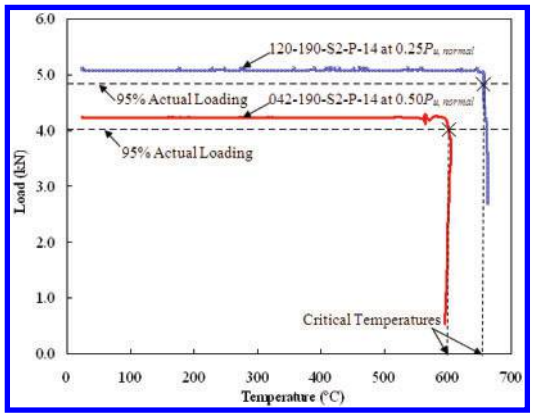

Figure 3. Definition of critical temperatures.

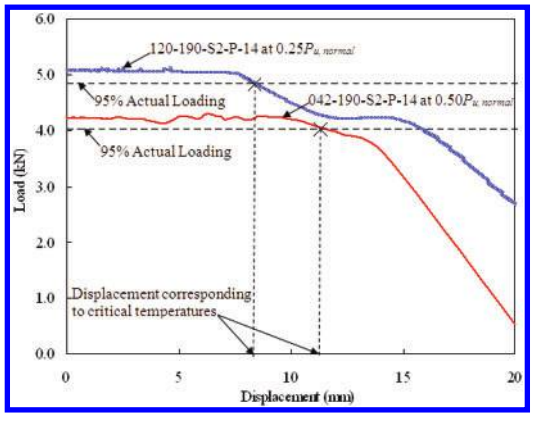

Figure 4. Definition of displacement at critical temperatures.

in minute against the temperature in degrees Celsius (°C). Due to the effect of heat convection and heat conduction, a short delay of approximately 30 seconds on the temperatures recorded by the two external thermocouples was usually observed at the beginning of the test. It is shown that the temperatures obtained from these two external thermocouples were very close to each other. Hence, the temperature inside the furnace is quite uniform. In this study, the specimen temperature was recorded by the thermocouple No. 1.

3 SCREWED CONNECTION TEST RESULTS

The critical temperature of the single shear screwed connection specimen is defined at the temperature when the load drops by 5% of the pre-selected load level from the load-temperature curve. Figure 3 shows the determination of the critical temperature of the specimens042-190-S2-P-14 at the load level of $0.50P_{u,normal}$and 120-190-S2-P-14 at the load level of $0.25P_{u,normal}$. The horizontal axis represents the specimen temperature, and the vertical axis plotted the applied load of the specimen. Figure 4 illustrated the corresponding load-displacement curves of these specimens. The displacement of the screwed connections at critical temperature can be determined from Figure 4 in which the load plotted against the displacement of the hydraulic actuator movement. Table 1 summarized the critical temperatures and the corresponding displacements of the single shear screwed connections in transient state tests. The repeated test specimens were mainly conducted at the load level of $0.50P_{u,normal}$. This is due to the fact that the critical temperatures corresponding to this load level always occur in the temperature range where the strength drops rapidly as observed in the steady state tests.

The transient state test results listed in Table 1 indicate that the critical Temperatures of screwed connections of thin sheet steels reduce as the load levels on the test specimen increases. For instance, the critical temperature dropped from 645.2°C to 357.8°C for specimen 042-190-S2-V-8, at the load levels of $0.25P_{u,normal}$ and $0.75P_{u,normal}$, respectively, as shown in Table 1. It is found that the displacements corresponding to the critical temperatures measured in any series of single shear screwed connections are much more scattered than those measured in the single shear bolted connections as reported by Yan and Young (2011b).The range of displacement for the screwed connections was measured from 2.4 mm to 14.2 mm. This may be due to the friction between the screw shank and screw holes are more vulnerable than those in the bolted connections with nuts at one end of the bolts.

4 DISCUSSION

The transient state test results of single shear screwed connections are compared with the steady state test results obtained by Yan and Young (2012), as shown in Figures 5–7. The material deterioration due to elevated temperatures for 0.2% proof stress ($f_{0.2,normal}$ and $f_{0.2,T}$) and tensile strength ($f_{u,normal}$ and $f_{u,T}$) obtained from the coupon tests (Yan & Young 2011a) for the same batch of sheet steels in this study are also shown in Figures 5–7. The temperature is plotted in the horizontal axis, whereas the vertical axis represents the normalized $f_{0.2,T}/f_{0.2,normal}$, $f_{u,T}/f_{u,normal}$ and $P_{u,T}/P_{u,normal}$. It is shown that the tendency of reduction of the screwed connection test strengths obtained from the transient state tests is similar to that from the steady state tests. The screwed connections had a distinct drop in the strengths of the critical temperatures for the load levels increased from $0.25P_{u,normal}$ to $0.75P_{u,normal}$.

The test strengths obtained from the transient state tests of single shear screwed connections of thin sheet steels are generally higher when compared with those deduced from the steady state test results at similar load levels, which represents that the critical temperatures determined by the transient state tests are generally higher than those steady state test results. The critical temperatures corresponding to the load levels of $0.25P_{u,normal}$ and $0.75P_{u,normal}$ for specimen 120-190-S2-P-14 were approximately 660°C and 550°C, respectively. However, the critical temperatures based on the steady state tests (Yan & Young

		0.50	10.19	610.9	10.8	TB + SS
		0.75	15.28	550.3	12.8	TB + SS

Note: BT = Bearing failure accompanied with screw tilting; T = Tear out failure; MF = Material failure; B = Bearing failure; SS = Screw shear failure; TB = Tilting and bearing failure.

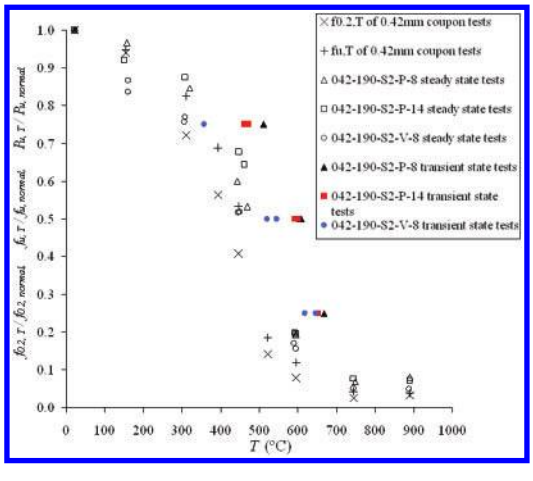

Figure 5. Comparison of transient state test results and steady state test results for 042-190-S2 single shear screwed connections.

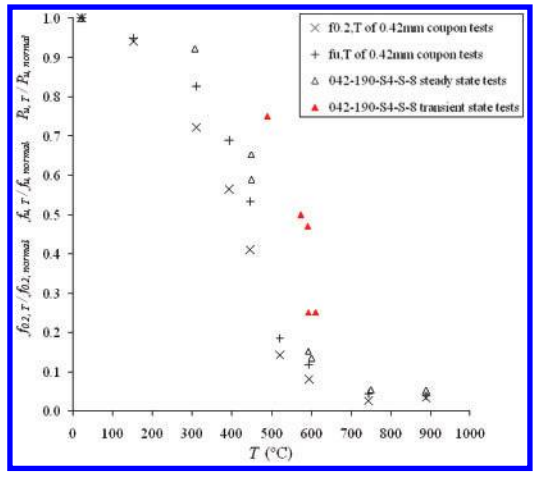

Figure 6. Comparison of transient state test results and steady state test results for 042-190-S4-S-8 single shear screwed connections.

2012) are 590°C and 443°C for the load levels of $0.22P_{u,normal}$ and $0.57P_{u,normal}$ for the same specimen 120-190-S2-P-14, respectively. The critical temperatures for specimen 042-190-S2-P-14 in the load levels of $0.25P_{u,normal}$ and $0.75P_{u,normal}$ were approximately 650°C and 465°C, whereas the corresponding critical temperatures based on the steady state tests are lower than 591°C and 447°C, respectively. The critical temperatures determined by the transient state test results of the single shear screwed connections are revealed to be even higher when compared with the coupon test results (Yan & Young 2011a), as shown in Figures 5–7.

The difference between the critical temperatures obtained from the transient state tests and that deduced from the steady state tests for the specimens assembled

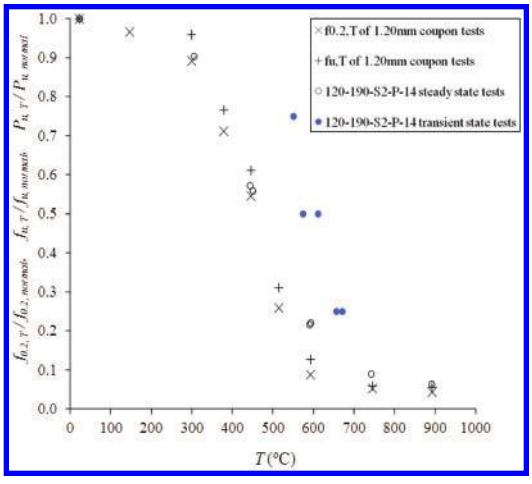

Figure 7. Comparison of transient state test results and steady state test results for 120-190-S2-P-14 single shear screwed connections.

using 1.20 and 1.90 mm sheet steels is generally larger in the high load level conditions than in the low load level conditions, as shown in Figure 7. The difference of the critical temperatures for specimen 120-190-S2-P-14 in the load level $0.25P_{u,normal}$ is approximate 70°C, and it was larger than 110°C for the load level $0.75P_{u,normal}$.

5 FAILURE MODES

Table 1 shows the failure modes of the single shear screwed connection specimens. The symbol 'BT' means the bearing failure accompanied with screw tilting which is explained in Yan and Young (2012);'B' represents the bearing failure; 'T' is the tear out failure which is specified as connection shear limited by end distance in the AISI (2007); 'SS' means the screw shear failure; and 'MF' stands for material failure as shown in Figure 8.

Some specimens failed by combined failure modes, such as the combination of tilting and bearing as well as screw shear failure 'TB+SS' for specimen 120-190-S2-P-14 for all three load levels. The combination of bearing failure accompanied with screw tilting as well as tear out failure 'BT + T' was observed for specimen 042-190-S2-P-8 at the load levels $0.50P_{u,normal}$ and $0.75P_{u,normal}$. The same failure mode 'BT+T' was also observed for specimen 042-190-S2-P-14 at the load level $0.75\ P_{u,normal}$. The combination of bearing and tear out failure 'B+T' was observed for specimen 042-190-S2-V-8 at the load level $0.75P_{u,normal}$. The specimen 042-190-S2-P-14 failed in the sheet steel beyond the overlapped connection part for material failure 'MF' at the load levels $0.25P_{u,normal}$ and $0.50P_{u,normal}$. However, bearing failure accompanied with screw tilting 'BT' instead of material failure for specimen 042-190-S2-P-14 at the load level $0.50P_{u,normal}$ was

Figure 8. Material failure (042-190-S4-S-8 at $0.25P_{u,normal}$).

observed for one of the specimen. The critical temperature for the two tests was very close to each other of approximately 600°C. The specimen 042-190-S4-S-8 failed in material for all load levels, but it is interesting to note that the same specimen was failed by net section tension in the steady state tests. The specimen 042-190-S2-V-8 was failed by bearing only at the load levels $0.25P_{u,normal}$ and $0.50P_{u,normal}$. The bearing failure accompanied with screw tilting was observed for specimen 042-190-S2-P-8 at the load level $0.25P_{u,normal}$.

It is found that the failure mode changes for some of the 042-190-S2 screwed connections when the load level increased. As mentioned earlier that the specimen 042-190-S2-V-8 failed by bearing only at the load levels $0.25P_{u,normal}$ and $0.50P_{u,normal}$. However, it is found that bearing failure in addition of tear out failure was found when the load level increases, as shown in Table 1.

6 CONCLUSIONS

The structural behaviour of single shear screwed connections of thin sheet steels at elevated temperatures was investigated. The tests were conducted using the transient state test method. Three different load levels were considered in the investigation. The critical temperatures and the failure modes were reported. The failure modes of tilting and bearing, bearing failure accompanied with screw tilting, bearing failure, tear out failure, screw shear failure, and material failure were observed in the tests. It is found that the failure mode of the screwed connections may change as the load level increases. The test results of the single shear screwed connections obtained using the transient state test method were compared with the steady state test results and the tensile coupon test results. The comparison showed a similar strength reduction tendency at elevated temperatures. However, the critical temperatures determined by the transient state test results are slightly higher compared with those deduced from the

steady state test results at similar load levels, and even higher than those from the coupon test results.

ABSTRACT: Industrial Storage Systems are usually built by cold-formed profiles, and their sections, called "rack section", specially designed to make assemblage easier, have perforations through their high to fit connections. This section geometry and holes induce behavior unexpected in other sections. This paper presents a theoretical-experimental analysis of buckling modes development in rack sections. This analysis is carried out by numerical analysis, using Generalised Beam Theory (GBT) and Finite Element Method (FEM) by softwares GBTul and ANSYS. The element type, mesh refinement and boundary conditions in Finite Element model are carefully developed from comparisons with Generalized Beam Theory (GBT) results to columns without holes. Once Finite Element parameters are adjusted, holes are introduced in ANSYS model. Numerical results were compared with experimental Stub Columns tests results. Experimental and Finite Element results showed good agreement, proving the Finite Element Model is suitable to predict perforated rack section stub columns behavior.

1 INTRODUCTION

Industrial Storage Systems are widely used in factories, warehouses and other places in that high storage density is needed. They are usually built by cold-formed profiles, and their sections are specially designed to make assemblage easier, called "rack section". In addiction, columns have perforations arrangements through their high to fit connections and bolts. The special rack section and the perforations sets modify the columns behavior and resistance, because they induce failure modes unexpected in other sections, as channel, for example. So, they are under local plate buckling, distortional or global buckling and these buckling modes can occur separately or under interaction.

There are several works that analyze rack systems. They are focused in global system stability and its components behavior (Freitas et al (2005, 2010), Godley (2000, 2002)). There are also recent works that consider the perforations sets (Moen & Schaffer (2008), Eccher et al, 2008), Schaffer (2012).

The existence of perforations modifies the columns behavior. This analysis is especially difficult, because available numerical tools, such as finite strip analysis (CUFSM (Schaffer & Àdáni (2006))) and generalized beam theory (GBTul (Bebiano et al (2008)) are used only to evaluate sections without holes. Thus, the analysis of a perforated rack column must be carried out using finite element analysis.

This paper shows a finite element analysis of rack sections with perforations. The purpose of this analysis is to develop a finite element model, in software ANSYS (ANSYS (2007)), which predicts the buckling load of the cold-formed perforated columns. This elastic buckling load is important to design methods, like Direct Strength Method.

The development of a finite element model must consider many important aspects, such as finite element type, mesh refinement and loading and boundary conditions. The model is often very sensitive to these parameters, and they can lead to an inaccurate finite element model.

The model consists in a stub column with fixed ends, under pure compression. In the first step, the results of column without perforations analyzed by FEM Generalized Beam Theory (GBT) were compared, in order to evaluate the finite element model suitability in buckling load prediction. So, the finite element parameters were adjusted to get good precision.

In a second moment, perforations were introduced in finite element models, using the parameters previously adjusted in first step. The results of perforated model were then compared to experimental ones.

2 FINITE ELEMENT MODEL DEVELOPMENT

In this section, a finite element model for cold-formed compressed member is developed. These analyses were carried out in order to develop and validate finite element procedure to evaluate the column without holes behavior by comparison with other numerical

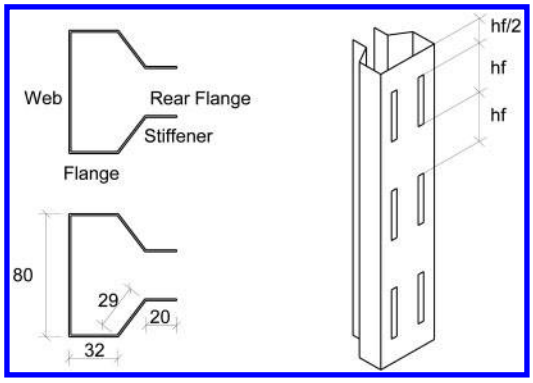

Figure 1. Section dimensions.

techniques results. Section components and dimensions are shown in Figure 1. In this stage, it was considered columns without perforations.

The finite element results were compared to GBT results in order to determine the element type, mesh refinement and boundary conditions suitable for this analysis. Eigenbuckling analysis were performed, in order to evaluate buckling load and column failure mode. There were simulated column lengths in that first buckling mode was local mode (70 mm) and distortional mode (400 mm), to evaluate model efficiency in columns affected by these phenomena.

Firstly, the element type was chosen. Three shell element types were tested to simulate the column: SHELL63, SHELL181 and SHELL281. They are similar and have the same input data. ANSYS manual indicated that SHELL63 is suitable for elastic analysis, SHELL181 is strongly indicated for plastic analysis and SHELL281 has a midside node, i.e., this element has eight nodes, while SHELL63 and SHELL181 have four nodes.

Element SHELL281, due to fact that has quadratic approximation, usually leads to better results, but increases processing time. Element SHELL181 has two options. The default option uses reduced integration, but in this work was used the full integration, due to the improvement in the results provided by its option.

Finite element type definition was based in accuracy and processing time. Results from finite element method (ANSYS) were compared to GBTul results. From these analyses, it was observed that the best element, considering the basic assumptions, was SHELL181 with full integration. This element was, then, adopted in this work.

Once the finite element type was chosen, it was analyzed the mesh refinement suitable for columns analysis, provided by comparison with generalized beam theory results. For these analyses, the manual element size set-up available in ANSYS was used. A range of element side sizes were tested, and the best results agreement was observed with element size equal to 10% web width (8.4 mm).

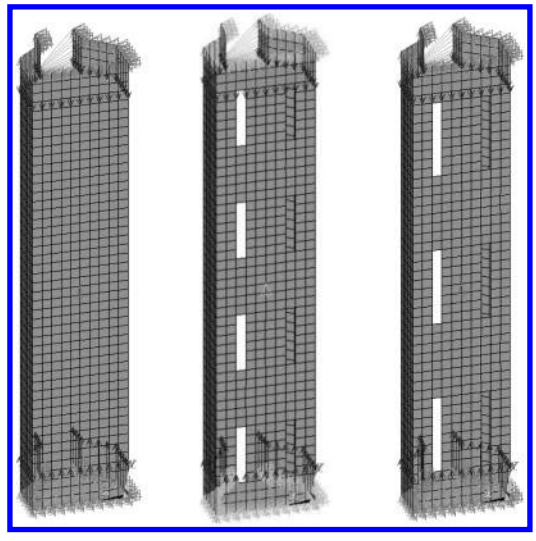

Figure 2. Finite element mesh and boundary conditions.

After choosing element type and mesh refinement, the column with pinned ends and fixed warping degree of freedom was analyzed. Consideration of this support condition is very important because it is the situation observed in experimental tests, where load plates restrict warping effects. For this analysis a generalized beam theory simulation carried out in GBTul is used as reference.

Element SHELL181 and the refinement level determined previously were used in this model. The nodes in both column extremity have translational degrees of freedom restricted in directions perpendicular to column axis, and a node in mid high column had the axial degree of freedom constrained. Loading was applied in all end nodes. The end nodes have all rotational degrees of freedom coupled, what assures that all of them will rotate equally, keeping plan extreme sections during the loading history, and the warping effects are completely restricted.

Various column lengths were simulated in ANSYS by eigen buckling analysis, in order to obtain a Buckling Load x length curve. Comparison between finite element (ANSYS) and GBT (GBTul) results shows an excellent fit between results, what indicating that the finite element procedure developed is suitable to evaluate cold formed columns behavior. Then, the model was modified to introduce perforations in the columns, to analyze its influence in columns resistance and stability. Figure 2 shows finite element meshes generated and boundary conditions for columns with and without holes.

3 EXPERIMENTAL ANALYSIS

In order to evaluate the influence of perforations is cold formed perforated stub columns, there were tested a series of specimens in the Laboratory of Structures "Prof. Altamiro Tibiriçá Dias" in Federal University

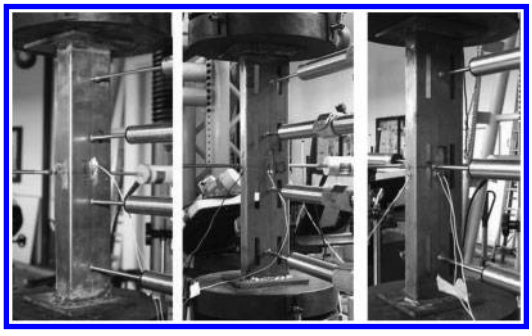

Figure 3. Specimens with and without holes positioned in testing machine.

of Ouro Preto. There were tested columns with and without holes, and their results were compared to finite element ones.

The specimens tested were stub columns with globally pinned ends and restrained warping under compression. In order to assure warping restriction and the fixed conditions, plates were welded in both extremities. The specimens were 384 mm high and section and holes dimensions is shown in Figure 1. Dimensions were chosen in order to avoid failure by material yielding and to induce the occurrence of distortional buckling. Linear finite element analysis was carried out previously to verify the specimens behavior and verify their suitability to this study.

There were tested three column types: without holes, with holes 60% web wide ($h_f = 48$ mm) and 80% web wide ($h_f = 64$ mm). The experimental tests were carried out in a Universal Testing Machine Instron Satec Series 5569. This machine permits load application velocity control and complete testing settings from specific software Partner (Instron, 2008). It was used a parallel data acquisition from HBM Spider8 and software Catman (HBM, 2003) in order to get all data needed in this analysis. Figure 3 shows the specimens with and without holes positioned in the universal testing machine.

Three specimens of each holes setup were tested, and then was determined buckling load for each one. The tests set up was defined in order to assure that specimens were under pure compression. Loadind was applied with displacement control, applied in sections mass center, and loading rate was limited to avoid abrupt collapse, letting complete phenomena observation.

Displacement transducers were positioned in columns web and rear flanges in order to determine occurrence of local or distortional modes. Strain gages were positioned in columns web and flanges, to prove the specimens are under uniform compression.

Experimental results shows, in all specimens, distortional buckling with one half wave formation. Table 1 shown experimental buckling load for each specimen and the mean value for the series. Figure 4 shows the displacements observed in specimens

4 FINITE ELEMENT LINEAR BUCKLING ANALYSIS

The finite element model presented in item 2 was used to analyze the specimens tested. The purpose of this analysis is to determine the buckling loads in order to compare to experimental results. Figure 2 shows the finite element model created.

The model was firstly used in linear buckling analysis in ANSYS. In this analysis, the buckling loads (eigenvalues) and the buckling modes were determined, and the results were compared to experimental ones. Table 2 presents the comparison between numerical and experimental results. In table 2 it can be observed that the main difference between finite element and experimental results is 12,75%, in the column without holes. This indicates that parameters such geometrical imperfections and second order effects

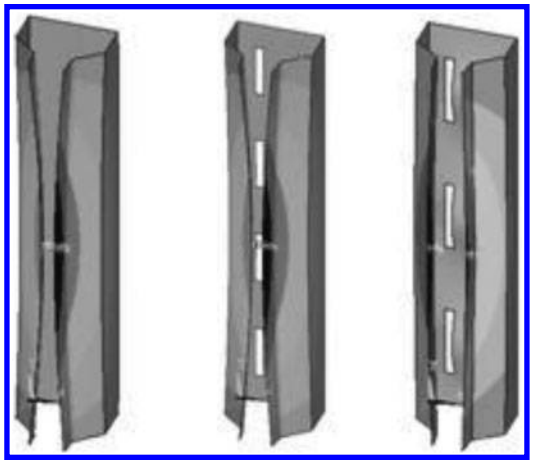

Figure 5. Distortional buckling observed in linear buckling finite element analysis.

must be considered, once they are not included in linear buckling analysis.

Despite the difference in critical loads, the linear buckling model leads to consistent buckling modes in comparison to that observed experimentally. Figure 5 shows buckling modes obtained in finite elemet analyses. It can be observed the similarity between these modes and experminental ones showed in figure 4.

5 FINITE ELEMENT NONLINEAR BUCKLING ANALYSIS

In this stage, nonlinear buckling analysis of tested specimens was carried out by ANSYS. The finite element procedure presented in item 2 was used to build the ANSYS models. For nonlinear buckling purposes nonlinear steel properties and geometrical imperfections were introduced in the model. The stress-strain relationship was introduced by a bilinear approximation. The initial imperfections were introduced by updating geometry from modes obtained in previous linear buckling analysis and amplitudes defined by specimens actual dimensions.

Results from nonlinear buckling analyses are shown in table 3. It can be observed a improvement in comparison between experimental and finite element results if results from linear buckling analysis presented in table 2 is considered. The main difference between buckling loads in nonlinear analysis is is 4,79%, observed in specimen with perforation 64 mm high. In all three specimens it can be observed improvement in numerical and experimental results fitting.

It can also be observed the nonlinear buckling analysis is efficiency in predicting buckling mode. In all specimens, it was observed the occurrence of distortional mode with one halfwave formation, which is the same mode observed experimentally. Figure 6 presents buckling modes observed in nonlinear buckling analysis.

Table 3. Comparison between experimental and Finite Element nonlinear buckling results.

h_f (mm)	L (mm)	$P_{u\,Exp}$ (kN)	$Mode_{Exp}$	$P_{u\,FE}$ (kN)	$Mode_{FE}$	Dif (%)
No hole	384	40,82	D1	39,7	D1	2,74
48	384	36,95	D1	37,47	D1	−1,41
64	384	38,21	D1	36,38	D1	4,79

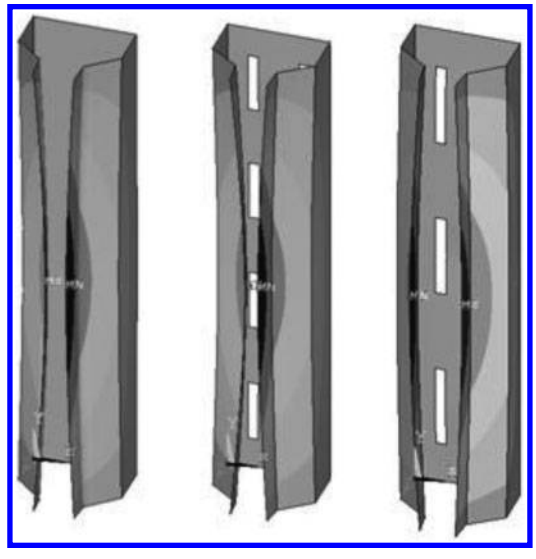

Figure 6. Distortional buckling observed in nonlinear buckling finite element analysis.

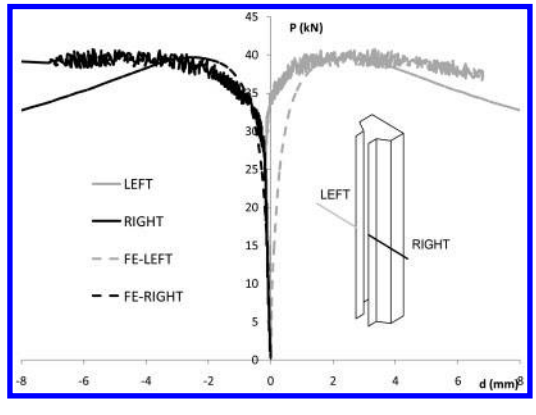

Figure 7. Displacement in column without holes mid high position in rear flanges.

The finite element nonlinear buckling analysis is also suitable to determine structural post-buckling behavior. The ANSYS finite element model was then used with this purpose, and the results comparison with experimental ones showed numerical model efficiency. Figures 7 to 9 presents the comparison between numerical and experimental displacements in column mid high position in sections rear flanges to columns

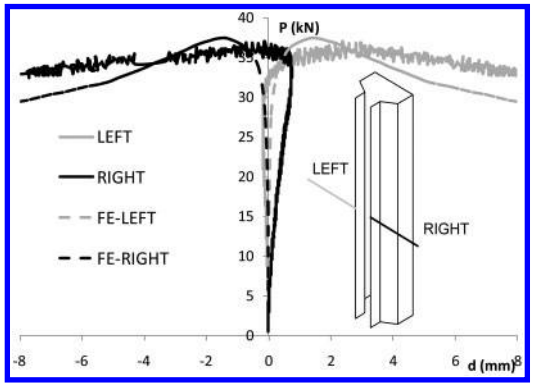

Figure 8. Displacement in column with holes 48 mm high inmid high position in rear flanges.

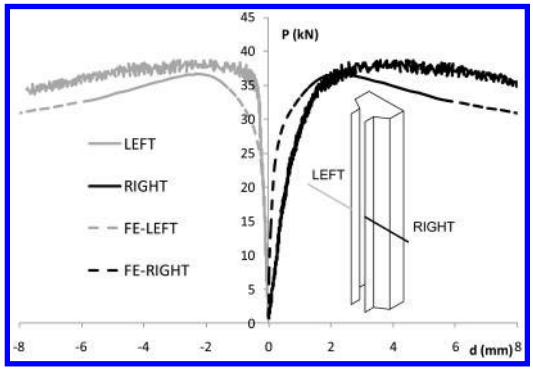

Figure 9. Displacement in column with holes 64 mm high inmid high position in rear flanges.

without perforations and with perforations 48 mm high and 64 mm high respectively. It can be observed that in all specimens the finite element model was capable to predict actual behavior, proving again its suitability to simulate cold formed columns with perforations.

It can be observed in figures 7 and 8 that transducers measured displacements indicate section closing, because left transducer indicate displacements in right directions and right transducer indicates displacements to left. Otherwise, figure 9 indicates section opening. During all loading stages, finite element displacements are close to that obtained experimentally. That shows the model suitability in post-buckling analysis of perforated rack sections columns.

6 CONCLUSIONS

The purpose of this paper is to develop a finite element procedure to simulate cold formed rack sections with perforation along their length under compression. It is used finite element commercial software ANSYS. Finite element type SHELL181 with full integration proved being suitable to this model, and meshing level was adjusted. Boundary conditions and loading applications were also developed.

The finite modeling procedure developed is suitable to analyze perforated rack sections stub columns. Comparison between finite element and experimental results indicated that the numerical model predict accurately the columns behavior and resistance.

It is observed, thus, that linear buckling analysis leads to less precise results than nonlinear buckling analysis, in that material nonlinearities, geometrical imperfections and second order effects are considered. It is also observed that nonlinear finite element model describes correctly the column post-buckling behavior. This indicates the importance of considering the nonlinear buckling analyses in cold formed steel columns, because these members high slenderness make them highly sensitive to physical and geometrical nonlinearities and initial imperfections.

Inelastic post-buckling GBT analysis of tubular thin-walled metal members

M. Abambres, D. Camotim & N. Silvestre
Civil Engineering Department, ICIST, Instituto Superior Técnico, Technical University of Lisbon, Portugal

ABSTRACT: After providing a brief overview of a recently developed and validated elastoplastic post-buckling Generalised Beam Theory (GBT) formulation, the paper presents and discusses illustrative numerical results concerning three tubular members exhibiting bi-linear and non-linear material behaviours. The GBT results consist of equilibrium paths, modal participation diagrams, stress contours, displacement profiles and collapse mechanisms, most of which are compared with values obtained from Abaqus shell finite element analyses. The GBT modal nature makes it possible to (i) acquire in-depth knowledge about the member behavioural mechanics at any given equilibrium state (elastic or elastic-plastic), as well as (ii) evidence the GBT computational efficiency (d.o.f. reduction of over 75%), partly due to the exclusion from the analyses of all deformation modes playing no role in a given member response.

1 INTRODUCTION

Most thin-walled metal members exhibit slenderness values leading to structural behaviours and ultimate strengths governed by interaction between plasticity and instability, which renders their rigorous analysis a complex task. This stimulates the development of more efficient design rules and methods of structural analysis. In this context, even if conventional structural design concerns mostly serviceability/ultimate limit states, a performance-based design also requires accurate member post-collapse response predictions (Hiriyur & Schafer 2005). As experimental studies are invariably scarce, alternative approaches must be sought. The most universal is performing non-linear shell finite element analyses (SFEA), involving (i) large degree of freedom (d.o.f.) numbers, (ii) time-consuming/error-prone data processing and interpretation, and (iii) nodal stress/displacement outputs, rather than modal ones (*e.g.*, stress resultants).

Generalised Beam Theory (GBT) is an alternative to the above structural analysis methods. In spite of its limited current field of application (prismatic, straight and non-perforated thin-walled bars) and dissemination, GBT is recognised as an elegant and efficient approach to analyse thin-walled members and structural systems. These traits arise mostly from its modal nature: displacement field expressed as a linear combination of cross-section deformation modes with amplitudes varying continuously along the member length. This feature makes it possible to (i) acquire in-depth insight on the member behaviour and (ii) judiciously exclude from future similar analyses those modes found to play no role in the particular behaviour under scrutiny, thus further reducing the d.o.f. number. GBT has attracted the interest of several researchers, leading to new formulations and applications concerning various types of analysis, support and loading conditions, and materials (Camotim *et al.* 2010). With a few exceptions, the material models considered were linear elastic. The first physically non-linear GBT formulations are due to Gonçalves & Camotim (2004, 2011, 2012): beam finite elements (BFE) based on J_2-flow plasticity theory aimed to perform member bifurcation, first and second-order inelastic analyses. The authors (Abambres *et al.* 2012, 2013a-c) developed and validated alternative 1st and 2nd order elastoplastic GBT formulations, also based on J_2-flow theory but differing from the previous ones in the (i) deformation mode determination and (ii) consideration of warping rotations (novel d.o.f.) – in these works, GBT was first applied to strain-hardening materials, namely stainless steel. When compared with carbon steel, stainless steel (i) has no well-defined yield point and (ii) exhibits a high non-linearity beyond the proportional limit.

The aim of this paper is (i) to present a brief overview of the materially and geometrically non-linear GBT formulation, and (ii) to illustrate its application and potential by studying the post-buckling behaviour and strength of tubular members made of perfectly-plastic, bi-linear and non-linear materials. The analyses include local and/or global initial geometrical imperfections, but neglect membrane residual stresses and corner strength effects. For validation, most GBT results (equilibrium paths, displacement profiles, stress contours, collapse mechanisms) are compared with Abaqus SFEA values. The GBT modal nature is highlighted through the presentation of modal participation diagrams.

2 GBT NON-LINEAR ELASTIC-PLASTIC FORMULATION – OVERVIEW

Only an overview of the main concepts and procedures involved in the development and implementation of the proposed GBT formulation is reported. After focusing on aspects related to kinematics and cross-section analysis, the member non-linear equilibrium equations are established and their BFE incremental solution addressed.

2.1 *Kinematics and equilibrium equations*

Consider the local coordinate system (x, s, z) shown in Figure 1(a) at each wall mid-surface of a thin-walled bar, where x, s and z are the longitudinal ($0 \le x \le L$ – member length), transverse ($0 \le s \le b$ – wall width) and through-thickness ($-t/2 \le z \le t/2$ – wall thickness) coordinates – the associated displacements are u (warping), v (transverse) and w (flexural). The GBT analysis consists of two main steps: (i) cross-section analysis and (ii) member analysis. The former leads to the deformation mode displacement profiles u_k, v_k and w_k (for mode k), along s, while the member analysis determines the modal amplitude functions $\zeta_k(x)$ – displacement profile longitudinal variations. Then, the GBT mid-surface displacement field is given by a linear combination of products between modal displacement profiles and their amplitude functions,

$$u(s,x) = u_k(s)\zeta_{k,x}(x) \qquad v(s,x) = v_k(s)\zeta_k(x) \qquad w(s,x) = w_k(s)\zeta_k(x) \tag{1}$$

where k satisfies the summation convention. The cross-section analysis adopted considers 4 deformation mode families: conventional, cell shear flow, warping shear and transverse extension. The existing analyses, considering either 3 (u, v, w) or 4 (u, v, w, θ_x – rotation about the x-axis) d.o.f. per section node, require fine discretisations to capture highly non-linear axial displacement variations along the cross-section mid-line, due to spread of yielding and/or shear deformation. This justifies the convenience of enhancing the warping representation, done here through additional nodal d.o.f. ("warping rotations"): rotations about the z-axis θ_z – one per intermediate node and more than one per natural node (independent θ_z per converging wall direction). This enables the approximation of each warping profile u_k by piecewise (in each wall segment) *cubic* polynomials, instead of piecewise linear functions (see warping shear modes in Figs. 4 and 6).

Note that the formulation keeps the GBT plane-stress assumption (null σ_{xz}, σ_{sz}, σ_{zz} stresses and γ_{xz}, γ_{sz}, ε_{zz} strains). Accordingly, the Principle of Virtual Work leads to the GBT equilibrium equations $(m, n = \{x, s\})$

$$\int_L \int_b \int_t \sigma_{mn}\delta\varepsilon_{mn}\, dz\, ds\, dx = \int_L \int_b \left[\begin{matrix}(q_x u_i)\delta\zeta_{i,x} + \\ (q_s v_i + q_z w_i)\delta\zeta_i\end{matrix}\right] ds\, dx \tag{2}$$

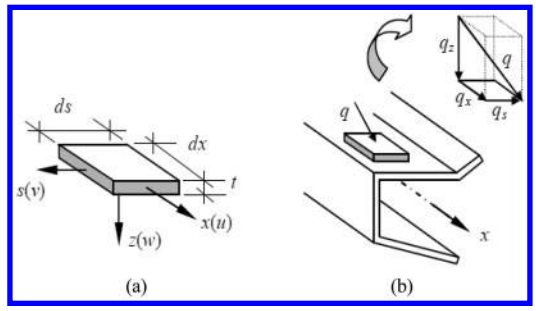

Figure 1. (a) Local coordinate system at each wall mid-surface and (b) general external distributed load $q(x, s)$.

where (i) σ_{xx}, σ_{ss}, σ_{xs} are axial, transverse and shear 2^{nd} Piola-Kirchhoff stresses, (ii) q_x, q_s, q_z are local components of a distributed load on the member mid-surface (see Fig. 1(b)), and (iii) $\delta\varepsilon_{xx}$, $\delta\varepsilon_{ss}$, $\delta\gamma_{xs}$ are axial, transverse and shear Green-Saint-Venant non-linear virtual strains, expressed in terms of the modal amplitude functions $\zeta_k(x)$ and their derivatives, through Eqs. (1).The formulation also accounts for (i) residual stresses and geometrical imperfections, and (ii) arbitrary single-parameter (λ) loadings, including concentrated forces and moments.

2.2 *Non-linear beam finite element*

The cylindrical arc-length method is adopted, involving (i) incremental equilibrium equations based on the tangent stiffness matrix K_{tan}, (ii) internal force vectors f^{int} and (iii) a path-independent iterative strategy: strain increments evaluated w.r.t. the last converged equilibrium state.

The results shown in section 3 were obtained using Hermite cubic polynomials to approximate the GBT modal amplitude functions in each BFE, *i.e.*,

$$\zeta_{k,x}^{v,w=0}(x) = \Psi_H(x)\, d_k \qquad \zeta_k^{v,w\neq 0}(x) = \Psi_H(x)\, d_k \tag{3}$$

where (i) the 1×4 Ψ_H vector stores the Hermite polynomials, (ii) d_k is the 4×1 displacement vector related to the mode k approximation, (iii) the first expression concerns only axial extension and warping shear modes ($v = w = 0$), and (iv) the second expression applies to all other modes ($v \neq 0$ and/or $w \neq 0$). After inserting the above approximations in Eq. (2) (including virtual strains), the internal and external force vectors interrelation for a generic "equilibrium configuration" ($mn = xx, ss, xs$)

$$\sum_{mn} f_{i(mn)}^{int} = \lambda \bar{f}_i, \qquad f_{i(mn)}^{int} = \int_{L_e}\int_b\int_t \sigma_{mn}\, F_{i(mn)}^{int}\, dV_e \tag{4}$$

is obtained, where (i) the ith components are 4×1 sub-vectors related to deformation mode i and (ii) $\bar{f}$ is the external force vector for a unit load parameter λ. Then, the incremental equilibrium

equation for a deformed configuration j can be established as

$$K_{\tan}\Big|_j \Delta d = \Delta\lambda\, \bar{f} \tag{5}$$

where (i) d is the displacement vector and (ii) the tangent stiffness matrix (i, p)th component, $K_{\mathrm{ip,tan}}$, is a 4×4 sub-matrix concerning deformation modes i and p, reading

$$K_{ip,\tan} = \frac{\partial f_i^{\mathrm{int}}}{\partial d_p}, \qquad \frac{\partial f_i^{\mathrm{int}}}{\partial d_{pl}} = \frac{\partial f_{i(xx)}^{\mathrm{int}}}{\partial d_{pl}} + \frac{\partial f_{i(ss)}^{\mathrm{int}}}{\partial d_{pl}} + \frac{\partial f_{i(xs)}^{\mathrm{int}}}{\partial d_{pl}} \tag{6}$$

$$\frac{\partial f_{i(mn)}^{\mathrm{int}}}{\partial d_{pl}} = \int_{L_e}\int_b\int_t \left\{ \frac{\partial \sigma_{mn}}{\partial d_{pl}} F_{i(mn)}^{\mathrm{int}} + \sigma_{mn} \frac{\partial F_{i(mn)}^{\mathrm{int}}}{\partial d_{pl}} \right\} dV_e \tag{7}$$

It corresponds to the Jacobian of the internal force vector ith component, w.r.t. the mode p displacement vector – its components are d_{pl} ($l = 1, \ldots, 4$). For any inelastic material, the stress gradients at every point read

$$\frac{\partial \sigma_{mn}}{\partial d_{pl}} = \frac{\partial \sigma_{mn}}{\partial \varepsilon_{xx}} \frac{\partial \varepsilon_{xx}}{\partial d_{pl}} + \frac{\partial \sigma_{mn}}{\partial \varepsilon_{ss}} \frac{\partial \varepsilon_{ss}}{\partial d_{pl}} + \frac{\partial \sigma_{mn}}{\partial \gamma_{xs}} \frac{\partial \gamma_{xs}}{\partial d_{pl}} \tag{8}$$

($\partial\varepsilon/\partial d_{\mathrm{pl}}$ obtained from writing the strain-displacement relations according to the FE approximations in Eq.(3)).

The stresses and their gradients ($\partial\sigma/\partial\varepsilon$) appearing in previous relations stem from the J_2-flow theory with associated flow rule, by resorting to implicit and/or explicit numerical integration schemes wherever plastic flow takes place. Then, at every Gauss point and after each arc-length iteration, one must (i) compute the elastic stress variation, from the imposed strain variation ($\Delta\varepsilon$) w.r.t. the last equilibrium state i (stresses σ_{i} and hardening parameter κ_{i}), and then (ii) check whether the final stresses ($\sigma_{\mathrm{e}} = \sigma_{\mathrm{i}} + D^e \Delta\varepsilon$) fall outside the yield surface $f\ (\sigma, \kappa_{\mathrm{i}}) = 0$. If yes, numerical integration of the incremental constitutive equations is performed to update the stresses and hardening parameter κ – the Mean-Normal and Euler-Backward methods were used to obtain the results presented in 3.2 and 3.3–3.4, respectively. Once those variables are updated, gradients $\partial\sigma/\partial\varepsilon$ are directly computed from the consistent elastoplastic constitutive matrix.

3 ILLUSTRATIVE EXAMPLES

The application of the GBT formulation for inelastic post-buckling analysis, implemented in MATLAB (MathWorks 2010), is now illustrated. The results discussed next concern 3 numerical examples involving (i) SHS and hollow flange (HF) I-section columns and (ii) a RHS beam-column. Material models with a linear elastic regime and involving different types of strain-hardening were considered, namely the (i) perfectly-plastic (PP), (ii) bi-linear (BL – linear hardening), and (iii) non-linear (NL) models. Concerning the latter, the σ-ε relation due to Quach *et al.* (2008) is adopted – it is (i) suitable for stainless steel alloys and (ii) defined by the 3 basic Ramberg-Osgood parameters (E, $\sigma_{0.2}$, n) (implementation details reported in Abambres *et al.* 2013c). For validation purposes, GBT equilibrium paths, stress contours and deformed configurations (referred to the bar mid-surface) are compared with those yielded from ABAQUS (DS Simulia 2008) SFEA.

Table 1. Illustrative examples: material properties.

Example	E (GPA)	E_{SH}	σ_0^Y (MPA)	$\sigma_{0.2}$ (MPA)	n
SHS	$E^c = 198.2$	–	390.3	$\sigma_{0.2}^c = 560$	$n^c = 8.3$
	$E^t = 198.8$			$\sigma_{0.2}^T = 586$	$n^t = 9.0$
HF I-sec (*PP & BL*)	205	$E/50$	290	–	–
HF I-sec	$E^c = 205$	–	289.5	$\sigma_{0.2}^c = 515$	$n^c = 5.2$
(*NL*)	$E^t = 208$			$\sigma_{0.2}^t = 560$	$n^t = 6.9$
RHS	200	0	450	–	–

Table 2. Illustrative examples: FE discretisation and d.o.f. numbers.

	GBT	ABAQUS		Number of d.o.f.		
Example	BFEs	SFES (x)	SFEs (s)	GBT	ABQ	GBT/ ABQ (%)
SHS	16	50	48	865	14401	6
HF I-sec	66(*)	80	62	7391	29651	24.9
RHS	50	160	36	6462	34452	18.8

*Only non-uniform (symmetric) mesh: 18 BFEs ($x < 0.35L$) + 15 BFEs ($0.35L \le x \le 0.5L$).

Table 1 shows the material properties adopted in each analysis: (i) E, E_{sh}, are the Young's modulus and strain-hardening slope (BL model), (ii) σ_0^y, $\sigma_{0.2}$, are the initial yield and 0.2% proof stresses, and (iii) n is the hardening power (NL model – 0.01% proof stress taken as the initial yield stress) – c, t denote compressive and tensile. All these (isotropic) models are employed to simulate the compressive behaviour and a $\nu = 0.3$ Poisson's ratio is assumed. Table 2 shows the numbers of (i) GBT BFEs, (ii) axial and transverse (x, s) ABAQUS SFEs, and (iii) d.o.f. involved in each model. As for the numbers of Gauss integration points per BFE wall segment direction s, z, x (Fig. 1(a)) in each GBT analysis, they are (i) (3, 3, 3) for the SHS, (ii) (4, 5, 3) for the HF I-section and (iii) (2, 5, 4) for the RHS – the SFEA involved fairly uniform S4 FE meshes, adopting the same through-thickness integration points as the GBT analyses.

After providing information about the selected GBT modes, in 3.1, the results of each analysis are addressed in 3.2–3.4. The first one concerns a fixed-ended SHS

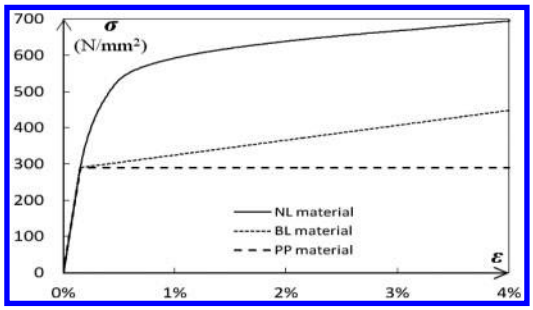

Figure 2. HF I-section column material model (stress-strain curves).

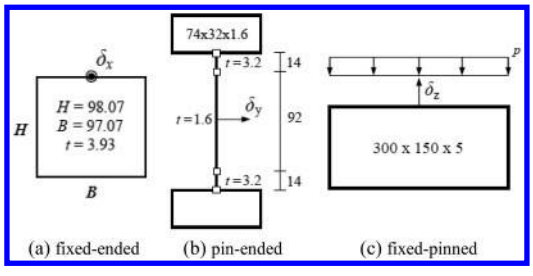

Figure 3. (a) SHS, (b) HF I-section, (c) RHS mid-line dimensions.

stub column (Fig. 3(a) – $L = 400$ mm), made of EN 1.4162 duplex stainless steel and acted by a (uniformly distributed) compressive end force $F = 102.2 \times 10^4$ λN (experimental results reported by Theofanous & Gardner 2009). The initial geometrical imperfection, akin to the 1st symmetric local buckling mode, has a $t/100$ amplitude (maximum in-plane displacement). The second problem deals with a pin-ended HF I-section column (Fig. 3(b) – $L = 1200$ mm) acted by a compressive end force $F = 100 \times 10^3$ λN – besides the end-shortening, the pinned supports allow for global flexural rotations In order to assess the impact of strain-hardening on the column behaviour and strength, analyses were carried out for PP, BL and NL material models with the same initial yield stress – Figure 2 shows their σ-ε curves. The initial imperfections combine the 1st global (flexural – $L/1000$ amplitude) and 13 half-wave local (1.18 mm amplitude) buckling modes. Lastly, a fixed-pinned (no in-plane motions) RHS beam-column (Fig. 3(c) – $L = 4000$ mm) made of a PP material is analysed, subjected to (i) a uniformly distributed vertical load acting along the full top flange ($p = 0.01$ λ N/mm^2) and (ii) an axial compression $F = 100 \times 10^3$ λN. The imperfection is akin to the 2nd local buckling mode and has amplitude equal to $t/100$.

The results shown in 3.2–3.4 correspond to the points indicated on the equilibrium path, denoted as BP (before peak), P (peak) and AP (after peak). It is also worth noting that the GBT modal participation diagrams are based on the cross-section having the maximum overall or in-plane displacement (initial imperfection not included) – each deformation mode

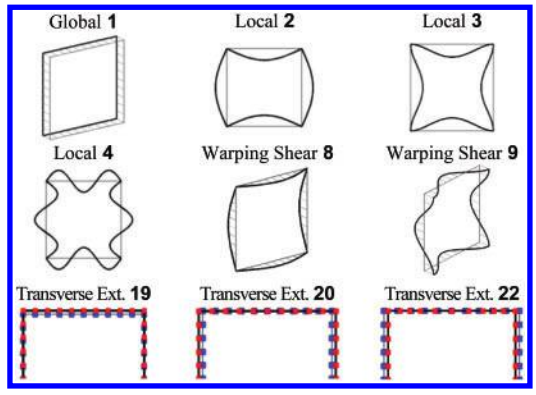

Figure 4. SHS most relevant GBT deformation modes.

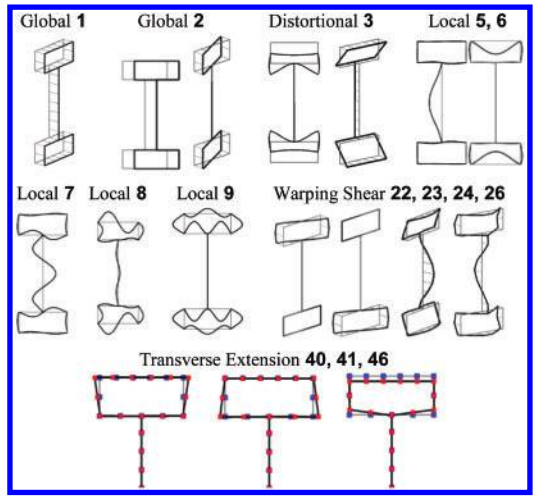

Figure 5. HF I-section most relevant GBT deformation modes.

contribution is the ratio between its maximum displacement and the sum of all such modal values, not necessarily occurring at the same point.

3.1 *GBT deformation modes*

The GBT deformation modes (**G**-global, **D**-distortional, **L**-local, **WS**-warping shear, **TE**-transverse extension and **CS**-non-global cell shear flow) included in each analysis are the following: (i) 28 modes out of 204 (1 **G**, 6 **L**, 11 **WS**, 10 **TE**), all bi-symmetric (SHS), (ii) 56 modes out of 132 (2 **G**, 1 **D**, 15 **L**, 20 **WS**, 17 **TE**, 1 **CS**), mostly symmetric w.r.t. the horizontal centroidal axis (HF I-section), and (iii) 65 modes out of 184 (2 **G**, 20 **L**, 18 **TE**, 25 **WS**), symmetric w.r.t. the vertical centroidal axis (RHS) – all these modes are renumbered sequentially, since they are just a fraction of the cross-section analysis full set. The in/out-of-plane shapes of the most relevant modes in each analysis are shown in Figures 4–6 – the discretisations adopted are shown in the symmetric TE mode half-section shapes – warping rotation d.o.f. θ_z (addressed in subsection 2.1) were used in the SHS and RHS member analyses.

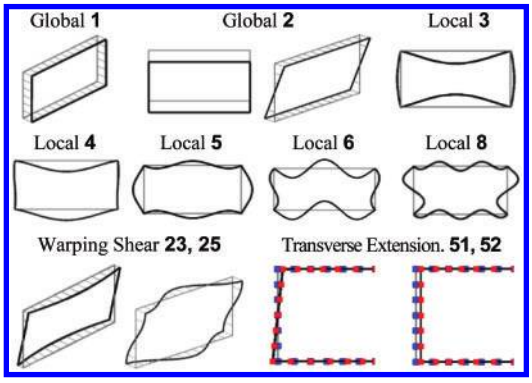

Figure 6. RHS most relevant GBT deformation modes.

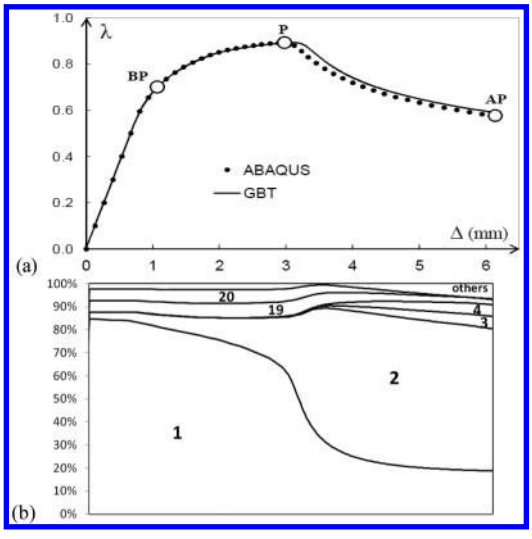

Figure 7. (a) GBT and ABAQUS equilibrium paths and (b) GBT modal participation diagram.

3.2 *SHS column*

Figure 7(a) shows the GBT and ABAQUS $\lambda(\Delta)$ equilibrium paths (Δ is the column end shortening) – the BP, P and AP λ values are: $\lambda_{GBT} = 0.701 + \lambda_{ABQ} = 0.701$ (BP), $\lambda_{GBT} = 0.893 + \lambda_{ABQ} = 0.893$(P), $\lambda_{GBT} = 0.590 + \lambda_{ABQ} = 0.577$ (AP). Fig. 7(b) shows the GBT modal participations concerning the evolution, with Δ, of the mid-span cross-section deformed shape. The following remarks are due:

(i) The agreement between the GBT and ABAQUS paths is very good (differences below 4.9%).

ii) The GBT participation diagram indicates two markedly different behaviours: (ii_1) one prior to the peak, involving mostly mode **1** (58.6–84.7%), and (ii_2) another after the peak: growth of local mode **2** (27.1–64.5%), "sweeping aside" mode **1**.

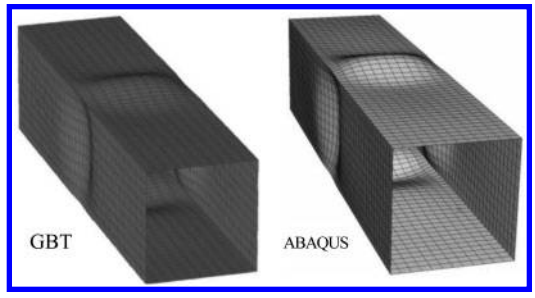

Figure 8. Column collapse mechanism (AP equilibrium state).

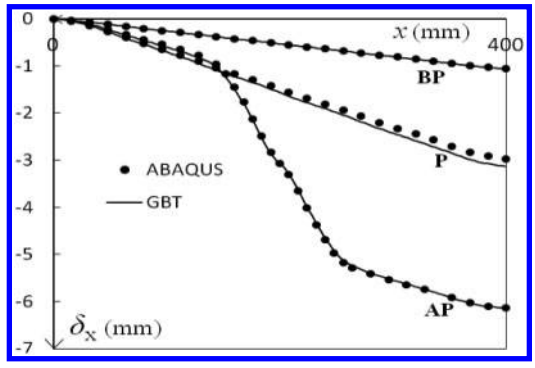

Figure 9. Axial displacement profiles of the top wall mid-point at the BP, P and AP equilibrium states.

(iii) Concerning the **TE** modes **19** and **20**, whose presence is intrinsically linked to modes **1** (Poisson effects) and **2**, it should be noted that, in spite of their small contributions (≈6% each), they play a key role. Indeed, their removal from the analysis would considerably stiffen the column behaviour since local buckling would be "artificially restrained". The post-peak participation decrease of these **TE** modes stems from elastic unloading and local deformation "localisation" very close to mid-height (see Fig. 8).

Figure 9 depicts the BP, P and AP axial displacement profiles δ_x (x) of the top wall mid-point (see Fig. 3(a)). First of all, it is readily observed that the ABAQUS and GBT results virtually coincide at the BP and AP states, and exhibit small differences at the P state. Moreover, note the linearity of the BP profile, while its P counterpart exhibits a mild non-linearity close to the column ends. At the AP state, on the other hand, δ_x exhibits three "almost linear" segments, the two outer ones with similar (small) slopes and a much steeper inner one – this axial stiffness drop occurring in the column central region stems from the plastic deformations associated with the increasing participations of the local modes **2**, **3** and **4** (see Fig. 7(b)).

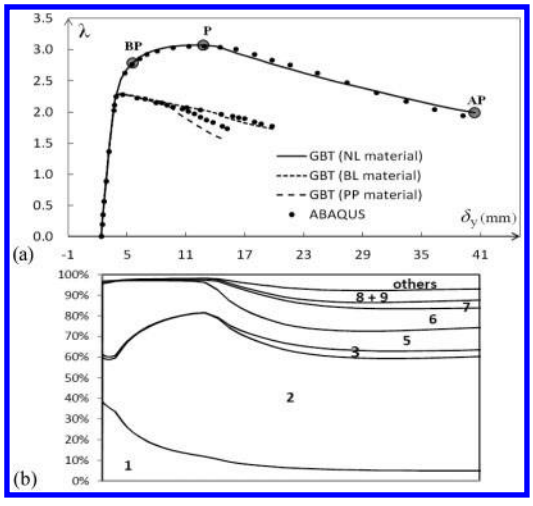

Figure 10. (a) GBT and ABAQUS equilibrium paths and (b) GBT modal participation diagram (NL column).

3.3 *HF I-section column*

Figure 10(a) shows the GBT and ABAQUS $\lambda(\delta_y)$ equilibrium paths concerning the PP, BL and NL material models (δ_y is the mid-span cross-section mid-height lateral displacement – see Fig. 3(b)). For the NL paths, the BP, P and AP applied load values are $\lambda_{GBT} = 2.79 + \lambda_{ABQ} = 2.76$ (BP), $\lambda_{GBT} = 3.08 + \lambda_{ABQ} = 3.05$ (P), $\lambda_{GBT} = 1.99 + \lambda_{ABQ} = 1.94$ (AP). As for Figure 10(b), it provides the evolution, with δ_y, of the mid-span cross-section deformed configuration (via the GBT modal participation diagram). Note that:

(i) Except for the PP material at advanced post-collapse stages, the GBT and ABAQUS curves agree very well – *e.g.*, the NL paths do not differ by more than 4%.

(ii) The PP and BL column responses prior to the later collapse stages virtually coincide (in spite of the inelastic collapse). However, the behaviour is much stiffer for the NL column ($\lambda_{u,NL} = 3.05$, $\lambda_{u,BL} = 2.28$), due to the large strain-hardening (partly responsible for the high non-linearity prior to reaching the peak load).

(iii) Figure 10(b) shows that the column behaviour exhibits relevant contributions from (iii_1) global modes **1** and **2** (21.2–69.7%), and (iii_2) local modes **5** (8.9–36.1%), **6** and **8**+**9**. Although the web-driven mode **5** dominates the local deformation in the path ascending branch (recall it participates in the initial imperfection), important contributions from the flange-driven modes **6,8** and **9** occur in the post-collapse phase – this can be attested by the failure mechanism (AP state) depicted in Fig. 11 (note the yield-line forming at the most compressed flange regions).

Figure 12 concerns the NL material response at the BP, P and AP states and shows the web mid-height lateral displacement profiles $\delta_y(x)$ (Fig. 3(b)). The agreement between GBT and SFEA results is fairly good – visible discrepancies stem mostly from differences in the initial imperfection prediction. In order to assess the material model influence, Figure 13 compares the GBT $\delta_y(x)$ profiles for $\lambda_{GBT} = 1.99$ (AP state) – it is observed that, in spite of the expected quantitative differences, they all follow the same trend (same number of half-waves).

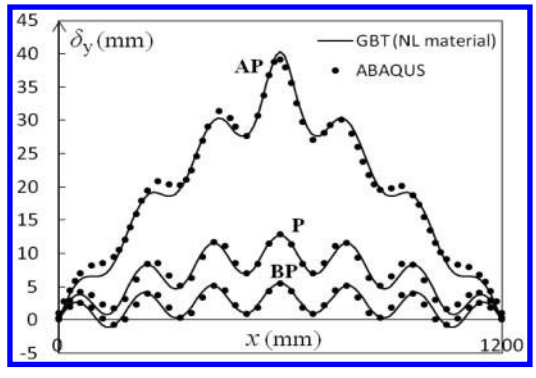

Figure 12. Cross-section mid-height lateral displacement profiles of the NL column at the BP, P and AP equilibrium states.

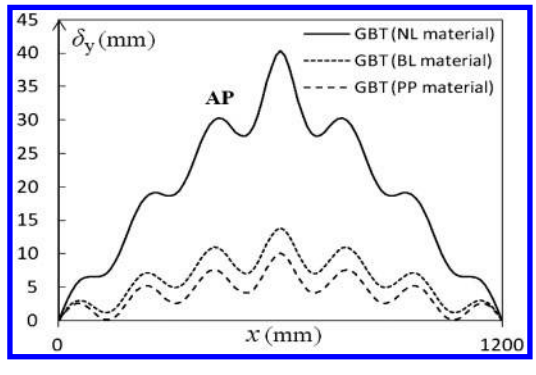

Figure 13. Cross-section mid-height lateral displacement profiles at $\lambda_{GBT} = 1.99$ for the NL, BL and PP columns.

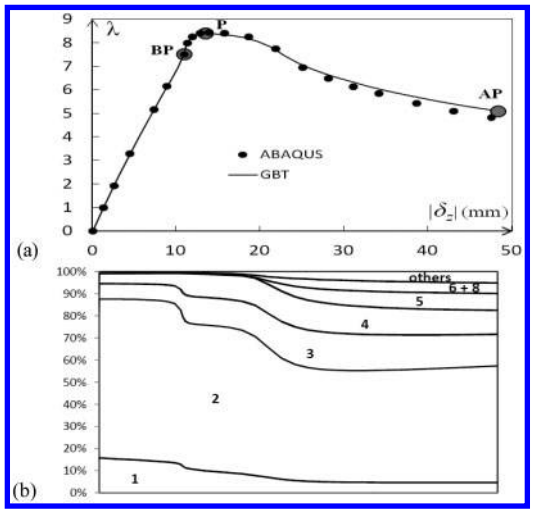

Figure 14. (a) GBT and ABAQUS equilibrium paths and (b) GBT modal participation diagram.

3.4 *RHS beam-column*

Figure 14(a) shows the GBT and ABAQUS $\lambda(|\delta_z|)$ equilibrium paths (δ_z is the mid-span top flange mid-point vertical displacement – Fig. 3(c)). The BP, P and AP λ values are $\lambda_{GBT} = 7.51 + \lambda_{ABQ} = 7.50$ (BP), $\lambda_{GBT} = 8.38 + \lambda_{ABQ} = 8.43$ (P), $\lambda_{GBT} = 5.09 + \lambda_{ABQ} = 4.81$ (AP). Figure 14(b) shows the modal participation diagram providing the evolution of the most deformed cross-section shape. It is possible to draw the following conclusions:

(i) The GBT and ABAQUS curves show a very good correlation in most of the deformation range. Even if the differences increase as loading progresses, they never exceed 6% (5% excluding the last 2 ABAQUS points).

(ii) Figure 14(b) clearly shows that the early loading stages are governed by axial extension and minor-axis bending (modes **1** and **2** – 65.7–72.7%). The local modes **3** (7.0–12.5%) and **4** (4.6–10.5%), which stem from the loaded top flange transverse bending and oppose each other in the bottom flange (Fig. 6), also have visible contributions. Lastly, mode **23** (one of the "others") captures the shear deformation associated with minor-axis bending.

(iii) In the post-peak stage there is a clear global deformation decrease (modes **1**+**2**), mostly compensated by the gradual growth, for $|\delta_z| \geq 20$ mm, of local modes **5** (web-driven – 0.3–7.6%) and **6**+**8**(1.0–4.7%). The presence of local deformation in the member yield-line mechanism can be confirmed in Figure 15.

Figure 16 compares the top flange mid-point vertical displacement profiles at the BP, P and AP states. Besides the excellent agreement between the GBT and ABAQUS outputs, note that the half-wave patterns change significantly in-between states P and AP, due to the plastic flow and elastic unloading associated with the failure mechanism. Finally, the half-column Mises stress contours depicted in Figure 17, concerning state P and evidencing excellent agreement, make

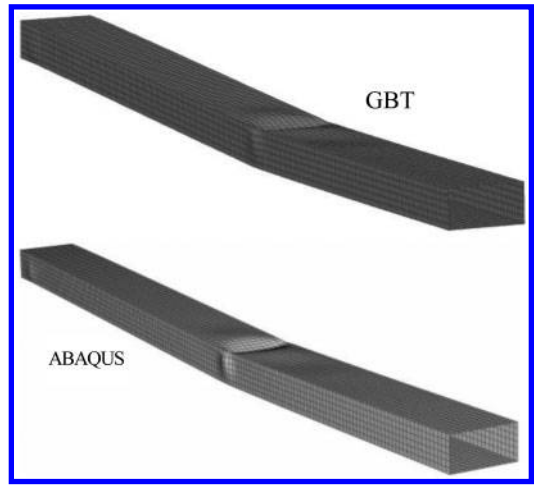

Figure 15. Member collapse mechanism (AP equilibrium state).

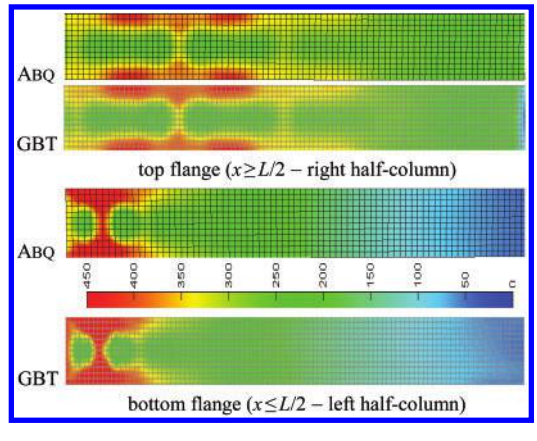

Figure 17. Mises stress (N/mm^2) contours at the P equilibrium state.

it possible to visualise the most yielded (and compressed) flange regions at collapse: the vicinities of the (i) fixed end section bottom flange ($x \leq L/2$) and (ii) most deformed cross-section top flange ($x \geq L/2$).

4 CONCLUDING REMARKS

This paper (i) provided an overview of a recently developed and validated GBT formulation to assess the inelastic post-buckling behaviour of thin-walled members, and (ii) illustrated its application and potential by presenting and discussing the analysis of several tubular members, namely a stainless steel SHS stub column, a perfectly plastic RHS beam-column and three hollow-flange I-section columns made of perfectly plastic, bi-linear and non-linear materials with identical yield stresses – the non-linear material exhibited a large strain-hardening and led to a significant strength increase. For validation purposes, most GBT results (equilibrium paths, collapse mechanisms, displacements profiles and stress contours) were compared with values yielded by ABAQUS shell finite element analyses. It was shown that the GBT analyses provide similarly accurate results, while requiring no more than 25% (16.6% on average) of the d.o.f. numbers involved in the corresponding SFEA. Moreover, it was also shown, through modal participation diagrams, that the GBT analyses provide in-depth insight on the member mechanics associated with both the elastic and elastic-plastic regimes (including the collapse mechanisms).

Direct stability analysis of steel beam-column with an elastic restraints

I. Misiunaite & A. Juozapaitis
Department of Bridge and Special Structures, Vilnius Gediminas Technical University, Vilnius, Lithuania

ABSTRACT: The paper proposes the stability analysis of beam-column with an intermediate elastic restraint and arbitrary end conditions based upon direct analysis method. The proposal accounts for the second-order effects, geometrical imperfections, material nonlinearities and interaction of bending end compression. The material nonlinearity is implemented using the concept of multiple column curves. Furthermore, paper discusses the concept of equivalent imperfections based upon generalized imperfections factor and its application for the evaluation of the geometrical and material nonlinearities. The stability verification provided by the derived governing equations, discussed and compared with the numerical values obtained from the large displacement static analysis performed by means of the finite element method code, ANSYS. On the basis of comparative study several conclusions are drawn concerning the safety and accuracy of the verification of the stability by the proposed computational method.

1 INTRODUCTION

The development of form-finding to increase efficiency and fulfill aesthetical requirements of steel structures refers to the necessity of the appropriate design methods. Many of current design codes for the stability verification alongside conventional individual member check allows advanced analysis methods known as global analysis in EN 1993-1-1 (2005) and direct analysis method in ANSI/AISC 360-10 (2010). However, despite popular use of conventional design methods in the past and present as a basis for structural analysis, the methods have their major limitations. In the conventional methods, first-order or second-order elastic analysis is carried out to analyze a behavior of a structural system. The members are isolated from the structural system between the points of restraints, and their structural verification is based upon the member strength curves and interaction formulae, which implicitly account for the effect of deformed geometry, material and geometrical imperfections. The compatibility between the isolated member and the member as the part of a structural system is implemented through the concept of the effective length factor. The direct analysis method is discussed here, as it offers an advantage to eliminate the need to calculate effective length factor verifying the structural stability of the systems. The effective length factor is a long-standing feature and generally provides a good solution in structural frame design, but its limitations and underlying assumptions are rarely satisfied in current modern structures.

Alternative methods may be necessary in order to overcome the limitations of the effective length method as well as account for the geometrical and material nonlinearities inherent in all structures. The advanced methods introduced in current design codes have the form of requirements rather than practical application. Referring to their efficiency, many research efforts have been devoted to the development of practical implementation of the advanced analysis methods.

Most of the studies pursuit of the methods to perform direct analysis and design of frame steel structures. Murat et al. (2008) considers partial base fixity using the direct analysis method for column and frames containing web-tapered members design. Kim & Choi (2001) develop a practical advanced analysis of semi-rigid frames, Kim et al. (2006) presented the advanced analysis of 3D steel frames for lateral-torsional buckling, White et al. (2006) verifies the stability of steel building frames using the 2005 AISC specifications.

Kim & Choi (2001) apply practical advanced analysis for the design of three-dimensional truss bridge. Although, there are not much studies spread in the literature which are based on attempt to analyze more complex structures. Some of them rely on the computational programs developed on the basis of the inelastic stability of beam-column elements (Landesmann & Batista 2005)

The paper presents computational method based upon elastic stability of the steel beam-column element with an intermediate elastic restraint and arbitrary end conditions, including material nonlinearities associated with residual stress, second-order effects, and geometrical imperfections. The considering calculation model reflects the structural behavior of innovative steel structures with applied supporting system which in bridge engineering refer to underdeck cable-stayed bridges and in civil engineering to

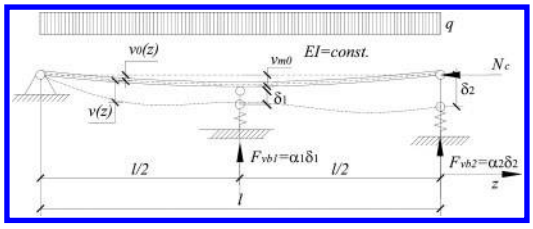

Figure 1. Calculation model of a beam-column with an intermediate elastic restraint and an elastic end support.

beam-string structures (Xue & Liu 2009). The possibility to assess structural behavior of under-deck cable-stayed bridge by applying simplified calculation models of beam-column was described by Misiunaite et al. (2012).

2 CALCULATION MODEL

The most fundamental theoretical formulation in the verification of the elastic stability of structures is the Euler formula, which defines the elastic axial buckling strength of an individual member and essentially refers to the structural analysis based on the individual member check. The theory assumes that the member is perfectly straight, behaves in-plane elastically and has a pinned ends. These assumptions all are commonly violated in real structures. In practice, elements are out-of straightness between braced points due to fabrication tolerances. Residual stresses are presented that cause inelastic behavior. Further, as a structure is loaded, deformations also occur, adding second-order forces and moments. Furthermore, it should be noted the fact that buckling always involves both an axial force and bending effects. The considering calculation model formed to implement all previously mentioned effects and moreover, the beam-column shown in Figure 1 has an intermediate restraint to cover the case when the structure is additionally supported at the mid-span, thus obtaining the semi-continuous structure. Consequently the end support assumed to be elastic to widen the applicability of the calculation model. The verification of the stability of the beam-column shown in Figure 1 performed with the approach of the Direct Analysis Method based upon nonlinear geometric elastic analysis.

2.1 *Imperfections*

Appropriate allowances shall be incorporated in the structural analysis to cover the effects of imperfections, including residual stresses and geometrical imperfections.

Residual stresses are introduced into structural shapes as a result of the production. The direct inclusion of the residual stresses in the analysis is connected with the manufacture-related approaches, which lies in the formulation of requirements that will appropriately consider all relevant factors, thus it becomes a task so complex as to be impossible. Theoretical values, for example, of the residual stresses in a shape, can be used, but this may impair the quality of the results. There are other methods based on the theoretical developments. The most important among the theoretical based methods is the one that utilizes several column strength curves. It has been included in methods proposed in many those days modern design codes. For the sake of simplicity in the proposed computational method the residual stresses are accounted by concept of equivalent geometric imperfections, with values which reflect both geometrical and material imperfections and are based on the column strength curves.

Geometrical imperfections are inherent in all structures. Small unavoidable eccentricities of loading and lack of initial straightness can be simulated mathematically by assuming an initial curvature which produces a small central deflection v_{m0}. According to equivalent geometric imperfections concept central deflection is modified on the bases of generalized imperfection factor. The generalized imperfection factor was introduced in the Perry-Robertson formula. The value of the generalized imperfection factor originally obtained by Robertson in 1925 has varied over the years and rearranged in the form of:

$$\eta = 0.001a\left(\lambda - \lambda_0\right) > 0 \tag{1}$$

where a varies from 2 to 8 depending on the shape of the section and limiting slenderness ratio:

$$\lambda_0 = 0.2\sqrt{\frac{\pi^2 E}{f_y}} > 0 \tag{2}$$

where $E =$ Elastic modulus; $f_y =$ yield strength.

Substituting Equation 2 into Equation 1 and introducing non-dimensionless slenderness:

$$\overline{\lambda} = \frac{\lambda}{\sqrt{\frac{\pi^2 E}{f_y}}} \tag{3}$$

hence:

$$\eta = \alpha\left(\overline{\lambda} - 0.2\right) \tag{4}$$

where $\alpha = 0.001a(\pi^2 E/f_y)^{1/2}$ is an imperfection factor based on the column strength curves and the multiplier 0.001 presents the maximum tolerance on elements out of straightness specified in many design codes.

The magnitude of the equivalent geometric imperfections by introducing generalized imperfection factor can be obtained:

$$v_{m0} = \alpha\left(\overline{\lambda} - 0.2\right)\frac{W}{A} \tag{5}$$

where $A =$ cross section area; $W =$ section modulus.

2.2 *Governing Equations*

The governing equations for the stability verification of the beam-column presented in Figure 1 derived considering the equilibrium by approach of moderately large displacement theory. Determining the equilibrium equations by moderately large displacement theory the structure is in equilibrium in its deformed state thus the second order effects will be accounted.

When considering simultaneous bending and compression with applying axial load N_c the deflection at z is increased by v and the differential equation of bending becomes:

$$M'' - N_c\left(v - v_0\right)'' + q = 0 \tag{6}$$

Adopting a sinusoidal function for an initial lack of straightness:

$$v_0 = v_{m0}\sin\left(\frac{\pi z}{l}\right) \tag{7}$$

and introducing:

$$k^2 = \frac{N_c}{EI} \tag{8}$$

The arbitrary solutions to the Equation 1, considering both sides of the calculation model (left: $0 \le l/z \le l/2$ and right $l/2 \le l/z \le l$) is:

$$v^{l(r)} = C_{1(5)}\sin kz + C_{2(6)}\cos kz + C_{3(7)} + C_{4(8)} + v_{part} \tag{9}$$

where superscriptions l and r indicates left and right sides of the calculation model respectively.

When the transverse distributed force is assumed to be constant and introducing:

$$n = \frac{(kl)^2}{\pi^2 - (kl)^2} \tag{10}$$

the particular solution can be taken as:

$$v_{part} = \frac{qz^2}{EIk^2} + nv_{m0}\sin\frac{\pi z}{l} \tag{11}$$

By combining Equations 3 and 5 with the boundary and continuity conditions for the beam-column with the intermediate elastic restraint and arbitrary support conditions shown in Figure 1:

$$\begin{aligned} &v^l = v^{l\,\prime\prime} = 0 \ \text{ at } z = 0, \\ &\left.\begin{aligned} v^l &= v^r = \delta_1 \\ v^{l\,\prime} &= v^{r\,\prime} \\ v^{l\,\prime\prime} &= v^{r\,\prime\prime} \end{aligned}\right\} \text{ at } z = l/2, \\ &\left.\begin{aligned} v^r &= \delta_2 \\ v^{r\,\prime\prime} &= 0 \end{aligned}\right\} \text{ at } z = l \end{aligned} \tag{12}$$

the deflection of the left and right sides of the beam-column is obtained as:

$$v^l = \frac{ql^4}{EI}\frac{1}{(kl)^2}\left[\frac{1}{(kl)^2}\left(\frac{\cos(kl/2 - kz)}{\cos kl/2} - 1\right) - \frac{F_{vb,1}}{2ql}\times\right.$$
$$\left.\times\left(\frac{\sin kz}{kl\cos kl/2} - \frac{z}{l}\right) - \frac{z}{2l}\left(1 - \frac{z}{l}\right)\right] + \delta_2\frac{z}{l} + nv_{m0}\sin\frac{\pi z}{l} \tag{13}$$

$$v^r = \frac{ql^4}{EI}\frac{1}{(kl)^2}\left[\frac{1}{(kl)^2}\left(\frac{\cos(kl/2 - kz)}{\cos kl/2} - 1\right) - \frac{F_{vb,1}}{2ql}\times\right.$$
$$\left.\times\left(\frac{\sin(kl - kz)}{kl\cos kl/2} + z/l - 1\right) - \frac{z}{2l}\left(1 - \frac{z}{l}\right)\right] + \delta_2\frac{z}{l} + \tag{14}$$
$$+nv_{m0}\sin\frac{\pi z}{l}$$

The bending moment may be expressed in terms of the displacement as:

$$M = -EIv'' \tag{15}$$

Accordingly, by Equation 15, the moments are given by:

$$M^l = \frac{ql^2}{(kl)^2}\left(\frac{\cos(kl/2 - kz)}{\cos kl/2} - 1\right) - \frac{F_{vb,1}l}{2}\frac{\sin kz}{kl\cos kl/2} \tag{16}$$

$$M^r = \frac{ql^2}{(kl)^2}\left(\frac{\cos(kl/2 - kz)}{\cos kl/2} - 1\right) - \frac{F_{vb,1}l}{2}\frac{\sin(kl - kz)}{kl\cos kl/2} \tag{17}$$

The restoring force $F_{vb,1}$ in Equations 13, 14 and 16, 17 can be taken as:

$$F_{vb.1} = EIv''' \tag{18}$$

Accordingly, by substituting Equation 18 the restoring force can be obtained as:

$$F_{vb,2} = \frac{ql}{kl}\frac{\left(1 + (kl/2)^2 - 1/\cos kl/2\right)}{kl/2 - \tan kl/2} + \frac{EI(kl)^3}{l^2\left(kl/2 - \tan kl/2\right)}\times$$
$$\times\frac{\left(\delta_1 - \delta_2/2 - nv_{m0}\right)}{l} \tag{19}$$

Elastic support at the middle of the considering beam-column shown in Figure 1 restrains its deflection to δ_1. Thus restoring force $F_{vb,1}$ can be expressed as a product of δ_1 and restraint stiffness α_1, substituting it into Equation 19 restrained deflection may be obtained as:

$$\delta_1 = \frac{ql^4}{EI(kl)^4}\frac{\left(1 + (kl/2)^2 - 1/\cos kl/2\right)}{\alpha_1/\alpha_L - 1} - \frac{\left(\delta_2/2 + nv_{m0}\right)}{\alpha_1/\alpha_L - 1} \tag{20}$$

where $\alpha_L =$ limiting restraint stiffness.

The variation with the dimensionless restraint stiffness α/α_L of the dimensionless buckling load on the bases of simply supported additionally elastically restrained compressed element was described by Trahair (2008) and the restraint stiffness expressed as:

$$\alpha_L = 16\pi^2 EI / l^3 \tag{21}$$

and was assumed to be limiting as considering element buckles in the asymmetric second mode.

Further for the sake of simplicity the limiting restraint stiffness in Equation 20 is assumed to be equal to the one obtained by Equation 21.

It follows from Equation 20 that intermediate restraint stiffness supposed to be non-equal and greater than minimum restraint stiffness, otherwise restrained deflection approach infinity and turns to unrestraint one. Furthermore, the shift from the unrestraint deflection shape to restraint one asserts between the values of 2 to 4 of the relative restraint stiffness α_1/α_L depending on slenderness parameter *kl* (Misiunaite & Juozapaitis 2012).

2.3 *Governing parameters*

All governing equations of considering structural element derived in Section 2.2 contain undetermined variable *kl*. The variable *kl* is known as slenderness parameter and may be assumed as the governing parameter performing parametric analysis of the additionally elastically restrained beam-column shown in Figure 1. The slenderness parameter relates the axial load, the flexural rigidity and the length of the structural element and may be expressed as:

$$kl = l\sqrt{\frac{N_c}{EI}} \tag{22}$$

The structural stability of the beam-column with the intermediate elastic restraint and arbitrary support conditions can be verified with the variation of slenderness parameter which for the case of buckling analysis corresponds to:

$$kl = \pi\sqrt{\frac{N_c}{N_{cr}}} \tag{22}$$

where N_{cr} = Euler critical load.

The invariable transverse distributed force q applied on an axially compressed element causes initial eccentricity which increases the stress, but does not affect the elastic stability of the considering structural element. While in case of elastic restraint, it results in a deflection dependent lateral load and a restoring force as the deflection takes place (Gambhir 2004). Thus the applied elastic restraint affects the elastic stability of the structural element. The relative restraint stiffness given in Equation 20 is assumed as one of the governing parameters and its effect on the deflection shape of the beam-column shown in Figure 1 will be considered in Section 3.2.

3 NUMERICAL IMPLEMENTATION

The derived governing equations, as a direct nonlinear solution technique is used in the analysis. The numerical procedure is straightforward in concept and implementation. The advantage of this method is its practical applicability.

3.1 *Accuracy evaluation*

The accuracy evaluation of the proposed method for the stability verification of the additionally elastically restrained beam-column element with arbitrary end conditions presented in Figure 1 performed on the bases of the finite element method by nonlinear solver of the software ANSYS. The large displacement static analysis performed and full Newton-Raphson option used for the solution. Initial sinusoidal configuration of the imperfect shape of the element simulated using B-spline which reflects to sinusoidal function.

The imperfection factor chosen on the bases of central member strength curve, due to compatibility among design codes. The central member strength curves introduced in many design codes are of similar shape and match closely (Rotter 1981). The geometric characteristics of European I-sections rely on considering member strength curve assumed on performing comparison analysis. The magnitude of the initial equivalent geometrical imperfection varies from 43.0 mm to 52.0 mm relay on slenderness of the element referring to geometric characteristics of considering shapes, as the length of the beam-column is taken 18.0 m for all cases being analyzed.

Calculation model of the beam-column element shown in Figure 1 reflects to the structural behavior of the element subjected to a compressive axial force N_c which rely on slenderness parameter and a constant distributed load q = 20 kN/m. The analysis performed for $kl = 3.0$, 4.0 and 5.0. The stiffness of the end restraint is assumed to be equal to limiting restraint stiffness and may be obtained by Equation 21. The restraint stiffness ratio α_1/α_L set to be equal to 5.0 implementing restrained deflection shape of the considering structural element.

The numerical values of the restoring force at the intermediate support, extreme bending moments and deflections for the $z = l/4$ and $z = 3l/4$ are obtained both by using governing equations derived in Section 2.3 and nonlinear solver of ANSYS. Table 1 presents the relative errors.

Table 1 shows that the proposal is safe and efficient, and that the errors obtained are in the desirable limits of accuracy.

3.2 *Verification*

Considering the beam-column element of the length of 18.0 m. shown in Figure 1 which is subjected to an axial force N_c rely on the slenderness parameter *kl*. The verification of the stability is carried out with the variation of the slenderness parameter from 2.0 to 6.0 with

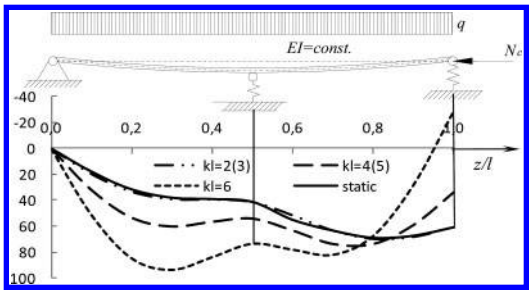

Figure 2. Verification of the deformational response of the beam-column.

increment of 1.0. The deflection and bending moment are obtained using governing equations and shown in Figures 2 and 3 respectively. The transverse distributed load is assumed to be constant with the numerical value of 20 kN/m. The geometrical and material characteristics of the considering beam-column are assumed to be equal to that of a section HEB 300 and the magnitude of the initial imperfections $v_{m0} = 43$ mm.

Figure 2 shows that the deflection shapes of the considering element with the values of the slenderness parameter 2.0 and 3.0 slightly differs from the results obtained on the bases of small displacement static theory. A sudden increase of the deflection at the slenderness parameter values of 4.0 and 5.0 indicates the element shift from the stable to unstable behavior and with the value of 6.0 it becomes unstable. The increase of slenderness parameter increases the axial response rather than flexural and the deflection shape of beam-column approaches the restraint shape of simply supported element with the intermediate elastic restraint.

Figure 3 presents the flexural response of the additionally elastically restrained beam-column element with the arbitrary end conditions presented in Figure 1. The increase of the slenderness parameter and it relying axial force in the considering beam-column element determines the increase of the extreme values

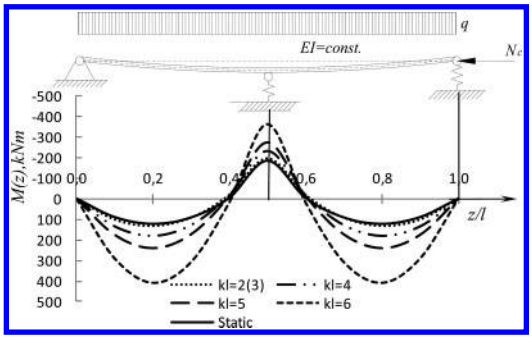

Figure 3. Verification of the flexural response of the beam-column.

of the bending moments. The significant shift of the extreme values of the bending moments at the values of 6.0 of the slenderness parameter can be assumed as the stability loss of the element.

4 CONCLUSIONS

The stability verification of the additionally elastically restrained beam-column with the arbitrary end conditions has been investigated using the finite element nonlinear solver of ANSYS in comparison with the derived governing equation with the approach of Direct Analysis Method. The analytical solution found to be in a good agreement with the results of finite element analysis.

Analysis based upon calculation model of the initially imperfect beam-column with the intermediate elastic restraint and arbitrary end conditions to reflect the behavior of more complex structures than steel frames.

The governing equations determined on the basis of the moderately large displacement theory thus accounting the effect of deformed geometry. The concept of equivalent geometrical imperfections with approach of the generalized imperfection factor is discussed. Furthermore, the modeling of initially imperfect member for the computer aided-analysis described.

Moreover, the influence of the intermediate elastic restraint on the elastic stability of the structure discussed. The governing slenderness parameter introduced to vary the axial effect on the structure and the numerical analysis carried out for the different values of slenderness parameter.

Stabilization of members with I-sections against flexural torsional buckling

R. Stroetmann
Technische Universität Dresden, Institute of Steel and Timber Construction, Germany

ABSTRACT: The following paper addresses the structural behavior of continuously restrained beams and beam-columns concerning flexural torsional buckling and second order effects. Beside the influence of different loadings, moment distributions and assumptions of imperfections, various restraining effects are considered. Approximate solutions for bifurcation buckling and second order analysis for calculations in practice are developed by using the energy method. The quality of the approximate solutions is reviewed by means of examples and comparisons with results of more complex FEM calculations.

1 INTRODUCTION

Stabilizing effects of adjacent structural elements are often taken into account in the verification of sufficient structural safety of beams and beam-columns (members) that are susceptible in terms of flexural torsional buckling. This is all the more required in case of increasing the slenderness and the strength of the used steel grades. The connections as well as the stabilizing elements themselves must be able to transfer the stabilization forces.

Suitable calculation models are necessary for the assessment of members and the determination of stabilization forces. On the one hand the structural behavior of the involved elements must be sufficiently accurately recorded; on the other hand the efforts for the calculation need to be limited for the practical use.

Often separate calculations for the assessment of members and stabilizing elements are carried out. For members, the use of the equivalent member methods is common, e.g. in Europe by Eurocode 3, part 1–1, chapter 6.3. For the determination of stabilization forces and moments, different calculation models with more or less major simplifications were developed in the past decades (see for example chapter 5.3.3 in EN 1993-1-1). The finding that the suitable use of these approximations is limited and that significant deviations to more accurate calculations can occur gave rise to the investigations described below.

2 STRUCTURAL BEHAVIOR OF CONTINUOUS RESTRAINT BEAMS

2.1 *Influence of shear fields*

The influence of a shear field related to the buckling load and the mode of lateral torsional buckling is illustrated by the example of a simply supported beam (Fig. 1). Figure 2 shows the buckling modes for different stiffnesses S. With increasing values S, the lateral displacement v of the upper chord decreases. At the same time the twist rotation ϑ increases. At a certain value S, the lower chord deforms in the negative y-direction in several waves. For small values S, the shape of the deformations v and ϑ can be described in good approximation by a sinusoidal half-wave. With increasing S, the deviations to this shape become larger.

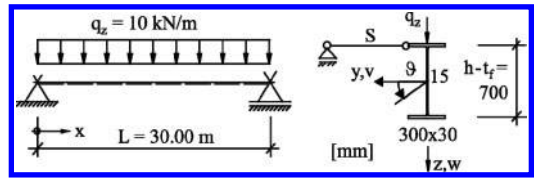

Figure 1. Simply supported beam with transverse load and shear field connecting at the top flange.

Figure 3 shows an almost linear relationship between the buckling load and the shear stiffness S. This does not apply generally and is not the case for moment distributions with different signs.

In practice, different approximations for the determination of stabilization forces on shear fields and bracing systems are common (e.g. EN 1993-1-1, chapter 5.3.3). An often used substantial simplification is to replace the beams by their compression chords (Fig. 4).

For simply supported beams with uniform distributed load q_z, lateral bow imperfections e_0 and horizontal loads q_y, the resulting stabilization force q_s can be determined by the Equations 1 and 2. The buckling load is reached, if q_s becomes infinite. From this, an approximation for α_{cr} may be deduced (Eq. 3).

$$q_s = \left(\frac{q_{y,m} + e_0 \cdot \sum P_i \cdot \pi^2 / L^2}{1 - \sum P_i / S} - q_{y,m} \right) \cdot \sin\left(\frac{\pi \cdot x}{L} \right) \quad (1)$$

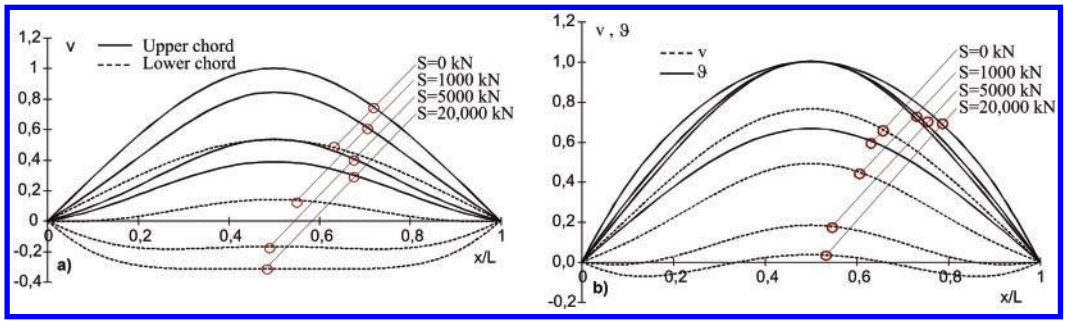

Figure 2. Standardized buckling deformations for different shear field stiffnesses S, a) Flange displacements v, b) Displacements v and twist rotations ϑ of the beam.

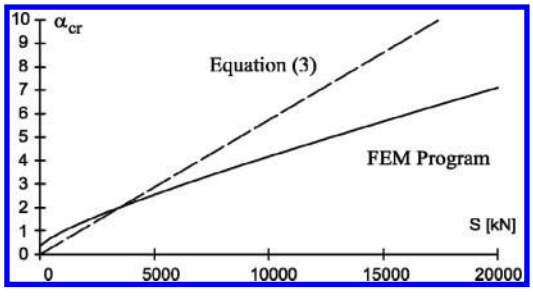

Figure 3. Buckling load calculated by FEM program and Equation 3.

$$P_i = \frac{\max M_{y,i}}{h_i - t_{f,i}} = \frac{q_{z,i} \cdot L^2}{8 \cdot (h_i - t_{f,i})} \qquad (2)$$

$$\alpha_{cr} = \frac{P_{cr}}{\sum P_i} = S \cdot \sum_i \frac{8 \cdot (h_i - t_{f,i})}{q_{z,i} \cdot L^2} \qquad (3)$$

$h - t_f$ distance of the chord axis

Figure 3 shows a diagram obtained by evaluating Equation 3 using the example in Figure 1. Neglecting the stiffness of the beam itself leads to conservative results of Equation 3 for small values S. For increasing values S, the value α_{cr} is more and more overestimated. Besides other reasons, this results from neglecting the nonlinear term due to the load q_z in combination with the twist rotation ϑ.

To show the influence of different moment distributions M_y and loads q_z on the shear field, the beam of Figure 1 was analyzed for three load cases (Fig. 5).

The stabilization loads and shear forces, its distributions and maximum values are rather different (Fig. 6).

Often the hypothesis is stated that it is conservative to simplify a variable moment distribution into a constant moment diagram with the maximum ordinate when determining the stabilizing forces. The comparison of the results for load case 3 with those from load case 1 and 2 shows that this is not generalizable.

The magnitude of the stabilization force q_s (Fig. 6) gives an idea about its influence for the design of shear fields and bracings. If, for instance, 5 to 10 beams are to be stabilized by a bracing system, this influence

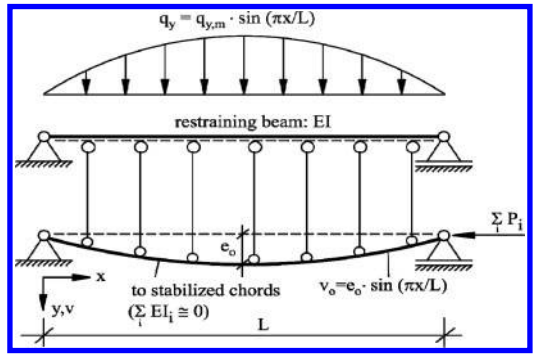

Figure 4. Approximate model to determine stabilization forces.

often cannot be considered by only a small addition to the wind load. Outer loads q_y, e.g. from wind or thrust of inclined roofs, are leading to larger deflections and increasing the stabilization forces additionally (see Eq. 1).

2.2 *Influence of different assumptions of imperfections*

For the assessment of flexural buckling of columns and frames, the formulation of equivalent loads to consider imperfections is well known. The influence of initial bow and sway imperfections in combination with compression forces may be replaced by systems of equivalent loads.

The procedure is similar for the assessment of lateral torsional buckling. In the following, the influences are clarified.

Equation 4 gives the system of coupled differential equations for a beam with doubly symmetric cross-section that is continuously restrained by a shear field. The used deflections v_g and ϑ_g, which are multiplied by bending moments M_y and cross loads q_z, are total deflections. They consist of elastic deflections and geometrical imperfections (Eq. 5). v_0 and ϑ_0 are describing the stressless initial deformed shape of the beam.

$$EI_z \cdot v''' - S \cdot (v'' - z_S \cdot \vartheta'') + (M_y \cdot \vartheta_g)'' = q_y \qquad (4a)$$

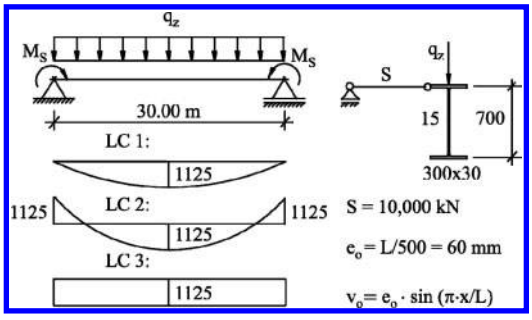

Figure 5. Structural system, imperfection and moment distributions for load cases 1 to 3.

$$EI_\omega \cdot \vartheta''' - GI_T \cdot \vartheta'' + S \cdot z_S \cdot (v'' - z_S \cdot \vartheta'') + M_y \cdot v_g'' + q_z \cdot z_q \cdot \vartheta_g = m_x \quad (4b)$$

$$v_g = v + v_0 \quad (5a)$$

$$\vartheta_g = \vartheta + \vartheta_0 \quad (5b)$$

Inserting Equation 5 into 4 and transferring the terms, which are combined with v_0 and ϑ_0, to the right side provides the equivalent loads $q_{y,0}$ and $m_{x,0}$ along the beam. For the equilibrium, additional nodal forces and moments are necessary, which are not treated here.

$$q_{y,0} = -(M_y \cdot \vartheta_0)'' = q_z \cdot \vartheta_0 - 2 \cdot Q_z \cdot \vartheta_0' - M_y \cdot \vartheta_0'' \quad (6a)$$

$$m_{x,0} = -M_y \cdot v_0'' - q_z \cdot z_q \cdot \vartheta_0 \quad (6b)$$

$$M_y = M_S + 4 \cdot M_0 \cdot (\xi - \xi^2) \quad (7)$$

with $M_0 = \frac{q_z \cdot L^2}{8}$; $\xi = \frac{x}{L}$ M_s = hogging moment

Figure 7 shows the normalized equivalent loads resulting from a sinusoidal shape of v_0 and ϑ_0 for different moment distributions. The normalization is done in terms of $q_z = 8 \cdot M_0 / L^2$ and the maximum ordinate of the respective imperfection.

From Figures 6 and 7 as well as from Equation 6 it becomes obvious that simplifying assumptions for the moment distribution and the structural behavior do not apply generally. The imperfections v_0 provides in combination with bending moments M_y torsional loads $m_{x,0}$. The maximum area of $m_{x,0}$ results from the constant bending moment. In the presence of hogging and sagging moments, the sign is changing (Fig. 7a). Twist rotations ϑ_0 lead to equivalent cross loads $q_{y,0}$. They can lead to unsafe results.

Furthermore, depending on the span length and the cross-section properties of the beam, the structural behavior for torsion can be different (parts of St. Venant torsion and warping torsion). This affects the loads and stresses of the shear field again (Friemann & Stroetmann 1998).

3 APPROXIMATE CALCULATION OF FLEXURAL TORSIONAL BUCKLING

In the following, an approximate calculation of flexural torsional buckling based on the energy method is presented. Subjects are simply supported beams and beam-columns with doubly symmetric cross-sections and continuous restraints. By using sine series for the shape of v and ϑ, matrix equations are derived, which can be easily solved by calculators,

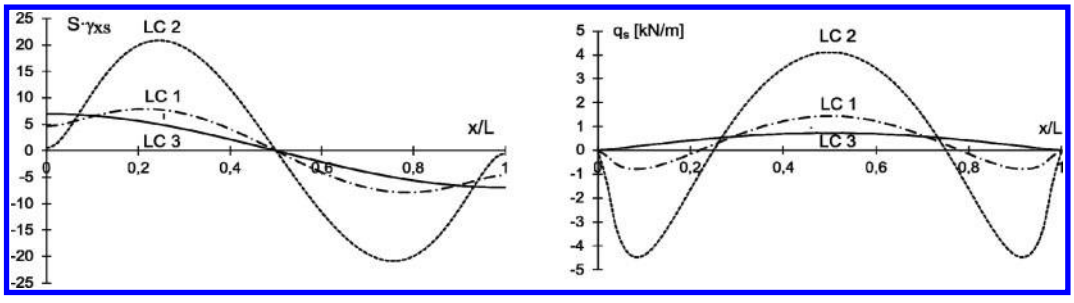

Figure 6. Distribution of shear and stabilization forces for the load cases 1 to 3 by Fig. 5.

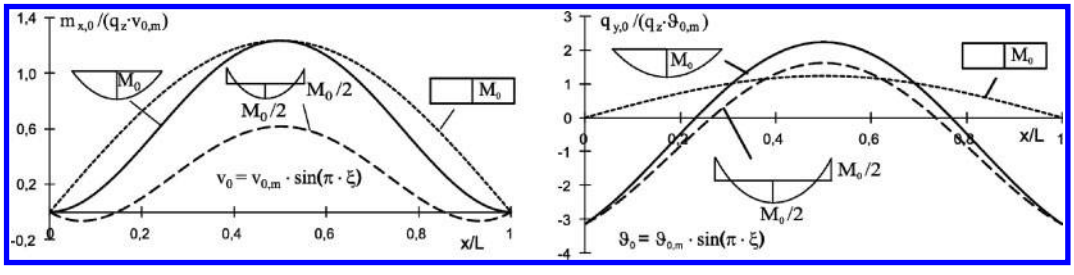

Figure 7. Equivalent torsional loads and horizontal loads for different assumptions of imperfections and moment distributions.

spreadsheets or computational software programs. The elasticity matrix considers different continuous restraining effects, whereas the stability matrix considers the normal forces, the bending moments M_y and the uniformly distributed cross load q_z. Individual parameters may set to zero to adapt to specific cases.

Five sine series terms for v and ϑ are considered in the given matrices (Fig. 8). In many cases, two sine series terms for each deformation leads to sufficiently accurate results. The user may adapt the matrix equation to a certain case and desired accuracy by eliminating columns and rows.

The Equations 8a to 8d describe the first variation of the strain energy and the potential energy (virtual work for the description of equilibrium). Inserting the sine series (Eq. 9), the moment distribution M_y (Eq. 10) and integrating over the length leads to the stiffness and stability matrices as well as to the load vector P_1 (s. Fig. 8). The indices of v and ϑ represent the number of sine half-waves over the length of the member.

$$\delta\Pi = \delta\Pi_e = \delta\Pi_g = \delta\Pi_p \tag{8a}$$

$$\begin{aligned}\delta\Pi_e = \int_L [&EI_z \cdot v'' \cdot \delta v'' + EI_\omega \cdot \vartheta'' \cdot \delta\vartheta'' + GI_T \cdot \vartheta' \cdot \delta\vartheta' \\ &+ B \cdot (v'' - z_B \cdot \vartheta'') \cdot (\delta v'' - z_B \cdot \delta\vartheta'') \\ &+ S \cdot (v' - z_S \cdot \vartheta') \cdot (\delta v' - z_S \cdot \delta\vartheta') \\ &+ c_y \cdot (v - z_C \cdot \vartheta) \cdot (\delta v - z_C \cdot \delta\vartheta) \\ &+ c_\vartheta \cdot \vartheta \cdot \delta\vartheta] \cdot dx\end{aligned} \tag{8b}$$

$$\begin{aligned}\delta\Pi_g = \int_L [&N \cdot (v' \cdot \delta v' + i_p^2 \cdot \vartheta' \cdot \delta\vartheta') \\ &+ M_y \cdot (v'' \cdot \delta\vartheta + \vartheta \cdot \delta v'') \\ &+ q_z \cdot z_q \cdot \vartheta \cdot \delta\vartheta] \cdot dx\end{aligned} \tag{8c}$$

$$\delta\Pi_p = -\int_L [q_y \cdot \delta v + m_x \cdot \delta\vartheta] \cdot dx \tag{8d}$$

$$v = \sum_i v_i \cdot \sin\left(\frac{i \cdot \pi \cdot x}{L}\right) \tag{9a}$$

$$\vartheta = \sum_j \vartheta_j \cdot \sin\left(\frac{j \cdot \pi \cdot x}{L}\right) \tag{9b}$$

$$\mathbf{M}_y(x) = M_i \cdot (1 - \xi) + M_k \cdot \xi + 4 \cdot M_0 \cdot (\xi - \xi^2) \tag{10}$$

The second order analysis follows by Equation 11,

$$(\mathbf{K}_e + \mathbf{K}_g) \cdot \mathbf{V} = \mathbf{P} = \sum \mathbf{P}_i \tag{11}$$

in which

$$\begin{aligned}&\mathbf{V}^T = [\mathbf{v}^T, \vartheta^T] = \\ &[v_1, v_2, v_3, v_4, v_5, \vartheta_1, \vartheta_2, \vartheta_3, \vartheta_4, \vartheta_5].\end{aligned} \tag{12}$$

Initial imperfections, which can be described by sine functions, can be taken into account by additional load vectors $\boldsymbol{P}_V$ (see $\boldsymbol{P}_2$ and $\boldsymbol{P}_3$ in Fig. 8).

$$\mathbf{P}_V = -\mathbf{K}_g \cdot \mathbf{V}_0 \tag{13}$$

in which

$$\begin{aligned}&\mathbf{V}_0^T = [\mathbf{v}_0^T, \vartheta_0^T] = \\ &[v_{1,0}, v_{2,0}, v_{3,0}, v_{4,0}, v_{5,0}, \vartheta_{1,0}, \vartheta_{2,0}, \vartheta_{3,0}, \vartheta_{4,0}, \vartheta_{5,0}].\end{aligned} \tag{14}$$

The calculation of the internal forces of the members and the restraining forces will implemented by means of the solution vector $\boldsymbol{V}$ and the respective equations of elasticity. This is exemplified by Equations 15 to 17. It should be noted that the accuracy of the results decreases with the order of the derivative of the deformations.

$$M_z = EI_z \cdot v'' = -EI_z \cdot \sum_i v_i \cdot \left(\frac{i \cdot \pi}{L}\right)^2 \cdot \sin\left(\frac{i \cdot \pi \cdot x}{L}\right) \tag{15}$$

$$M_\omega = -EI_\omega \cdot \vartheta'' = EI_\omega \cdot \sum_j \vartheta_j \cdot \left(\frac{j \cdot \pi}{L}\right)^2 \cdot \sin\left(\frac{j \cdot \pi \cdot x}{L}\right) \tag{16}$$

$$\begin{aligned}S \cdot \gamma_{xy} = S \cdot \Bigg[&\sum_i v_i \cdot \frac{i \cdot \pi}{L} \cdot \cos\left(\frac{i \cdot \pi \cdot x}{L}\right) - \\ &z_S \cdot \sum_j \vartheta_j \cdot \frac{j \cdot \pi}{L} \cdot \cos\left(\frac{j \cdot \pi \cdot x}{L}\right)\Bigg]\end{aligned} \tag{17}$$

For bifurcation buckling, the eigenvalues and eigenvectors can be determined by solving Equation 18.

$$(\mathbf{K}_e + \alpha_{cr} \cdot \mathbf{K}_g) \cdot \mathbf{V}_{cr} = 0 \tag{18}$$

α_{cr} is the lowest positive increasing factor when reaching the buckling load. Inserting $\boldsymbol{V}_{cr}$ into Equation 9 leads to the buckling shape v_{cr}, ϑ_{cr}.

4 EXAMPLE

The assessment and comparison of the approximate solution with a FEM calculation is done using the example of the beam in Figure 5 for the load cases 1 and 2. Because of the expected symmetrical shape of v and ϑ, only series elements with odd-numbered sine halve-waves are considered. Their numbers are varied. In the finite element calculation, the beam was divided into 50 elements. Third-order Hermite polynomials are used as basis functions for v and ϑ (Stroetmann 1999, 2011). The consideration of different load cases with various sets of shape functions allows deducing the necessary effort to get acceptable results. The results are listed in Table 1. Figure 9 shows the shear field force $S \cdot \gamma_{xs}$ as a function of the beam length. As

expected, increasing the number of sinusoidal shape functions leads to closer approximations of the FEM results. Especially for moment distributions with hogging and sagging moments, it is obvious that a setup function with only one sine half-wave leads to inaccurate results and an overestimation of the buckling factor α_{cr}.

5 CONCLUSIONS

The presented paper describes the structural behavior of continuously restrained beams and beam-columns with the help of examples. It is shown that with typical simplifying assumptions unsafe results may be obtained for the buckling load and stabilizing forces. This is also true for the internal forces of the members. For typical cases, an approximation procedure is presented which allows to compute the buckling loads and the internal forces according to second order theory for flexural torsional buckling with moderate effort. Stabilizing forces may become significant when compared to the external loads. Besides imperfections relevant for practice, further effects such as restraints due to tangent rotations and temperature differences may increase the internal forces of the members. Therefore, the assumptions for the imperfections must be sufficiently large as well as the restraining and bracing system designed safely.

Lateral-distortional buckling formulae for hollow tubular flange plate girders with slender unstiffened webs

M.F. Hassanein
Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt

N. Silvestre
Department of Civil Engineering, ICIST/IST, TU Lisbon, Lisboa, Portugal

ABSTRACT: In this paper, the Lateral-Distortional Buckling (LDB) of Hollow Tubular Flange Plate Girders (HTFPGs) with slender unstiffened webs is investigated. Firstly, shell finite strip analyses are performed to have a first glance on the elastic buckling behaviour of simply supported girders under uniform bending. The numerical results clearly show the girder length range in which LDB is relevant. After these analyses, analytical models to calculate the critical LDB moment are proposed and validated by comparison with numerical values. The formulae for lateral-distortional buckling of HTFPGs are shown to be accurate and they provide the means to obtain M_{cr} values analytically without resorting to numerical tools.

1 INTRODUCTION

Members having thin-walled cross-sections are usually very slender, thus being highly susceptible to local, distortional and global buckling. One of the buckling modes that involve web distortion in I-sections is known as lateral-distortional buckling (LDB) mode. This mode is due to the simultaneous occurrence of (i) high lateral displacement and rotation of the compressed flange, (ii) low lateral displacement of the tensioned flange and (iii) distortion (transverse bending) of the web. The distortion of the web becomes even more evident if the I-section is attached to stiffer structural components such as concrete slabs in composite girders. In this case, it is designated as restrained-distortional buckling (RDB). Both LDB and RDB have been studied during the last twenty years, due to the work of several researchers. To study the RDB of I-sections, Bradford (1997) developed a model with three degrees of freedom: the twisting rotations of the restrained and unrestrained flanges and the lateral displacement of the unrestrained flange. In order to improve the twisting strength of beams with open sections and decrease their sensitivity to lateral-torsional buckling (LTB), the flat single-plated flanges have been replaced by hollow flanges. Thus, the hollow flange (HF) sections are torsionally very stiff but remain sensitive to LDB because the minor axis second moment of area of their hollow flanges slightly increases. Nowadays, the hollow tubular flange plate girder (HTFPG) with slender web shown in Figure 1 is studied. To the authors' best knowledge, the LDB of HTFPGs under bending has never been studied nor addressed in design standards. The main goal of this paper is to investigate the LDB behaviour of hollow tubular flange plate girders (HTFPGs) with slender unstiffened webs. A glance on the elastic buckling behaviour of HTFPGs with unstiffened webs is made by using shell finite strip (FS) analyses. After that, analytical models to predict the critical LDB moment are proposed and validated by comparison with numerical values.

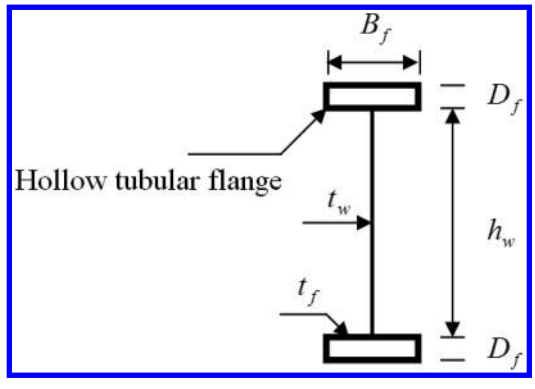

Figure 1. HTFPG geometry and dimensions.

In order to achieve these objectives, we (i) use a finite strip model in section 2, (ii) develop a simplified model with 4 degrees-of-freedom (d.o.f.) in section 3 and (iii) propose an analytical model in section 4. The HTFPG is composed of two rectangular compact flanges and a slender web as shown in Figure 1. The outside dimensions of HTFPG are also presented in Figure 1 and the corresponding mid-line dimensions of the flange are $d_f = D_f - t_f$ and $b_f = B_f - t_f$. In order to avoid the influence of several factors, we consider the simplest case regarding the load application and the support conditions: a simply supported HTFPG under uniform bending.

Table 1. Dimensions [mm] of HTFPGs used in the FSA.

S4		101.6			6.0
S5		203.2			
S6		304.8			

2 FINITE STRIP ANALYSES

In this study, we use the CUFSM software (Schafer 2010) which is based on the finite strip method (FSM). The key parameters that influence the buckling response of the HTFPGs are the following: (i) flange width-to-depth ratio (B_f/D_f), (ii) web slenderness (h_w/t_w) and (iii) span length (L). Three different flange cross-sections for the HTFPGs are used in the current study as listed in Table 1. They have the same width (B_f) and thickness (t_f) but with different depths (D_f). For the finite strip model, the web depth is fixed to $h_w = 1500$ mm. Two different web thicknesses of $t_w = 6.0$ and 10.0 mm are used, ensuring that the webs are slender. In elastic buckling analyses, the steel is considered an elastic material fully characterised by the values of Young's modulus ($E = 200 \times 10^3$ N/mm^2) and Poisson's ratio ($\nu = 0.3$).

Concerning the FS model, the cross-section is discretized with 27 nodes (10 in each flange and 9 in the web – note that there are 2 web-flange connecting nodes), 28 strips (10 in each flange and 8 along the web height), and 108 d.o.f. ($4 \times$ n, where n is the number of nodes). Despite being stiffer than the web, the flanges are also discretised with a fine mesh in order to capture the effect of local buckling. Furthermore, a stress diagram associated to major axis bending is applied to the beam end sections to produce uniform bending along its length L. In order to evaluate the influence of different buckling modes (local, lateral-distortional and lateral-torsional) on the buckling behaviour of HTFPGs under bending, it is necessary to consider a set of buckling half-wavelengths. In this study we consider a minimum length of $L_{min} = 100$ mm, a maximum length of $L_{max} = 100000$ mm, and 100 length values equally spaced in the L-logarithmic scale. The results of this study are shown in the form of curves displaying the variation of critical moment M_{cr} with L, often designated as "signature curves".

Figure 2 shows the curves $M_{cr}(L)$ obtained for the six cross-sections considered in Table 1. The following comments are due:

(i) Each curve $M_{cr}(L)$ displays a local minimum in the short half-wavelength range and a descendent branch in the moderate to long half-wavelength range. The transition between these two ranges occurs between L = 4000 and 5000 mm, depending on the cross-section geometry.

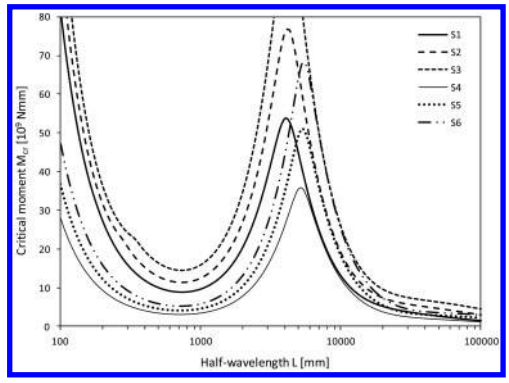

Figure 2. Variation of M_{cr} with L (single-wave FSA).

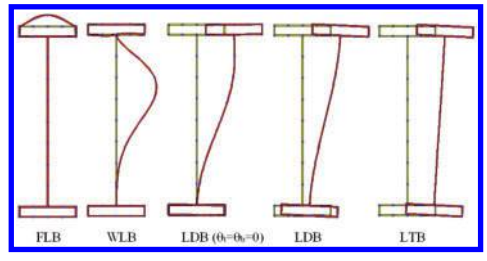

Figure 3. Buckling modes of HTFPG under bending.

(ii) In the short half-wavelength range, the descending and ascending branches of $M_{cr}(L)$ concern the local buckling (LB) mode of HTFPG. The descending branch of the S1, S2 and S3 beams is related to the local buckling of the upper plate of the top flange (FLB mode shown in Figure 3). The local minimum zone and the ascending branch of the S1, S2 and S3 beams are related to local buckling of the upper zone of the web (WLB mode shown in Figure 3). In the case of beams S4, S5 and S6, the descending and ascending branches of $M_{cr}(L)$, as well as the local minimum, concern the web local buckling (WLB). This is due to the decrease of web thickness t_w from 10 mm (S1, S2, S3) to 6 mm (S4, S5, S6), which does not influence the M_{cr} value for FLB but lowers it in the case of WLB.

(iii) Local minima of the $M_{cr}(L)$ curves occur for the same WLB half-wavelength ($L_{cr} = 705$ mm), regardless of the cross-section geometry. It means that both t_w and D_f values have no impact on the WLB half-wavelength L_{cr}.

(iv) The minimum values of the WLB moment M_{cr} (in kNm) are 8780 (S1), 11380 (S2), 14450 (S3), 3130 (S4), 4100 (S5) and 5260 (S6). Due to the decrease of t_w, the beams S4, S5 and S6 have lower WLB moment M_{cr} than the beams S1, S2 and S3. Due to the increase of flange depth D_f, the WLB moment M_{cr} increases from S1 to S3 and from S4 to S6. This increase (in absolute value) is more evident for beams S1 → S2 → S3 than for beams S4 → S5 → S6. However, and regarding the relative values, the percentage increase for

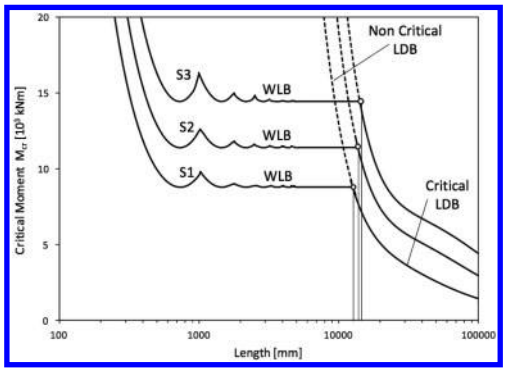

Figure 4. Variation of M_{cr} with L (multi-wave FSA).

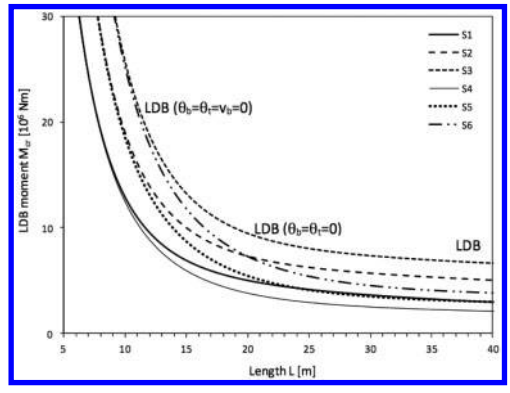

Figure 5. Variation of M_{cr} with L for LDB.

beams S1 → S2 → S3 is similar to that of beams S4 → S5 → S6.

(v) In the descendent branch of the moderate to long half-wavelength range, LDB and lateral-torsional buckling (LTB) prevail – see Figure 3. The top zone of the descendent branches corresponds to LDB modes without flange twisting ($\theta_t = \theta_b = 0$) and null displacement of the bottom flange ($v_t \neq 0$, $v_b = 0$). The middle zone of the descendent branches corresponds to LDB modes with no flange twisting ($\theta_t = \theta_b = 0$) but with movement of both flanges ($v_t \neq 0$, $v_b \neq 0$). The bottom zone of the descendent branches corresponds to LDB modes with both flange twisting ($\theta_t \neq 0$, $\theta_b \neq 0$) and lateral displacement ($v_t \neq 0$, $v_b \neq 0$). For very long half-wavelength, LTB occurs.

(vi) The considerations made before are valid for buckling modes with single half-wave. However, LB takes place for multi-wave mode. Figure 4 shows the variation of the critical buckling moment M_{cr} with the length of the HTFPG with sections S1, S2 and S3. For the beam S1, LB takes place from 1 to 19 waves and, for $L_t = 13100$ mm, changes to LDB. Qualitatively similar trend is shown by beams S2 and S3, but for transition lengths $L_t = 13900$ mm and $L_t = 14200$ mm, respectively.

(vii) The fact that LDB mode is critical for $L > L_t$ and becomes non-critical for $L < L_t$ (see the dashed parts of the curve in Figure 4), where LB mode is critical, does not mean that LDB should only be considered in design of HTFPGs for $L > L_t$. Remember that critical LB occurring for $L < L_t$ often exhibits very high post-buckling strength reserve and, therefore, the HTFPG collapse may by triggered by the non-critical LDB mode.

Figure 5 shows a portion of the curves presented in Figure 3, but only for the moderate to long HTFPGs that buckle in LDB. Concerning the influence of the cross-section dimensions on LDB of HTFPG, the following comments are due:

(i) In the steep descending branch ($L < 15$ m), characterised by LDB mode without flange twisting ($\theta_t = \theta_b = 0$), there is not too much influence of the M_{cr} value on the web thickness t_w. In fact, we see that there is almost perfect coincidence between curves S1 and S4, S2 and S5, S3 and S6. Thus, we can conclude that the M_{cr} value associated with LDB ($\theta_t = \theta_b = 0$) strongly depends on the HTFPG length L and flange depth D_f but scarcely depends on the web thickness t_w. Probably, the most influential parameter in LDB ($\theta_t = \theta_b = 0$) is the flange second moment of area about the cross-section weak axis I_{fz} and the correspondent lateral stiffness (EI_{fz}/L^2) which depends on L.

(ii) In the moderate descending branch ($15 < L < 25$ m), characterised by LDB mode without flange twisting ($\theta_t = \theta_b = 0$) but with lateral displacements ($v_t \neq 0$, $v_b \neq 0$), the web thickness influences the M_{cr} value. The web thickness affects the relative displacement between top and bottom flanges ($v_t - v_b$).

(iii) In the smooth descending branch ($L > 25$ m), characterised by LDB mode with flange twisting ($\theta_t \neq 0$, $\theta_b \neq 0$) and lateral displacements ($v_t \neq 0$, $v_b \neq 0$), we observe a pronounced difference between HTFPGs with deep flanges and shallow flanges (the difference between curves S3 and S6 is larger than that between curves S1 and S4). Thus, we can conclude that the M_{cr} value associated with LDB strongly depends on the HTFPG flange depth D_f and fairly depends on the length L and web thickness t_w. Most likely, the most influential parameter in LDB is the flange torsional constant J_f and associated twisting stiffness (GJ_f), which does not depend on L.

3 MODEL FOR LDB WITH 4 D.O.F.

From the previous FS study, we conclude that the LDB mode of HTFPGs may exhibit (i) flange rigid body movement, including twisting rotation and lateral displacement (higher for the compressed flange) and (ii) transverse bending (distortion) of the web. Thus, we present herein a simple numerical model with 4

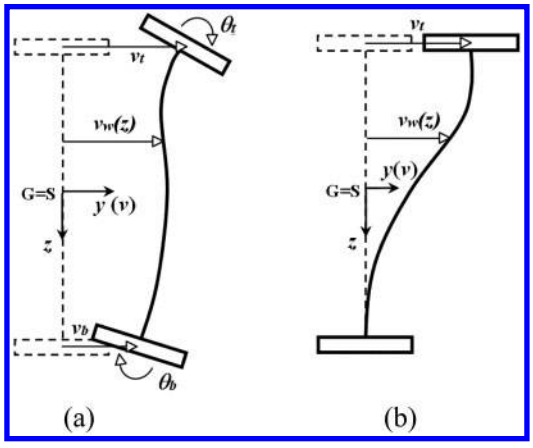

Figure 6. Models for LDB: (a) 4 d.o.f., (b) 1 d.o.f. (analytical).

degrees of freedom (d.o.f): the lateral displacements (v_t, v_b) and twisting rotations (θ_t, θ_b) of the top and bottom flanges, as seen in Figure 6(a).

The formulation presented herein resembles that proposed by Chen and Ye (2010) for LDB of I-beams. In comparison with the formulation of Chen and Ye (2010) for LDB of I-beams, a set of changes have been made in the present work to account for the hollow flanges: (i) the warping stiffness I_{fw} of the hollow flanges is included, (ii) the applied stress σ gradient along the flange depth D_f is accurately taken into account and (iii) the geometric stiffness is enlarged by the parameter (y^2+z^2) to consider the correct distance between any point of the hollow flange and its centroid. The expressions for the strain energy of the top flange, bottom flange and web are

$$U_t = \frac{EI_{fz}}{2}\int_0^L v_{t,xx}^2 dx + \frac{GJ_f}{2}\int_0^L \theta_{t,x}^2 dx + \frac{EI_{fw}}{2}\int_0^L \theta_{t,xx}^2 dx \quad (1)$$

$$U_b = \frac{EI_{fz}}{2}\int_0^L v_{b,xx}^2 dx + \frac{GJ_f}{2}\int_0^L \theta_{b,x}^2 dx + \frac{EI_{fw}}{2}\int_0^L \theta_{b,xx}^2 dx \quad (2)$$

$$U_w = \frac{Et_w^3}{24(1-\nu^2)}\int_0^L\int_{-h_w/2}^{h_w/2} v_{w,zz}^2 dz\,dx \quad (3)$$

In these equations, (i) x is the axial coordinate and (i) I_{fz}, J_f and I_{fw} are the flange minor axis second moment of area, flange torsional constant and flange warping constant, respectively. Note also that $v_t, \theta_t, v_b, \theta_b$ depend only on x while v_w depends on both x and z (coordinate along the web height). The potentials of the applied moments M, written in terms of internal stresses $\sigma(z)$, are given by

$$\Pi_t = -\frac{1}{2}\int_0^L\int_{A_t}\sigma[v_{t,x}^2 + (y^2+z^2)\theta_{t,x}^2]dA\,dx \quad (4)$$

$$\Pi_b = -\frac{1}{2}\int_0^L\int_{A_b}\sigma[v_{b,x}^2 + (y^2+z^2)\theta_{b,x}^2]dA\,dx \quad (5)$$

$$\Pi_w = -\frac{t_w}{2}\int_0^L\int_{-h_w/2}^{-h_w/2}\sigma v_{w,x}^2 dz\,dx \quad (6)$$

In these equations, (i) A_t and A_b are the area occupied by the top and bottom flanges, respectively ($dA = dzdy$) and (ii) the normal stress, considered uniform along the beam length (independent of x), is given by

$$\sigma = -\frac{M}{I_y}z \quad (7)$$

with (i) I_y being the major axis second moment of area for the whole cross-section and (ii) the vertical coordinate z varying in the ranges $-d_f - h_w/2 \le z \le -h_w/2$ (top flange), $-h_w/2 \le z \le h_w/2$ (web), $h_w/2 \le z \le h_w/2 + d_f$ (bottom flange). On the basis of the Ritz method, the following exact solutions are adopted for the top and bottom flange displacements and twisting rotations,

$$v_t(x) = A_1 \sin\left(\frac{\pi x}{L}\right) \qquad \theta_t(x) = A_2 \sin\left(\frac{\pi x}{L}\right) \quad (8)$$

$$v_b(x) = A_3 \sin\left(\frac{\pi x}{L}\right) \qquad \theta_b(x) = A_4 \sin\left(\frac{\pi x}{L}\right) \quad (9)$$

The web lateral displacement is given by

$$v_w(x,z) = v_t(x)\phi_1(z) + \theta_t(x)\phi_2(z) + v_b(x)\phi_3(z) + \theta_b(x)\phi_4(z) \quad (10)$$

with the functions $\phi_i(z)$ $(i = 1,2,3,4)$ being defined by

$$\phi_1(\eta) = 1 - 3\eta^2 + 2\eta^3$$
$$\phi_2(\eta) = (h_w + h_f)(\eta - 2\eta^2 + \eta^3) \quad (11)$$
$$\phi_3(\eta) = 3\eta^2 - 2\eta^3 \qquad \phi_4(\eta) = (h_w + h_f)(-\eta^2 + \eta^3)$$

where the non dimensional variable η reads

$$\eta = \frac{1}{2} + \frac{z}{h_w + h_f} \quad (12)$$

Note that the function $v_w(z,x)$ satisfies the compatibility between the web and the flange displacements and rotation. It is assumed that $v_w(z = -d_f/2 - h_w/2, x) = v_t(x)$, $v_{w,x}(z = -d_f/2 - h_w/2, x) = \theta_t(x)$, $v_w(z = d_f/2 + h_w/2, x) = v_b(x)$, $v_{w,x}(z = d_f/2 + h_w/2, x) = \theta_b(x)$. Introducing equations (8)–(9) and (11)–(12) in (10), we obtain the web lateral deflection v_w depending on the coordinates x and z, as well as the flange degrees of freedom (A_1, A_2, A_3, A_4). Introducing this expression and those of equations (7)–(9) into the strain energy (equations (1)–(3)) and potential of applied moments (equations (4)–(6)) and integrating over the web height, flange area and beam length, we obtain the total potential energy

$$V = U_t + U_b + U_w + \Pi_t + \Pi_b + \Pi_w \equiv V(A_1, A_2, A_3, A_4) \quad (13)$$

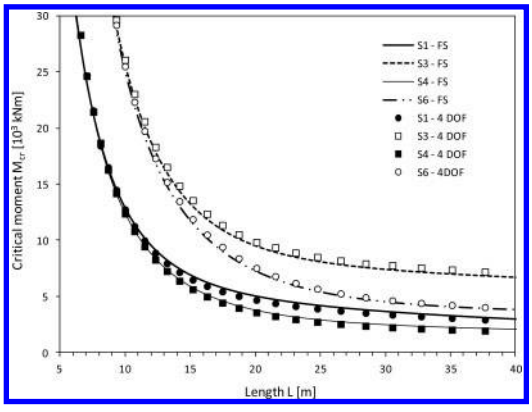

Figure 7. FS vs. 4 d.o.f. model results for LDB.

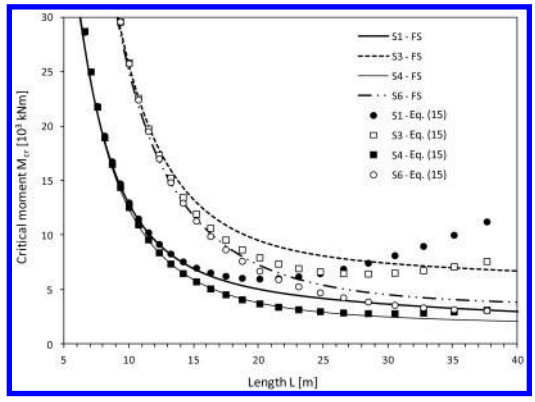

Figure 8. FS vs. Eq. (15) (1 d.o.f. model) results for LDB.

depending quadratically on the 4 parameters (A_1, A_2, A_3, A_4) and linearly on the applied moment M. Equating to zero the first derivatives of V with respect to A_i, we obtain the system of 4 equilibrium equations given by,

$$\frac{d^2V}{dA_i^2} = 0 \Leftrightarrow (K_{ij} - MG_{ij})A_j = 0 \quad i,j = 1\text{-}4 \qquad (14)$$

where K_{ij} and G_{ij} are the components of the 4×4 linear and geometric stiffness matrices [K] and [G], respectively, and A_j is the component of the 4×1 displacement vector {A}. The system in equation (14) corresponds to a fourth order eigenvalue problem and its solutions are the buckling moments M_b (eingenvalues) and buckling modes $\{A_j\}$ (eigenvectors). The 4 d.o.f. model was implemented in a symbolic computation code Maple (2009). Figure 7 shows the results obtained from the model (circles and squares) as well as the curves obtained from FS analyses – the results for S2 and S5 are qualitatively similar and are not presented in Figure 7 for the sake of simplicity and clearness of presentation. Generally, the results of the 4 d.o.f. model follow the trend of all FS curves, regardless of the HTFPG length L, web thickness t_w and flange depth D_f. This means that the model is capable of simulate the behaviour of HTFPG both for LDB ($\theta = 0$) and LDB ($\theta \neq 0$). For the HTFPGs with shallow flanges (S1 and S4), the M_{cr} values determined from the 4 d.o.f. model are slightly lower than those of FS analyses (maximum difference of 7%). For HTFPGs with deeper flanges (S3 and S6), the M_{cr} values obtained from the 4 d.o.f. model are slightly higher than the FS ones (maximum difference of 5%). In conclusion, the 4 d.o.f. model and FS results show a good agreement.

4 ANALYTICAL MODELS FOR LDB

From the previous results, we may conclude that the LDB mode for HTFPGs with moderate lengths is characterized by null flange twisting rotation ($\theta_t = 0$, $\theta_b = 0$) – see Figure 6. Thus, for HTFPGs with moderate lengths, it is possible to reduce the 4 degrees of freedom to only two (v_t and v_b) without compromising the accuracy of the solution. With this model, we can apply it to two different situations:

- LDB ($\theta_b = \theta_t = v_b = 0$): In this case, the bottom flange is fixed ($v_b = 0$) and only the top flange is allowed to displace laterally ($v_t \neq 0$). The critical moment is given by

$$M_{cr} = EI_y \cdot \frac{I_{fz}\frac{\pi^2}{L^2} + \frac{t_w^3 h_w^3}{(1-\nu^2)h^6}\frac{L^2}{\pi^2}}{ht_f(b_f + d_f) + \frac{(5h^2 - h_w^2)h_w^3 t_w}{40h^3}} \qquad (15)$$

  where $h = h_w + d_f$ is the total distance between the centroids of both flanges.
- LDB ($\theta_b = \theta_t = 0$): In this case, both flanges are free to displace laterally ($v_t \neq 0$ and $v_b \neq 0$). The critical moment is given by

$$M_{cr} = EI_y \cdot \frac{\sqrt{\frac{\pi^4 I_{fz}^2}{L^4} + \frac{2I_{fz} t_w^3 h_w^3}{(1-\nu^2)h^6}}}{ht_f(b_f + d_f) + \frac{(5h^2 - h_w^2)h_w^3 t_w}{40h^3}} \qquad (16)$$

Figure 8 displays the results determined from the Eq. (15) (1 d.o.f. model) and FS analyses. It is seen that the M_{cr} values given by Eq. (15) are generally accurate for $L < 16$ m. Obviously, this evidence agrees with the fact that LDB ($\theta_b = \theta_t = v_b = 0$) occurs in this length range. For L > 16 m (moderate to long beams), there are two distinct features. For the beams with thinner webs (S4 and S6), the analytical results become less accurate but the black squares (beam S4) and white circles (beam S6) do not diverge too much from the thin solid (beam S4) and dash-point (beam S6) curves, respectively. However, in the case of the beams with thicker webs (S1 and S3), the results become less accurate as the black circles (beam S1) and white squares (beam S3) diverge too much from the thick solid (beam S1) and dashed (beam S3) curves, respectively. We

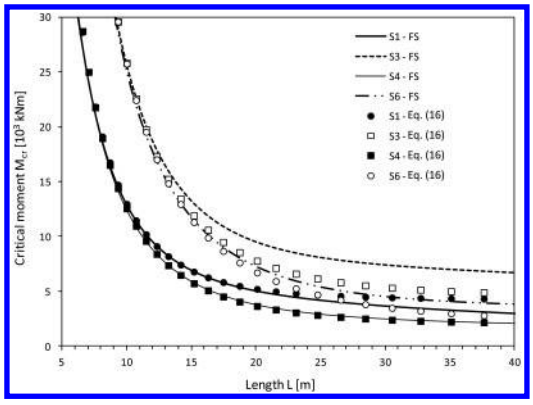

Figure 9. FS vs. Eq. (16) (2 d.o.f. model) results for LDB.

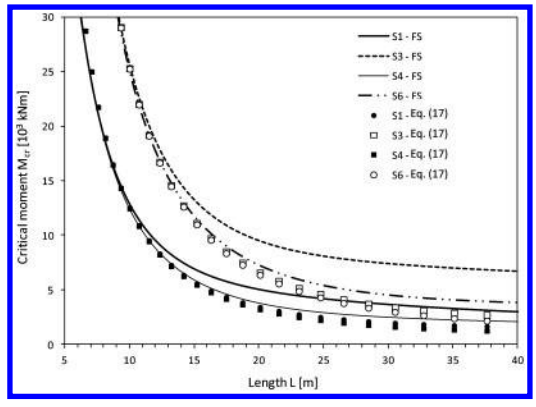

Figure 10. FS vs. Eq. (17) (Pi and Trahair 1997) results.

conclude that the analytical expression (Eq. 15) gives accurate results for beams with moderate lengths but it also gives inaccurate (non conservative) results for long beams.

Figure 9 displays the results determined from the Eq. (16) (2 d.o.f. model) as well as the curves obtained from FS analyses. It is seen that the M_{cr} values given by Eq. (16) are more accurate than those of Eq. (15). Regardless of the length, the results are very accurate for the beam S4, which has slender web and not too deep flanges. For the beam S1, which has thicker web and not too deep flanges, the results are accurate for L < 25 m (10% difference) but become overly non conservative for L > 25 m. For the beam S6, characterized by slender web and deep flanges, the results are accurate for L < 22 m (10% difference) and become fairly conservative for L > 22 m. For the beam S3, which has thicker web and deep flanges, the results are accurate for L < 16 m (10% difference) and become conservative for L > 16 m. From these comparisons, we conclude that the analytical expression (Eq. 16) gives accurate results for beams with moderate lengths and fairly good results for beams with moderate to long lengths. For beam with long to very long lengths, both flanges start to twist differently (the top flange twist further than the bottom one) and only the 4 d.o.f. model becomes the accurate one. However, an analytical formula becomes too complex and inappropriate for current practical design. For very long lengths, both twist rotations become identical and lateral-torsional buckling (LTB) takes place.

Moreover, Pi and Trahair (1997) proposed an analytical formula to determine the LDB moment of beams with hollow flanges, given by

$$M_{cr} = \sqrt{\frac{\pi^2 EI_z}{L^2}\left(\frac{2GJ_f \dfrac{Et_w^2 L^2}{(1-\nu^2)\pi^2 h_w}}{2GJ_f + \dfrac{Et_w^2 L^2}{(1-\nu^2)\pi^2 h_w}} + \frac{\pi^2 EI_w}{L^2}\right)} \qquad (17)$$

where (i) J_f is the flange torsional constant and (ii) I_z and I_w are the minor axis second moment of area and warping constant of the whole cross-section, respectively. They adapted the classical formula of LTB moment and replaced the standard torsional stiffness GJ by an effective torsional stiffness that depends not only on the flange torsional constant J_f but also on the web dimensions (h_w, t_w). Recently, Kurniawan and Mahendran (2009) used this formula to evaluate the LDB critical moment of cold-formed LiteSteel Beams. Figure 10 presents a comparison between the FS results and the M_{cr} values given by Eq. (17). It is seen that the analytical results are not sensitive to the web thickness, since the black circles and squares (beams S1 and S4) remain always quite close (the same applies for the beams S3 and S6). Due to this fact, we observe that Eq. (17) gives good predictions for moderate to long beams with thin webs (S4 and S6) but provide very inaccurate results for beams with thicker webs (S1 and S3).

Modeling of force deformation characteristic of angle bracing members

M.A. Gizejowski & A.M. Barszcz
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Braced frames composed of angle diagonals are commonly used to reduce the frame drifts and to enhance the sway stability resistance. In practice, the diagonal bracing members are connected to the frame elements by direct welding or bolting through a gusset plate. Such brace systems are modeled to act as vertical trusses comprising of members that are carrying predominantly axial forces. It is justifiable therefore to use an equivalent truss element for modeling of the behavior of bracing members. This paper deals with analytical formulation of the force-deformation characteristic of a single angle brace subjected to one cycle compression. It constitutes a contribution to the development of a simple model describing the equilibrium path of imperfect compressed angles. The strut model developed herein takes into consideration the effect of brace end connections. Two different boundary conditions typical for engineering practice are dealt with, namely corresponding to braces with mono-eccentric connections and braces with bi-eccentric connections. The results of experimental program of testing the behavior of angle brace in portal subframe specimens are used for the calibration of developed analytical model of the brace behavior.

1 INTRODUCTION

Diagonals of truss bracings are traditionally designed for the pre-buckling compression or elastic tension. In case of X-type bracings, the compression diagonals are assumed to buckle and only the tension elements are considered to effectively resist sway. Brace members subjected to post-buckling compression are usually treated as ineffective and designed not to yield under tension. Such members are subjected to changing force conditions due to variable load components acting on the braced structure within the envelope prescribed by design load combinations.

Compression brace elements, after reaching their buckling strength, do not maintain the ultimate strength level, as in case of yielded tension elements. The strength drop in the post-buckling region depends upon the brace slenderness, grade of steel the member is made of and other factors among which the structural imperfections play an important role. Buckled members are subjected to straightening out under the force reversal as a result of change in variable components of load combinations. If the brace is subjected to yielding in the straightening out phase, their reloading path is somewhat different from that of unloading path and the member is not able to reach the load level corresponding to that at which the unloading has started. The behavior is a hysteretic type with its maximum force being dependent upon the amount of plastic deformations accumulated during the unloading phase.

For collapse behavior of braced frame structures and the evaluation of their strength at the ultimate limit state, the investigations of compression braces have been restricted to one cycle behavior and carried out in such a way that for different section geometry, slenderness and steel grades, a developed simple analytical model could efficiently describe the equilibrium path of imperfect member in both pre-limit and post-limit phases. Moreover, the developed models are usually able to reproduce the buckling curves from design codes in case of concentric end connections (Barszcz & Gizejowski 2007).

This paper constitutes a contribution to the development of a simple and yet accurate analytical model describing the equilibrium path of imperfect compressed angle braces. It is an extension of research work carried out by authors for members loaded in compression. Two different boundary conditions, typical for engineering practice, are dealt with, namely braces with welded fork type mono-eccentric connections (called hereafter as connections with in-plane eccentricity) and braces with bolted lap through-leg bi-eccentric connections (called hereafter as connections with out-of-plane eccentricity). Experimental program of testing the behavior of angle braces in portal subframe specimens was carried out at the Warsaw University of Technology (Barszcz 2010). Test results are used for the calibration of developed analytical model of the brace behavior.

2 ELASTIC BEHAVIOUR OF A COMPRESSED ANGLE BRACE

Let us considered a single unequal leg angle as a brace being eccentrically compressed. The eccentricity e results from the constructional details of member end connections. In a general case, the eccentricity e has to be resolved along the Cartesian principal axes

(u, v) the origin of which is at the section center of gravity C. The third principal axis is the member axis w. The principal eccentricity components are denoted $(e_u; e_v)$. There is also another useful set of axes (y, z) parallel/perpendicular to midlines of angle legs, with the same origin in the gravity center as for the principal axes (u, v). The axis x of this coordinate system coincides with the axis w of the principal coordinate system. The shear center S is placed away from the gravity center at distances u_S and v_S along the principal axes. In turn, the gravity center is located at the distances y_S and z_S from the midlines of angle legs. Considering the arbitrary point of applied axial load, being in equilibrium with the load effects of axial force N_E as well as bending moments M_{uE} and M_{vE}, the stability condition may be formulated in the well known way:

$$[S]\{\delta_b\} = \{0\} \tag{1}$$

where $[S]$ = stability matrix; $\{\delta_b\}$ = buckling shape coordinates vector.

In case of angle brace, the following stability matrix is obtained:

$$[S] = \begin{bmatrix} EI_v k_v^2 - N_E & 0 & (v_S - e_v)N_E \\ & I_u k_u^2 - N_E & -(u_S - e_u)N_E \\ \text{symm.} & & GI_T - i_S^2 N_E \end{bmatrix} \tag{2}$$

where $k_v^2 = [\pi/(\mu_v l)]^2$ and $k_u^2 = [\pi/(\mu_u l)]^2$; μ_u, μ_v = flexural buckling length factors; i_S = generalized polar radius of gyration of the eccentrically connected angle with respect to the shear center S:

$$i_S^2 = i_T^2\left(1 + \frac{e_u\beta_u + e_v\beta_v}{i_T^2}\right), \tag{3}$$

i_T = polar radius of gyration of centrically loaded angle with respect to the shear center S:

$$i_T^2 = i_u^2 + i_v^2 + u_S^2 + v_S^2, \tag{4}$$

β_u, β_v = cross-sectional properties associated with bowing effects in principal planes:

$$\beta_u = \frac{1}{I_u}\left(\int_A v^3 dA + \int_A u^2 v dA\right) - 2v_S, \tag{5}$$

$$\beta_v = \frac{1}{I_v}\left(\int_A u^3 dA + \int_A v^2 u dA\right) - 2u_S, \tag{6}$$

I_u, I_v = cross-sectional moments of inertia with respect to principal axes; I_T = uniform torsion constant; E, G = modules of elasticity and rigidity.

Equating the determinant of stability matrix to zero and its expanding gives the following algebraic equation of third degree:

$$\begin{aligned} &(N_{Fu} - N_E)(N_{Fv} - N_E)(N_T - N_E) + \\ &-(N_{Fu} - N_E)N_E^2\frac{(v_S - e_v)^2}{i_S^2} + \\ &-(N_{Fv} - N_E)N_E^2\frac{(u_S - e_u)^2}{i_S^2} = 0 \end{aligned} \tag{7}$$

where N_{Fu}, N_{Fv}, N_T = reference forces:

– N_{Fv} for flexural buckling about $v - v$ axis:

$$N_{Fv} = \frac{\pi^2 EI_v}{(\mu_v l)^2}, \tag{8}$$

– N_{Fu} for flexural buckling about $u - u$ axis:

$$N_{Fu} = \frac{\pi^2 EI_u}{(\mu_u l)^2}, \tag{9}$$

– N_T for torsional buckling about the member shear center axis:

$$N_T = \frac{GI_T}{i_S^2}. \tag{10}$$

In case of the axial force applied along the shear center axis ($e_u = u_S$ and $e_v = v_S$), the reference forces are the bifurcation ones and the critical force $N_E = N_{cr}$ is the lowest force from all the above mentioned forces:

$$N_{cr} = \min(N_{Fu}, N_{Fv}, N_T). \tag{11}$$

In case of axial force applied away from the shear center, the bifurcation forces of the above three buckling modes are coupled to produce the flexural-torsional critical forces $N_E = N_{FT,i}$ $(i = 1, 2, 3)$. Thus, the cubic Eqn. (7) must be solved for each set of reference forces N_{Fu}, N_{Fv}, N_T in order to calculate the critical force as the lowest flexural-torsional bifurcation force.

The above general approach for treating unequal leg angles is adopted hereafter for equal leg angles. Since the equal leg angle section is monosymmetric, Eqns. (1) through (10) hold for $v_S = 0$. There are two distinctive directions considered hereafter along which the axial force can be positioned. The first is along the midline of the angle leg (points S, A, B & D in Fig. 1). All the force eccentricities e associated with this direction are referred to the brace connected through one leg. Point A corresponds to the equal eccentricities about principal axes ($e_u = e_v$). Point B corresponds to the eccentricity component $e_v = 0$. Points S and D correspond to the edge points of angle legs. The other direction coincides with the principal axis u (points S, C & E in Fig. 1).

One can notice that a special case of the force application at the shear center S can be treated as a reference

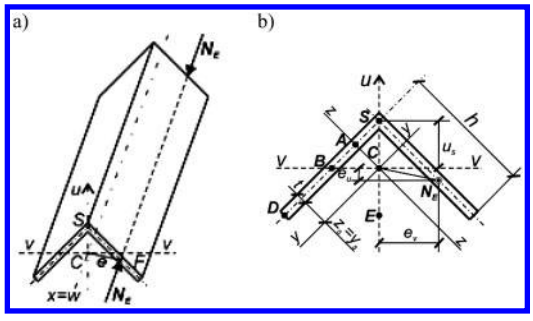

Figure 1. General notation for equal leg angle; a) member, b) cross section.

one for all the other cases of possible distinctive directions of force applications. It is clear that in this case the torsional bifurcation force does not govern the critical state. For all the angle lengths, regarding the relations between the effective length factors, the flexural mode of buckling about $v-v$ axis corresponds to the critical state when the following relationship holds:

$$I_u \mu_v^2 \geq I_v \mu_u^2 . \tag{12}$$

It might be assumed in practice that for all other eccentricities, except the range of short brace lengths, the torsional behavior might be neglected. Therefore only the member flexural buckling about $v-v$ axis could have been considered (Barszcz 2007 & 2012).

2.1 *Eccentricity out of the plane of section symmetry*

The ratio of critical force (normalized with reference to the flexural bifurcation force N_{Fv}) is evaluated numerically from Eqn. (7). In the following, three cases corresponding to force application at points A, B & D (see Fig. 1 for location of the considered points) are dealt with. It can be proven that for the force application at point S, the numerical solution of Eqn. (7) leads to the results obtained by Eqns. (8) through (10) and leading to Eqn. (11).

The numerical results of normalized critical forces are shown in Figures 2–4 with reference to force application points A, B & D, respectively.

From the presented results it is obvious that the effect of torsional behavior is in general needed to be considered for angle bracing members connected through one leg.

2.2 *Eccentricity in the plane of section symmetry*

In the stability matrix (2) and Eqn. (7) one should substitute in this case $v_S = e_v = 0$. Hence, the third term in Eqn. (7) vanishes and a quadratic algebraic equation of the following form is obtained:

$$\left(N_{Fu} - N_E\right)\left(N_T - N_E\right) + N_E^2 \frac{\left(u_S - e_u\right)^2}{i_S^2} = 0 \tag{13}$$

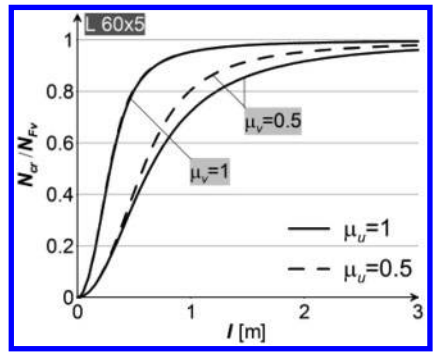

Figure 2. Normalized flexural-torsional buckling for the force application at A for different effective length factors.

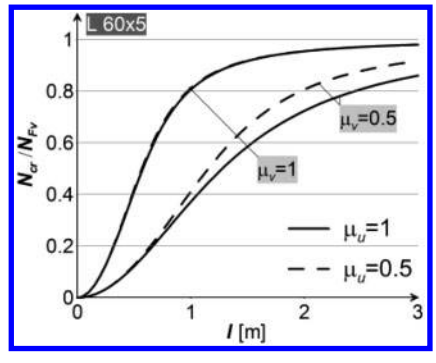

Figure 3. Normalized flexural-torsional buckling for the force application at B for different effective length factors.

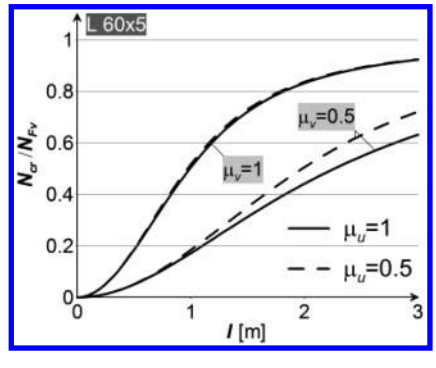

Figure 4. Normalized flexural-torsional buckling for the force application at D for different effective length factors.

As a result of canceling of the term $(N_{Fv} - N_E)$, the first in-plane flexural bifurcation force is obtained as $N_E = N_{Fv}$. The solution of Eqn. (13) leads to the remaining two flexural-torsional bifurcation forces $N_E = N_{FT,i}$ $(i = 1,2)$:

$$N_{FT,1/2} = \frac{\left(N_{Fu} + N_T\right) \pm \sqrt{\left(N_{Fu} + N_T\right)^2 - 4\kappa N_{Fu} N_T}}{2\kappa} \tag{14}$$

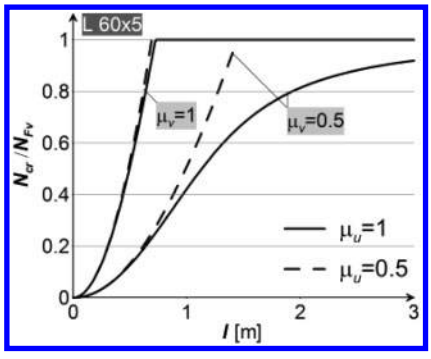

Figure 5. Normalized flexural-torsional buckling for the force application at C for different effective length factors.

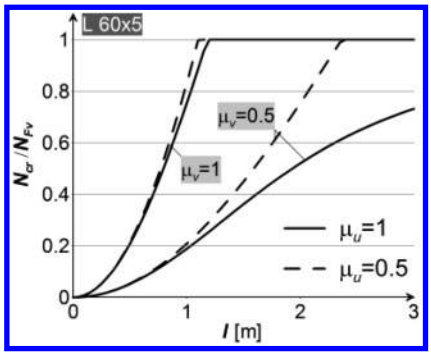

Figure 6. Normalized flexural-torsional buckling for the force application at E for different effective length factors.

where κ = dimensionless coefficient

$$\kappa = \frac{i_u^2 + i_v^2 + e_u \beta_u}{i_u^2 + i_v^2 + e_u \beta_u + u_S^2} \tag{15}$$

The critical force is therefore to be calculated as follows:

$$N_{cr} = \min\left(N_{Fv}, N_{FT,1}, N_{FT,2}\right) \tag{16}$$

Eqn. (7) is used hereafter for the similar study as it has been presented in the previous subsection. Substituting $e_v = 0$ to Eqn. (7), the resultant equation is solved for the critical force numerically for two cases corresponding to the force application at points C & E (see Fig. 1 for location of the considered points). The numerical results of normalized critical forces are shown in Figures 5 & 6 with reference to force application points C & E, respectively.

It is proven that the results obtained numerically are the same as calculated from Eqns. (13) – (14). From the presented results it is obvious that the effect of torsional behavior might be neglected for modeling of the angle brace fork-connected by welding at the member both ends.

3 PLASTIC RESISTANCE OF ANGLE SECTION

3.1 *Compression with one directional bending*

Plastic resistance of equal leg angle section for compression and bending in the plane of symmetry was given by Vayas et al. (2009) in the following form:

$$n^2 + m_v = 1 \tag{17}$$

where n = dimensionless axial force; m_v = dimensionless bending moment about $v - v$ axis:

$$n = \frac{N_E}{N_{pl}} = \frac{N_E}{A f_y}, m_v = \frac{M_{v,E}}{M_{v,pl} f_y} = \frac{M_{v,E}}{W_{v,pl} f_y}, \tag{18}$$

f_y = yield stress; A = cross section area and $W_{v,pl}$ = plastic section modulus

$$W_{v,pl} = \frac{Ah}{4\sqrt{2}}. \tag{19}$$

For bending in the other principal plane, the interaction formula can be approximated as:

$$n + m_u = 1 \tag{20}$$

where m_u = dimensionless bending moment about $u - u$ axis:

$$m_u = \frac{M_{u,E}}{M_{u,pl}} = \frac{M_{u,E}}{W_{u,pl} f_y}; W_{u,pl} = \frac{Ah}{2\sqrt{2}} = 2W_{v,pl}. \tag{21}$$

3.2 *Compression with two directional bending*

For equal angles, the limit curve for the plastic behavior can be approximated with use of the following equation:

$$m_{un}^2 + m_{vn} = 1 \tag{22}$$

where m_{un} = reduced dimensionless bending moment about $u - u$ axis

$$m_{un} = \frac{M_{u,E}}{M_{un,pl}} = \frac{M_{u,E}}{W_{u,pl} f_y (1-n)} \tag{23}$$

and m_{uv} = reduced dimensionless bending moment about $v - v$ axis

$$m_{vn} = \frac{M_{v,E}}{M_{vn,pl}} = \frac{M_{v,E}}{W_{v,pl} f_y \left(1-n^2\right)}. \tag{24}$$

If case of $n = 0$, Eqn. (22) becomes of that given by Vayas et al. (2009).

4 DIMENSIONLESS FORCE-DEFORMATION CHARACTERISTIC OF COMPRESSED ANGLE BRACES

4.1 *Analytical model*

Since the eccentrically connected brace is bent from the beginning of loading, the angle axial deformation is a superposition of axial shortening and shortening due to the bowing effect and as such can be approximated by:

$$\bar{\varepsilon} = \frac{\bar{\sigma}_E}{\psi} + \frac{8E}{3f_y}\left(\frac{f^{II}}{l}\right)^2 = \frac{\bar{\sigma}_E}{\psi} + \frac{8E}{3f_y}\left(\frac{f^{I}}{l}\frac{1}{1-\bar{\sigma}_E/\bar{\sigma}_{cr}}\right)^2 \quad (25)$$

where $\bar{\varepsilon}$ = dimensionless axial deformation; f^{II}, f^{I} = second order and first order, respectively, maximum bow coordinates; $\bar{\sigma}_E$ = dimensionless axial force corresponding to the deformation $\bar{\varepsilon}$; $\bar{\sigma}_{cr} = \sigma_{cr}/f_y$ dimensionless elastic critical force concerned with the lowest bifurcation force as it has been explained in section 2, and ψ = reduction factor equal to one in case of axial compression and compression with in-plane eccentricity while in case of compression with out-of-plane eccentricity:

$$\psi = 1 - \frac{3}{2\left(1+\bar{\lambda}^2\right)} \geq \frac{1}{4}. \quad (26)$$

Combining the elastic deformation mechanism given by Eqn. (25) with inelastic mechanisms of linear plastic-strain-hardening and nonlinear post-limit ones, the dimensionless force-deformation relationship describing the behavior of angle brace can be derived from probabilistic considerations as proposed by Barszcz & Gizejowski (2007):

$$\bar{\sigma} = \left\{\left(\frac{\bar{\sigma}_E}{\psi}\right)^{-n} + \left(1+\alpha_h\bar{\varepsilon}\right)^{-n} + \left[\frac{1}{a\left(\bar{\lambda}^2\bar{\varepsilon}\right)^m}\right]^{-n}\right\} \quad (27)$$

where $\bar{\sigma}_E/\psi$ = solution of Eqn. (25); $m = 0.5$ for centrically compressed angles and angles with eccentricity in the plane of symmetry; $m = 1.0$ for angles with the eccentricity out of the plane of symmetry; a, n = constants evaluated on the basis of experimental data; $\bar{\lambda}$ = relative slenderness ratio

$$\bar{\lambda} = \sqrt{\frac{N_{c,R}}{N_{cr}}} \quad (28)$$

and $N_{c,R}$ = class dependent section resistance in axial compression.

In case of an axially loaded member, Eqn. (25) is replaced by two separate equations, describing independent mechanisms, namely one referred to axial shortening $\bar{\sigma}_E/\psi = \bar{\varepsilon}$ and the second one – to buckling state in a neutral equilibrium $\bar{\sigma} = 1/\bar{\lambda}^2$. Equation (27) may then be transformed to that originally developed by Barszcz & Gizejowski (2007):

$$\bar{\sigma} = \left[\left(\bar{\varepsilon}\right)^{-n} + \left(1+\alpha_h\bar{\varepsilon}\right)^{-n} + \left(\frac{1}{\bar{\lambda}^2}\right)^{-n} + \left[\frac{1}{a\left(\bar{\lambda}^2\bar{\varepsilon}\right)^m}\right]^{-n}\right]^{\frac{1}{n}} \quad (29)$$

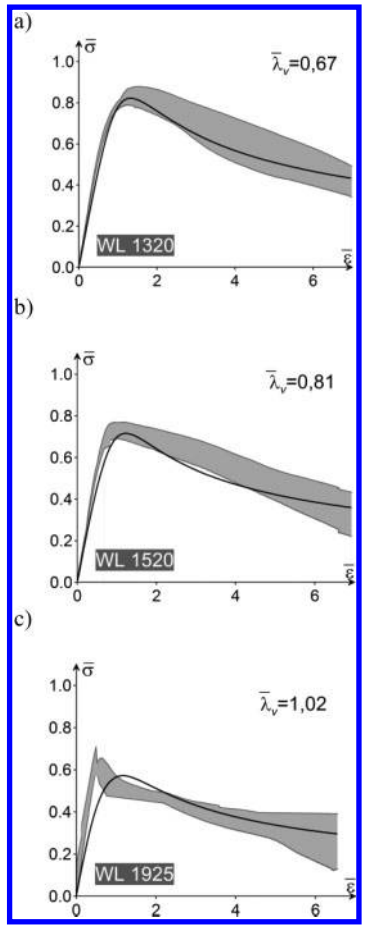

Figure 7. Comparison of experimental and analytical force-deformation curves for welded braces.

4.2 *Calibration of proposed analytical model*

Experimental investigations were carried out for subframe specimens WL with welded braces and in-pane eccentricities, and for subframe specimens BL with bolted braces and out-of-plane eccentricities.

Experiments have generally proven that angles with bolted connections are weaker, i.e. exhibit the lower

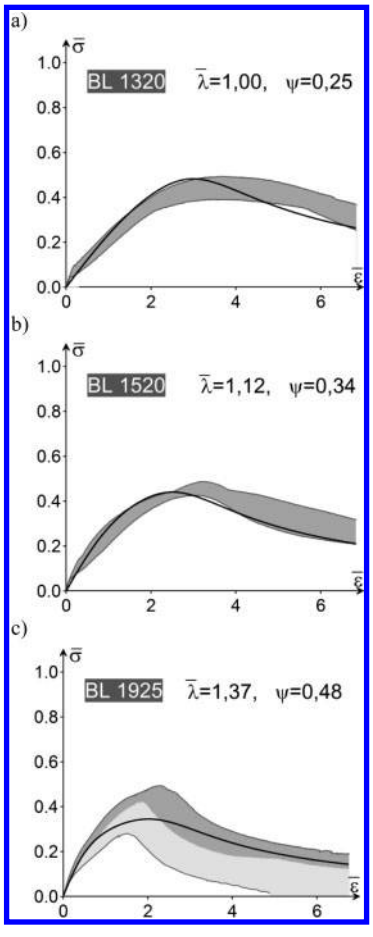

Figure 8. Comparison of experimental and analytical force-deformation curves for bolted braces.

buckling strengths and lower placement of force-deformation characteristics than those with welded connections. The calibration of model parameters was carried out considering the flexural effective length factors $\mu_v = \mu_u = 0.7$. The calibrated parameter $n = 5$ and the parameter a is the eccentricity type dependent. It is equal to 1.30 for braces with in-plane eccentricities while for braces with out-of-plane eccentricities is equal to 0.55.

Comparison of experimental force-deformation curves and analytical curves constructed with use of calibrated model parametersare presented in Figure 7 for welded angles (specimens of WL type) and in Figure 8 for bolted angles (specimens of BL type). The experimental envelope of results obtained for individual tests of each angle length and joint type is used. The area enclosed by the upper and lower boundary lines of the envelope utilized for the calibration exercise is shown in a dark grey color. The light gray color refers to the result that was regarded as less reliable. The analytical formulation developed herein when applied together with calibrated model parameters leads to a prediction of the analytical characteristics acceptable from the practical point of view for both types of welded and bolted braces.

5 CONCLUDING REMARKS

This paper presents the comprehensive study of the behavior of angle braces with fork-welded and through-leg bolted end connections. Member buckling and section resistance are discussed first, and then the modeling technique for the development of dimensionless brace force-deformation characteristic is presented.

Next, the approximate model reflecting not only the flexural behavior of angle brace is dealt with, and the way of its model parameters calibration exercise is summarized. The results of experimental investigations performed at the Warsaw University of Technology on two groups of braced subframes, namely WL and BL with braces welded and bolted, respectively, and three subgroups of different brace lengths are used for the calibration of developed model.

Finally, the validation is presented and the developed force-deformation curves with use of calibrated model parameters are compared with the envelope of experimental curves obtained for three tests in each subgroup of each group of tested specimens.

The approach presented in this paper for prediction of the force-deformation characteristic of angle braces may be used for other shapes of bracing members to create a catalogue of curves to be used in nonlinear analysis and direct design of steel braced frameworks.

Experimental and numerical research on longitudinally stiffened tapered steel plate girders subjected to shear

A. Bedynek, E. Mirambell & E. Real
Universitat Politècnica de Catalunya, Department of Construction Engineering, Barcelona, Spain

ABSTRACT: Tapered steel plate girders offer greater structural benefits than prismatic members. Their advantages include greater strength and slenderness, as well as a reduction in steel consumption. Often, they are used in long-span bridges and portal frames. In order to maintain slender webs and to reduce the consumption of steel, longitudinal stiffeners are often required.

This paper is focused on the behaviour of tapered steel plate girders with one longitudinal stiffener, subjected to shear. Four medium-scale tests of such girders were carried out and relevant experimental results are presented. Moreover, the geometrical and the structural imperfections are discussed. Based on experimental results the numerical model was validated and used in further parametric studies. The influence of the primary factors affecting the structural behaviour of tapered panels with longitudinal stiffening is studied.

Finally, a comparison of the numerical results with the results derived from EN 1993-1-5 (2006) rules (valid for prismatic members) is made. A discussion about their extended application for tapered girders is also presented.

1 INTRODUCTION

In many modern structures such as long-spans of steel bridges or industrial warehouses, girders with non-prismatic cross-section are used. Due to their trapezoidal shape, they can be better adapted to the non-uniform distribution of existing internal forces, thereby achieving greater efficiency and economy. Tapered panels are often used in large-scale structures, and are susceptible to instability problems. The most common solution to avoid local buckling and to limit their elevated slenderness is to weld additional profiles as longitudinal stiffeners. Depending on the panel slenderness and the stress distribution, these extra profiles usually have a closed cross-section (providing greater flexural and torsional rigidity in the entire panel) (Pavlovčič et al. (2007)) and, if necessary, more than one profile can be welded to the same panel, normally on the same side. Moreover, longitudinal stiffeners are most beneficial in those parts of steel panels subject to compression in order to divide large surfaces into smaller sub-panels with lower individual slenderness. In this way the problem of local buckling of the panel can be simplified to the phenomenon of local buckling in each sub-panel, which is usually more favourable.

2 EXPERIMENTAL PROCEDURE

2.1 *Geometry of tested girders*

All girders were tested as simply supported, rigid end posted, short beams with the load applied at the mid-span to consequently obtain a constant shear value. Two extra transverse stiffeners were welded on the both sides of the non instrumented web panel to ensure that shear buckling started in the instrumented one. The tested web panels are designed as slender ones in order to assure that critical shear load will be lower than the ultimate shear strength. Thanks to this, it was possible to observe the development of a diagonal tension field and post-buckling reserve.

In the laboratory tests two different geometries of tapered girders were tested. Specimens A (A1, A2) had the same dimensions and aspect ratio $\alpha = a/h_1 = 1.0$ and they varied only by the position of the longitudinal stiffener. The same scenario took place for girders B (B1, B2). Both of them have the same dimensions, the aspect ratio $\alpha = 1.5$ and they differ from each other only by the position of the longitudinal stiffener. In girders A1 and B1, longitudinal stiffener was placed horizontally in the centre of their shorter depth (Fig. 1a) and in girders A2 and B2 the stiffener was inclined in such a way that two points in the centre of the larger and smaller depths (respectively) were connected (Fig. 1b). All dimensions and corresponding symbols are presented in Table 1 and Fig. 1. The following example explains the notation of girders: A1_600_800_800_3_180_15 means a girder with the following dimensions: shortest depth $h_0 = 600$ mm, largest depth $h_1 = 800$ mm, panel length $a = 800$ mm, web thickness $t_w = 3$ mm, flange width $b_f = 180$ mm and flange (and stiffener) thickness $t_f = t_s = 15$ mm (see Table 1).

2.2 *Material properties*

All girders used in the laboratory testing were made of S235 steel. Previous standard tensile coupon tests,

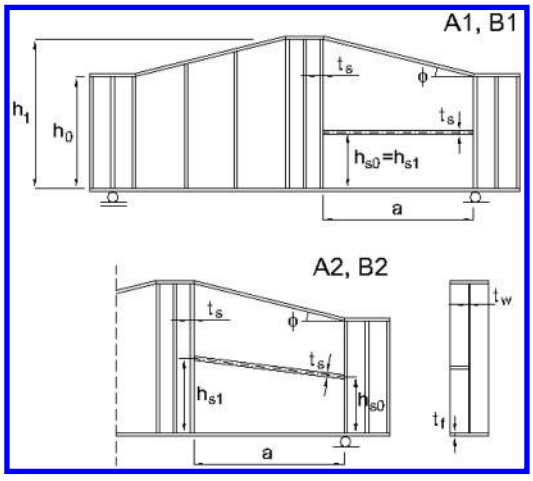

Figure 1. Geometry and symbols of the tested specimens.

Table 1. Dimensions of the tested girders.

Girder	h_0 mm	h_1 mm	a mm	t_w mm	b_f mm	t_f,t_s mm	h_{s0} mm	h_{s1} mm		$\alpha \tan(\phi)$
A1	600	800	800	3	180	15	300	300	1.0	0.25
A2	600	800	800	3	180	15	300	400	1.0	0.25
B1	500	800	1200	3	180	15	250	250	1.5	0.25
B2	500	800	1200	3	180	15	250	400	1.5	0.25

which were done for 6 specimens, allowed setting an average value of the yield stress of 300 MPa (all values between 290-322 MPa). In order to make further comparison of the numerical and experimental results, nominal values (for steel) of Young's modulus E = 210 GPa and Poisson's ratio $\nu = 0.3$ were assumed.

2.3 *Imperfections*

The web thickness of all tested girders was $t_w = 3.0$ mm and the flange (and stiffeners) thickness was $t_f = t_s = 15.0$ mm. This difference in rigidity of the connected plates and overall production process caused not only structural imperfections (flame cutting) but also considerable and visible geometrical imperfections (due to welding) observed as initial deformed shapes of the webs. This problem was observed especially in girders type B (B1, B2) due to their larger aspect ratio ($\alpha = 1.5$). Obviously, it was necessary to take into account the aforementioned factor, since previous numerical analyses proved its importance. Moreover, the presence of significant visual imperfections could possibly account for differences between experimental and numerical results.

2.4 *Test results*

Full analysis of all tested girders included 40 measurement points (24 strain gauges and 16 displacements). In this section, the most significant and representative results are presented and analysed.

For girders B1 and B2 the experimental results are shown within a limited range. Large imperfections detected in both girders made it impossible to continue the tests over a certain value of applied load (at approximately halfway to the ultimate shear resistance, both tests had to be stopped). As a result of the aforementioned initial deformed shapes, an additional horizontal force in the point of applied load occurred and started to push tested girders outside of their plane. Nevertheless, in the range where the measurements were registered, a good correlation of all results was observed.

2.5 *Load-deflection curves (A1, A2, B1, B2)*

A comparison of load-deflection curves P-δ obtained from numerical simulations and experimental tests is shown below (Fig. 2a–d). Maximum vertical displacement δ was measured at the mid-span of the girder. The correlation shown between each pair of numerical and laboratory curves is good.

2.6 *Deformed shape*

Fig. 3 shows an example of a qualitative comparison of the deformed shape of the tested panel. Here a very good correlation is also observed between experimental and numerical "buckling waves". In this case (girder A1), the upper trapezoidal sub-panel buckled first, followed by the rectangular one. Two diagonal tension fields were being created independently and they are formed as a function of their slenderness (meaning the more slender sub-panel buckles first). The darker grey tones seen in Fig. 3b are representing yielding zones, according to von Mises criterion. It may be concluded from quantitative analyses of yielding and locations where plastic hinges appeared (two flanges and longitudinal stiffener) that both subpanels may be considered separately, since the same mechanism is observed in both of them.

2.7 *Numerical model validation*

Table 2 shows experimental and numerical values of the critical shear load V_{cr} and the ultimate shear resistance V_u obtained for the tapered girders tested. Values of the numerical critical shear load $V_{cr(FEM)}$ were obtained from buckle analysis, based on the first positive eigenvalue. Experimental critical shear loads $V_{cr(test)}$ were obtained on the basis on the load-vertical displacement relationships, approximately in the point where the curve losses its linearity.

It is important to mention that all tested girders had excessive structural imperfections (manufacturers' tolerances were exceeded) which for specimens A1 and A2 led to lower ultimate shear resistance V_u comparing them to numerical equivalents (up to 11.3%). Additionally, the initial deformed shapes in girders B1 and B2 made it impossible to continue both tests

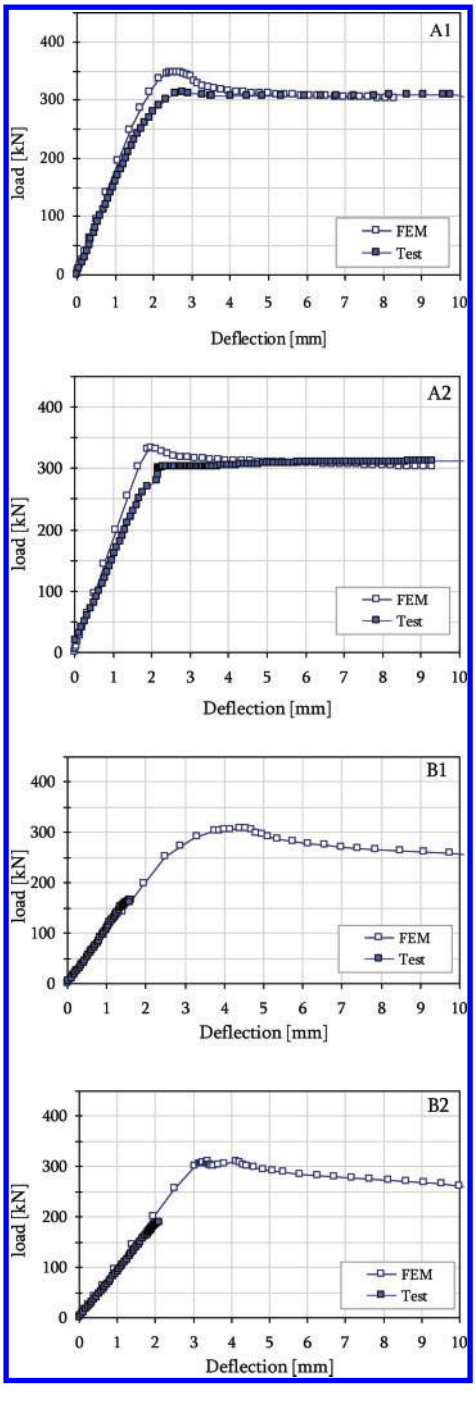

Figure 2. Numerical and experimental load-deflection curves for girders a) A1, b) A2, c) B1, d) B2.

with loads exceeding their critical shear level (see Fig. 2c–d).

For this reason, validation of the numerical model was only based on two specimens A1 and A2. Good agreement is observed between the numerical results and experimental results (see Table 2).

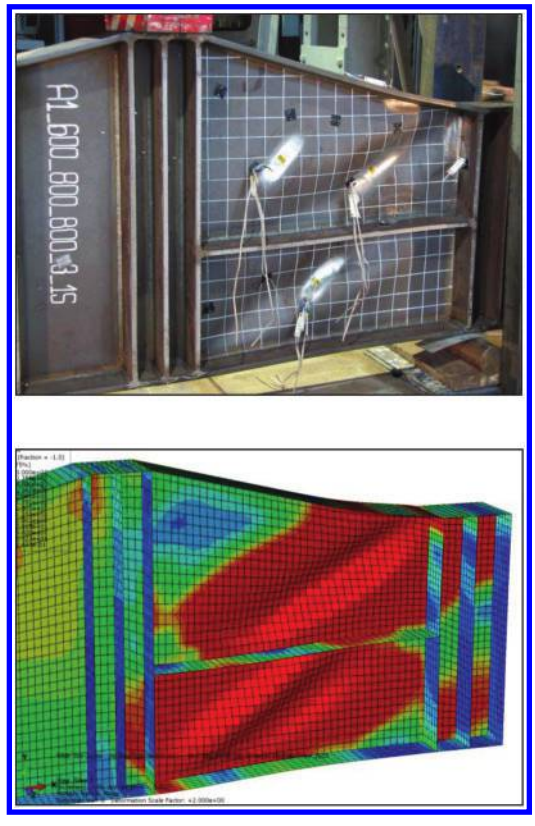

Figure 3. Qualitative comparison of deformed shape for girder A1. a) Experimental test, b) FEM model.

Table 2. Numerical and experimental results.

Girder	V_{cr_FEM} kN	$V_{cr_(test)}$ kN	Diff. %	$V_{u_(FEM)}$ kN	$V_{u_(test)}$ kN	Diff. %
A1	223.2	210.0	−6.3	347.8	312.5	−11.3
A2	295.2	270.0	−9.3	333.1	311.9	−6.8
B1	188.5	–	–	307.9	–	–
B2	280.8	–	–	310.8	–	–

The analysis of the overall behaviour of tested girders and their comparison with numerical analyses (load-deflection curves in Fig. 2a–d) show very good correlation between them, allowing us to conclude that numerical model was validated correctly.

3 PARAMETRIC STUDY

3.1 *Numerical model*

Several numerical analyses of tapered steel plate girders subjected to shear were conducted using the Abaqus code (2010). In order to reproduce the influence of large deformations that occur during the shear buckling phenomenon, 4-node shell element S4R5 was used. To deal with the geometric and material

nonlinearities (post-buckling behaviour, softening and collapse) "modified Riks" method was applied. The stress-strain relationship was based on the simplified bi-linear diagram $\sigma - \varepsilon$ with kinematic hardening and on the von Mises criterion for yield stress assumed for ductile materials.

3.2 *Material properties*

Selected material for the parametric study was S275 steel with bi-linear simplified model, yield strength of 275 MPa, Young's modulus E = 210 GPa and Poisson's ratio $\nu = 0.3$. This work is a continuation of previous analytical and numerical investigations, in which steel S275 was used (Real et al. (2010) and Bedynek et al. (2011)). In order to adapt the experimental tests on the tapered steel plate girders to the capabilities of the laboratory, steel S235 was selected.

3.3 *Geometric and structural imperfections*

Previous studies presented by Bedynek et al. (2013) for tapered plate girders with transversal stiffeners and Pavlovčič et al. (2007) for rectangular plate girders with longitudinal stiffeners concluded that plate girders are not very sensitive to the influence of structural imperfections such as residual stresses. Consequently, only geometrical imperfections are considered in this research. In order to introduce the geometrical imperfections, a scaled deformed shape from the first eigenvalue mode in buckle analysis was used (values calculated according to EN 1993-1-5 and the maximum fabrication tolerances).

3.4 *Longitudinal stiffeners*

In all analysed girders, the longitudinal stiffener has the same thickness $t_s = 15$ mm and approximately the same width $b_s = 0.5(b_f - t_w)$. The longitudinal stiffener was designed to assure enough rigidity in order to prevent the overall panel buckling. Only local buckling of sub-panels is allowed. More research about the optimum rigidity of the longitudinal stiffeners has been carried out in recent works (Pavlovčič et al. (2007) and Estrada et al. (2008)).

4 NUMERICAL RESULTS. COMPARISON WITH EN 1993-1-5

In Table 3 some of the numerical (FEM) and analytical (EN 1993-1-5) results of the ultimate shear resistance V_u are presented and compared. Additionally, in the first column, the numerical values of critical shear load V_{cr} for each girder are shown. Girders with symbol "0" do not have any longitudinal stiffener. They provide a reference value for plates having such stiffener.

Four different situations of the location of the longitudinal stiffener were studied; the values concerning to each case (Girders I-IV) are indicated in Table 3) (see Fig. 4).

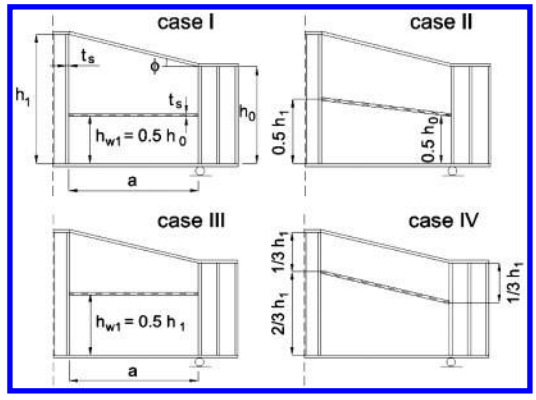

Figure 4. Four cases (I-IV) of position of the longitudinal stiffener.

Analysed girders varied by geometric parameters such as: a slope of the inclined flange (tan (ϕ) from 0.13 to 0.5), an aspect ratio (girders A: $\alpha = 1$, girders B: $\alpha = 2$ and girders C: $\alpha = 3$) and a thickness of the web ($t_w = 2$ mm and 3 mm). The thickness of both flanges and all stiffeners (transversal and longitudinal) was always $t_f = t_s = 15$ mm.

Only a specification provided by EN 1993-1-5 and commented by Johansson et al. (2007) addresses prismatic plates with various combinations of longitudinal stiffeners. In this work the attempt to adapt existing rules for non-prismatic (tapered plates) members has been made; possible limitations of their use are discussed.

The general norm for non-prismatic plates without longitudinal stiffeners proposed in EN 1993-1-5 is based on a simplification of their trapezoidal shape, reducing it to a rectangular one, assuming its larger depth h_1. The same assumption was made in this work for tapered plate girders with one longitudinal stiffener. All tested girders were examined in the mid-span, in the cross-section where the greatest bending moment occurs. The ultimate shear resistance is calculated for a rectangular plate with maximum depth h_1 and with horizontal longitudinal stiffeners (even for non-horizontal, inclined stiffeners as tested in cases II and IV) adopting depth h_{wi} for each sub-panel (see Fig. 4). Nearly all of the results obtained in this way are on the safe side, but some of them (especially cases I and IV) seem to be very conservative.

This significant underestimation of the ultimate shear load may be due to the assumption of non-prismatic sub-panels to be rectangular ones. As it is shown in Fig. 4, for cases I and IV, the trapezoidal sub-panel has a larger slenderness ratio, which could directly be the cause of the general collapse of the girder.

Each girder has been examined in two ways: as an entire panel and as separate sub-panels. According to EN 1993-1-5, from three slenderness parameters (in the case of only one longitudinal stiffener), calculated for both whole panels and sub-panels, that which gives

the higher value in the calculation of the contribution from the web should be used.

In EN 1993-1-5 (point 5.3 (5)) is stated that for webs with longitudinal stiffeners the slenderness $\bar{\lambda}_w$ should not be taken as less than (Eq.1)

$$\bar{\lambda}_w = \frac{h_{wi}}{37.4t\varepsilon\sqrt{k_{\tau i}}} \tag{1}$$

where h_{wi} and $k_{\tau i}$ refer to the sub-panel with the largest parameter $\bar{\lambda}_w$ of all sub-panels within the web panel under consideration.

The shear buckling coefficient $k_{\tau i}$ for a singular sub-panel is calculated according to the classic formulae for simply-supported rectangular plates. If the sub-panel is non-prismatic, it should also be simplified by assuming it to be a rectangular panel, using its largest depth h_{w1}.

As can be observed in Table 3, some situations seem to be more favourable than others. There is also no clear rule for the relationship between the position of the longitudinal stiffener and the ultimate shear resistance of the girder.

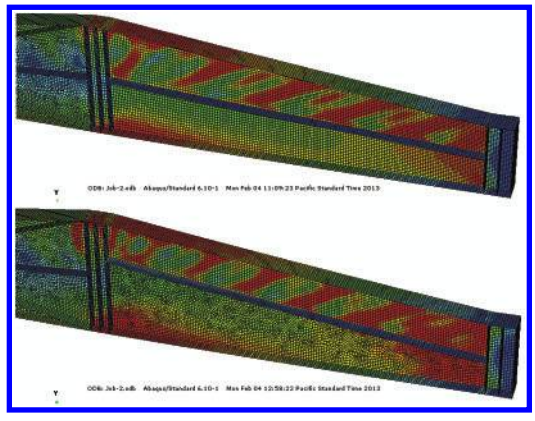

Figure 5. Mid-span section yielding: a) girder CII_600_1000_3000_3_180_15 b) girder CIV_600_1000_3000_3_180_15.

In the case of the presence of both shear forces and bending moments, two different locations for the stiffener could be considered. In the case when only shear forces are present, the optimal position of the longitudinal stiffener would be at the mid-depth of the panel, as this will reduce the slenderness ratio of the panel and will achieve similar slenderness ratios for both sub-panels.

On the other hand, if only bending moment forces are being considered, optimal results will be obtained if the longitudinal stiffener is placed in the compression zone.

In reality, all girders are subjected to both shear forces and bending moments. Therefore, the ultimate shear resistance calculation and the optimal positioning of longitudinal stiffeners are more complex, and strictly depend on the entire geometry of the panel under consideration.

On the other hand, highest values of the shear critical load were observed in cases II and IV, where the slenderness of both sub-panels was reduced and where there was not a significant disproportion between their dimensions. Nevertheless, in the cases where the higher values of the shear critical load are observed, there does not seem to be a correlation with their ultimate shear resistance.

It can also be observed that the ultimate shear resistances V_u varied in larger range for those girders, where the slope of the inclined flange is greater (girders A, up to 130%). The larger aspect ratio in girders B and C, up to 31%), the smaller inclination and the more rectangular shape of the panel explain why the position of the longitudinal stiffener plays a smaller role in the estimation of the ultimate shear resistance.

Due to their specific geometry and larger aspect ratios, two tapered girders (CII and CIV as marked with an asterisk in Table 3) did not exhibit full post-buckling shear capacity. It was observed that for those girders, ultimate shear resistance could not be achieved because of the yielding of both flanges in the cross-section where the greatest bending moment occurs (Fig. 5a–b).

5 CONCLUSIONS

The analysis of the results of experimental tests performed on four tapered steel plate girders with one longitudinal stiffener, under shear, have led to a better understanding of the structural behaviour of these girders. Parametric studies conducted have shown the importance of certain factors. In particular, further research should be focussed on the optimal arrangement of the longitudinal stiffener in order to achieve an efficient design of these girders.

The significance of this research is the applicability of EN 1993-1-5 rules for the case of tapered steel plate girders with longitudinal stiffening.

Generally speaking, an adaptation of existing procedures, for prismatic panels, can be used for non-prismatic panels with one longitudinal stiffener with the aim of determining the ultimate shear resistance of tapered steel plate girders V_u. Nevertheless, when greater precision is required, additional checks should be done. Nearly all of the values obtained for ultimate shear strength by means of the above-mentioned method are conservative and are generally underestimated (up to 48.3%). Only one exception was observed in the case of the girder CIII_600_1000_3000_3_180_15 in which the ultimate shear resistance was overestimated −4.5%. In order to avoid such differences, additional studies with a wide range of geometric parameters should be carried out.

A new design methodology for steel hollow sections: The Overall Interaction Concept

J. Nseir, E. Saloumi & N. Boissonnade
University of Applied Sciences of Western Switzerland, Fribourg, Switzerland

ABSTRACT: This paper deals with the application of the Overall Interaction Concept (OIC) to the design of tubular cross-sections. More precisely, the concern is here to demonstrate the ability of the OIC to accurately account for the influence of local buckling on the cross-sectional carrying capacity. In this respect, extensive numerical investigations have been led, covering the various influences of i) plastic to slender cross-sectional behavior, ii) rectangular and square cross-section shapes, iii) strain-hardening effects, and iv) both simple and combined load cases. The results show that the OIC is perfectly suited to characterize the influence of local buckling on the carrying capacity, despite relying on simple application steps, namely cancelling the classification step as well as the use of the effective width method. Also, early results on the behavior of members are given, showing a potential accurate extension of the concept to members as well. Further investigations are actually under way for the derivation of a full "code-like" procedure, especially regarding interaction curves needed in the proposed design procedure.

1 INTRODUCTION

The present paper is related to the stability, resistance and design of steel hollow section members. More precisely, the behavior of sections is investigated. The intention is to improve the way the performance and the carrying capacity of tubular members are actually characterized, through the development of an original "Overall Interaction Concept" (OIC). Taking into account the resistance and stability interaction, the OIC further incorporates the effects of imperfections (non-homogenous material, residual stresses, out-of-straightness…) through the derivation of adequate "interaction curves" to accurately predict the real behavior of structural elements. The proposed concept is powerful enough to i) increase accuracy and bridge the specificities of the different materials under a unified, simple and effective basis, ii) deal with the effects of non-linear material behavior and local/global instabilities, and iii) advance consistency with the possibility of straightforwardly deal with all load cases, including combined ones (cf. Boissonnade 2013).

At present, for what regards cross-sectional instability, design codes (e.g. Eurocode 3, CEN 2005) usually characterize the sensitivity to early or late occurrence of local buckling by means of a classification of the cross-section, with respect to the b/t ratios of each wall comprised within the cross-section. Different sets of design formulae are provided, either plastic or elastic, depending on the (weakest) element having the highest class.

This concept of classes causes many practical application difficulties, such as a gap of resistance as shown in Figure 1, and almost no attempts have been made to overcome this unsatisfactory situation in a global way. In particular, the classification concept was shown to be inappropriate for hollow sections (Boissonnade 2012, Gardner 2008, Semi-Comp 2007). Figure 2 plots an example of a comparison between recommended b/t flange limits according to various standards for cold-formed hollow sections under major-axis bending moment. The observed discrepancies are so important that several b/t limit values seem questionable, to say the least.

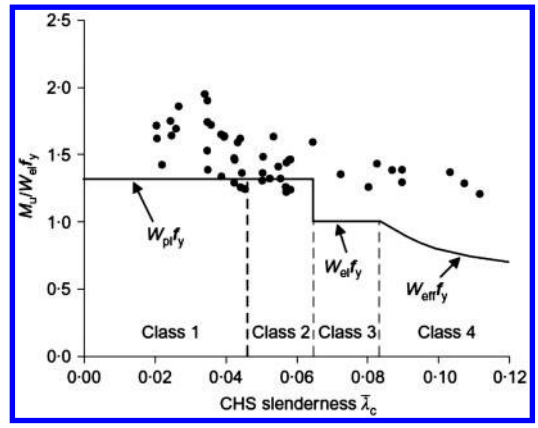

Figure 1. Circular hollow sections in bending: test results vs. concept of classes (Gardner 2008).

The aim of present research investigations is to show how the OIC can improve this situation, and

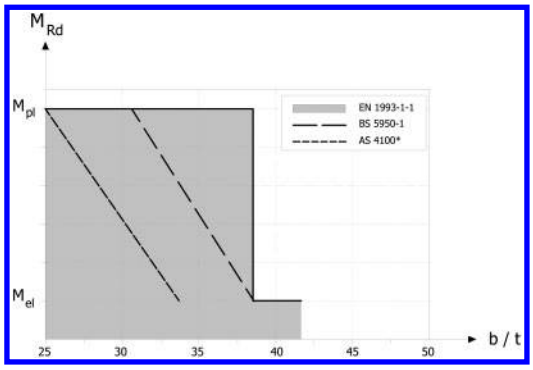

Figure 2. b/t limit values according to various design codes (cold-formed hollow sections submitted to major-axis bending).

to demonstrate that the OIC is perfectly suited to the determination of the design resistance of both hollow sections and members. Following section 2 presents the bases and features of the proposed approach, along with a first set of results for sections. Section 3 then provides results for member behavior, and actual and future research directions are addressed in section 4.

2 APPLICATION OF THE OIC TO HOLLOW SECTIONS

2.1 *Methodology – Application steps*

The proposed OIC approach first relies on the generalization of the relative slenderness concept, establishing this parameter as the key to rule the interaction between resistance and instability. The concept of relative slenderness is familiar to Structural Engineers, and is widely used nowadays to deal with flexural buckling behavior for example. It is suggested within the OIC to enlarge the field of application of this slenderness-related approach through the following generalization of the relative slenderness:

$$l_{rel} = \sqrt{\frac{R_{RESIST}}{R_{STAB}}} \qquad (1)$$

In Equation (1), R_{RESIST} represents the factor by which the actual loading has to be multiplied to reach the pure *resistance* limit, while R_{STAB} is the factor used to reach the buckling load of the ideal member (*instability* limit). Doing so allows the generalized relative slenderness taking a non-dimensional balance between the relative influences of instability and resistance, and makes it capable of dealing with combined loading situations or cross-sectional (local) instability effects (cf. Figure 3).

Once determined, this λ_{rel} value is further used in the design procedure to get into a so-called "interaction curve" and leads to the determination of a "χ" value (see Figure 4). This χ value (from analogy with Eurocode 3, CEN 2005), which may also be called "reduction factor", represents the penalty due

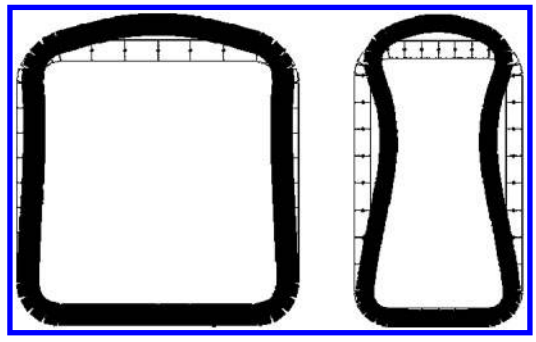

Figure 3. Local buckling of square and rectangular cross-section subjected to major-axis bending.

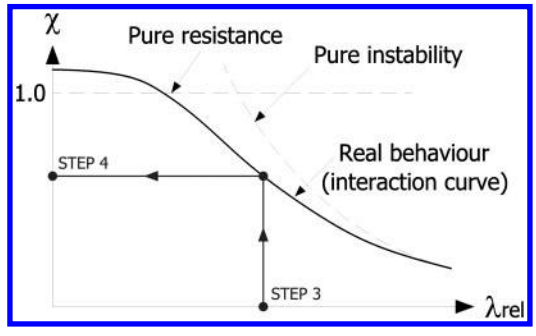

Figure 4. Resistance – instability interaction.

$$STEP\,1 : R_{RESIST}$$
$$STEP\,2 : R_{STAB}$$
$$STEP\,3 : \lambda_{rel} = \sqrt{\frac{R_{RESIST}}{R_{STAB}}}$$
$$STEP\,4 : \chi = f^{\circ}\left(\lambda_{rel}\right)$$
$$STEP\,5 : R_{REAL} = \chi \cdot R_{RESIST}$$

Figure 5. Application steps of the OIC.

to instability effects on the "pure resistant behavior"; obviously, χ can only be lower than 1.0. Then, the final resistance is evaluated as $\chi.R_{RESIST}$; Figure 5 further illustrates the proposed approach and its application steps. This rather simple procedure can be applied to many situations within Structural Engineering and become a general approach to each design situation where instability affects the resistance.

2.2 *Comparison with test results*

In an attempt to validate the pertinence of the OIC for handling the resistance-instability interaction for hollow sections, Figure 6 presents various test results collected in the literature (Kettler 2008). Its axes are "OIC-defined", i.e. the horizontal axis relates to the generalized slenderness λ_{rel} while the vertical axis reports on the cross-section reduction factor χ_{CS}.

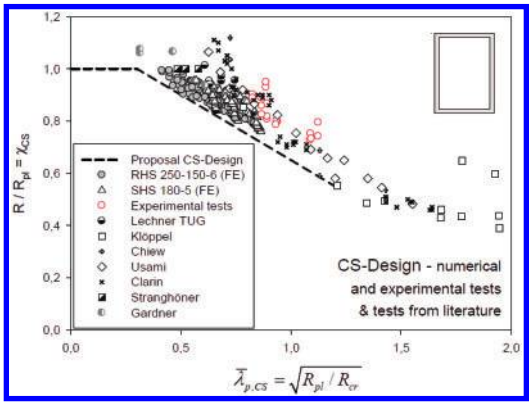

Figure 6. Cross-sectional test results (from Kettler 2008).

The OIC approach is seen to lead to highly satisfactory and consistent results, as indicated by the limited scatter observed; this is especially remarkable given the fact that some of the test results are relative to combined loading situations, such as compression with mono-axial bending.

Further, as Figure 1 experimental results show, significant over-strength may exist beyond the plastic design strength, due to a well-known conservatism in the assumption of a rigid-plastic material; this is especially true for cold-formed hollow sections. These potential resistance reserves may nevertheless be taken into account within the OIC approach in resorting to interaction curves leading to χ values above 1.0 for low relative slenderness – see Figure 4; from a mechanical point of view, this means that the OIC allows going beyond the usual perfectly-plastic behavior assumption. Numerical results presented in the next paragraph bring further evidence that this is effective and shall be accounted for.

2.3 *Numerical results*

This paragraph presents a first series of results relative to the cross-sectional behavior of tubular profiles. R_{STAB} values have been determined numerically with CUFSM (i.e. cross-sections were considered as a whole), and R_{RESIST} values have been derived by means of Eurocode 3 plastic interaction equations. Extensive numerical FE analyses have been led for the calculation of χ_{CS} values, through the use of non-linear FEM software FINELg (FINELg 2012); numerical models made of quadrangular 4-nodes plate-shell finite elements with typical features have been used (corotational total Lagrangian formulation, Kirchhoff's theory for bending). The FE-models being shown to be adequate (Boissonnade et al 2012), they have been extensively used within parametric studies and some 5500 non-linear shell numerical results have been collected – 296 tubular geometries were considered: 156 *rectangular* (RHS) + 140 *square* (SHS) hollow sections. The elastic-perfectly plastic with 2% hardening material law of Figure 7 was adopted for all

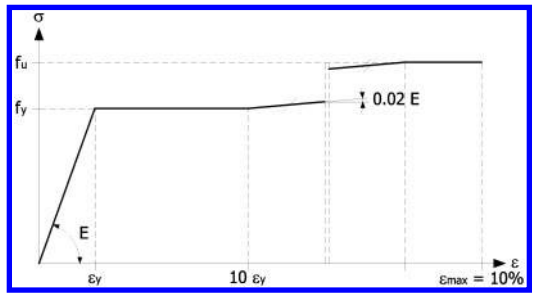

Figure 7. Stress-strain relationship adopted in FE models.

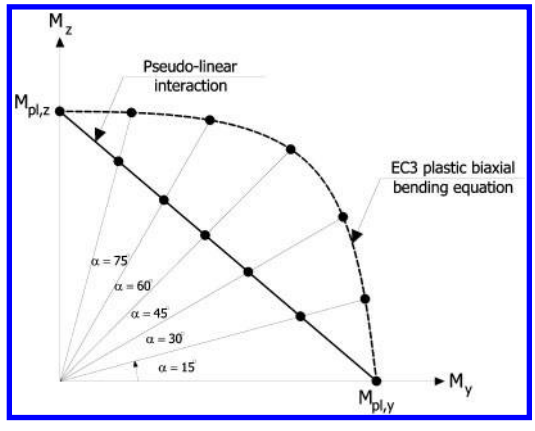

Figure 8. Stress-strain relationship adopted in FE models.

calculations, and suitable initial imperfection sets have been considered.

The numerical studies comprised the following set of parameters:

- 296 cross-section shapes (European database);
- 3 different steel grades: S235, S460, S690;
- Different loading conditions:
  - Pure compression;
  - Major-axis bending;
  - A first series of combined compression (30% of N_{pl}) and biaxial bending;
  - A second series of biaxial bending + 70% axial compression.

In order to better evidence the uniformity of the results, a distinction has been made between the different loading situations, namely with respect to the degree of biaxiality, i.e. the M_y/M_z ratio; this ratio was varied on the basis of 15° angles between plastic capacities $M_{pl,y}$ and $M_{pl,z}$ in a pseudo-linear biaxial bending interaction plot (see Figure 8).

Figures 9 and 10 show some of the obtained results, in OIC format and axes, and the proposed approach is seen to be fully appropriate, as demonstrated by the little scatters observed. It can be noticed that an increase in f_y obviously increases the relative slenderness λ_{CS} and thus decreases the χ_{CS} value, i.e. the section become more slender and prone to local buckling; a relatively small dispersion in the results is

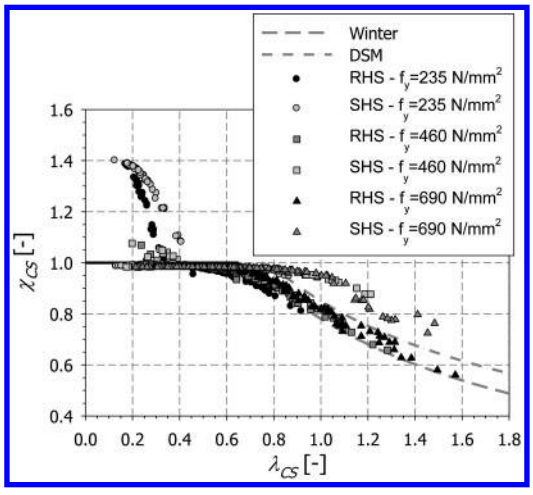

Figure 9. FE results for hollow sections under compression.

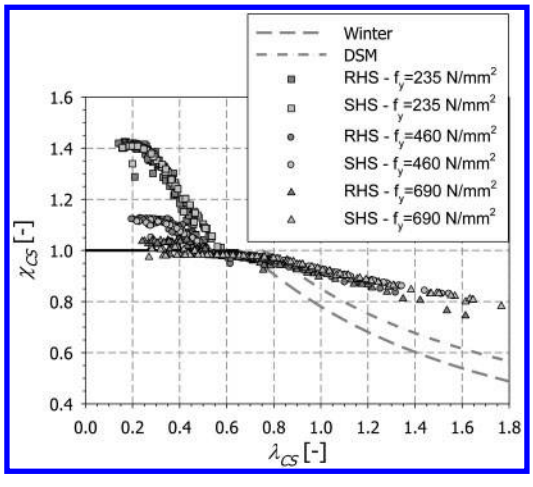

Figure 10. FE results for hollow sections under major-axis bending.

noted, though, and tendencies for slightly higher χ_{CS} values for high steel grades is observed. Too, an important level of over-strength brought by strain-hardening effects for the lowest steel grade can be noted.

As for the combined load cases, clear trends have been observed as well. For such situations, the OIC has been applied with an identical methodology as before, i.e. with R_{STAB} values numerically computed with CUFSM and R_{RESIST} values determined from the plastic $N-M_y-M_z$ equations of Eurocode 3. presents some results obtained for the 30% compression cases with yield stress $f_y = 235\,N/mm^2$. A detailed look at the results revealed that higher χ_{CS} values are reached for cases where minor axis bending takes over major axis bending, due to variations in the observed local buckling collapse modes, which obviously change with α, in addition to a certain conservatism in the $N-M_y-M_z$ plastic interaction equations adopted herein. In conclusion, the

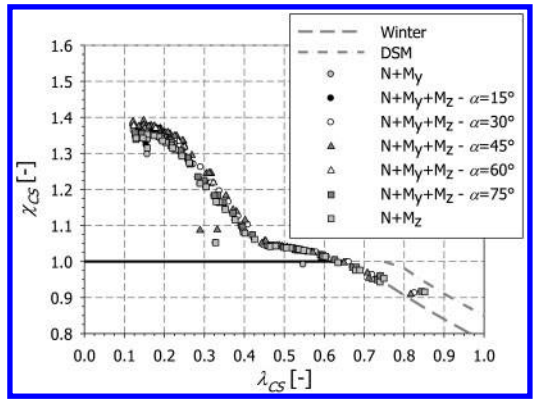

Figure 11. FE results for hollow sections under pure compression.

proposed concept is shown to be successfully applicable to tubular sections, and able to capture the mechanically-governing parameters, despite a rather simple conceptual background.

3 BEHAVIOUR OF TUBULAR MEMBERS

This section reports on the application of the OIC to *members*, with a special focus on combined load cases. Indeed, the (simple) load cases of members in compression (i.e. flexural buckling) or subjected to major-axis bending (lateral torsional buckling) immediately fit in the OIC approach, since these situations lie at the bases of the concept. For this purpose, thousands of FE-results have been reused (gathered from Ofner 1997). These numerical results are all relative to cases where local instability of the cross-section can be neglected (i.e. λ_{CS} is such that $\chi_{CS} \geq 1.0$ – Class 1 or 2 sections), and accordingly have been obtained by means of beam models – it shall be noted that the vast majority of these results is concerned with combined loading situations.

Figure 12 first shows results obtained to characterize the behavior of members with tubular sections, for $N+M_y$ cases; Figure 12 axes are here relative to *global* buckling through the *member* slenderness λ_{MB} (calculated with R_{STAB} values relative to member instability) and its associated χ_{MB} reduction factor. In this Figure, ψ stands as the ratio between applied end moments; as can be noticed, ψ can be identified as a key parameter, and a detailed analysis also showed that the M_y/N ratio can be shown to rule the differences in scatter for a given ψ value. Similar conclusions can be drawn for $N+M_y+M_z$ cases (Figure 13), however with clearer tendencies and a better level of uniformity with ψ.

These results confirm the ability of the OIC to correctly predict the response of hollow members under combined loadings. Further developments are under way to propose relevant interaction curves, on the basis of the tendencies observed.

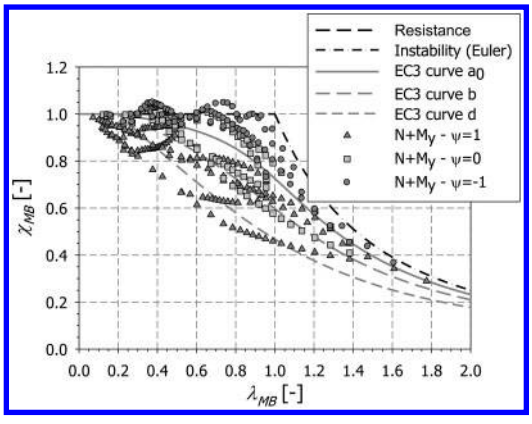

Figure 12. Results for hollow section members under combined loading ($N + M_y$).

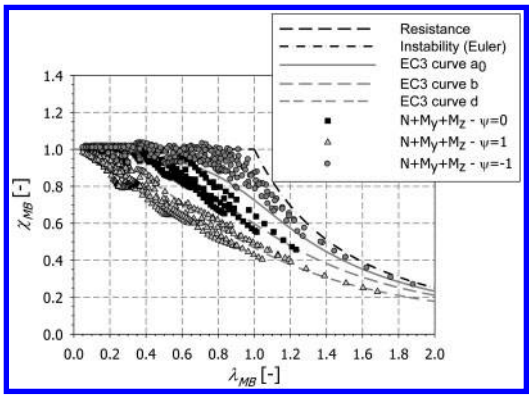

Figure 13. Results for hollow section members under combined loading ($N + M_y + M_z$).

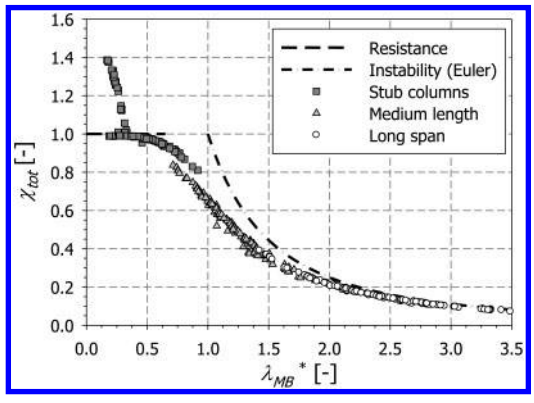

Figure 14. Results for rectangular hollow section *members* under pure compression (S235 steel).

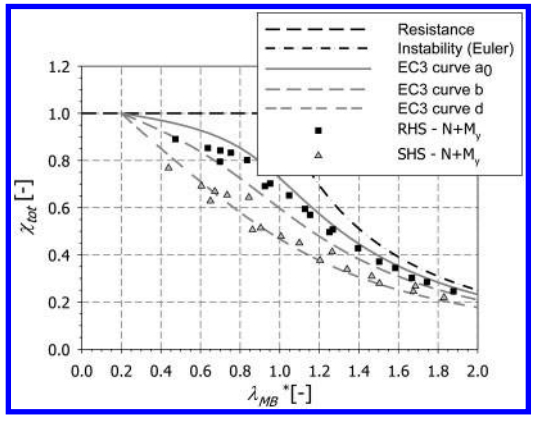

Figure 15. Results for hollow section *members* under combined loading (slender sections).

Deeper investigations also revealed that the cross-section h/b ratio plays a role on the global response of rectangular profiles. For this purpose, additional FE simulations have been performed on some 150 rectangular hollow section members (European database) submitted to axial compression only. The length of the members was varied from short to long (i.e. from stub column typical lengths to long spans leading to relative slenderness above 3.0, see Figure 14). Since some of the investigated sections were also concerned with *local* buckling (so-called "coupled instabilities"), use of a modified member relative slenderness λ^*_{MB} has been made, where R_{RESIST} is substituted by $\chi_{CS} \times R_{RESIST}$; results are plotted in Figure 14.

The observed discontinuity between the results of short length members and medium length members can be explained by the fact that the sections whose values belong to the "right side" of the stub columns' set typically have h/b ratios different from the "left side" of the medium length ones, and therefore should better be related to the values at the right end of the medium length set. This corroborates the need to resort to parameter-dependent interaction curves, rather than fixed ones as is nevertheless done in many codes for flexural buckling.

Finally, situations involving both local and global instabilities under combined load cases have been investigated, referring to SHS 250 × 250 × 5 and RHS 250 × 150 × 5 (slender) cross-sections. Both sections have been shown to exhibit an important influence of local buckling effects, with χ_{CS} values ranging from 0.4 to 0.9, depending on the load combination and on the level of web-flange interaction within local buckling modes. Use of λ^*_{MB} generalized relative slenderness has also been made, and Figure 15 depicts some of the obtained results ($N + M_y$ cases). Again, clear trends can be observed, further confirming the potential of the OIC to be relevant in such cases.

4 CONCLUSION – FUTURE DEVELOPMENTS

In the present paper, the Overall Interaction Concept has been shown to be a fully appropriate alternative to the current well-known design rules to account for the interaction between resistance and instability effects.

In particular, results on both tubular *sections* and *members* (i.e. including local and/or global instability), for simple or combined load cases have been presented.

The application of the OIC to predict the resistance of tubular cross-sections was shown to be fully appropriate, whatever the dimensions, steel grade or loading conditions. This approach is able to catch the governing parameters and to lead to consistent results, even for non-trivial situations and despite quite simple application steps. Consequently, the possibility to derive practical but accurate expressions for χ-curves exists, and is currently under completion – multiple mechanically-based expressions are foreseen, according to the trends observed for the combined load cases.

The OIC approach is actually at the core of the STSS project ("Simple Tools Sell Steel", STSS 2012), whose main objective is to develop and assess new design concepts to predict accurately the response of members made of standard and high-strength steel up to collapse (open and tubular sections). In an international effort, many related developments are conducted, involving deep, varied and extensive activities, both at the experimental, numerical, theoretical and practical level.

Besides, OIC-based investigations on high and ultra-high performance fiber concrete elements (columns and beam-columns) are currently under way. The future research directions related to an OIC approach will first be oriented towards its application to other materials, in situations where instability is of prime importance. This concerns for example members made of composite sections, stainless steel, aluminum, ultra-high performance concrete with fibers, structural glass…

Moreover, the development of new cross-sectional shapes, deliberately slender, is intended with the objective of taking the benefits from the new generation of high strength steels. Also, investigations within fire and earthquake steel design will become necessary, as a consequence of the calling off of the classification concept. Further, the OIC approach and principles, as described herein, should appreciably improve the design of specific members where coupled instabilities and/or complex solutions to implement require (partial) numerical solutions and the associated conceptual framework (e.g. tapered members, cellular beams…). Last, in the perspective of seeing the OIC embedded in various standards worldwide, the OIC should allow for a certain harmonization of standard and design habits, since relying on a general and global concept.

Use of the Overall Interaction Concept for the practical design of steel sections and members

N. Boissonnade, J. Nseir & E. Saloumi
University of Applied Sciences of Western Switzerland, Fribourg, Switzerland

ABSTRACT: The Overall Interaction Concept (OIC) stands as a new design approach that aims at a straightforward design check of the stability and resistance of steel members. It was developed in response to the expansion of high strength steel products, where instability has more influence and deserves specific attention, especially at the cross-sectional level. Based on the use of a generalized relative slenderness and so-called interaction curves, it applies to both open and tubular cross-sections, further includes potential non-linear material behavior (beneficial strain hardening effects, e.g. stainless steel or cold formed hollow profiles) and covers combined load cases. In addition, it can be applied in a similar manner to cross-section or to member verifications. The present paper describes the bases and features of the OIC, and its accuracy and applicability is tested against thousands of FE results, and the potential for the OIC to become an accurate and effective approach for practical design is demonstrated. Provided additional complementary developments, the OIC may appear as a powerful alternative to the current design methodologies, and serve as a basis for the next generation of standards and practical tools, especially in the frame of an increasing use of high steel grades.

1 INTRODUCTION

This paper deals with the behavior and design of steel profiles, in situations where instabilities (both local and global) play a significant role. A recently-developed new approach, the Overall Interaction Concept (OIC), is presented and detailed. Applicable to the design of both sections and members, it has been developed mainly to i) improve actual design practice, ii) increase accuracy, and iii) advance simplicity and consistency.

In particular, the research developments have been directed towards actual and future high and ultra-high strength steel grades, for which the influence of buckling is more important. Indeed, for sections made of steel whose yield stress lies above 65 ksi (S460 grades and above for Europe), many profiles fall into the slender range, yielding long and tedious calculations for the designer, and a somewhat tempered economical interest as long as all fibers of the cross-section cannot reach the yield stress at peak load.

Design codes usually characterize this sensitivity to early or late occurrence of local buckling by means of a classification of the cross-section: this consists in an additional step prior to section and member design checks, where the width-to-thickness b/t ratios of the different plates comprised within the cross-section are compared with limits provided by the code; depending on its weakest element (i.e. the one with the worst class), different sets of design formulae are provided, either plastic or elastic.

It is however nowadays commonly agreed that this concept of classes causes many practical application difficulties (Boissonnade et al. 2013, Boissonnade 2011, Gardner 2008). In particular, discrepancies and discontinuities are reported (Semi-Comp 2007, Kettler 2008), in addition to a gap of resistance that has no physical meaning (see Figure 1).

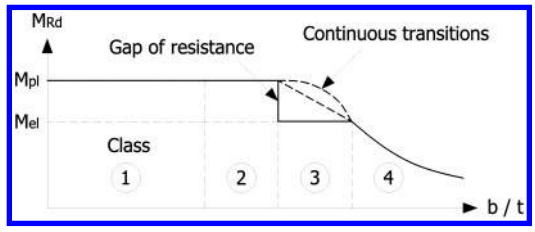

Figure 1. Classification concept according to Eurocode 3 (section in bending).

The Overall Interaction Concept detailed here is aimed at improving this situation. This approach, through the generalization of the relative slenderness concept, sets a general, simple, effective and sound framework to the design of all structural elements. Taking due account of resistance and stability phenomena, the OIC further incorporates the effects of imperfections to accurately predict the real behavior of members. Moreover, the concept is able to maintain simple application steps through the use of modern calculation tools.

Following section 2 presents the bases and features of the proposed approach, and sections 3 and 4 proposes results for sections and members, respectively. Finally, actual and future research directions are given in section 5.

2 THE OVERALL INTERACTION CONCEPT

2.1 *General concept*

The OIC aims at handling the interaction between *resistance* and *instability* ("ideal behaviors") to describe the carrying capacity of a member. On the one hand, the classical concept of *resistance* mainly characterizes the cross-sectional capacity of the member, while, on the other hand, the theory of *stability* describes the inclination of members and sections to buckle under compression stresses. In addition, the influence of imperfections (both material and geometrical imperfections) has to be taken into account.

The proposed OIC approach first relies on the generalization of the relative slenderness concept, and on establishing this parameter as the key to rule this interaction. The concept of relative slenderness is familiar to Structural Engineers, and is widely used nowadays to deal with flexural buckling behavior for example. It is suggested within the OIC to drastically enlarge the field of application of this slenderness-related approach through the following generalization of the relative slenderness:

$$\lambda_{rel} = \sqrt{\frac{R_{RESIST}}{R_{STAB}}} \qquad (1)$$

R_{RESIST} represents the factor by which the actual loading has to be multiplied to reach the pure *resistance* limit, while R_{STAB} is the factor used to reach the buckling load of the ideal member (*instability* limit). Doing so allows the generalized relative slenderness taking a non-dimensional balance between the relative influences of instability and resistance, and makes it capable of dealing with combined loading situations or cross-sectional (local) instability effects as well. Once determined, this λ_{rel} value is further used in the design procedure to get into a so-called "interaction curve" (also sometimes referred to as "buckling curve") and leads to the determination of a "χ" value (see Figure 2). This χ value (analogous to the one used in Eurocode 3, CEN 2005), which may also be called "reduction factor", represents the penalty due to instability effects on the "pure resistant behavior"; χ can obviously only be lower than 1.0. Eventually, the final resistance is evaluated as χ. R_{RESIST}; Figure 3 further illustrates the proposed approach and its application steps.

2.2 *Application to cross-sectional behavior*

The adoption of a generalized slenderness allows applying the OIC procedure to determine the resistance of slender sections. Indeed, while R_{RESIST} remains unchanged when λ_{rel} is relative to either sections or members, R_{STAB} may relate to *global* (member) buckling as well as to *local* (cross-sectional) buckling).

Therefore, the tendency of slender sections to experience early local buckling may be characterized in applying the OIC approach as well, provided that R_{STAB} corresponds to the local or distortional buckling mode of the cross-section. Usually, this is achieved through the determination of so-called critical stresses σ_{cr}, and R_{STAB} is simply set as the ratio between σ_{cr} and the actual stress on the considered wall.

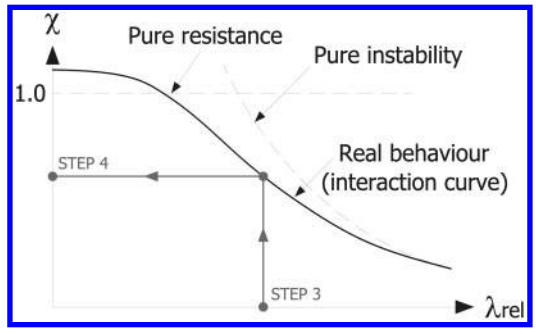

Figure 2. Resistance – instability interaction.

$$STEP\ 1: R_{RESIST}$$
$$STEP\ 2: R_{STAB}$$
$$STEP\ 3: \lambda_{rel} = \sqrt{\frac{R_{RESIST}}{R_{STAB}}}$$
$$STEP\ 4: \chi = f^{\circ}\left(\lambda_{rel}\right)$$
$$STEP\ 5: R_{REAL} = \chi \cdot R_{RESIST}$$

Figure 3. Application steps of the OIC.

It is suggested within the OIC to resort to modern, numerical tools to calculate accurate R_{STAB} values, such as CUFSM (Li & Schafer 2010) or GBTUL (Bebiano et al. 2008) for example. These (free) software not only allow for a much more accurate R_{STAB} value – usually also more favorable –, but also permit to consider the cross-section as a whole, benefiting from potential resistance reserves brought by adjacent walls restraints. Steps 3 to 5 of the design procedure (see Figure 3) then apply, however with dedicated interaction curves. This shall be seen as an important improvement brought to the current design practice that usually resorts to the effective width method for slender sections (AISC 2005): further to removing the need for classification and providing a smooth, continuous transition of the resistance from the plastic to the slender range, the method avoids the fastidious determination of effective properties.

2.3 *Combined load cases*

The OIC approach and application steps, as detailed in §2.1, remain valid whatever the loading situation considered. In particular, combined load cases (e.g. for beam-columns) can be treated as easily as simple ones, thanks to i) the use of "R-factors" as defined previously, and to ii) a generalized definition

of λ_{rel}. Moreover, if numerical evaluations of R_{RESIST} and/or R_{STAB} are contemplated, combined load cases can be afforded rather efficiently, without resorting to complex interaction equations.

2.4 *Main features of the OIC*

Further to calling off the classification concept and its many difficulties (additional step, discontinuities, complexity...), the OIC enables to keep a strong mechanical background to handle the balance between resistance and stability effects. Through a limited number of well-defined governing parameters and a simple but sound physical background, it provides practitioners with a high level of control on their design.

Simplicity arises from the definition of the generalized relative slenderness: it allows i) combined loading conditions to be treated as easily as simple ones – therefore avoiding to resort to complex interaction formulae –, ii) the use of a unique concept to characterize the resistance of sections as well as the resistance of members, and iii) the treatment of all sections shapes in a unique procedure, i.e. no distinction is made between open and tubular sections for example.

Then, the use of modern powerful analysis tools such as CUFSM, GBTUL ... provides quick and accurate results, and deeply simplifies the determination of critical stresses (or, equivalently, of R_{STAB}) as well as the resolution of so-called "coupled instabilities" problems, i.e. involving both cross-sectional (local) and member (global) instabilities.

Next, although being applied in this paper to structural steel design, the OIC remains open to any material, in particular to elements made of tomorrow's high performance materials highly susceptible to buckle (e.g. columns or beam-columns made of high performance concrete, fiber-reinforced concrete, high strength steel, composite materials...). The application to such materials is straightforward, as the bases and concept remain whatever the material considered. Particularly, materials that exhibit a high degree of nonlinearity and strain hardening (high strength steel, stainless steel, aluminum...) shall be exploited more effectively (see also Gardner et al. 2011).

Last, as already explained, resorting to the OIC approach, offering smooth and continuous transitions along the whole slenderness range, will particularly be beneficial in the frame of an increasing use of high strength steel, for which an efficient treatment of local instabilities will be crucial, especially at the cross-sectional level.

3 CROSS-SECTIONAL RESISTANCE

This paragraph presents a first series of results relative to cross-sectional behavior. Accordingly, the OIC was applied with respect to R_{STAB} values relative to *local* buckling – this was achieved with the use of CUFSM –. First, a detailed examination of the results obtained for

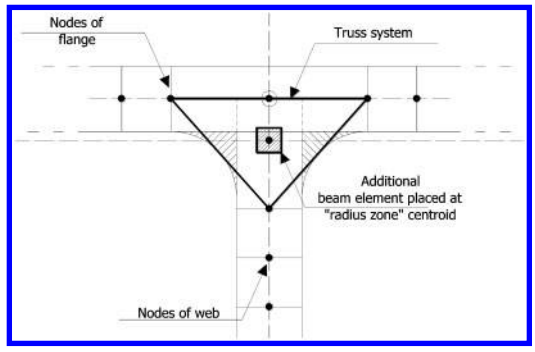

Figure 4. Shell FE-modeling detail at web-flange junction.

R_{STAB} (or σ_{cr}) values showed considerable differences between the numerically-obtained CUFSM results and the classical plate buckling theory ones (i.e. assuming ideal support conditions for webs and flanges).

Then, in order to test the adequacy of the proposed concept, a series of numerical results have been collected, by means of non-linear software FINELg, 2012. Obviously, shell models have been developed, with nowadays common features (Boissonnade et al. 2012, Boissonnade & Somja 2012).

As particular modeling features, the web-flange junction has received a careful treatment. First, an additional beam element which allows for nearly-exact cross-sectional properties was added. Then, a "truss system" was attached to the models in the web-flange junction zone, in order to keep this region nearly rigid. This ensures local buckling waves to develop as realistically as possible and an accurate characterization of the onset of buckling.

The following set of parameters has been used for this numerical study on cross-sectional resistance:

- 292 cross-section shapes (203 US + 89 European ones);
- 3 different steel grades: S235, S460, S690 for European profiles, and 36, 65 and 100 ksi steel for US profiles;
- Various load cases, from simple compression or major-axis bending to combined loading situations (predominantly $N + M_y + M_z$);

In total, more than 3 400 non-linear FE computations have been performed.

Figures 5–7 plot some of the obtained results. Their axes are "OIC-defined", i.e. the horizontal axis relates to the generalized slenderness λ_{rel}, while the vertical axis reports on the cross-section reduction factor χ_{CS}. As Figure 5 shows, an excellent level of consistency can be reached, indicated by a very limited scatter. These results demonstrate that λ_{rel} is a key parameter to rule the resistance-stability interaction and that the possibility to derive accurate and consistent equations to calculate χ values exists; such investigations are currently under development.

One may also note, for low steel grades, a rather important resistance reserve for $\lambda_{rel} < 0.3$, due to

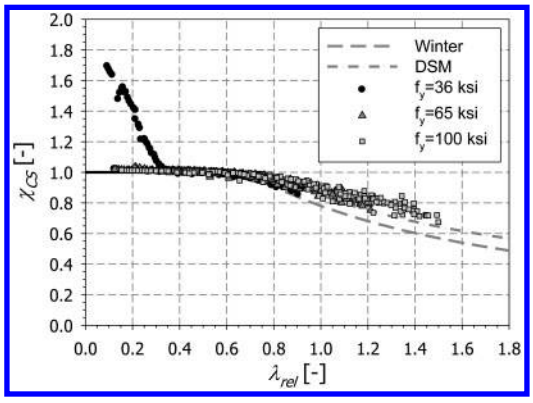

Figure 5. WF sections under compression (AISC database).

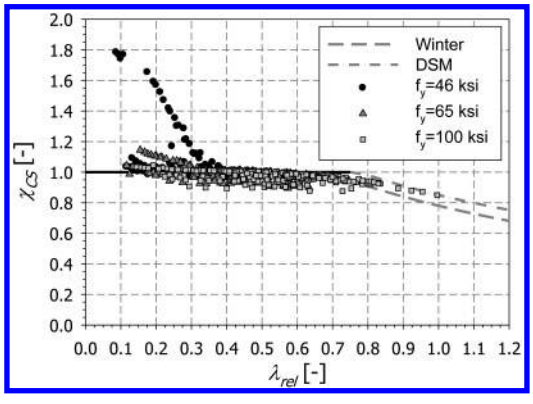

Figure 6. WF sections under major-axis bending (AISC database).

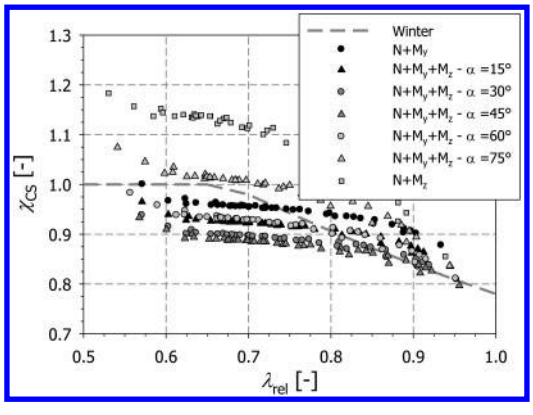

Figure 7. IPE and HEB sections under combined loading (biaxial bending with 70% compression – $fy = 460$ N/mm^2).

strain hardening effects. Similar results obtained in the same way for sections bent about the major-axis are given in Figure 6, and identical conclusions can be drawn.

Combined loading situations yielded results such as those plotted in Figure 7. In such cases, R_{STAB} values were determined numerically with CUFSM, and R_{RESIST} values have been calculated from the $N - M_y - M_z$ plastic equations of Eurocode 3. For sake of clarity, a distinction has been made between the different loading situations, with respect to the degree of biaxiality, i.e. the M_y/M_z ratio. Again clear tendencies may be emphasized, namely with respect to the degree of biaxiality as cross-sectional failure modes vary with the M_y/M_z ratio.

The application of the OIC to predict the resistance of open cross-sections is therefore seen to be fully appropriate, whatever the dimensions, steel grade or loading conditions; as presumed in the definition of a generalized relative slenderness, this approach is able to catch the governing parameters and to lead to consistent results, even for non-trivial situations and despite quite simple application steps. Consequently, the possibility to derive practical but accurate expressions for χ-curves exists, and is currently under completion (multiple mechanically-based expressions are foreseen, according to the trends observed for the combined load cases).

4 MEMBER RESISTANCE

Present paragraph now deals with *member* resistance, with a particular focus on *combined* load cases. Indeed, simply-loaded elements such as columns (flexural buckling) or beams (lateral torsional buckling) naturally fit with the OIC format, see application steps detailed in §2.

In an effort to distinguish between global and local buckling modes, a series of more than 14 000 FE results obtained by means of beam models – thus ignoring cross-sectional deformation modes – has been collected. These have been gathered from Ofner 1997 and are all relative to cases where local instability of the cross-section can be neglected (i.e. χ_{CS} is such that $\chi_{CS} \geq 1.0$ – Class 1 or 2 sections). They comprise various effects expected to have a significant influence on the member's behavior, such as different section shapes, bending moment distributions, slenderness...

Some of the results are plotted on Figure 8 under the OIC format, for members submitted to $N - M_y - M_z$ loading; it shows that as a first parameter to influence the resistance, the bending moment distribution plays a key role (ψ stands as the ratio between applied end moments: $\psi = 1$ indicates constant bending moment distribution, $\psi = 0$ triangular distribution, and $\psi = -1$ a bi-triangular pattern). It has indeed since long been shown to have a significant influence on the extent of yielding along the member (see Boissonnade et al. 2006). Also, a careful analysis of the results indicates that the M_y/N and M_z/N ratios shall be considered too as leading parameters for the derivation of appropriate interaction curves. $\chi_{MB} \geq 1.0$ results can also be pointed out, indicating a reserve of resistance up to 10%, mostly due to conservative estimates of R_{RESIST} adopted here (Eurocode 3 equations).

These results confirm the potential of the OIC approach to capture the behavior of beam-columns

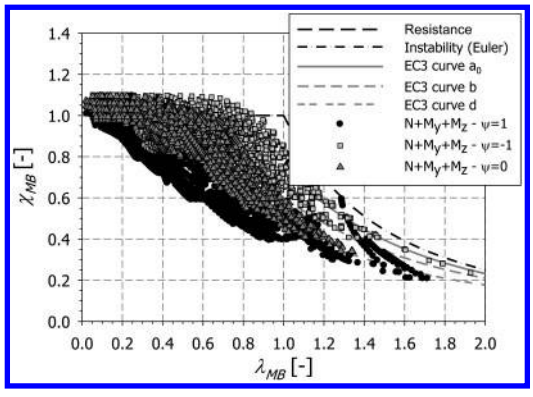

Figure 8. FE results for member under compression and biaxial bending.

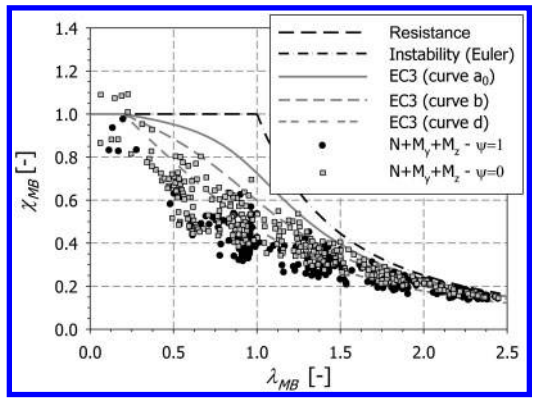

Figure 9. Members with slender sections – Global & local instabilities.

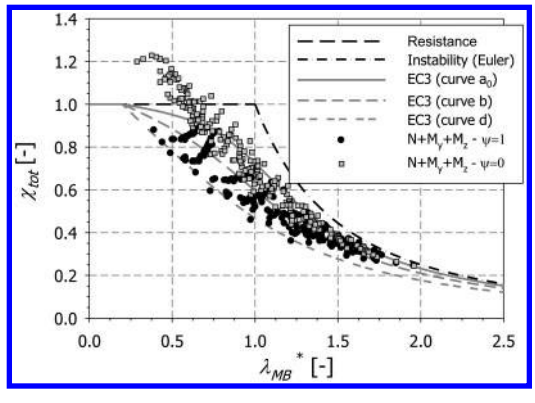

Figure 10. Members with slender sections – "DSM-like" approach.

in a straightforward manner, i.e. without resorting to so-called member interaction formulae. Provided the governing parameters are identified, the possibility to derive accurate and suitable, mechanically-based interaction curves seems obvious, and is actually under completion.

As the last and most complex structural behavior being investigated, the case of members with slender sections is addressed now, i.e. situations involving both local and global buckling – so-called "coupled instabilities". In this respect, some 2 000 non-linear shell-FE calculations with suitable sets of initial imperfections were computed for (exaggerated) slender sections, with a series of parameters as follows:

- 6 different sections defined for being slender either i) for the flange or for the web only, or ii) for both flange and web:
- 4 values of the global relative slenderness λ_{MB};
- $\psi = 1$ and $\psi = 0$ bending moment distributions;
- Various loading situations, again from simple compression or major-axis bending to combined loading situations (predominantly $N + M_y + M_z$);

All sections have been shown to exhibit an important influence of local buckling effects, with χ_{CS} values ranging from 0.4 to 0.9, depending on the load combination and on the level of web-flange interaction within local buckling modes.

Figure 9 shows the obtained results, where the horizontal axis refers to λ_{MB} – calculated from Equation (1) with an R_{STAB} value relative to global instability; χ_{tot} values reported on the vertical axis are those obtained from GMNIA shell computations, and therefore include local and global instability effects.

As can be noticed, the influence of local instability, visible at low λ_{MB} values, is often significant. Also, the complex coupling between local and global instabilities generates a rather large scatter.

These results show that additional investigations are required to provide an efficient treatment of coupled instabilities by means of the OIC. Further developments on this topic are in progress, and several ways of dealing with this coupling are actually under scrutiny, such as a "DSM-like" approach (cf. AISC 2005), where λ^*_{MB} is defined with R_{RESIST} being substituted by $\chi_{CS}.R_{RESIST}$; promising results can be shown, such as those of Figure 10.

5 CONCLUSIONS – ACTUAL AND FUTURE INVESTIGATIONS

The present paper contributed to evidence the potential for the Overall Interaction Concept to become a reliable and practical alternative to the current well-known design rules to account for the interaction between resistance and instability effects. In particular, results on both sections and members, as well as for simple or combined load cases have been presented; they demonstrate that, although being based on simple principles and with straightforward application steps, the OIC may appear as an accurate and consistent approach, and serve as a basis for the next generation of standards and practical tools, especially in the frame of an increasing use of high steel or ultra-high steel grades.

The OIC approach is actually at the core of the S.T.S.S. project ("Simple Tools Sell Steel", STSS 2012), whose main objective is to develop and assess new design concepts to predict accurately the response of members made of standard and high-strength steel up to collapse. The project focuses on cross-sectional and member resistance, materials with non-linear behavior, and on the development of new criteria to allow for plastic analysis. It will result in new practical tools and design software, and provide the scientific background for the implementation of an OIC approach in design codes.

Besides, OIC-based investigations on high and ultra-high performance fiber concrete elements (columns and beam-columns) are currently under way. Also, applications to other materials are contemplated (composite sections, stainless steel, aluminum, structural glass. . .).

As a consequence of the disappearance of the classification concept, investigations within fire and earthquake steel design are necessary. Further, the OIC approach and principles, as described herein, should appreciably improve the design of specific members where coupled instabilities and/or complex solutions to implement require (partial) numerical solutions and the associated conceptual framework (e.g. tapered members, cellular beams. . .).

Influence of imperfections and geometrical discontinuities on the behavior of the steel towers

A.I. Dogariu & D. Dubina
"Politehnica" University, Timişoara, România

ABSTRACT: This paper analyzes the possible influence of different types of imperfections on the behavior of the steel towers. Two types of tubular towers, exposed at wind load, will be described. The first one is a wind tower of thin-walled circular section and the second one a high-mast lighting tower of polygonal cross-section. In the first case the discontinuities are due to the bolted ring stiffened joints, while in second case are the press-lapped joints. The specific technological imperfections raised from lack of evenness of joints and residual stresses caused by pressing are interacting with the usual cylindrical shell imperfection. Without experimental tests, the study offers the references for the sensitivity of such structures to imperfections and geometrical discontinuities on the buckling behavior.

1 INTRODUCTORY REMARKS

1.1 *Common applications of the steel tubular towers*

The proposed paper analyzes the influence of different types of possible imperfections on the behavior of the steel towers.

The steel towers are mostly used as supporting structures for wind turbines, lighting systems, communication technologies equipments, etc. Some of the most typical details and technological features of tubular towers, exposed at wind load, will be described.

Nowadays the society should attempt to fully exploit the most from available environmentally friendly and renewable energies sources. In this context, lately the wind power resources receive a major attention from the national and European regulations and legislation that sustain their development and permanent increase of the installed capacity. For the wind tower, the following structural concepts are used: concrete, hybrid and metallic towers, which can be lattice towers, small guyed poles or tubular towers. Even if have a higher cost, due to their structural advantages in case of large application, one can notice an significant increase in the use of the of thin-walled circular section for supporting the wind turbines.

The communication facilities as cellular worldwide networks, air traffic control, satellite reception systems, receivers and terrestrial reception antennas for radio and TV, and distribution technology for community antenna nets, have become indispensable for modern society and for the people comfort. As a direct consequence in the last decades this industry have greatly expanded, requiring a large number of supporting towers, towers which through their technological features should offer an optimal solution, both from structural and economical point of view.

An other wide used application of steel towers it's found in case of high masts lighting towers, that reach heights up to 70 m for big sports stadiums where are required high level for night shoots, and therefore considerable heights and remarkable number of floodlights. If for the before mentioned applications are used a ticker circular cross-section, in case of lighting-masts a thin polygonal cross-section is more rational to be used because of the smaller height and reduced operational loads

1.2 *Technological features*

The research studies trying to optimize the steel towers are mainly concentrated on two directions, regarding the optimization of the cross-section and element shape and the connection procedures.

The first one consists in choosing the most appropriate shape of the cross-section feasible from the technological point of view, together with the proper variation of the cross-section diameter along the height. The above parameters are dependent on the design loads magnitude and stress level, height of the structure, and the nature of the local loads effects.

Generally the tubular wind towers reaches heights over 50 m (100–140 m) supporting very heavy turbine mass, requiring large base that frequently exceed diameters of 3 m and wall thickness of 30 mm. Due to large geometrical dimensions, the 20-30 m expedition segments are obtained by rolling of the steel plates in such a way to obtain a shape of a truncated cone (see Figure 1). Each strip is welded on the longitudinal direction (see Figure 2a) and after connected with the

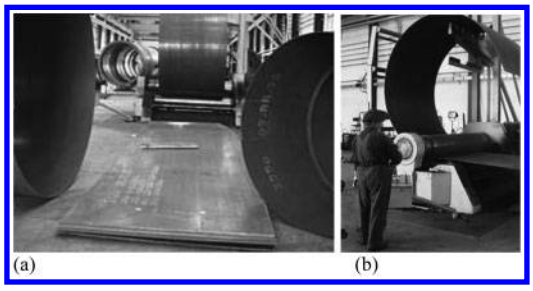

Figure 1. Steel strip fabrication: cutting (a) and rolling (b).

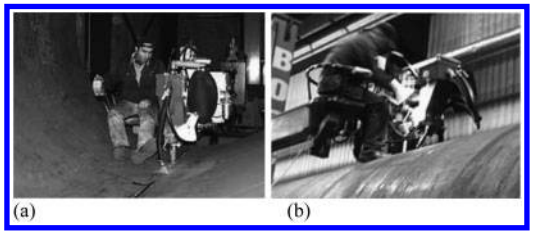

Figure 2. Welding of the tower segments.

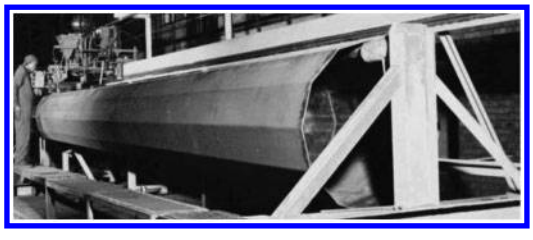

Figure 3. Cold forming of lighting-mast segments by folding the steel plates.

following next strip by a transversal circular weld (see Figure 2b) carried out by automatic MAG process.

Because of the smaller heights and reduced operational loads, compared with wind towers, the monotubular tapered steel lighting -masts have a base section that usually don't exceed 2 m in diameter and 10 mm thickness of the walls that allow to obtain the truncated cone segments polygonal cross-section by cold folding the steel sheets (see Figure 3) and subsequent external longitudinal welded along the slant.

The possibility to improve the element local behavior by longitudinal folds that acts like stiffeners allow to obtain very slender shape as well a reduce material quantity.

The second intensive investigated aspect that has a paramount importance is the segment joining method. The authors of this study believed that technology used for the connection may introduce a series of local effects with a direct influence on global behavior of the structure. In case of wind tower are traditionally used flange connection (see Figure 4) and more recent, friction connections (see Figure 5).

This connection have been studied in detail and extensively used in many applications. For both of

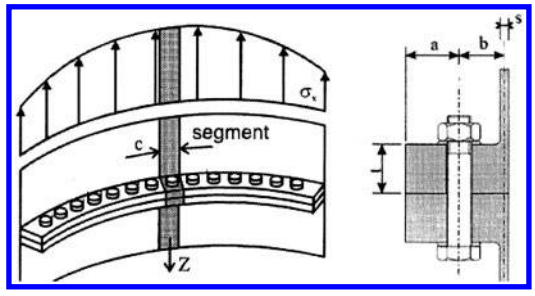

Figure 4. Calculation model for traditional bolted flange connection (L-flange / half of the T-stub connection EC3).

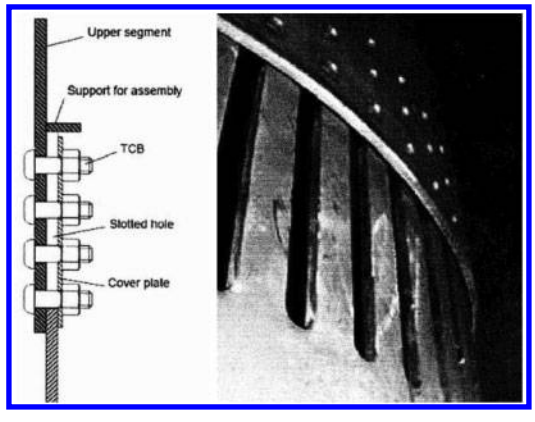

Figure 5. Friction connection between two segments using tension control bolts.

Figure 6. The high-mast lighting from "Dan Păltinişanu" soccer stadium, in Timişoara.

these connection typologies, in scientific literature, research reports and design codes, one can found: experimental results, mechanical behavior characteristics, finite element modelling strategies for numerical simulations and complete analytical models for both strength and buckling verifications. Due to this fact is very easy to control and to avoid all the undesirable effect that can introduce significant imperfection in such a way to strongly compromise the tower safety. For such connections, the EN 1993-1-6, suggest introducing the intended offset at a joint and an accidental eccentricity.

In case of lighting-mast a press-fit interference jointing is used. The connected segments (see Figure 6) act as shaft and bracket and are to be assembled at site by forced overlapping (see Figure 7).

Figure 7. The forced overlapping process of joining the shaft segments.

This type of connection technology gives unique assembly simplicity and quickness as well as a cheaper price, and is suitable when aren't imposed very sever geometric deviation (final length of the mast).

As a jointing method is very common for mechanical tools engineering, but is not so used in civil engineering applications. First important difference in application of this jointing method is the fact that in case of machining thick cylinders are used and for civil engineering structures thin-walled cylinders are used. Also the mechanical joint must be able to take and transmit the torque moment, meanwhile in structural application this connections works in bending. The reduce thickness of the segments cross-sectional walls may lead to the conclusion that the segments are forced overlapped until the cross section material yield occurrences and the hardening phenomenon. In the machining applications this connections works by friction, and was normal to initially suppose that the same working principle will be apply also for lighting-masts.

The authors of this article didn't find any available studies of this type of connection for structural application or standard rules for design and accounting the mechanical behavior, so this study will try to identify some of the possible effects that can appear due to the connection behavior. The obvious effects of cold-folding of the polygonal shape section, are residual stresses and variation of yield limit. In the same time the connection technology by the site forced cold-overlapping beside significant residual stresses and high pressure forces, may also introduce geometrical deviations and discontinuities, changes of cross-section shape, that are not described in the design rules.

2 ANALYSIS CONSIDERATIONS AND DESIGN REQUIREMENTS

2.1 *Static scheme and loading conditions*

The static scheme is the simplest thing that can be realized in structural ambit. In essence, all this supporting towers are very long vertical cantilevers subjected to wind load, operational loads, seismic load etc. These design load cases acts, more or less, as uniform distributed loads along the tower height, together with a higher concentrated horizontal force (resulted from wind or earthquake load) and gravitational self-weight force at the top of the tower, were either the wind turbines, either communication equipments or floodlights panels are position. These loads pattern induce in the structure mainly bending effects.

In order to find-out the internal forces needed for the global check of the tower capacity, in a simplified manner this types of structures may be treated, as a cantilever bar of class 4 thin circular section and it can be calculated as a 1D beam structure, with or without the account of global imperfection, using an elastic material law.

Even if the design and verification seems at first sight a simple problem, due to the complexity of curved shells behavior, refined local analysis using 3D shell models with 2D finite elements are needed, but can be limited for relevant segments only. These free body segments should be placed between two, consecutive or not, flanges that will assure the appropriate boundary condition, i.e. radial restrained. These segments must be chosen such as to contain the critical cross-sections of higher internal forces (i.e. bending moment), cross-section reduction due to the visiting door or ventilation opening, cable entry etc., or zones of expected high local imperfections due to the residual stresses, connections details and discontinuities.

2.2 *Design concepts and normalization*

The European design codes-series, by EN1993-1-6 cover the most of the resistance and stability design criteria for this types of tubular structures and by EN1993-1-8 the connection design issues. Also EN1993 part 3-1 gives specific rules for tower and masts, and some useful information can be find in EN1993-3-2 Chimneys.

Beside the general design issues stated in EN1993, other specific regulations comes to offer more detailed or more clear design methodologies and requirements for wind tower and for high-mast lighting, like IEC 61400-1 (2005-08) Wind Turbine – Part 1:Design requirements (International Electro technical Commission), respective „Technical Report number 7 – High Mast Lighting – Specification for design, manufacture, assembly, erection, painting, testing and maintenance" (The Institution of Lighting Engineers).

Because the European Standard is not permitted to include explanatory or educational materials, in European Steel Shell Buckling Recommendations (2005) which are fully compatible with EN1993-6, designers can find extended rules to cover all the arisen problems of steel tubular section.

The EN1993-6 Standard is concerned with the requirements for design against the ultimate limit states of: plastic limit (LS1), cyclic plasticity (LS2), buckling (LS3) and fatigue (LS4). The described structures are all very slender (diameter/total height ratio, ~1/25–1/35) and with thin walls (thickness/diameter ratio, ~1/100-1/150), so the buckling limit state (LS3) design criterion is the most server one. Also fatigue limit state should be considering, but is beyond the goal of this study.

From the standard procedures arise three levels of design procedures at LS3: Buckling (see Figure 8),

starting from a complete hand calculation based on analytical formulas, a simple computer calculation, and a advanced complete numerical-based design.

For carrying out the various limit states LS verifications and checks are required and are available the following types of analysis, depending on considering or ignoring the material and geometrical nonlinearities and second order effects, and the introducing of equivalent geometrical imperfections.

The most common procedure, based on LBA and MNA available on most commercial software, used in practical design for buckling capacity assessment is shown in Figure 9.

The simplified procedures are rather conservative, so the most accurate and complicated in the same time is GMNIA. Even if is one of the most complex and precise design method it require the introduction of the imperfections. The most important effects are those due to geometric imperfection of shape.

2.3 *Imperfections and their expected effects*

For common design cases the EN1993-6 specify the prescribed relevant geometrical imperfection for

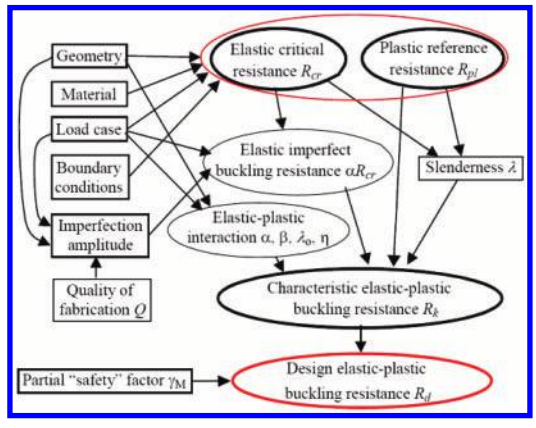

Figure 9. Buckling strength assessment using simple computer calculations.

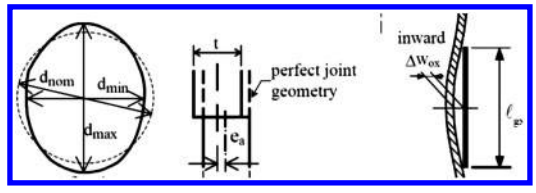

Figure 10. Geometrical imperfections prescribed by EN1993-6.

cylindrical shell, to take into account of, i.e. out-of-roundness (deviation from circularity), eccentricities (deviations from a continuous middle surface in the direction normal to the shell along junctions of plates), and local dimples (local normal deviations from the nominal middle surface) (see Figure 10).

The design impose accounting of the prescribed types of the imperfection patterns in order to fully understand and quantify their influence on buckling behavior. In case of shells even small imperfection may cause significant drop of the capacity. Depending on shell geometry and loading type, some forms of imperfection or higher amplitude imperfections strengthen and increase the buckling capacity. The assessment of the form and amplitude of the imperfection it is most important and also very difficult as specially when few or non regulation exist in this way. It is the case of forced overlapping connections of high mast lighting.

In this case the structure imperfections may raise from lack of evenness of joints, flexibilities of connections, and residual stresses caused by pressing are interacting with the usual imperfection. The available design regulations, i.e. TR 7 – High Mast Lighting, didn't make any special reference related to the connection design principle and behavior characteristics. Accounting the normative lack of information it is believed that the technology of press-fit connection should avoid appearance of any discontinuity, and the shaft could be consider as a continuum element. Even there are not available experimental results, the numerical study is based on real applications and tries to

offers the references for the sensitivity of such structures to imperfections and geometrical discontinuities on the buckling behavior.

3 NUMERICAL SIMULATIONS

3.1 *Numerical goal*

Several numerical investigation have been carried out for assessing the prescribed influence of imperfections, most of them for wind towers, and the effect of discontinuities introduced by openings. Also the authors of this paper have previously investigated the benefic behavior of the cold-folded polygonal tubular shaft for lighting mast. Even if the governing phenomenon are very complex, the capacity of this type of structures may be obtain using a very simple, rather trivial formula (1):

$$M^* = \frac{M_p}{\gamma_M}\left\{0.9241\cdot\left[\left(90\cdot\sigma_y\frac{D}{NEt}\right)^{-0.2858}\right]-0.1266\right\} \quad (1)$$

From these reasons, this study will present only the numerical simulation program dedicated to offer a qualitative view related to the overlapped connection behavior and possible modelling and influences.

Starting from the high-mast lighting from "Dan Păltinişanu" stadium from Timişoara, several connection geometries have been study to verify the above mentioned hypothesis that the connection don't introduce unfavorable effects. It is believed that because of forced overlapping appearance of any eccentricities will be avoid, but the flexibility of the connection and the state of stress will influence the behavior.

Cross section of the 55 m height mast is a regular polygon with 20 sides with wall thickness of 10 mm for the bottom segments up to 35.38 m, 8 mm up to 44.82 m and 6 mm for upper segments up to 55.00 m. The diameter varies from 1400 mm at base to 500 mm at the top.

3.2 *Finite element model*

Using ABAQUS Software 3D Shell models have been build to study the effect of the connection discontinuity.

In a first step, thirteen connection along the shaft have been numerically investigated. Three types of models have been build. An explicit contact model (T_{i-i+1}) (see Table 2) with the consideration of separate segments and two continues models. In first one (T_{const}) considering the constant thickness of the upper segment along the overlap length, and in the second one (T_{duble}) the added thickness of the two connected segments.

For the explicit model, considering that the connection work like a friction one, was supposed that the diameter misfit will cause the hardening of the sections and will introduce a uniform pressure p_n that

should facilitate the appearance of a sufficient friction force in order to assure the connection resistance and rigidity. Due to the high level of the appeared friction forces, bending behavior and failure of the connections, the friction law was neglected in the after and presented FE models results.

The segments assembly was considered double pined. The load was applied in two steps. In the first step the two segment were pressed, imposing to the upper support a displacement equal with overlap length. In the second Static Risk step an equal imposed rotation was applied at the free ends (see Figure 11).

In a second phase considering an appropriate detailing of the connection in such way offer continuity (maybe a larger overlapping lengths, more fit diameters to limit or remove the yield zones etc.), a comparison between the two continuous models

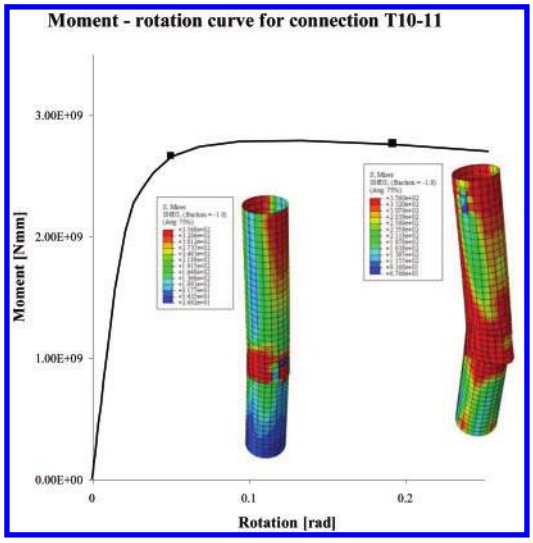

Figure 12. Numerical result for T10-11.

(i.e T_{const} and T_{duble}) accounting prescribed imperfection (i.e. out-of-roundness, local dimples) have been performed in order to emphasis the eventual behavioral differences in case of global analysis.

3.3 *Numerical results and comments*

Using the described geometrical parameters from Table 2 the moment-rotation curves shown a more flexible and less resistant behavior ($M_c = 2850$ kNm < $M_{sect} = 4200$ kNm) of the connections, fact that should be considered in the global analysis of the structures. In the Figure 12 are shown the results for model T10-11, in terms of moment-rotation $M_c - \theta_c$ (2) of the connections and failure modes. All the other models exhibits similar behavior.

These results emphases the need to clearly identify and characterize the effects of local behavior of such type of connections and to be accounted through specific imperfections that should be codified and use together with the geometrical imperfections prescribed by EN1993-6 (see Figure 10).

How it was stated before, it is believed that proper connection detail can assure a better behavior and to limit the negative effects notice based on previous numerical simulations. Further investigation will be done in this way in future studies. From this reason the next step of this study have investigated the above described continuous models.

The connection difference haven't reveal any significant behavior difference or different sensitivity at the various pattern of considered imperfections (see Figure 13). As a comment, it is believed that even if a small benefic effect have been shown in case of T_{duble} model and clearly acting like a local ring stiffener, for the global numerical analysis the two models are equal, and the T_{const} model being more simple is recommended to be used.

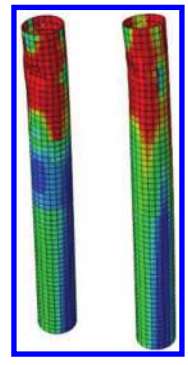

Figure 13. Comparison between T_{duble} and T_{const} failure modes.

4 FINAL REMARKS

The present study doesn't intend to offer a final and undisputed solution of the above identified problems however it can be regarded as a general guidelines, proposing a way of investigation and showing difficulties of approaching numerical solutions of these structures. Without the support of a relevant program of experimental investigations results, enabling for physical identification of problems and a base of calibration the numerical simulation provide qualitative estimation only.

Consequently, further investigations still are required in order to offer clear recommendations for maximum diameter misfit, minimum overlap length and imperfection to be considered if the recommended parameters are not respected.

ABSTRACT: Restrictions of space and height are often imposed to residential, commercial and industrial buildings with one, or several floors, due to aspects like regional regulations, technical, economic or aesthetic nature. In order to provide the passage of pipes and ducts with large diameter under steel girders, that normally requires great heights, sometimes leads to floors building highs with an unviable magnitude. Among others, castellated beams are a possible structural solution to overcome these obstacles. These beams are considered stability issues, since the unbraced span lengths generally reached by them are often long enough to cause instability effects. However, the substantial enhancement in the flexural strength of such members, due to the extra height coming from the manufacturing process in relation with the original profile, combined with the economy of material and utility services, ensures to the designers the attractiveness of this solution, especially when applied to large spans. The present investigation aims to develop a numerical model that calibrated with experimental results, enables the development of a parametric analysis centred on the finite element method. This analysis aimed to determine the structural behaviour of the castellated beams and their associated failure mechanisms, considering an elastic-plastic behaviour as well the geometric non-linearities. The results showed coherency and no relevant technical objections were verified, when considered the application of the castellated beams in alternative of the traditional plated beams since the advantages arising from the beams openings justify their application.

1 INTRODUCTION

In order to allow the passage of large diameter pipes and ducts under steel beams or due to architectural demands, large beam heights are normally required. A often used solution is the use beams with webs containing one or more openings with various geometries to accommodate the passage of pipes and other purposes. One of the commonly adopted web openings are the cellular (circular) and castellated (hexagonal) – with the last being the focus of the present paper.

Castellated beams are characterized by their multiple polygonal openings symmetrically distributed along the beam length. The present investigation aimed to develop an elasto-plastic numeric model including geometric nonlinearities, calibrated with experimental results [7], to evaluate the structural behaviour of castellated beams focused on their collapse mechanisms. This study had also the objective to assess, quantify and determine the influence of geometric characteristics differences of castellated beams when compared to solid in relation to the solid beams with the same disproportions for various span lengths. The methodology was based on a parametric analysis with the finite element method [1].

2 DESIGN STANDARDS

Nowadays there are several structural design standards and design procedures for steel beams that considers the possibility of using web openings. However, in general, these are limited to the restriction of parameters and scenarios where the gaps may, or may not, be adopted depending on the geometrical configurations of the structural element in question. Considering the European standard Eurocode 3 [5] as a reference to the design theoretical values of the elastic critical moments were evaluated, using two design alternatives: For beams with double symmetry sections, like the castellated beams profiles studied in this work, the

general design method is depicted by equation (1) for the critical moments calculation.

$$M_{cr} = A\left[\sqrt{B+C+D} - E\right] \quad (1)$$

where

$$A = C_1 \times \pi^2 \times E \times I_Z / (k_z \times L)^2 \quad (2)$$

$$B = (k_z / k_W)^2 \times C_W / I_Z \quad (3)$$

$$C = [(k_z \times L)^2 \times G \times I_T] / \pi^2 \times E \times I_Z \quad (4)$$

$$D = (C_2 \times z_g)^2 \quad (5)$$

$$E = C_2 \times z_g \quad (6)$$

with where: C_1 and C_2 are coefficients that depend on the type of loading and boundary conditions and special constraints; k_z is the end sections rotations restriction in the minor inertia axis; k_w is the warping restriction, also at the end sections; L is the beam lateral bracing length; E is the material longitudinal elasticity modulus; G is the material transverse elasticity modulus; I_z is the minor axis moment of inertia; C_w is the warping constant; I_T is the SaintVenant torsion constant; z_g is the distance measures from the load application point to the shear centre in relation to the section gravity centre. In the second particular method, considering the applicable boundary conditions the following equation was used:

$$M_{cr} = \alpha_m \times M_{cr}^E \times \left(\sqrt{1 + \left(\frac{0{,}4\alpha_m y_Q}{M_{cr}^E / N_{cr,z}} \right)^2} + \frac{0{,}4\alpha_m y_Q}{M_{cr}^E / N_{cr,z}} \right) \quad (7)$$

where: α_m is the factor that considers loading conditions, being equal to 1.35 for the studied beams; y_Q is the distance between the load application point to the section centre of gravity (in this case coincides with the shear centre); N_{cr}, z is the column Euler load evaluated on I_z axis that corresponds to the section lowest inertia and with a length L corresponding to distance between laterally braced sections; M_{cr}^E is the critical moment of a solid web beams subject to pure bending moment. According to Eurocode 3 (2005), the LTB (Lateral Torsional Buckling) resistance of the analysed members is performed with
while the beam plastic
moment capacity can be calculated with equation (9).

$$M_{b,Rd} = \chi_{LT} \times \frac{W_y \times f_y}{\gamma_{M1}} \quad (8)$$

$$M_{pl,Rd} = \frac{(W_y \times f_y)}{\gamma_{M0}} \quad (9)$$

where: W_y is the section elastic static moment; f_y is the material yield stress; γ_{M1} is the safety factor; χ_{LT} is the reduction coefficient due to lateral buckling.

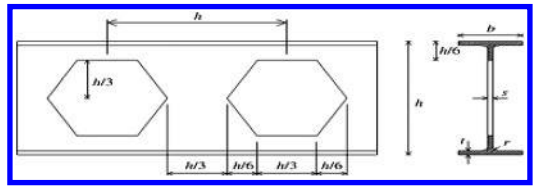

Figure 1. Cross-section and opening geometry (Zirakian & Showkati, 2006).

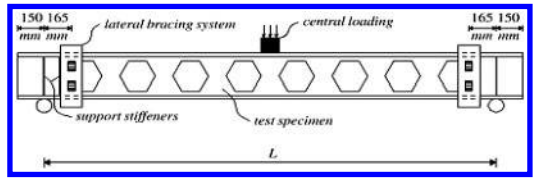

Figure 2. Adopted boundary conditions geometry (Zirakian & Showkati, 2006).

3 NUMERICAL MODELS

The numerical model calibration was carried out with the Zirakian & Showkati (2006) experiments [7], for a castellated beam (C180-3600) with the following dimensions (in mm): nominal height (h = 180) and measured (h = 176); flange width (b_f = 64); flange thickness (t_f = 6.3); web thickness (t_w or s = 4.4); curvature radius (r = 7) and length (L = 3600). The studied castellated beam openings were made with hexagonal non-regular polygons so that the maximum width and height of the opening are equal, as well as the side lengths (horizontal) and the smallest distance between them occur between its ends, Figure 1.

The experimental tests were performed on simply supported beams with two stiffeners near of the supports to prevent the web local buckling at these points due to the concentration of high shear stresses, Figure 2. The material mechanical properties that were used in experimental and numerical model of C180-3600 beam were: a 206010 MPa elasticity modulus, and yield stresses of 279.31 MPa (flange) and 233.93 MPa (web) and ultimate stresses of 894.35 MPa (flange) and 892.23 MPa (web).

The developed numerical model during the calibration phase had its geometry, loading and boundary conditions based on the experimental beam. Slender webs, as well as beams with large span lengths, in practice, are not perfectly straight. So it is essential to properly represent these imperfections in the finite element numerical model. The initially perfect beam (without any kind of imperfection), was evaluated as linear elastic. The elastic buckling load evaluation was performed based on eigenvalue analysis using the ANSYS (2009) program. The deformed configuration resulting from the beam first elastic buckling mode were introduced as the initial imperfection of the model.

Later, with these imperfections, the beam model was submitted to a non-linear elasto-plastic analysis, with the controlling displacement strategy, until the

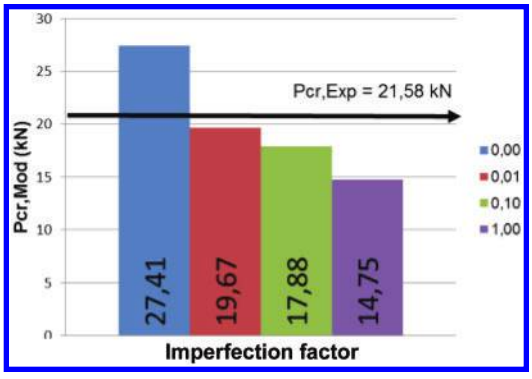

Figure 3. Influence of the adopted initial imperfection magnitude (C180-3600). Copying old text onto new file.

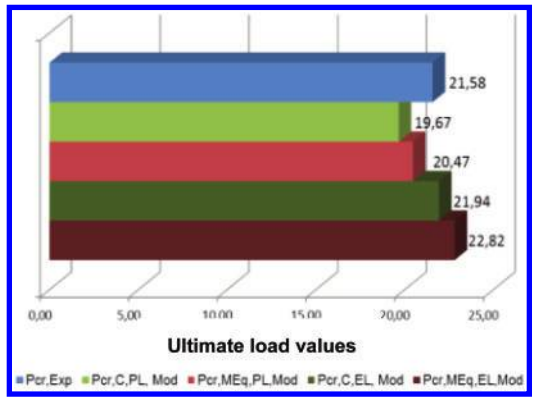

Figure 4. Ultimate load comparison (C180-3600).

lateral buckling LTB failure peak followed by the unloading phase. However, albeit within the limits allowed by the standard, the optimum magnitude of the initial imperfections are initially unknown and needed to be determined. A numerical model sensitivity analysis followed and its results are shown in Figure 3.

As has been seen, between the two extremes of the examined interval, the critical load nearly doubled, indicating the large model sensitivity to initial geometric imperfections variations. The imperfection factor optimal value however, was found to be close to the minimum imperfection values (Figure 3). These facts enabled the adoption of a 0.01 imperfection factor to be used in the nonlinear analysis. Additionally, in order to access the results robustness, solid beams, equivalent to the investigated castellated beams, were also analysed with the same initial imperfections.

Figures 4 and 5 depicts the above mentioned results where $_{Pcr,Exp}$ is the castellated beam critical load obtained in a plastic analysis in the experimental model; $P_{cr,c,EL,Mod}$ is the castellated beam critical load obtained in an elastic analysis on the numerical model; $P_{cr,C,PL,Mod}$ is the castellated beam critical load obtained in a plastic analysis on the numerical model; $P_{cr,MEq,El,Mod}$ is the equivalent solid beam critical load obtained in a elastic analysis on the numerical model; $P_{cr,MEq,PL,Mod}$ is the equivalent solid beam critical load obtained in a plastic analysis on the numerical model.

As can be inferred from Figure 4, for the critical loads of beams C180-3600 the numerical models non-linear analysis loads were 8.85% lower than the experiments, while the elastic critical loads were found to be 11.5% higher than those obtained in the nonlinear analysis, ratifying the numerical model calibration.

Figure 5 presents the load vs. lateral displacement curves obtained in numerical model and experimental results, superimposed at the section height most critical region (compression flange) for the beam C180-3600. The numerical curves followed the trend and the direction of the observed in the experimental curves.

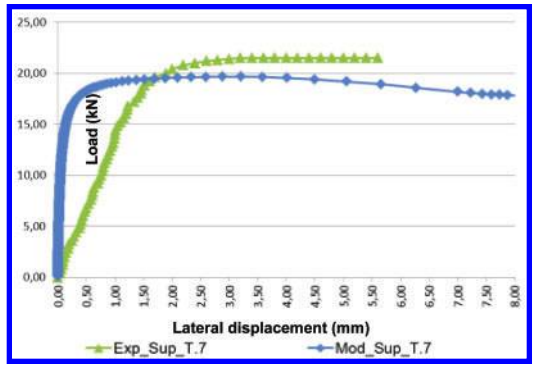

Figure 5. Load vs. lateral displacement curves (numerical & experiments) – top flange.

The above mentioned results enabled the adoption of the 0.01 initial imperfection factor in numerical models of this work since their ultimate loads were closer to the value obtained experimentally.

4 PARAMETRIC ANALYSIS AND RESULTS

A simplified verification of the LTB resistance is proposed in the Eurocode 3 (1998), which is nothing more than a calculation method similar to what is used in the solid beams, considering the reduction of the cross-section geometrical characteristics due to the openings. This motivated an evaluation of the elastic critical moment of these elements with the ANSYS (2009) program.

Once calibrated the numerical mode was used to all the investigated beam spans formed from by European IPEs steel profiles (200, 300, 400, 500 and 600), with the aim of covering from simple residential roofs and small frames (pipe racks, etc.) up to large structures such as bridges and viaducts. The Profiles have been chosen to embrace various design alternatives. Due to space limitation the present paper only highlights the

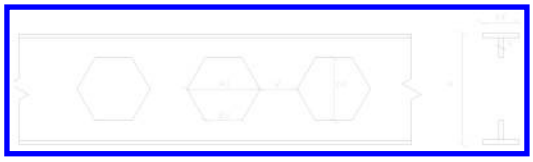

Figure 6. Castellated beams geometrical characteristics.

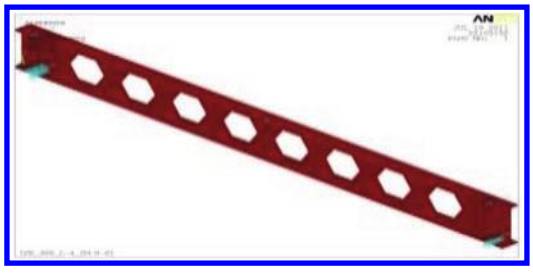

Figure 7. Adopted boundary conditions.

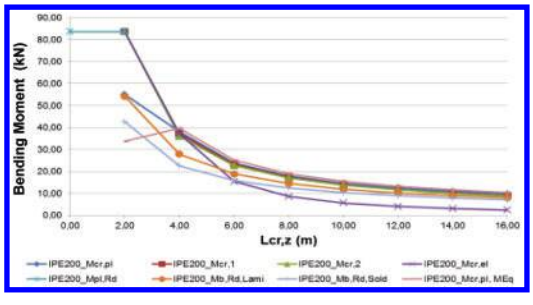

Figure 8. Moment rotation curves for the analysed IPE200 profile.

IPE 200 results. The studied castellated beams geometry are illustrated in Figure 6 where A0 and h0 are equal an all the openings had a hexagonal geometry.

In the case of the IPE 200 the geometric parameters were (in mm): height ($H_i = 200$); flange width ($b_f = 100$); thicknesses of the web (t_w or $s = 5.6$) and flanges ($t_f = 8.5$); curvature radius ($r = 12$); castellated beam height ($H_n = 300$); hole height ($H_0 = 200$); hole width ($A_0 = 200$); The hole base ($B_0 = 100$); area ($A = 2.164.8\ mm^2$). The material was modelled as a perfect elasto-plastic steel, bilinear and isotropic, but the properties and characteristics were changed to the material nominal values: modulus of elasticity ($E = 210\ GPa$); yield stress ($\sigma_y = 275\ MPa$).

The boundary conditions in general were maintained, the only modification was the location of the lateral braces that were positioned on the support, but acting on both ends of the beam at the top and bottom flanges. Figure 7 presents the new beams configuration where it should be noted that the warping is free in the support sections and the loading was applied as a prescribed displacement.

In this figure $M_{cr,1}$ is the standard elastic critical moment; $M_{cr,2}$ is the general elastic critical moment;

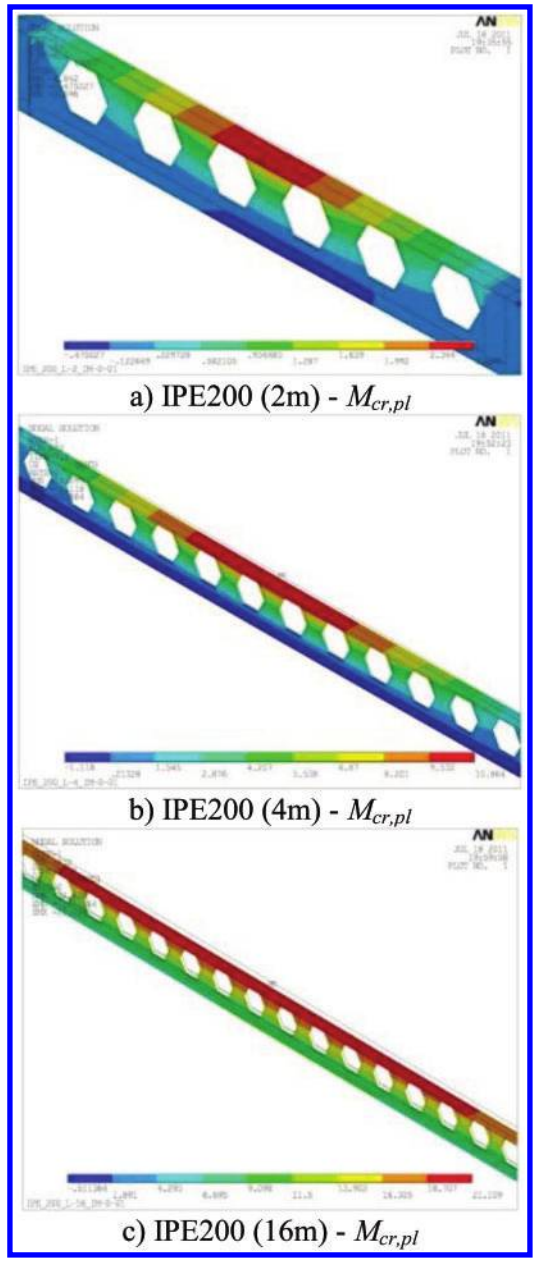

Figure 9. Lateral displacements UZ (in mm).

$M_{b,Rd,Lami}$ is the hot-rolled beam LTB critical moment; $M_{b,Rd,Sold}$ is the welded beam LTB critical moment; $M_{pl,Rd}$ is the hot-rolled beam plastic moment; $M_{cr,el}$ is the numerical model elastic critical moment; $M_{cr,pl}$ is the plastic critical moment from the nonlinear analysis; $M_{cr,pl,MEq}$ is the plastic critical moment from the nonlinear analysis for the equivalent solid beam; $M_{cr,1,Mor}$ is the elastic critical moment standard for the solid original beam; $M_{cr2,Mor}$ is the elastic critical moment for the general case of the solid original

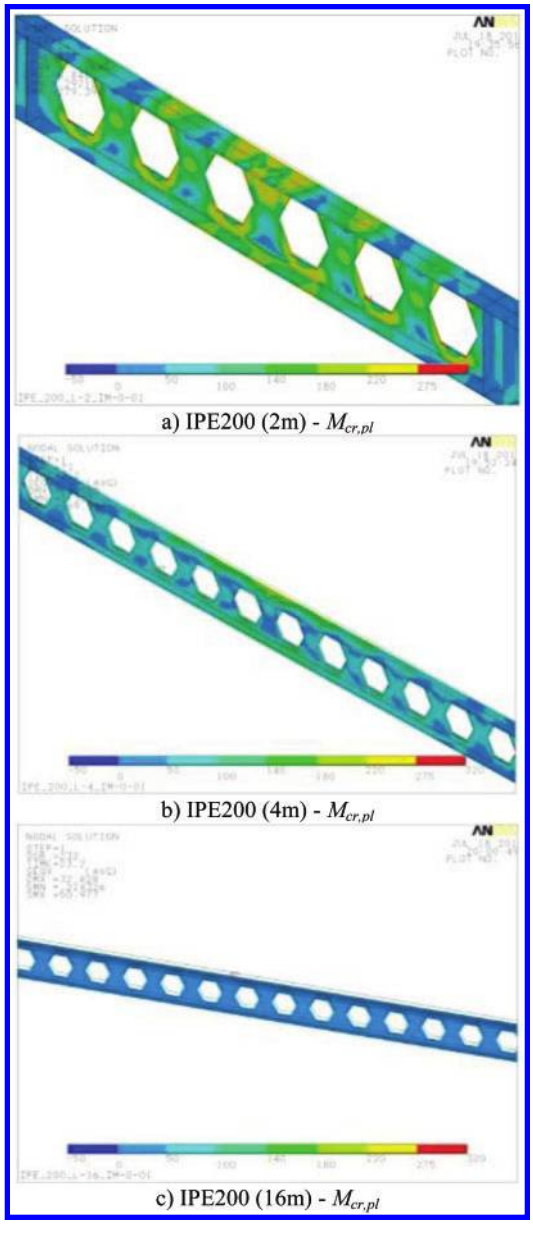

Figure 10. Von mises stress distributions (in MPa).

girder. The plastic moment capacity of the IPE 200 section ($M_{pl,Rd}$) was 83.57 kNm. Figure 8 below depicts the curves for the critical moments mentioned above.

To illustrate the obtained failure mechanisms: web local buckling (WLB) and the lateral torsional buckling (LTB) the spans present in Figures 9 and 10 were selected.

Notwithstanding the previous figures only refer to the IPE 200 figure 11 presents some data with the other analyzed profiles with the same spans since a similar behaviour has been observed on all the investigated beams regardless of the adopted profile.

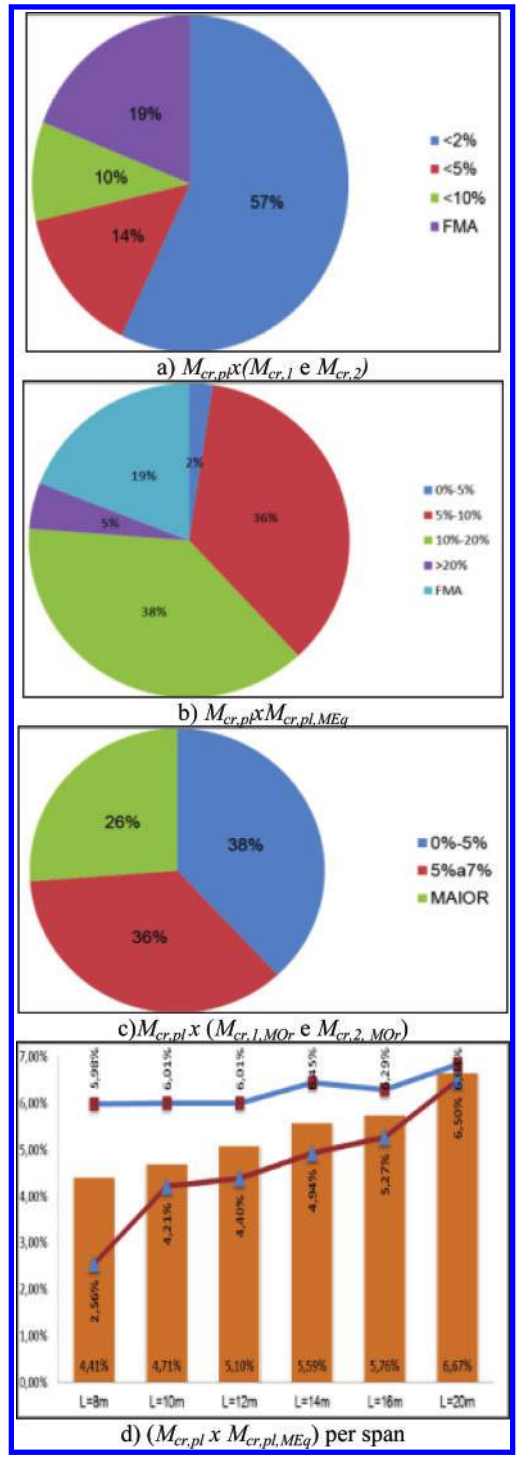

Figure 11. Results comparisons in terms of distribution of errors.

5 CONCLUSIONS

This paper presented some aspects of the structural behaviour of steel beams with web openings of

hexagonal geometry and castellated beams. From the results it was possible to observe that the vast majority of the differences between the moments ($M_{cr,pl}$ x ($M_{cr,1}$ and $M_{cr,2}$)) were less than 2% indicating that using the Eurocode 3 (1998) procedure for calculating of the elastic critical moment of beams castellated using the formulation applicable to solid beams, but considering the geometric differences between cross sections, can be used effectively for verification of this limit State. This can be done as long as the investigated beams did not present large initial imperfections.

The moment capacity results ($M_{b,Rd,Sold}$ and $M_{b,Rd,Lami}$) were consistent with the developed model, since the curves related to the rolled profiles LTB resistance ($M_{b,Rd,Lami}$) were closer to the curves obtained with the numerical nonlinear modelling ($M_{cr,pl}$).

For spans up to four meters in general, the failure mechanism that determines the structural capacity is the WLB (web local buckling), which occurs due to excessive longitudinal forces in the beam web, which in turn, as a function of castellated beams geometric conformation favours such occurrence. Increasing the beam span the lateral instability becomes more evident as the failure mechanism controller. As expected, due to the highest geometric properties values for the solid beams cross sections, when compared to the equivalent castellated beams, the critical moments values were about 9% and 6.5% higher for the solid section beams. However, these values have remained close those obtained experimentally and numerically.

As in practice the castellated beams are manufactured with profiles 33.3% smaller than the equivalent solid sections when gains inherent to the reduction of the structure weight are added it becomes evident the economy provided by the castellated structural solution. The same reasoning can be applied to solid profiles originating from the castellated beams, which referred to the small additional investments that arise from the castellated beams industrialization, offer gains of bending moment capacity ranging from 5% to 20% for the vast majority of the investigated beams (74%).

Buckling mode decomposition of thin-walled members with holes

M. Nedelcu, N. Chira, H.L. Cucu & A.G. Popa
Faculty of Civil Engineering, Technical University of Cluj-Napoca, Romania

ABSTRACT: Perforated cold-formed steel members are often used in civil engineering as structural elements for residential buildings and storage racks systems. The design capacity of any thin-walled member subjected to compressive stresses is usually governed by combinations of the fundamental buckling types (global, distortional and local). The paper presents an original method based on the Generalised Beam Theory (GBT) whereby the general buckling modes, provided by the Shell Finite Element Analysis (SFEA) of perforated thin-walled members, are decomposed in terms of the fundamental buckling types. The contribution of each fundamental buckling type can be calculated, allowing a better understanding of the member buckling behaviour and post-buckling strength reserve. The main feature of this method lies in using only the GBT cross-sectional deformation modes instead of member base mode shapes.

1 INTRODUCTION

Each fundamental buckling type (global, distortional or local) has its characteristic post-buckling behaviour; consequently, the derivation of the modal participation for a general buckling mode is a crucial step in assessing the real design resistance of the member. Nowadays there are a number of specialized methods capable to provide the modal decomposition, for example the constrained Finite Strip Method, or the Generalized Beam Theory (GBT), the only problem is that they are not able to perform this task for arbitrary cross-sections, boundary conditions, and loads. On the other hand, the shell Finite Element Analysis (SFEA), the most commonly used instrument to study the behaviour of thin-walled members, can easily handle complex geometries of perforated/unperforated members and arbitrary load and member end conditions, but it has no possibility of providing the modal decomposition.

To eliminate this drawback Nedelcu (2012) developed a method for unperforated thin-walled members, able to quantify the modal participation of the fundamental deformation types for any eigenvalue FEM buckling mode provided by SFEA. The method is based on GBT originally created by Schardt (1989) and extensively developed by Camotim, Silvestre et al. (2002). A conventional GBT analysis involves two steps: (i) *a cross-sectional analysis* leading to the GBT *cross-sectional deformation modes* and corresponding modal stiffness components and (ii) *a member stability analysis* to obtain the critical loading factors and the associated mode shapes (given by *the amplitude functions*). The method presented here performs only the GBT 1st step and uses the special orthogonality properties of the cross-sectional deformation modes, to extract from any general FEM buckling mode, the fundamental mode shapes and finally the modal participation. There is no need of the second step which is by far the largest part of a conventional GBT analysis. Following the GBT classical assumptions, the membrane shear strains and transverse extensions are neglected.

The main goal of this paper is to present the theoretical extension of the GBT-based modal decomposition method for the special case of isotropic thin-walled members with holes. In principle, the method uses the same technique as for the case of unperforated elements and it starts with a classic buckling SFEA. The GBT 1st step is used only to define the cross-sectional deformation modes, each one corresponding to a fundamental buckling type. Next, they are used to extract from buckling SFEA, discrete values of *the amplitude functions* of each fundamental buckling mode on a regular mesh of points along the member's axis. For the perforated regions, special assumptions and theoretical developments are introduced. Based on the obtained amplitude functions, the modal participation is computed. For validation, the displacement field provided by SFEA is compared with the one recreated using the extracted amplitude functions and the GBT cross-sectional deformation modes. This last step provides the approximation error of the entire procedure. Based on the versatility of SFEA there are no restrictions regarding the element cross-sectional shape, loading and boundary conditions (Nedelcu et al. 2012).

2 GENERALISED BEAM THEORY – SHORT PRESENTATION

Figure 1 presents an arbitrary thin-walled member with the local coordinate system *x-s-z* and the corresponding displacement field *u-v-w*. Classical

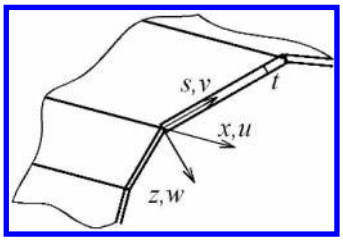

Figure 1. Thin-walled member: local axes/displacements.

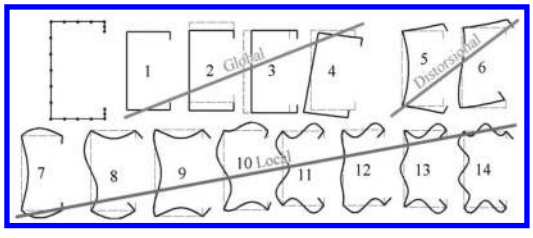

Figure 2. C-section: the cross-sectional deformation modes.

GBT assumes the classical Kirchhoff-Love hypotheses ($\varepsilon_{zz} = \gamma_{xz} = \gamma_{yz} = 0$) and also Vlasov's simplifying hypotheses (null membrane transverse extensions and membrane shear strains).

According to GBT, any displacement is considered as a linear combination of n orthogonal deformation modes, each one expressed as a product of two functions.

$$u(s,x) = \sum_{k=1}^{n} u_k(s)\phi_k'(x) \qquad v(s,x) = \sum_{k=1}^{n} v_k(s)\phi_k(x)$$
$$w(s,x) = \sum_{k=1}^{n} w_k(s)\phi_k(x) \tag{1}$$

where $u_k(s)$, $v_k(s)$, $w_k(s)$ are the components of the *cross-section deformation modes* and $\Phi_k(x)$ are the *amplitude functions* describing their variation along the member's length, and n depends on the cross-section type, the number of the fold-lines and the considered intermediate nodes. As an example, the cross-sectional deformation modes are given in Figure 2, by their in-plane shapes, for a lipped channel section.

For this particular discretisation of the cross-section, the number of fundamental modes $n = 21$, and one can see the 4 Global deformation modes (axial extension, major/minor axis bending and torsion), the 2 Distorsional modes (the cross-section exhibits edge displacements and also plate flexural deformations) and the first 8 Local modes (only plate flexural deformations).

Next, the member equilibrium equations are written based on Hamilton's variational principle, yielding the GBT system of differential equations in modal formulation. Considering only pre-buckling axial compression, the system is written (Bebiano et al. 2007):

$$C_{ik}\phi_k^{IV} - D_{ik}\phi_k'' + B_{ik}\phi_k = \lambda X_{ik}\left(N\phi_k'\right)' \tag{2}$$

where C, D, B and X are the cross-section linear and geometrical stiffness matrices provided by GBT 1st step, and N is the pre-buckling axial force. The GBT 2nd step (the *member stability* analysis) consists in solving the differential equations system, providing the critical load factors λ and the corresponding modal amplitude functions $\Phi_k(x)$, but this step is not used by the method described in this paper.

3 BUCKLING MODE DECOMPOSITION

3.1 *Unperforated thin-walled members*

A buckling SFEA of a thin-walled member is performed and the cross-sectional displacement field is extracted on a mesh of points along the member's axis ($0 \le x_1 < \ldots < x_g < \ldots \le L =$ the bar's length) and the GBT product formulation is considered according to Eq. 1:

$$u_{FE}(s,x_g) = \sum_{k=1}^{n} u_k(s)\phi_k'(x_g)$$
$$v_{FE}(s,x_g) = \sum_{k=1}^{n} v_k(s)\phi_k(x_g) \tag{3}$$
$$w_{FE}(s,x_g) = \sum_{k=1}^{n} w_k(s)\phi_k(x_g)$$

Next, the method uses two stiffness matrices, the *warping* stiffness matrix C and the *geometrical* stiffness matrix X. The first one has the following expression (involving Membrane and Bending components):

$$C_{ik} = C_{ik}^{M} + C_{ik}^{B} = E\int_s tu_i u_k ds + \int_s Kw_i w_k ds \tag{4}$$

where $K = Et^3/(12(1-\mu^2))$ is the plate bending stiffness. Matrix C is a diagonal matrix based on a simultaneous diagonalisation process of the warping and transverse bending stiffness matrices C and B (Schardt 1989).

The geometrical stiffness matrix X stands for the stiffness degradation due to pre-buckling axial force and has the expression:

$$X_{ik} = -\frac{1}{A}\int_s (v_i v_k + w_i w_k)tds \tag{5}$$

where A is the cross-sectional area.

Looking again at Equations 3 and 5, one can see the following relation

$$X_{FE,i} = -\frac{1}{A}\int_s (v_i v_{FE} + w_i w_{FE})tds = \ldots$$
$$= \sum_{k=1}^{n}\left(-\frac{1}{A}\int_s (v_i v_k + w_i w_k)tds\right)\phi_k(x_g) = \sum_{k=1}^{n} X_{ik}\phi_k(x_g) \tag{6}$$

which, written in matrix formulation, becomes

$$X\phi(x_g) = X_{FE} \tag{7}$$

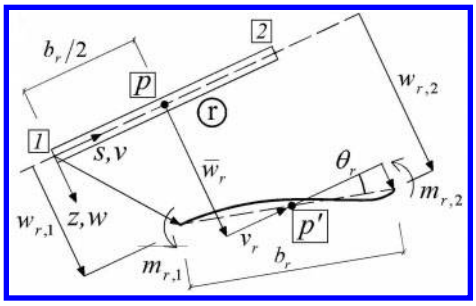

Figure 3. Discrete values of the deformation in the s-z plane.

Using the discrete values given in Figure 3 that approximate the element deformation, the expression X_{FE} becomes:

$$X_{FE,i} = -\frac{1}{A}\sum_{r=1}^{np} b_r t_r \left[v_{i,r} v_{FE,r} + \overline{w}_{i,r}\overline{w}_{FE,r} + \ldots + \theta_{i,r}\theta_{FE,r}\frac{b_r^2}{12} + \overline{m}_{i,r}\overline{w}_{FE,r}\frac{b_r^2}{12K} + \hat{m}_{i,r}\theta_{k,r}\frac{b_r^3}{360K} \right] \quad (8)$$

where np is the number of segments considered along the cross-section, delimitated by the fold-lines and the considered intermediate nodes, and having width and thickness b_r and t_r, respectively. For a segment r, $\overline{w}_r$ is the middle transversal displacement, θ_r is the plate absolute rotation, $\overline{m}_r$ and $\hat{m}_r$ are the semi-sum and the semi-difference, respectively, of the edge transversal moments m_r. The plate absolute rotations θ_r and the edge transversal moments m_r are provided by GBT 1st step for each cross-sectional deformation mode.

Next, the column vector Φ containing the discrete values of the amplitude functions for any specified point x_g ($0 \le x_g \le L$), is calculating by solving the system of linear equations given by Equation 7. By interpolation, the amplitude functions can be found on the entire domain.

Having the amplitudes functions, one can recreate the transversal displacements v and w using Equation 1b,c for the entire member. In order to recreate also the warping displacements u, one has to extract the derivatives of the amplitude functions $\Phi'_k(x)$. Of course, one could just make numerical derivation, but the process is very sensible of the mesh density along the bar's axis.

The procedure of extracting discrete values of Φ'_k is similar with the previously described; the difference stays in using stiffness matrix C instead of X. The bending components of the warping stiffness matrix given in Equation 4 are neglected in this paper. The membrane components are calculated using the nodal warping values (Fig. 4), considering linear warping along the cross-section.

$$C_{ik}^M = E\sum_{r=1}^{np} t_r b_r \left(\frac{u_{i,r1}u_{k,r1} + u_{i,r2}u_{k,r2}}{3} + \ldots + \frac{u_{i,r1}u_{k,r2} + u_{i,r2}u_{k,r1}}{6} \right) \quad (9)$$

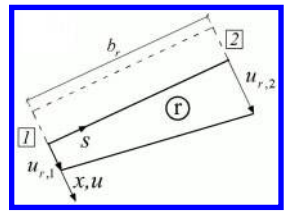

Figure 4. Discrete values of the warping displacements.

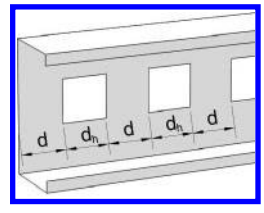

Figure 5. Thin-walled member with holes.

One recreates matrix C^M, by introducing the displacement field extracted from SFEA.

$$C_{FE,i}^M = E\int_s t u_i u_{FE} ds = \sum_{k=1}^{n} C_{ik}^M \phi_k(x_g) \quad (10)$$

and the final matrix equation yields:

$$C^M \phi' = C_{FE}^M \quad (11)$$

Having the amplitude functions and their derivatives, the entire displacement field (d_{GBT}) is recreated and compared with the initial one (d_{FE}), extracted from SFEA. An error vector is constructed $d_{err} = d_{FE} - d_{GBT}$ and the *approximation error* of the proposed method is measured as the norm of the error vector relative to the norm of the FE displacement vector.

$$error = \sqrt{d_{err}{}^T d_{err}} \Big/ \sqrt{d_{FE}{}^T d_{FE}} \quad (12)$$

Finally, the method provides the modal participation, the goal of the entire procedure, using the same procedure proposed by Silvestre et al. (2002), an easy and intuitive method based only on the amplitude functions. The modal participation factor (P_i) is introduced as follows:

$$P_i = \int_L |\phi_i(x)| dx \Big/ \sum_{k=1}^{n} \int_L |\phi_k(x)| dx \quad (13)$$

3.2 *Perforated thin-walled members*

The member is divided in two regions along its length as shown in Figure 5: continuous regions given by the intervals d, and regions with holes given by the intervals d_h.

These intervals don't have to be equal, there are no theoretical limitations concerning the shape, size and

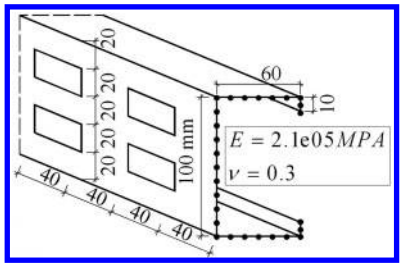

Figure 6. Lipped channel.

distribution of the holes. Of course a regular pattern will highly increase the speed of this procedure and it will ease its implementation in a computer application. Fortunately, in reality the vast majority of perforated thin-walled members have this property.

The buckling SFEA is performed. For any point $x_g (0 \le x_g \le L)$, situated inside and at the borders of the continuous regions, the method described in the previous section can be directly applied.

For the perforated regions, the method can be applied if a minor modification is performed, taking into account the missing segments along the cross-section. The cross-section deformation modes for the example given in Figure 2, remain the same, so the GBT 1st step is still applied for the continuous cross-section. The modification is introduced with respect the stiffness matrices. Basically, the components of these matrices are given by the virtual work produced by unit values of the amplitude functions, or their derivatives (Schardt 1989). So, for each missing segment, the virtual work is eliminated. Equations 8 and 9 are modified only by the number of segments *np*, which is now the initial number of segments minus the ones corresponding to the hole. The simplest example is of the warping matrix component $C_{11} = EA_h$, where A_h is now the area of the perforated cross-section. Next the procedure is applied for any point x_g $(0 \le x_g \le L)$ situated inside (and not at the borders) of the perforated regions.

4 ILLUSTRATIVE EXAMPLE

The parametric study is completed on a perforated symmetric steel lipped channel with boundary conditions of type clamped-free (cantilever member). Figure 5 presents the cross-sectional dimensions referred for the mid-line, the size and distribution of the holes, and the material properties (Young's modulus and Poisson's ratio). The thickness for all walls is $t = 2\,mm$ and the bar's length is $L = 1240\,mm$. The holes are rectangular, have equal size and they are placed in a regular pattern. The GBT cross-section discretisation is made with 5, 9 and 1 intermediate nodes between the corners, respectively in the flanges, web and flange lips. The GBT 1st step provides a number of 29 fundamental deformation modes; the first 14 can be seen on Figure 2.

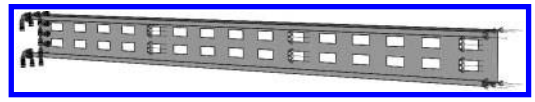

Figure 7. Loading and boundary conditions.

Table 1. Modal participation and approximation error for the first 10 buckling modes.

Buckling mode	G	D	L	error (%)
1	98.85	3.02	1.13	0.11
2	38.61	6.39	55.00	1.46
3	62.74	6.34	30.93	0.64
4	91.31	5.07	3.62	0.29
5	59.06	10.97	29.97	0.63
6	25.62	8.14	66.24	1.15
7	52.15	9.85	38.00	0.77
8	43.35	15.77	40.88	0.83
9	16.15	26.26	57.59	1.54
10	22.90	20.30	56.80	1.14

A buckling SFEA of a thin-walled member was performed using ABAQUS (Hibbit et al. 2002) for the first 50 eigenvalues. 2984 shell elements of type S4 were considered, in a highly regular square mesh (see Fig.7). The cross-section discretisation is constant along the member length and identical with the one used by the GBT 1st step. In longitudinal direction, all the elements have the same size of 10 *mm*. In order to implement the described method of buckling decomposition and to calculate the modal participation, a MATLAB (MathWorks 2005) application was written. It uses the FE displacement field of 125 cross-sections given by the shell elements sides normal to the member longitudinal axis. The member is axially compressed by edge uniform loads applied on the free end and also on one edge of the six holes indicated in Figure 6. For the free end, the loading magnitude is $q_1 = 4.1667\,N/mm$ and for the holes $q_2 = 12.5\,N/mm$.

The analysis provides the modal participation of the Global, Distorsional and Local deformation modes for the first 50 buckling modes and also the approximation error which had a maximum value of 5.89% for mode no. 38. A better approximation can be achieved by refining the GBT cross-sectional discretisation and also the member longitudinal mesh, but not significant changes were observed regarding the modal participation. Table 1 shows these results for the first 10 buckling modes. Figure 7 presents the deformated shapes of the first 5 buckling modes given by SFEA. Figure 8 presents the corresponding amplitude functions of the first 5 most significant fundamental modes, provided by the presented method and used to compute the modal participation by Equation 13.

It can be concluded that the first buckling mode is a Global mode of flexural-torsional type. Modes 2,3 exhibit a Global-Local behaviour, mode 4 is a global mode (flexural over the minor axis) and the rest are coupled instabilities of GDL type.

Figure 8. First 5 buckling modes provided by SFEA.

5 CONCLUSIONS

The paper presents a GBT-based method (originally developed by Nedelcu 2012) capable of identifying in a general buckling mode, the modal participation of the fundamental deformation modes of global, distorsional and local type. The buckling deformations to be decomposed can be determined by using FEM or any similar numerical method.

The main goal of the paper is to present the theoretical extensions and the applicability of the proposed method for the special case of perforated thin-walled members. There are no restrictions concerning the shape, size and distribution of the holes.

Only the GBT 1st step is used (the cross-section analysis) in order to have the modal cross-section deformation components, edge transverse moments, warping and geometrical stiffness matrices. Using the special orthogonality properties of the cross-section deformation modes, the GBT amplitude functions of the fundamental deformation modes, are extracted from the FEM deformations. Finally, the modal participation factors are computed based on the amplitude functions and also the approximation error of the entire procedure.

One numerical example is presented, in which the eigenvalue buckling modes are calculated by using SFEA. The small approximation errors and the comparison between the FEM mode shapes and the amplitude functions of the fundamental modes, prove the validity of the proposed method.

Regarding the method limitations, following the GBT classical hypotheses, the shear strains and membrane transverse extensions are neglected, together with the fundamental deformation modes which may

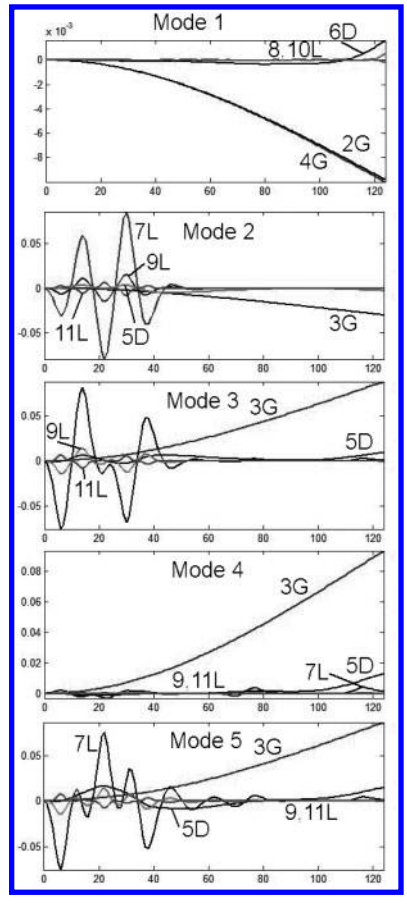

Figure 9. The amplitude functions $\Phi(x)$.

contain these deformations. At the present time, intensive research is dedicated to eliminate the Vlasov's hypotheses.

Regarding the method advantages, GBT is widely accepted as an elegant and fast method to analyse the behaviour of thin-walled members. The proposed method combines the best features of FEM and GBT, namely the FEM versatility with the GBT capability of providing the modal decomposition. As a consequence there are no restrictions regarding the cross-section shape, loading and boundary conditions. Its high speed must also be mentioned, and depends almost entirely of the time required by the SFEA. This is true because GBT 1st step involves an eigenvalue problem of small dimensions and there is no need for the GBT 2nd step (the member analysis) which is usually the most time-consuming in a GBT analysis (except for the use of analytical solutions, which are restricted to simply supported members).

Also, the derivation of the amplitude functions, modal participation and approximation error follow an analytical and simple procedure.

For all these reasons, the proposed method is elegant, extremely fast and a promising candidate to be combined with a general purpose finite element

code, providing in this way the buckling mode decomposition for arbitrary thin-walled members with and without holes.

Resistance assessment of the sinusoidal openings in cellular beams

S. Durif & A. Bouchaïr
Clermont Université, Université Blaise Pascal, Institut Pascal, Clermont-Ferrand
CNRS, Institut Pascal, Aubière, France

ABSTRACT: Experimental and numerical investigations have been conducted on cellular beams with sinusoidal openings. They showed new failure modes around the openings. Thus, a study is performed to develop a new analytical model adapted to the sinusoidal opening shape. Close numerical and experimental studies led on isolated opening parts pointed out the influence of the intermediate web-post on the stability of the opening panel and consequently on its ultimate failure load. The existing criteria of Eurocodes, initially developed for simple beams, is adapted to check the resistance of the tee sections along the sinusoidal opening considering more representative boundary conditions in the calculation of the local buckling critical stress.

1 INTRODUCTION

Castellated and cellular beams have a growing use in steel construction as long span system offering an efficient strength to weight ratio (Durif 2012, Tsavdaridis 2010). A new type of cellular beam has been developed by ArcelorMittal (Angelina™ beam) composed of regularly spaced sinusoidal openings (Fig. 1). In fact, changing the opening shape has an impact on the behavior of the beam and mainly its failure modes. Thus, experimental tests have been conducted on three full scale cellular beams with sinusoidal openings at Blaise Pascal University (Clermont-Ferrand) in order to evaluate and understand their complex behavior at ultimate limit state.

They showed the specific failure modes of sinusoidal openings that depend on the opening geometry (Durif et al. 2013). Thus, in the most stressed opening, it has been observed either the formation of plastic hinges at the four opening corners (Fig. 2) or the local buckling in the compressed panels (Fig. 3). Both failure modes can be linked to the well-known Vierendeel mechanism due to the local bending induced by the shear transfer around the large opening, presented by Chung et al. (2001) for circular web openings.

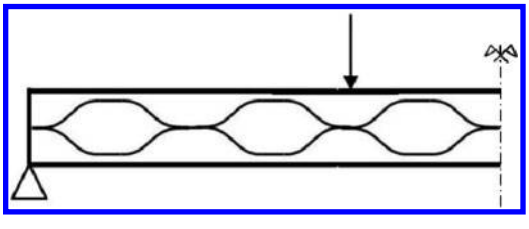

Figure 1. Cellular beam with sinusoidal opening.

A finite element model has been validated through the comparison with the tests results (Durif et al. 2013). The validated numerical model provided the evolution of the stress distribution around the opening allowing the understanding of the complex behaviour of those beams (Durif et al. 2013).

This analysis showed that, due to its length, the sinusoidal opening exhibits a mechanical behaviour similar to that of the rectangular or hexagonal openings mainly for the plastic failure mode as observed in Figure 2. It is characterized by the formation of four plastic hinges at the four opening corners.

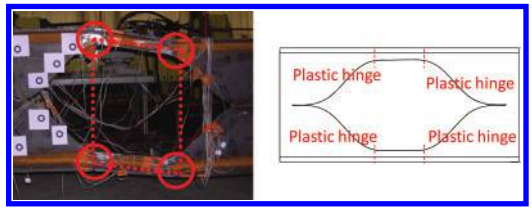

Figure 2. Failure by formation of plastic hinges.

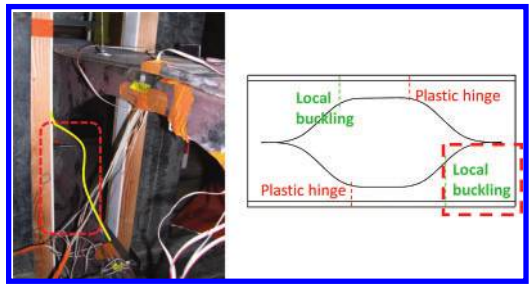

Figure 3. Failure by combination of local buckling and yielding of the opening quarters.

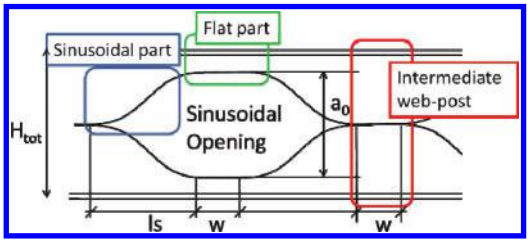

Figure 4. Terminology along a sinusoidal opening.

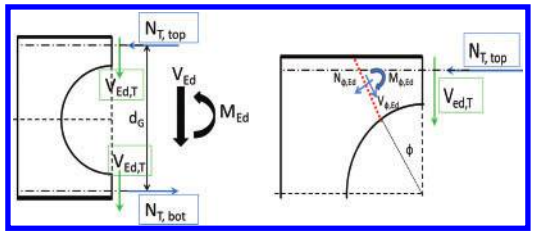

Figure 5. Distribution of forces around a circular opening.

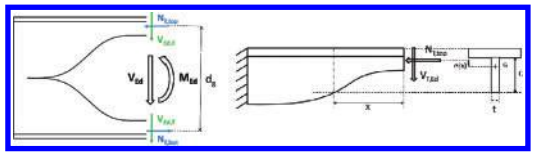

Figure 6. Distribution of forces around a sinusoidal opening.

However, due to the continuous variation of section along the sinusoidal part of the opening (Fig. 4), the position of the critical section to be checked (internal stress/resistance) is not known, especially with local buckling (Fig. 3). In the analytical models developed for circular opening, the position of the critical section is determined by small increments of angles of all the inclined sections around the opening.

In order to develop an analytical model predicting the resistance of the cellular beams with sinusoidal openings, the existing approaches used for circular openings are adapted to that specific opening shape. They are based on the evaluation of the internal forces and the resistances of the openings parts.

The adaptation of those methods to sinusoidal openings is presented. Then, this paper summarizes the principles of the analytical approach developed to predict the strength of the cellular beams with sinusoidal openings.

2 INTERNAL FORCES AND RESISTANCES AROUND OPENING

In general, the resistance of a cellular beam is checked considering the similarity with Vierendeel beam (Chung et al. 2001). Thus, the global moments and shear forces are transformed to local normal and shear forces around the opening (Fig. 5).

Then, the circular opening is checked considering each inclined tee section around the opening under the combined local axial force, shear force and local bending moment (Fig. 5). This method, initially proposed by Ward (1990), remains the common way to predict the resistance of the openings (Lawson et al. 2006). Each inclined tee section is considered with plastic or elastic strength regarding the class section criterion initially developed for rectangular openings and adapted to circular opening (Annex N of ENV 1993-1-1, 1995). This criterion gives a classification of opening that defines whether the section of the opening reaches their plastic of elastic resistance.

The Vierendeel beam equivalence is proposed for sinusoidal opening (Fig. 6). Due to the significant variation of section along the opening length, incremental verification of tee sections is considered.

Figure 6 presents an opening quarter submitted to the local forces $N_{T,top}$ and $V_{Ed,T}$. The authors made the choice to consider vertical tee sections in order to simplify the verification as the sinusoidal part can vary in function of the different opening parameters. This assumption has been validated through numerical simulations (Durif 2012). It has been concluded that the similarity between a cellular beam and a Vierendeel beam is independent of the opening shape, as much as the openings of a cellular beam remain enough deep and large.

However, no existing methods allow predicting the sinusoidal opening resistance. Indeed, the existing criterions for castellated and common cellular beams (Annex N ENV 1993-1-1, 1995) cannot be well adapted to the sinusoidal shape, especially because this opening shape implies a combination of different failure modes around the opening with either the yielding or the local buckling of the constituting opening quarters (Fig. 3) (Durif 2012). Thus an opening classification cannot be representative of the sinusoidal opening failure mode.

As a consequence, in this study, the resistance of each opening quarter is checked separately through incremental verification of each tee section along the opening length.

On the basis of the design rules for steel plates described in the Eurocodes (EC3-1-1 2003, EC3-1-5 2004), the authors propose to adapt the existing criterion for outstand flanges, to check the resistance of the tee sections along the opening length, considering the corresponding boundary conditions.

3 PROPOSITION FOR THE OPENING RESISTANCE

It has been chosen to develop the new analytical model on the basis of the principles of Eurocode 3. Those European rules define criterions based on the sections slenderness to assess the strain capacity of the compressed fibers before the ignition of local buckling.

The resistance of the tee sections can then be evaluated considering the classification of cross sections of

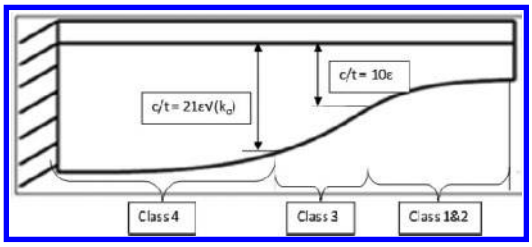

Figure 7. Example of classification of sections along a sinusoidal opening quarter.

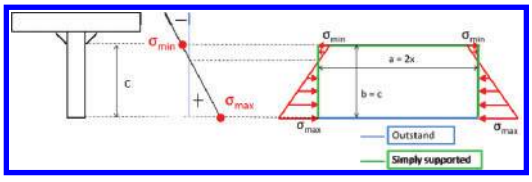

Figure 8. Tee section and its equivalent cantilever plate.

Eurocode 3 (EC3-1-1 2003, EC3-1-5 2004). However, those criterions have been developed for the design of beam flanges and webs and are not adapted to the verification of the tee sections in the opening quarters (Durif 2012).

Those criterions are function of the dimension (c) which is the tee web height. The transposition of those criterions to the vertical tee sections of a quarter of opening is presented in Figure 7.

As a consequence, this transposition considers that the sections the most expected to buckle (class 4 sections), are the sections of maximum vertical height. However, the authors have shown in previous works that this transposition of classification is too conservative. Indeed, the authors showed that the intermediate web-post (represented by hatchings in Fig. 7) supplies an out-of-plane support and should be considered in the calculation of the section resistance (Durif et al. (under review)).This out-of-plane support should be integrated in the formulas that define each section resistance.

The classifications of the Tee sections are based on the calculation of the critical stresses of equivalent cantilever plates (Johansson & Veljkovic 2001), submitted to axial stresses deduced from the corresponding forces (Fig. 8).

In the case of a tee section along an opening quarter (Fig. 6), the web of the tee section is submitted to linear varying axial stresses along its height, due to the axial and bending forces, as illustrated in Figure 8.

Figure 8 presents the equivalent cantilever plate considered to define the critical stress of the tee section web. The width of the plate "b" is taken equal to the tee web height "c".

Furthermore, in order to consider the stiffness supplied by the intermediate web-post to the adjacent tee sections, the authors propose to consider an equivalent plate of a defined length "a" taken equal to the double of the abscissa x of the studied tee section. This assumption remains conservative as it considers an equivalent plate simply supported on the three border lines without any rotational restraint (Durif 2012).

As a consequence, to calculate the critical stress of the tee sections along the opening quarter, the method consists of calculating the critical stress of the equivalent cantilever plates defined in Figure 8.

However, there is no existing formula defining the critical stress of such plates with a linear axial stress diagram. The authors propose a resolution with the energy method of this stability problem in order to get a formula of the critical stress coefficient k_σ which can directly be used in the design formulas of the Eurocodes (based on the work of Winter) in order to define the ultimate strength of steel plates (Johansson et al. 2007).

4 CRITICAL STRESS IN CANTILEVER PLATE

4.1 *Literature review*

Many works on the stability of steel plates show the efficiency of the energy method to solve the problem of plates buckling. For example, the paper of S.T. Smith, M.A. Bradford & D.J. Oehlers (1999) provides the values of buckling coefficients for different support conditions of a plate in pure shear. The method is similar to that developed by Timoshenko (1943), considering a virtual function of displacement "w" corresponding to the boundary conditions to calculate the strain energy of bending of the plate (U) and the external forces work (T). The critical value of the stresses is found when the strain energy of bending is equal to the external forces work (Timoshenko, 1943).

Klöppel and Sheer proposed abacuses that allow finding the critical stress value for different configurations of loading, boundary conditions and stiffeners properties. In the present study a value of the buckling coefficient is needed for a linear varying axial stress diagram. Thus, in order to get the value of the critical stress in function of the plate and loading parameters, it is necessary to go back to the resolution of the problem of stability or to use numerical tools (Yamashita & Kato 2001). Timoshenko (1943) and then, Bulson (1970), present a good description of the resolution of this kind of problems but do not give the solution for the case of the cantilever plate with linear varying load.

The paper of Kang & Leissa (2005) presents the resolution of the stability problem of a plate with various boundary conditions, with the problem of the cantilever plate. It gives the resolution method that is the same as Timoshenko, by integrating the equilibrium equation and by choosing a serial of Fourier for the function of displacement. The same results as the one obtained by Timoshenko and Bulson in the case of the fully compressed cantilever plate are observed. However, the paper does not give any useful formula that can be used in an analytical calculation.

Thus, no analytical formula is available in the literature for the cantilever plate, loaded by a linear diagram of axial stresses. Consequently, it has been chosen to propose a formula able to predict the critical stress of a cantilever plate submitted to a linear varying axial stress diagram. This formula has been developed using the energy method for both cases, whether the maximum compressive stress is on the out-stand fiber or on the simply supported fiber. In the present paper, just the first case is presented as the second one uses the same principles.

In order to use the energy method, the authors have chosen to use the deflected shape proposed by Bulson (1970) and described by the Equation 1.

$$w = A\frac{y}{b}sin\left(\frac{\pi x}{a}\right) \quad (1)$$

4.2 *Cantilever plate with maximum compression on the out-stand fiber*

The cantilever plate with linear distribution of normal stresses is analyzed. The results are summarized for the more sensitive case to local buckling mobilized by the maximum compressive stress on the out-stand fiber. The critical forces are obtained by comparing the internal energy U and the external work T obtained with a virtual displacement assumed to have the shape " w " defined by the Equation 1 (Bleich, 1952). The strain bending energy is given by the equation 2 (Timoshenko 1943).

$$U = \frac{D}{2}\int_{00}^{ab}\left\{\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}\right)^2 - 2(1-\nu)\left[\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial y^2}-\left(\frac{\partial^2 w}{\partial x \partial y}\right)^2\right]\right\}dxdy \quad (2)$$

The external forces work can be defined by the Equation 3 (Timoshenko 1943).

$$T = \frac{\sigma_{max}t}{2}\int_{00}^{ab}(\psi+(1-\psi)\frac{y}{b})(\frac{\partial w}{\partial x})^2 dxdy \quad (3)$$

The resolution of the energy method equations gives the critical stress defined by the Equation 4.

$$\sigma_{cr} = 4.D.\frac{(-6.a^2.\nu+6.a^2+\pi^2.b^2)}{t.b^2.a^2.(3+\psi)} \quad (4)$$

The value of the coefficient k_σ (Eq. 5) is obtained by comparison of this critical stress with the well-known Euler stress σ_E:

$$\sigma_{cr} = k_\sigma.\sigma_E$$

Where:

$$\sigma_E = \frac{\pi^2.E.(t/b)^2}{12.(1-\nu^2)}$$

$$k_\sigma = 4.\frac{(-6.\nu.a^2+6.a^2+\pi^2.b^2)}{a^2.(3+\psi).\pi^2} \quad (5)$$

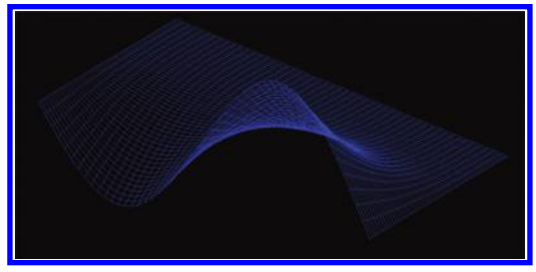

Figure 9. Buckling mode in two half waves for a plate with $\psi = -4$.

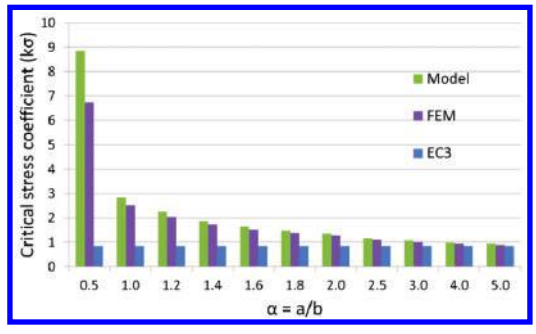

Figure 10. Comparison of k_σ values for the different methods with a stress ratio $\psi = -1$.

It can be noticed that the value of k_σ is not defined for a stress ratio $\psi = -3$. In this case, the authors chose to limit the value of k_σ considering a minimum stress ratio of -2.9. This limit value leads to conservative results of k_σ.

For cases with values of $\psi < -3$, the plates change of buckling shape. The buckling mode changes and leads to a buckling shape with several half waves (Fig. 9). Thus the shape function "w" assumed in the model of Equation 1 is no more representative.

Indeed, values of $\psi < -3$ correspond to an axial stress diagram with a maximum tensile stress three times higher than the compressive one. Thus, this configuration of plate is very stiff, which explain the buckling mode shape. However, those configurations do not have interest in the present study because those types of loading conditions generate a compressed part very small along the plate width, which should lead to the plate plastification before local buckling.

4.3 *Application of of the proposed model in pure bending ($\psi = -1$)*

The evaluation of the proposed model is done for the case with pure bending ($\psi = -1$). Figure 10 compares the critical stresses obtained with the analytical model, the Eurocode formulas (that are independent of the plate length " a ") and the numerical model (FEM).

The comparison is done for various values of aspect ratio (a/b) varying from 0.5 to 5. It can be observed in Figure 10 that the results of the analytical model are close to those of the numerical model. Furthermore,

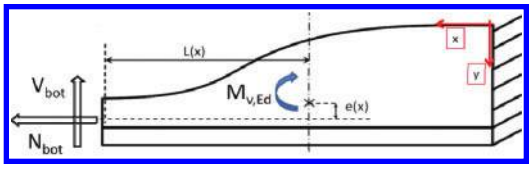

Figure 11. Bottom right opening quarter with corresponding forces.

the formulas of Eurocode, developed for infinitely long plates, are not well adapted for plates with an aspect ratio $\alpha < 3$.

Finally, the ultimate strength of each section is determined in function of the calculated critical stresses. To do so, the authors based the model on the design rules of EN1993-1-3 regarding the case of semi-compact plates.

5 SEMI-COMPACT PLATES

The work presented in the report (Greiner et al., 2009) proposes a formula in order to define the elasto-plastic strength of plates considered with class 3 in the Eurocodes. This formula considers a linear interaction between the plastic and the elastic moment resistance depending on the plate slenderness (Greiner et al., 2009). It has an equivalent formula in EN1993-1-3 (2006) presented hereafter.

– if the effective section modulus W_{eff} is less than the gross elastic section modulus W_{el} (EC3-1-3, 2006).

$$M_{c,Rd} = W_{eff} f_y / \gamma_{M0} \quad (6)$$

– if the effective section modulus W_{eff} is equal to the gross section modulus W_{el} (EC3-1-3, 2006).

$$M_{c,Rd} = f_y (W_{el} + (W_{pl} - W_{el}) 4 (1 - \lambda_p / \lambda_{el}) / \gamma_{M0} \quad (7)$$

In the case of cantilever plates:

$\lambda_p = \frac{(c/t)}{28{,}4\varepsilon\sqrt{k_\sigma}}$ and $\lambda_{el} = 0748$ (and not 0673 given in the Eurocode 3 part 1–3) (Johansson et al., 2007).

The new model proposed in this study to calculate k_σ can be incorporated in those formulas (Eq. 6) in order to take into account a more realistic stiffness of the sections close to the intermediate web-post.

As an example (Fig. 11), it is proposed to study the bottom right opening quarter of the opening of the tested beam presented in Figure 3.

This example aims at comparing two methods. First, the adaptation of the Eurocode design rules to the verification of the opening quarter is presented in Figure 12. Then the verification that considers the new calculation of critical stress proposed in the present paper is presented in Figure 13.

Both Figures, 12 and 13, show the diagrams of the plastic moment resistance (reduced by the axial force N_{bot}) $M_{pl,N}$, the elastic moment resistance $M_{el,N}$, the solicitant bending moment M_{Sd} and the resistant bending moment M_{Rd}.

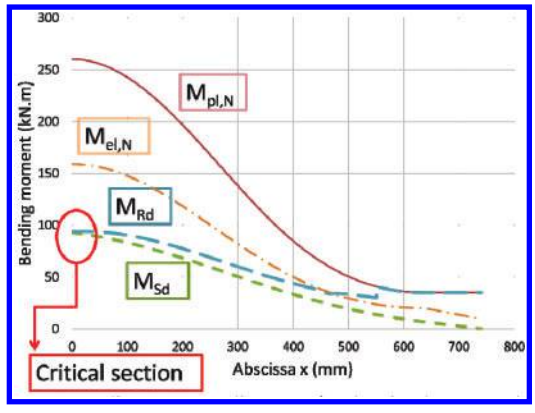

Figure 12. Bending moment diagrams for the simple approach along the opening quarter.

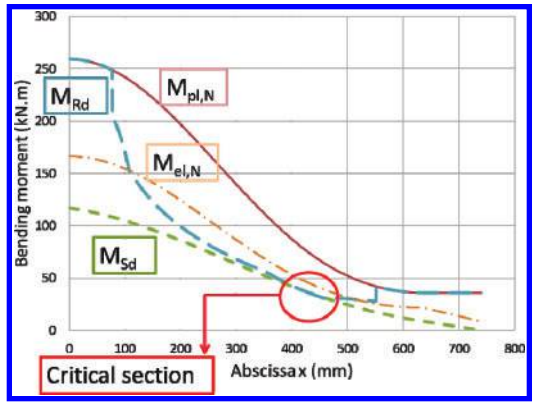

Figure 13. Bending moment diagrams for the proposed model approach along the opening quarter.

Figure 12 gives a bending resistance diagram M_{Rd} deduced from the direct adaptation of the Eurocode 3 part1-1 design rules. The critical section, where the failure is expected to arise analytically, is located at the junction of the sinusoidal panel and the intermediate web-post by local buckling.

Figure 13 gives another bending moment resistance diagram. It can be seen on this figure that the bending resistance of the sections close to the intermediate web-post reaches the plastic resistance. Thus, the failure occurs at a critical section which is deviated from the intermediate web-post and corresponds more to the corresponding failure mode observed experimentally and numerically (Fig. 3) by Durif et al. (2013).

It can be seen in Figure 14 that the bending resistance of the critical section remains under the elastic resistance. This resistance remains conservative in comparison to numerical results (Durif 2012). In order to better assess the opening resistance it should be necessary to consider the rotational restraint supplied by the flange and the intermediate web-post to the sinusoidal panel. Furthermore, so as to get the ultimate

load of the opening, the analytical model has to consider the opening failure mechanism of all the opening quarters (Durif 2012).

6 CONCLUSION

The work described in this paper proposes an original approach to define the opening quarter resistances. In order to predict the failure mode of the four opening quarters, a new analytical model has been developed. This model is based on the existing methods for standard cellular beams. However, a new calculation of critical stresses has been integrated in order to better represent the stiffness of the opening quarter panel. Thus, the new model allows taking into account the out-of-plane support supplied by the intermediate web-post. The formula proposed for the calculation of the critical stress has been compared and validated with numerical results. Finally, the proposed method appears representative of the behavior observed numerically or experimentally. Thus, this method can be used in order to assess each opening's quarter strength, which can define the partial failure of a sinusoidal opening which remains conservative in comparison to numerical ultimate failure loads.

In addition, so as to get a more accurate ultimate failure load, the authors proposed a cinematic approach which allows combining the different opening quarter strength. This analytical method can then be implemented in a cinematic approach in order to consider the opening failure mechanism (Durif 2012).

ACKNOWLEDGMENTS

This paper has been prepared as a result of a research carried out at University Blaise Pascal for the completeness of a PhDD degree. The authors would like to thank the Ministry of Research for the scholarship and ArcelorMittal group for the financial support and the supply of steel specimens for the experimental tests.

GBT buckling analysis of I-section steel girders under concentrated loads

P. Natário, N. Silvestre & D. Camotim
Department of Civil Engineering, ICIST/IST, TU Lisbon, Lisboa, Portugal

ABSTRACT: This paper illustrates the application of a Generalised Beam Theory (GBT) formulation to analyze the elastic localized web buckling of I-section steel girders under concentrated loads. The studied cases regard welded steel I-section beams with patch loading configurations: Patch Loading Test (PLT) and Opposite Patch Loading Test (OPLT). It is found that both pre-buckling longitudinal normal (σ_{ss}^0) and shear (σ_{xx}^0) stresses have to be included in the buckling analyses of I-section steel girders with PLT configuration. Furthermore, the pre-buckling transverse normal (τ_{xs}^0) stresses have to be included in the buckling analysis of I-section steel girders with OPLT configuration. In girders with PLT configurations, the GBT pre-buckling analysis should consider global and shear modes while the GBT buckling analysis may only consider local modes. In girders with OPLT configurations, the GBT pre-buckling analysis should consider transverse extension modes while the GBT buckling analysis may only consider local modes. The two illustrative examples (PLT and OPLT) are validated by comparison with Shell Finite Element (SFE) results.

1 INTRODUCTION

Due to the reduced width-to-thickness ratio of steel plates, the structural behaviour of I-section steel girders is strongly affected by the occurrence of several types of collapse with intrinsically nonlinear nature. The collapse of such thin-walled members is always associated with buckling phenomena, which arises due to action of (i) compressive normal stresses in the longitudinal direction, (ii) shear stresses and (iii) compressive normal stresses in the transverse direction, or due to a combination of these types. The buckling phenomenon arising from the action of compressive longitudinal normal stresses is, by far, the most well known and may be classified into one of three categories: global (flexural, torsional, flexural-torsional), lateral-distortional and local buckling. In I-section steel girders, the shear buckling phenomenon is also relevant in practical applications and its consideration is often needed in design safety checking procedures. However, the localized buckling phenomenon arising from compressive normal stresses acting in the member transverse direction is less well understood. This particular occurrence is due to concentrated loads applied transversally to the member axis or due to the simultaneous action of applied concentrated loads and the corresponding support reactions. The compressive normal stresses acting in the transverse direction also cause substantial material degradation due to gradual yielding and spread of plasticity. The failure of I-section steel girders under concentrated loads is mostly known as "patch loading collapse". This failure is due to the simultaneous occurrence of localized buckling (instability) and yield line mechanism (plasticity) in the web of the beam.

Due to the intrinsic tri-dimensional character of the phenomena, involving three stress components and their interaction in elastic buckling as well as the ensuing spread of plasticity, the success of theoretically grounded design procedures have not been reached. For more than 60 years, researchers used experimental test results of patch loading failure of welded steel beams (Granholm 1960, Tryland et al. 1999) to calibrate analytical expressions. These design procedures avoided the complexity of theoretical background inherent to localized web buckling but rendered their scope of application much narrower, i.e. specific for the case they were calibrated. Now that computational tools are widely available, accurate analysis of localised web buckling can be achieved using reliable numerical methods. Until now, this can only be achieved by using the shell finite element (SFE) method (Tryland et al. 1999). One very promising alternative to SFE method is the Generalised Beam Theory (GBT), a beam theory that incorporates genuine folded-plate concepts. GBT has been extensively applied to study the global, distortional and local buckling behaviour of members under longitudinal normal stresses. Most of all GBT formulations neglected the effect of transverse normal stresses. A first attempt to use GBT for localized web buckling analysis was done by Silva et al. (2008). Very recently, Natário et al (2012) developed a GBT formulation to study, systematically, the localized web buckling of thin-walled beams under concentrated loads. In this paper, GBT is applied to investigate the localized web buckling of a welded I-section girder.

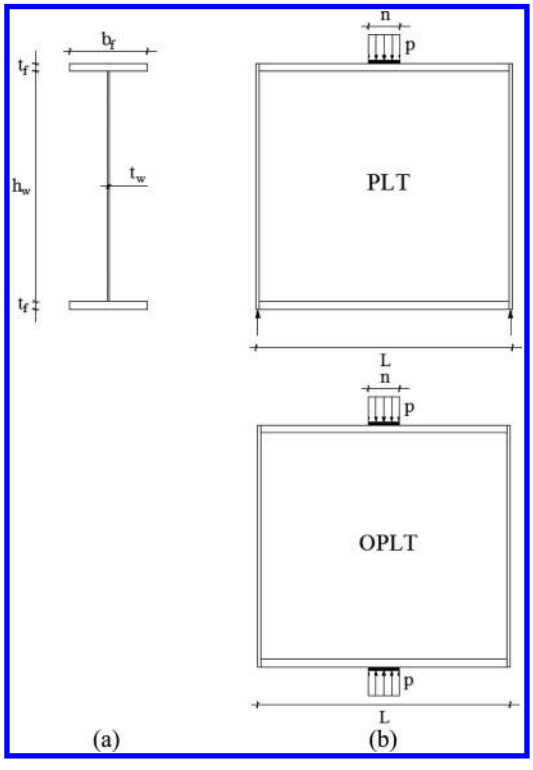

Figure 1. (a) Welded I-section dimensions and (b) patch loading configurations (PLT and OPLT).

2 ILLUSTRATIVE EXAMPLE

Consider now the welded steel ($E = 204000\,\mathrm{N/mm^2}$ and $\nu = 0.3$) I-section beam shown in Figure 1(a), which was tested and analysed by Tryland et al. (1999) for patch loading failure. The I-section dimensions are $h_w = 359.6\,\mathrm{mm}$ and $t_w = 3.8\,\mathrm{mm}$ (web), $b_f = 120.5\,\mathrm{mm}$ and $t_f = 11.9\,\mathrm{mm}$ (flanges). In GBT analysis, the I-section mid-line dimensions were used – the web height is $h_w + t_f$, as seen in Figure 1(a).

The cross-section discretization considers $n = 23$ nodes and 22 elements: each flange has 6 elements and the web has 10 elements. Thus, $4n = 92$ unit shape functions were imposed and 92 deformation modes were obtained from the GBT cross-section analysis, corresponding to 4 global modes (G), 44 local modes (L), 22 shear modes (S) and 22 transverse extension modes (TE). Figures 2 and 3 show some of the most relevant modes yielded by the cross-section analysis.

Mode 2-G, corresponding to major axis bending (see Figure 2), is the only global mode that is relevant for the analysis. The most relevant local modes (5-L, 6-L, 7-L and 8-L) are mainly characterized by web deformation (see Figure 2): the web bends transversally in single curvature for modes 5-L and 7-L while it bends in double curvature for modes 6-L and 8-L. It is also clear that the web-flange nodes exhibit significant rotation in modes 5-L and 6-L

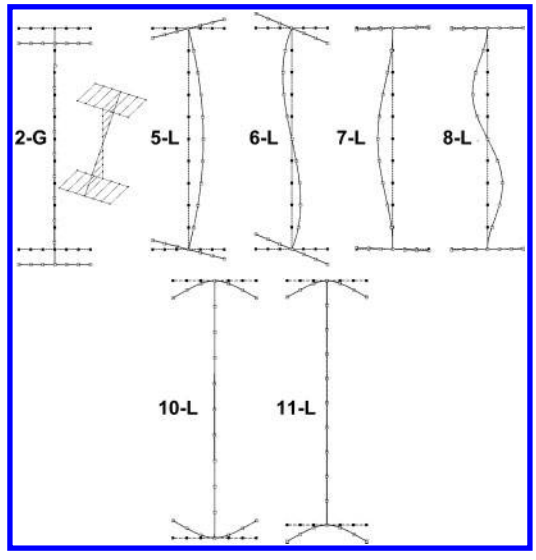

Figure 2. Most relevant global (G) and local (L) deformation modes for patch loading.

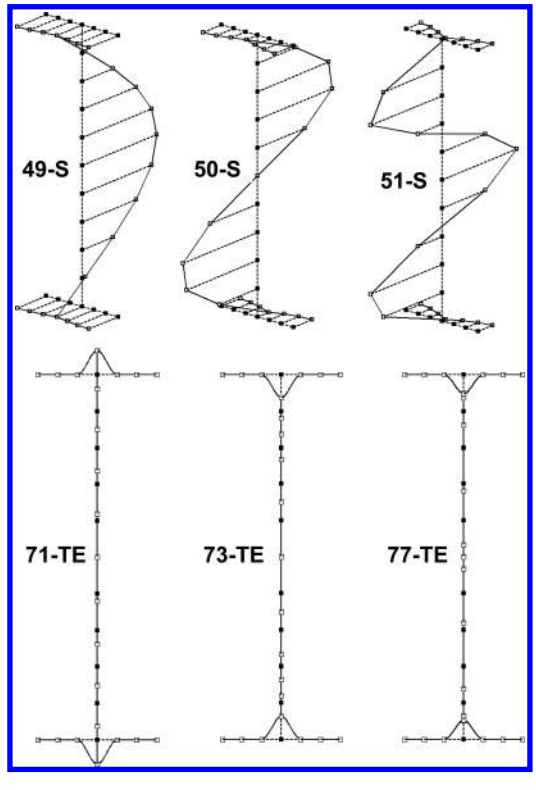

Figure 3. Most relevant shear (S) and transverse extension (TE) deformation modes for patch loading.

(web almost "simply supported") while their rotation is highly restrained in modes 7-L and 8-L (web almost "clamped"). In terms of shear deformation, the most relevant modes (49-S, 50-S and 51-S) are

depicted in Figure 3. They present negligible in-plane displacements but meaningful warping displacements. The number of warping displacement waves in the web increases from one (mode 49-S) to three (mode 51-S). Since the in-plane displacements are null ($v_k(s)=0$), it should be mentioned that the membrane shear strain varies with respect to the 1st derivative of the warping displacement ($\gamma_{xs}^M = u_(k,s)(s)$). Figure 3 also shows that flange shear lag effects increase from mode 49-S (almost uniform $u_k(s)$) to mode 51-S (slightly linear $u_k(s)$). Finally, the transverse extension modes deemed relevant (71-TE, 73-TE and 77-TE) involve solely the web deformation, as it is seen in Figure 3. In particular, the variation of the in-plane displacement $v_k(s)$ along the web height is shown in the left side of the modes in smaller scale. In all these modes, the web mid-point doesn't move ($v_k(s)=0$) and the non linearity of $v_k(s)$ increases from the mode 71-TE to the mode 77-TE. Figure 3 shows the in-plane deformed shapes of 71-TE, 73-TE and 77-TE modes. Since the transverse extension varies with respect to the 1st derivative of the in-plane displacement ($\varepsilon_{ss}^M \sim v_{(k,s)}(s)$, it is seen that the web is (i) stretched along its overall height (mode 71-TE), (ii) stretched in the bottom and top 1/3 part of the web and shortened in the middle 1/3 part (mode 73-TE), and (iii) stretched in the bottom, middle and top 1/5 part of the web and shortened in the remaining two 1/5 parts (mode 77-TE).

Following Tryland et al. (1999), the PLT (Patch Loading Test) and OPLT (Opposite Patch Loading Test) configurations are adopted herein (see Figure 1(b)). Load and support conditions were adapted according to the report by the aforementioned authors. The cross-section geometry defined before was considered for both PLT and OPLT configurations. Next, each test case is described in terms of the GBT modeling. The PLT case consists of a beam with length $L = 1315\,mm$. The top flange of the mid-span section is subjected to a load distributed along $n = 40\,mm$ (bearing length), as seen in Figure 1(b). In order to maximize the similarity between Tryland's and GBT models, the latter considers an imposition of the equal vertical displacement in every node contained in the load bearing region. As for the supports, all the displacements were restrained in the beam supports in order to simulate the rigid end-plates attached in the Tryland's experiments. The OPLT case considers a beam with $L = 1523\,mm$. Both top and bottom flanges of mid-span section are subjected to loads distributed along $n = 40\,mm$ (bearing length) and oriented in opposite directions (Figure 1(b)). Once again, the GBT model considers (i) an imposition of equal vertical displacement in every node contained in the load bearing region and (ii) null displacements at the beam supports. In order to maintain full symmetry of OPLT, the vertical and longitudinal displacements of the web midpoint at mid span section were set null. In both PLT and OPLT cases, the beam longitudinal discretization considers 20 beam finite elements.

First, we present the results of first-order GBT analysis, which are essential to characterize the pre-buckling behaviour of the beam in patch loading tests. Figures 4(a) and 4(b) show the variation of mode amplitude functions $phi_k(x)$ along the beam axis for PLT and OPLT, respectively.

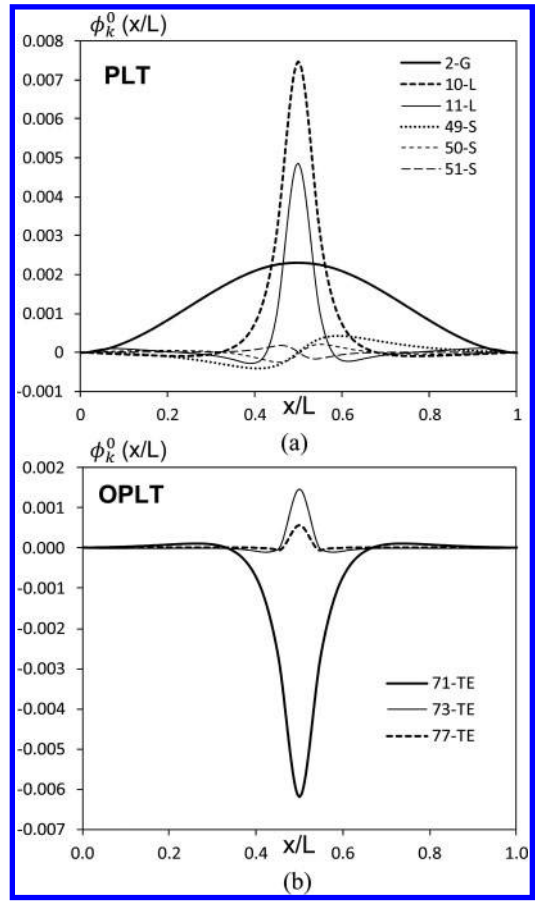

Figure 4. Pre-buckling mode functions $\phi_k^0(x/L)$ determined from 1st order analysis for (a) PLT and (b) OPLT.

The PLT (Figure 4(a)) is mostly influenced by modes 2-G, 10-L, 11-L, 49-S, 50-S and 51-S. It is seen that the amplitude of major-axis bending mode 2-G increases smoothly from the supports to the mid-span section while that of local modes 10-L and 11-L is null in a large portion of the beam length and increases hugely near the mid-span, thus exhibiting very pronounced local peak in the mid-span section. Since both amplitudes are positive at mid-span, the combination of these local modes (see Figure 4) leads a local deformation of the top flange (mode contributions add) where the load is applied but implies no deformation of the bottom flange (mode contributions cancel). Finally, the shear modes 49-S, 50-S and 51-S also have minor participations in the pre-buckling deformed shape of the beam. Since the local modes do not exhibit membrane stresses σ_{ss}^0 but only flexural ones, it is expected that pre-buckling longitudinal normal stress σ_{xx}^0 associated with major axis bending

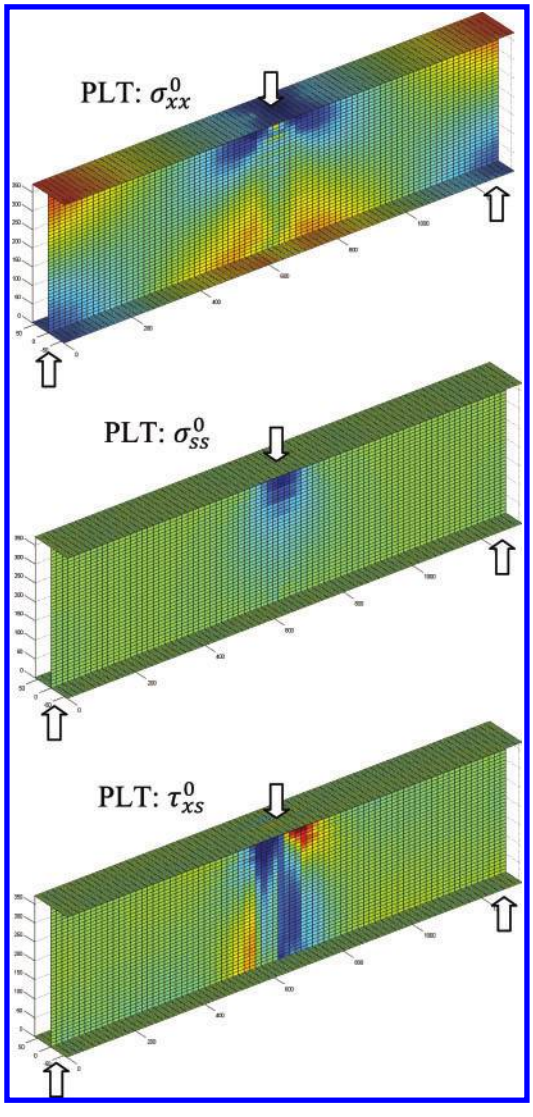

Figure 5. Pre-buckling stress (σ^0_{xx}, σ^0_{ss} and τ^0_{xs}) distributions obtained from GBT analysis for PLT.

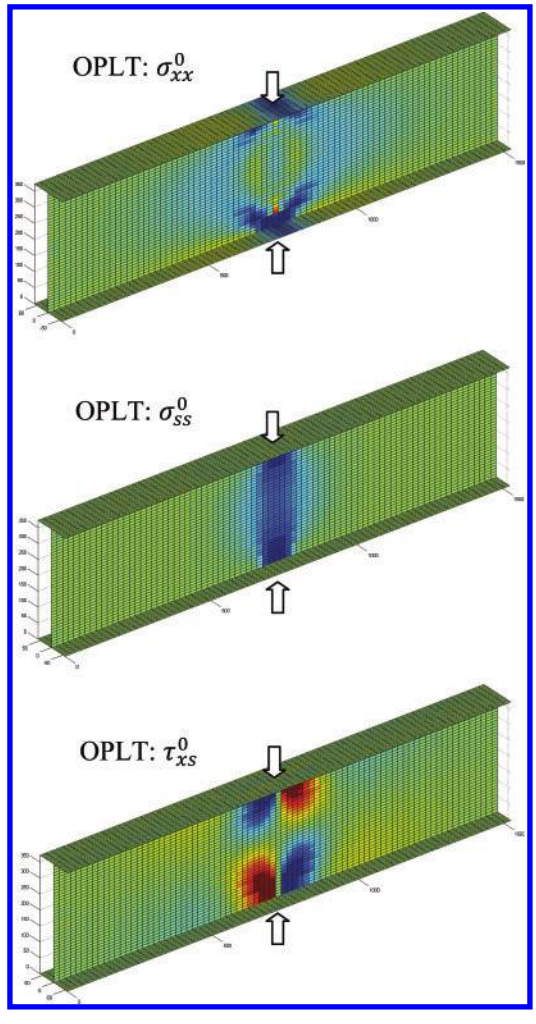

Figure 6. Pre-buckling stress (σ^0_{xx}, σ^0_{ss} and τ^0_{xs}) distributions obtained from GBT analysis for OPLT.

mode (2-G) and shear stress τ^0_{xs} associated with shear modes (49-S, 50-S and 51-S) will be the most relevant ones in the PLT case.

The OPLT (Figure 4(b)) is only affected by modes 71-TE, 73- TE and 77- TE. As expected, the participation of these modes occurs mainly in the mid-span region, where the loads are applied in opposite direction, leading to a local peak of $\phi_k(x)$ curves. Thus, modes 71-TE, 73-TE and 77-TE contribute to the web shortening in the mid-span region. Notice that mode 71-TE has higher contribution than the others since its $v_k(s)$ linear variation (see Figure 3) is more relevant that the non-linear variation of $v_k(s)$ of modes 73-TE and 77-TE. Since the web stretches in mode 71-TE (see Figure 3), its amplitude function depicted in Figure 4(b) is negative ($\phi_{71}(x) < 0$), giving a real (expected) web shortening ($v = v_{71}(s)\phi_{71}(x)$) due to opposite loads. Thus, if only these three modes are included in the GBT pre-buckling analysis, we certainly get the exact results. It is expected that pre-buckling transverse normal stress σ^0_{ss} associated with transverse extension modes (71-TE, 73-TE and 77-TE) will be the most relevant component in the OPLT case. Figure 5 presents tri-dimensional plots of the pre-buckling stress distributions (σ^0_{xx} – longitudinal normal stress, σ^0_{ss} – transverse normal stress, τ^0_{xs} – shear stress) for PLT – note that these plots are not obtained from a SFE analysis, but solely from the GBT first-order analysis. Figure 6 presents similar plots for the OPLT case.

First, it is obvious that PLT and OPLT stress distributions are clearly distinct (blue and red mean negative and positive values). One may observe that the longitudinal normal stress σ^0_{xx} is the most relevant component in the PLT case, whereas in the OPLT case we observe

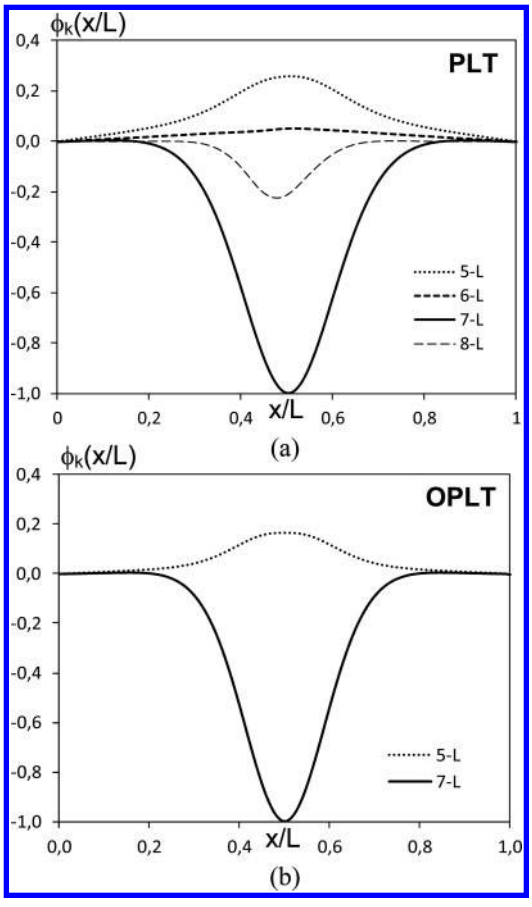

Figure 7. Buckling mode functions $\phi_k(x/L)$ for (a) PLT and (b) OPLT.

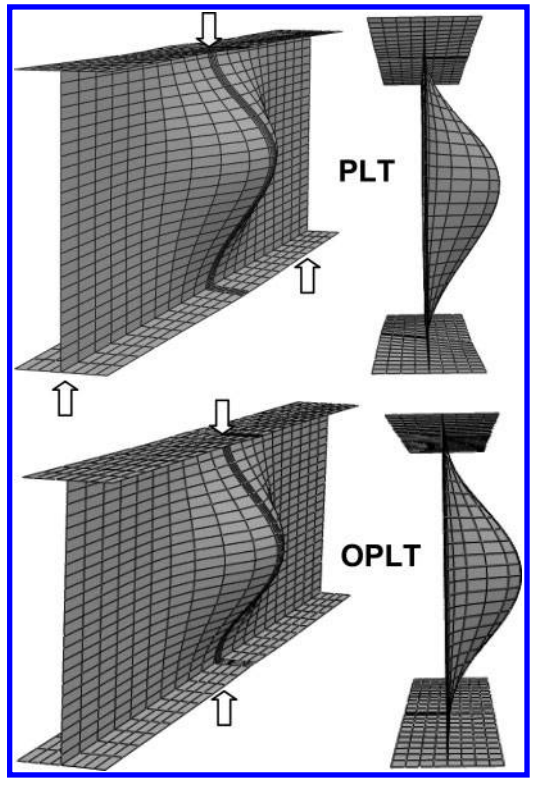

Figure 8. Buckling mode shapes obtained from SFE analysis.

that this stress component only displays high values very close to the load bearing plates. Concerning the transverse normal σ^0_{ss} component, it is clear that the roles are inverted, as it is possible to observe the high compressive (negative) stress level at the mid-span region due to load transfer between the top and bottom flange in the OPLT case. In terms of the shear stress τ^0_{xs}, both PLT and OPLT cases are characterized by relevant stresses in the mid span region.

After introducing the pre-buckling results (σ^0_{xx}, σ^0_{ss} and τ^0_{xs}) into the geometric stiffness matrices and solving the equilibrium equations, the results of buckling analysis are obtained. Figure 7 shows the variation of mode amplitude functions $\phi_k^{\$\$}(x)$ along the beam length determined from GBT buckling analysis for PLT (Figure 7(a)) and OPLT (Figure 7 (b)). In parallel, SFE analyses were performed and the beam buckling modes in PLT (Figure 8(a)) and OPLT (Figure 8(b)) are also shown. From a qualitative comparison between these results and those obtained in the web crippling tests by Tryland *et al.* (1999), it is possible to conclude that the local modes (5-L, 6-L, 7-L and 8-L) govern the beam deformed shape in patch loading tests. Since the flange rotation is restrained in the supports and load bearing region, it is observed that the local mode 7-L becomes the most important one in both PLT and OPLT, as it presents negligible flange rotation. To a much lesser extent, mode 5-L also contributes to the buckling mode deformed shape and introduces a slight flange rotation. Be aware of the fact that both 5-L and 7-L modes are symmetric as the web bends in single curvature.

From the comparison between Figures 7(a) and 7(b), it is seen that the individual contribution of local modes 5-L and 7-L is very similar in PLT and PLT cases. The main difference between PLT and OPLT resides in the contribution of local modes 6-L and 8-L, which are present in PLT but absent in OPLT. Since these modes are anti-symmetric (the web bends in double curvature), their "addition" to modes 5-L and 7-L in PLT case (see Figure 7(a)) leads to a buckling mode shape that is not totally symmetric with respect to the cross-section major axis. This evidence is confirmed by the SFE deformed shape shown in Figure 8(a), where it is seen that the maximum displacement occurs slightly above the web mid-point.

Due to the modal nature of GBT, if we include only (i) 4 local modes (5-L, 6-L, 7-L and 8-L) in the buckling analysis of PLT and (ii) 2 local modes (5-L and 7-L) in the buckling analysis of OPLT, surely we obtain the same results of all-mode analysis. The GBT and SFE buckling analysis presented the following elastic

critical load values: (i) 194 kN and 198 kN for PLT and (ii) 113 kN and 118 kN for OPLT. The results show a good agreement since the differences found were 1.8% for PLT and 3.8% for OPLT.

3 CONCLUSION

This paper illustrated a GBT formulation to analyse the elastic localized web buckling of thin-walled steel beams under concentrated loads. Details on the GBT formulation to analyse the localized web buckling of thin-walled steel beams under concentrated loads can be found in Natário et al (2012). The cases of welded steel I-section beams with PLT and OPLT configurations were considered for illustration purposes. It was found that:

- Few global and shear modes play a key role in the pre-buckling (1st order) behaviour of beams with PLT configurations. Transverse extension modes have a residual participation in the beam pre-buckling displacements. These facts imply that pre-buckling longitudinal normal (σ^0_{xx}) and shear (τ^0_{xs}) stresses associated with global and shear modes have to be included in the buckling analyses of beams with PLT configurations.
- Few transverse extension modes are needed to characterize the pre-buckling (1st order) behaviour of beams with OPLT configurations. Global and shear modes exhibit a negligible contribution to the beam pre-buckling displacements. These facts show that pre-buckling transverse normal (σ^0_{ss}) stresses associated with transverse extension modes must be considered in the buckling analyses of beams with OPLT configurations.
- The local modes also participate in the pre-buckling displacements of the beam, either in PLT or OPLT configurations. However, the membrane pre-buckling stresses (σ^0_{xx}, τ^0_{xs}, σ^0_{ss}) are not influenced by them and they can be disregarded in the pre-buckling analysis.
- In all cases, a stress concentration phenomenon exists and it leads to high non uniformity of pre-buckling stress distributions. The modal nature of GBT helps understanding the origin of this stress concentration, as well as the factors (i.e., deformation modes) that most affect the accuracy of the pre-buckling solution.
- As a consequence of this pre-buckling stress concentration, the results of buckling analyses show a strong localization of deformation. Thus, and conversely to pre-buckling analysis, the local modes are essential to correctly characterize the buckling behaviour of beams, either in PLT or OPLT configurations. Global modes may have residual participation in the beam buckling mode shape whereas the shear and transverse extension modes have null contribution.

From these remarks, the following conclusions are appropriate:

- Beams with PLT configurations: Pre-buckling analysis should consider global and shear modes while buckling analysis should consider local modes.
- Beams with OPLT configurations: Pre-buckling analysis should consider transverse extension modes while buckling analysis should consider local modes.

In conclusion, there are many parameters affecting the localized web buckling of thin-walled members under concentrated loads, such as (i) the type of concentrated loading, (ii) the geometric configuration of the web, (iii) the restraining effect provided by the flanges and (iv) the non uniformity of pre-buckling stress distributions. Only the consideration of a complete set of stresses (transverse normal stress, shear stress and longitudinal normal stress) ensuing exact distribution can lead to accurate solutions for localized web buckling of thin-walled members under concentrated loads. The GBT formulation presented in this paper has proven to be an efficient but rigorous way of dealing with this problem.

Design by inelastic analysis – 2010 AISC specification

R.D. Ziemian
Bucknell University, Lewisburg, PA, USA

ABSTRACT: In the latest edition of the American Institute of Steel Construction's *Specification for Structural Steel Buildings*, the design provisions for employing inelastic analysis have been fully revised. This paper provides an overview of the Specification's Appendix 1- *Design by Inelastic Analysis* and describes the new opportunities it presents to engineers who want to take better advantage of nonlinear material behavior, especially the redistribution of member forces as a result of yielding. Of particular interest to the design profession is that certain levels of inelastic analysis may now be used in place of the Specification's design equations in confirming the adequacy of components and/or the structural system. With this in mind, the associated requirements on this approach will be presented. The paper concludes by identifying topics in research that will need to be addressed in order to further expand current opportunities for design by inelastic analysis.

1 INTRODUCTION

Appendix 1 – *Design by Inelastic Analysis* of the 14th Edition of the American Institute of Steel Construction's *Specification for Structural Steel Buildings* (AISC 2010a) has been fully revised to permit engineers to take better advantage of advanced methods of inelastic analysis. The appendix allows for the use of a wide range of inelastic analysis methods, which vary from the traditional plastic design approaches to the more advanced nonlinear finite element analysis methods, to design continuous beams, moment frames, braced frames and combined systems. Presented as an extension of the Specification's primary design approach, termed the direct analysis method, a noteworthy feature of Appendix 1 is that for the first-time in an AISC Specification, engineers are permitted to evaluate strength limit states through the use of sophisticated methods of analysis in place of the Specification's design equations. Of course, the application of such an approach requires the designer to have a complete understanding of the particular method of inelastic analysis employed, the provisions of Appendix 1, and the Specification design equations being superseded.

2 GOALS OF APPENDIX 1

Strength limit states of structural steel systems almost always include significant amounts of yielding accompanied by large deformations. As a result of these destabilizing influences, significant redistribution of member and connections forces often occurs. The general objective of inelastic analysis and design (historically called *plastic design*) is to gain increases in economy through a better understanding and prediction of a structure's ultimate strength (Wong 2008). Such increases can come in the form of simply being able to use smaller member sizes by accounting for potential force redistribution or more broadly by providing structural systems with increased ductility through more informed design decisions.

There were four basic goals in preparing Appendix 1, including (1) recognizing the wide range of inelastic analysis available to today's engineer; (2) aligning the basic philosophy of inelastic analysis and design to the Specification's primary approach of the direct analysis method; (3) attempting to move in the direction of future design standards that are rooted in performance based engineering; and (4) being transparent and self-contained. Each of these goals will be covered in more detail below.

2.1 *Wide range of inelastic analysis methods*

In general, inelastic analysis covers a wide range of approaches based on concentrated plasticity models to the much more refined methods based on distributed plasticity procedures (McGuire et al. 2000). In addition, such methods may be classified as first- or second-order depending on whether or not equilibrium is formulated on the geometry of the deformed structure.

The concentrated plasticity or plastic hinge methods are typically based on comparing internal member forces and/or moments (stress resultants) to yield criteria and thus, lend themselves to the efficient analysis of systems such as continuous beams and two- or three-dimensional frames. Such methods may be modified

to indirectly include the effects of partial yielding that may be accentuated by the presence of thermal residual stresses due to nonuniform cooling during the manufacturing process. By doing so and also including second-order effects, these methods can provide the engineer with an analysis that is much more sophisticated than a program based on detecting plastic mechanisms.

In contrast, distributed plasticity algorithms are often stress-based and hence, can account for gradual yielding through the depth and along the length of structural members. These methods rely on at least discretizing the cross-section into fiber elements or, at the extreme, representing members and/or connections by a two- or three-dimensional mesh of continuum elements. When these methods include geometric nonlinear effects and explicitly model residual stresses by defining initial states of stress within the elements, they are often consider the most comprehensive or "exact." Such methods of analysis are available in commercial programs such as ABAQUS, ANSYS, and ADINA.

In all previous editions to the AISC Specifications, inelastic analysis was simply assumed to be the least rigorous of the plastic hinge methods, and although inelastic force redistribution was permitted, all member strength checks were based on satisfying the same Specification design equations that are defined for force distributions calculated from an elastic analysis. Given that most of these design equations were previously developed using the more refined (but now generally available) inelastic analysis methods, and further given that such sophisticated methods of analysis can model complex forms of nonlinear behavior and detect member and/or frame instabilities well before the formation of a plastic mechanism, one of the primary goals in developing Appendix 1 was to provide certain liberties to engineers who were willing to employ more rigorous and accurate methods of analysis. These liberties may include, for example, waiving the use of Specification design equations in lieu of the analysis being able to accurately model the strength limit state being considered. On the other hand, such liberties would be more restricted or eliminated if the inelastic analysis is too simplistic. Of course, in all cases it is the engineer's responsibility to fully comprehend the structural behavior being simulated and just as importantly, understand the theory, abilities, and limitations of the software being employed.

2.2 *Align with the direct analysis method*

In the 13th edition of AISC Specification for Structural Steel Buildings (AISC 2005), an alternative method for addressing structural stability was provided in its Appendix 7. This approach, termed the direct analysis method (Ziemian 2010), was well received and upgraded to Chapter C in the most recent 14th edition of the AISC Specification. The direct analysis method consists of calculating strength demands following fairly detailed analysis requirements and then comparing these required strengths with available strengths or capacities that are determined in accordance with design equations provided in the remaining chapters of the Specification. One of the key advantages of providing analysis requirements is that they can be defined such that assessment of stability of the system and members could be achieved without the need to rely on effective length K-factors. In other words, the direct analysis method provides an acceptable alternative to the effective length (KL) method, which had been the staple of the U.S. steel design profession for the past 50 years. This thereby allows engineers to simply use the unbraced length (L, with $K = 1$) of compression members in all related Specification design equations.

In breaking new ground in an AISC Specification by defining analysis requirements, the general philosophy of the direct analysis method could be easily extended beyond its original intent for elastic analysis and be equally employed in design based on inelastic analysis. Of course, the key is to define a set of analysis requirements that could apply to the wide range of inelastic methods described above.

2.3 *Move towards performance based engineering*

Performance-based engineering is a design philosophy that is receiving serious consideration by many standards organizations worldwide, including AISC, as they plan for the future. In general, functional objectives are defined and quantified such that the economies of improved performance can include life-cycle considerations that are well beyond initial construction costs. One of the keys to quantifying performance is an accurate prediction of structural behavior under a wide range of environmental effects.

Although Appendix 1 does not provide all of the elements of a performance-based engineering philosophy, it does include the general concept of applying more advanced methods of analysis to better predict structural response. That is, it provides for making more informed cost-benefit analyses when attempting to provide better performance.

2.4 *Transparent and self-contained*

One of the primary objectives in preparing all sections of the 13th and 14th editions to the AISC Specification was to provide provisions intended to be transparent (AISC 2005, AISC, 2010a). Design clauses and equations are now given in a format that allows the engineer to better understand which limit state behavior is being targeted by specific terms and mathematical expressions appearing in the Specification.

In addition to providing this same level of improved clarity, it was also desired that Appendix 1 should have its own self-contained provisions for assessing limit state behavior. Fortunately, this goal could be met with minimal repetition of information found in other parts of the Specification.

3 OVERVIEW AND GENERAL REQUIREMENTS

In meeting the above goals, Appendix 1 is presented in two basic tiers. The first provides general requirements that apply to all levels of inelastic analysis, varying from the traditional plastic mechanism methods to the much more sophisticated finite element procedures. The second tier provides the basis for an AISC-approved design method that is specific to second-order inelastic frame analysis. As such, this method can be used to assess the required strength of most structural members and systems. On the other hand, the first tier would provide the basis for employing a nonlinear finite element analysis using shell or brick elements to design more a complex component, such as a connection. In all cases, design by inelastic analysis is only permitted in accordance with the Specification's principles of load and resistance factor design, LRFD (the Specification also includes allowable strength design provisions).

3.1 *Essential 5*

Given that inelastic analysis permits the redistribution of forces and moments within structural systems or stresses within a connection, it is essential that the analysis provide an accurate representation of the effects of load on the system or component being designed. Factors that typically influence the stability of a structural system or component include deformations and reductions in stiffness due to yielding as well as variations in the design loads and anticipated strengths. With this in mind, Appendix 1 requires that the inelastic analysis shall take into account:

- Flexural, shear and axial member deformations, and all other component and connection deformations that contribute to the displacements of the structure
- Second-order effects (including P-Δ and P-δ effects)
- Geometric imperfections
- Stiffness reductions due to inelasticity, including the effect of residual stresses and partial yielding of the cross section
- Uncertainty in system, member, and connection strength and stiffness

It is important to note that these five requirements also appear in Chapter C where stability requirements for elastic analysis are provided. There is, however, one important distinction; in Chapter C it states that the requirements shall be considered, in contrast to the stronger language of shall take into account in Appendix 1. The committee felt that the firmer language of Appendix 1 was needed because engineering judgment of the importance of these factors is often much more difficult to exercise when employing a design procedure based on inelastic analysis.

Also in contrast to Chapter C, no further details are provided in this section regarding geometric imperfections or stiffness reductions, including predefined residual stress patterns. In this regard, such definitions vary greatly depending in the structural system or component being investigated. In general, it is expected that the engineer would define for example initial imperfections based on tolerances defined by the contract documents or include residual stress patterns that are specific to the profiles being analyzed.

Beyond requiring that uncertainty in strength and stiffness be included, the engineer is provided with the opportunity to define system and component reliabilities based on available theories that apply to the specifics of the design problem at hand (Buonopane & Schafer 2006, Nowak & Collins 2000, Thoft-Christensen & Murotsu 1986). In all cases, it is expected that a comparable or higher level of reliability forming the basis of the Specification will be provided.

3.2 *Assessing strength*

One of the primary objectives in developing Appendix 1 was to provide engineers the opportunity to better use advanced methods of inelastic analysis to confirm the adequacy of structural members, connections, and systems. All strength limit states assessed by the Specification must be considered, although the analysis could be used in place of the Specification design equations to demonstrate adequacy.

Consider, for example, assessing the strength of a compression member without slender elements. Section E3 of the Specification provides the pertinent design equation that accounts for several destabilizing factors including partial yielding accentuated by the presence of thermal residual stresses, initial member out-of-straightness, and second-order (P-δ) effects. If a level of inelastic analysis is employed that directly incorporates all of these factors, that is the analysis would be able to detect the limit state of inelastic/elastic flexural buckling, and a comparable or higher level of reliability can be assured, then that specific design equation need not be evaluated.

On the other hand, if the analysis does not accurately model flexural-torsional buckling or lateral-torsional buckling, then Specification equations given for these strength limit states would govern. In general, strength limit states not accurately modeled by the analysis would need to be assessed by the corresponding provisions of the Specification's Chapters D-tension, E-compression, F-flexure, G-shear, H-combined forces and torsion, I-composite, J-connections, and K-HSS and box sections.

3.3 *Ductility*

As a structural system reaches a strength limit state, significant force redistribution may take place as a result of yielding within members and connections. If a design procedure relies on this redistribution occurring, then all structural components subject to

yielding must be able to maintain their strength by accommodating the inelastic deformation demands.

There are two general methods for assuring this. The first, and more common approach, is to limit material properties, cross-section slenderness, and member unbraced length. The second is to make a direct comparison of inelastic deformation or strain demands with the component's deformation capacity. Examples of the first approach are provided below and examples of the second are provided in the literature (Galambos 1968, Gioncu & Petcu 1997, Kemp 1996, FEMA 2000, Ziemian 2010). Appendix 1 permits the use of either method to assure that adequate ductility is provided. In no case is force redistribution due to tensile rupture of an element of cross-section or connection permitted.

3.4 *Serviceability*

Beyond the general requirements for structural behavior at service loads provided in the body of the Specification, no provisions specific to design by inelastic analysis are included in Appendix 1. This should be expected given that (1) permanent deformations due to yielding at service loads should almost always be avoided, and (2) the benefits of inelastic analysis are only realized when assessing strength limit states.

3.5 *Seismic*

One of the more frustrating outcomes in preparing Appendix 1 was that its provisions had to be limited to non-seismic design applications, despite the fact that inelastic analysis has great potential in earthquake engineering. Two basic points complicated this matter, including (1) the equivalent static loads often used to represent seismic effects within factored load combinations assume a particular level of yielding and force redistribution has occurred, and as such it would be unconservative to use these loads within a design procedure based on inelastic analysis; and (2) all of the ductility requirements defined within Appendix 1 are unique to non-seismic effects and more stringent requirements would be needed for seismic design. Provisions for employing inelastic analysis in seismic design, however, are provided in *Seismic Provisions for Structural Steel Buildings* (AISC 2010b), *Minimum Design Loads for Buildings and Other Structures* (ASCE 2010) and *Seismic Rehabilitation of Existing Buildings* (ASCE 2006).

4 SPECIFIC PROVISIONS FOR FRAME DESIGN

As mentioned above, Appendix 1 is presented in two tiers, one universal and the other specific to frame design. With regard to the latter, detailed ductility and analysis provisions are given that collectively satisfy the above general requirements defined above. As such, these provisions define an AISC-approved procedure for using inelastic analysis to design structural systems, including frames and trusses, which are comprised of beams, columns, braces, and connections. An overview of these provisions is provided below.

4.1 *Ductility requirements*

To assure that structural components subject to yielding have adequate ductility, several design requirements are provided. The first is that the yield strength of the steel is not to exceed 450 MPa (65 ksi). This value was selected because extensive research into the use of such grades of steel in plastic design has been completed over the past 50 years. It is important to note that the use of higher strength steels is permitted per the general requirements presented in the first tier of Appendix 1, but not in association with the specific requirements given for frame design.

In assessing ductility, adequate inelastic deformation capacity can be confirmed by decoupling inelastic local buckling from inelastic lateral-torsional buckling, although in reality they often occur simultaneously. In both of these forms of buckling, requirements on the elements of the cross-section and on the unbraced length have been defined to provide adequate an rotation capacity at a plastic hinge of approximately $R_{cap} = 3$. Due to the complexity in inelastic behavior of members composed of singly- or non-symmetric cross-sections and their often-insufficient ability to provide adequate levels of ductility, this tier of Appendix 1 was purposely limited to doubly symmetric sections.

To prevent premature inelastic local buckling, guidelines are provided that limit the width-to-thickness ratios of cross-section components such as flanges and webs in the area of plastic hinges. Collectively, these slenderness requirements define "compact" sections, which are sections that have been shown experimentally and/or analytically to provide the desired inelastic rotation of capacity of $R_{cap} = 3$.

Inelastic lateral-torsional buckling can also significantly reduce the ductility of structural members with plastic hinges. In this regard, more closely spaced bracing in the vicinity of a plastic hinge will reduce the unbraced length of the member and thereby provide adequate rotation capacity. Appendix 1 provides unbraced-length requirements that are a function of the moment gradient for wide-flange and rectangular shapes bent about the major axis.

Finally, the axial force in a compression member is limited to 80% of the design yield load. This provision reflects a dearth of research that has been completed to ensure adequate inelastic rotation capacity in members subject to high levels of compressive axial force.

4.2 *Analysis requirements*

Per the requirements given above, a second-order analysis must be employed. The one exception to this rule would be for the design of continuous beams that are not subject to axial force.

Although there are several ways for including uncertainty in design based on inelastic analysis, Appendix 1 permits the simple strategy of reducing the system, member, and connection strength and stiffness by the AISC resistance factor of 0.9. In practice, this would typically be accomplished by using material yield strengths and stiffnesses of $0.9F_y$ and 0.9E, respectively. For a system of little-to-no redundancy, this factor will provide the same level of reliability as for design by elastic analysis. For more redundant systems, it can be shown that this approach is conservative.

Given that yielding in most frame design is the consequence of normal stresses acting in a direction parallel to the length axis of the members, Appendix 1 requires that these normal stresses include contributions by major- and minor-axis bending as well as axial force. In all cases, strain hardening is prohibited, thereby limiting the strength of a member to the plastic strength of its cross-section.

Initial imperfections, which include both member out-of-straightness and frame out-of-plumbness, must be included in the analysis. Although its impact depends on the amount of axial force in the member, its slenderness, and whether or not the member is subject to single- or reverse-curvature bending, a reasonable initial out-of-straightness might be of parabolic or sinusoidal shape with amplitude of L/1000, where L is the member length.

With regard to initial out-of-plumbness, the same provisions in Chapter C associated with the direct analysis method are to be used. Specifically, this would include incorporating a story sway out-of-plumbness of h/500, where h is the story height, or the use of an equivalent notional load at each level equal to the product of 0.002 and the factored gravity load on that particular level. In all cases, the initial imperfections should be modeled to produce the maximum destabilizing effect.

Finally, frame design by second-order inelastic analysis must include the effects of partial yielding, which can be accentuated by the presence of thermal residual stresses. Partial yielding may be included in the analysis either directly through the use of a distributed plasticity model or by a modified concentrated plasticity model (Ziemian and McGuire, 2002). It should be noted that no specific residual stress pattern is provided because the committee felt that it was not possible to provide a single idealized pattern for all potential cross sections and manufacturing processes. Instead, it is expected that the designer would reference the literature to obtain residual stress patterns that are appropriate to the given cross-sections employed.

5 FUTURE DIRECTIONS AND RESEARCH NEEDS

In preparing Appendix 1, several of the below limitations on the general application of design by inelastic analysis became apparent. Almost all of these limitations are the result of insufficient research. The committee is hopeful that such research will be completed in the near future and forthcoming editions of Appendix 1 will see increased opportunities in the following directions.

5.1 *Seismic design*

For the reasons indicated above, Appendix 1 does not permit buildings to be designed for seismic effects using inelastic analysis. Current thinking is that either Appendix 1 can be modified to include seismic design, or better yet, engineers will simply transition to other more applicable codes such as *Seismic Provisions for Structural Steel Buildings* (AISC 2010b) or *Minimum Design Loads for Buildings and Other Structures* (ASCE 2010).

5.2 *Singly-symmetric and non-symmetric shapes*

With additional research into the plastic rotation of capacity of singly-symmetric and non-symmetric shapes, the frame design tier for Appendix 1 can be expanded beyond permitting only doubly-symmetric shapes. Such research will need to address both slenderness requirements of cross-section elements and unbraced length requirements.

5.3 *Ductility requirements for high axial forces*

In providing guidance for frame design, Appendix1 limits the axial force to 80% of a shape's design yield load. With more research, this limitation could be relaxed or perhaps removed.

5.4 *High-strength steels*

A careful assessment of completed and future research of high-strength steels could provide their associated ductility requirements. In this regard, the benefits of steels with yield strengths in excess of 450 MPa (65 ksi) could be realized in frames designed by inelastic analysis.

6 SUMMARY

This paper presents an overview of Appendix 1 – *Design by Inelastic Analysis* that appears in the most recent 14th edition of AISC's *Specification for Structural Steel Buildings*. The appendix has been fully revised to permit the use of a wide range of inelastic analysis methods, in which significant advantages are provided for more sophisticated levels of analysis. In this regard, computational analysis (e.g., nonlinear finite element analysis) may be used in place of design equations to evaluate the strength limit states covered in the Specification. Of course, superseding Specification equations requires a thorough understanding of both the associated strength limit states and the

completeness and accuracy of the analysis software being employed to do so.

The appendix is presented in two tiers; one that is intended to cover all levels of inelastic analysis and a second that provides specific details that define a basis for an AISC-approved second-order inelastic frame analysis and design method. In both tiers, strength, ductility, and analysis requirements are provided. This paper concludes by suggesting future research that could provide more opportunities to design by inelastic analysis.

Three-dimensional joist member design using equivalent beam theory

S.J. Kilber & A.E. Surovek
South Dakota School of Mines and Technology, Rapid City, South Dakota, USA

ABSTRACT: When selecting steel joists for a structure, design engineers have traditionally relied on standard load tables, but this is limiting when commercial software is used. Current structural design software packages lack the necessary capacities to estimate joist member weights and section properties accurately. Using custom tables for joist members with the application of Equivalent Beam Theory (EBT) allows joist member limit states to be analyzed by strength checks built into the design software. The custom tables for joist members are developed to represent approximate prismatic members based on the properties of typical chord sizes readily used in industry. This study presents the validation of custom tables for joist members. A case study illustrates the application of joist and joist girder tables in the design of a three-dimensional building.

1 INTRODUCTION

1.1 *Background*

Most current design software packages are limited to selecting simply-supported joists from standard load tables. These tables do not provide the design engineer with member section properties. They do provide member weights but only for specific joists types under uniform load conditions. The standard load tables are limited in that they are not equipped to support automated design of joists with non-uniform loads, such as drifted snow, pattern loading or point loads. Considering that joists and joists girders are custom designed by different manufacturers using proprietary combinations of chord and web components, the possibility of developing an all-inclusive list of the properties of available joists is infeasible. A more practical approach is to develop tables of approximate joist and joist girder weights and section properties based on the typical chord configurations used by joist manufacturers; these tables be then used with current software design packages. This method was originally validated for use with joist girder moment frames (Knodel et al. 2013).

1.2 *Equivalent beam theory (EBT)*

EBT is a simple modeling approach in which the properties of a flexural system (such as a steel joist) are approximated as those of a homogeneous, prismatic beam. The application of EBT has been shown to adequately capture the behavior of complex flexural systems in a single beam element. Giltner & Kassimali (2000) applied equivalent beam principles to modeling full truss systems. They evaluated two different equivalent beam methods:

1. The equivalent beam's stiffness was calculated from the deflection of the load truss.
2. Parallel axis-theorem was used to develop the equivalent beam moment of inertia based on the truss cross-sectional area. The vertical and diagonal web members were not considered in the calculation of the equivalent moment of inertia.

In their studies, Giltner & Kassimali compared and evaluated displacement and reaction values taken from a real three-dimensional model and those from equivalent models. They found that both equivalent methods provided acceptable results and two primary advantages. Equivalent beam theory greatly reduces the computational time needed for structural design software to analyze the given member. It also significantly reduces the overall time to model the structural (Knodel et al 2013).

Using EBT in the form of a Virtual Joist (VJ) table allows the multi-element flexural system to be modeled as a single beam element. This simplified element has approximate beam properties equivalent to those of the more complex system. In addition, the application of EBT allows both the design engineer and the joist designers to address common non-uniform loading conditions on their design members. If the section properties of the EBT accurately capture the properties of the joist within a reasonable variance, use of EBT allows the designers to move past the restrictions of simply-supported load tables when selecting an appropriate member. Panel-point loads, drifted snow loads, non-continuous uniform loads, etc. can be handled directly when selecting an appropriately sized member.

1.3 *Virtual joist and joist girder property tables*

The two joist properties that the design engineer must communicate to the joist designer are the moment of inertia (I_z) and the weight; both properties are based on chord sizes and are related to the combined chord areas

(A_x). The member weight is calculated from the cross-sectional areas of both the top and bottom chords; however, this calculation does not consider the web members due to the large variability in web member selection. To account for the web member weight, the density of joist and joist girder material is increased by 18%. This density increase provides a simple means to approximately account for web member weight in the virtual joist girder (VJG) and virtual joist (VJ) tables without affecting calculated values of axial capacity.

Because the tables represent complex geometry of a truss with a single beam member, they do not adequately capture out-of-plane joist behavior, nor can they capture local buckling of the joist member components. SJI developed these VJG and VJ tables based on industry bracing standards that eliminate out-of-plane limit states as member failure modes. For these studies, the joist members were considered to have continuous lateral bracing.

2 TABLE VALIDATION STUDIES

2.1 *Virtual joist girder table validation study*

The objective of the validation study, as detailed in Knodel et al. (2013), was to determine if the VJG moment of inertia and weight, as selected by the commercial design software, are within an acceptable variance from the moment of inertia and weight designed by the proprietary joist design software. First, simply-supported joist girder members were analyzed to eliminate the effect of support conditions. Second, fixed-end joist girder members were considered to account for end moment. Finally, portal frames were developed to establish proof of concept and to examine if the variation between VJG stiffness and the actual joist-girder stiffness has any impact on column or system design. These frame studies accounted for the influences of adjoining beam-columns on the member design.

Parameters for the single joist girder studies were selected to represent a practical range of design requirements. The parameter ranges for the single member studies are summarized in Table 1 (Knodel et al. 2013). The joist girder depth was not an independent parameter. The span-to-depth ratios were limited in the tests to a practical ratio of 12 to 24. For the single joist girder studies, the maximum chord depth was set to 15.2 cm. STAAD.Pro V8i (Bentley 2012b) was the design software used in all of the parametric studies.

Results of a single test were deemed "acceptable" if the value of Equation 1 was within a designated variance

$$\frac{\text{Design}_{\text{value}}\text{-P.Software}_{\text{value}}}{\text{P.Software}_{\text{value}}} \times 100 \qquad (1)$$

where:

$\text{Design}_{\text{value}}$ = member moment of inertia or weight selected by the design software; and

Table 1. Parameters for single joist girder studies.

Parameter	Range	Interval
Span (m)	6.10–24.38	3.05
Panel Point Loads (kN)	44.48–400.3	88.96

Both Acceptable	70%	91%	99%

$\text{P.Software}_{\text{value}}$ = member moment of inertia or weight designed by the proprietary joist software.

2.1.1 *Simply-supported joist girder studies*

With the parameters given, 78 simply-supported cases were designed. Table 2 summarizes the results.

As can be seen in Table 2, within the +/−10% variance, the moment of inertia approximation is close to complete acceptability and the weight approximation is at 72% of acceptability. When the variance is increased to +/−20% the weight approximation is also close to complete acceptability.

2.1.2 *Fixed-end joist girder studies*

Based on the single beam study parameters, 82 fixed-end joist girders were designed. Table 3 summarizes the results.

2.1.3 *Moment frame study*

To account for the effects of adjoining members on the design with the virtual joist girder table, a series of frames were analyzed in a similar manner as the single member studies (Knodel et al. 2013). The parameters and design loads for the frames studies are listed in Tables 4 and 5, respectively. Figure 1 gives a general frame layout.

From the moment frame studies, 72 joist girder designs were analyzed. The moment of inertia and weight variances of the moment frames studies are shown in Table 6.

Table 4. Parameters for frame studies.

Parameter [Symbol]	Increments
Length [L] (m)	12.2, 15.2
Height [H] (m)	6.10, 10.7
Load Amplifier [α]	0, 2, 6

Table 5. Design loads and for frame studies.

Load Type [Symbol]	Load kPa
Snow [S]	0.96, 1.92
Dead [D]	0.96

	10%	12.5%	15%
# Considered	72	72	72
I Acceptable	88%	96%	100%
Weight Acceptable	90%	100%	100%

Similar to the single joist girder studies, the moment frame cases demonstrated a high level of acceptability for both the moment of inertia and weight approximations within the +/−10% variance. With the variance was increased to +/−15%, both the moment of inertia and weight approximations were at compete acceptability.

2.2 *Virtual joist table validation study*

The VJ table validation was carried out in a similar manner as the VJG table validation. Simply-supported members were analyzed, and then followed by fixed-end member cases. Tables 7 and 8 show the single joist members used in both the simply-supported and fixed-end cases. The results were acceptable as defined by Equation 1.

2.2.1 *Simply-supported joist studies*

A total of 20 K-Series and 42 LH-Series joists were tested in the simply-supported condition to ensure that the VJ table functioned well in the simplest design case. Tables 9 and 10 show the results for the K-Series and LH-Series studies, respectively.

From Table 9, both the moment of inertia and weight approximations for the K-Series joists are at complete acceptability within the +/−15% variance. From

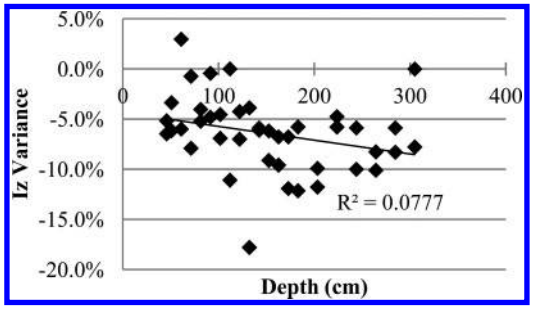

Figure 2. Moment of inertia variance vs. depth for simply-supported LH-Series tests.

Table 10 for the LH-series joists, the moment of inertia approximation is close to complete acceptability and weight approximation is at complete acceptability within the +/−15% variance.

Figure 2 shows the relationship between the moment of inertia variance and the member depth for the LH-series joists.

Figure 2 shows a downward trend, but insignificant correlation, in the moment of inertia variance as the joist depth increases. The design software selected virtual joist members with smaller moments of inertia than what the proprietary joist software calculated in a majority of the LH-Series tests. Further investigation into this difference yielded that the LH-Series joists have high interaction check values for the top chord in the end panels. Therefore, even in the simply-supported case, the top chord experiences combined axial and bending forces that need to be accounted for in the design software. This interaction is not captured by the equivalent beam.

2.2.2 *Fixed-end joist studies*

Similar to the simply-supported cases, 20 K-Series joists were tested with fixed-end conditions. Table 11 summarizes the results.

Table 11 shows that both the moment of inertia and weight approximations are at complete acceptability within the +/−15% variance.

3 THREE DIMENSIONAL BUILDING CASE STUDY

In order to demonstrate the effectiveness of both the VJ and VJG tables in a more realistic design situation,

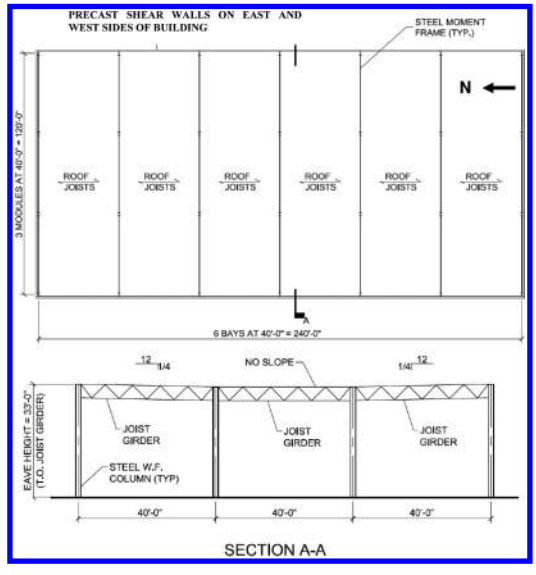

Figure 3. Building model dimensions and layout.

Table 12. Gravity design loads.

*Acts over 5.2 m in the north bays.

a three dimensional building model was developed. There were two primary goals for this case study: One was to adjust the table layouts to make them functional with RAM Structural System (Bentley 2012a) and the other was to determine the VJ table functionality with non-uniform member loads. In this instance, triangular drifted snow loads were applied on selected joists. The building geometry is shown in Figure 3 (Fisher et al. 2007). The bay dimensions in each direction are 12.2 m with overall building dimensions of 36.6 m by 73.2 m. Table 12 shows the gravity design loads. The wind loads were developed according to Structural Engineering Institute 7-05 (2006) requirements and were only applied in the E-W direction. Shear Walls are provided to withstand wind-load in the N-S direction.

I (mm^4)	1.7E+08	1.6E+08	1.4E+08	1.3E+08
W Variance	−2.4%		−6.0%	
I Variance	5.1%		8.9%	

3.1 *Case study results – joist selection*

There are four different types of joists that needed to be designed in this case study: Perimeter Drift Joists, Interior Drift Joists, Perimeter Drift Joists, and Interior Joists. In the design, all of these members were considered to be pinned-pinned and have continuous bracing of the top flange. The results of the joist selection are shown in Tables 13 and 14.

Table 14 shows that for the two types of interior joists, both the moment of inertia and weight approximations fell within the +/−10% variance. Table 13 shows that for the exterior joists, the moment of inertia approximation fell within the +/−10% variance and the weight variance fell within the +/−20% variance. These results demonstrate the VJ table functionality with both drifted snow and uniform loading conditions.

3.2 *Case study results – joist girder selection*

For the design of the joist girders, the first-order analysis method as defined Appendix 7 of the American Institute of Steel Institute (AISC) Specification for Structural Steel Buildings, 14th Edition (2011) was applied. This approach is similar to notional load approaches currently used in various international design specifications (Galambos & Surovek 2008).

With joist girder moment frames (JGMF's) carrying the lateral loads in the east-west direction, there were four different types of joist girders that were designed: North Frame Drift Girders, Frame Drift Girders, Frame Girders, and South Frame Girders. For each of these frames, the first-order analysis member reactions were entered into the proprietary software, which designed the required member sizes. Then the equivalent virtual joist girder section was entered in RAM Structural System and analyzed using AISC 360-05 ASD design requirements. The results are summarized in Tables 15–18.

Table 15. North frame drift girder results.

	North Frame Drift	
Girder Type	Design	Proprietary
Designation	VJG36-40	36G8N8.1K/6.1
W (kN)	6.00	6.18
I (mm^4)	8.8E+08	8.8E+08
W Variance	−3.0%	
I Variance	0.0%	

Table 16. Frame drift girder results.

	Frame Drift	
Girder Type	Design	Proprietary
Designation	VJG36-52	36G8N10.9K/6.9
W (kN)	8.44	8.28
I (mm^4)	1.2E+09	1.2E+09
W Variance	1.9%	
I Variance	2.4%	

Table 17. Frame girder results.

	Frame	
Girder Type	Design	Proprietary
Designation	VJG36-48	36G8N10.4K/6.4
W (kN)	7.49	7.70
I (mm^4)	1.1E+09	1.1E+09
W Variance	−2.7%	
I Variance	0.8%	

Table 18. South frame girder results.

	South Frame	
Girder Type	Design	Proprietary
Designation	VJG36-19	36G8N5.2K/3.2
W (kN)	3.59	4.01
I (mm^4)	5.3E+08	5.6E+08
W Variance	−10.4%	
I Variance	−5.4%	

From Tables 15–17, the moment of inertia and weight approximations for three girder types fell within a +/−5% variance. In Table 18, the moment of inertia approximation fell within a +/−10% variance and the weight approximation fell just outside this variance. These results illustrate the functionality of VJG tables in RAM Structural System. Since the individual studies and the building design were both

able to produce acceptable results, the two studies validate the application of the tables and their adaptability to different commercial software packages.

3.3 *Case study results – overall member weight*

The total member weights from RAM Structural System and the proprietary joist design software were compared. The total member weight required by RAM was 340 kN; whereas, the proprietary joist design software required 356 kN of material. Thus, RAM was only 4.4% lower than the actual member weight required by the proprietary design software. In light of the total material needed, this is a minimal variance that would provide a design engineer a good initial material estimate. It should be noted that RAM Structural System does not allow for the creation of new design materials; thus, the member weights were adjusted after the analysis to account for the required joist density discussed in Section 1.3.

4 CONCLUSIONS AND FUTURE WORK

These studies show that the application of EBT to joist and joist girder design provides a reasonable approximation for the design engineer when estimating required stiffness and member weights. The case study provided a preliminary proof-of-concept and illustrates the use of the virtual joist and virtual joist girder tables in a more practical problem.

Further study is necessary to validate the use of EBT on joists, however. As stated earlier, equivalent beam theory allows complex models to be simplified and modeled as a single element. However, by simplifying a complex model, certain failure mechanisms, such as localized interaction of flexure and axial forces and local buckling, are not addressed in the simplified element. This was illustrated in the LH-Series studies. By using the VJ Table and EBT, the design software picked LH-Series joists with smaller moments of inertia than the same joists designed by the proprietary joist software. The design analysis failed to address the combined flexure and axial forces that these large joists experience when uniformly loaded. Thus, the selected members had smaller top chords; this results in lower moments of inertia and member weights. The next portion of this research will address methods to account for joist component interaction that cannot be captured by the EBT.

ACKNOWLEDGEMENTS

This research project was sponsored by the Steel Joist Institute. Bentley Systems, Inc. provided the STAAD.Pro and RAM Structural System software used in the research, and Habco Erectors, Inc. provided the proprietary joist design software.

The authors wish to acknowledge the input and assistance offered by the SJI Research Committee especially Dave Samuelson of Nucor Research and Development for Downstream Products and Walter Worthley with Valley Joist, Inc. In addition, the authors want to acknowledge Joe Pote with New Millennium Building Systems for both for developing the virtual joist and virtual joist girder tables and for his input on the project, as well as Jim Fisher of Computerized Structural Design for providing the building example. Findings, conclusions and recommendations are those of the authors and do not necessarily reflect those of the sponsoring organizations.

ABSTRACT: An extension of recent work on the local–global buckling mode interaction in thin-walled I-section columns is presented. The results obtained from an analytical model based on variational principles, which describes the column nonlinear buckling behaviour, are compared with those yielded by finite element analyses from the commercial software ANSYS. The comparisons are good and this provides encouragement to advance the understanding of the complex instability phenomena associated with nonlinear modal interactions.

1 INTRODUCTION

The buckling of struts and columns represents the most common type of structural instability problem. In the current work, the classic problem of a linear elastic column under axial compression with an open and doubly-symmetric cross-section – an "I-section" – is studied. Under this type of loading, long members are primarily susceptible to a global (or overall) mode of instability namely Euler buckling, where flexure about the weak axis occurs once the Euler buckling load is reached. However, when the individual plate elements of the column cross-section are relatively thin or slender, elastic local buckling of these may also occur. The interactive buckling behaviour of the aforementioned buckling modes is usually far more unstable than when the modes are triggered individually (Thompson & Hunt, 1973). Relevant recent work on interactive buckling include studies on stainless steel columns (Becque & Rasmussen, 2009a; Becque & Rasmussen, 2009b) with studies on thin-walled beams under uniform bending (Wadee & Gardner, 2012), sandwich struts (Hunt & Wadee, 1998) and corrugated plates (Pignataro *et al.*, 2000). Advances have been made recently on column behaviour where the junction of the web and the flange is assumed to be pinned (Wadee & Bai, 2012); cellular buckling (Hunt *et al.*, 2000) is thus triggered and a sequence of snap-backs is observed during the interactive buckling process.

The current work focuses on the scenario where the flanges and web have a rigid connection. In analytical terms, the boundary condition was currently switched from pinned to rigid and so the original model has been modified. It is found that this smoothes the post-buckling behaviour, the number of snap-backs is reduced and the response becomes more amenable to finite element (FE) simulation; the latter is performed in the commercial package ANSYS (2009). Comparisons between the analytical and FE model are found to be good and this offers encouragement to extend the study later using Generalized Beam Theory (GBT), where a semi-analytical approach may allow structural analysis to be performed for more generic cases (Basaglia *et al.*, 2011).

2 ANALYTICAL MODELLING

Figures 1(a) and (b) show the elevation and cross-section of the column with the coordinate system. The section geometries are chosen such that the local critical buckling load P_l^{C} is sufficiently close to the global buckling load P_o^{C}.

The investigation begins with defining appropriate descriptions for both the global and the local modes. The "sway" and "tilt" components from the previous work – see Figure 1(c) (Hunt & Wadee, 1998) – are combined to construct the global buckling mode such that shear deformations are allowed; this has been shown to be key in successfully modelling interactive buckling in an analytical framework. The lateral deflection W and the rotation of the plane sections θ are given by the following expressions:

$$W(z) = q_s L \sin\frac{\pi z}{L}, \quad \theta(z) = q_t \pi \cos\frac{\pi z}{L}, \tag{1}$$

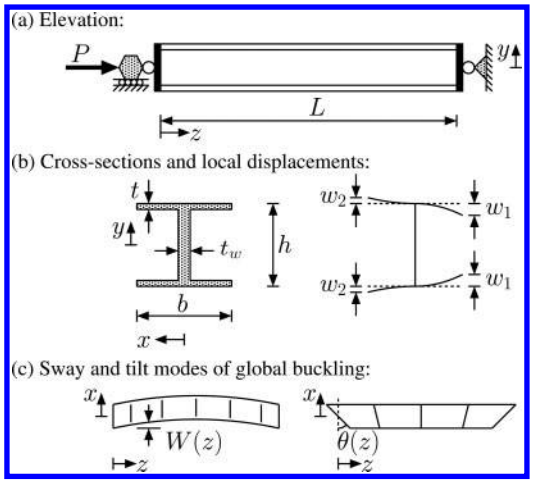

Figure 1. (a) Column elevation. (b) Cross-section dimensions and lateral flange displacements defining the local buckling mode. (c) Sway and tilt components of the minor axis global buckling mode.

where L is the column length with q_s and q_t being defined as generalized coordinates for the sway and tilt modes respectively. The shear strain γ_{xz} for the global mode is therefore given by the following expression:

$$\gamma_{xz,\text{global}} = \frac{\mathrm{d}W}{\mathrm{d}z} - \theta. \tag{2}$$

This is in essence a Timoshenko beam formulation (Wadee *et al.*, 2010).

An additional set of functions, w_i and u_i, where $i = \{1, 2\}$ representing the local lateral and in-plane displacements of the flange outstands respectively, is introduced (Wadee & Bai, 2012):

$$\begin{aligned} w_i(z,x) &= (-1)^i \left[\left(1 - \cos\frac{\pi x}{b}\right)\right] w_i(z), \\ u_i(z,x) &= (-1)^i \left(\frac{2x}{b}\right) u_i(z), \end{aligned} \tag{3}$$

where x is the transverse coordinate as shown in Figure 1(b), which also shows the cross-section lateral displacements w_i. Figure 2 shows the corresponding in-plane displacements u_i. For w_i, a sinusoidal distribution of displacement in the transverse direction is taken such that the flange–web connection is assumed to be rigid. For u_i the distribution is taken to be linear which is in accord with the Timoshenko beam assumption.

2.1 *Energy formulation*

The formulation of the total potential energy V is now presented. The component of the strain energy due to bending from global buckling U_B is given by:

$$U_B = \frac{1}{2} E I_w \int_0^L \left(\frac{\mathrm{d}^2 W}{\mathrm{d}z^2}\right)^2 \mathrm{d}z, \tag{4}$$

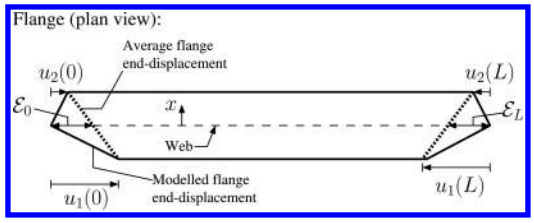

Figure 2. In-plane flange displacements u_1 and u_2 defining the local buckling mode. End shortening expressions $\mathcal{E}_0$ and $\mathcal{E}_L$ are $[u_1(0) + u_2(0)]/2$ and $[u_1(L) + u_2(L)]/2$ respectively.

where E is the Young's modulus and I_w is the second moment of area of the web about the global weak axis of the column cross-section and is given by $(h - 2t)t_w^3/12$. The local bending energy, accounting for both flanges buckling, is thus:

$$\begin{aligned} U_b = D \int_{-b/2}^{b/2} \int_0^L \Bigg\{ &\left(\frac{\partial^2 w_i}{\partial x^2} + \frac{\partial^2 w_i}{\partial z^2}\right)^2 \\ &- 2(1-\nu)\left[\frac{\partial^2 w_i}{\partial x^2}\frac{\partial^2 w_i}{\partial z^2} - \left(\frac{\partial^2 w_i}{\partial x \partial z}\right)^2\right]\Bigg\} \mathrm{d}z\,\mathrm{d}x, \end{aligned} \tag{5}$$

where $D = Et^3/[12(1-\nu^2)]$ is the flange plate flexural rigidity and ν is the Poisson's ratio. The integration with respect to x needs to be split; the integration is performed from $x = [-b/2, 0]$ with $i = 1$ and between $x = [0, b/2]$ with $i = 2$. The expression for the membrane strain energy U_m is given next and includes the contribution of the bending of the flanges from global buckling. The expression for U_m in fact neglects the transverse component ε_x, since it has been shown that it does not contribute significantly to the post-buckling stiffness of a rectangular plate with one free long edge and one rigid long edge (Koiter & Pig-nataro,1976). The longitudinal strain ε_z has to be modelled separately for the more and the less compressed flanges. The membrane energy is given by:

$$U_m = \frac{1}{2} E t \int_{-b/2}^{b/2} \int_0^L \varepsilon_z^2 \,\mathrm{d}z\,\mathrm{d}x, \tag{6}$$

where ε_z is given by the expression from von Kármán plate theory:

$$\varepsilon_z = x\frac{\mathrm{d}\theta}{\mathrm{d}z} + \frac{\partial u_i}{\partial z} + \frac{1}{2}\left(\frac{\partial w_i}{\partial z}\right)^2 - \Delta, \tag{7}$$

where Δ is defined as a purely compressive displacement to allow for elastic deformation before buckling. The integration with respect to x is split in precisely the same as for U_b. The shear strain γ_{xz} is also modelled separately for the more and less compressed sides of the flanges, and the shear strain energy is thus:

$$U_s = \frac{1}{2} G t \int_{-b/2}^{b/2} \int_0^L \gamma_{xz}^2 \,\mathrm{d}z\,\mathrm{d}x, \tag{8}$$

where G is the material shear modulus and γ_{xz} is given by the expression from von Kármán plate theory:

$$\gamma_{xz} = \gamma_{xz,\text{global}} + \frac{\partial u_i}{\partial x} + \frac{\partial w_i}{\partial x}\frac{\partial w_i}{\partial z}, \tag{9}$$

and the integration with respect to x is again split in precisely the same as for U_b. The work done by the axial load P is given by:

$$P\mathcal{E} = \frac{P}{2}\int_0^L \left[\left(\frac{\mathrm{d}W}{\mathrm{d}z}\right)^2 - \frac{\mathrm{d}}{\mathrm{d}z}(u_1+u_2) + 2\Delta\right]\mathrm{d}z, \tag{10}$$

where $\mathcal{E}$ is the total end-displacement of the roller support. The total potential energy V can then be obtained by the sum:

$$V = U_B + U_b + U_m + U_s - P\mathcal{E}. \tag{11}$$

2.2 *Governing equations*

The governing equilibrium equations are obtained by performing the calculus of variations on the total potential energy V. A system of nonlinear ordinary differential equations (ODEs) are derived. They comprise two fourth order ODEs for w_i and two second order ODEs for u_i. Equilibrium also requires the minimization of the total potential energy with respect to the generalized coordinates q_s, q_t and Δ – this essentially provides three additional integral equations. Finally, simply-supported boundary conditions for w_i and end strain conditions for u_i are derived from the first variation of V.

Linear eigenvalue analysis is carried out to determine the global buckling critical load, P_o^{C}:

$$P_o^{\mathrm{C}} = \frac{\pi^2 E I_w}{L^2} + \frac{2}{1/Gtb + 12L^2/Etb^3\pi^2}. \tag{12}$$

The critical stress σ_l^{C} for local plate buckling is determined using the well-known expression:

$$\sigma_l^{\mathrm{C}} = \frac{kD\pi^2}{b^2 t}, \tag{13}$$

where k is the plate buckling coefficient that depends on the edge conditions. The value of $k = 1.25$ represents the specific boundary conditions of the problem (Bulson,1970) and gives a slight upper bound on the actual computed solution. The local critical buckling load $P_l^{\mathrm{C}} = A\sigma_l^{\mathrm{C}}$ can then be determined, where A is the total area of the cross-section. For comparison purposes, it was possible for global (W_0) and local (w_0) imperfections to be included in the analytical model. These were introduced by assuming that the strain energy was zero in the initially deformed state.

L (mm)	P_o^{C} (kN)	P_l^{C} (kN)	Critical mode
2250	71.75	67.14	Local
2350	65.45	67.15	Interactive (approx.)
2450	60.61	67.13	Global

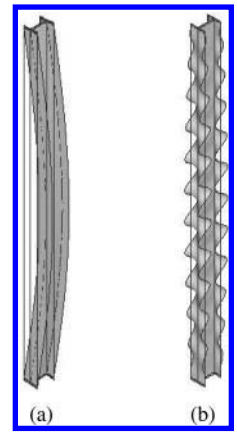

Figure 3. Buckling modes obtained by the FE model. (a) Global. (b) Local.

3 FINITE ELEMENT MODELLING

To validate the analytical model, an FE model within the commercial software ANSYS (2009) was created using a fine mesh of the "Shell181" element, which is an isoparametric 4-noded shell element; the "full integration" option was also employed. Buckling analysis was performed to obtain the local and global modes of instability. These were then substituted into the model as initial imperfections to conduct the nonlinear analysis for determining the post-buckling behaviour.

4 NUMERICAL RESULTS AND DISCUSSION

The system of nonlinear equations based on the analytical model was solved using the continuation and bifurcation software AUTO-07P (Doedel & Oldeman, 2009), which can capture bifurcation points and compute the post-buckling paths. To perform the numerical runs, the following isotropic material and cross-section properties were chosen: $E = 210000\,\mathrm{N/mm^2}$, $\nu = 0.3$, $b = 96$ mm, $t = 1.2$ mm, $t_w = 2.4$ mm and $h = 120$ mm. In this study, three separate lengths L were considered: global buckling being critical ($L = 2.45$ metre); local buckling being critical ($L = 2.25$ metre) and where the loads approximately coincide ($L = 2.35$ metre). The buckling loads from the FE model are given in Table 1.

Figure 3 shows the buckling modes that are obtained from the ANSYS analysis. As stated above, these are used as imperfections of small amplitudes to trigger the initial instability. For the global imperfection,

Length (m)	Column	P (kN)	q_s	$w_{1,\max}/t$
2.25	1a	57.59	0.0020	0.546
	1b	57.23	0.0049	0.992
	1c	56.29	0.0148	1.63
2.35	2a	54.27	0.0022	0.524
	2b	52.85	0.0075	1.15
	2c	52.38	0.0118	1.44
2.45	3a	51.19	0.0014	0.220
	3b	50.44	0.0026	0.577
	3c	48.47	0.0076	1.13

an out-of-straightness of $L/5000$ was used. For the local imperfection the flange was assumed to be initially deflected out of the plane by an amount $t/1000$. For the analytical results, only a global imperfection of the same size was introduced to facilitate model comparisons.

For each case studied, four snapshots of the column modelled by FE and three snapshots of the column from the analytical model are presented in Figures 4–6. Table 2 show the loads, the relative magnitudes of the global and the local mode in the images shown in (e–g) of Figures 4–6. Figures 7–9 show comparisons of the equilibrium diagrams for all three cases, where $w_{\max}$ is the amplitude of w_1, and the plots in Figure 10 show comparisons of the local buckling mode.

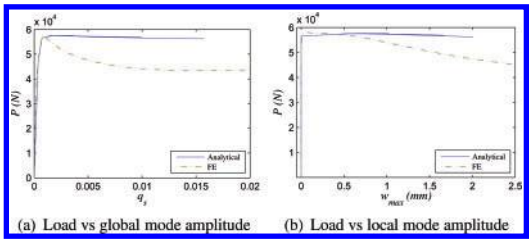

Figure 7. Comparisons between FE and analytical equilibrium paths for $L = 2.25$ metre.

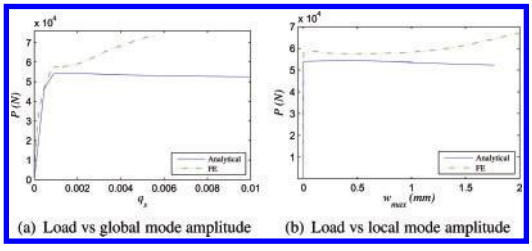

Figure 8. Comparisons between FE and analytical equilibrium paths for $L = 2.35$ metre.

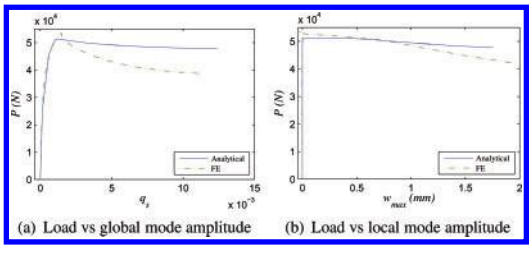

Figure 9. Comparisons between FE and analytical equilibrium paths for $L = 2.45$ metre.

These all demonstrate good correlation between the FE and analytical models. In particular, the buckling wavelength and the loads for the initial post-buckling compare very well, although there is some divergence as the post-buckling advances. Table 3 shows numerical comparisons of the lowest critical loads calculated by FE and those computed by the analytical model. The analytical model shows local buckling critical loads that are slightly below those calculated through Equation (13). All of the errors are seen to be well below 7%, which is most encouraging.

The comparisons of the analytical and FE models are quite interesting. As mentioned above, the load at the initial instability from the FE compares very well with the peak load from the analytical model. However, it is seen for the local and global buckling cases that the post-buckling response from the FE model is more unstable than the flatter results from the analytical model. If the FE results are taken as the benchmark, it suggests that the analytical model is too stiff and perhaps suggests that an extra degree-of-freedom is missing. It is worth emphasizing that the web is modelled not to buckle locally in the

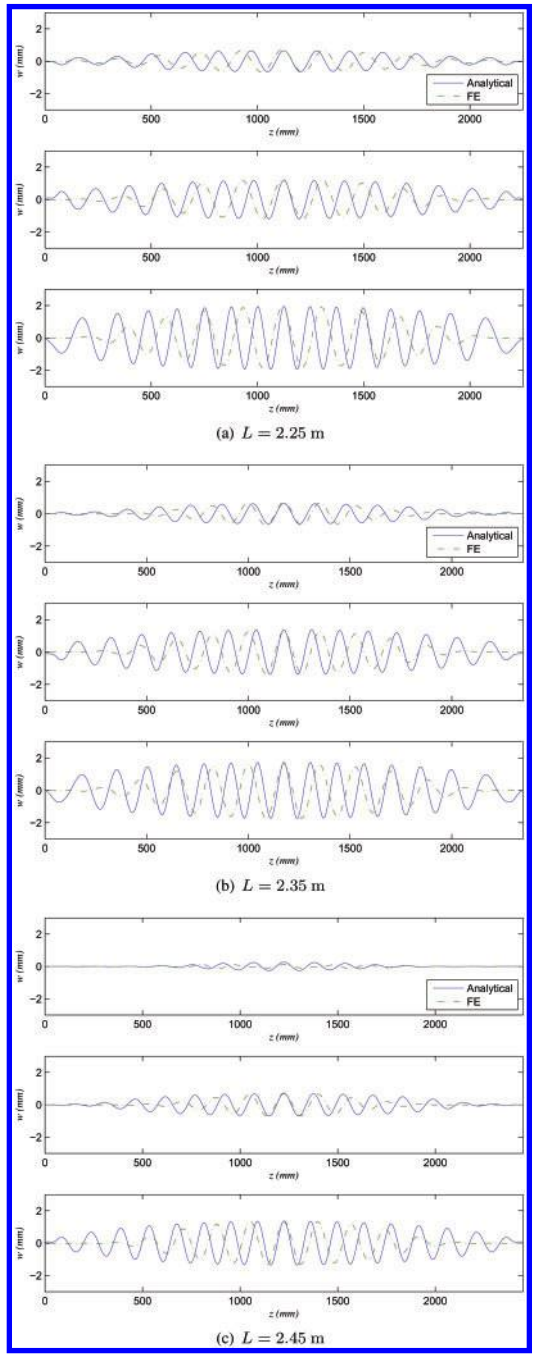

Figure 10. Comparisons between FE and analytical results of the local modes $w \equiv w_{1,\max}$ at different amplitudes for the different lengths as the column response advances in the post-buckling range.

analytical model currently, which could be important; allowing this would destiffen the column and may be sufficient to match the negative stiffness of the post-buckling better. Finally, the case where the buckling loads approximately coincide show a stable

Table 3. Key load comparisons.

Length (m)	Model	P^C (kN)	P_{peak} (kN)
2.25	Analytical	70.12	57.61
	FE	67.14	57.99
	Error	4.4%	0.7%
2.35	Analytical	66.23	54.49
	FE	65.45	58.44
	Error	1.2%	6.8%
2.45	Analytical	60.95	51.20
	FE	60.61	53.53
	Error	0.6%	4.3%

form of post-buckling in the FE model, which is a rather surprising result. The analytical model, however, shows a consistent pattern as the length changes which implies that there may be a possible discrepancy that requires further investigation. During the interactive post-buckling response, the convex side of the flanges continues to buckle locally in the FE model. This was not to be expected and perhaps is the source of the increased post-buckling stability exhibited. In the analytical model, local buckling on the convex side rapidly diminishes as the post-buckling advances, which perhaps is a more expected response.

5 CONCLUDING REMARKS

An analytical and a finite element model have been formulated to simulate interactive buckling in an I-section column with a rigid connection between the flange and the web. Generally, very good agreement has been found between the models for the critical and earlier post-buckling stages. Although certain modelling shortcomings have been identified, the results are very encouraging and the aim is to advance the study by using Generalized Beam Theory in future modelling. This is because it has been shown to be highly efficient and able to capture complex instability phenomena at times more reliably than the conventional finite element approach and is readily applicable to more generic loading cases and more complex geometries.

Work is also advancing on the analytical modelling front with the possible inclusion of the effect of lipped cross-sections; this would allow the modelling of global–distortional buckling mode interaction for which there has been little in the way of analytical studies in the literature, although semi-analytical models have been successful (Hancock, 1978; Schafer, 2002) in capturing the individual modes.

Influence of the cross section slenderness on the buckling behaviour of steel welded tapered beam-column

I.M. Cristutiu & D.L. Nunes
"Politehnica" University of Timisoara, Timisoara, Romania

ABSTRACT: Pitched roof portal frames are often made of welded plate elements with tapered web classified as class 3 (semi-compact) and 4 (elastic) according to EN 1993-1-1. Moreover the class of flange, with constant variation along the element, can range from class 2 (compact) to class 3(semi-compact), function of their width to thickness ratio. Under gravitational load, that is the dominant case in design practice, these elements are mainly subjected to combined action of bending moment and axial compression force. Hence the tapering of the elements is made in accordance with internal force distribution under gravitational loads. Due to their cross section class type, the failure in buckling can be of different types. When class 2 and 3 sections, are restrained against lateral and/or torsional buckling, the coupling between sectional plastic buckling and overall in plane buckling of the members in compression and/or in bending is possible. When class 4 (slender) sections are used, which generally is the case of the rafter at the maximum height of the tapered web, the sectional buckling (e.g. local buckling of walls or distortion) may occur in the elastic domain. If no lateral restrains, or when they are not effective enough, the lateral torsional mode could characterize the global behaviour of the frame members, or interaction with sectional buckling modes may occur as well. The paper presents the results obtained experimentally, along with FEM analyses and a parametric study results. The failure mechanism, and hence the ultimate capacity is mainly influenced by the cross sectional and/or overall slenderness as well as the applied lateral restraints.

1 INTRODUCTION

Steel structures with pitched roof portal frames are widely used for low raised industrial and/or commercial buildings due to several advantages. Among them we can mention adaptability for long span (obtaining wide range of covered area without supplementary column), flexibility for further extension, accurate design solutions, easy assembling, cost efficiency and the last but not the least easy relocation. In most of the cases the main frame is designed accounting for gravitational load combinations, with significant values for dead, technological and snow load, which lead to important bending moment in the component elements. Besides bending moment, important compression forces develop within the column and rafter due to its pitch roof angle. Tapering of the component elements is made in accordance with the stress distribution. The variable section of the elements can be obtained in two different distinct ways: first one consist in hunching a prismatic European I profile in the requested zone (important values of bending moments), the second one consist in building the section with tapered web from welded steel plates, case which also makes the subject of the present study.

Due to web variation along the elements, the cross section is likely to vary as well, according to the provisions of EN1993-1-1. It can start from class 1 or 2 at the bottom of the column and can reach class 3 or even 4, function of the web thickness and cross section height. Although the flange class may fall into class 1 or 2, the final class of the cross section is dominated by the weakest class value, in our particular case the web class. These will lead the structural engineers to check the elements within the elastic range.

According to current European standard EN 1993-1-1 buckling verification only covers regular geometrical shapes, simple load cases and classical supports (rigid or pinned) and does not cover every case met regularly in design practice. However, advanced numerical computer aided analyses can be performed nowadays which allow the investigation of complex structures by using European provisions.

Structures made of slender elements with variable welded sections were previously studied by the authors, Cristutiu&Nunes, in 2012. The study was made on steel single story frames with pitch angle, different type of lateral restraints (rigid/actual), and initial imperfections. These studies revealed the importance of the lateral restraints on the capacity and structural behavior of frames made of elements with variable cross sections. For all the cases out-of-plane buckling of the frame elements was noticed to be independent of the applied lateral restraints. There were cases for which the global lateral- torsional buckling of the frames was coupled with local buckling of the web.

This was mainly observed when the restraints applied on the frame element are more effective against overall buckling. It was noticed that the considered imperfections has a low to significant influence on the final capacity of the frame, function of the applied lateral restraints.

Even though many papers regarding the behavior of steel elements subjected to bending moment and compression can be found in the literature (Taras 2008, Szalai 2009), the information regarding the ultimate capacity and behavior of the individual elements with variable cross section is still limited.

The ultimate capacity was determined by Shanmugam 2007 for tapered steel plate girders subjected to shear and by Salem 2009 for axially loaded thin-walled tapered columns with doubly symmetric sections. Shanmugam 2007 experimentally determined the ultimate behavior of tapered steel plate girders and concluded that the shear capacity of the girder is 5% less than the case of prismatic one, if the inclined flange is tensioned. Whilst the inclined flange is subjected to compression, the ultimate load of the tapered girder becomes higher than that of straight girders by more than 5%. In 2012 Marques et all developed a consistent buckling procedure for evaluating the ultimate capacity of tapered members subjected to compression. This procedure is rather difficult to apply in the actual design as it implies advanced numerical analysis. Behaviour under horizontal forces (earthquake) was studied analytically by Cristutiu&Nunes 2012 and experimentally by Hong&Uang 2012. Both studies concluded that the main failure mode is out of plane buckling and, consequently the seismic behavior could be improved by proper lateral restraints.

The aim of this paper is to analyze the behavior of tapered elements subjected to bending moment and axial compressive force when different type of lateral restraints are applied. For this purpose the results of an experimental program carried out at the "Politehnica" University of Timisoara, Romania, in the Laboratory of Steel Structures will be presented, along with a three dimensional FEM analysis results.

2 EXPERIMENTAL PROGRAM

2.1 *Specimens*

For the purpose of defining realistic specimen configurations a pitched-roof portal frame of 12 m span, 6 m bay, 4 m height and a pitch roof angle $\alpha = 8°$ was designed at first. The following load cases were considered: characteristic dead load of roof cladding $g_k = 0.7\,kN/m^2$; characteristic snow load $s_k = 2.0\,kN/m^2$. Both gravitational (dead, snow) and sidewise (wind and seismic) loads as well as corresponding load combinations were considered in the design. The steel frame was analyzed and designed according to the current EN 1993-1-1 provisions. The frames were considered pinned at the foundation level, while the rafter-to-column connection was considered fully rigid. The cross section dimensions of the two types of specimens and their codification are presented in Table 1.

Table 1. Main dimensions of the tested specimens.

Specimen	L [mm]	h_1 [mm]	h_2 [mm]	b [mm]	t_f [mm]	t_w [mm]
C3_8	3376	250	600	160	10	8
C4_6	3376	250	600	160	10	6
C5_8	3376	250	600	180	10	8
C6_6	3376	250	600	180	10	6

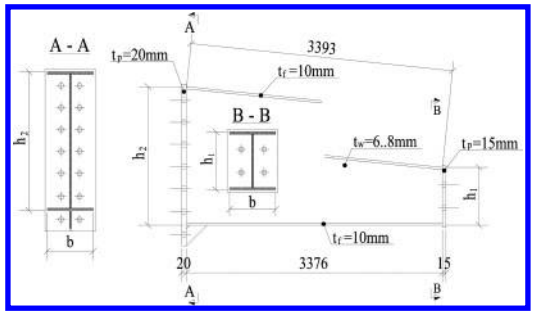

Figure 1. Specimen typology (dimensions are in mm).

The column specimens were extracted from the resulting frame and their global geometrical dimensions are presented in Figure 1. In order to analyse the influence of the web thickness (t_w) on the column behavior, two different values (i.e. 6 and 8 mm) were considered.

Each specimen was tested in its horizontal position. The bottom flange of the column was kept horizontally, whilst the opposite one was inclined following the shape of the tapered web. The connection at the left hand side (top in case of frames) of the specimen was assumed to be rigid and therefore an extended end plate with 8 bolt rows was provided. The opposite side of the specimen was considered pinned with a 15 mm end plate and 2 bolt row. The web cross section classes for the two specimens, ranging from 1(plastic) to 4(elastic), were evaluated and are plot in Table 2 along with its slenderness ratio (c/t). The flanges are of Class 2 and 3 (compact and semi-compact). The non-dimensional slenderness for the lateral torsional buckling, λ_{LT}, (that is the predominant way of failure) of the elements is presented in Table 2 as well.

Tensile tests were performed on coupons extracted from the same plate as the one used for the fabrication of the tests specimen. Three coupons were tested for each thickness. The tensile test was carried out using a UTS RSA 250kN-universal test machine. The obtained results confirmed that S355 steel was used for the fabrication of the tested specimens.

Three specimens of each configuration were tested, finally resulting in a number of twelve experimental tests (Table 2). The difference between the tests,

for each specimen, was the provided type of lateral restraints. Six of the specimens had 8 mm tapered web (C3-8 and C5-8) and the other six were designed with 6 mm tapered web (C4-6 and C6-6).

The types of lateral restraints considered for each specimen configuration were (Fig. 3): (NR) – no restraints, (LR) – lateral restraints; and (TR) – torsional restraints respectively. Lateral restraints (LR) were provided by thin walled cold formed "Zed" purlins (Z150/1.5 mm), while in the case of torsional restraints (TR) supplementary L50x50x5 fly braces were provided at the compressed flange.

Figure 4. Testing set-up.

2.2 *Test set up*

The specimens were tested in horizontal position. The applied static scheme is a simple one, i.e. pinned connection at the right end of the column, and a roller at the bottom of the vertical element. The latter was designed stiff enough, so as not to suffer major deformations during testing as a horizontal force was being applied at the end of the vertical element.

The applied load and boundary conditions were designed in such a way as to load the specimen with a combination of axial compressive load and bending moment (Fig. 3 & Fig. 4). Apart from allowing a free horizontal displacement, the simple support also prevented the appearance of a horizontal reaction force that would lead to the change of the bending moment diagram in the tested specimen.

3 RESULTS OF EXPERIMENTAL TEST VS FEM ANALYSIS

A finite element model was built following the exact nominal geometrical dimensions and material properties of the tested specimens. Both geometrical and

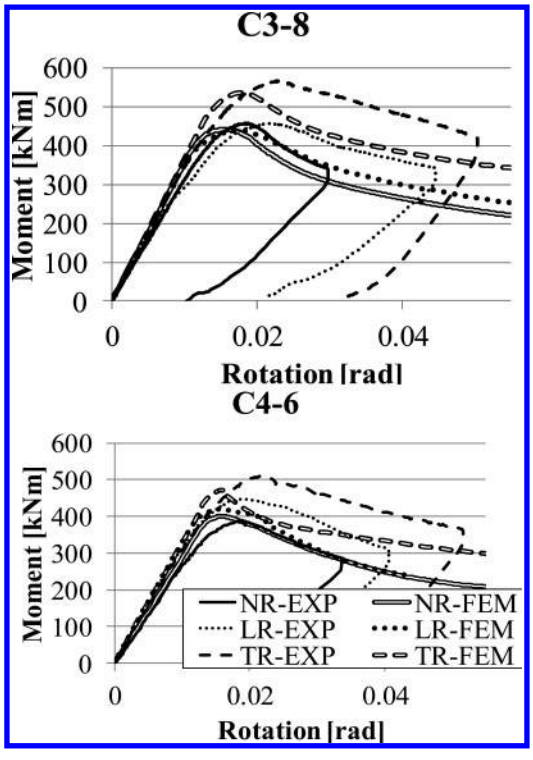

Figure 5. Moment rotation curve experimental/FEM.

material nonlinear behavior were considered, together with the equivalent global bow geometric imperfection, to determine elastic-plastic resistance in ULS, using GMNIA according to EN1993-1-5. Imperfections were applied according to EN1993-1-1 provisions, i.e. out of plane initial bow imperfection with the amplitude of L/150 from the length of the tested specimen, corresponding to a plastic analysis of a welded I-section element (buckling curve c about minor axis z-z). The material behaviour was generated with an elastic-plastic and linear strain hardening model according to the real experimental measured material parameters.

The experimental results recorded during the tests were initially in terms of forces (F) and displacements (d). These results were converted thereafter in terms of bending moment (M) and rotation (Φ) and finally the M-Φ curve was built. The moment rotation curve, plotted in Figure 5 for specimen C3-8 and C4-6, shows the behavior from the elastic point to the ultimate capacity of the tapered columns, laterally restrained or not.

Evaluation of the bending moment capacity was made according to the ECCS recommendations. The method of evaluation is presented in Fig. 6, where the bending moment capacity represents the intersection between two lines. First one corresponds to the initial rigidity while the second one represents the tangent to the capacity curve with a slope of 10% of the initial rigidity. An example is illustrated in Figure 6 for the C5-8-TR specimen.

The experimental bending moment ($M_{y,EXP}$) within the specimen and the corresponding values obtained from the finite element ($M_{y,FEM}$) analysis are summarized in Table 3. In the same table $M_{u,EXP}$ represents the peak moment extracted from the capacity curve.

As it can be seen, for the case of 8 mm web series, the failure mode and capacity is influenced by the type of the lateral restraints. The specimens of 6 mm web thickness behaved in the similar manner (Tabel 3).

The failure modes of the 8 mm series of tests were the following: 8_NR – at first, overall lateral-torsional buckling of the column, followed by distortion of the compressed flange and finally the specimen failed by sectional plastic buckling; 8_LR – at first overall lateral-torsional buckling of the column, followed by distortion of the compressed flange an finally the specimen failing by sectional plastic buckling; 8_TR – started with distortion of the compressed flange and was followed by a slight overall torsional buckling ending in sectional plastic buckling.

In conclusion, the main failure mode is distortion of the compressed flange coupled with lateral torsional buckling, in function of the type of the lateral restraint. Lateral torsional buckling prevails in the case of 8_NR

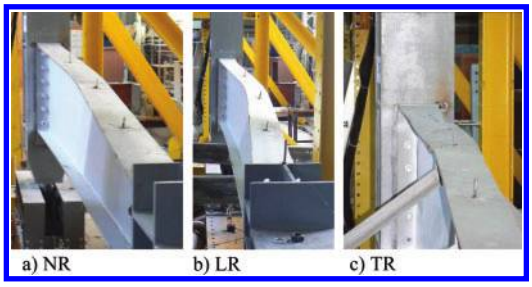

Figure 7. Failure of the 8 mm web specimen typology.

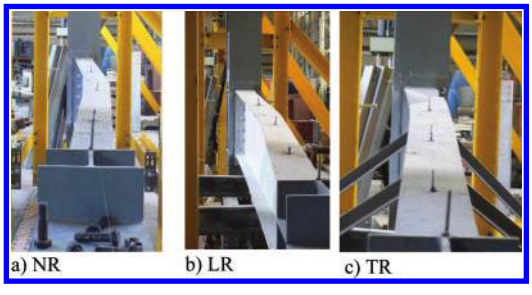

Figure 8. Failure of the 6 mm web specimen typology.

and 8_LR, while sectional plastic buckling with distortion of the compressed flange prevails in case 8_TR. In what concerns their ultimate capacity, this is slightly improved for the case with TR restraints.

Similar behavior was obtained from FEM analyses (Fig. 7). It was noticed that the flange slenderness did not influence the failure mode of the specimen.

The failure modes of the C2-6 series of tests were the following: C2_6_NR – started with distortion of the compressed flange, followed by isolated sectional buckling and slight overall lateral-torsional buckling of the column; C2_6_LR – started with distortion of the compressed flange, followed by isolated sectional buckling and slight overall lateral-torsional buckling of the column; C2_6_TR started with distortion of the compressed flange, followed by isolated sectional buckling and slight overall lateral-torsional buckling of the column.

The isolated sectional buckling for this series of tests prevailed over the global out of plane buckling. For this type of specimen series, the failure was almost the same regardless of the type of lateral restraints.

As it was described at the beginning of the present chapter, advanced FEM analyses were performed for all tested cases. The capacity curves were recorded as well as the failure mode. It was noticed that the failure mode is influenced by the type of lateral restraints as in the case of the experimental tests.

Due to lack of space herein only the failure mode of the 6 and 8 mm web thickness with 160 mm flange width are presented (Fig. 8&9). Although the 6 mm web thickness is more slender no difference was noticed in the behaviour for the same type of lateral restraint though.

4 PARAMETRIC STUDY ON TAPERED BEAM-COLUMNS

It is very well known that experimental test, especially when dealing with big specimens, are time and labor consuming. An alternative to experimental test are numerical simulations, where all the effects that might appear during test should be taken into consideration as well.

Further on numerical simulation were made using GMNIA in order to determine the behavior of beam-column elements with variable cross section, while different values of flange slenderness were applied. The analyses cases are descried in Table 4. The same length and height was kept for all the analyzed cases, while the flange varies between 60 to 180 mm, with an increment of 20 mm.

In Figure 10 is illustrated the behaviour of tapered beam columns with NR restraint (see Fig. 2). In Figure 10 an evolution from out of plane buckling (case of 60-8) to coupling of out of plane buckling and sectional plastic buckling (160-8) can be observed. The same evolution was observed in case of LR and TR

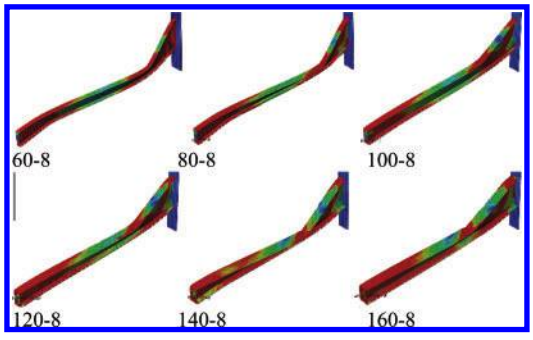

Figure 11. FEM- parametric – Failure of the 8 mm web specimen typology with NR.

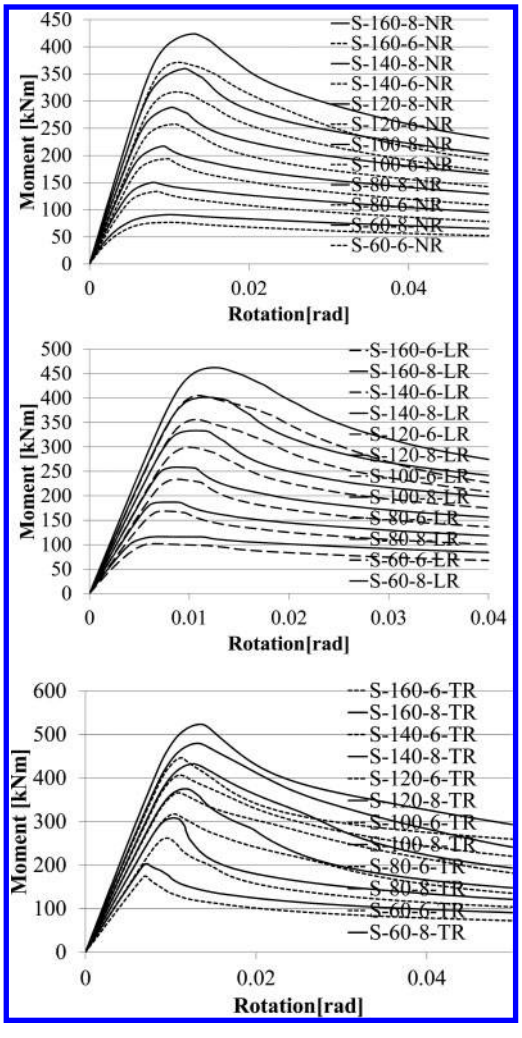

Figure 12. FEM- parametric – Capacity curves.

as well, except the position of the buckle changing correspondingly.

The corresponding capacity curves are plotted in Figure 11 for all the 3 type of lateral restraints.

5 CONCLUSIONS

Both the experimental and finite element study of the behaviour of tapered web beam-columns were depicted in the present work. A number of twelve specimens with different web thicknesses and lateral restraints were tested, while in the second part of the paper is presented a parametric study.

The failure mechanism for the selected specimen series varies in function of the cross section/overall slenderness and lateral restraints.

Although the initial rigidity increases from the slenderer case the less slender one, the post critical behaviour differs by the lateral restraints. The ductility decreases in case of less effective lateral restraints (NR, LR), while for the case of TR ductile behaviour is reversed.

Analyzing portal frames using rotational springs

T.N. Haas, H.L. Albertyn & P.E. Dunaiski
Department of Civil Engineering, Stellenbosch University, South Africa

ABSTRACT: Portal frames are steel structures used in the construction of various types of industrial buildings. Very few portal frames are required to cover large areas. Portal frames predominantly consist of steel columns and rafters. Haunched connections are usually used to connect the columns to the rafters and rafters to each other. The base of the column is connected to the foundation through base plates. Design engineering professionals in South Africa consider the connections at the base as perfectly pinned, while all other connections are considered infinitely rigid (i.e. traditional analysis). This assumption is flawed and does not occur in reality, resulting in inaccurate displacement behaviour of the portal frame. This is especially more prominent when wind loads are applied to the side of the portal frame. An experimental and numerical study was conducted to determine the actual displacement response of the portal frame when subjected horizontal loading. When a horizontal point load was applied to the apex of the column, the traditional analysis yielded displacement responses that varied significantly from the experimental results. This led to obtaining a more accurate numerical solution. This was achieved by modelling the connections of the portal frame with rotational springs in a second order non-linear analysis. The rotational spring stiffness's were obtained from the moment-rotation behaviour of each connection. These were obtained from a detailed finite element analysis of each connection considering all members and their contact interaction properties. The displacement results of the advanced model yielded displacement responses which were comparable with the experimental results. However, the computational effort needed in obtaining the advanced model does not make it feasible to analyse the portal frame with rotational springs in structures which requires a limited number of portal frames.

1 INTRODUCTION

Portal frames are simple structures constructed of two columns and two rafters. The columns are connected to the rafters at its apex, while the rafters are connected to each other at the ridge. The column base is connected to the plinth/foundation through base plates. The connections between these members can either be considered infinitely rigid (fixed) or hinged (pinned). Haunches are introduced at connections to achieve a rigid connection. Figure 1 shows a two dimensional view of a portal frame consisting of a ridge connection without a haunch and eave connections with a haunch.

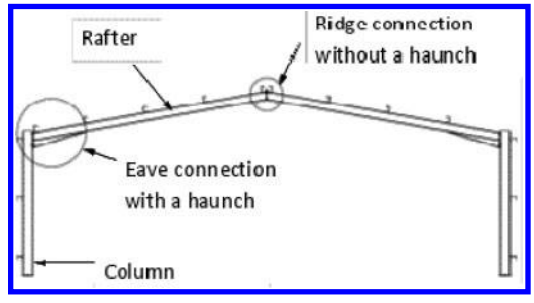

Figure 1. Two dimensional view of a portal frame.

In South Africa, design engineering professionals assume the column base connection as hinged, while all other connections are infinitely rigid. Based on SAISC (2001), this condition leads to a more economical design when compared to column bases which are considered infinitely rigid. Eave and ridge connections are always designed as infinitely rigid, i.e. a moment fixed connection which allows the transfer of bending moment between the respective members. Narayanan, (2003), showed that tension bolts within the height of the rafters are inadequate to develop sufficient bending moment capacity at the connections. For adequate bending moment to develop, haunches are introduced to the bottom flange of the rafters at these connections, Moore & Wald, 2003) and Narayanan, (2003). The design assumptions using infinitely rigid and perfectly hinged connections are flawed and leads to inaccurate displacement behaviour of the portal frame. This leads to uneconomical steel sections being used for construction, (Kruger et al., 1995).

Over the last few decades, higher grades of steel has been rolled in South Africa, which has led to higher yield strengths, SAISC Handbook (2008). The design of portal frames is governed by Serviceability Limit State requirements. The displacement of the structure is a function of the flexural stiffness and not the yield

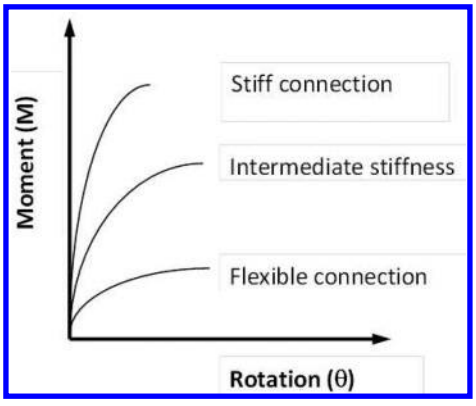

Figure 2. Moment-rotation behaviour of connections, Kruger *et al.*, (1995).

strength of the member. Therefore the use of higher grade of steel has no effect on the allowable informative codified guide presented in SANS 10162-1: 2004. This led to investigating the real behaviour of portal frames when modeled with rotational springs with the correct yield strength of the members.

2 MOMENT-ROTATION CONNECTION BEHAVIOUR

Kruger *et al.*, (1995), showed that deformations caused by axial and shear forces are negligible in comparison to in-plane rotational deformations caused by the bending moment at the connection. As a result only the in-plane rotational deformations will be considered in this study. From this, it can be established that the rotation of the connection is a function of the moment applied to it. Since no connection is infinitely rigid or perfectly pinned, the real behaviour of a connection lie somewhere between these theoretical conditions as shown in Figure 2, Kruger *et al.*, (1995).

The vertical axis (M) in Figure 2 represents a rigid connection, whereas the horizontal axis (θ) represents a hinged connection. The slope of the curve in the elastic region provides an indication of the stiffness of the connection, whereas the peak provides an indication of the ultimate moment capacity of the connection, Kruger *et al.*, (1995).

This suggests that modelling the real behaviour of the connection surely has an influence on the distribution of forces, the bending moment and also affects the displacement behaviour of the portal frame, Gerstle (1988). Therefore if the connection is modeled with incorrect stiffness, it will lead to some rotational deformation occurring before the bending moment is transferred. This will also lead to larger displacements occurring in the portal frame before the ultimate capacity of the connection is achieved. To overcome this problem the connections must be modeled using rotational spring with appropriate stiffness, Simitses *et al.*, (1984), Chan *et al.*, (2005).

Figure 3a. Pin (Hinged) column base support.

3 PORTAL FRAME CONFIGURATION

The investigation for this research was conducted on a 5 m portal frame with a column height of 1.5 m. The columns and rafters are composed of IPE AA 100 sections. The eave connections are supported by haunches 0.5 m in length, while the ridge connection consists of end plates. The experimental model was constructed in a manner that the column bases could be fitted with either hinged or grouted supports.

4 RESEARCH METHODOLOGY

The investigation was separated into an experimental and numerical study. For the experimental study, a horizontal load of 7.85 kN simulating the wind load was applied to the apex of the column in the direction of the span, when the model was fitted with hinged and grouted supports. A numerical model of the full scale experimental configuration was developed for both support conditions. In the numerical model, the hinged connections were easily modeled with pins. However, for grouted supports, rotational springs with appropriate stiffness were required. The rotational spring stiffness' was obtained from a detailed finite element (FE) analysis of each connection.

5 COLUMN SUPPORT CONDITIONS

As mentioned earlier, column bases in portal frames are usually analyzed using pin supports as shown in Figure 3a. The corresponding grouted support in practice is shown in Figure 3b. From Figure 3b it is clear that the grouted support provide some rotational restraint due to the base plate – concrete interaction. If this connection is modeled incorrectly in the numerical analysis it will result in inaccurate horizontal displacement behaviour of the portal frame.

Figure 3b. Actual (grouted) column base support.

6 NUMERICAL MODEL

Strand 7, a commercially available structural analysis software was used to develop a numerical model of the full scale experimental test configurations. After a displacement sensitivity analysis on a simple beam, the 1.5 m columns and the 2.54 m rafters were meshed with 0.1 m quadratic shear flexible (Timoshenko) beam elements. To obtain an accurate numerical model of the experimental configuration, a number of different types of connections were modeled, namely; hinged, rigid and rotational spring connections. The hinged and rigid connections were easily modeled using pin and fixed connections. The pin connections transfers axial and shear forces while the fixed connection transfers axial forces, shear forces and bending moments between the members. The rotational spring connection is however different from the fixed support as it allows a percentage of the bending moment to be transferred to the members depending on the rotational stiffness of the connection. Before the portal frame could be modeled with rotational spring connections, the rotational spring stiffness needed to be determined.

6.1 *Rotational spring stiffness*

Each connection of the portal frame is unique which results in different rotational spring stiffness's. The experimental rotational stiffness's are affected by various factors which include, but not limited to; the size of the steel profiles, the size of the haunch, the number and size of bolts, the position of the bolts, the torque of the bolts and the size of the connection end plate. However, the rotational spring stiffness's in a numerical analysis is also affected by; element type, element mesh density, contact formulation and material properties. The rotational spring stiffness's are obtained from the elastic region of the moment – rotation curve of each connection. The moment rotation curve of each connection was obtained by modelling a portion of the connection with all the necessary elements connected to it. This was accomplished in ABAQUS, a general FE analysis software. The moment rotation curves were obtained based on the guidelines presented by Prabha, (2007).

A previous experimental study conducted by Truter (1997), was used to determine the accuracy of the FE simulations based on the guidelines presented by Prabha. The FE simulation results within the elastic region yielded virtually an identical response compared to the experimental results. Based on the accuracy obtained, all other moment rotation curves were determined. The reader is referred to Albertyn (2010), for a complete review of all the moment – rotation curves as well as the spring rotational stiffness's of the connections. The displacement behaviour of the portal frame could now be determined using these rotational spring stiffness's.

Table 2. Description of the types of connections used in various models.

Model Name	Connection type at eaves and ridge	Connection type at column base
Exp hinged	Rigid	Hinged
Conv numer	Rigid	Hinged
Exp grouted	Rigid	Grouted
Rot spring	Rotational spring	Rotational spring

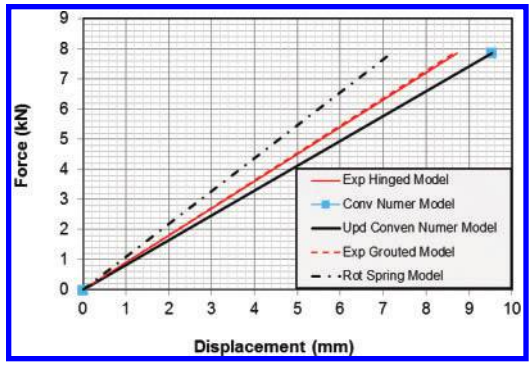

Figure 4a. Ridge's vertical displacement response when subjected to a horizontal point load at the apex of the column.

7 RESULTS AND DISCUSSIONS

Table 2 describes the different types of connections which were investigated for the hinged and grouted models.

Figure 4a presents the ridge's vertical displacement behaviour for the hinged and grouted models when a horizontal load is applied to the apex of the column. Figure 4b presents the column's apex displacement behaviour for the hinged and grouted models when a horizontal load is applied to the apex of the column.

From Figure 4a, it is observed that there is an insignificant difference of 0.08 mm or 0.9% which

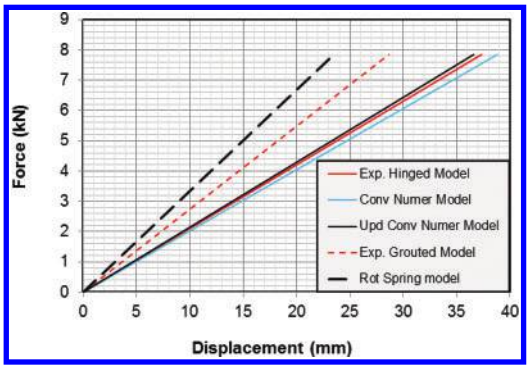

Figure 4b. The horizontal displacement response at the column apex when subjected to a horizontal point load at the apex of the column.

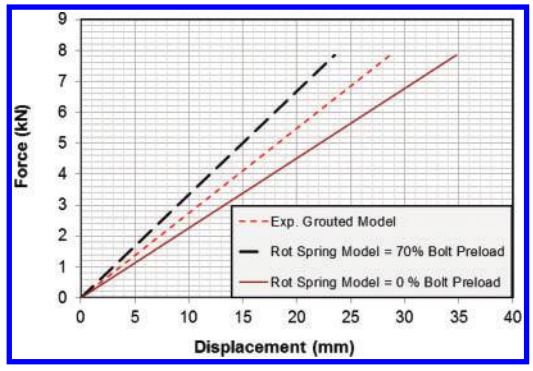

Figure 5. Horizontal column displacement.

exists between the experimental hinged and experimental grouted model's displacement behaviour. A difference of 2.4 mm or 24.6 % exist between the conventional numerical and the numerical model with rotational springs. A difference of 1.5 mm or 16.9 % exist between the experimental grouted and the numerical model with rotational springs.

When comparing Figures 4a and 4b, it is observed that the maximum horizontal displacement is 410% greater than the vertical displacement. From Figure 4b, it is observed that the maximum difference between the experimental hinged and grouted models' displacement is 8.7 mm or 23.3 %. This implies that the grout interface at the column base has a significant influence on the portal frame's displacement response. The maximum difference between the two numerical model's displacement is 15.3 mm or 39.4 %. The conventional numerical model over-estimates the experimental hinged model's displacement by 1.5 mm or 3.9%. The numerical model with rotational spring's under-estimates the experimental grouted model's displacement by 5.1 mm or 17.8%.

The true behaviour of the portal frame is expected to be the same as the experimental grouted model, due to the column base plate-foundation interaction. Therefore the only models of interest in this investigation now become the experimental grouted and the numerical model with rotational spring. A sensitivity analysis was conducted to quantify the effect of the column base plate-foundation interaction.

8 SENSITIVITY ANALYSIS

The results of the previous section probed an interest to determine what causes the discrepancies in the displacement responses of the experimental grouted and the numerical model with rotational springs. Since only the column base connection was changed, the sensitivity analysis focused on the preload of holding-down bolts.

8.1 *Effect of preload on the holding-down bolts*

Kulak et al., (2001), states that ordinary bolts in steel connections are tightened according to the "turn of the nut" method. Previous experimental studies found that the method results in a bolt preload of approximately 70% of the bolt proof stress. In the FE analysis a bolt preload of 70% was applied to all bolted connections to determine the moment rotation curves. Figure 5 shows the horizontal displacement responses of the 0% and 70% bolt preload superimposed with the experimental grouted support model's displacement response.

The displacement of the portal frame is affected by the stiffness of the column base connection. Therefore, the rotational spring stiffness of the column connection was adjusted until the same experimental displacement response was obtained. A numerical displacement of 28.8 mm was obtained when the linear rotational spring stiffness at the column base was adjusted to 52 kNm/rad. Based on the moment-rotation curves obtained from the FE analysis, a rotational spring stiffness of 219 and 290 kNm/rad was obtained for the 0 and 70% bolt preload. Since the experimental displacement response lie almost midway between these responses, a rotational spring stiffness of 250 kNm/rad was expected. The actual rotational spring stiffness was a quarter of what was expected. From this observation is could be concluded that the experimental model is less stiff than anticipated.

This led to careful inspection of the connection bases after the experimental tests were completed. When the base plate was removed, it was observed that the holding down bolts had insignificantly separated from the concrete. The authors felt that this could lead to excessive displacement of the portal frame. A simple calculation reveals that a slight rotation of the base plate can lead to large displacement of the portal frame. Table 3 presents the magnitude of the column displacement as a function of the rotation of the base plate.

From Table 3 we notice that a base plate rotation of 0.26^0 will lead to a horizontal column displacement of 6.8 mm. This implies that for an insignificant rotation of the base plate the portal frame's displacement will increase by 6.8 mm.

Table 3. Horizontal column displacement due to base plate rotation.

Vertical lift at end of base plate (mm)	Half base plate width (mm)	Base plate rotation (^{0})	Horizontal displacement of column (mm)
0.25	55	0.26	6.8
0.50	55	0.52	13.6
1.00	55	1.04	27.3

The numerical model with 0 and 70% bolt preload yield displacements of 34.8 and 23.5 mm, respectively. The experimental grouted model yields a displacement of 28.6 mm. This proves that the numerical model yields accurate results since the experimental results fall within these numerical displacements. If it is assumed that no slip of the holding down bolts occurs, an experimental displacement of 21.8 mm would be achieved.

9 CONCLUSION

This study shows that the numerical model with rotational springs yield accurate displacement responses of the portal frame, depending of the degree of fixity of the column base support.

The important question which now needs to be answered is whether the numerical model is an economically viable option. The rotational spring stiffness must first be determined before these stiffness's can be used in a non-linear 2nd order two dimensional numerical analysis. In order to obtain the rotational spring stiffness each connection was required to be modeled in ABAQUS. The computational time of each analysis was approximately 12 hours. This excludes the time the designer needs to become familiar with the software and to develop an accurate model of each connection. Based on this and considering that most industrial building are less than 50 m in length, it becomes uneconomical to model the portal frame with rotational springs, even though it yields more accurate results.

Behaviour of pitched-roof portal frames with tapered web and flange members considering lateral restraints

I.M. Cristutiu & D.L. Nunes
"Politehnica" University of Timisoara, Timisoara, Romania

ABSTRACT: Pitched-roof portal steel frame, ranging from short to long free span, is the most commonly used type of structural system for single storey industrial buildings. Structural members are generally made of welded plate I sections with tapered web. The tapering is made according to the distribution of the bending moment along the major axis, resulting in a more economical use of the material. Besides web tapering, the flange can be tapered as well in order to obtain a more economical/structural efficient solution. Due to its non-prismatic shape, a slender web/flange section is likely to occur at the maximum cross section height. More than that being subjected to important compressive axial force, the length of the rafter is significant (function of the free span) and hence the problem of stability is much more complex than in the case of multi-storey buildings. They are partially restrained against out of plane buckling by side-rails and roof purlins cooperating with sheeting. If no lateral restraints, or when they are not effective enough, the lateral-torsional mode characterizes the global behaviour of frame members and interaction with sectional bucking modes may occur as well. The paper summarizes the outcome of a numerical study on a considerable number of such type of frames, performed by authors, considering different types of lateral restraints, (rigid and actual). A sophisticated nonlinear elastic-plastic FEM model and different types of initial imperfections were used to analyse the behaviour of the frames. Comparisons of FEM results with those obtained when applying the general method of EN1993-1-1 will also be provided. It was observed that the reduction of the flange by a certain slope, influences significantly the bearing capacity of the frame and their behaviour.

1 INTRODUCTION

Steel structural elements with variable cross section, made of welded plates, are largely used in the construction industry for both beams and columns in accordance with the stress and stiffness demand in the structure. Nonrectangular shape of the element might lead to thin/slender web section at its maximum height hence elastic to slender web results for the case of double T welded cross section. Due to their large relative slenderness about the minor axis, out of plane buckling usually governs their ultimate capacity. Nevertheless, the out of plane buckling strength of these structures is directly influenced by the lateral restraining, end support and initial imperfections.

The design, execution and erection of steel structures must take place under certain constraints. If in the design process, one must ensure strength, stability and rigidity to the structure, in the manufacturing and erection process certain admissible tolerance limits must be accounted for. EN 1090-2 is the European standard that establishes the values of admissible limit tolerances for the manufacturing and erection of steel structures. The European norm EN1993-1.1 contains provisions for several initial imperfections (vertical deviation and initial arc imperfections), which take values function of the considered buckling curve (a0, a, b, c, d) and buckling mode (minimum or maximum axis).

Nevertheless actual design codes do not cover the practical design of this kind of structure. The interaction formulas of EN1993-1-1 are provided only for uniform members, and it is rather difficult to be applied and many interpretations are necessary for non-uniform members. The General Method of EN1993-1-1 might be applied for these types of structures, but the constituent coefficients shall be obtained accounting for lateral restraints, end supports, initial imperfections. According to EN1993-1-1, different imperfection shapes shall be considered in the global analysis of steel frames. On this purpose a preliminary analysis shall be performed in order to emphasize the importance of imperfection shape to be considered in the analysis.

Previous studies made by Cristutiu&Nunes 2012, emphasized that the ultimate capacity and failure under gravitational loads of the whole frame is mainly influenced by lateral restraints. Although different types of initial imperfections were considered, their influence on the frame behaviour is rather small, unless the imperfections are applied all together (e.g. initial out-of-plane bow for elements and initial out of plane sway). Behaviour of pitched-roof frames with tapered members under horizontal loads were studied

in several papers. Cristutiu&Nunes 2012 analytically studied the behaviour under horizontal forces while experimental studies were performed by Hong&Uang 2012. Both studies concluded that the main failure mode is out of plane buckling and, consequently the seismic behaviour could be improved by proper lateral restraints.

Isolated members made of double T section with tapered web were investigated in several papers. The ultimate capacity was determined by Shanmugam 2007 for tapered steel plate girders subjected to shear and by Salem 2009 for axially loaded thin-walled tapered columns with double symmetric sections. Shanmugam 2007 experimentally determined the ultimate behaviour of tapered steel plate girders and concluded that the shear capacity of the girder is 5% less than the case of prismatic one, if the inclined flange is tensioned. Whilst the inclined flange is subjected to compression, the ultimate load of the tapered girder becomes higher than that of straight girders by more than 5%. In 2012 Marques et all developed a consistent buckling procedure for evaluation of the ultimate capacity of tapered members subjected to compression. This procedure is rather difficult to apply in the actual design as it implies advanced numerical analysis.

The objective of the present paper is to extend the previously obtained results by the authors to pitched roof portal frames made of variable web and flange simultaneously. Variation of the web along the element is made for both aesthetical and economic reasons. Variation of the flange shall be made according with the stress and stiffness distribution as well, allowing the use of a more efficient structural element. For the purpose of the work an advanced FEM model was built, different types of lateral restraints were applied and different values of the flange reduction slope. A series of frames of different spans and heights were analysed at first.

2 PARAMETRIC STUDY AND FEM MODEL

2.1 *Analysed frames*

A number of six pitched roof portal frames commonly used for the execution of single story buildings were analysed. They are of different spans and heights (see Fig. 1), to cover a wide range. The frames were designed to verify the ULS and SLS criteria under the gravitational loads. They have pinned column base, tapered columns, tapered rafters and a pitch roof angle of 8^0. Tapering ratio, h_{max}/h_{min}, is approximately equal to 2 for all the cases. The rafter is composes by both uniform and non-uniform regions, as can be seen from Figure 1. The length of the rafter haunch is 15% from the span in all the cases. The main sectional characteristics of frames are presented in Table 1. The chosen dimensions were selected as being quite common in practical applications

Four different slopes were analysed separately, i.e.: 0%, 0,5%, 1,0 % and 1,5% reduction of the maximum

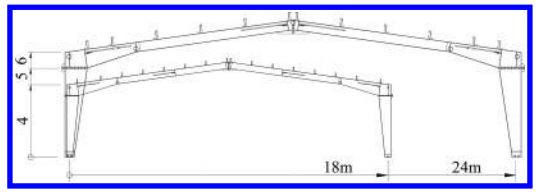

Figure 1. Geometry of the frames.

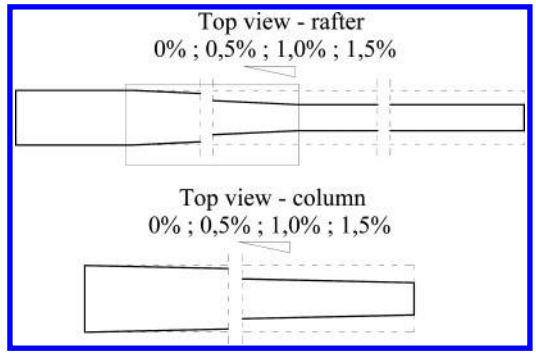

Figure 2. Reduction in size of the flange.

width of the tapered element, resulting thereafter a number of 24 analysed cases. The reduction in size of the flange is presented in Figure 2.

The same principle was applied both for column and rafter for the whole length of the tapered web. It has to be mentioned that the prismatic width of the rafter kept the minimum width of the tapered flange within its whole constant length.

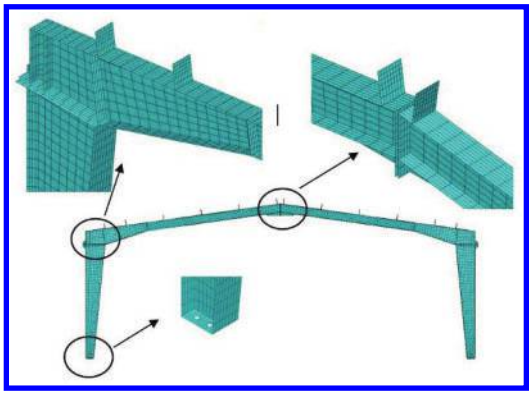

Figure 3. FEM modeling of the analysed frames.

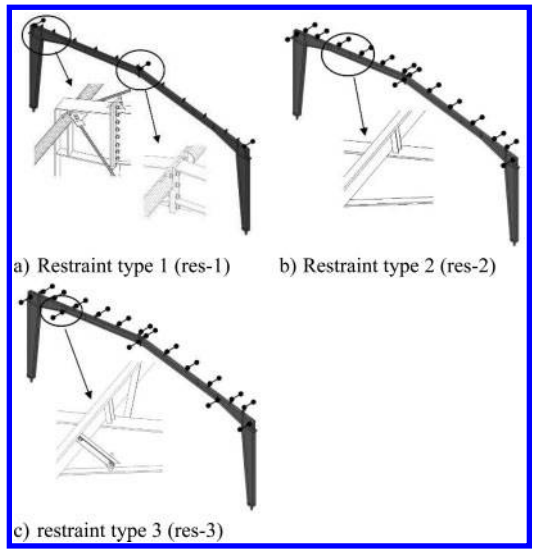

Figure 4. Types of lateral restrains.

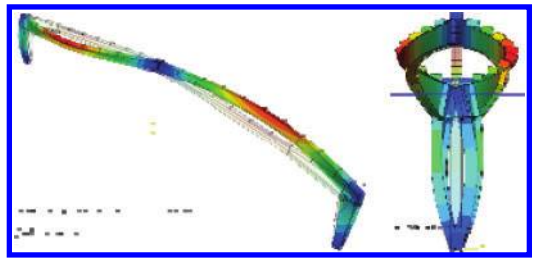

Figure 5. Manufacturing imperfections considered in the GMNIA analyses.

2.2 *FEM model*

For the analysis of the objects in study was developed a finite element model capable to overtake both geometrical and material nonlinearities. Both linear Eigen buckling (LEA) and nonlinear elastic-plastic considering geometric nonlinearities (GMNA and GMNIA) analyses, according to EN1993-1.5 have been applied using the finite element program ABAQUS. S4R-type elements were used (4-node shell elements with reduced integration) with 6 degrees of freedom on each node (translation and rotation in regard to the x, y and z-axis).

To determine the structural response of the nonlinear problem an implicit solution strategy was used. A load stepping routine was used in which the increment size follows from accuracy and convergence criteria. Within each increment, the equilibrium equations are solved by means of the Newton-Raphson iteration (through the arc-length method).

All plates were modeled in their mid-plane and the connections between beams and between beams and columns were defined as a surface-to-surface tie between both end-plates (Fig. 3). The material model was defined as elastic – perfectly plastic ($E = 210000$ N/mm2, $\upsilon = 0{,}3$, $f_y = 355$ N/mm2) and vertical loads from permanent and snow actions were introduced at the purlin location (e.g 1.2 m along the rafter). In all these cases, it was simulated the restraining effect induced by longitudinal beams located at eaves and ridges.

The lateral restraints applied are of 3 different types, as shown in Figure. 4, and were applied through a real model. Types 2 represent the purlin/sheeting effect, when the purlin is pinned when intersecting the rafter. Type 3 is similar with type 2 with an additional fly brace. Type 1, actually means no lateral restraints introduced by purlins. At first, to simplify the computational model, the lateral restrains had been considered axially rigid, in the analysis. The actual behaviour of the purlins (Z150/1.5) was considered later on. The three types of lateral restraints lead therefore to a number of 72 cases.

Manufacturing imperfections were considered in the analyses. The applied imperfections are presented in Figure 5 and consist of an initial out-of-plane bow imperfection of both rafter and column, with a magnitude of l/150. The magnitude of the imperfections was considered according to EN1993-1.1, curve c, for plastic analysis. For rafter a 60 mm initial bow was considered in the case of 18 m span, and 80 mm for 24 m span respectively. While for the column 3 values were considered, one for each corresponding height: 26.67 mm (4 m height), 33.33 mm (5 m height) and 40.00 mm (6 m height). Using shell elements, the imperfections are slightly different from those applied on bar elements, where perfect bending or perfect inclination might be applied. Herein twisting of the element was also recorded, this will lead to a more complex model and a more realistic imperfection shape.

3 RESULTS AND COMMENTS ON THE FEM ANALYSES

In order to identify the failure of the frames and their elastic buckling behaviour 3D GMNIA and 3D LEA

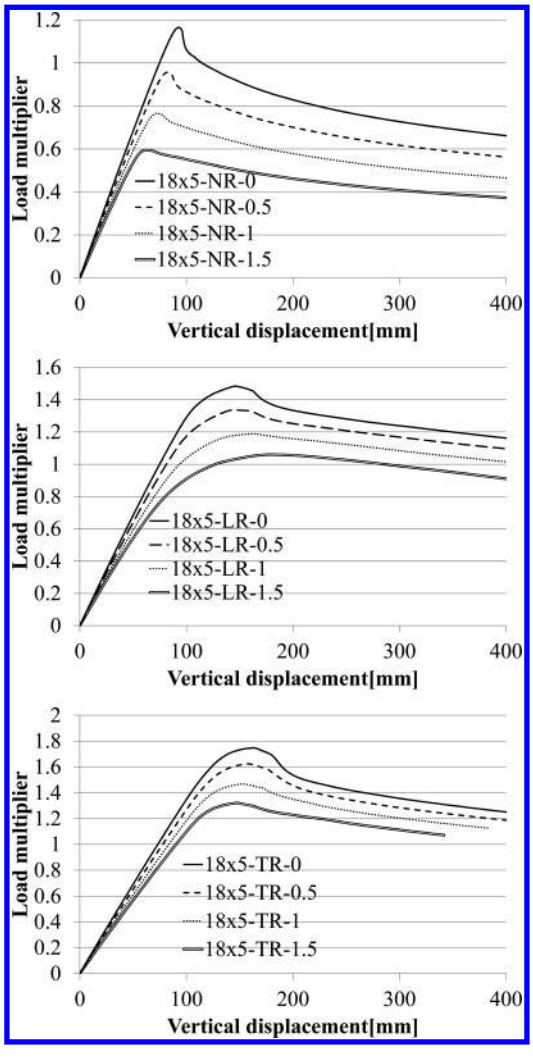

Figure 6. Capacity curves for 18 × 5 frame.

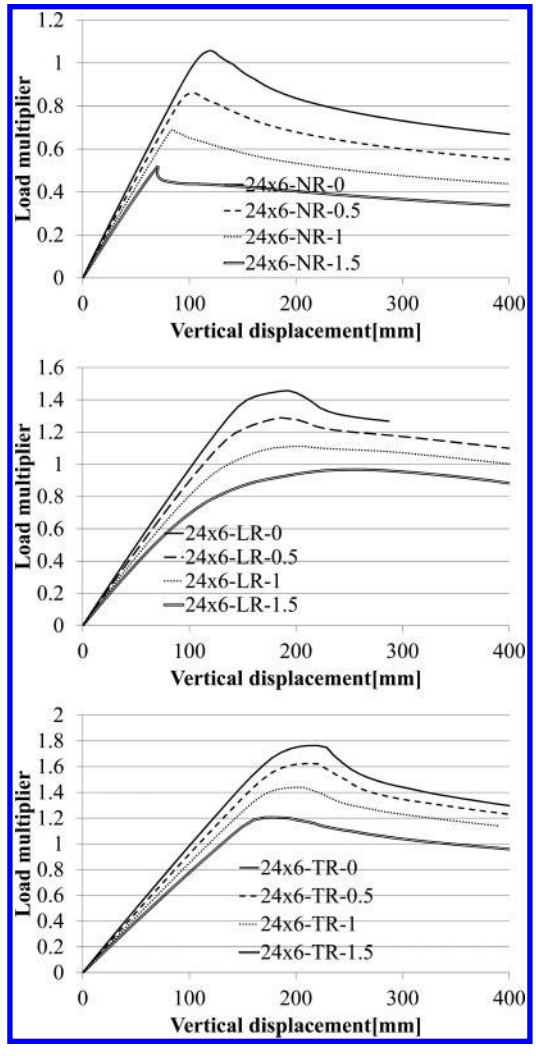

Figure 7. Capacity curves for 24 × 6 frame

analyses were performed. For the GMNIA analysis, initial out-of plane imperfections as the one presented in Figure 5 were considered. The capacity curve were recorder for each case of lateral restraints (NR, LR, TR, see Fig. 4) and slope of the flange (0%, 0,5%, 1,0 % and 1,5% see Fig. 2). The obtained results are presented in Figure 6&7. The critical load multipliers and ultimate load multipliers corresponding to the eigen-buckling shape and failure of the structure respectively were determined for all analysed frames. In the analysis, lateral restraints were taken into account, as actual elastic ones. Herein, due to lack of space only the case of 18 × 5 and 24 × 6 are presented in Figure 6&7.

Analysing Figure 6, one can conclude that the tapering ratio of the flange influences significantly the ultimate capacity of the frame. This influence is more consistent in the case of frames without lateral restraints. The lack of restraining leads to a greater non-dimensional slenderness according to EN1993-1.1, thus their buckling capacity is highly reduced. A reduction in the buckling strength was noticed in the case of laterally restrained frame (case of LR and TR see Fig. 3) as well. This reduction could be explained rather by the reduction in the elastic strength modulus, W_{el}, of the cross section, than by it's out of plane buckling strength.

The curves plotted in Figure 7, for the case of 24x6 frames, experience the same behaviour as those described in the previous paragraph. Namely the difference in the frame capacity is more pronounced for the case of less restrained frame (NR).

In Figure 8, the failure modes of GMNIA analysis are illustrated for the case 18 × 6 frames, with 3 types of lateral restraints (see Fig. 4) and two different values of the flange taper slope (i.e. 0% and 1.5%). The failure mode is influenced both by lateral restraints and

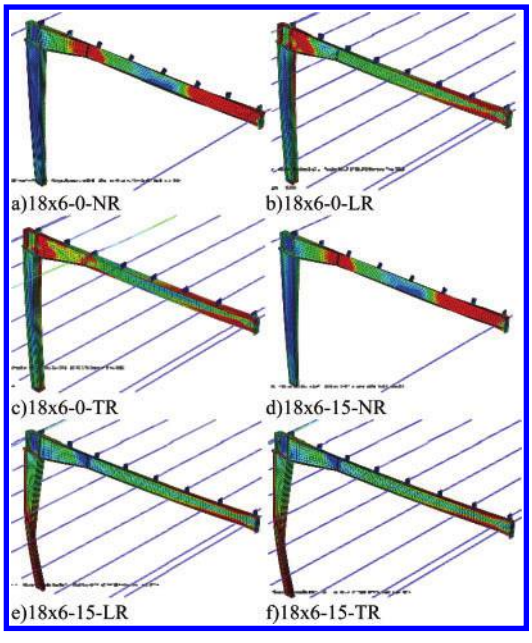

Figure 8. Failure modes – GMNIA analysis (Von Misses stress distribution scale factor 1).

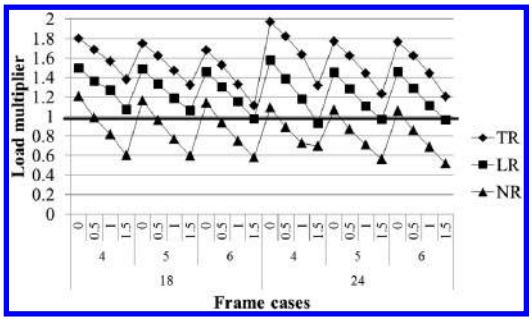

Figure 9. Ultimate load multiplier – GMNIA analysis.

flange taper slope. The latter one might influence the sequence of the element failure, i.e. rafter of column.

In Figure 9, the corresponding values of the ultimate load multiplier, resulting from GMNIA analysis, are illustrated. These values are significantly influenced by the slope reduction of the flange.

4 ANALYTICAL EVALUATION OF THE ULTIMATE CAPACITY

The European standard, EN 1993-1-1, describes three different procedures for verifying the stability of steel elements, including beam-columns (members under combined axial load and bending).

The first approach is the imperfection approach. This is achieved by incorporating in the second order structural analysis appropriate equivalent geometric imperfections to cover the possible effects of all type of imperfections. This approach is not widely used in current design practice, but it becomes useful when advanced finite element simulation is required. The second procedure deals with isolated members, and is the conventional engineering solution for buckling problems, but its application is limited to uniform members with simple support and loading conditions. This method makes two simplifications, one by considering the member isolated from the structure while applying boundary conditions (supports, restraints or loads). And the other by determining the buckling of the member separately for the pure buckling modes (i.e. flexural buckling for pure compression and lateral-torsional buckling for pure bending) and combined by applying interaction factors.

The method that might cover the particular case of frames in study is the "so-called" „general method". The method no longer isolates members nor separates the pure buckling modes. It considers the complex system of forces in the member and evaluates the appropriate compound buckling modes instead. One of the advantages of the general method is that it can examine irregular structural members such as tapered members, hunched members, and built-up members. Although in the current version of the EN1993-1-1 the general method is recommended only for lateral and lateral-torsional buckling of structural components, the basic approach may be extended to other cases as well. Many research projects are underway across Europe that intended to verify and widen its applicability.

According to the "general method" overall resistance to out-of-plane buckling can be verified assuring that:

$$\frac{\chi_{op} \cdot \alpha_{ult.k}}{\gamma_{M1}} \geq 1 \qquad (1)$$

where $\alpha_{ult.k}$ = is the minimum load amplifier of the design loads to reach the characteristic resistance of the most critical cross-section of the structural component, considering its in-plane behaviour without taking lateral or lateral-torsional buckling into account, however accounting for all effects due to in-plane geometrical imperfections, global and local, where relevant; and χ_{op} = is the reduction factor for non-dimensional slenderness to take account of lateral and lateral-torsional buckling.

The global non-dimensional slenderness, $\overline{\lambda}_{op}$, of the structural component should be deter-mined from:

$$\overline{\lambda}_{op} = \sqrt{\frac{\alpha_{ult.k}}{\alpha_{cr.op}}} \qquad (2)$$

where: $\alpha_{cr,op}$ = is the minimum load amplifier for the in-plane design loads to reach the elastic critical resistance of the structural component with regards to lateral or lateral torsional buckling without accounting for in plane flexural buckling.

This method was applied for the frames described in Table 1 and Figure 2. The minimum critical load

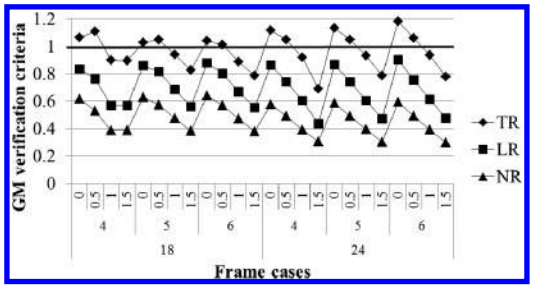

Figure 10. Verification criteria Eqn. (1) – general method.

multiplier was computed by means of linear eigen-buckling analysis using 3D FEM for different type of lateral restraints (see Fig. 4). The buckling reduction factor was evaluated for the case of lateral-torsional buckling according to EN1993-1-1 and γ_{M1} was set equal to 1,0. The minimum ultimate load amplifier, $\alpha_{ult,k}$, corresponding to the characteristic resistance of the most critical cross-section of the structural components was evaluated using a 3D FEM linear elastic analysis.

Comparison of the results obtained by applying the general method for all the analysed frames is illustrated in Fig. 8. The results are presented individually for each frame type, accounting for different lateral restraints.

The obtained results confirm once again the importance of the application of lateral restraints, when dealing with the buckling of tapered elements with respect to their minor axis. Restraints of type 1, provided by secondary structural elements (e.g. roof bracings and pinned longitudinal beams), are not enough in stability check of the structural elements, mainly when the span of the structure is significant. There are some cases in which restraints of type 2 satisfy Eq (1) but not for all the analysed frames. Type 3 provides enough lateral restraints against stability failure in all the cases. The bearing capacity of the frame is significantly influenced by the application of the flange reduction slope.

5 CONCLUSION

A parametric study was performed in order to analyse the sensitivity of different types of lateral restraints on pitched-roof portal frames made of elements with tapered web and flange as well with out-of-plane initial imperfections. For this purpose 72 cases were analysed and three different types of lateral restraints were considered. The magnitude of the imperfections was set equal with those prescribed in EN1993-1-1.

For all the cases out-of-plane buckling of the frame elements was observed to be the main failure mode indifferent of the applied lateral restraints, although there were cases in which the global lateral-torsional buckling of the frames was coupled with local buckling of the web. This was mainly observed when the restraints applied on the frame element are more effective against overall buckling (e.g. type 3 restraints).

It was noticed that the reduction of the flange by a certain slope influences significantly the behaviour of the frame and their ultimate capacity as well.

Compressive resistance of circular hollow sections with squashed ends

M. Dundu & J. Tumkou
University of Johannesburg, Johannesburg, South Africa

ABSTRACT: Circular hollow steel sections are normal specified in truss and dome structures to take advantage of their efficiency in compression and the ease in which they can be curved to match the various radii of the different domes. However, it is not easy to connect these members together or to other members. In order to connect them together or to other members the ends are usually squashed or flattened. Although the process of flattening does not reduce area of the section, it does reduce the flexural stiffness the section. The aim of this paper is to study the behaviour of circular hollow members with flattened edges, in compression.

1 INTRODUCTION

Circular hollow sections (CHSs) are specified in many structural systems because of the inherent excellent geometric properties they have with respect to compression, torsion and bending and the ease in which they can be curved to match the various radii of different domes. A comparison of an open section with a CHS of the same size and area shows that a CHS will have a significantly higher compressive resistance because of the larger radius of gyration about the buckling axis (Kurobane et al., 2004). The manufacturing process of circular hollow sections also distributes residual stresses more effectively, which also results in a greater compressive resistance (Kurobane et al., 2004). In addition CHS do not contain sharp corners; this reduces the area to be protected and increases the corrosion protection life of a structure (Wardenier et al., 2008). However, connecting CHS together or to other members is cumbersome and difficult, and once they have been connected especially for complicated connections, accessing both sides for inspection and maintenance can be a challenge (Grundy, 1989).

One way of connecting CHS is to flatten the ends and then bolt the members together or to other members. Flattening the ends of the section does not reduce the area, but it does reduce the flexural stiffness (moment of inertia), since the squashed ends shape is no longer circular. This implies that the ends of the compression member may failure, which is not typical of member subjected to a compressive force. Most design codes do not provide guidance for the design of CHSs with reduced stiffness at the ends.

This paper seeks to establish the compressive strength of circular hollow sections (CHSs) with squashed/flattened ends, through laboratory tests. Variations in the tests include the diameter, thickness, material strength and bolt configuration of the CHS. Results from the tests are compared with the flexural compressive resistance in the South African code, SANS10162-1, with a view of determining a simple formula of designing such members. SANS10162-1 is based on the Canadian code, CAN/CSAS16.1-M01.

	101.6×2	285.00	340.00	209.16

2 MATERIAL PROPERTIES

In order to determine the material properties of the CHSs, coupons were cut and machined into standard dimensions. The coupons were tested according to the requirements of the British Standard, BS 18. Before testing the width and the thickness of the coupon were measured in order to determine the cross sectional area. The tests were performed using an 1195 Instron, at a rate of 3 mm/min. An extensometer was placed on the reduced length of the specimen to measure strain. After testing, stress-strain graphs were plotted, from which the yield stress (f_y), ultimate stress (f_u) and the elastic modulus (E) were obtained. The average material properties from these tests are given in Table 1.

3 SECTION CLASS LIMITATION

Circular hollow sections of different diameters ($60 \leq d \leq 101.6$) and thicknesses ($2 \leq t \leq 3$) were chosen in this investigation so as to vary slenderness and

Table 2. Slenderness ratio and diameter-to-thickness.

Series	CHS	f_y (MPa)	r (mm)	KL/r	d/t	Limit (d/t)
Series 1	60.0 × 3	450.51	20.20	79.21	20.00	51.00
	76.2 × 3	425.00	25.80	62.12	25.40	54.12
	101.6 × 3	409.73	35.00	45.71	33.87	56.13

	76.2 × 2	272.50	26.24	60.98	38.10	84.40
	101.6 × 2	285.00	35.22	45.43	50.80	80.70

diameter-to-thickness ratios. The slenderness ratios (*KL/r*) of the columns are given in Table 2, and ranges from 46 to 99. This range is significantly smaller that the slenderness limit of compression members of 200, prescribed by SANS10162-1. Parameters K, L, r, d, and t, in Table 2, represent the effective length factor, clear length (equivalent to 1600mm), radius of gyration, outside diameter, and thickness of the circular hollow steel sections, respectively. Since the stiffness of CHSs has been reduced significantly by flattening and huge rotations are expected at the end of the clear length, the effective length factor is taken as one Limitations are also prescribed by SANS10162-1 about the diameter-to-thickness ratio that must be used in circular hollow sections. SANS10162-1 requires that the maximum diameter-to-thickness ratio for circular hollow sections be $d/t \leq 23000/f_y$ to avoid local buckling. The actual values of the diameter-to-thickness ratios are given in Table 2. The diameter-to-thickness ratio, calculated using SANS 10162-1 suggests that all columns yields before failure.

4 TEST PROCEDURE

A total number of 24 specimens were tested; 18 specimens of these were flattened (squashed) at the ends and the remaining 6 CHS specimens were taken as control specimens. To ensure that the flattening process was done well an experienced company was hired to perform this function. The flattening process was performed mechanically by placing the ends of the circular hollow sections between dies, and then flattened. This deformed the member plastically in both the longitudinal and transversal directions. No cracks were observed after this process. As expected, flattening created a transition zone from a circular profile of the tube to a flattened section. The length of the transition zone (L) ranged from 1.2d to 1.5d, as recommended by Dutta (1998).

The clear length between the top and bottom connection of each specimen remained constant at 1600 mm length, however, the flattened length varied depending on the number of bolts of each specimen. Three different bolt configurations were investigated, namely; 1) with 2 bolts, 2) with 3 bolts and 3) with 4 bolts. As a result the 4 bolts CHS specimen had the longest squashed ends in comparison to the 2 bolts

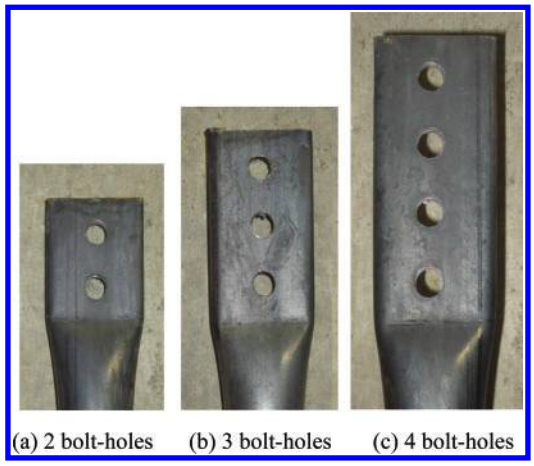

Figure 1. Bolt-hole configuration.

CHS specimen. A minimum of 2 bolts were used in each connection to reduce the amount of rotation at the end of the member. Figure 1 shows the squashed ends and the configuration of the bolt-holes of the CHSs. The lengths for the flat portions of the 2 bolt-hole, 3 bolt-hole and 4 bolt-hole configurations are 115 mm, 170 mm and 225 mm, respectively. The spacing of the bolt-holes was specified according to the requirements given in SANS 10162-1. The distance between the bolts is 55 mm and the end distance is 30 mm. SANS 10162-1 requires that the minimum end distance in a bolted connection with two or more bolts parallel to the direction of the load be at least 1.5 times the bolt diameter and the minimum distance between centres of bolt holes be 2.7 times the bolt diameter.

Figure 2(a) shows the test set-up of the CHSs. Details of the top and bottom connections of the set-up are given in Figures 2(b) and (c), respectively. Spacers were used to align the specimen vertical. M16, grade 8.8 bolts with ultimate tensile strength of 800MPa were selected in order to provide sufficient shear resistance for the double shear plane. Note that an M16 diameter bolt is the minimum structural bolt used in South Africa. The shear resistances for the 2, 3 and 4 bolts, in double shear, are 216kN, 324kN and 432, respectively.

No material tests were conducted on these bolts since the strength of the bolt was found to be less critical than the strength of the flattened portion. All bolts were fully threaded. An increasing compressive axial load was applied to the CHS, at a rate of 2 mm per minute in order to obtain a gradual displacement, until the specimen failed. The displacement and compressive load were recorded by a data acquisition system. Control specimens were tested with a steel ball between two plates at the top at the bottom-end of the member to simulate simply supported conditions.

5 FAILURE MODES

Two failure modes were observed in Series 1 tests. The first mode of failure observed was overall flexural

Figure 2. Test set-up and connection configuration.

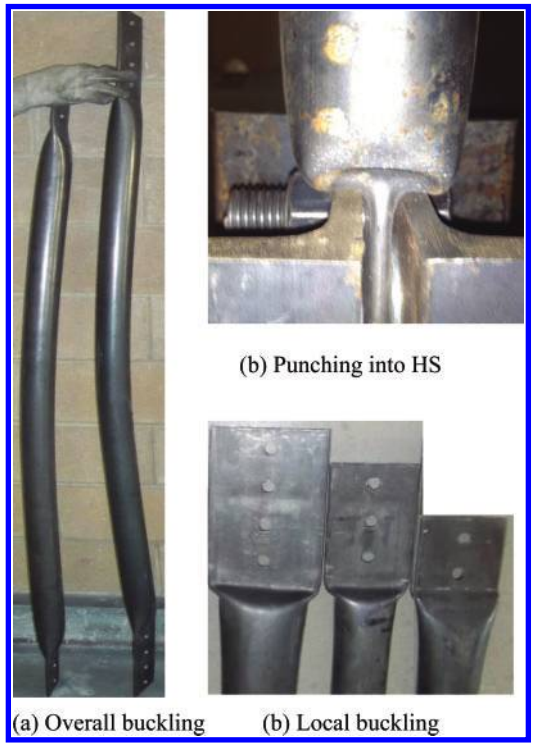

Figure 3. Failure modes.

buckling (F.B) of the member (Figure 3(a)). Overall flexural buckling was evident in the 60 × 3 mm CHSs. The second failure mode witnessed was local buckling (L.B), which formed at the beginning of the transition zone, from flat to circular section (Figures 3(b) and (c)). This mode of failure was common in larger diameter sections (typically the 76.2 × 3 mm and 101.6 × 101.6 × 3 mm), and was previously noted by Mistakidis and Tsiogas (2003). As shown in Figure 3(b), the specimens experienced extensive yielding or excessive plastic deformation in the transition zone. The deformation was caused by the punching effect of the flattened portion into the top of the circular region as it moved downwards, forcing the transition zone to bulge outwards. Both ends of the members (top and bottom) experienced this failure mode.

The modes of failure observed in Series 1 were governed by the diameter-to-thickness ratio (d/t) of CHSs. CHSs with larger diameter-to-thickness ratios failed by local buckling at the transition zone whilst those with lower diameter-to-thickness ratios failed by overall buckling. A significant number of specimens in Series 2 tests were expected to fail by overall flexural buckling because of the large slenderness ratios, however, this did not happen. Instead all sections failed by local buckling in the transition zone, near the flattened edge One possible cause of this local failure is the lower quality of steel exhibited by these sections. The second possible cause of this failure mode is the smaller thickness of the CHSs, which made it easier for the flat section to punch through circular hollow part of the member.

6 TEST RESULTS

Using the material properties in Table 1 and SANS10162-1, the axial compressive resistances (N_S) of CHSs in Table 3 were calculated. Table 3 also summarizes the test results obtained for the various specimens. In this table N_E is the maximum load applied to the tested flattened specimen and N_C is the compressive resistance of the control tests. Note that SANS10162-1 is based on the Canadian Code, CAN/CSAS16.1-M01. According to SANS10162-1, the unfactored compressive resistance of CHS for class 1, 2, or 3 sections is given by

$$C_r = Af_y(1+\lambda^{2n})^{-1/n} \quad (1)$$

where, A is the gross cross-sectional area and the parameter n reflect the difference in the patterns and levels of residual stresses and initial out-of-straightness. The value of n is equal to 1.34 for hot rolled, fabricated structural sections, and non-stress relieved hollow structural sections, and equal to 2.24 for doubly symmetric welded three-plate members with flange edges oxy-flame-cut and stress relieved

Table 3. Experimental and theoretical results.

		3	56.00	167.00	157.00	0.34	0.36	L.B
		4	54.00	167.00	157.00	0.32	0.34	L.B

hollow structural sections. Equation 1 was evaluated with the value of n=1.34. The non-dimensional parameter

$$\lambda = \frac{KL}{r}\sqrt{\frac{f_y}{\pi^2 E}} = \sqrt{\frac{f_y}{f_e}} \qquad (2)$$

where, r is the radius of gyration and E is the modulus of elasticity (200 000MPa). The effective length factor (K) is taken as 1 since the flattened end is considered as a flexible component. Whilst the first part of Equation 2 is more applicable to the common flexural buckling mode, the second part of Equation 2 is more general, since the elastic buckling stress (f_e) accounts for all possible forms of buckling.

With the exception of the 60 × 2 mm CHS, which has a significantly larger yield stress than the other sections in Series 2 (S2), the failure loads of larger diameter sections are generally higher than the smaller diameter sections (Table 3). A comparison of the test compressive strength of the flattened CHSs and the control compressive strengths in Table 3 shows the test strengths of the flattened CHSs to be significantly smaller than the control compressive strength. In Series 1 (S1), the flattened test strength range from an average of 75% of the control strength for the 60 × 3 mm specimens down to an average of 50% of the control strength for the 101.6 × 3 mm. This suggests that there is a 25% reduction in axial capacity for the 60 × 3 mm tubes, 30% reduction in axial capacity for the 76.2 × 3 tubes and 50% reduction in axial capacity for the 101.6 × 3 mm tubes, when the end is flattened. The flattened test strength range from a maximum of 71% to a minimum of 32% of the control strength for the 60 × 2 mm and 101.6 × 2 mm, respectively, for Series 2.

The axial capacity of the 60 × 2 mm, 76.2 × 2 mm, 101.6 × 2 mm tubes were reduced by an average percentage of 35%, 58%, and 67%, respectively, when the end is flattened. The section that experienced overall buckling (60 × 3 mm) was less affected by flattening. Local buckling in the transition zone resulted in a considerable loss of compressive strength when compared with standard circular hollow section of the same properties. This effect was felt more in sections with larger diameter-to-thickness ratios, lower yield strength of the material and smaller slenderness ratios than those with smaller diameter-to-thickness and high yield strength of the steel and larger slenderness ratio. CHSs with larger diameter-to-thickness ratio failed by local buckling at the transition zone whilst those with lower diameter-to-thickness ratio failed by overall buckling. From this analysis, it is clear that local buckling in the transition zone is more critical than overall flexural buckling of the member.

Although SANS10162-1 was able to predict the strength of the 60 × 3 mm section, which failed due to overall flexural buckling, the code could not predict all the sections that failed due to local buckling in the transition zone. The buckling strengths obtained using SANS10162-1 are larger than the test strengths for the specimens that experienced local buckling or excessive plastic deformation within the transition zone. As indicated above the effect is also more severe in sections with larger diameter-to-thickness ratios, lower yield strength of the material and smaller slenderness ratios than those with smaller diameter-to-thickness, high yield strength of the steel and larger slenderness ratio. These results compare well with the findings of Mistakidis and Tsiogas, who found the theoretical compressive strengths obtained from Eurocode 3 to be much larger than the experimentally strengths. Table 3 also shows that the number of bolts (2, 3 or 4 bolts) did not have any significant influence on the magnitude of the compressive resistance of the CHS specimens. The strengths obtained from bolt configurations were almost the same. The lower strength achieved by the larger flattened sections suggest that it might be uneconomic to use such sections as compression members.

7 PROPOSED DESIGN METHOD

Based on the analysis above the strength of flattened members has to be related either to the strength of the bolts or to the strength of the reduced cross sectional area of the flattened ends. The design method of the member, proposed in this paper, is an ultimate limit state approach and accounts for the two different failure methods observed in the tests. It is shown in Table 3 that the failure mode observed is governed by the diameter-to-thickness ratio of CHSs. CHSs with smaller diameter-to-thickness ratios (60 × 3 mm) failed by overall bucking and Equation 1 is able to model the results of these section. It is proposed to use this equation for CHSs with smaller diameter-to-thickness ($d/t \leq 20$).

Table 4. Design compressive resistance.

Diameter-to-thickness ratio	Design compressive resistance
$d/t \leq 20$	$C_r = \phi A f_y (1+\lambda^{2n})^{-1/n}$
$20 < d/t \leq 30$	$C_r = 0.75\phi A f_y (1+\lambda^{2n})^{-1/n}$
$30 < d/t \leq 38$	$C_r = 0.50\phi A f_y (1+\lambda^{2n})^{-1/n}$
$38 < d/t \leq 50$	$C_r = 0.35\phi A f_y (1+\lambda^{2n})^{-1/n}$

The second mode of failure observed is local buckling in the transition zone. This failure mode affected flattened tubes with larger slenderness ratios. The effect was felt more in tubes with larger diameters-to-thickness ratios ($d/t > 20$) and lower yield strength. Based on the analysis of the results in Table 3 it is proposed to reduce the strength of the tubes with $20 < d/t \leq 30$, $30 < d/t \leq 38$, $38 < d/t \leq 50$ by 25%, 50%, and 65%, respectively. The proposed expressions for designing such members are given in Table 4. In this table $\phi = 0.9$ is the resistance factor, to account for the variability of material properties, dimensions, workmanship, type of failure, and uncertainty in the prediction of member resistance.

Where flattened sections are used the effective length factor should be taken as 1 and the transition zone should be as short as possible to avoid a negative effect on the buckling behaviour.

8 CONCLUSION

This research shows that there are two possible failure modes of circular hollow sections with flattened ends, namely; overall flexural buckling of the member and local buckling in the transition zone. Local buckling was the dominant mode of failure and was associated with excessive plastification of the transition zone. Each mode of failure is directly connected to the ratio between the diameter and the thickness of the cross section. Smaller values of this ratio ($d/t \leq 20$) lead to the flexural buckling failure mode, while larger values ($d/t > 20$) promote the local buckling failure in the transition zone.

Local buckling in the transition zone was also promoted by CHSs of lower strength steel and lower slenderness ratio. This implies that CHSs of higher strength steel and larger slenderness ratio are more likely to favour overall flexural buckling. The investigation shows that the process of flattening CHSs reduces its compressive strength by big margin, and that all members that failed due to local buckling of the transition experienced a significantly lower ultimate compressive strength than those that failed due overall flexural buckling.

ABSTRACT: Drive-in steel storage racks represent a popular alternative to the more common selective racks when available space is restricted or when storing the same good. In drive-in racks, the forklift truck drives into the rack and stores the pallets on beam rails on the "first-in last-out" principle. Recent experimental studies have shown that by acting as horizontal ties between uprights, pallets significantly influence the structural behaviour of the rack. However, due to the uncertainty in the degree of friction between the rail beams and the pallets, current industry design practice does not consider this effect. This paper quantifies the influence of the pallets on the bending moment distribution in the uprights using a 3D finite element model calibrated against experimental results on a full scale drive-in rack. Additionally, as 3D models may be computationally intensive when a large number of analyses are required, this paper presents an improved version of the 2D model of drive-in racks introduced by Godley. In the improved 2D model, all possible loading scenarios and the influence of pallets on the structural behaviour of the rack are considered. When compared to advanced 3D finite element analyses, the model is able to accurately reproduce the bending moment distribution in the upright, with and without the presence of pallets.

1 INTRODUCTION

Worldwide, steel storage racks are extensively used in the manufacturing, wholesale and retail industry to store goods. They are mostly freestanding structures and are often assembled from cold-formed steel profiles. Two main types of racks prevail, referred to as "selective racks" and "drive-in racks". In drive-in racks, pallets are stored on rail beams one after the other, and the forklift truck drives into the rack to store the pallets on the "first-in last-out" principle. The rail beams are offset from the centreline of the uprights so that the pallets apply both bending moments and axial compressive forces to the uprights. To allow the forklift truck passage, the rack is only braced horizontally at the top (plan bracing) and vertically at the back (spine bracing) in the down-aisle direction. Due to their floor space efficiency, drive-in racks are usually preferred to selective racks in storing the same goods with quick turnover, or in expensive storage spaces such as industrial freezers. Figure 1 shows an example of a drive-in rack.

Figure 1. Example of a drive-in rack.

Experimental tests performed by Gilbert and Rasmussen (2009a, 2012) have shown that pallets act as horizontal braces between adjacent uprights, significantly influence the structural behaviour of drive-in

racks and must be considered in order to accurately capture the 3D behaviour of drive-in racks. Similarly, earlier research by Salmon et al. (1973), who numerically investigated the buckling behaviour of symmetrically loaded drive-in racks by alternately considering and ignoring the pallet bracing restraints in the analysis, showed that pallet bracing restraints had significant influence on the non-sway buckling mode, although they had less influence on the sway buckling mode.

However, due to the uncertainty concerning the friction between the pallet bases and the rail beams, drive-in racks are currently designed without considering the bracing effects.

Hua and Rasmussen (2010) measured the friction coefficient between wood pallets and rail beams and found that the average static friction coefficient between the rail beams and the pallet bases to be as high as 0.576, with a recommended a design static friction coefficient of 0.439. This friction coefficient suggests that significant horizontal forces can develop between the pallets and the rail beams before sliding occurs, allowing the pallets to play a structural role in the behaviour of drive-in racks. It is noted, however, that this design static friction coefficient does not take into account grease or ice (in the case of industrial freezers) that may accumulate on rail beams.

The current paper evaluates the influence of the horizontal bracing effect of pallets on the bending moment distribution of the upright in the down-aisle direction only, as due to the upright frames, pallets are not believed to influence the behaviour of drive-in racks in the cross-aisle direction.

The 2D analysis model for drive-in racks proposed by Godley (2002) is improved herein by introducing the horizontal restraints provided by both the rail beams and the pallet bracing restraints. All possible loading scenarios are also able to be computed in the improved model. This model is checked against the 3D model developed by Gilbert and Rasmussen (2009b, 2012) that is calibrated against laboratory test results.

2 SINGLE UPRIGHT MODEL

2.1 *Single upright model proposed by Godley*

In order to reduce the computation time associated with large models, Godley (2002) developed a "single upright model" to analyse fully loaded drive-in racks in the down-aisle direction. The upright is restrained at its base by a spring support having a rotational stiffness K_c, and at its top by another having a rotational stiffness K_b and a translational stiffness K_t, as shown in Figure 2. K_c represents the restraint provided by the base plate to the floor connection, K_b the restraint provided by the portal beams in double curvature (sway mode) having semi-rigid connections to the upright, and K_t the combined restraint from the plan bracing (spanning the entire rack), spine bracing (spaning one bay) and upright frames. Pallet loads and out-of-plumb loads are applied to the upright as shown in Figure 2.

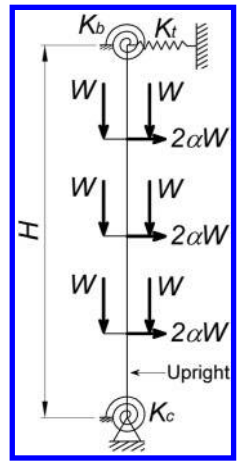

Figure 2. Drive-in rack single upright model from Godley (2002).

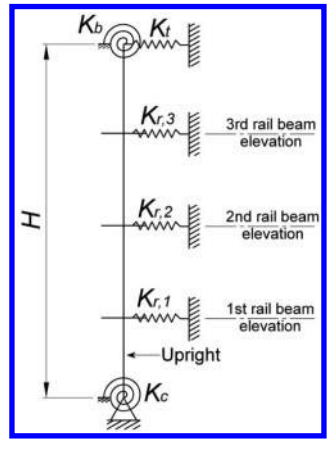

Figure 3. Single upright model with rail beam restraints for a 4 stories drive-in rack.

Detailed calculations for K_c, K_b and K_t, can be found in Godley (2002).

Despite its attractiveness, this model has limitations as it (i) ignores the restraint provided by the rail beams, (ii) does not take into account the horizontal bracing restraint provided by pallets, and (iii) does not consider all possible upright loading scenarios. The previous limitations are addressed in following sections.

2.2 *Improved single upright model*

2.2.1 *Rail beam restraints*

Typically, the out-of-plumb in drive-in racks is modelled by horizontal forces at the rail beam supports that are linearly proportional to the gravity loads of the pallets. For a fully loaded rail beam, the front and the back uprights are less loaded than the inner uprights, resulting in smaller out-of-plumb forces being applied to the front and back uprights. Therefore and since rail beams link the uprights together, they restrain the deflection of the inner uprights when subjected to the out-of-plumb forces.

Consequently, these restraints provided by the rail beams are introduced into the single upright model by adding a horizontal translational stiffness $K_{r,i}$ at each rail beam elevation i, as shown in Figure 3. While such an addition to the single upright model over-represents the restraints since it implies that there are no deflections of the front and back uprights, it has been found to lead to more accurate results than the neglect of same (Gilbert et al., 2013).

The stiffness $K_{r,i}$ is derived in Gilbert et al. (2013) for the critical upright (second from the front) of a drive-in rack with two upright frames and uniform spacing between uprights. For simplicity, the restraints provided by all rail beams to an upright are assumed to be independent of each other. $K_{r,i}$ is then expressed as,

$$K_{r,i} = \frac{11K_{uh,fb} - 4K_{uh,m}}{\frac{55L^3K_{uh,fb}}{6EI_r} + 15} \quad (1)$$

where $K_{uh,fb}$ and $K_{uh,m}$ are the down-aisle stiffness of the front and back uprights and inner uprights, respectively (Gilbert et al., 2013), L is the distance between two uprights in the cross-aisle direction, E is the Young's modulus of steel and I_r is twice the second moment of area of the rail beam, as two rail beams are typically connected to the uprights.

2.2.2 *Pallet bracing restraints*

The bracing effect provided by the pallets is now considered for any loading scenario of a studied single upright. Bays not directly in the vicinity of this upright are assumed to be fully loaded, as it would maximise the down-aisle displacement Δ of the rack and therefore the P-Δ effects in the upright. Specifically, two loading scenarios are considered for these bays, believed to represent the two design envelopes:

Bay loading scenario A: all bays not directly connected to the studied upright are fully loaded, as shown in Figure 4 (a).

Bay loading scenario B: the two bays on each side of the two bays directed connected to the studied upright are empty, while remaining bays are fully loaded, as shown in Figure 4 (b). This loading scenario aims to limit the influence of the pallets on the bending moment distribution in the studied upright, as contrary to the previous bay loading scenario A, the pallets only link the studied upright and its two neighbours.

2.2.2.1 Improved model for Bay loading scenario A

In a fully loaded rack, the influence of the pallets on the deformed shape of the uprights would be minimal, as all internal uprights in a row of uprights in the down-aisle direction would identically deform. Therefore, the overall deformation of the rack at the critical row of uprights can be found using the fully loaded improved single upright model introduced in Section 2.2.1, i.e. not considering pallets, as illustrated in Figure 5. Moreover, if the number of bays of the rack is large enough, as frequently encountered in drive-in racks (see Figure 1), removing pallets from each side

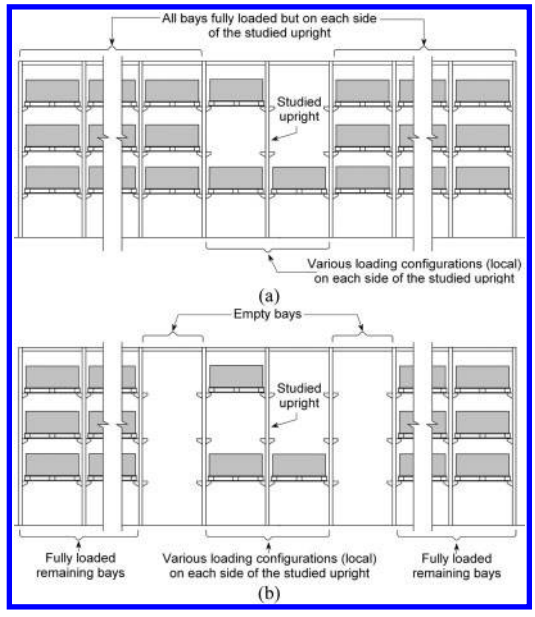

Figure 4. Studied upright for (a) Bay loading scenario A and (b) Bay loading scenario B.

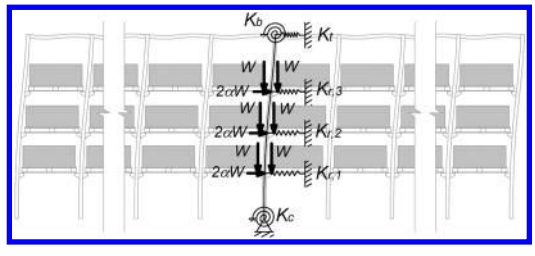

Figure 5. Deformed shape of the single upright model for a fully loaded rack.

of the studied upright would have negligible influence on the overall deformation of the rack, and the deformation of this upright would be a function of both its immediate loading configuration and the overall deformation of the rack imposed to the upright by the portal beams and the pallet bracing restraints.

Therefore, the bracing restraint provided by the pallets for a given loading scenario of the single upright is introduced into the model in the following manner, as illustrated in Figure 6:

Step 1: The overall down-aisle displacements of the rack at each rail beam elevation and at the top of the rack are determined using the fully loaded single upright model with out-of-plumb forces, as shown in Figure 5. The base plate to floor rotational stiffness K_c, and rail beam stiffness $K_{r,i}$ are calculated for the fully loaded configuration.

Step 2: The single upright model is loaded with its studied loading scenario, with the corresponding base plate to floor rotational stiffness K_c and rail beam stiffness $K_{r,i}$.

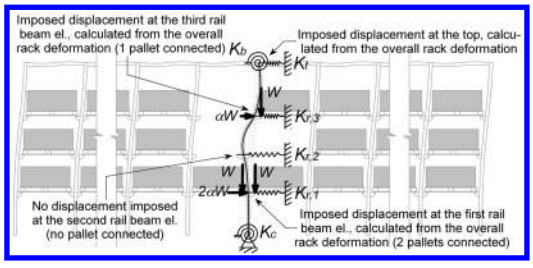

Figure 6. Improved single upright model for Bay loading scenario A.

Step 3: The overall down-aisle displacement at the top of the rack (portal beam elevation) found in Step 1 is imposed at the top of the single upright model created in Step 2.

Step 4: For each rail beam elevation of the model in Step 2, if there is at least one pallet at the elevation, then the overall down-aisle displacement at that elevation found in Step 1 is imposed on the upright.

2.2.2.2 Improved model for Bay loading scenario B As with previous Bay loading scenario A, the overall displacement imposed by the rack at the top of the critical upright in Figure 4 (b) and its two adjacent uprights can be determined from the fully loaded single upright model shown in Figure 5.

In order to determine the bending moment distribution in the studied upright for a given loading scenario of the upright, three single upright models are used and linked together by pinned rigid elements (ties) representing the pallet bracing restraints. The following steps are carried out as illustrated in Figure 7:

Step 1: The overall down-aisle displacement at the top of the rack is determined using the fully loaded single upright model with out-of-plumb forces, as shown in Figure 5. The base plate to floor rotational stiffness K_c, and rail beam stiffness $K_{r,i}$ are calculated for the fully loaded configuration.

Step 2: Three single upright models are created and loaded with the studied loading scenario, with the corresponding base plate to floor rotational stiffness K_c and rail beam stiffness $K_{r,i}$.

Step 3: The overall down-aisle displacement at the top of the rack (portal beam elevation) found in Step 1 is imposed at the top of the three uprights created in Step 2.

Step 4: Pallet bracing restraints are modelled using horizontal ties between rail beams, as shown in Figure 7.

3 INFLUENCE OF THE PALLET RESTRAINT ON THE BENDING MOMENT DISTRIBUTION AND VALIDATION OF THE SINGLE UPRIGHT MODEL

The 3D advanced Finite Element model for drive-in racks developed by Gilbert and Rasmussen Gilbert and

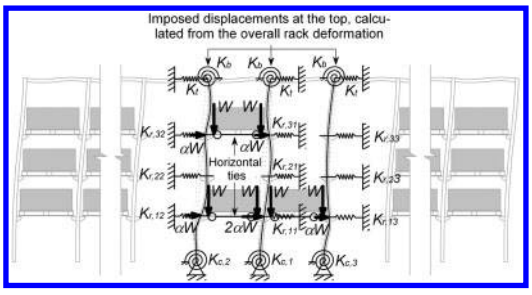

Figure 7. Improved single upright model for Bay loading scenario B.

Rasmussen (2009b, 2012) is used herein to (i) analyse the influence of the pallet restraint on the bending moment distribution in the upright and (ii) validate the improved single upright model introduced in Section 2.2. The 3D model has been calibrated against experimental test results and considers joint eccentricities, nonlinear portal beam-to-upright connections, nonlinear base-plate connections, and pallet bracing restraints, see Gilbert and Rasmussen (2009b, 2012) for more details. In the present 3D second-order analysis, the FE software Abaqus Abaqus (2010) is used, while the FE software Strand7 (2010) is used to run the 2D second-order analysis of the improved single upright model.

A rack with similar characteristics to the one tested by Gilbert and Rasmussen (2012) is used as a case study. Specifically, the rack is 12 bays wide, 4 pallets and 2 upright frames deep, and 4 stories high (i.e. featuring 3 rail beam levels). It has 3 spine bracing modules, each spanning one-bay, and 4 plan bracing modules, each spanning three bays. Each pallet is 2 tonnes. The rack is loaded as in Bay loading scenario A, described in Section 2.2.2. The shear stiffness of the pallets is taken as 7.2 N/mm, which is within the range experimentally found by Hua and Rasmussen (2010). The pallets are considered to be fastened to the rail beams as the static friction coefficient is assumed to be sufficiently high to prevent sliding. Two loading scenarios are studied, with a out-of-plumb of 0.0044 rad and other design parameters given in Gilbert et al. (2013). Further verification of the improved single upright model can be found in Gilbert et al. (2013).

3.1 *First loading scenario – Maximum combined axial compression and bending*

The load case involving the loading scenario shown in elevation in Figure 8 generally represents the governing load case for combined axial compression and bending of the adjacent upright to the unloaded compartment and to the aisle upright (critical upright) (FEM 10.2.07, 2010).

The down-aisle bending moment distribution of the critical upright from the 3D model accounting for pallet bracing restraints is plotted in Figure 9(a), and that obtained from the 3D model ignoring same in Figure 9(b). Figure 9 shows that the pallet bracing restraints significantly affect the bending moment distribution

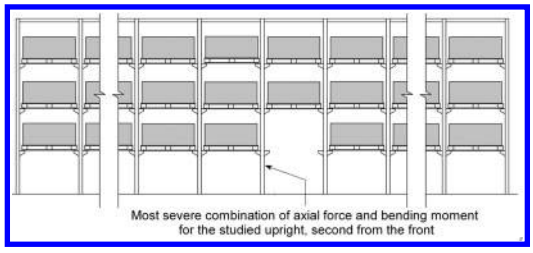

Figure 8. Loading scenario believed to generally govern the design.

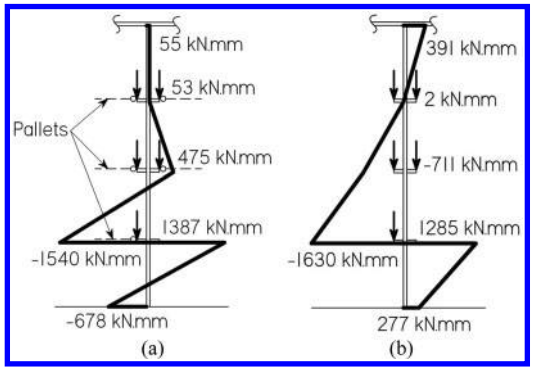

Figure 9. Bending moment distribution in the critical upright under vertical and out-of-plumb loads for the loading scenario shown in Figure 8 and 3D advanced analysis for (a) pallets considered and (b) pallets ignored.

of the critical upright, but have only a relatively minor impact on the design bending moment. This observation appears to be general for this type of loading scenario.

The down-aisle bending moment distribution of the critical obtained from the single upright model accounting for pallet bracing restraints described in Section 2.2.2.1 is plotted in Figure 10 (a), and that obtained from the single upright model ignoring same (i.e. ignoring Step 4 in Section 2.2.2.1) in Figure 10 (b). It can be seen from the comparison between Figure 9 and Figure 10 that the single model upright is able to accurately reproduce the bending moment distribution of the critical upright, with or without the pallet bracing restraints. The difference in the design bending moment between the 3D and the single upright models is less than 6%.

3.2 *Second loading scenario – Maximum bending*

The load case involving the loading scenario shown in Figure 11 typically incurs the largest design bending moment in the critical upright.

The down-aisle bending moment distribution of the critical upright under the second load case obtained from the 3D model accounting for pallet bracing restraints is plotted in Figure 12 (a), and that obtained

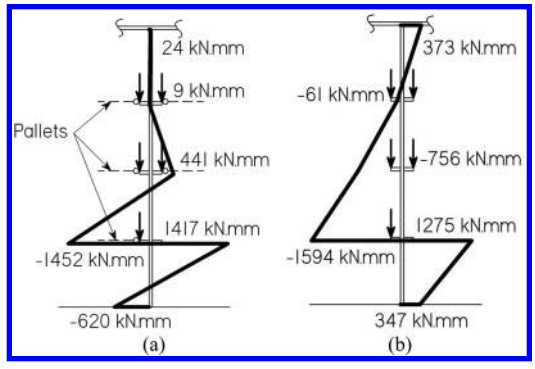

Figure 10. Bending moment distribution in the critical upright under vertical and out-of-plumb loads for the loading scenario shown in Figure 8 and 2D analyses for (a) pallets considered and (b) pallets ignored.

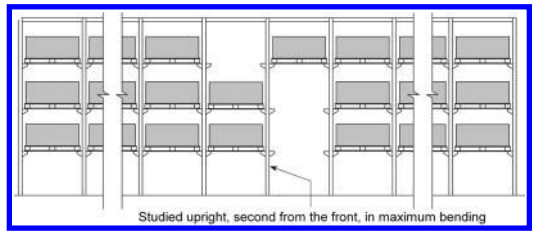

Figure 11. Loading scenario inducing maximum bending moment in a row of uprights.

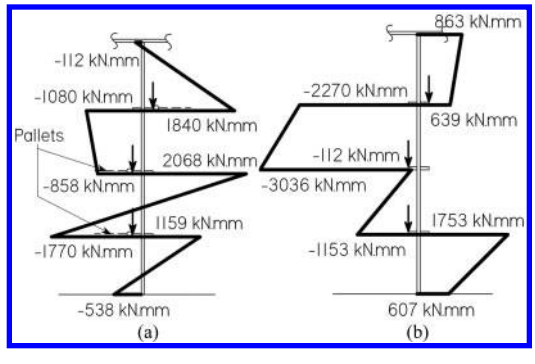

Figure 12. Bending moment distribution in the critical upright under vertical and out-of-plumb loads for the loading scenario shown in Figure 11 and 3D advanced analysis for (a) pallets considered and (b) pallets ignored.

from the 3D model ignoring same in Figure 12 (b). Figure 12 shows that not only the pallet bracing restraints significantly affect the bending moment distribution of the critical upright, but also reduces the design bending moment by almost one third under the second load case.

The down-aisle bending moment distribution of the critical upright obtained from the single upright model accounting for pallet bracing restraints is plotted in Figure 13 (a), and that obtained from the single upright model ignoring same in Figure 13 (b). Consistent with

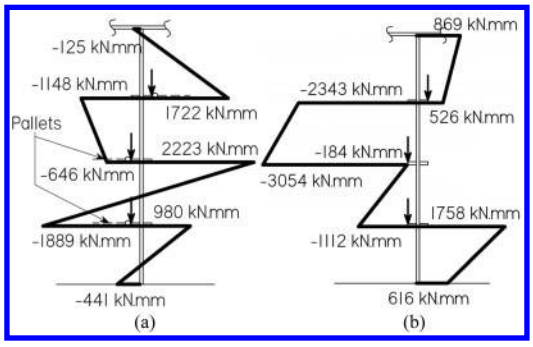

Figure 13. Bending moment distribution in the critical upright under vertical and out-of-plumb loads for the loading scenario shown in Figure 12 and 2D analyses for (a) pallets considered and (b) pallets ignored.

the results for the previous loading scenario, the comparison between Figure 12 and Figure 13 shows that the single model upright is able to accurately reproduce the bending moment distribution of the critical upright, with or without the pallet bracing restraints. The difference in the design bending moment between the 3D and the single upright models is less than 7%.

4 CONCLUSION

This paper analyses the influence of horizontal bracing restraints provided by the pallets on the behaviour of steel drive-in racks. The pallets are shown to significantly influence the bending moment distribution in the uprights. The single upright model presented by Godley is improved by including the restraints provided by the rail beams and the pallets. Comparison with advanced 3D Finite Element Analyses shows that the improved model is able to accurately reproduce the bending moment distribution in the upright in the down-aisle direction under gravity and out-of plumb loads and can be used to avoid large computational time associated with 3D models.

ABSTRACT: This paper analyses the influence of the horizontal restraints provided by pallets on the ultimate capacity of drive-in racks. The paper is based on the assumption that one can accurately determine the coefficient of friction between the rail beams and the pallets or can design a device that restrains the pallets from sliding on the rail beams. Thirty-six drive-in racks representing the global sale of an Australian manufacturer over three years are analysed for all possible loading scenarios. For the sake of computational efficiency, the simple 2D model introduced in the companion paper is used for the study. The load case(s) governing the structural design is(are) also clarified and the friction coefficient or strength of a restraining device required to prevent the pallets from sliding is determined.

1 INTRODUCTION

This paper analyses the influence of the horizontal restraints provided by pallets on the ultimate capacity of drive-in racks. As introduced in the companion paper (Gilbert et al., 2013a), by acting as horizontal braces between adjacent uprights, pallets significantly influence the structural behaviour of drive-in racks and must be considered in order to accurately capture the 3D behaviour of this type of structure.

However, due to the uncertainty concerning the friction between the pallet bases and the rail beams, drive-in racks are currently designed without considering this bracing effects. If a device can prevent the pallets from sliding on the rail beams or if the coefficient of friction between the pallet bases and the rail beams can be reliably determined, the horizontal bracing effect provided by the pallets could be fully exploited in the design.

The current paper analyses the influence of the horizontal bracing effect of pallets on the design of steel drive-in racks in the down-aisle direction only. As mentioned in the companion paper (Gilbert et al., 2013a), due to the upright frames, pallets are not believed to influence the behaviour of the racks in the cross-aisle direction. It should also be noted that the friction between pallet bases and the rail beams would prevent the pallets from dropping through on account of the upright bowing deformations. As such, the serviceability check against upright bowing deformations is not considered in this paper.

Thirty six drive-in racks representing the global sale of an Australian manufacturer over three years are then analysed using the improved 2D single model introduced in the companion paper (Gilbert et al., 2013a) under all possible loading scenarios, alternately considering and ignoring the pallet bracing restraints. This paper evaluates the influence of pallet bracing restraints on the ultimate capacity of steel drive-in racks in the down-aisle direction, clarifies the loading scenario(s) governing the design and determines the friction coefficient or the strength of a restraining device required to prevent the pallets from sliding.

2 PARAMETRIC STUDIES

Thirty-six rack configurations, representing the global sale of an Australian manufacturer over three years and designed using industry practice (Dematic, 2006), are analysed using the improved single upright models introduced in the companion paper (Gilbert et al., 2013a). The racks are considered to be 4 pallets deep, with rail beams equally spaced apart along the rack height. The uprights are referred to as "SD" for standard uprights and "RF" for rear flanged uprights, their

widths range from 70 mm to 150 mm and their thicknesses from 1.2 mm to 2.4 mm. Table 1 summarises the rack configurations including the rack height, design pallet load, number of stories and upright type. More details can be found in (Gilbert, 2010, Gilbert et al., 2013b).

Specifically, three different single upright models are considered and their member action-to-capacity ratios are used as a measure to quantify the influence of the pallet restraints on the design of drive-in racks:

- Model A considers the pallet bracing restraints and represents the Bay loading scenario A. The model is described in the companion paper (Gilbert et al., 2013a) in its Section 2.2.2.1 and illustrated in its Figure 6.
- Model B considers the pallet bracing restraints and represents the Bay loading scenario B. The model is described in the companion paper (Gilbert et al., 2013a) in Section 2.2.2.2 and illustrated in its Figure 7.
- Model C is based on the current industry practice of neglecting the pallet bracing restraints. The model is similar to Model A at the exception of Step 4 in Section 2.2.2.1 of the companion paper (Gilbert et al., 2013a).

2.1 *Design parameters*

2.1.1 *Base plate to floor connection stiffness*

Base plates are generally bolted to the floor, and the strength and initial rotational stiffness of the base plate to floor connection depend on the axial load in the upright (Godley et al., 1998). Numerical investigations on the non-linear behaviour of a typical storage rack base plate assembly (Gilbert and Rasmussen, 2011) showed that (i) the connection strength is proportional to the upright width, (ii) in the presence of axial load in the upright, the initial rotational stiffness of the base plate to floor connection is proportional to the cube of the upright width and (iii) when no axial load is applied to the upright, the initial rotational stiffness is independent of the upright width.

The rules described above, combined with the test results in (Gilbert and Rasmussen, 2011) and applied to a 125 mm wide base plate assembly, are used in the following sections to determine the initial stiffness and strength of base plate to floor connections as functions of base plate widths. Detailed moment-rotation curves used in the present work are given in Gilbert et al. (2013b).

2.1.2 *Out-of-plumb*

The main international racking specifications (AS 4084, 2012, EN 15512, 2009, RMI, 2008) consider the initial looseness in the member connections as well as the initial out-of-plumb as frame imperfections, which are generally accounted for in the design by means of horizontal forces $F_{out\text{-}of\text{-}plumb}$ applied at each rail beam elevation as,

$$F_{out-of-plumb} = \alpha W \tag{1}$$

where α is the out-of-plumb angle and W is the vertical load applied to the upright by the pallets at the rail beam elevation. The out-of-plumb angle α is typically a function of the number of interconnected bays and the looseness in the portal beam to upright connections. A out-of-plumb angle of 0.0044 rad (about 1/250) is used in the present work. See Gilbert et al. (2013b) for more details.

2.1.3 *Other parameters*

Other design parameters used in the present work, which correspond to some drive-in rack configurations currently commercialised in Australia, are given in Gilbert et al. (2013b). The height of the rack$H$, the number of pallet levels N_s and the cross-sectional area of the upright A_u depend on the studied rack characteristics and are given in Table 1 and Gilbert et al. (2013b).

2.2 *Upright load cases*

According to the draft FEM specification for the design of drive-in racks (FEM 10.2.07, 2010), the load case involving the loading scenario depicted in Figure 5 in the companion paper (Gilbert et al., 2013a) and a fully loaded upright are usually "sufficient to consider the pattern load effects" for the Ultimate Limit State (ULS) design in the down-aisle direction. However, it is currently unclear if a different load case may govern the design. Moreover, in light of the horizontal bracing effect offered by the pallets, the load case involving the loading scenario depicted in in Figure 5 in the companion paper (Gilbert et al., 2013a) and a fully loaded upright may not always be sufficient for the ULS design of the upright.

Consequently, every possible load case is investigated in the present work for the 36 drive-in racks given in Table 1. Second-order geometric analyses are carried out using the general purpose FE software Strand7 (2010). The number of load cases analysed per rack is a function of the number rail beams and is equal to 4^{Ns}, where N_s is the number of rail beam elevations.

2.3 *Ultimate capacity*

For each of the three rack models and each upright load case, the Australasian cold-formed steel structures standard AS/NZS 4600 (2005) is used to calculate the member action-to-capacity ratios of the critical upright. When second order-geometric analyses are used, members subjected to combined axial compression and bending must satisfy the ULS design check in Eq. (2),

$$\frac{N^*}{\phi_c N_c}+\frac{M_x^*}{\phi_b M_{bx}}+\frac{M_y^*}{\phi_b M_{by}}\le 1 \tag{2}$$

where $N*$ is the design axial compression load, and M_x* and M_y* are the design bending moments about the x- (cross-aisle) and y- (down-aisle) axes, respectively, N_c is the nominal axial compression member capacity, M_{bx} and M_{by} are the nominal member bending moment capacities about the x- and y- axes, respectively, ϕ_c and ϕ_b are reduction capacity factors for members in compression and bending, taken as 0.85 and 0.90, respectively. As the present work is concerned with the design of drive-in racks in the down-aisle direction, the bending moment about the down-aisle axis is considered negligible and for the 2D single upright model, Eq. (2) becomes,

$$\frac{N^*}{\phi_c N_c}+\frac{M_x^*}{\phi_b M_{bx}}\le 1 \tag{3}$$

A load factor of 1.4 is used for the pallets to determine the design loads $N*$ and bending moments M_x*. The self-weight of the rack is ignored.

The Direct Strength Method (Schafer, 2006) in Section 7 of the AS/NZS 4600 (2005) is used in the present work to calculate the nominal capacities N_c and M_{bx} of the upright. Specifically, the axial capacity in compression N_c is defined as the lesser of the axial global, local and distortional nominal capacities N_{ce}, N_{cl} and N_{cd}, respectively, as,

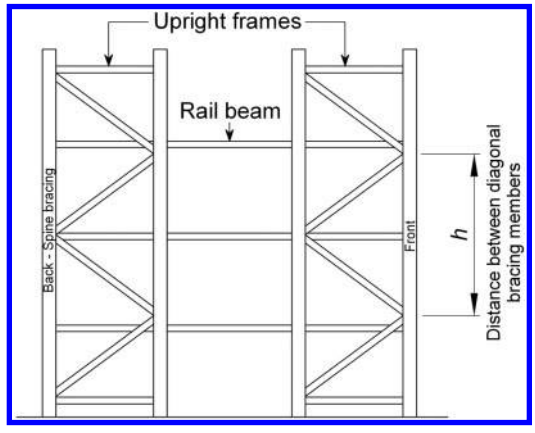

Figure 1. Frame bracing pitch h, unbraced segment.

$$N_c=\min\left(N_{ce},N_{cl},N_{cd}\right) \tag{4}$$

and the nominal bending moment capacityM_{bx} about the x-axis of bending is defined as the lesser of the global, local and distortional nominal moment capacities M_{bxe}, M_{bxl}, M_{bxd}, respectively, as,

$$M_{bx}=\min\left(M_{bxe},M_{bxl},M_{bxl}\right) \tag{5}$$

Specifically, the global nominal capacity M_{bxe} is a function of the bending moment distribution in the upright through the elastic buckling moment M_o,

$$M_o=C_b A_u r_{ol}\sqrt{f_{oy}f_{oz}} \tag{6}$$

where C_b is a coefficient depending on moment distribution in the unbraced segment of the upright,A_u is the gross cross-sectional area,r_{ol} is the polar radius of gyration about the shear centre and f_{oy} and f_{oz} are the elastic buckling stresses for flexural buckling about the y-axes (perpendicular to the symmetry axis) and torsional buckling, respectively.

Detailled rules to determine N_{ce}, N_{cl}, N_{cd}, M_{bxe}, M_{bxl}, M_{bxd} are given in AS/NZS 4600 (2005).

2.3.1 *Effective buckling lengths*

The Australian Standard AS 4084 (2012) recommends effective lengths l_{ey} and l_{ez} for buckling about the y- (down-aisle) and z- (torsional) axes equal to h and 0.7 times h, respectively, where h represents the upright frame bracing pitch, as shown in Figure 1. These values are adopted in the present work.

For each member of the simple upright model, the effective length l_{ex} for buckling about the x-axis (in

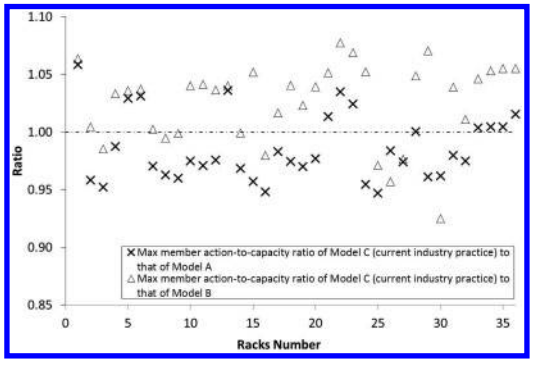

Figure 2. Influence of the horizontal pallet restraint on the action- to-capacity ratio for h = 1,500 mm.

the down-aisle plane) is calculated as (Teh and Gilbert, 2013),

$$l_{ex} = \pi \sqrt{\frac{EI_x}{N_{crb}}} \tag{7}$$

where I_x is the second moment of area about the x axis, and N_{crb} is the elastic buckling load of the upright determined from a rational frame buckling analysis (Teh and Gilbert, 2013).

3 RESULTS

3.1 *Effects of pallet restraint*

In this study, two values for the frame bracing pitch h, being 1,500 mm and 2,000 mm, are considered.

3.1.1 *Frame bracing pitch h = 1,500 mm*

Figure 2 plots the ratios of the maximum member action-to-capacity ratio of Model C (current industry practice) to that of Model A, and to that of Model B, for the 36 racks given in Table 1 having a frame bracing pitch h of 1500 mm. Detailed results can be found in Gilbert et al. (2013b). A ratio greater than 1.0 in Figure 2 indicates that the current industry practice results in uneconomical designs.

Figure 2 shows that for 12 racks out of 36, incorporating the horizontal restraining effect provided by the pallets would provide more economical designs than the current industry practice, with a decrease in the member action-to-capacity ratio of up to 6% (Rack 1). On average for the 12 racks, the decrease is 2%.

For the remaining 24 racks, ignoring the pallet restraints would lead to less conservative designs, with a increase in the member action-to-capacity ratio of up to 7% (Rack 30). On average for the 24 racks, ignoring the pallet restraints increases the design capacity by 3%. This counterintuitive result is mainly due to the effect of the pallet restraints on the design bending moment of the upright under the critical load case. Figure 3 shows the bending moment distribution in the upright for Models A and C, and the coefficient C_b

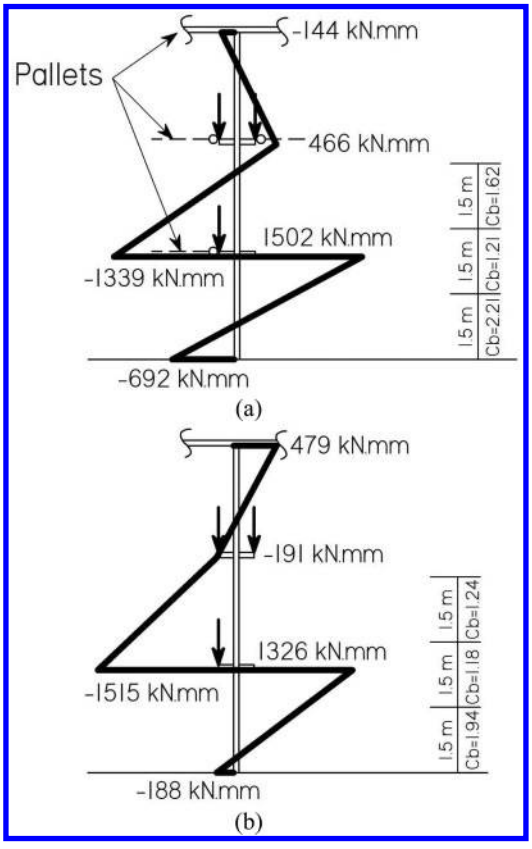

Figure 3. Bending moment distribution for the critical load case for rack 25 for (a) Model A and (b) Model C.

Table 2. Frame bracing pitch h, unbraced segment.

	Model C (current practice)/Model A		Model C (current practice)/Model B	
h (mm)	Average ratio	CoV	Average ratio	CoV
1,500 mm	0.99	0.029	1.03	0.034
2,000 mm	0.99	0.026	1.04	0.016

in Eq. (6), under the critical load case of Rack 25. It can be seen that ignoring the pallet restraints leads to a design bending moment that is 12% less than when considering same, but with similar C_b coefficient.

Table 2 summarises the average maximum member action-to-capacity ratios given in Figure 2.

3.1.2 *Frame bracing pitch h = 2,000 mm*

Figure 4 plots the ratios of the maximum member action-to-capacity ratio of Model C (current industry practice) to that of Model A, and to that of Model B, for the 36 racks given in Table 1 having a frame bracing pitch h of 2000 mm. Detailed results can be found in Gilbert et al. (2013b).

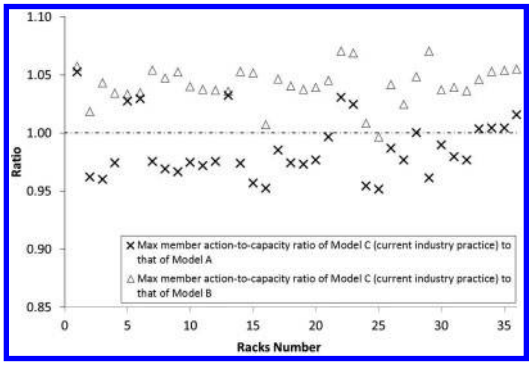

Figure 4. Influence of the horizontal pallet restraint on the action- to-capacity ratio for h = 2,000 mm.

Similar conclusions to those in Section 3.1.1 can be drawn. Results show that for 11 racks out of 36, considering the horizontal restraining effect provided by the pallets would provide more economical designs than the current industry practice, with a decrease in the member action-to- capacity ratio of up to 5% (Rack 1) and an average decrease of 2%. For the remaining 25 racks, ignoring the pallet restraints would lead to less conservative designs, with a maximum increase in the member action-to-capacity ratio of 5% (Rack 25) and an average increase of 3%. Table 2 summarises the average maximum member action-to-capacity ratios given in Figure 4.

3.1.3 *Critical load cases*

When the pallet restraints are considered in the analysis (Models A and B), the load case involving the loading scenario shown in Figure 5 in the companion paper (Gilbert et al., 2013a), which corresponds to a fully loaded rack except for one compartment at the first rail beam elevation, is found to govern the design in general. However, for the 4-storey drive-in racks number 26 and 30, the load case shown in Figure 5 (a) is found to provide an action-to-capacity ratio up to 13% higher than the load case involving the loading scenario shown in Figure 5 in the companion paper (Gilbert et al., 2013a). Despite a lower axial load incurred in the critical upright, the loading scenario induces a buckling length l_{ex} about twice that for the loading scenario shown in Figure 13, and therefore leads to a reduced axial capacity.

When the pallet restraints are ignored in the analysis, the load case involving the loading scenario shown in Figure 5 in the companion paper (Gilbert et al., 2013a) is also found to generally govern the design. However, the load cases shown in Figure 5 (b) for the 4-storey drive-in rack number 4, Figure 5 (c) for the 5-storey rack number 21 and Figure 5 (d) for the 6-storey drive-in racks number 21, 22 and 36 govern the design with an action-to-capacity ratio 2%, 3% and 4.5% higher that the loading scenario shown in Figure 5 in the companion paper (Gilbert et al., 2013a), respectively.

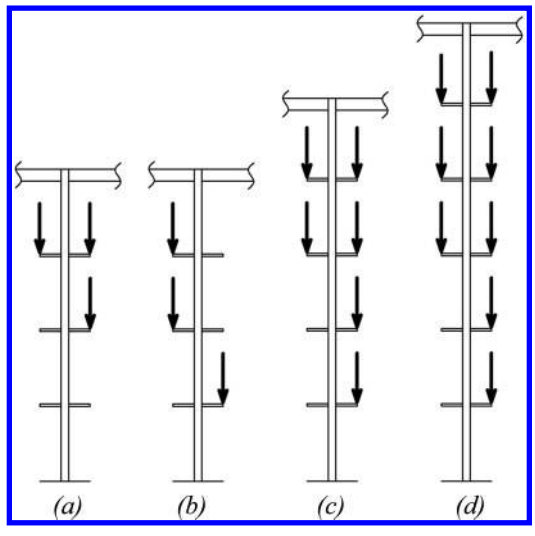

Figure 5. Specific load cases governing the design.

In view of the above results, for ULS design ignoring pallet bracing effects, limiting the analysis to the load case involving the loading scenario shown in Figure 5 in the companion paper (Gilbert et al., 2013a) and a fully loaded rack, would only induce a limited error in the action-to-capacity ratio and may be considered to be "sufficient for considering the pattern load effects".

3.2 *Friction coefficient analysis*

The minimum friction coefficient μ needed to prevent the pallets from sliding on the rail beams is investigated herein for Model A. The friction forces S_f developed between the pallets and the rail beams are extracted from the horizontal reactions at each loaded rail beam elevation of the single upright model. The friction coefficient μ is then calculated as,

$$\mu = \frac{S_f}{W} \tag{8}$$

where W is the axial load applied by the pallets to the upright at the rail beam elevation.

Figure 6 shows the minimum friction coefficient needed to prevent sliding of the pallets found for all loading cases and for the 36 drive-in racks in Table 1. All values in Figure 6 are less than the design static friction coefficient of 0.439 recommended by Hua and Rasmussen (2010) (see companion paper), indicating that, under normal operating conditions, sliding is unlikely to occur between the pallets and the rail beams, and that pallet bracing restraints could be considered in the design of drive-in racks. Moreover, the minimum friction coefficient μ is dependent on the number of stories (or rail beam elevations), as seen in Figure 6. The more the stories, the more likely the pallets are to slide. Results show that, for a given

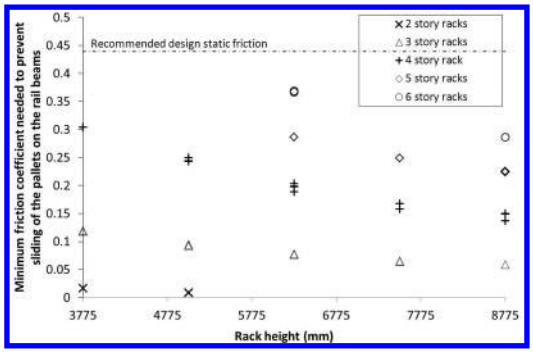

Figure 6. Minimum friction coefficient μ needed to prevent pallets from sliding.

number of stories, the minimum coefficient of friction required to avoid sliding of the pallets decreases somewhat linearly with the height of the rack.

4 CONCLUSIONS

This paper analyses the influence of horizontal bracing restraints provided by the pallets on the design of steel drive-in racks. Using the improved single upright model presented in the companion paper, analyses were run for 36 drive-in rack configurations. All possible loading cases were analysed. Results showed that ignoring the pallet bracing effects in design, as in the current industry practice, usually leads to a less conservative design with an action-to-capacity ratio for the critical upright being reduced in the order of 4%.

The load case involving a fully loaded rack except for one compartment at the first rail beam elevation was found to govern the Ultimate Limit State design of most racks. However, loading scenarios inducing the maximum bending moments were also found to govern the design of some drive-in racks having 4 to 6 storeys, with action-to-capacity ratios up to 5% greater than the previous load case when pallets are ignored.

Results show that under normal operating conditions, the friction coefficient between the pallets and the rail beams is sufficient to prevent sliding of the pallets, and therefore pallets could be considered in the design of drive-in racks.

Extension of the DSM to welded H profile cross-sections

B. Rossi & Li Y.
University of Liège, Belgium

ABSTRACT: The objective of the paper is to assess the accuracy of current Direct Strength Method (DSM) equations applied to steel structural welded H shapes in axial compression. Commercialised hot-rolled H sections covering IPE, HE, HD, HL, HP, W and UB profiles and made of three grades (235 MPa, 355 MPa and 460 MPa) were treated in (Li & Rossi 2012). This analysis focuses on welded sections made of the same three grades, including sections characterized by local buckling with a significant post-buckling reserve. The finite element model is described. Then, the results of a parametric analysis using the finite element model are reported. The codified resistances are also compared to the numerical results. For each cross-section, the recently developed analytical expressions provided in (Seif & Schafer 2010) for hot-rolled profiles are used to calculate the elastic cross-section local buckling stress. A comparison with CUFSM results is also reported. Then, the possibility to use the concept of DSM for the design of structural welded steel shapes is discussed.

1 INTRODUCTION

In most of the standards (CEN 2005a,b, NAS 2007a AISI 2005), the cross-section capacity of Class 4 sections is assessed using the Effective Width Method (EWM) to account for the effect of local buckling. The method proposes width-to-thickness b/tlimit ratios that each of the cross-section wall has to fulfill to be considered as non-affected by local buckling. The dimensions of the walls affected by local buckling are reduced to their effective parts.

Because of the complexity and limitations of this method – it has been shown that several values of the b/tlimit ratios in Eurocode 3 are frequently misleading and that the assumed support conditions of the plates composing the cross-section is not representative of the interaction between them (Semi- Comp 2007, Seif & Schafer 2009, Li et al. 2011) –, alternative methods have been developed, such as the Direct Strength Method (DSM) for cold-formed thin-walled profiles and the Continuous Strength Method (Schafer 2008, Gardner 2008). The DSM method is based on the assumption that the strength can be predicted using the yield strength to elastic critical load ratio in conjunction with a strength reduction curve. It has gained importance over recent years and the expressions of the strength reduction curves, validated against numerous experimental data for cold-formed thin-walled members, are now suggested in North American and Australian standards (NAS 2007b, SA 1996).

In Li & Rossi 2012, commercialized hot-rolled H sections covering IPE, HE, HD, HL, HP, W and UB profiles and made of three grades (235MPa, 355MPa and 460MPa) were studied. A finite element model was validated against tests results achieved in the frame of the Semi comp (2007) project and used to perform a parametric analysis. The resistance of the cross-sections under pure compression was dominantly governed by yielding. For slender sections, local buckling occurred in the web and involved rotation of the flange – in opposite directions by the same amount – about the line of the flange-web junction sometimes followed by post-buckling reserve. In this analysis, the elastic local buckling stress was calculated using the recently developed analytical expressions of Seif & Schafer (2010), which allow for cross-section slenderness evaluation. It was then possible to derive a DSM strength curve for this range of sections i.e. characterized by slenderness ranging from 0.7 to 1.3.

In Boissonnade et al. (2013), a series of tests results collected in the literature (Semi Comp 2007, Kettler 2008) together with some 400 FE results relative to semi-compact sections (HEA 280, HEAA 220 and HEAA 300) are used to assess the applicability of the design approach called Overall Interaction Concept in which, similarly, a generalized relative slenderness is used to calculate the strength of open and hollow sections via interaction curves.

Presently, welded sections are considered. A geometrically and materially nonlinear analysis using the FE method has been conducted to evaluate the resistance of axially compressed welded H profile cross-sections. The FE model was firstly verified against experimental data and then used to carry a parametric analysis. The combination of flange and web thickness and/or depth therefore led to various kind of interaction between the flange and the web. In the next sections, the FE model is detailed. The local buckling and post-local buckling behavior of short length welded H profiles is described. The numerical strengths are

compared to current Eurocode 3 and DSM predictions. The goal of the analysis is to discuss the opportunity of using the DSM concepts for calculating the resistance of non-compact and slender welded H profile cross-sections i.e. to check the generalization of the slenderness concept as the key parameter to rule the strength via a strength reduction curve.

2 EXPERIMENTAL INVESTIGATIONS

In the project Semi comp (2007), a testing program covering hot-rolled and welded HEAA sections as well as square hollow section (SHS) and rectangular hollow section (RHS) was carried out in the Laboratory for Structural Engineering at Graz University of Technology. Ten stub column tests were carried out between fixed end supports for all different cross-section types and materials i.e. hotrolled HEA260, S235; hot-rolled HEA260, S355; welded HEA260, S235; SHS 180/180/5, S355; RHS 200/120/4, S275. All specimens were welded to a thick steel plate (120mm thick) on both sides to facilitate a uniform loading condition. Both top and bottom compression plates of the testing machine were fully restrained in translation and rotation except the vertical translation of the top plate. The length of the specimens was 900 mm for H sections and 700 mm for tubular sections, based on the principle that the length is sufficiently small to prevent member buckling while long enough to avoid the influence of the boundary conditions. In practice, the length is chosen equal to approximately three times the largest cross-sectional dimension. Tensile coupons, cut from the webs and the flanges, were tested using a RKM testing machine to determine the material stress-strain behavior. The local geometrical imperfection was measured with linear variable displacement transducers for all the specimens while the residual stresses were measured only for one HEAA240 cross-section, in the frame of another experimental campaign carried out at the Materials and Structures Laboratory of the University of Liège. The axial load and vertical displacements were recorded during the stub column tests. For that purpose, four W200 inductive displacement gauges were used. Two welded sections were tested. The average measured crosssection dimensions $h \times b \times tw \times tf$ were 259.3 mm × 244.4 mm × 6 mm × 10 mm, where $h$is the web height, b is the flanges width and tf and tw are the flange and web thicknesses respectively. The ultimate loads for the two welded specimens are provided in Table 1.

Figure 1 shows the failure mode for the specimen A24-2.

3 FE MODEL

In the present work, a nonlinear FEM software FineLg (2012) has been used to model the aforementioned stub column tests. In this model, special attention was paid to the modeling of the initial geometric imperfection, residual stress distribution and interaction between flanges and web.

Table 1. Comparison of experimental and numerical results for stub column tests.

Specimen	FExp[kN]	FFEM[kN]	FFEM/FExp
A24-1	2135	2038	0.955
A24-2	2025	2038	1.006
		Mean	0.982
		CoV	0.026

Figure 1. Failure mode (yielding) for a loaded specimen.

3.1 *Geometry and boundary conditions*

The averaged measured geometrical dimensions were used in the FE model intended for calibration against the tests.

One way to simulate the boundary condition is to fix the bottom part of the specimen while the top is allowed for free translation along the stub column length direction. In the model, a thick rigid elastic plate is fixed to the specimen on both sides and the axial load is applied via the plates. The plates stiffness ensures that the movements of the nodes composing the profile cross-section occur simultaneously and allows even distribution of the concentrated load applied at the centroid of the plate. The plates prevent the cross-sectional deformation at both ends but allow the rotations. So, in the FE model, the boundary condition is a pinned-end condition.

3.2 *Cross-section discretisation*

Shell elements were employed to discretize the model. The QSCRA element, a general purpose shell element

with four nodes and reduced integration to form the element stiffness (S4R), was used to simulate the web and flanges.

Since a common node was used for the web and flange modelling, there exists an overlapped area of $tf \times tw/2$ mm2. Also, the area of the weld is neglected. The weld geometry is considered as being an isosceles triangle, the height of which is the minimum between $1,5\,t1$ and $1.2t2$ where $t1$ and $t2$ are the thicknesses of the thicker and the thinner plate respectively (Davids & Hancock1986, Welding Handbook 1976, GB50017 2003). In order to model this, an additional node is placed within the web height, at the exact vertical position of the centroid of the weld. It bears an addtional beam element, oriented in the longitutional direction, with an area that equals the welded area minus the overlapped area.

Another important aspect in the modeling of the H-shaped profiles concerns the development of local plate buckling. The zone at the intersection of the flange and the web remains unaffected by the extent of local buckling. Therefore, in the model, a truss system has been added in the web-flange junction zone meant to keep this zone rigid (Boissonnade & Somja 2012, Li & Rossi 2012).

3.3 *Local geometrical imperfections*

FE models generally include imperfections that correspond to the lowest buckling mode shape. Usually, the imperfections are introduced as eigenmodes that are scaled to a proper magnitude, Johannsson et al. (2007). This procedure may sometimes be lengthy to achieve if not implemented in the code. In this sense, it may be simpler to use the pre-knowledge of what are the possible instability modes and therefore to use a sinusoidal shape to represent the initial deformation, CEN (2005). Using this approach, the amplitude of the deformation for each plate element is chosen individually. The literature and measurements performed during the Semi Comp project indicates that, in welded sections, the geometric imperfection is a combination of overall twisting and plate ripple (Figure 2). This shape is due to shrinkage further to welding (Davids & Hancock 1986, Welding Handbook 1976, Kettler 2008). According to this, a half wavelength sine is used in the flanges and a sine is used in the web (as depicted in Figure 3). The amplitude is set to $h/200$as suggested in (CEN 2005b, Semi Comp 2007), where $h$is the clear width of the web or flange.

3.4 *Material stress-strain curve and residual stress*

The adopted material model is a perfectly elasticplastic model (CEN 2005b). The Young's modulus E and the yield strength fy are obtained from the tensile coupon tests perfromed during the Semi Comp project. Residual stresses are caused by the welding process. Based on recommendations (Boulton 1936, Weck, R. 1949, Tall & Rao 1961, Rao et al 1964, ECCS 1984a,b, Davids & Hancock 1986 and BSK 1999), a rectangular

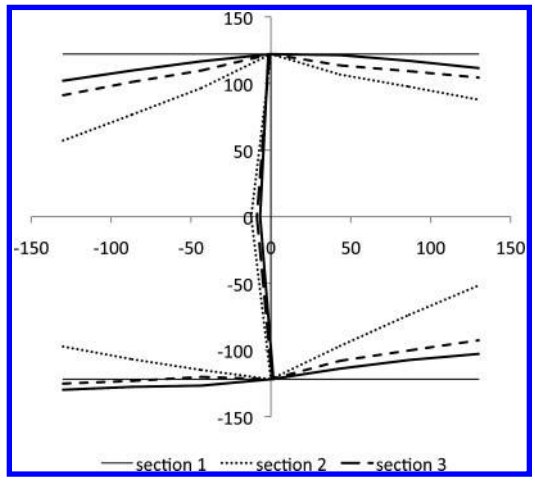

Figure 2. Measured geometrical imperfection (amplified by 20) for 3 sections (section 1: front, section 2: mid-length, section 3: back) along the profile length.

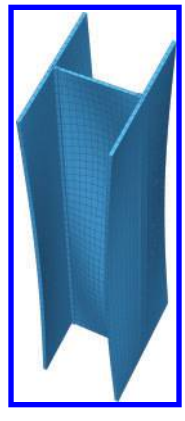

Figure 3. Local geometrical imperfection shape introduced in the FE model.

bloc distribution of the longitudinal residual stresses is considered in the FE model, as shown in Figure 4. The magnitude is assumed to be the yield strength at the junction of the flange and web, the rest of the distribution is calculated on the basis of the principle of autoequilibrium in the profile cross-sections.

3.5 *Comparison of numerical and experimental*

In Figure 5, the results of the linear elastic analysis, the Materially Nonlinear Analysis (MNA), and the Geometrically and Materially Nonlinear Analysis (GMNIA) with or without local geometrical imperfection and residual stresses respectively are provided together with the test results for the specimen A24-2.

It can be seen that the load-displacement curves coincide in the elastic range indicating that the FE model has the same stiffness as the tested specimen. This proves the effectiveness of the representation of the welded area.

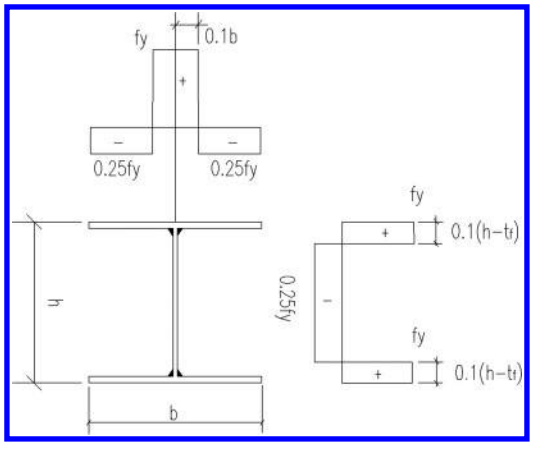

Figure 4. Assumed residual stress distribution and amplitude in the FE model.

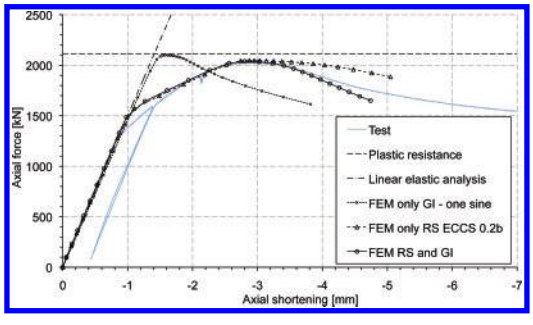

Figure 5. Finite element analysis of specimen A24-2.

Also, it can be noted that the residual stresses influence the axial stiffness by making the curve departs from linearity at an earlier point (the curve labeled with white triangle represents the model without local geometrical imperfection).

The plate geometric imperfections and residual welding stresses have a significant influence on the ultimate load. For the two tests, good agreement has been achieved between the numerical and experimental results (Table 1).

4 PARAMETRIC ANALYSIS

The parametric study firstly examines H profiles geometries taken from European, British and American catalogues. In total, 157 geometries covering IPE, HE, HD, HL, HP, W and UB profiles and made of three grades (235 MPa, 355 Pa and 460 MPa) have been considered resulting in 471 FE models. The FE model is similar to the one discussed in the previous paragraphs but with the following distinctions: (1) The cross-section dimensions are taken as the nominal ones (CEN 2005b); (2) The young's modulus E equals 210000 $N/mm2$and the yield strength $fy$is the nominal one. Second, the section geometries were changed by decreasing the thickness of the flange and web to

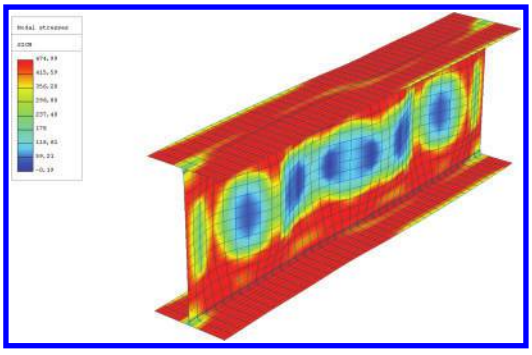

Figure 6. Failure mode: HE600A with a web thickness of 6 mm instead of 12 mm. The flanges remain straight and parallel to each other.

50% of their values in the catalogue resulting in a total additional number of simulations of 715. The range of cross-sections studied involves compact sections and slender sections (in the sense of Eurocode 3). It is extremely improbable that designers would select sections for which the web is thicker than the flange plates; a few of such sections are nevertheless included in the present analysis. This constitutes a first step into a more comprehensive parametric analysis to be performed in the future.

Looking at the results, it can be seen that different failure modes were tackled. Either the full plastic resistance was attained (yielding of the whole crosssection) or local buckling prevents the development of it. In this case, either the buckling mode involves rotation of the flange – in opposite directions by the same amount – about the line of the flange-web junction sometimes followed by post-buckling reserve, or, in sections with strong flanges, the local buckling develops in the web and the flanges remain parallel to each other (very little deformation). Loading in the post-buckling domain results in the attainment of the ultimate load with a significant post buckling reserve.

4.1 *Assessment of current design guidance*

The results of the simulations have been compared to the resistances predicted by the Eurocode 3 using the EWM. The usual plate slenderness limit ratios and approximation of critical stress assuming simple support conditions in Eurocode 3 provide reliable predictions: the codified-to-numerical predictions yield an average of 1.03 and coefficient of variation (CoV) of 0.06.

Nowadays, numerical advanced calculation of the elastic cross-section buckling stress is possible using software such as CUFSM or THIN-WALL for example. Herein, the expressions of $k$for hot-rolled H sections under pure compression suggested in Seif & Schafer (2010) was used to calculate the elastic local buckling stress and the cross-section slenderness for the geometries for which the normalized dimension $(h/tw) \times (2tf/b)$ ranges from 1.8 to 10.94 (the range for which the empirical expressions of the local plate

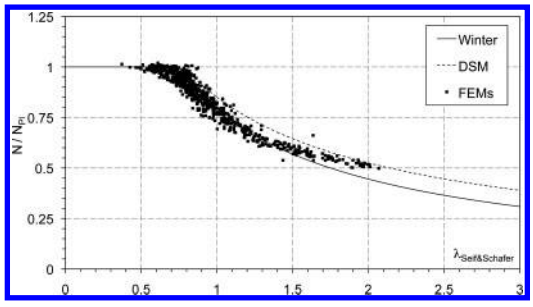

Figure 7. FEMs and DSM predictions versus Seif & Shafer (2010) slenderness.

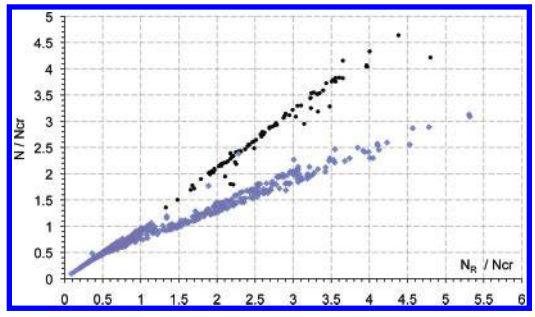

Figure 8. FEMs predictions versus predictions obtained using equations (1) (normalized by the critical load).

buckling coefficient k was developed). Even though it is not used as intended, the DSM equations NAS (2007b) were used to evaluate the strength using the (Schafer & Seif 2010) slenderness. It yields relatively good predictions as well, with an average of 1.05 and CoV of 0.06. For this range of geometries, the numerical failure loads normalized by the yield load Npl are depicted in Figure 7 together with the current DSM predictions. A comparison of the numerical loads with those computed using Winter's effective width formulas is also presented.

In this analysis, sections presenting very thick flanges are also included. When the web is much more slender than the flange, the DSM approach is overly conservative. For example, the following cross-section $460 \times 191 \times 4.95 \times 16$ with slender web and strong flanges is characterized by a normalized dimension $(h/tw) \times (2tf/b)$ of about 15 and has a strength equal to $0.87 \times$ NPl. Whereas, the section $450 \times 304 \times 7.6 \times 5.4$ (of approximately the same slenderness if calculated with Schafer & Seif expressions) has a strength equal to $0.52 \times$ NPl. For these geometries i.e. for which the normalized dimension ranges from 10.94 to 23.41, the elastic critical stress evaluated using Seif & Schafer (2010) expression is always underestimated. The elastic cross-section buckling stress was thus recalculated using the software CUFSM. In these cases, there exists a substantial post local buckling reserve after the web buckling leading to yielding in the flanges, with little flange deformation. As expected, the current DSM predictions are overly conservative (DSM-to-numerical predictions average = 0.75; CoV = 0.16).

In fact, for the whole range of sections corresponding to $(h/tw) \times (2tf/b)$ greater than 10.94, it is advised to evaluate the cross-section strength using:

$$N_R = 2bt_f f_y + h_{clear} t_w \sigma_{cr}, \quad (1)$$

where σ_{cr} is the elastic critical local buckling stress related to the web,

$$\sigma_{cr} = k \frac{\pi^2 E}{12\left(1-\nu^2\right)} \left(\frac{t_w}{h_{clear}}\right)^2, \quad (2)$$

and h_{clear} = the clear web height, E is Young's modulus of elasticity, ν is Poisson's ratio, and k is the local plate buckling coefficient, which accounts for the boundary conditions and loading (for this case, k is assumed to be equal to 4.0 i.e. simply supported compressed inner element). The numerical resistance versus the resistance obtained with equations (1) for this range of sections (strong flanges, bisector of the first quadrant angle, $(h/tw) \times (2tf/b) > 10.94$) together with the other group of sections ($1.8 < (h/tw) \times (2tf/b) < 10.94$) is depicted in Figure 8.

5 CONCLUSIONS

In this paper, a geometrically and materially nonlinear analysis using the FE method has been conducted to evaluate the resistance of axially compressed welded H profile cross-sections. The FE model was firstly verified against experimental data and then used to carry a first parametric analysis. Commercialized geometries covering IPE, HE, HD, HL, HP, W and UB profiles and made of three grades (235MPa, 355MPa and 460MPa) are considered. Then, the flange and web thicknesses are varied. The numerical results are then compared to Eurocode 3 predictions and predictions using the Direct Strength method established for cold-formed thin walled profiles. The application of the DSM equations in conjunction with Seif & Schafer (2010) expressions of the slenderness to predict the resistance is seen to be appropriate for sections with normalized dimension $(h/tw) \times (2tf/b)$ ranging from 1.8 to 10.94. For sections with strong flanges characterized by local buckling of the web (little deformation of the flanges) and yielding of the flanges in the post local domain, another approach seems to be required. In these cases, preliminary conclusions show that the strength can be predicted by adding the flange plastic resistance and the web critical elastic resistance, which is basically the concept underlying the Eurocode 3 EWM method.

On the strength of T-section columns

F. Sena Cardoso & K.J.R. Rasmussen
School of Civil Engineering, The University of Sydney, Sydney, Australia

ABSTRACT: The paper concerns hot-rolled T-section members and their failure behaviour under concentrically applied load. The paper first calibrates an accurate shell element Finite Element Model (FEM) against tests on steel T-section columns, and subsequently uses the model to determine the strength of several series of T-sections covering a wide range of cross-section geometries and column lengths. The paper then compares the numerical strengths obtained and test strengths with strength predictions by the Australian and European specifications for hot-rolled and fabricated steel structures, and suggests more accurate design approaches than those currently available.

1 INTRODUCTION

Despite the fact that T-sections are readily available commercially and can be easily obtained by cutting standard I-sections through the middle of the web, the failure behaviour of these members when subjected to a compressive force is still not fully understood as corroborated by the numerous different design approaches in various national specifications for steel structures.

Several features of T-sections contribute to a non-standard buckling and post-buckling behaviour and partly explain the non-existence of a uniform design methodology for T-section members.

T-sections feature negligible warping constants (I_w) derived only from secondary warping and small torsion constants (J), the combination of which leads to a weak resistance to torsion. Consequently, the failure mode commonly involves torsion.

On buckling behaviour, T-section columns are singly symmetric and hence, critical overall buckling modes are the flexural buckling mode in the plane of symmetry and the flexural-torsional buckling mode (coupled flexural about the symmetry axis and torsion about the shear centre).

Furthermore, when the flange and web elements are equal in width and thickness, the local buckling mode is essentially the same as the torsional buckling mode. Conversely, when the thickness of the flanges and web differ or for very slender component plates, the local buckling mode may involve plate flexure.

Because of the resemblance between the torsion and local buckling modes, care needs to be taken when designing T-section (or angles or cruciform section) columns in order to avoid taking into account the torsional/local buckling mode twice in strength predictions.

On the post-buckling behaviour, slender T-sections axially loaded are affected by the stress redistribution associated with local buckling, which leads to a shift of the effective centroid and induces bending when the column is loaded between pinned ends.

Both the buckling and post-buckling behaviour of a T-section column under compression are discussed in detail in (Sena Cardoso and Rasmussen, 2013).

2 FINITE ELEMENT MODEL (FEM) AND PARAMETRIC STUDY

2.1 *The model*

Because of the limited number of experimental tests available on T-section columns, a FEM was calibrated using available test data and subsequently used to perform a comprehensive parametric study of the strength of a wide range of T-section geometries. In all cases, the column was assumed to be pinned at the ends with respect to both principal axes and loaded through the geometric centroid.

The general purpose commercial finite element package ABAQUS was used for the finite element simulations. It is generally accepted that shell-element-based inelastic large displacement analysis can accurately predict the behaviour and ultimate capacity of structures undergoing local instability provided geometric imperfections and residual stresses are incorporated in the analysis (Bakker and Peköz, 2003, Sarawit et al., 2003). Thus, and considering the remarks made by Schafer (Schafer et al., 2010), T-section columns were modelled using S8R shell-elements. This type of element is available from the ABAQUS library and consists of an 8-node doubly curved thick shell with reduced integration. It employs quadratic shape functions and assigns six degrees of freedom per node. The default Simpson's rule was used considering five integration points through the thickness of the element and assuming a homogeneous cross-section. The mesh

Figure 1. Finite Element Model of a T-section column, a) undeformed shape and b) deformed shape of first buckling mode.

had no elements with width-to-thickness ratios greater than four.

To materialize the prescribed boundary conditions, two rigid plates were attached to each end of the T-section column and a reference point axially coincident with the geometric centroid of the T-section was assigned to each rigid plate. At one reference point, the three translational and the twisting degrees of freedom where fully restrained while at the other reference point, the two transverse translational and the twisting degrees of freedom were fully restrained.

Additionally, the described setup does not prevent secondary warping and thus the warping degree of freedom is deemed unrestrained at both ends. At the axially unrestrained end, a point load is applied at the reference point in order to simulate a concentric compression load. An example of the developed FEM is shown in Figure 1.

As for the hot-rolled steel material, the stress-strain curve was chosen as elastic-perfectly plastic being defined by Young's modulus (E) and yield stress (f_y). The following sections details how both residual stresses and geometric imperfections were incorporated in the FEM.

2.2 *Calibration*

The FEM was calibrated by comparing the results of (i) elastic buckling analyses to the global buckling loads and modes obtained from classical theory and (ii) ultimate strength analyses with the test strengths reported in (Kitipornchai and Lee, 1986).

Three cross-sections were tested by Kitipornchai and Lee. The sections were obtained by cutting three I-sections lengthwise through the centre of the web so as to produce two T-sections for each length of I-section, resulting in a total of six T-section specimens. The cross-section dimensions and column lengths are shown in (Kitipornchai and Lee, 1986). The measured values of Young's modulus and yield stress were 214 GPa and 300 MPa respectively.

Elastic buckling analyses were performed on the tested columns ignoring geometric imperfections and residual stresses. The first two buckling modes and loads obtained using ABAQUS were compared with the ones obtained from classical theory, showing that the FEM predicts the 1st and 2nd buckling loads to within 2.6% and 1.6% error, respectively. This degree of accuracy was deemed acceptable.

The residual stresses incorporated in the non-linear inelastic analyses were based on the ECCS I-section model (ECCS, 1976) where in this study the peak residual stress (σ_r) was taken as $0.3f_y$. When the I-section model is applied to a T-section, a non-zero moment results which causes bending in the plane of symmetry and a change in residual stress pattern, see (Sena Cardoso and Rasmussen, 2013) for details. These effects were included in the numerical model.

Imperfections were also included for deflections in the direction perpendicular to the web and twist rotations. These imperfections were incorporated by scaling the flexural-torsional buckling mode obtained from a linear buckling analysis by scaling factors of L/2000, L/1750 and L/1500. The resulting ultimate loads are compared with the experimental ultimate loads in (Sena Cardoso and Rasmussen, 2013).

Overall, it was concluded that the best agreement was obtained for a scale factor of L/2000. However, the ultimate loads are not strongly dependent on the magnitude of flexural-torsional imperfection and to comply with Bjorhovde's survey, which found that the mean minor axis geometric imperfection of rolled I-sections is L/1470 (Bjorhovde, 1972), the scale factor of L/1500 was chosen for generating imperfections in the shape of the flexural-torsional buckling mode in the parametric study. These were in addition to the residual stresses and associated imperfections in the plane of symmetry mentioned above.

2.3 *Parametric study – Methodology*

Two series of parametric studies were conducted, referred to as the N- and M-series. In the N-series, three generic cross-sections were selected to cover a wide range of geometries by changing the widths of the flange and web elements and assuming the same thickness for both flange and web, whereby $k_2 = T_w/T = 1$. Two cross-sections were chosen so that H/B=2 ($k_1 \cong 4$) and 1/4 ($k_1 \cong 0.5$), where B and H are the total flange width and the web width, respectively. The third section was chosen such that $I_x = I_y$, which implied equal flexural buckling stresses for buckling about the x- and y-axes. For each cross-section, four values of thickness were selected so as to obtain the values of the ratio N_Y/N_T ($I_w = 0$) of 0.5, 1.0, 1.5 and 2.0, where N_Y is the squash capacity ($A.f_y$) of the section and N_T ($I_w = 0$) is the torsional buckling load ignoring secondary warping.

For each cross-section, in order to determine the column strength curve, a minimum of five lengths were selected corresponding to normalised flexural slenderness values of $\lambda_e = 0.25$, 0.50, 1.00, 2.00 and 4.00, where the normalised flexural slenderness is given by:

$$\lambda_e = \max\left\{\sqrt{\frac{N_Y}{N_{Fx}}}, \sqrt{\frac{N_Y}{N_{Fy}}}\right\} \quad (1)$$

For some cross-sections, additional short lengths were chosen in order to determine the column strength

curve when plotted against the normalised global slenderness (λ_r) given by,

$$\lambda_r = \max\left\{\sqrt{\frac{N_Y}{N_{Fx}}}, \sqrt{\frac{N_Y}{N_{FT}}}\right\} \quad (2)$$

The M-series T-sections were chosen as one half of a selection of common Australian hot-rolled I-sections (OneSteel, 2011). Five cross-sections were chosen and modelled by ignoring the rounded transition between the web and flange elements. The column lengths for each cross-section were chosen in a similar manner as for the N-series T-sections. The cross-section geometry, column lengths, geometric properties, elastic buckling loads, column slenderness values and key ratios are shown in (Sena Cardoso and Rasmussen, 2013) for the Series N and M T-section columns.

For all Series N and M models, the assumed values of Young's modulus (E) and yield stress (f_y) were 210 GPa and 355 MPa respectively.

2.4 *Parametric study – Results*

Two separate numerical analyses were performed using ABAQUS for each of the aforementioned T-section columns, namely:

1 An elastic eigenvalue buckling analysis that provided the deformed shape of the flexural-torsional mode for implementing the geometric imperfection in this mode in the subsequent non-linear analysis.
2 A geometric and material non-linear failure analysis that used the modified Riks method including the effects of geometric imperfections and residual stresses. (The modified Riks method employs, in each step, proportional loading, solving simultaneously for both loads and displacements. ABAQUS uses the arc length along the static equilibrium path in the load-displacement space to measure the progress of the solution. (Simulia, 2011)).

The ultimate load (N_u) and the prominent mode of failure observed for each specimen are presented in (Sena Cardoso and Rasmussen, 2013).

3 DESIGN PROVISIONS

3.1 *General*

This section compares strength predictions obtained using the provisions of the Australian Standard AS4100 (AS4100, 1998) and Eurocode3 Part 1.1 (EN1993-1-1, 2005) with the ultimate strength data obtained from the parametric study described in Section 2.4 and experiments by Kitipornchai and Lee (Kitipornchai and Lee, 1986). The design approaches adapted in the two specifications are substantially different as will be highlighted in the following sections, which also propose improvements to existing provisions.

The two main difficulties encountered in formulating design provisions for T-sections are:

1 The cross-section deformations of the local and torsional buckling modes are similar, albeit the corresponding half-wavelengths may be different, as discussed in (Sena Cardoso and Rasmussen, 2013) and hence, strength predictions are conservative if both modes are accounted for through effective area and flexural-torsional buckling calculations.
2 When ignoring secondary warping ($I_w = 0$), as is customary in design, the critical buckling stress becomes the pure torsional buckling stress ($\sigma_{cr,T}$) in the limit $L \to 0$, implying a non-zero column slenderness of $\lambda_r = \sqrt{\sigma_y/\sigma_{cr,T}} \neq 0$. As a result, the design stress is less than the yield stress (σ_y) in the limit $L \to 0$. This is in contrast to designing for flexural buckling where $\sigma_{cr,Fx} \to \infty$ in the limit $L \to 0$, so that $\lambda_r = \sqrt{\sigma_y/\sigma_{cr,Fx}} \to 0$ and the design stress becomes the yield stress as required.

The abovementioned design specifications present different approaches to addressing these difficulties, or not.

3.2 *AS4100*

According to the Australian Specification for steel structures (AS4100, 1998), the strength of a concentrically loaded column is given by

$$N_c = \alpha_c \cdot A_e \cdot f_y \quad (3)$$

where α_c, A_e and f_y represent the geometric slenderness reduction factor, the effective area of the cross-section and the nominal yield stress, respectively.

The first variable (α_c) reflects the effect of flexural buckling on the member capacity as well as the distribution and magnitudes of the residual stresses for standard Australian sections. This parameter is function of the *flexural* geometric slenderness ratio (L/r), yield stress and section type. The second variable (A_e) is obtained by incorporating the effect of local buckling through the effective width methodology in determining the net area.

The ratios (N_u/N_c) between the experimental or numerical ultimate strengths and the AS4100 predictions are presented in (Sena Cardoso and Rasmussen, 2013), including the statistics of the same ratio. The mean value and CoV of the ratio are 1.12 and 0.170, respectively, while the minimum and maximum values of the ratio are 0.73 and 1.67, respectively. This implies a generally conservative design approach with a relative small scatter, except for a few particularly slender cross-sections with seriously low ultimate strengths. Sorted statistics for non-slender ($A_e/A = 1$) and slender ($A_e/A < 1$) sections were also presented in (Sena Cardoso and Rasmussen, 2013) from which followed that the AS4100 procedure is slightly more accurate for non-slender than slender sections. The fourth set of statistics exclude slenderness values (λ_e) less than 0.15. Since the mean and CoV are nearly unchanged from the statistics including all slenderness values,

1.08 and 0.153 respectively, it follows that the AS4100 procedure works equally well for columns of short and intermediate to long lengths.

Using the 4th set of statistics (excluding columns with $\lambda_e < 0.15$) and denoting the mean and CoV of the N_u/N_c-ratio by P_m and V_P, respectively, in conjunction with the LRFD framework for the dead and live load combination, the resistance factor is calculated as $\varphi = 0.88$ using,

$$\phi = 1.48\, M_m F_m P_m\, e^{-\beta_0 \sqrt{V_M^2 + V_F^2 + V_P^2 + V_G^2}} \tag{4}$$

where values of $M_m = 1.1$, $V_M = 0.1$, $F_m = 1.0$, $V_F = 0.05$, are assumed (Ellingwood et al., 1980). Equation (4) is derived on the basis of the load combination $G = \gamma_D D_n + \gamma_L L_n$ using $\gamma_D = 1.2$ and $\gamma_L = 1.6$ as per the ASCE-7 Standard (ASCE, 2010) and assuming a ratio (D_n/L_n) of nominal dead to nominal live load of 1/3. Using $V_D = 0.1$ and $V_L = 0.25$, the CoV of the load effect is obtained as $V_G = 0.19$. Consistent with the calibration of the AISC-360 Specification, the target reliability index is chosen as $\beta_0 = 2.6$.

The calculated value of resistance factor ($\varphi = 0.88$) is close to the value of 0.9 prescribed in AS4100.

3.3 *Eurocode 3*

According to Eurocode 3, Part 1.1 (EN1993-1-1, 2005), the nominal strength of a concentrically loaded column is given by,

$$N_{b,Rk} = \chi\, A_{eff}\, f_y \tag{5}$$

where χ, A_{eff} and f_y represent the geometric slenderness reduction factor, the effective area of the cross-section and the nominal yield stress, respectively. The reduction factor χ depends on the non-dimensional slenderness $\bar{\lambda}$ defined by,

$$\bar{\lambda} = \sqrt{\frac{A_{eff} \cdot f_y}{N_{cr}}} \tag{6}$$

where N_{cr} is the critical elastic buckling load, taken as the lower of the flexural (N_{Fx}) and flexural-torsional (N_{FT}) elastic buckling loads. In this study, the flexural-torsional buckling load (N_{FT}) has been determined using classical Timoshenko theory with I_w taken as zero. EN1993-1.1 specifies column curve 'c' for both the flexural and flexural-torsional buckling strength calculations of T-sections.

For slender cross-sections, EN1993-1.1 requires calculation of the effective centroid and the eccentricity between the effective and gross section centroids. In singly and non-symmetric cross-sections, the eccentricity causes overall bending in the plane of symmetry and accordingly, EN1993-1.1 requires the column to be designed as a beam-column. This approach is in contrast to AS4100, which does not require this effect to be considered. To enable a direct comparison between the column strength predictions of the various specifications, the effect of the shift of the effective centroid in slender T-sections is ignored in this paper.

The ratios ($N_u/N_{b,Rk}$) between the experimental or numerical strengths to the EN1993-1.1 strength predictions are again shown in (Sena Cardoso and Rasmussen, 2013). The mean and CoV of the ratio are 1.60 and 0.400, respectively, suggesting a very conservative design approach of poor accuracy. When considering only slender cross-sections, the mean and CoV change slightly to 1.62 and 0.403, respectively, suggesting that the design approach is conservative and of poor accuracy for both slender and stocky cross-sections.

The main reason for the conservative prediction of design strengths is that EN1993-1.1 accounts for both torsional buckling (in the calculation of N_{FT}) and local buckling (in the A_{eff} calculation), and as such, notwithstanding that the buckling half-wavelengths of the two modes may be different, accounts for the same mode twice. The conservatism is brought out by the fact that in calculating the flexural-torsional buckling strength, in the limit $L \to 0$, the buckling load equals the torsional buckling load ($N_T = GJ/(Ar_o^2)$) so that $\bar{\lambda}_{FT} \to \sqrt{A_{eff} f_y / N_T} \neq 0$ and consequently, $\chi_{FT} < 1$ rather than $\chi_{FT} = 1$ for $L \to 0$. When determining the column strength using equation 5, the section capacity $A_{eff} f_y$ is then unnecessarily further reduced by the factor $\chi_{FT} < 1$.

The conservatism of the Eurocode3 approach is particularly pronounced for short columns and the high $N_u/N_{b,Rk}$-ratios at short lengths contribute substantially to the high CoV. When excluding columns with slenderness $\lambda_e < 0.15$, the mean and CoV of the $N_u/N_{b,Rk}$-ratio reduce to 1.38 and 0.226 respectively. Based on these values for P_m and V_P, the resistance factor is calculated as $\varphi = 0.93$.

3.4 *Modified Eurocode 3 Approach ($N_{C,Rd} = A.f_y.\chi(\lambda_r)$)*

The main issue in improving the Eurocode design approach is to resolve the double consideration of the torsional/local buckling mode in the strength prediction, as discussed in Section 3.3. This may be achieved by ignoring flexural-torsional buckling in determining the member buckling load, as in the AS4100 approach, or by using the gross area rather than the effective area. Motivated by the plots of normalised strength (N_u/N_y) against slenderness shown in Figs 2a and 2b, the latter approach is here selected. As shown in Fig 2, when the normalised strength is plotted against the "global" slenderness (λ_r), which is defined by equation (2) and considers both flexural and flexural-torsional buckling, the strengths are grouped in a much narrower band than when plotted against the flexural slenderness (λ_e) defined by equation (1), suggesting that a more direct design approach may be achieved by employing the global slenderness. This implies the consideration of the flexural-torsional buckling load in determining the design strength, in which case the

area is taken as the gross area rather than the effective area, i.e.

$$N_{b,Rk} = \chi(\lambda_r)\, A\, f_y \tag{7}$$

Comparisons also show that a more accurate design procedure can be achieved using the b-curve rather than the c-curve as currently specified for T-sections in Eurocode3. The resulting strength predictions are shown in (Sena Cardoso and Rasmussen, 2013) for the cases where secondary warping is ignored ($I_w = 0$) and considered ($I_w > 0$), respectively. When secondary warping is ignored, the mean and CoV of the ratio between the experimental or numerical strength to the modified EN1993-1.1 strength prediction (N_u/N_{Rd}) are 1.36 and 0.353. These statistics compared to the mean and CoV of 1.60 and 0.400 obtained using the existing provisions. Excluding the results for short lengths ($\lambda_e < 0.15$), the mean and CoV improve to 1.20 and 0.205 respectively, leading to a resistance factor of $\varphi = 0.89$.

If secondary warping is taken account of, the mean and CoV of all columns are 1.15 and 0.132 respectively, indicating a relatively conservative procedure with a small scatter. The mean and CoV change slightly to 1.14 and 0.141 when the results for short lengths ($\lambda_e < 0.15$) are excluded, suggesting that the proposed procedure is consistent in terms of length. The resistance factor calculated on the basis of the latter statistics is $\varphi = 0.94$.

3.5 *Discussion*

As shown in (Sena Cardoso and Rasmussen, 2013), AS4100 is mainly optimistic for slender cross-sections in the short flexural slenderness range ($\lambda_e \in [0.25,0.5]$) where the design strength exceeds the ultimate strength by 20% or more. This result is attributed to the effect of bending induced by the shift of the effective centroid which is not considered in the design guidelines of the AS4100 Specification.

The provisions of AS4100 are generally satisfactory for T-section columns except when the web is slender and the column is pinned about the x-axis (the axis perpendicular to the plane of symmetry). It is suggested that such columns should be required to be designed as beam-columns when the A_e/A ratio is less than 0.8. This requirement is not necessary when the columns are fixed against rotations about the x-axis at the two ends, since local buckling does not induce overall bending in this case (Rasmussen and Hancock, 1994).

The statistics of the current and proposed modified design procedures of AS4100 and EN1993-1.1 are summarised in Table 1. The statistics exclude short columns (λ_e) and are based on design predictions that ignore secondary warping. It follows from the Table that comparable levels of accuracy and (P_m and V_P) and reliability (φ) are achieved using the current rules of AS4100 and the proposed modified rules

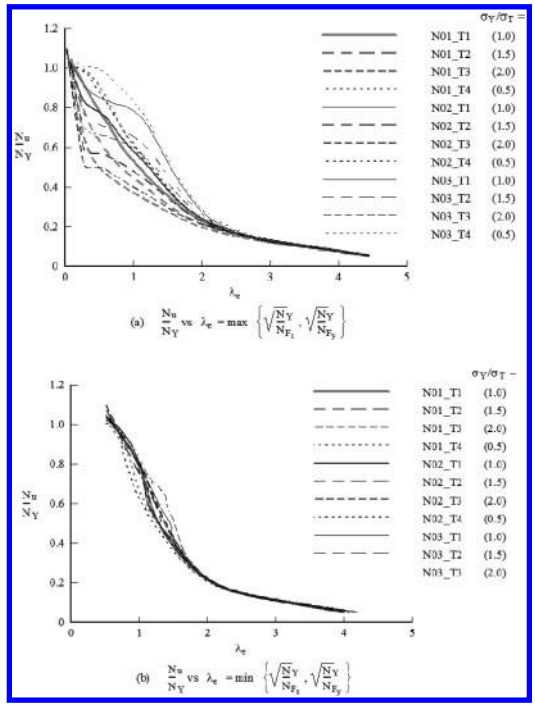

Figure 2. Relationship between the non-dimensional failure stress/yielding stress and: a) the normalised flexural slenderness (λ_e), b) the normalised global slenderness (λ_r). Note: In calculating λ_r, the flexural-torsional buckling load includes secondary warping rigidity by determining I_w.

Table 1. Statistics of current and modified versions of AS4100 (AS) and EN1993-1.1 (EC) specifications excluding short columns ($\lambda_e < 0.15$); P is the ratio of ultimate strength to design strength, P_m and V_P are the mean and CoV of the same ratio.

	Current procedure					Proposed modified procedure				
	P_m	V_P	φ	λ	A	P_m	V_P	φ	λ	A
AS	1.08	0.15	0.88	λ_e^*	A_e	–	–	–	–	–
EC	1.38	0.26	0.93	$\lambda_r^\#$	A_e	1.20	0.21	0.89	λ_r	A

* λ_e defined by equation (1), (flexure only)
\# λ_r defined by equation (2).

of the EN1993-1.1 Specification. The accuracy deteriorates considerably if short columns are included in the statistics and secondary warping is ignored. While the accuracy can be greatly improved for short columns by including secondary warping, it is considered appropriate to maintain $I_w = 0$ in the proposed modified design approaches for simplicity. A note could be added to the proposed modified design procedures to the effect that when designing short T-section columns, say $\lambda_e < 0.2$, the designer should consider to include secondary warping when determining the flexural-torsional buckling load.

4 CONCLUSIONS

A study of the strength of hot-rolled steel T-section columns has been presented. The study was motivated by the fact that the torsional and local buckling modes are similar for this cross-section, whereby design strength predictions may be conservative if accounting for both modes. The focus of the study is on columns compressed between pinned ends.

Numerically obtained ultimate strength data is compared with predictions obtained using the Australian and European specifications for hot-rolled steel structures. It is shown that the Australian Standard (AS4100) is reliable except for pin-ended columns with slender webs, for which the design strength may be seriously optimistic because of the effect of the shift of the effective centroid. It is proposed that pin-ended T-section columns shall be required to be designed as beam-columns when the A_e/A-ratio is less than 0.8, as determined using AS4100. However, this requirement is not necessary for fixed-ended columns.

The European (EN1993-1.1) code is shown to be excessively conservative because (i) it considers both flexural-torsional buckling and local buckling in the strength calculation, and (ii) the column slenderness for flexural-torsional buckling does not approach to zero for short lengths as in the design for flexural buckling. The paper proposes a modification to EN1993-1.1, allowing (i) the area to be taken as the full area (A) irrespective of cross-section slenderness and (ii) the b-curve to be used rather than the c-curve currently specified. It is shown that adequate reliability is achieved using this approach without considering bending arising from the shift of the effective centroid, which is required to be accounted for in the current version of the code.

The proposed rules for the European specification are shown to have comparable reliability to those of the current version of the Australian standard. This is remarkable seeing that the design approaches of the two specifications are completely different. The study shows that T-section columns with slender cross-sections are not required to be designed as beam-columns to account for the effect of the shift of the effective centroid, except for the Australian standard when the A_e/A-ratio is less than 0.8.

ABSTRACT: This paper reports the results of an analytical, numerical and experimental investigation dealing with I-section steel members acted by a combination of major-axis bending and axial tension ("beams subjected to tension"), which is relatively rare in practice and, therefore, has received little attention in the literature. In particular, almost no guidelines for the design against buckling ultimate limit states may be found. As a consequence, the axial tension favorable effect on lateral-torsional failure is usually neglected, leading to over-conservative designs. In order to acquire scientific knowledge and to provide design guidance on this topic, the lateral-torsional stability, failure and design of hot-rolled steel I-beams with fork-type end supports and acted by in-plane transverse loadings combined with various axial tension values are addressed here. A modified analytical expression to calculate the critical bending moments of beams under uniform bending and axial tension is first presented. Then, two full-scale tests involving a narrow and a wide flange beam under eccentric tension are described and their results are used to develop finite element models, subsequently employed to perform a parametric study aimed at gathering a fairly extensive ultimate strength database. These reference results are used to assess the merits of a design approach which consists of slightly modifying the current procedure prescribed in Eurocode 3. It is shown to provide accurate predictions that correlate very well with the values obtained from the numerical simulations.

1 INTRODUCTION

Over the past decades, many research efforts have been devoted to "stability-related" topics within structural steel. As an example, Boissonnade et al. 2006 summarizes the most recent development on the behavior and design of steel beam-columns within Europe. However, quite surprisingly, virtually no information can currently be found concerning the structural response and design of I-section members subjected to major-axis bending and *tension* (i.e., beams under tension), namely on how the presence of tension affects (improves) the beam lateral-torsional buckling behavior.

Very little references indeed exist on this topic; the rather complete literature search carried out by the authors only resulted in one document, namely the Eurocode 3 "ENV" pre-normative design rules – yet not providing any background information on the proposed rules. Of course, part of the explanation for the "information void" on this problem is due to the fact that (i) beams under tension occur seldom in practice and (ii) neglecting the tension effects leads to conservative ultimate strength estimates regarding lateral-torsional failure modes, where the member is checked as a "pure beam".

The objective of this paper is precisely to contribute to such an investigation, by bridging the lack of scientific information and technical guidance concerning the lateral-torsional stability, behavior and design of beams under tension. It deals specifically with hot-rolled steel I-section beams exhibiting "fork-type" end supports and subjected to simple in-plane loading (e.g., applied end moments or uniformly distributed loads), and which are not affected by local buckling phenomena – beams with compact cross-sections that can reach their plastic resistance (class 1 "plastic" or 2 "slender" according to Eurocode 3 nomenclature).

Following section 2 first characterizes the lateral torsional stability and behavior of members under major-axis bending and tension. In particular, two full-scale experimental tests are described, as well as the development of shell FE models and their assessment against the experimental results. Section 2

Figure 1. Beam subjected to major-axis bending M_y and axial tension N_t.

also details consecutive numerical parametric studies where more than 2000 GMNIA reference results have been gathered.

Then, section 3 describes a new design approach for beams under tension and assesses its merits in comparison with the values obtained from the numerical simulations. The ability of the proposed rules to yield safe and accurate estimates of the carrying capacity of such members is clearly demonstrated, as well as the quite significant positive influence of tension on lateral torsional buckling – potentially leading to interesting material savings.

2 BEHAVIOR OF BEAMS SUBJECTED TO TENSION

2.1 *Lateral Torsional Stability*

This section addresses the influence of tension on the lateral-torsional stability behavior of simply supported ("fork-type" supports), doubly-symmetric I-section beams subjected to major-axis bending M_y and axial tension N_t (see Figure 1). The objective is to assess how the presence of an axial tension N_t increases the critical buckling moment M_{cr}. Obviously, it is assumed that N_t is such that the beam cross-section resistance is not reached prior to the occurrence of instability, *i.e.*, the beam collapse is not exclusively due to plasticity effects.

Following well-known analytical derivations presented in classical monographs (see for example Chen & Atsuta 1977 or Trahair 1993), adapted to ensure adjacent equilibrium for members subjected to constant major-axis bending and axial tension, it is possible to obtain the following expression:

$$M_{cr}(N_t) = \sqrt{\left(1+\frac{N_t}{P_{cr,z}}\right)\times\left(1+\frac{N_t}{P_{cr,f}}\right)}\times M_{cr}(0) \qquad (1)$$

which provides the critical buckling moment of a member subjected to bending and tension. In this expression, M_{cr} (0) denotes the critical buckling moment of the member under uniform bending only and $P_{cr.z}$ and$P_{cr.\phi}$ correspond to the minor-axis flexural and torsion buckling loads of the "pure column", respectively.

In order to assess the proposed expression, a series of corresponding ABAQUS beam finite element analyses (BFEA) have been conducted, which revealed a perfect agreement with analytical values (cf. Tomás 2013); further validation was contemplated through numerical investigations covering beams built from

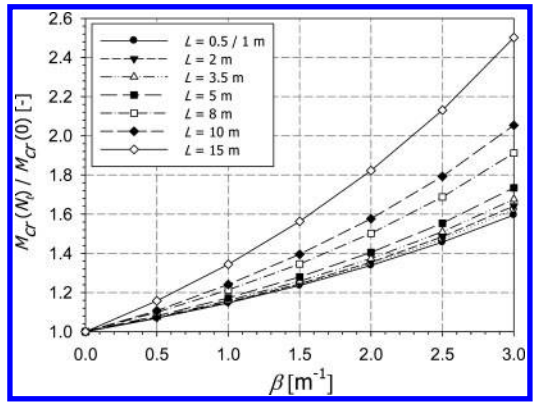

Figure 2. Evolution of M_{cr} $(N_t)/M_{cr}$ (0) with β for 0.5 m $\leq L \leq$ 15 m IPE300 beams, $\psi = 0$.

four hot-rolled profiles (IPE300, IPE500, HEB300, HEB500), with lengths comprised between 0.5 and 25 m, and subjected to various loading situations (linear bending moments characterized by end moment ratios $\psi = 1$; 0.5; 0; -0.5, -1 or a uniformly distributed load applied at the shear center level), and acted by N_t values such that $\beta = N_t/M_y = 0$; 0.5; 0.75; 1.0; 1.5; 2.0 (bending and axial load being applied proportionally).

Figure 2 shows a representative example of the obtained results, and the following comments may be made:

(i) Naturally, the critical moment increase always grows with β, *i.e.*, the amount of tension acting on the beam. Note that, eventually, the M_{cr} $(N_t)/M_{cr}$ (0) *vs.* β curves would tend to infinity as β approaches the "limit tension value" which is such that no section is acted by compressive stresses anymore;

(ii) Obviously, the importance of the tension effects grows with the beam length, as the beam becomes more prone to lateral-torsional instability;

(iii) Moreover, it possible to assess how the beneficial tension effects vary with the bending moment diagram shape. The key factor is the shape of the axial force diagram acting on the whole beam compression flange, combining the constant tensile value N_t with varying compressive values due to the bending moments. It is observed that this combination leads to tension effects that are highest for the $\psi = 0$ triangular diagram ("least compressed" compression flange) and lowest for the $\psi = 1$ uniform diagram ("most compressed" compressed flange).

2.2 *Ultimate Strength – Experimental Investigation*

This paragraph investigates the ultimate strength of beams under tension, and first describes two full-scale experimental tests performed to acquire in-depth knowledge about the problem under consideration and

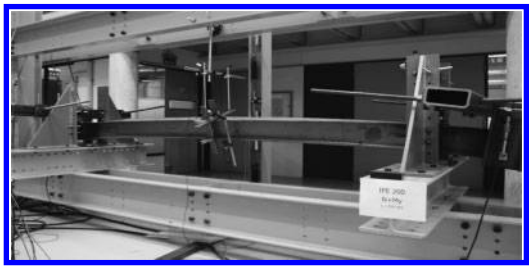

Figure 3. Overall view of the experimental set-up and deformed configuration at the brink of collapse for the IPE200.

to provide the means to develop and validate beam and shell finite element models.

Figure 3 provides an overall picture of the experimental set-up; it shows an $L = 4.00$ m beam submitted to eccentrically-applied tension at both ends, by means of rigid lever arms and 4 of hydraulic jacks. The (reduced) test program involved an IPE200 beam loaded with a 0.25 m N_t eccentricity, and a HEA160 beam loaded with a 0.5 m eccentricity.

Prior to the performance of each test, usual preliminary measurements have been carried out: tensile tests, residual stresses measurements and initial geometrical imperfections determination (both local and global). These were done with particular care, in order to use the measured information in shell FE models for validation purposes; detailed information can be found in Tomás 2013. Combinations of load or displacement-controlled increments have been set up to collapse, and suitable sets of LVDTs and inclinometers were used to record the behavior of the member at mid-span and at the end sections.

2.3 *Ultimate Strength – Numerical Investigations*

The experimental results were then employed to calibrate and validate a shell finite element model able to handle a realistic comparison with the experimental tests, including all measured properties (material, imperfections) and actual test configuration.

This was done using the non-linear finite FEM software FINELg; the experimental set-up was entirely modeled with fine meshes of 4-node shell elements (Kirchhoff's theory in bending), thus ensuring that the beam "real" end support conditions and "surroundings" were adequately simulated.

The results obtained during the performance of each test consisted of (i) experimental evidence concerning the occurrence of lateral-torsional buckling in beams acted by tension, (ii) equilibrium paths relating the applied load with various measured displacements and/or rotations and (iii) experimental failure loads: 269.2 kN (IPE200) and 150.0 kN (HEA160).

The numerical and experimental ultimate moments were found to correlate quite well: the numerical simulations either underestimate by 6% (IPE200 specimen) or overestimate by 2% (HEA160 specimen) the experimental values. Figure 4 also shows the IPE200 specimen deformed configuration at collapse, provided by

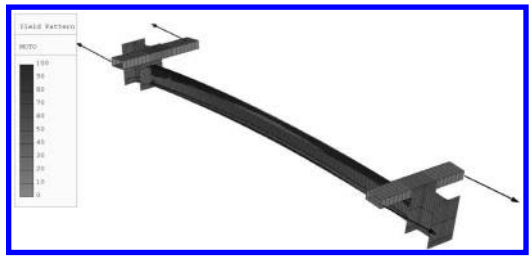

Figure 4. FE deformed shape and extent of yielding at peak load (IPE200 specimen).

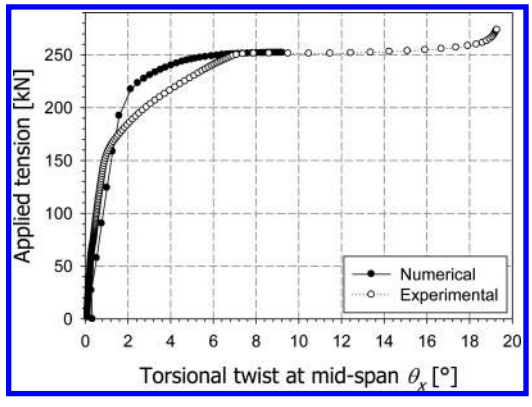

Figure 5. Test vs. FE model comparison (IPE200 specimen).

the FINELg analysis – note the qualitative and quantitative similarity with its experimental counterpart, shown in Figure 3.

Finally, Figure 5 compares the experimental equilibrium paths relating the applied load at the end section and mid-span torsional twist θ_x with the corresponding numerical simulations, where a visible perfect coincidence is observed in the elastic regime, beyond which the numerical model is a bit stiffer and, therefore, underestimates the θ_x values.

On the basis of the comparisons between the test results obtained and the corresponding numerical simulations, most of which were not presented here and can be found in Tomás 2013, it seems fair to conclude that the shell FE model developed provides reasonably accurate results and, thus, can be adequately used to validate the finite element model employed to perform the parametric study addressed in the next section.

2.4 *Parametric study*

The now-validated finite element model has been employed to perform about 2000 Geometrically and Materially Non-linear with Imperfections Analyses (GMNIA) of beams under tension. They comprised beams exhibiting several slenderness values, stemming from (i) 8 span lengths (between 0.5 and 25 m), (ii) two yield stresses ($f_y = 355$; 460 N/mm^2 – the steel material behavior modeled corresponds to the usual elastic-perfectly plastic constitutively with a marginal strain-hardening occurring for very large

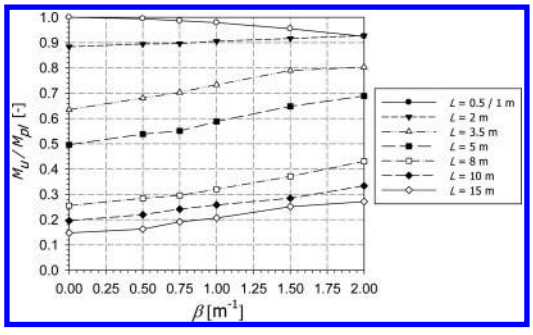

Figure 6. M_u/M_{pl} vs. β as a function of member length (S460 grade, IPE300 and $\psi = 1$).

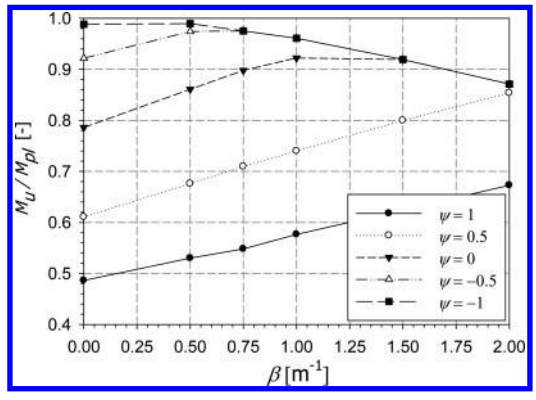

Figure 7. M_u/M_{pl} vs. β as a function of bending moment distribution (S355 grade, HEB300 and $L = 15$ m).

strains) and (iii) four cross-section shapes (IPE300, IPE500, HEB300, HEB500). The members were subjected to (i) five bending moment diagrams ($\psi = 1$; 0.5; 0; -0.5; -1) and (ii) six tension levels, corresponding to $\beta = N_t/M_y$ ratios equal to 0; 0.5; 0.75; 1.0; 1.5; 2.0. The non-linear analyses were performed with FINELg and the members were discretized into standard 3D beam finite elements based on Vlasov's theory for open-section thin-walled members. The numerical models also contained longitudinal normal residual stresses with a parabolic pattern as well as global sinusoidal initial geometrical imperfections that combine minor-axis flexure and torsion – shapes and values were adopted as proposed by Boissonnade & Somja 2012.

A detailed analysis of the results yields the following conclusions:

(i) First of all, as expected, the presence of axial tension is completely different in the stocky and slender beams, in the sense that their collapse is governed by either plasticity or instability effects, respectively. In the former, axial tension leads to an ultimate moment decrease, stemming exclusively from the drop in cross-section resistance; in the latter, axial tension leads to a ultimate moment increase, which grows with β and stems from the improved lateral-torsional buckling resistance;

(ii) The comparison between the M_u/M_{pl} vs. β curves (Figure 7) concerning the (ii$_1$) $L = 8$; 10; 15 m and (ii$_2$) $L = 3.5$; 5 m beams show different trends, even if all these curves have positive slopes throughout the whole β range considered. While in the former M_u/M_{pl} grows with β at an always increasing rate, which becomes percentage-wise more relevant as L increases, the latter exhibit points of inflexion at a given β value that seems to increase with L. These different trends reflect the contradicting influence of axial tension on the lateral-torsional buckling and cross-sectional resistances: the latter becomes progressively more relevant as β increases and L decreases. This assertion is fully confirmed by looking at the M_u / M_{pl} vs. β curve concerning the $L = 2$ m beam, which exhibits very little growth and ends up merging with their $L = 0.5$; 1.0 m beam counterparts for $\beta = 2.0$ – it would start decrease for larger β values, whenever collapse would start being governed by plasticity in the beam mid-span region;

(iii) Then, the influence of the bending moment diagram shape on the axial tension benefit, as shown in Figure 8 for the $L = 15$ m, S355 HEB300 beams, demonstrate that only the $\psi = 1$ and $\psi = 0.5$ curves (i.e., those leading to more relevant lateral-torsional buckling effects) are not limited by the descending curve associated to the mid-span cross-section full yielding up to $\beta = 2.0$. Indeed, the $\psi = 0$ and $\psi = -0.5$ curves merge into this curve at lower β values and following an "almost horizontal" segment. Finally the $\psi = -1$ curve decreases monotonically with ψ, meaning that the beam collapse is always governed by the mid-span cross-section resistance;

(iv) Quantitatively speaking, the highest M_u percentage increases due to the presence of axial tension occurs for the beams acted by the $\psi = 0.5$ bending moment diagram – they are slightly larger than their $\psi = 0$ and $\psi = 1$ diagram counterparts.

Finally, Figure 8 clearly shows the double influence of an increasing N_t, moving the M_u / M_{pl} vs. λ_{LT} plots (i) to the left (lateral-torsional slenderness decrease) and (ii) upwards (ultimate moment increase). Moreover, it can also be observed in this figure that the whole set of points, corresponding to various beams and β values (including $\beta = 0$), remain nicely "aligned" along a "design-like" curve. The design approach for beams subjected to tension that is proposed in the next section takes advantage of this feature.

3 PROPOSED DESIGN APPROACH

The current Eurocode 3 methodology stipulates that the ultimate moment of (compact) beams subjected to axial tension is the least of two values: (i) the cross-section reduced plastic moment and (ii) the beam bending resistance against a failure stemming from

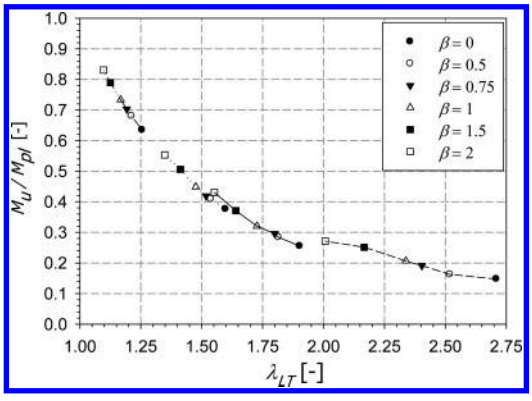

Figure 8. Variation of Mu / Mpl with the beam slenderness λ_{LT}.

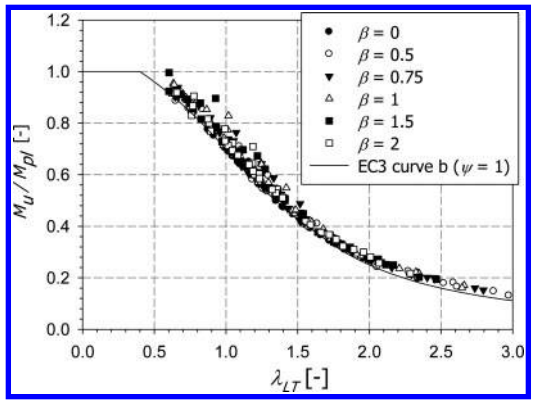

Figure 9. Comparison between the $M_{u,FE}$ / M_{pl} (points) and $M_{u,proposal}$ / M_{pl} (curve) for $\psi = 0$.

lateral-torsional buckling. While the former is determined through classical strength of materials concepts, the latter is obtained by means of a procedure based on the use of "beam strength curves". This procedure involves the following steps (Eurocode 3 nomenclature is adopted):

(i) Determine the beam lateral-torsional slenderness $\lambda_{LT} = (M_{pl}/M_{cr})^{0.5}$, where M_{pl} is the cross-section plastic moment (bending resistance) and M_{cr} is the beam critical buckling moment;
(ii) On the basis of λ_{LT}, use the appropriate buckling curve to obtain the reduction factor χ_{LT};
(iii) Further modify (increase) the reduction factor obtained in the previous step, by means of coefficient $\chi_{LT,mod} = \chi_{LT} / f$, where $f \leq 1.0$ is a parameter that aims at increasing the design resistance of the beam for non-constant bending moment diagrams, thanks to inelastic effects;
(iv) Evaluate the beam ultimate bending resistance against from lateral-torsional buckling failure $M_u = \chi_{LT,mod} \times M_{pl}$.

The proposed design approach consists of incorporating the axial tension beneficial effects into the critical buckling moment used to determine the beam slenderness, while keeping all the remaining steps unchanged – in particular, M_{pl} remains the cross-section pure bending resistance (i.e., does not account for the presence of axial tension). In other words, $M_{cr} \equiv M_{cr}$ (0) is replaced by M_{cr} (N_t), where N_t is the acting axial tension, which implies a λ_{LT} decrease and, therefore, larger $\chi_{LT,mod}$ and M_u values. It shall be noted that the calculation of M_{cr} (N_t) must be done by means of a numerical beam buckling analysis (e.g., using beam finite elements) – in the future, the authors plan to develop analytical expressions and/or other design aids that will render the performance of this task easier and more straightforward.

The assessment of the quality of the proposed design rules has been based on the results of the numerical simulations partially reported in Figure 9 – again, the full set of results can be found in Tomás 2013. It should be clarified here that the comparison between the proposed rules and the FE reference results that follows excludes members whose failure mode correspond to cross-sectional resistance, i.e., beams not collapsing in lateral-torsional modes, as the proposed design approach only concern the latter.

Table 1. Averages, standard deviations and maximum/minimum value of the ratio R_M.

	Aveg.	St.Dev.	Max.	Min.	Nb. results
$\beta = 0$	1.03	0.04	1.14	0.92	188
$\beta = 0.5$	1.04	0.03	1.13	0.93	172
$\beta = 0.75$	1.05	0.03	1.16	0.95	160
$\beta = 1$	1.06	0.03	1.20	0.97	149
$\beta = 1.5$	1.05	0.04	1.21	0.92	119
$\beta = 2$	1.05	0.03	1.21	0.98	91

Figure 9 concerns the various members analyzed under bending moment diagrams defined by $\psi = 1$ and compares the numerical ultimate moments with their predictions provided by the proposed design approach – use of Eurocode 3 buckling curve b with a lateral-torsional slenderness modified through the inclusion of the critical buckling dependence on N_t. Figure 9 appeals the following comments:

(i) It is impossible not to notice the remarkable agreement between $M_{u,FE}$ and $M_{u,proposal}$, both results being almost aligned;
(ii) Table 1 provides the detailed statistical values of the ratio $R_M = M_{u,FE}/M_{u,proposal}$ corresponding to Figure 9 results and for various N_t values. These indicators reflect the excellent quality of the ultimate moment estimates, the vast majority of them being safe and extremely accurate.

In order to better evidence the beneficial influence of axial tension on the beam ultimate strength, Table 2 provides the averages, standard deviations and maximum/minimum percentage values of the ultimate moment increase ΔM_u due to axial tension with respect to beam ultimate moments. It is observed that all the above generally increase with β, except for the

Table 2. Averages, standard deviations and maximum/minimum values of ΔM_u.

	Avg.	St. Dev.	Max.	Min.	Nb. FE
$\beta = 0.5$	14.7%	8.9%	43%	0.01%	172
$\beta = 0.75$	24.5%	14.3%	64%	0.01%	160
$\beta = 1$	34.0%	19.3%	91%	0.02%	149
$\beta = 1.5$	53.7%	30.4%	135%	0.01%	119
$\beta = 2$	79.9%	46.4%	202%	0.01%	91

minimum value that remains constant and very small, as it always corresponds to a slenderness located very close to the end of the design curve plateau.

4 CONCLUSIONS

This paper reported the results of an analytical, numerical and experimental investigation on the lateral-torsional stability, failure and design of hot-rolled steel I-section beams with fork-type end supports and acted by simple in-plane loadings and various axial tension values. Initially, the derivation and validation of an analytical expression providing critical buckling moments of uniformly bent beams subjected to tension was presented. Then, this analytical finding was followed by a numerical study on the beneficial influence of axial tension on beams under non-uniform bending, namely caused by unequal applied end moments or a uniformly distributed load – several beam finite element results were presented and discussed in detail.

Next, the paper addressed the performance of two experimental tests, carried out at the University of Applied Sciences of Western Switzerland – Fribourg and aimed at determining the behavior and ultimate strength of a narrow and a wide flange beam subjected to eccentric axial tension. These results were also used to validate FINELg beam and shell finite element models that were subsequently employed to perform an extensive parametric study that (i) involved more than 2000 numerical simulations, concerning beams with various cross-section shapes, lengths, yield stresses, acting bending moment diagrams and axial tension levels, and (ii) was aimed at gathering a fairly large ultimate strength/moment database.

These data were then used to assess the merits of a design approach proposed for beams subjected to tension and collapsing in lateral-torsional modes – this design approach consists of slightly modifying the current procedure prescribed in Eurocode 3 through the incorporation of the axial tension influence in a modified critical buckling moment.

The ultimate moment estimates provided by the proposed design approach were shown to correlate extremely well with the values obtained from the numerical simulations, thus making it a very promising candidate for inclusion in a future version of Eurocode 3. Last, the paper closed with a quick assessment of the beneficial influence of axial tension on the ultimate moment of beams failing in lateral-torsional modes; as expected, it was found that this influence can be quite significant and, thus, neglecting it (as is currently done in practically all steel structures codes) will certainly lead to over-conservative designs.

Lateral torsional buckling behavior of members in steel structures with hanging-profile connections

Dasu Liu & Jörg Lange
Technical University Darmstadt, Darmstadt, Germany

ABSTRACT: The "hanging profile" is a commonly used type of joint in steel structures for horizontal bracing systems in large building projects, where huge compression forces are transferred. This kind of joint is characterized by the connection of a bracing beam to gusset plates only at the top flanges. This type of structures is usually simplified as a single-span beam with so-called fork bearings at ends. The present study using finite-element-methods to investigate structures with "hanging profiles" in 3d modeling showed partially unexpected but interesting results. According to this study this simplification is not generally valid because the individual shapes of the gusset plates as well as the distortional effects of beams and gusset plates at end supports are not taken into account.

1 INTRODUCTION

In large building projects, such as power plants (e.g. Medupi and Kusile in South Africa), the "hanging-profile" is very commonly used joint type for horizontal bracing systems. As illustrated in Figure 1 only top flanges of the bracing beam are connected to the gusset plates. This brings a significant advantage to the onsite assembly since the member is in vertical direction only restraint at only one height and the bolt hole clearance of 2 mm each side of the member should cover the possible erection imperfections.

Due to the eccentric load transfer a constant offset bending moment with an eccentricity of the half beam height is caused in addition to the axial force (see Figure 2 left). This type of structures is usually designed and verified as single-span member with so-called end fork bearings (see Figure 2 right), which strictly restraints the in plane cross section deformations.

Since the cross section deformation in connection areas and the twisting of the gusset plates are not taken into account under the fork bearing assumption, this assumption cannot reflect the reality correctly. Therefore the idealization of the support situation as fork bearing is incorrect and not justified. Due to the overestimation of the system stiffness in connection areas basic engineering with this conventional approach is considered generally not safe.

Being aware of this problem, however being lack of other satisfying approach the designers in practice have no choice but calculate conservatively to avoid high utilization. The reserve in the verification should hopefully compensate the unsafe assumption.

This study attempts to shed light on the calculation of this type of structures and develop a new and improved design method derived from Euro Code for lateral torsional buckling verification of here discussed cases.

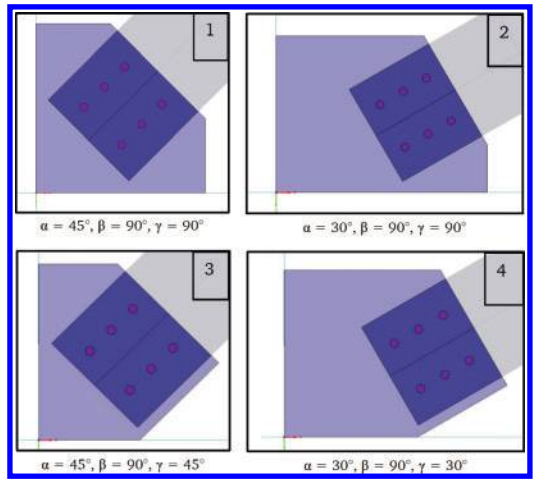

Figure 4. 4 general cases of gusset plate geometry with corresponding angle combinations (top view).

2 FINITE ELEMENT ANALYSIS

A geometrically und materially nonlinear analysis was conducted using FEM-program ANSYS Workbench to evaluate the resistance of structures with hanging profile connections. A 3-D large numeric model has been developed to represent the real properties of the aforementioned static system as close as possible. Special attention was paid to the correct representation of the interaction between the major joint components as well as the initial geometric imperfections and residual stresses. The details of this model are provided in the subsequent sections.

2.1 *Simplified gusset plate form and boundary conditions*

Depending on the geometric relation between bracing members and main beams as well as the load transfer situation, the form of the gusset plates can be very diversified and complex. To facilitate the parametric study the form of the gusset plates has been divided into 4 general cases, which are distinguished from each other by the angles α, β und γ (see Figure 3 and Figure 4).

The dimensions e_{min} and u were uniformly set to 3 cm and 2.5 cm for the whole parametric analysis. These are common dimensions for this kind of connections in Germen steel construction.

The gusset plates were assumed restraint in translation perpendicular to their plate plane at the boundary welded to the main beam web and at the boundary where the vertical stiffener (meant to prevent local plate buckling, see Figure 1) was placed. This is because the vertical stiffener has much higher in-plane bending stiffness compared to the out-of-plane bending stiffness of the gusset plate, so that the vertical displacement of the gusset plate along the stiffener can be ignored. These two boundaries were also restraint in their longitudinal translation directions. However the in-plane translation perpendicular to these boundaries was considered not restraint, since the support in this direction by the main beam web was due to its slenderness negligible.

2.2 *Model discretization*

In order to study the interaction between the major connection components, especially the load transfer through the bolts, volume elements were employed to discretize the model. The SOLID 186 element in ANSYS Workbench, a general purposed volume element with 20 notes and reduced integration to form the element stiffness, was used to simulate the beam, the gusset plates and the bolts.

Particular attention was paid to the web-to-flange curve area to correctly represent the cross-section torsional stiffness as well as the elastic fixing of web and flanges in this area. This was crucial to the simulation since the lateral torsional buckling was the typical failure type and the cross-section torsional stiffness had huge influence on the lateral torsional buckling behavior.

The bolts were simplified as three composited cylinder bodies with 2 mm hole clearance. Since the bolts were mainly subject to shear loads, it was essential to choose the correct diameter depending on if the shear plane passes through the threaded or the unthreaded portion of the bolt. In the conducted parametric analysis the shear planes always pass through the threaded portion of the bolt, so the tensile stress areas of the bolts were adopted in the modeling. 50% of the full preload was applied to the bolts, as this is standard in practical execution for not mainly tensile loaded bolts made of steel grade 10.9.

The interactions between all 3-D bodies, such as beam to gusset plate, bolt to beam, bolt to gusset plate and bolt shank to holes, were defined as surface-to-surface contact, where only compression forces can

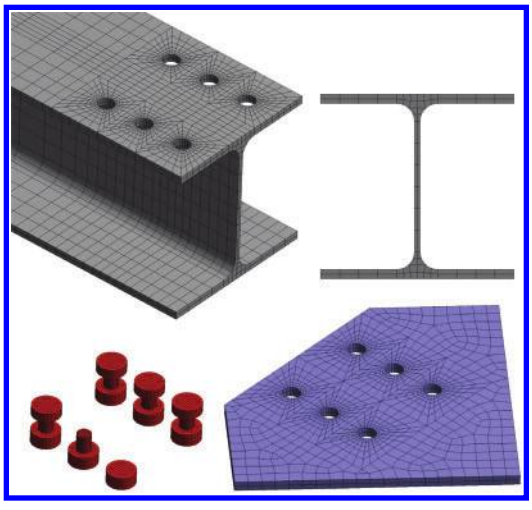

Figure 5. Model discretization: top left: beam; top right: cross-section; bottom left: bolts; bottom right: gusset plate.

be transferred. A friction coefficient of 0.2 was also adopted. This not only reflected the realistic steel to steel friction but also increased the numeric stability during the FE calculations.

2.3 *Geometric and structural imperfections*

The system imperfections were incorporated separately as geometric initial deformation and residual stress. As suggested in Annex C.5 in DIN EN 1993-1-5 (2010), the lowest buckling mode shape, which was in this case lateral torsional buckling (see Figure 6), was used for the geometric imperfection. This first buckling mode was scaled to a magnitude of 80% of the production tolerance (cf. DIN EN 10034 1993) also according to the aforementioned standard. For instance the scale for hot-rolled cross-section HEA260 was L/833, where L is the system length.

Structural imperfections are comprised of residual stresses and scatter of the yield limit over the cross-section. Since the distribution of yield limit is difficult to determine and there is no concrete general assumption, only residual stresses were adopted in the model.

As suggested by Wolf (2006), a linear distribution of the longitudinal residual stresses, which was adopted in ECCS-CECM-EKS (1984), was considered in the FE model. Compared to a parabolic distribution a linear distribution is more conservative, since there is no resultant tensile force built in each flange. A very important rule to the residual stresses is that the resultant force over the cross-section has to be zero, as the residual stresses are only internal stresses. However, the suggested distribution as shown in Figure 7 left is based the center lines of the profile. Because of the web-to-flange area this distribution has to be modified to avoid resultant tensile force over the cross-section. The modified distribution is depicted in Figure 7 right.

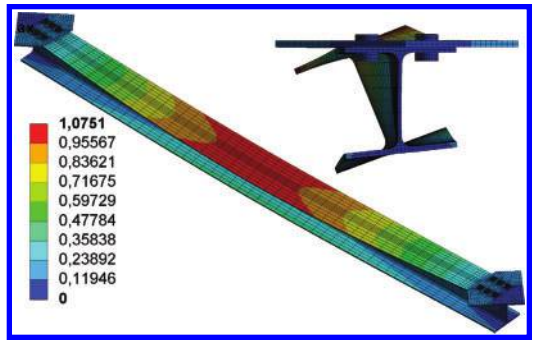

Figure 6. First system buckling mode: lateral torsional buckling (depicted only half of the model).

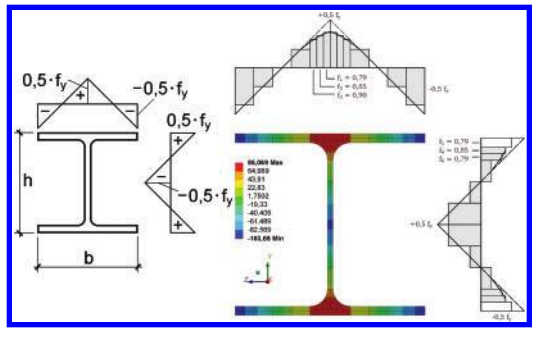

Figure 7. Residual stress distribution.

2.4 *Material properties and loading*

The adopted material model for the analyzed steel grade S235 was a perfectly elastic-plastic model without material hardening. Due to the possible large strain of the bolts true stress-strain curve instead of engineer stress-strain was adopted for the 10.9 grade bolts. The bolt material data were obtained from the tensile coupon tests by González (2011).

Systems with gusset plate angle combination $\alpha = 45°$, $\beta = 90°$ and $\gamma = 90°$ (see Figure 3) are symmetrical, while systems with other angle combinations are asymmetrical. To minimize the time consume of the FE calculations of symmetrical systems only half of the model was simulated and loaded with an imposed deformation at the plane of symmetry. The corresponding force was obtained from the bearing force at the support. For asymmetric systems however the loads were applied conventionally as external forces along the gusset plate boundaries.

2.5 *Parametric analysis*

A parametric analysis was conducted for hot-rolled HEA profile cross-sections with varied system lengths and different gusset plate forms. The results are presented in the subsequent sections.

The study aimed to analyze the stability behaviors of eccentrically compressed beam with hanging-profile connections, so it had to be assured that the connection

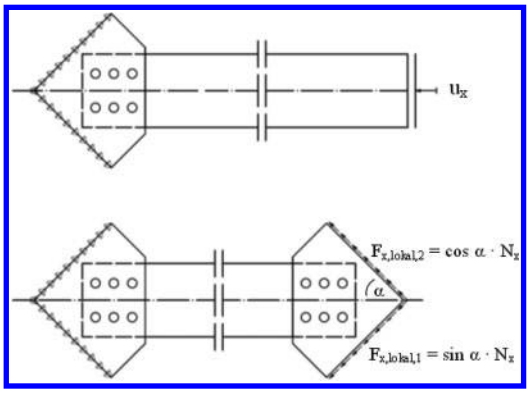

Figure 8. Loading for symmetric model as imposed deformation (top) and for asymmetric model as forces (bottom).

carrying capacities, such as shear- and bearing capacities of bolts, extended the member buckling load. In other words, the bolts and the gusset plates must over designed so that the system failed in form of lateral torsional buckling. The gusset plates were chosen at 5 mm steps and always thicker as the beam flange, which is also a common approach in practice.

The comparison models with endplates or full stiffeners at the beam ends were also analyzed to evaluate the influence of beam stiffening in connection areas on the system ultimate loads.

3 FE RESULTS

This section presents part of the results of the parametric analysis exemplarily on the hot-rolled HEA 260 profile cross-section with over designed 6 M24 bolts on each end of the beam as discussed in the previous paragraph. For each simulation the resistance was also calculated using the equivalent member method (further abbreviated as EMM) according to DIN EN 1993-1-1 (2010) bases on the assumption of single-span members with fork bearings. The partial safety factors were included in neither FE modeling nor calculation with EMM.

3.1 *Development of stress distribution and deformation on the critical cross-section*

The critical cross-section for the analyzed systems was located in the middle of the beam, where the cross-section lost its stiffness first with increasing external loads and so the system reached its labile status.

Figure 9 shows the development of equivalent stress (von Mises stress) and deformation on the critical cross-section with increasing load ranged from 428 kN to the ultimate load 741 kN on example of 5 m long HEA 260 profile with gusset plate geometry $\alpha = 45°$, $\beta = 90°$, $\gamma = 90°$ and thickness 20 mm (further abbreviated as 45° −90° −90° −20). It can be seen that the cross-section displacement grew proportionally to the cross-section area subjected to yield strength. After

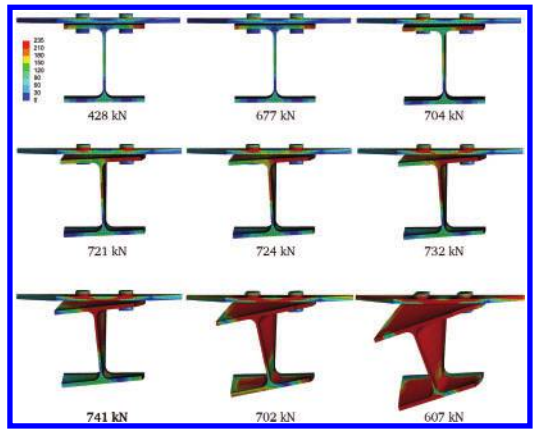

Figure 9. Development of equivalent stress distribution and deformation on critical cross-section.

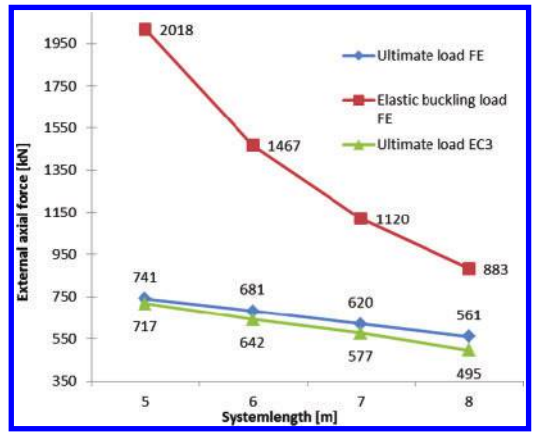

Figure 10. Ultimate loads comparison (HEA 260 S235 45° −90° −90° −20).

the system ultimate load was reached the cross-section continued to deform with further spread plastic area, while the external loads decreased.

3.2 *Length influence*

The numerical failure loads and elastic buckling loads compared with the results according to EMM are depicted in Figure 10. All three ultimate loads dropped with increased system length, which was plausible and expected. However, it was noticed that the FE ultimate loads were unexpectedly even higher than the failure loads according to EMM, despite of the fact that torsionally elastic boundary conditions are considered to be rigid (fork bearing) in EMM.

The higher ultimate loads of FE modeling are attributed to the fact that the beams are elastically fixed on the gusset plates through 3 lines of bolt each side and the gusset plates are also elastically fixed on the main beam and vertical stiffeners by the relatively long welds. These elastic fixings act favorably on the ultimate loads because a system with fixed end supports

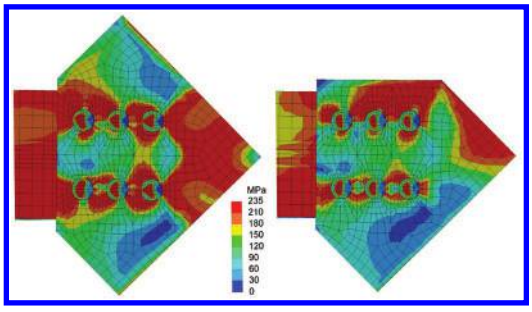

Figure 11. Geomery and equivalent stress distribution of gusset plates 45°–90° −90° (left) and 45° −90° −45° (right) (topview).

Table 1. Ultimate loads of systems with different gusset plate geometries (HEA 260 5 m S235).

Gusset plate geometry	Utimate load FE kN	Ultimate load EC3 kN
45° −90° −90°	741	717
45° −90° −45°	634	717

has a lower buckling length, which leads to a higher buckling load. This effect was so dominant that the incorrect assumed torsionally rigid end supports were fully compensated.

3.3 *Influence of gusset plate geometry*

It seems that in the cases presented in the last section the simplified design according to EMM suggested in EC3 is providing reliable predictions, since the system ultimate loads are underestimated. However, the results presented below will draw a different conclusion.

The result of a comparison simulation of the same HEA 260 profile and same bolts but with differ angle combination of gusset plate 45° −90° −45° −20 (see Figure 11) is shown in Table 1. Now the FE failure load is lower than the calculated ultimate load according to EMM and much lower compared with the FE result of gusset plate 45° −90° −90° . From the equivalent stress distribution (Figure 11) can be observed that due to the shorter boundary of gusset plate 45° −90° −45° the plastic stress spread over the entire short boundary, which cost highly percentual stiffness lost for the gusset plate. This led further to reduction of the system stiffness and consequently to lower ultimate load. On the contrary the yield area of gusset plate 45° −90° −90° concentrated mainly on the corner, thus the system stiffness were much less compromised.

3.4 *Beam stiffening*

Two alternatives were studied to evaluate the influence of beam stiffening on the system ultimate load.

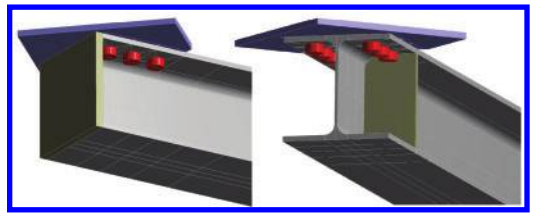

Figure 12. Beam stiffening with end plate (left) or full stiffener (right).

Table 2. Comparison between different stiffening alternatives.

Beam stiffening	Elastic buckling load FE kN	Ultimate load FE kN
End plate	2217	879
Full stiffener	2076	753
Without	2018	741

End plates and full stiffeners (see Figure 12) are common practical elements adopted in the steel construction for beam stiffening. These two kinds of stiffeners can be used to stiffen the cross-section in connection areas to prevent cross-section deformation.

Table 2 indicates that the end plates can increase the system ultimate load much more efficiently. This is due to the fact that end plates can not only prevent cross-section deformation but also act as a warp spring, which also increase the buckling load intensely.

4 CONCLUSIONS

This paper presented the results of the early stage of a research on the lateral torsional buckling behavior of members in steel structures with hanging-profile connections. A parametric study was conducted with nonlinear finite-element-models in ANSYS Workbench. The results of the analysis were compared with the Eurocode 3 predictions. It showed that the common design in practice based on the assumption single-span members with fork bearings was insufficient and not satisfying, since it provides sometimes overly conservative yet sometimes overestimated results. Therefore more detailed theoretical and experimental study is needed for this issue.

5 OUTLOOK

In the undergoing research the following points are being investigated. Firstly a test program will be carried out to verify the FE models. On the basis of the verified FE model, further parametric analysis will be performed to generate additional data covering a wider range of hot-rolled cross-section and more gusset plate geometries. In the meantime the formulized

elastic system buckling load considering the torsional stiffness of cross-section and gusset plate as well as the aforementioned elastic end fixing as springs is being studied. Ultimately a new and improved design method derived from Euro Code will be developed for lateral torsional buckling verification of here discussed cases.

Design bearing stresses for injection bolts with short and long duration high loads

A.M. (Nol) Gresnigt
Delft University of Technology, The Netherlands

D. (Darko) Beg
University of Ljubljana, Faculty of Civil and Geodetic Engineering, Slovenia

ABSTRACT: The present design bearing stress for injection bolts is based on long duration creep tests. Recent research has shown that for short duration loads higher design bearing stresses can be allowed. This is especially important for structures where the main load consists of short duration loads e.g. wind load, such as the new glass roof in the Amsterdam Central Railway Station. A summary is given of the results of recent monotonic and cyclic short duration testing in the University of Ljubljana and Delft, as well as a recommendation and motivation to modify the present rules in Eurocode 3 and EN1090-2.

1 INTRODUCTION

The present recommended design bearing stresses for injection bolts are based on long duration creep tests. The criterion is that the displacement is not larger than 0.30 mm. This is the same criterion as for high strength friction grip bolts.

Injection bolts however, have the advantage that in case of overloading no sudden large displacements occur as may happen in connections with high strength friction grip bolts when they slip.

In the European Recommendations for Bolted Connections with Injection Bolts (ECCS, 1994) the design bearing stress as determined in long duration testing is used for the serviceability limit state verification. For the ultimate limit state a higher bearing stress is given (factor 1.2), motivated by the above mentioned advantage of injection bolts. The factor 1.2 was chosen by engineering judgment; virtually no test results were available. It was expected that the chosen values would be sufficient to avoid that the ultimate limit state would govern the design. The Eurocode 3 rules are formulated somewhat different, but are practically the same.

In recent applications of injection bolts, such as a new glass roof in Amsterdam Central Railway Station, it appeared that the short duration loads in the glass supporting steel structures due to wind may be much more than anticipated when the ECCS recommendations were drafted.

It was asked whether it would be possible to allow much higher bearing stresses for short duration loadings. To answer this question the results of research performed in the University of Ljubljana could gratefully be used. In addition to that, short duration tests were performed in the Stevin Laboratory of Delft University of Technology. The test results together with test results from the research in Ljubljana were sufficient to allow much higher bearing stresses for the glass roof in Amsterdam.

In this publication the main results are summarized and a recommendation is given for a modification to the present design rules in the Eurocode 3.

2 INJECTION BOLTS

Injection bolts are bolts in which the cavity produced by the clearance between the bolt and the wall of the hole is completely filled up with a two component resin. Filling of the clearance of an injection bolt is carried out through a small hole in the head of the bolt. After injection and full curing of the resin, the connection is slip resistant. Shear load is transferred through bearing and shear of the bolt.

Injection bolts can be manufactured from normal standard structural bolts. The bolts and washers are adapted to enable the injection of the resin. As compared to other mechanical fasteners, injection

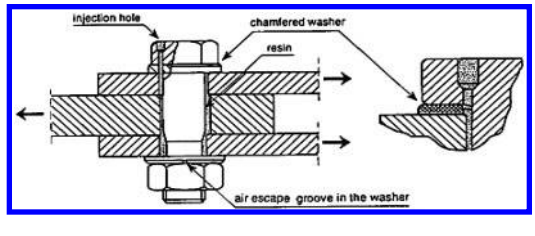

Figure 1. Injection bolt in a double lap joint.

bolts have several advantages. Injection bolts may be applied in new structures and in existing structures for repair and strengthening.

Design rules are given in the ECCS Recommendations (ECCS, 1994). These were the starting document for the sections on injection bolts in Eurocode 3 Part 1-8 (EN 1993-1-8, 2005). Rules for testing the resin and execution can be found in EN 1090-2 (EN 1090-2, 2008).

Resins are susceptible to creep deformation if the bearing stress is too high. In the Fourth International Workshop on Connections in Steel Structures in 2000 (Gresnigt et al., 2000), test results from long duration testing were presented on the two component epoxy resin Araldit SW 404 with HY2404 hardener, now available as RenGel SW 404 + Ren HY 2404.

The main conclusions are:

a. Injection bolts are an excellent alternative for replacing faulty rivets in (old) riveted structures.
b. Injection bolts can successfully be used for strengthening of (old) structures, especially where welding or HSFG bolting is difficult to apply.
c. Long duration creep tests were still going on at a bearing stress of 250 N/mm^2 without exceeding the allowable displacement.
d. A high temperature of 70°C as may occur in bridges has only a moderate influence on the deformations. The average creep for ambient temperature (20°C) is 0,19 mm and for 70°C 0,24 mm (at a bearing stress of 250 N/mm^2)
e. The allowable bearing stress may be raised from 130 N/mm^2 up to 175 or 200 N/mm^2.

3 UNIVERSITY OF LJUBLJANA

To promote the use of injection bolts in Slovenia and wider, a testing program on standard bolted lap connections was conducted at the University of Ljubljana. Altogether 22 tests were performed on three different types of connections:

a. Slip resistant connections
b. Connections with injection bolts
c. Connections with preloaded injection bolts.

For comparison, one test was performed on a standard connection with bolts in bearing. Monotonic long- and short duration tests were performed according to EN 1090-2. In addition, 4 cyclic tests were performed for a better insight into the behavior of injection bolts under cyclic loading.

3.1 *Description of the test program*

Monotonic tests: For all three types of connections monotonous tension tests followed strictly the procedure given in Annexes G and K of EN 1090-2.

With the results of the tests the slip factor μ and the bearing strength of the resin $f_{b.resin}$ were determined for the slip resistant connections (with pre-tensioned high strength bolts) and connections with injection bolts, respectively. The same procedure was also used to determine the resistance of connections with preloaded injection bolts, although this is explicitly not allowed for in EN 1090-2.

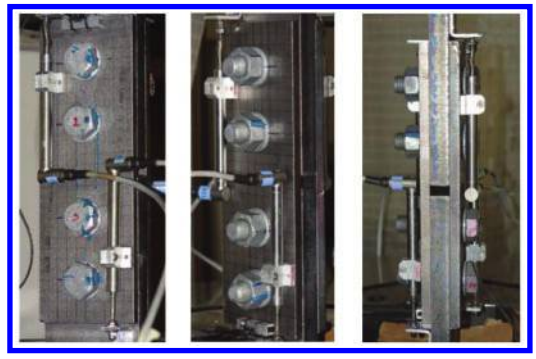

Figure 2. Instrumented test specimen.

The geometry of the standard test specimens with M20 bolts with instrumentation at the beginning of the test is shown in Figure 2. For each connection type 4 short-duration tests have to be done (10 min–15 min) where the resistance is determined at 0.15 mm slip. The fifth test is a long-duration creep test at constant load equal to 90% of the average resistances from the first four tests.

Because each specimen has two connections, there are actually eight results. The average slip in each of the four connections for the time period of 5 minutes – 3 hours after the full load is applied should not exceed 0.002 mm. If this is achieved, the specimen is tested to reach the slip of 0.15 mm and the characteristic resistance is determined based on the obtained results (mean – 2.05 × standard deviation).

If the creep test shows slip that exceeds 0.002 mm, the long-duration test should be extended until safe extrapolation of slip at 50 years is obtained; this slip should be smaller than 0.30 mm to guarantee appropriate long-term behavior of the connection.

It is worth mentioning that for connections with preloaded injection bolts EN 1993-1-8 allows summation of design slip resistance and design bearing resistance of the resin.

Cyclic tests: For connections with injection bolts cyclic tests are not standardized. Two tests at constant displacement amplitude of 0.135 mm (90% of allowable slip) and two tests at increasing the displacement amplitude were performed. The first of the constant amplitude tests was done at low frequency of 0.05 Hz for 120 cycles. The second test was performed at increasing frequency (0.5 Hz – 4 Hz) for 8000 cycles. The tests at increasing displacement amplitude were executed at low cyclic frequency 0.05 Hz.

Note: In the presentation of the test results the word slip is used for the measured displacements for both slip resistant connections with HSFG bolts and connections with injection bolts, although slip is not occurring with injection bolts.

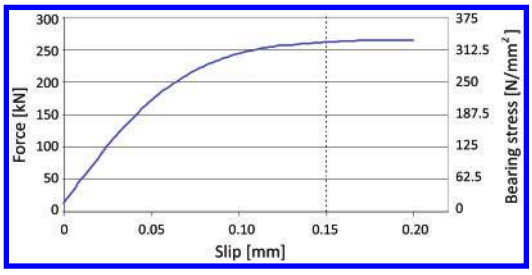

Figure 3. Slip resistant connection – Force-Slip diagram for average results from the first four short-duration tests.

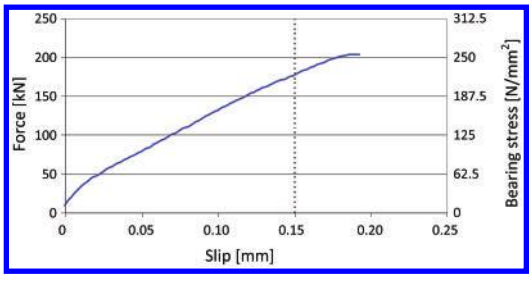

Figure 4. Connection with injection bolts – Force-Slip diagram for average results from the first four short-duration tests.

3.2 *Test results*

Monotonic tests: The results of the first four short-duration tests for all three types of connections are given in Figure 3 to Figure 6 in terms of the average force-displacement (slip) diagrams. Average values were determined for eight results (4 tests × 2 connections in each test specimen). For connections with injection bolts without preloading additional two "eccentric" tests were carried out (Figure 5), where the outer plates were shifted in relation to the inner plates as much as the hole clearance allowed. By this procedure the maximum thickness of the resin was 2 mm. This is the most unfavorable situation regarding the 0.15 mm slip criterion.

At 0.15 mm slip, the maximum value of the slip resistance is reached (Figure 3). The diagrams for injection bolts (Figure 4 and Figure 5) show a practically linear force-displacement relation and after the limit slip at 0.15 mm is exceeded, the force still increases.

The results for the most unfavorable eccentric test specimens give somewhat larger deformability that results in 14% smaller resistance, but from the diagram (Figure 5) it is evident that at slightly larger slip of 0.20 mm the same resistance as for "normal" test specimens can be obtained.

The results for preloaded injection bolts (Figure 6) show favorable summation of the contribution from the slip resistance and the bearing resistance without a force plateau at 0.15 mm slip.

In the three hour "long duration" creep tests according to EN 1090-2 at 90

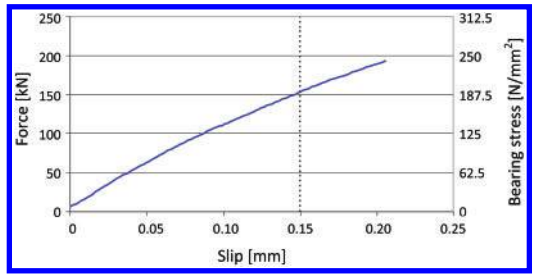

Figure 5. Eccentric connection with injection bolts – Force-Slip diagram for average results from the first four short-duration tests.

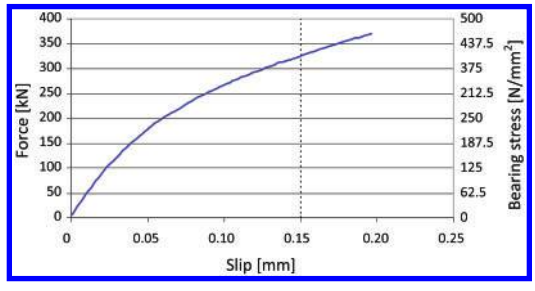

Figure 6. Connection with preloaded injection bolts – Force-Slip diagram for average results from the first four short-duration tests.

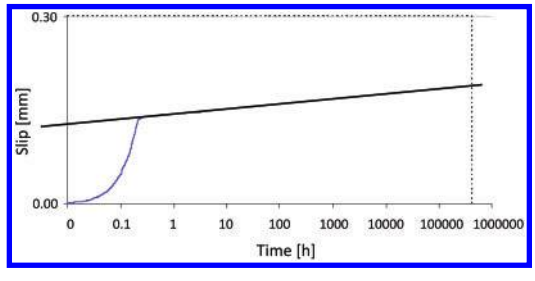

Figure 7. Connection with injection bolts – long-duration test and extrapolation of slip at 50 years.

% of average resistance from previous short-duration tests the additional creep limit of 0.002 mm was not exceeded. From tangent extrapolation to 50 years creep (Figure 7) it is evident that the final creep is less than 0.30 mm.

For the first two types of connections the characteristic values of the slip factor and of the bearing resistance of the resin can be determined from the characteristic resistances given in Table 1 and taking account of the corresponding resistance formulas from EN 1993-1-8:

$$\mu_k = 0.33$$
$$f_{b,resin} = 200 \text{ MPa}$$

Unfavorable eccentric location of bolts can reduce this bearing resistance up to 15%, if the same standard

Table 1. Test results of monotonous tests.

	Slip resistant F_{TEST}	Injection bolts F_{TEST}	Preloaded injection bolts F_{TEST}
Test 1	259.5	185.1	302.2
	251.2	166.3	320.2
Test 2	264.3	186.9	324.8
	255.5	182.0	303.5
Test 3	291.9	174.3	348.8
	286.1	188.5	337.9
Test 4	237	171.2	323.4
	244.3	177.7	331.3
Test 5	281.3	201.5	388.6
	285.8	197.4	407.9
$F_{TEST,AVER.}$	261.2	183.1	338.8
s	19.2	11.2	15.9
F_{RK}	221.8	160.1	306.2

deviation is assumed for eccentric specimens, as was obtained for normal specimens.

$$f_{b.resin}\ \min \approx 170\ \text{MPa}$$

In all test groups the spread of the results was small enough ($s/m \times 100 \leq 8\%$) that no additional tests (according to EN 1090-2) were necessary.

From Table 1 it appears that the connections with injection bolts have smaller resistance at the set deformation limit than the slip resistance connections. But it is remembered that for injection bolts the linearly increasing force-displacement diagram is more favorable (no sudden slip). Connections with preloaded injection bolts show good performance, but the obtained characteristic resistance $F_{RK}{}^{TEST} = 306.2$ kN is smaller than the sum of characteristic resistance of the slip resistant connection and the connection with injection bolts ($F_{RK}{}^{SUM} = 381.7$ kN).

It means that in this case the resistance obtained from EN 1993-1-8 (based on μ_K and $f_{b.resin,K}$ from the tests) is more than 20% higher than the test resistance of the connections with preloaded injection bolts. As stated above, this test resistance was determined with the same test procedure as for the basic two types of connections, although EN 1090-2 does not explicitly include this type of connections.

On the other hand it is evident that the Eurocode resistance is easy reachable at slip that is a bit larger than 0.15 mm (0.20 mm–0.25 mm).

Cyclic tests: Bridges under traffic loading and buildings under wind loading and in seismic events are subjected to cyclic loading. The basic idea is to examine the behavior of connections with injection bolts at cyclic loading that does not lead to exceeding of the bearing resistance of the resin. Namely, for larger actions such connection behaves as normal bearing connections with bolts in shear. For this reason only results of two cyclic tests at constant displacement amplitude of 0.135 mm are presented.

Force displacement diagrams for both tests are shown in Figure 8 and Figure 9. In both cases almost

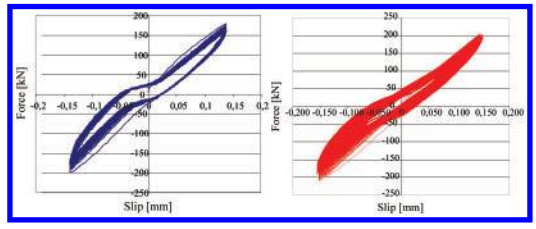

Figure 8. Force-slip diagrams for cyclic tests, a) test at 0.05 Hz, b) test at 0,5 Hz to 4 Hz.

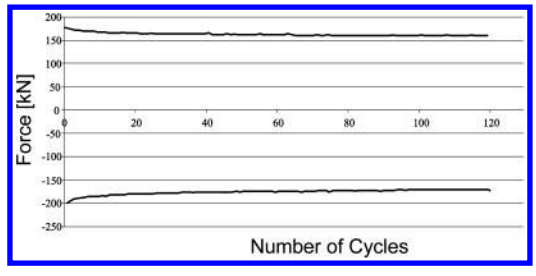

Figure 9. Force amplitudes for cyclic test at 0.05 Hz.

elastic behavior is observed with narrow hysteresis loops (Figure 8) and without visible influence on the loading frequency. In the first 10 or 20 cycles the force amplitude decreases by about 10%, but then it remains practically constant (Figure 9). This means that the behavior of connections with injection bolts at displacement amplitudes of 90% of the allowable slip is very good.

From the short duration cyclic tests it appeared that a much higher bearing stress could be applied without exceeding the deformation limits.

4 DELFT UNIVERSITY OF TECHNOLOGY

In Amsterdam an extension to the railway station is under construction (2011–2013) with a large glass roof (10). High demands were put on the stiffness of the glass supporting steel structure. Displacements in bolted connections had to be reduced to very low values. The main reason for that was the safety requirement in case of fire (bus station beneath). To avoid too much uneven heating of the glass a narrow supporting width of the glass panels was required.

The application of high strength friction grip bolts was problematic because of the need to remove locally the corrosion protection (paint system) and the risk of corrosion traces later on. Then it was decided to investigate the application of injection bolts M27.

The main load on the roof is wind load, which is short duration. It was asked whether it would be safe to allow higher bearing stresses for this load case than the bearing stresses based on long duration creep testing. Injection bolts would be applied in normal size and oversized holes.

To answer this question, the results of the tests in the University of Ljubljana were most helpful. The

Figure 10. Artist impression of the extension Railway Station Amsterdam and the glass roof under construction (April 2012, project IJSEI, see Google).

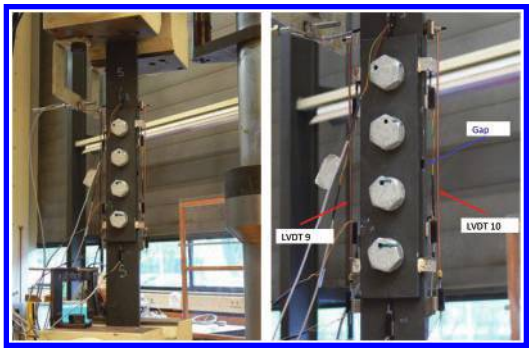

Figure 11. Test specimen with four short LVDT's and two long LVDT's.

authorities requested for extra testing focusing at the application in Amsterdam.

4.1 *Test program*

Six tests were performed on test specimens with M27 bolts as shown in Figure 11. The preparation of the test specimens was done by the contractor guided by the engineering office. The engineering office decided for at random position of bolts to simulate the situation in practice. This resulted in different distances of the main plates (position of bolts in the holes), giving different sizes of the gap.

The design bearing stress would be based on the allowed maximum displacement of 0.95 mm = 0.30 mm per bolt + 0.35 mm because of the elongation of the steel. Per test specimen 10 cycles were performed, with a loading speed of 2 kN/sec = 2 minutes till maximum load. Then waiting time was 5 sec followed by quick unloading, waiting 10 sec and start a new cycle.

4.2 *Test results*

Test main result of the first test is given in Figure 12. Other tests gave similar values.

The tests were displacement controlled. The maximum average displacement was 0.95 mm. The maximum bearing stress per cycle is given in Figure 13. The decline is the largest in the first cycles and then the average tends to stabilize at about 310 N/mm^2. It is noted that the last cycle had somewhat smaller displacement than 0.95 mm.

In test 5 and 6 the test was continued after the first 10 cycles with displacement 0.95 mm up to displacement

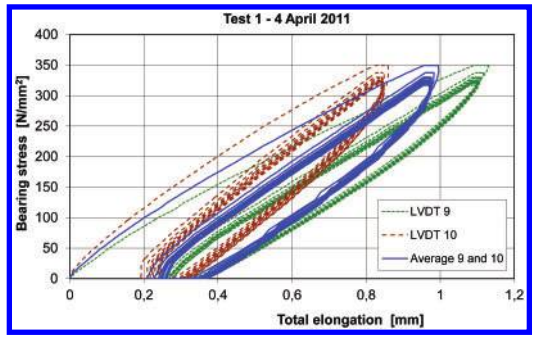

Figure 12. Main result of test 1: Bearing stress – Total elongation.

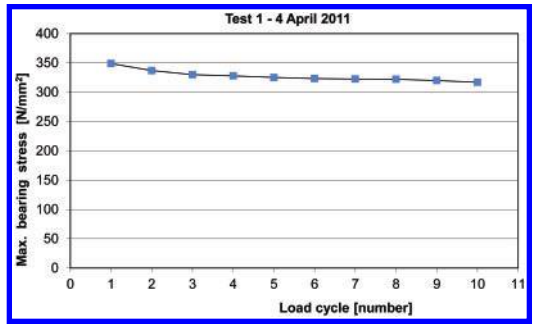

Figure 13. Maximum bearing stress per cycle in test 1.

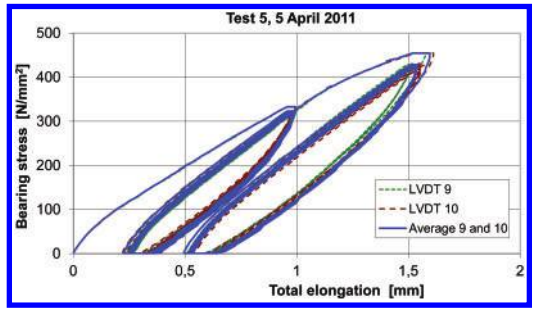

Figure 14. Main result of the fifth test: Bearing stress – Total elongation.

1.55 mm (Figure 14). Also at this larger displacement the decline in the bearing stress was very limited.

In Table 2 an overview of the main test results is given. Differences in the results probably must be mainly attributed to the differences in the position of the bolts in the holes as explained before.

For a 95% chance of exceeding the design value it was calculated that the allowable design bearing stress would be 284 N/mm^2. It was decided to adopt for the injection bolts in the glass roof the following values.

$$f_{b,resin,long\ duration} = 200\ N/mm^2$$

$$f_{b,resin,short\ duration} = 280\ N/mm^2$$

When short duration and long duration loads are considered in relation to creep it is noted that in the

Table 2. Overview of test main test results.

Test	F after 10th load cycle (kN)	$f_{b,resin}$ (N/mm^2)
1	257	317
2	233	287
3	242	298
4	262	323
5	250	309
6	242	299

Eurocode this is only applicable to structures where creep is relatively long duration (concrete, timber).

In injection bolts the creep process is quicker. Wind load is very short duration and will not lead to significant creep, but e.g. snow load and temperature load could be longer duration. In view of this it was decided to consider the following load combinations for the glass roof for the middle long term loads: and

$$1{,}2G+1{,}0Q_{snow}+0{,}5Q_{temp}$$

and

$$1{,}2G+1{,}0Q_{temp}$$

For the short term loads (wind) the standard load combinations were checked with $f_{b,resin,} = 280\ N/mm^2$.

5 CONCLUSIONS AND RECOMMENDATION

The main conclusions and recommendation from the research in the Universities of Ljubljana and Delft are:

a. The long duration bearing stress of the tested resin can be taken as $200\ N/mm^2$. It was proposed in the 2000 Roanoke paper on bases of the tests reported in that paper and conformed in the present testing.
b. The short duration bearing stress can be taken considerably higher than the long duration bearing stress.
c. It is recommended to modify Eurocode 3 part 1–8 and EN 1090-2 accordingly and make a distinction between long duration and short duration load combinations.

ABSTRACT: The steel and steel-concrete composite joints moment-rotation characteristic postulated in present structural eurocodes is based on a piecewise relationship consisting of the linear part, in the quasi-elastic region (up to the limiting value of two third of the joint moment resistance), and – from that point – of the curvilinear part, valid for the inelastic region (up to the limiting value termed the joint moment resistance). This characteristic for end-plate joints is proposed to be of the same format for steel and composite joints, therefore its shape is not dependent upon the reinforcement ratio. Such an approach has an advantage of being simple but, on the other hand, leads to a discontinuous function describing the joint tangent stiffness. It is also not general enough to be able to account for the effect of joint post-limit hardening stiffness. In order to capture the effect of joint progressive stiffness degradation with the hardening effect taken into account, a unified three parametric continuous analytical model is developed. All the details of this model are presented together with the calibration procedure for basic model parameters. Experimental data obtained from laboratory tests carried out at the Warsaw University of Technology is used for the calibration of developed model. Its results are given together with the proposed values of calibrated model parameters for practical application. Finally, moment-rotation characteristics according to the developed model obtained with the use of calibrated model parameters are compared with the experimental results for different values of the joint reinforcement ratio. Conclusions with regard to engineering practice are drawn.

1 INTRODUCTION

In the design of frame systems in skeletal buildings technological and economical profits can obtained by using end-plate beam-to-column joints with a reduced number of stiffeners and supplementary plates, if any. Such joints are to be considered semi-rigid steel or steel-concrete composite joints for which the behavioral characteristic needs to be included in the design for analysis and verification procedure. The basic behavioral characteristic of beam-to-column joints used in frame systems of skeletal buildings, describing their actual behavior, is the moment-rotation relationship M-ϕ in which ϕ is the angle of relative rotation of the beam with reference to the column in the considered joint and M is the bending moment $M_{j,E}$ being the action effect to be transferred by the joint. The M-ϕ curves may be obtained from experimental tests or from analytical modeling.

The steel and steel-concrete composite joints moment-rotation characteristic postulated in present structural eurocodes (EN 1993-1-1, EN 1993-1-8 & EN 1994-1-1) are based on piecewise relationship consisting of the linear part in the quasi-elastic region (up to the limiting value of two third of the joint moment resistance) and from that point – of the curvilinear part valid for the inelastic region (up to the limiting value termed the joint moment resistance). This characteristic is postulated to be for end-plate joints of the same format for steel and composite joints, therefore its shape is not dependent upon the reinforcement ratio ρ. Such an approach has an advantage of being simple but on the other hand leads to a discontinuous function describing the joint tangent stiffness and is too simple to take into account the effect of joint post-limit hardening stiffness on the shape of the characteristic.

It has been proven in the experimental work carried out at the Warsaw University of Technology that the joint moment-rotation characteristic is a continuous function consisting of the quasi-elastic region, inelastic region and rotation hardening region, with a continuous function of its first derivative describing

the joint actual stiffness (Barcewicz 2010). Taking the approach used in the present design codes, a new analytical formulation was developed in which the joint moment-rotation characteristic is postulated to be dependent upon the reinforcement ratio (Barcewicz & Gizejowski 2011). Therefore the characteristic has the shape changing from that corresponding in the present eurocodes for steel joints ($\rho = 0$) to the one corresponding to composite joints with a certain limiting value of the joint reinforcement ratio ($\rho = \rho_0$). The limiting reinforcement ratio ρ_0 for a given joint corresponds to a situation when the resultant of its fully stressed tension zone is equal to the resultant of its fully stressed compression zone. For reinforcement ratios $\rho \geq \rho_0$ the shape of composite joint characteristic remains the same as for the case corresponding to $\rho = \rho_0$. This model is briefly summarized in this paper together with the former structural eurocode. The joint characteristics obtained in both ways are however conservative because they maintain to disregard the effect of post-limit hardening stiffness.

In order to capture the effect of joint progressive stiffness degradation with the hardening effect taken into account, the three parametric continuous model is adopted hereafter for the analytical formulation (see the models classified by Gizejowski et al. 1998). The Continuous Stiffness Degradation model (CSD model), first applied to describe the joint behavior by Gizejowski et al. (2012), has been chosen for adoption. The current paper is an extension of the previous work (Gizejowski et al. 2012) giving all the details of the developed model together with a calibration procedure for basic model parameters. Experimental data obtained from laboratory tests carried out at the Warsaw University of Technology for beam-to-column joints of different reinforcement ratio, namely $\rho = 0$ for steel joints and for composite joints $\rho = 0.0035$, $\rho = 0.0060$ and $\rho = 0.0135$ is used for calibration. The results of calibration exercise as well as the values of calibrated model parameters are given for practical application.

2 MODELING OF JOINT MOMENT-ROTATION CHARACTERISTIC

2.1 *Generalized eurocode's model*

According to eurocodes (EN 1994-1-1) to evaluate the M-ϕ characteristic of steel-concrete composite joints the same analytical model as for bare steel joints (EN 1993-1-8) should be used. Moment-rotation characteristics of composite joints are therefore independent from the reinforcement ratio. Mathematical description of the joint characteristic is represented by the following formulae:

– in the quasi-elastic region, i.e. $M_{j,E} \leq 2M_{j,R}/3$

$$M_{j,E} = S_{j,ini}\phi \tag{1}$$

– in the inelastic region, i.e. $2M_{j,R}/3 < M_{j,E} \leq M_{j,R}$

$$M_{j,E} = S_j\phi \tag{2}$$

– and finally in the plastic region

$$M_{j,E} = M_{j,R} \tag{3}$$

where $S_{j,ini}$ = joint initial stiffness for the joint linear response in the quasi-elastic region; S_j = joint secant stiffness for the joint nonlinear response in the inelastic region:

$$S_j = \frac{S_{j,ini}}{\mu} \tag{4}$$

and $M_{j,R}$ = joint moment resistance.

The joint secant stiffness factor μ is expressed as follows:

$$\mu = \left(\frac{M_{j,E}}{\alpha M_{j,R}}\right)^{\psi} \tag{5}$$

where $\alpha = 2/3$ is the constant describing the upper limit of joint linear response; ψ = constant describing the shape of curvilinear part of M-ϕ characteristic that for bolted end-plate steel and steel-concrete composite joints is equal to 2.7.

Experimental investigations conducted at the Warsaw University of Technology have shown that the shape of composite joints M-ϕ characteristic is strongly affected by the reinforcement ratio (Barcewicz 2010). Barcewicz & Gizejowski (2011) proposed a generalized eurocode's analytical model that includes the change of the model parameters α and ψ with regard to the reinforcement ratio of composite joints. This generalized approach adopts the reference value of reinforcement ratio ρ_0 and the linear interpolation formulae for model parameters α and ψ in relation to the reinforcement ratio:

$$\alpha = \frac{2}{3}\left(1 - \frac{\rho}{3\rho_0}\right) \geq \frac{4}{9} \tag{6}$$

$$\psi = 2.7 - \frac{\rho}{\rho_0} \geq 1.7 \tag{7}$$

The proposed approach has an advantage of being versatile because it describes the behavior of composite joints when $\rho > 0$ as well as it is valid for bare steel joints when $\rho = 0$. The boundaries of the developed analytical model are shown in Figure 1. For increased values of the reinforcement ratio the limit of the joint linear response decreases from 2/3 to 4/9 of the joint moment resistance while the shape factor of the curvilinear part of the joint moment-rotation characteristic decreases from 2.7 to 1.7. The change of basic model parameters results in decreasing of the secant stiffness corresponding to the joint moment resistance from one third to one fourth of the initial stiffness, and results also in shifting the limiting rotation φ_X, at the intersection of moment-rotation curvilinear part and the moment resistance, from $\varphi_{X,min}$, to the a larger value of $\varphi_{X,max}$.

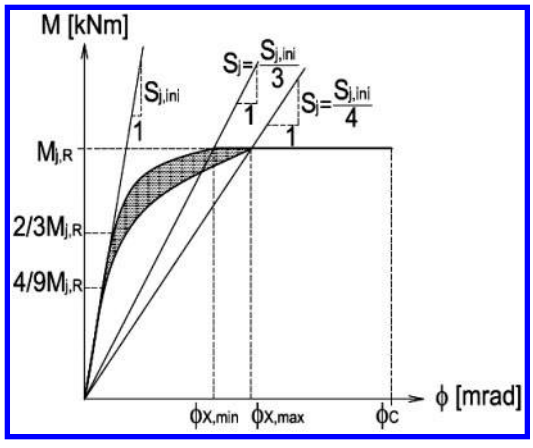

Figure 1. Envelope of reinforcement ratio dependent unified moment-rotation characteristics for steel and composite joints.

2.2 *Proposed CSD model*

As it has been mentioned before, present codification rules and their extensions for the evaluation of joint moment-rotation characteristic disregard the joint post-limit hardening stiffness (see Fig. 1). In order to capture the joint progressive stiffness degradation with hardening effect taken into account, the three parametric CSD model is adopted. It is based on a probabilistic considerations of independent linear mechanisms of initial response with the stiffness $S_{j,ini}$ and the post-limit response with the rotation hardening stiffness $S_{j,postlim} = \xi S_{j,ini}$ (Gizejowski et al. 1998). This relationship takes the following form:

$$M_{j,E} = \left[\left(\frac{1}{S_{j,ini}\phi} \right)^n + \left(\frac{1}{M_{j,R} + \xi S_{j,ini}\phi} \right)^n \right]^{-\frac{1}{n}} \tag{8}$$

where $\xi = S_{j,postlim}/S_{j,ini}$ is the factored hardening modulus; and $n =$ shape factor of the M-ϕ characteristic.

Note that for the evaluation of both factors, an optimization like procedure is needed with use of experimental data available from laboratory tests. As it has been mentioned earlier, results obtained from the tests conducted at the Warsaw University of Technology are considered throughout this paper.

3 CALIBRATION OF CSD MODEL PARAMETERS

3.1 *Error measures and approximation method*

Using any method for the best fit of developed theoretical model to experimental results, several error measures may be postulated. Referring to a single point, the routinely applied ones are the absolute (ABS) and relative (RE) errors:

$$ABS = M_{\exp,i} - M_{th,i} \tag{9}$$

$$RE = \frac{M_{\exp,i} - M_{th,i}}{M_{\exp,i}} \times 100\% \tag{10}$$

where, $\mathrm{Mexp}_{,i} =$ desired (known) value of the moment obtained from the experiment for the i^{th} recorded rotation φ_i; and $M_{th,i} =$ value of moment obtained from the developed CSD model for the same i^{th} value of rotation φ_i.

In case of assessment of the correlation of experimentally recorded joint multiple point moment-rotation characteristics, a number of error measures may be suggested to assess the accuracy of proposed analytical CSD model, among others:

– mean square error (MSE)

$$MSE = \frac{1}{m} \sum_{i=1}^{m} \left(M_{\exp,i} - M_{th,i} \right)^2 \tag{11}$$

– root mean square error (RMSE)

$$RMSE = \sqrt{\frac{1}{m} \sum_{i=1}^{m} \left(M_{\exp,i} - M_{th,i} \right)^2} \tag{12}$$

– maximal absolute error (MAE)

$$MAE = \max_{i=1,\ldots,m} \left| M_{\exp,i} - M_{th,i} \right| \tag{13}$$

– maximal relative error (MRE)

$$MRE = \max_{i=1,\ldots,m} \left| \frac{M_{\exp,i} - M_{th,i}}{M_{\exp,i}} \right| \times 100\% \tag{14}$$

– average relative error (ARE)

$$ARE = \frac{1}{m} \sum_{i=1}^{m} \left| \frac{M_{\exp,i} - M_{th,i}}{M_{\exp,i}} \right| \times 100\% \tag{15}$$

where, $m =$ number of recorded sets of $(M_{exp,i};\varphi_i)$ for an experimentally obtained moment-rotation characteristic of the tested joint.

In the least mean square approximation used hereafter for the best fit of moment-rotation characteristics of both steel and steel-concrete composite joints, the MSE measure is adopted.

3.2 *Experimental data used in calibration exercise*

The class of joints considered herein uses end-plates of the thickness ranging from 40 to 60% of the bolt diameter. The concrete slab of composite joints is cast on the deep-profiled sheeting and reinforced by the steel bars of the diameter ranging from 6 mm to 12 mm. The specimens are divided into four groups according to their reinforcement ratio in the hogging moment region. The summary of tested specimens and experimentally obtained joint properties of respective groups are presented in Table 1.

Table 1. Experimental data of considered joints.

* F- flush end-plate; E – extended end-plate.

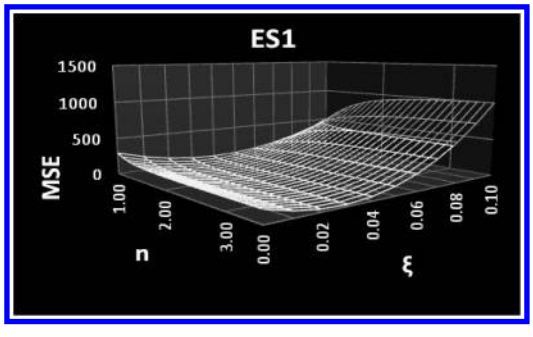

Figure 2. Surface of error measure MSE for specimen ES1.

3.3 *Results of calibration exercise*

For each tested specimen a set of experimentally obtained records ($M_{exp,i}$; φ_i) for $i = 1,2,\ldots,m$ and the number of records m were stored and used hereafter for the calibration exercise to find the best fit values of model parameters ξ and n. The ξ and n values are first established independently for experimentally obtained characteristics of each joint in Groups 0, 1 & 2. Figures 2 & 3 show typical MSE surfaces for specimens of Group 0 while Figures 4 & 5 for specimens of Group 1. The values of model parameter ξ and n leading to the best fit of these and other M-ϕ characteristics of Group 0, 1 & 2 joints are listed in Table 2.

From results obtained in the calibration exercise it is clear that: (a) some identified values of model parameters ξ and n are non-unique, (b) the applied approximation method leads to inaccurate results for specimens of Group 2 (shaded rows in Table 2). The non-uniqueness of the obtained solution is visible for example in Figure 3 where the MSE surface has a rather broad and flat valley meaning that there is a

number of ξ and n pairs giving similar accuracy of the prediction of M-ϕ characteristic. The reason for inaccuracy is that the moment-rotation characteristics of specimens belonging to Group 2 end at the

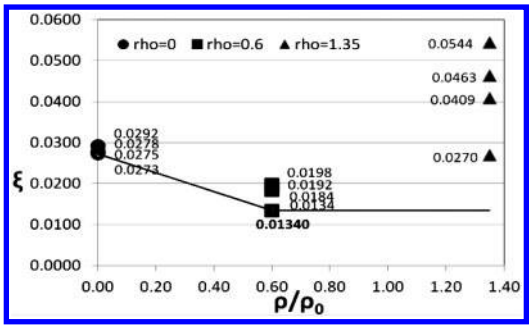

Figure 6. Proposed function of reinforcement ratio dependent model parameter ξ.

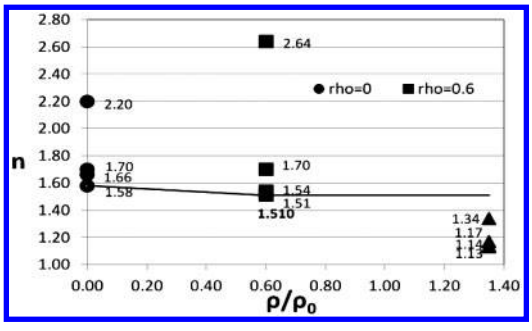

Figure 7. Proposed function of reinforcement ratio dependent model parameter n.

substantially smaller rotation if compared with the other two Groups 0 and 1, and therefore consist of substantially smaller number of records m. It is therefore postulated that at this stage of research, the model parameters ξ and n are approximated linearly at the lower bound values obtained for Groups 0 ($\rho = 0$) and 1 ($\rho = 0.006$), and for specimens with the reinforcement ratio $\rho > 0.006$ the values obtained for $\rho = 0.006$ are used.

3.4 *Proposed values of calibrated model parameters*

The specimens of Groups 0 and 1 are treated as belonging to two separate populations. The values of model parameters ξ and n are therefore evaluated at the lower bound level for each population. The value of ρ_0 ranges between 0.6% and 1.35% for the considered experimental investigations. For simplicity at this stage, an average value of $\rho_0 = 1.0\%$ is adopted.

Figures 6 & 7 present the proposed linear functions of lower bound approximation of model parameters ξ and n:

$$\xi = 0.0270 - 0.0227\frac{\rho}{\rho_0} \geq 0.0134 \tag{16}$$

$$n = 1.580 - 0.115\frac{\rho}{\rho_0} \geq 1.51 \tag{17}$$

The final values of calibrated parameters according to Eqns. (16) & (17) are used in the following section

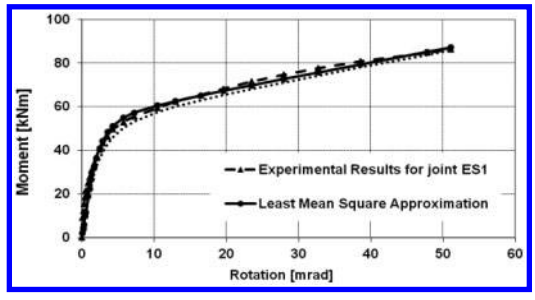

Figure 8. Comparison of moment-rotation curves for ES1.

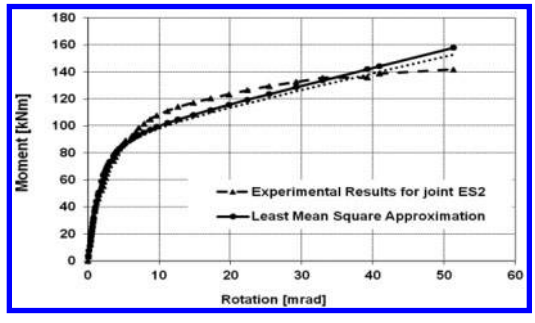

Figure 9. Comparison of moment-rotation curves for ES2.

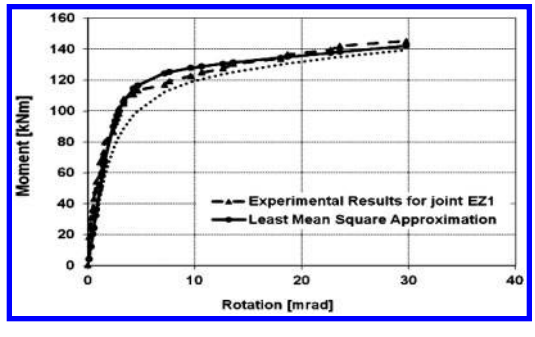

Figure 10. Comparison of moment-rotation curves for EZ1.

for the comparison of experimental characteristics and those evaluated according to Eqn. (8).

4 VERIFICATION OF DEVELOPED CSD MODEL

4.1 *Steel joints*

Verification of proposed unified moment-rotation characteristic is made for all tested joints of Group 0, with flush and extended end-plates. Exemplary results for the flush and extended end-plate steel joints are presented in Figures 8 & 9. The dotted line here and hereafter represents the results obtained with model parameter according to Eqns. (16) & (17).

4.2 *Composite steel-concrete joints*

The comparison is made also for all tested composite joints of Groups 1, 2 & 3. Figures 10 & 11 show typical results for the composite joints of Group 1 with

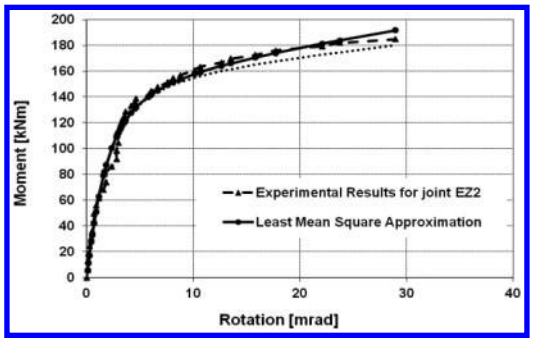

Figure 11. Comparison of moment-rotation curves for EZ2.

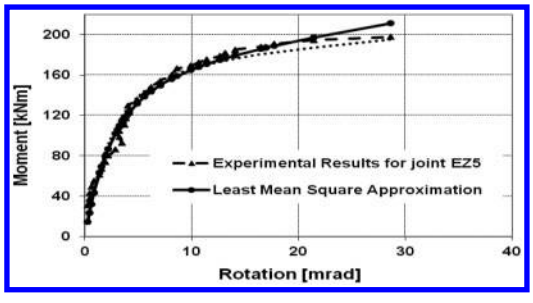

Figure 12. Comparison of moment-rotation curves for EZ5.

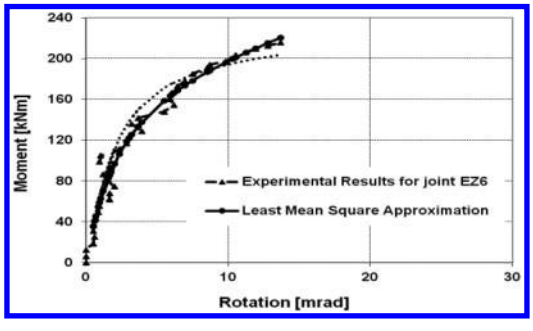

Figure 13. Comparison of moment-rotation curves for EZ6.

flush and extended end-plates. Similar comparison is made in Figures 12 & 13 for the composite flush and extended end-plate joints of Group 2.

4.3 *Joints under sagging moments*

Investigations presented herein deal with moment-rotation characteristics of joints subjected to hogging bending. Similar investigations are now underway for joints subjected to sagging bending (Saleh 2013).

5 CONCLUDING REMARKS

Semi-continuous frameworks composed of semi-rigid/partial-strength steel and/or steel-concrete composite joints are more frequently used in practical applications because of their technological and economical advantages. The most important factors affecting the performance of above mentioned joints are the moment-rotation characteristic and its property parameters, such as the initial stiffness, moment resistance, hardening stiffness and rotation capacity.

The paper investigates moment-rotation characteristic shape, also summarizing the eurocode's approach and its generalization to account for the effect of reinforcement ratio. A detailed study of Continuous Stiffness Degradation model (CSD model) parameters are presented using MSE approximation and experimental results obtained from tests conducted at the Warsaw University of Technology.

The proposed approximation method is proven to be a useful tool in the practical evaluation of model parameters in all the cases where there is a sufficient number m of records in the post-limit range of the experimental moment-rotation characteristic. The proposed best fit model parameters are therefore based only on the experimental results of joint Groups 0 ($\rho = 0$) and 1 ($\rho = 0.006$). The values of model parameters for the reinforcement ratio $\rho > 0.006$ are postulated to be the same as for $\rho = 0.006$.

Comparison of moment-rotation characteristics according to the developed model obtained with use of the calibrated model parameters with the experimentally obtained characteristics shows a good match. It supports the authors' confidence that the proposed unified approach to the evaluation of moment-rotation characteristics of both steel and steel-concrete composite joints adds the value to ongoing research on practical aspects of the behavior of semi-continuous structural systems.

The influence of the bolt grade on its behaviour under combined tension and shear

A. Renner & J. Lange
Institute for Steel Structures and Materials Mechanics, TU Darmstadt, Germany

ABSTRACT: Since the beginning of the use of bolts in steel construction structural engineers all around the world were used to limit the load bearing capacity of bolts that are loaded with both tension and shear against a quadratic interaction curve. When a few years ago new Europe wide valid standards – the so-called Eurocodes – where established, one was surprised to find a complete different and by far more conservative rule in this. Looking further into detail where this could come from, it occurs that both design rules go back on a very small number of test results, with sometimes questionable test methods and on arguable assumptions and statistical analyses. To ascertain how bolts under combined loads should be treated in future a new test series was conducted. The results are summarized in this paper.

1 BACKGROUND

1.1 *Interaction rules in standards*

A bolt can be loaded with a tension force parallel to its axis, or with a shear force normal to it. For both cases standards give a maximum resistance value to delimit the occurring force against it.

Then again, if a bolt gets a tension and a shear force at the same time the load bearing capacities will of course influence each other. An interaction of the forces has to be considered.

The long-time practised way to do so was by using a quadratic interaction rule (see i.e. German DIN (DIN 18800-1, 2008)):

$$\left(\frac{N}{N_{Rd}}\right)^2+\left(\frac{V}{V_{Rd}}\right)^2 \le 1{,}0 \qquad (1)$$

where N, V tensile/shear force in bolt
N_{Rd}, V_{Rd} loadbearing resistance of bolt under pure tension/shear

(some standards i.e. the British Standard (BS 5950-1, 2000) used a linearized version of this for the easier handling, but it basically describes the same borders).

Now, looking into the new established Eurocode 3 (EN 1993-1-8, 2010) one finds a different new interaction rule:

$$\frac{N}{1.4\cdot N_{Rd}}+\frac{V}{V_{Rd}} \le 1{,}0 \qquad (2)$$

In Figure 1 the functions of both interaction rules are pictured. It appears that for bolts with roundabout the same amount of tensile and shear force the new Eurocode rule is by far more conservative.

This gets even worse for bolts with the shank in the shear force: It would be sensible to look at that point of the bolt where the force interaction really happens, ergo in the shank. This was not a problem with earlier standards that gave a formula to determine the tension capacity of the shank as well (see i.e. DIN 18800-1, El. 809).

The Eurocode lacks a comparable method to determine the shank tension capacity. Following the Eurocode the bolt verification has to be done by mixing up the shear capacity of the shank with the

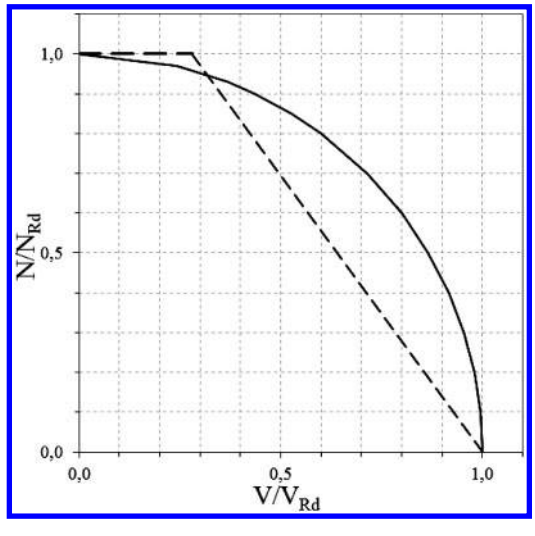

Figure 1. Comparison of interaction rules: Quadratic (i.e. German DIN (DIN 18800-1, 2008)) and linear (Eurocode 3 (EN 1993-1-8, 2010)).

Figure 2. High load connection in the main steel structure of a power plant.

tension capacity of the threaded part, which is not only inconsequent, but uneconomic.

In some adverse cases following the Eurocode this leads to up to 50 % more bolts that are needed.

1.2 *Background of the standard rules*

Of course, in most of the simple connections, which make a big part of steel construction, bolts are either loaded with tension or with shear (or at least were treated in design as if this was the case). So, the main focus in research was always on the load bearing behaviour under a pure load.

Nonetheless, when it comes to more spectacular buildings and the connections become larger and more ambitious and challenging, the occurring of tension and shear in a bolt occurs more often – and the necessity to tread it safe but efficient gets even higher.

Before in the 1980th the first interaction rules were included into the standards, designing engineers were left alone to find a way to handle interaction in bolts. The most common idea here was to superpose the load factors quadratically, as one would do in other interaction cases as well: The most common example is the equivalent stress for a combination of normal and shear stress:

$$\sigma_e = \sqrt{\sigma_x^2 + 3 \cdot \tau_{xy}^2} \tag{3}$$

where σ_e equivalent stress
σ_x normal stress
τ_{xy} shear stress

The transferability of the quadratic rule for the tension-shear-interaction in bolts was then derived from a rather small number of tests on the subject, which results showed indeed a roughly quadratic relation. Why the number of existing tests is so small and why the applicability of some of them could be questioned will be shown in Chapter 2.

For the Eurocode on the other hand in a first step the authors collected proposals for possible rules to include into the standard and then verified them via a statistical evaluation of existing test results. This

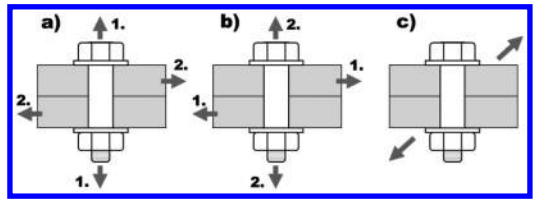

Figure 3. Ways to apply a combined load: a) apply tension force, then apply shear force until failure; b) first shear, then tension (hypothetical); c) diagonal force.)

worked rather well for most of the rules, but here again for tension-shear-interaction in bolts the number of tests on hand was rather small. Now, the statistical analysis showed that the quadratic interaction is not on the safe side for all of the test results, so the Eurocode authors decided to cut the interaction curve down to the now existing bi-linear function.

Sadly enough, the documentation on the utilised tests is quite poor (Snijder 1988 & Sedlacek 2004). It is possible to say that only a few of the tests missed the required safety level, but it is not possible to say which ones.

2 TENSION-SHEAR-INTERACTION TESTS

2.1 *Possible test methods*

To test a bold under a combined load one has to choose from three methods: First way would be to get the bolt onto a certain level of tension and then apply a shear force until the bolt fails (see Figure 3, a)). Second way would be to do so the other way around (first a shear force, then tension until failure, Figure 3, b)), but this way is rather theoretical for the shear force might bend the bolt that way that it will become impossible to apply a tension force afterwards. The third method would be to apply a diagonal force, which results in a corresponding tension and a shear force in the bolt (Figure 3, c)).

One major problem with interaction tests is to get the forces into the bolt. A bolt is a rather short, hard to grip item of a high strength material, there is not much space to grab the head and nut of it to apply tension and then apply shear via shear plates, as requested in the first way. Testers who followed this way helped themselves by not testing real bolts but round bars and threated rods (see chapter 2.2), which could be made much longer than a bolt and hence are easier to grab, but the negotiability of the results onto the behaviour of bolts is to be questioned.

To test a real bolt the test arrangement has to be rather large. For the load introduction stiff plates are needed. The force can be applied via a displacement of the plates, this would mean following the third way. It requests an appropriate construction for the load introduction – and therewith the number of different angles that can be tested is limited.

Additionally to the varying of the tested angles other factors to vary can be the bolt grade and the position of

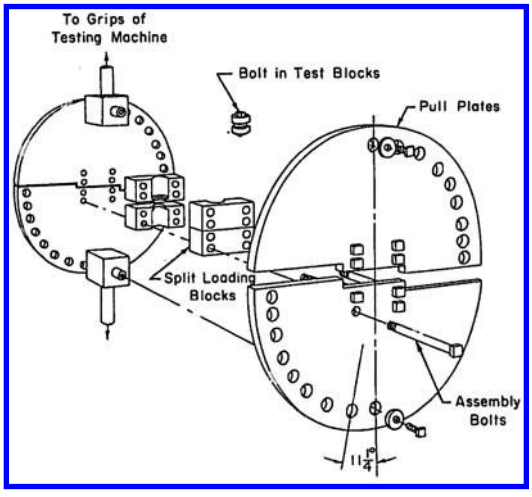

Figure 4. Test setup in Illinois, USA, 1965 (Chesso, 1965)

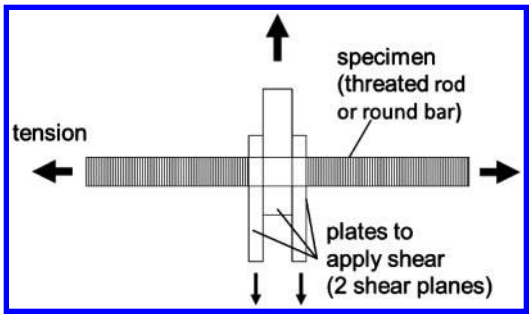

Figure 5. Schematic diagram of tests in Germany (Hassler 1973 & Knobloch 1987).

the shank, one could further think of varying the bolt diameter or even the clamping length. For the establishent of the Eurocode the results of 139 tested bolts were considered, considering the number of varieties this means for some combinations of bolt grade and tension-to-shear-ratio not more than 2 or 3 tests.

2.2 *Former test series*

The number of existing test series on bolts under combined load is limited. One of the earliest was conducted in Illinois, USA (Chesso, 1965), where an altered setup for tests on rivets was used (see Figure 4). The tests were done on real bolts that had fairly a material strength comparable to bolts today of a grade 8.8 or 10.9, but their properties can hardly be compared to them.

Two known tests series were conducted in Germany: The first one in Stuttgart in 1973 (Hassler 1973), the second, slightly bigger one in Essen in 1987 (Knobloch 1987). The later took a small part of a much bigger research project, in which mainly bolts under pure shear were tested.

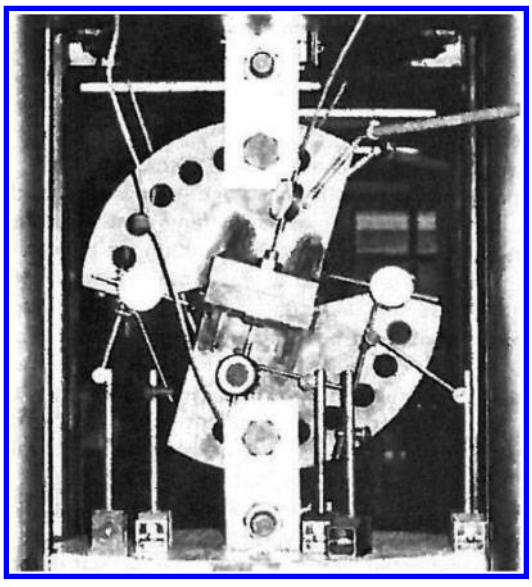

Figure 6. Test setup in Manchester, UK, 1979 (Shakir-Khalil 1979).

In both cases tests were not done on real bolts but on threaded rods and round steel bars instead. Figure 5 shows a schematic drawing of the test setup. First the rod is brought to e certain level of tension, then with a second machine a shear force is applied via the shear plates in the middle of the rod.

The use of rods made the handling a lot easier, but it stays to question whether the results are transferable for bolts, especially in a connection situation. Furthermore the shear force was applied using two shear planes – this keeps out an asymmetric bending in the rod, but it does not represent a possible situation in a connection.

Stuttgart only tested threated rods of grade 4.6 and a diameter of 24 mm. They conducted as a total 15 tests on three different tension levels.

The specimen in Essen were made from round bars with a diameter of 20 mm and the materials characteristics St 37-2, St 52-3, C 45 and 42 Cr Mo 4 that have comparable strength as the common bolt grades 4.6, 5.6, 8.8 and 10.9 (although not exactly the same). To represent bolts with the threat in the shear plane in Essen also threated rods with diameters of 16 mm and 24 mm were tested. It was planned to get materials that match the properties of a grade 5.6 and 10.9, but the available rods did slightly differ from that. They were tested anyway. All in all Essen conducted a total number of 68 tests, again on three different tension levels.

However, as with the Illinois tests before, the results indicated a basically quadratic relation between tension and shear capacity and, together with the theoretical assumptions described in 1.2, this sufficed to include the quadratic function into the standards.

Table 1. Tests for evaluating of Eurocode 3 rule.

	Bolt grade	thread in shear plane	shank in shear plane
Manchester	4.6	20	17
Delft	4.6, 8.8, 10.9	59	43

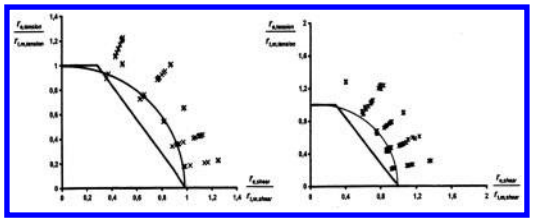

Figure 7. Test results evaluated for the Eurocode rule (Snijder 1988) with quadratic function laid over; left: thread in shear plane; right: shank in shear plane.

Two test series were analysed to evaluate the rule in the Eurocode, one from Manchester, UK conducted in 1979 (Shakir-Khalil 1979), and one from Delft, The Netherlands from 1971 (see Snijder 1988 & Sedlacek 2004).

Both test series were done on real bolts. Manchester used a T-stub-construction to induce the load, so in this case two bolts were tested in one go (setup see Figure 6). Delft used a test setup basically identical with the Illinois setup (Figure 4).

Manchester only tested bolts of a grade 4.6, Delft also tested grade 8.8 and 10.9. Both tested shank and thread in shear plane. The total numbers of tests conducted are shown in Table 1.

Both test series tested 6 different tension-to-shear-ratios plus pure tension and pure shear.

Unfortunately, the original report on the Delft test series is not available anymore. All information about the Delft tests is taken from the background report (Snijder 1988 & Sedlacek 2004) and it is not possible to separate the test results from each other. But by looking at the number of conducted tests and possibilities of variety one can easily tell that for some combinations (bolt grade, shear plane situation and tension-to-shear-level) there cannot be more than two or three evaluated tests results.

The background document shows all evaluated test results plotted into two graphs related to the basic material strength, see Figure 7. One cannot tell which point originates from which bolt grade test but it is obvious that indeed some tests lay below the quadratic function.

3 DARMSTADT TEST SERIES

To be able to judge, whether the bolt interaction rule was reasonably changed for the Eurocode or whether it would be appropriate to handle the subject more differentiated a series of new tests was conducted at the Technische Universität Darmstadt.

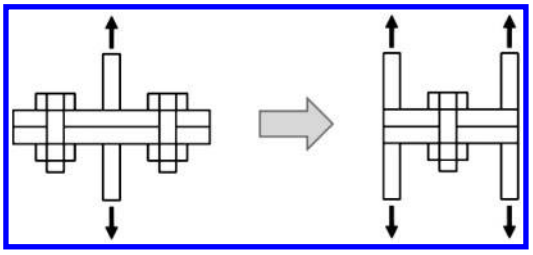

Figure 8. Principle of load introduction: U-Stub instead of T-stub to test only one bolt at a time.

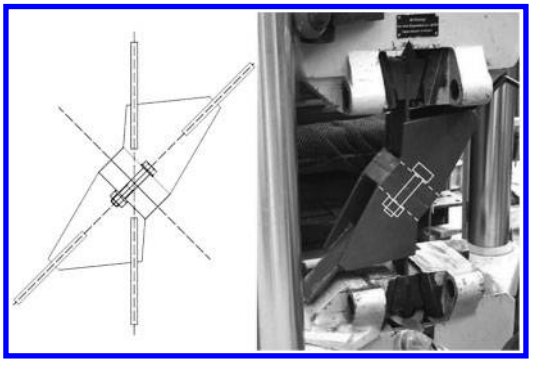

Figure 9. Test setup for tests under 45° and under pure tension (0°); schematic drawing and set up in tension machine (Renner 2012).

3.1 *Test setup*

A test setup was constructed that allows tests on real bolts in a realistic situation as would be found in a connection.

To be able to test only one bolt at a time the test arrangement was built as a U-stub, see Figure 8: The bolt is fixed between two head plates, which will be pulled apart at their sides.

To test a specific tension-to-shear-ratio the head plates are pulled under a certain angle by two plates that were fixed between the load introduction side plates, and which can be clamped into a tension machine, see Figure 9.

The prepared test setups could be used for two different angles each. It was chosen to test four different angles (15°, 30°, 45° and 67.5°) plus pure tension and pure shear. It was further decided to conduct an additional shear test with two shear planes.

Both bolts with thread and with shank in the shear plane were tested. From both types a low strength and a high strength bolt was chosen. For the high strength bolts with shank in the shear plane an additional test series was conducted with pre-loaded bolts to see whether this has any influence on the behaviour. All so far conducted tests are listed in Table 2. Table 3 lists all relevant test parameters.

Table 2. Conducted tests.

	Tension 0°	15°	30°	45°	68°	shear 90°	shrear 2 planes
Bolts with thread in shear plane:							
4.6	4	3	3	3	3	4	4
8.8	3	3	3	3	3	3	3
Bolts with shank in shear plane:

Testing rate:	2 to 5 mm/min
Test until failure	

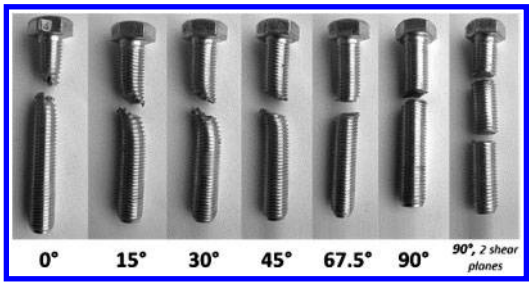

Figure 10. Grade 8.8 bolts with thread in shear plane after failure (Renner 2012).

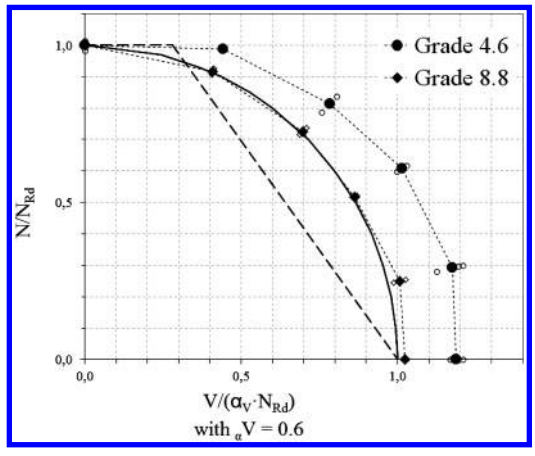

Figure 11. Test results for bolts with thread in the shear plane, related to pure tension and recalculated pure shear capacity.

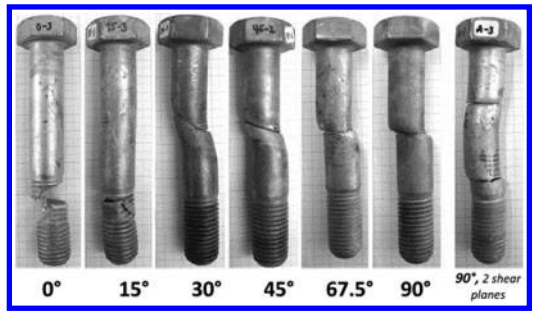

Figure 12. Grade 10.9 bolts with shank in shear plane after failure (Renner 2012).

3.2 *Test results*

All Bolts were loaded until failure. The resulting maximum load was divided into its tension and its shear part.

To plot the results into an interaction diagram the total values have to be related to the maximum pure tension and maximum pure shear load.

For threaded bolts the middle value of the maximum load from the pure tension tests can be used directly as reference value. It was further decided not to use the measured pure shear load for comparison, but to determine the reference value by multiplying the maximum tension load by the shear-to-tension reduction factor α_v given in the Eurocode, which is 0.6 for all tested bolts. This way the comparison to the standard rules is directly given.

Figure 11 shows the result for threaded bolts. In case of pure shear only the results of the two-shear-plane test are plotted here. A bolt tested under pure shear with only one shear plane gets higher load bearing results due to the inclination of the bolt under large deformations which makes the results useless for comparison.

For comparison there is also a quadratic and a bi-linear function as given in the Eurocode plotted into Figure 11. It is obvious that the test results of the bolts grade 8.8 matches the old quadratic function astonishing well. The test results for grade 4.6 are even on the safe side of it, which is due to the factor α_v which is on the safe side for low grade bolts. Apart from this, the resulting curve here is also perfectly quadratic.

For the bolts with a shank the pure tension capacity was recalculated to the capacity of the shank cross area. The results are plotted related to this value in Figure 13.

The bolts that were tested under pure tension and under an angle of 15° did not fail in the shank but in the thread, which has a cross section of 0.78 times the cross section of the shank. The interaction curves have to be limited at this value.

Figure 13 shows in grey a quadratic and bi-linear function for the interaction in the shank. As mentioned in 1.2 the Eurocode does not provide a possibility to consider the tension capacity of the shank, so

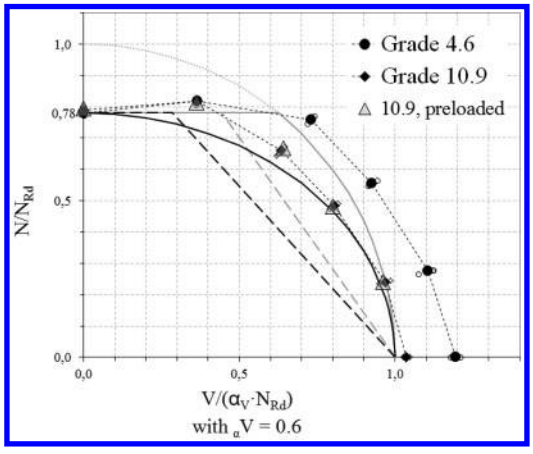

Figure 13. Test results for bolts with thread in the shear plane, related to pure tension and recalculated pure shear capacity of the shank.

the gray bi-linear function is just an adoption of the Eurocode rule. The two black comparison curves mark the non-existing case of interaction considering the shear capacity of the shank and the tension capacity of the thread.

The results in Figure 13 show that for both bolt grades 4.6 and 10.9 the Eurocode function (black bi-linear) lays by far on the safe side. The curve of the 4.6 bolts matches quite well with a quadratic function, here, again, it occurs that the α_v is lower than it could be for low strength bolts.

Nonetheless, the results of bolts with a grade 10.9 lay obviously below the quadratic function. It occurs that for high strength bolts the assumption of a full plastic utilisation of the bolt section is wrong. Due to the material being not as ductile as low strength steel the full plastic stage cannot be reached and the bolt loaded with a combined load fails before.

Figure 13 also shows the results of the tests on pre-loaded bolts. It shows that pre-loading has no influence at all on the load bearing behaviour.

The results of some of these tests can also be found in more detail in a previous paper, see Renner 2012.

4 CONCLUSION

A new test series helps to understand und judge the behaviour of bolts under a combined load of tension and shear. It shows that the long-time common assumption of a quadratic relation for the bolt interaction is not right for high strength bolts, which cannot reach a full plastic stage under a combined load. But for bolts of a lower grade the quadratic assumption fits perfectly well.

The approach of the Eurocode to change the interaction rule for bolts into a by far more conservative version is to a certain extent justified, but the rule that came out of this is too conservative even for the bolts concerned, let alone the bolts of a lower grade, for which a change of the rule was unnecessary. The new Eurocode rule does not allow a consideration of the tension capacity of the shank, if it lies in the shear plane, which makes it even more uneconomic. It stays to question whether it is wanted to stick with a simple one-fits-all rule that is in most of the cases inefficient, or to allow a more detailed treatment in future.

E. Y. Sayed-Ahmed
American University in Cairo – Professor (on leave), Ain Shams University, Egypt

ABSTRACT: Increasing the joint capacity of tubular structures has always been a challenge for designers because of their closed nature. This paper investigates a new technique for strengthening the circular chord at the T-joint location against ovalization when subjected to brace member compression loads. The strengthening technique is based on bracing the chord member by radial through bolts with different arrangement patterns. A parametric numerical study based on the finite element method is carried-out. Effects of the chord diameter, brace diameter-to-chord diameter ratio (β), number of bolts, and spacing between them are numerically analyzed. The study revealed that high efficiency for the through bolts technique can be reached with small chord diameter and large β values. A maximum gain in strength of 41% is achieved for a T-joint strengthened with four bolts spaced at 50 mm. It is also found that for large spacing values, odd number of bolts with a central bolt is more efficient in strengthening the CHS T-joints.

1 INTRODUCTION

Various methods for strengthening hollow structural sections (HSS) were introduced over the past decades. The most known method is the "can" method, where the chord is partially thickened at the joints. The can must be accounted for in the design stage of the joint, similar to welding ring stiffeners, diaphragms, doubler plates, or concrete filling. Doubler plate is directly welded to the brace member through penetration weld and then welded to the chord using fillet weld. Another strengthening technique is the collar plates, which are fitted and welded to the chord around the fabricated joint forming the "collar" shape.

Choo et al. (2005) conducted a series of studies on uniplanar T-joints with different parameters such as type of loading (i.e. brace tension or compression), strengthening method (i.e. collar or doubler plates), and different brace diameter-to-chord diameter ratios (β). The study showed that using doubler or collar plates with $\beta = 0.54$ increased the brace compression by 39% and brace tension by 16%. Whereas, for $\beta = 0.28$ strength gain increased by 53% for brace compression and 28% for brace tension.

Banes (1983) and Bradfield et al. (1994) were among the first to use through bolts in rectangular hollow section (RHS) chord members. Holes were first drilled in the vertical walls and bolts were inserted through one end then anchored at the other wall to prevent the chord webs from buckling, which increased the static strength of RHS joints. This led to a maximum increase of 18% in the joint capacity. Zhao (1999) suggested that a wooden block to be inserted into the RHS in addition to the through bolt to also prevent the inward buckling.

Aguilera et al. (2012) investigated the effect of the number and pattern of bolts, as well as the web height-to-wall thickness ratio (h/t) of the chord. An experimental study was conducted for the above parameters. The percentage gain in strength using 15 bolts increased from 3.1% to 29% for h/t ratios ranging from 34 to 65. The study showed that the number and pattern of bolts did not have a major effect on the strength gain for the selected bolts.

Sharaf & Fam (2013) conducted a parametric study using numerical analyses to investigate the effect of chord depth-to-width ratio, brace breadth-to-chord depth ratio, chord span-to-depth ratio, welding the through bolts to chord's web, and the boundary conditions of the chord. The results showed that welding the through bolts affected the ductility of the joint significantly. The strength gain in the joint with welded bolts is 32%, while the strength gain with unwelded bolts is 25%. Aguilera & Fam (2013) also investigated the effect of chord preload on the strength gain. The results showed strength increase of joints by 38%,

46% and 38% when the axial compression loads in the chord were zero, 45% and 80% of its axial strength, respectively.

This paper numerically investigates the effect of through bolts in strengthening circular hollow sections (CHS) T-joints using finite element modeling.

2 NUMERICAL MODELING AND VERIFICATION

A finite element model is developed for the circular hollow sections (CHS) T-joints. Prior to adopting the model for the intended parametric study, three independent experimental studies are used to verify the results of the proposed numerical model. These experimental studies were performed by Zhao & Hancock (1991), Choo et al. (2005), and Aguilera et al. (2012). The finite element program ANSYS (14) is adopted for pre-processing, equation solution and post-processing of the model results. A brief description of the elements used, material modeling, and verification of the model is discussed in the following sections.

2.1 *Element types and material modeling*

Figure 1a shows the structural shell element (SHELL 181) used to model the chord and brace members. SHELL181 is a four-node element with six degrees of freedom at each node. This element is suitable for analyzing thin to moderately-thick shell structures and well-suited for linear, large rotation and large strain nonlinear applications. Shell thickness option is applied to account for the bending stiffness in the walls. Element size is chosen equal to 25 mm and is kept constant for the whole specimen. Figure 1b shows the 3D spar (LINK180) used to model the through bolts. The element is a uniaxial tension-compression element with three degrees of freedom at each node: translations in the nodal x, y, and z directions. Tension-only and compression-only options are supported. As in a pin-jointed structure, no bending of the element is considered. Plasticity, rotation, large deflection, and large strain capabilities are included. Since the chord's web is free to buckle inwards, tension only option is chosen.

The stress-strain curves of all specimens are modeled using a bilinear isotropic hardening plasticity model with a tangent modulus ($E_t = E/100$). In specimens tested by Aguilera et al. (2012) the tangent modulus (E_t) was taken equal to E/1000 with the exception of two specimens (T13 and T14), where a multi linear isotropic hardening plasticity model was adopted to accurately simulate the presented material properties. A bilinear isotropic hardening plasticity model was implemented to model the high-strength bolts with yield and ultimate strengths of 894 and 1034 MPa, respectively.

2.2 *Model Verification*

Due to symmetry only one half of the specimen is modeled. In order to account for the most critical buckling mode, an elastic Eigen buckling analysis is initiated, and the specimen geometry is then updated to simulate the geometric imperfections. A scale factor of 0.2 mm, which is equal to one thousands of the chord height (h/1000), is chosen for the imperfections simulation.

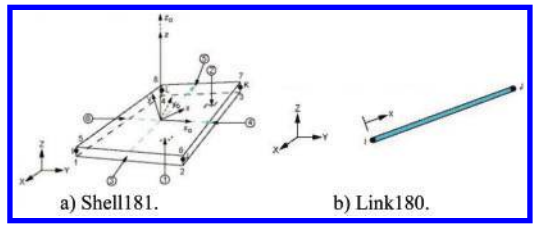

Figure 1. Elements used in the numerical analysis.

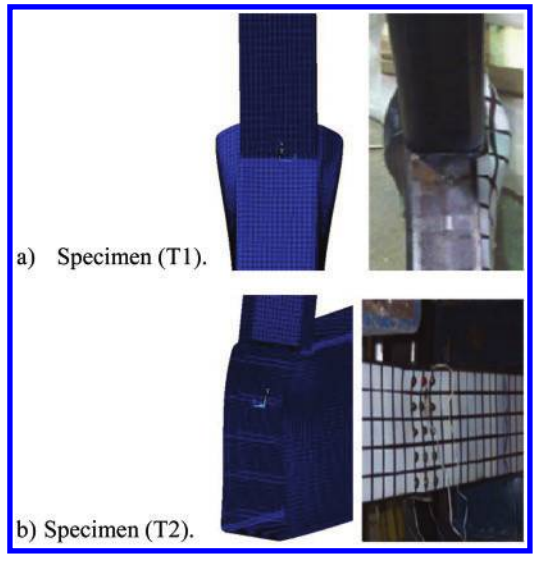

Figure 2. Comparison between failure modes of the FEM and experiments done by Aguilera et al. (2012).

Figure 2 shows the failure modes of specimens T1 & T2 resulting from the numerical model compared to those experimentally recorded by Aguilera et al. (2012). Figure 3 shows the failure modes and load-ovalization curves of specimens Ex-01 & Ex-10 resulting from the numerical model compared to those experimentally recorded by Choo et al. (2005).

A summary of the numerical model verification results in terms of the load at failure is presented in Table 1: it shows a minor discrepancy between the experimental and numerical results with an average of 1.00 and a standard deviation of 0.03.

As such, it can be concluded that the FE model provides realistic results and can capture the real behavior of the specimens. The model is considered suitable and dependable for the parametric study that follows.

3 PARAMETRIC STUDY

A parametric study is conducted using the verified numerical model. The study is performed on CHS

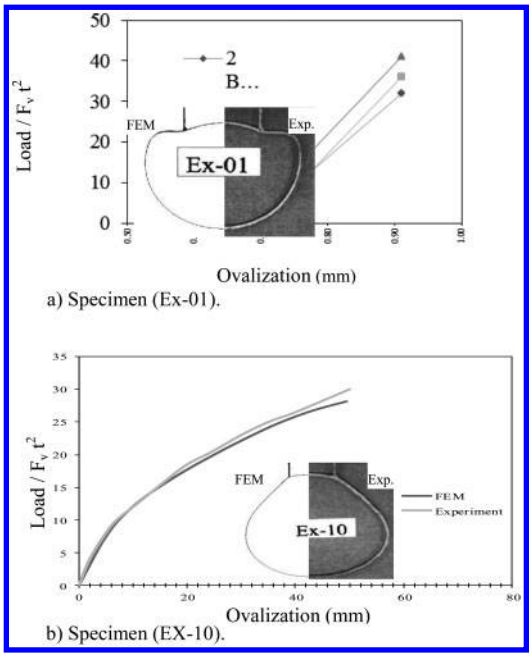

Figure 3. Comparison between failure modes of the FEM and experiments done by Choo et al. (2005).

T-joints strengthened using through bolts and subjected to brace compression force. The effects of the through bolts on the gain strength and reduction in chord ovalization are investigated. The chord ovalization is defined as the difference between the vertical deformations of points A & B, as shown in Figure 4.

Two sizes are selected for the chord members. The first size is of a diameter (d_{rmo}) equals to 356 mm and a thickness (t_o) equals to 6.35 mm, which gives diameter-to-thickness ratio (d_o/t_o) of 56.06. The second size is selected to provide almost the same (d_o/t_o) ratio of 54.80; it is of a diameter (d_o) equals to 610 mm and a thickness (t_o) equals to 11.13 mm. The chord length-to-chord radius ratio ($\alpha = 2L/d_o$) is taken equal to 8.99 (i.e. $L = 1600$ mm for $d_o = 356$ mm and $L = 2742$ mm for $d_o = 610$ mm). The radius-to-thickness ratio ($\gamma = d_o/2t_o$) is kept as constant as possible (i.e. $\gamma = 28.03$ for $d_o = 356$ mm and $\gamma = 27.40$ for $d_o = 610$ mm).

Six brace members are selected, three with each chord size. First group of brace members has diameters (d_1) of 219 mm, 273 mm and 324 mm and is used with chord diameter of 356 mm. These brace members provide different β ratios of 0.62, 0.77 and 0.91, respectively. The second group of brace members has diameters (d_1) of 406 mm, 508 mm and 559 mm and is used with chord diameter of 610 mm; they provide β ratios of 0.67, 0.83 and 0.92, respectively. The length of brace member is kept constant at 500 mm. All brace members are chosen with thick walls (11.13 mm) to avoid premature brace failure.

The load is applied as a point load on a thick plate at the top end of the brace member to ensure uniform

load distribution. The chord is rested on a half circle supporting saddle with an inner diameter equals to the outer diameter of the chord member. The saddle length is 300 mm; a vertical stiffener is fitted inside the chord member along the entire length of the saddle, as shown in Figure 4.

Due to symmetry, only one half of the specimen is modeled. The brace and the chord members are assumed to be welded using a full penetration weld

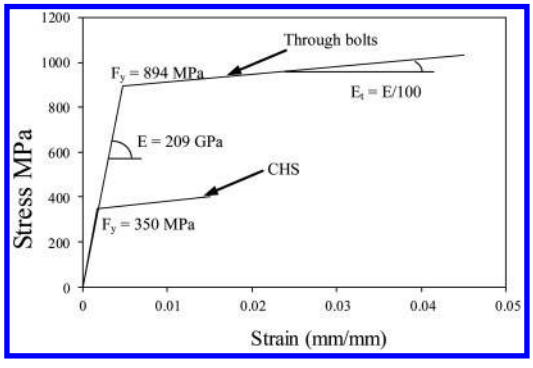

Figure 5. Stress-Strain curves for steel materials.

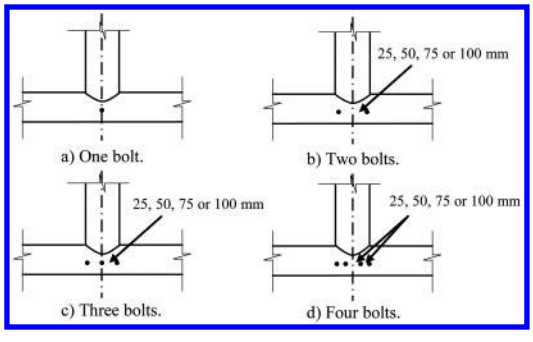

Figure 6. Number and configurations of bolts.

through the entire thickness of the member. Therefore, no additional elements are modeled to simulate the welding material. Yield strength is assumed to be 350 MPa and young's modulus of 209 GPa. Figure 5 shows the stress-strain curves for both the CHS and the through bolts.

A total of 84 specimens are considered in this parametric study: two groups each of 42 specimens. Each group consists of control specimen and 41 strengthened specimens.

The number of through bolts (n) studied is from one to four bolts. The arrangement of the bolts is always symmetric around the joint centerline. Different spacing values (s) between the through bolts along the centerline of the chord are considered (25 mm, 50 mm, 75 mm and 100 mm), as shown in Figure 6.

The following designation system (d_o-d_1-n-s) is considered in the parametric study. The first two numbers are for the diameter of the chord (d_o) and brace member (d_1) respectively, succeeded by the number of bolts (n) followed by the spacing between the bolts (s). For example, 356-219-3-075 designates a specimen with a chord diameter of 356 mm and a brace diameter of 219. The specimen has three bolts spaced at 75 mm. The specimens with zero number of bolts resemble the unstrengthened control specimens.

4 RESULTS

A summary of the results is given in Tables 2 and 3 for groups 1 and 2, respectively. Group 1 specimens are for chord diameter of 356 mm and thickness of 6.35 mm with brace members of 219 mm, 273 mm and 324 mm, while Group 2 specimens are for chord diameter of 610 mm and thickness of 11.13 mm with brace members of 406 mm, 508 mm and 559 mm.

4.1 *Effect of number of through bolts*

Figure 7 shows the load versus ovalization curves for specimens 356-324-n-050 strengthened with one, two, three, and four bolts at spacing of 50 mm. The figure indicates that the gain in strength increases with increasing the number of through bolts. The results illustrated in Table 2 show that for spacing between

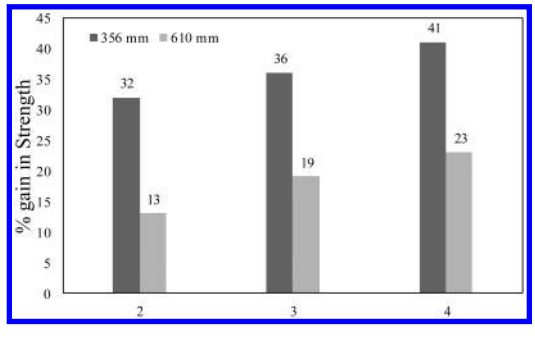

Figure 9. Percentage gain in strength versus number of bolts for two chord sizes 356 mm and 610 mm for 50 mm spacing (d_o-d_1-n-050).

bolts equals to 50 mm, the gain in joint strength is 21%, 32%, 36% and 41% for one, two, three, and four bolts, respectively.

4.2 *Effect of spacing between through bolts*

Figure 8 displays the percentage gain in strength versus the spacing between bolts for specimens 356-324-n-s strengthened with one, two, three, and four bolts. Figure 8 shows that a difference between the trends of the strength gain exists when using odd and even number of bolts. For small values of spacing (i.e. $s < 65$ mm), the trend in strength gain is consistent and in correlation with the number of bolts. For large values of spacing (i.e. $s \geq 65$ mm) the highest gain in strength cannot be achieved without a central bolt under the centerline of the brace member at the vicinity of the joint (i.e. odd number of bolts). The highest gain in strength may be estimated at spacing values of 30 mm, 50 mm, and 75 mm for specimens strengthened with 2, 4, and 3 bolts, respectively.

4.3 *Effect of chord diameter*

The results in Tables 2 and 3 reveal that increasing the diameter of the chord led to an increase in the joint

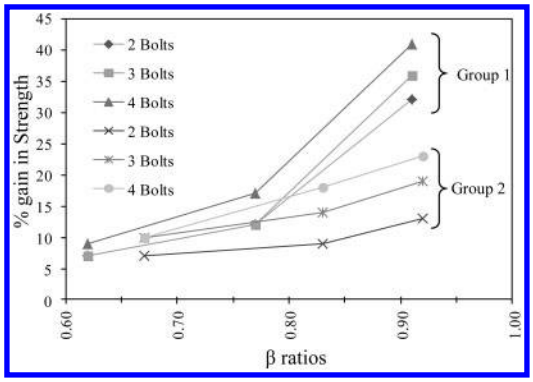

Figure 10. Percentage gain in strength versus different β ratios for 50 mm spacing for different bolts configuration (specimen d_o-d_1-n-050).

capacity. The diameter of the through bolts is kept constant; accordingly the bolts couldn't prevent the ovalization completely. However, increasing the number of bolts led to an increase in the strength gain. Figure 9 shows a comparison between the two sizes of chord (356 mm and 610 mm) for different number of bolts with the same spacing value of 50 mm.

4.4 *Effect of β ratio*

The results presented in Tables 2 and 3 show that β ratio has a significant effect on the gain in strength. Figure 10 shows the percentage gain in strength versus different β ratios for 50 mm spacing between bolts. In Group 1, the percentages gain in strength for specimens strengthened with four bolts are 9%, 17%, and 41% for β ratios of 0.62, 0.77 and 0.91, respectively. Similarly, in Group 2 the percentages gain in strength are 10%, 18%, and 23% for β ratios of 0.67, 0.83 and 0.92 for specimens 610-d_1-4-050, respectively.

5 CONCLUSIONS

This paper numerically investigates the effect of strengthening CHS using through bolts to prevent the ovalization of the chord under brace axial compression load. The study is carried out using ANSYS (14) program. The model is verified against independent experimental studies. The model accounts for geometric and material nonlinearities. It successfully provided realistic results. Accordingly, a parametric study is carried out to find the most suitable configuration for the through bolts, and the most suitable brace diameter-to-chord diameter ratio (β). The results are summarized as follows:

1) Increasing the number of through bolts has a significant effect on the percentage gain in strength. The maximum recorded gain in strength is 41% (specimen 356x324-4-050).
2) For large spacing values ($s \geq 65$ mm), a central bolt under the brace member centerline is very important to maximize the joint strength.
3) For the same configuration of through bolts, the smaller the chord diameter the more efficient the strengthening technique.
4) The larger the brace diameter-to-chord diameter (β) ratio, the more efficient the through bolts technique in strengthening CHS T-joints.

In-plane shear flexibility evaluation of fastened steel flat plate by numerical simulation considering the interaction between connectors and thin plate

F. Bakhti & R. Tremblay
École Polytechnique de Montréal, Montréal, Canada

C.A. Rogers
McGill University, Montréal, Canada

ABSTRACT: This paper presents finite element analysis performed to examine the shear stiffness of steel roof deck diaphragms. The diaphragms are made from 914 mm wide corrugated steel deck panels with screwed side lap connectors and power actuated fasteners to the underlying frame. A flat sheet finite element model was first developed in which the response of the fasteners could be isolated from the influence of the warping deformations of the corrugated deck panels. A representative sub-panel configuration in terms of fastener spacing, fastener pattern and panel size was modeled and subjected to in-plane shear loading. The results show the presence of an interaction between the pure shear and the connectors' flexibilities, and the total in-plane flexibility of the connected panel, which can be defined as a function of three component flexibilities: shear strain of the plate, slip of the plate on support members at fastener locations and a corrected flexibility that accounts for the interaction between the panel and its connections.

1 INTRODUCTION

The in-plane shear stiffness of connected thin-walled metal structures, which are widely used for roof decking, cladding and shear walls, is of interest to the structural engineer. The analysis of these structures is one of the challenging problems in structural engineering. For example, the predication of the fundamental period of vibration of a typical low-rise steel framed building is directly dependent on an accurate determination of the shear stiffness of its cold-formed steel corrugated roof deck diaphragm (Tremblay et al., 2008).

The two commonly used diaphragm design standards, SDI (Luttrell, 2004) and ECCS (Davies, 2006), are semi-empirical in terms of shear flexibility calculations, which rely on an evaluation of the pure shear, fastener and warping deformations separately without accounting for any interaction. The total in-plane shear flexibility is given by a simple summation of these flexibilities. The fastener type, stiffness and pattern directly affect the response of the diaphragm. A noteworthy empirical method is also available (Tri-Services, 1982) which is still in use in the industry (CSSBI, 2006) for specific connection configurations. In this approach an interaction between the flexibility of the fasteners and the warping deformation is included. Dynamic testing of steel roof deck diaphragms has shown that the predicted in-plane shear stiffness G' using current design methods can be 1.5 higher than that measured in the laboratory (Massarelli et al., 2012).

To understand the behaviour of the connected roof deck panels under in-plane shear loading, the stiffness and the stress developed on them should be known. In the case of continuous fasteners, the analysis of the stiffness and stresses is feasible. However, if the connections are discrete, the prediction of the stiffness and stress becomes more challenging. In this paper, the shear flexibility calculation procedure for steel deck diaphragms revisit numerically considering specifically the connections and the pure shear deformations of the steel panels. The SDI method is referred to as background to the investigation. The presence of an interaction between the connection slip and pure shear flexibilities is investigated by means of finite element analyses.

2 NUMERICAL ANALYSIS

2.1 *Background*

The diaphragms studied are made of 0.91 mm thick, 914 mm wide corrugated panels with screwed side lap connectors and power actuated fasteners to the underlying frame. To eliminate warping deformations from the study, the corrugations were removed and only a flat panel was studied. Cantilever diaphragms composed of one deck panel connected to edge beams

with two fastener configurations were studied (Fig. 1). For the first configuration, the plate was continuously fixed along its perimeter, while for the second configuration a discrete number of connections with different fastener types, stiffness and patterns (Fig. 2) were investigated. The diaphragm length, L_v, corresponds to typical joist spacing.

According to the SDI method, the in-plane shear flexibility due to the pure shear deformations, F_s, and to the connectors, F_c, is expressed by:

$$F_{sc.SDI} = F_s + F_c = \frac{2(1+\nu)}{Et}\frac{w}{L_v} + \frac{2}{(2\alpha_1 + n_e)K_f} \quad (1)$$

The pure shear flexibility is obtained according to the SDI (Luttrell, 2004) and ECCS (1977) methods and corresponds to the theoretical value. The connection slip flexibility, F_c, is evaluated according to the SDI method assuming a rigid plate. In these equations:

- P Shear load (P = 1 kN)
- L_v Diaphragm depth in the direction of loading (L_v = 1525 mm o/c)
- w Panel width between fasteners (w = 912 mm)
- n_e Number of intermediate sheet-to-structure connections along depth at the diaphragm edge (excluding ends)
- n_v Number of frame fasteners at the ends (over w_{sh}, including ends)
- K_f Fastener shear stiffness, deck-to-structure
- α_1 End distribution factor with summation across a full width panel w_{sh} of the panel; is determined assuming linear distribution of the internal force (Table 1) according to the fastener patterns shown in Fig. 2.

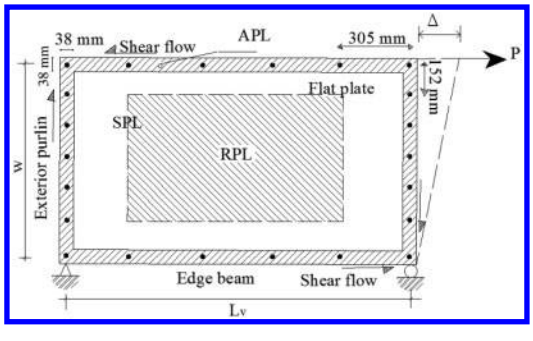

Figure 1. Typical cantilever diaphragm under monotonic shear load with connected flat plate.

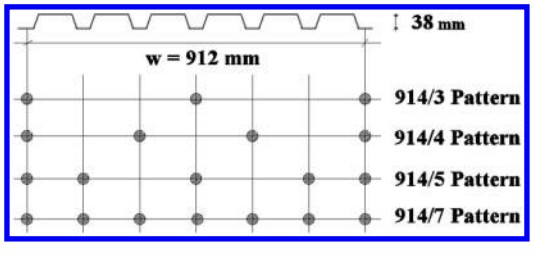

Figure 2. Frame fastener patterns, Canam panel P3606.

- E Young's Modulus (197 GPa)
- ν Poisson's ratio (for steel $\nu = 0.3$)
- t panel thickness (t = 0.91 mm)

The prediction of the overall response of the diaphragm is relevant to assess accurately the stiffness of the individual fastener, K_f, which influences the distribution of the internal forces (De Matheis, 1998). Semi-empirical formulations in North America and Europe are available to provide the equivalent elastic stiffness of connections for thin steel elements depending on the thickness. When the support thickness is greater than 1.21 mm (Sputo, 2010), the SDI (2004) equation for the stiffness K_f is expressed by:

$$K_f = 1000 c_f \sqrt{t} \quad (2)$$

where c_f is a coefficient that depends on the type of fastener.

2.2 *Finite element analyses*

2.2.1 *Numerical modelling*

Finite element analysis was carried out using the program Abaqus (2012). Diaphragms were subjected to applied in-plane shear loading lower than the critical buckling load such that out-of-plane deformations would not arise. Consequently, linear analyses were performed assuming linear material response and small displacements. The flat plate was discretized (Fig. 3) using four node shell elements (S4) having five degrees of freedom per node and five integration points, using Simpson's rule, over the thickness. The frame members which supported the panel were modelled using beam elements. The frame fasteners were modelled using zero length connectors with six degrees of freedom: two translational linear springs in the plane of the panel, one translational rigid spring out of plane of the deck and three rotational rigid springs. The deformations of the plate at the connection were not modeled in the connector, because the study was concerned with the relationship between the connector stiffness and the elastic stiffness K_o corresponding to the deformation of the plate at the connector vicinity due to the stress concentration.

2.2.2 *Finite element modelling assumptions*

The following assumptions were adopted for the finite element model:

– All edge framing was relatively stiff compared to the deck;

Table 1. α_1 factor modified values for each fastener pattern.

Fastener Pattern	α_1 (Modified)
914/3	1.000
914/4	1.111
914/5	1.444
914/7	1.555

– All edge framing connections were considered to be perfect pins to ensure complete shear transfer to the connected panel;
– The frame fasteners at the edge beams and purlins have unidirectional stiffness in the direction of loading (assuming that the direction of the corrugated panels is parallel to the direction of loading) according to the SDI method.

2.2.3 *Behaviour of mechanical fasteners*

The deformation of deck-to-frame connections under shear loading can be taken as the sum of the connector deformation and the localized deformations in the deck panel in the vicinity of the connection. Accordingly, the frame fastener stiffness K_f can be computed assuming two springs acting in series:

$$K_f = (K_0 + K_c)/K_0 K_c \quad (3)$$

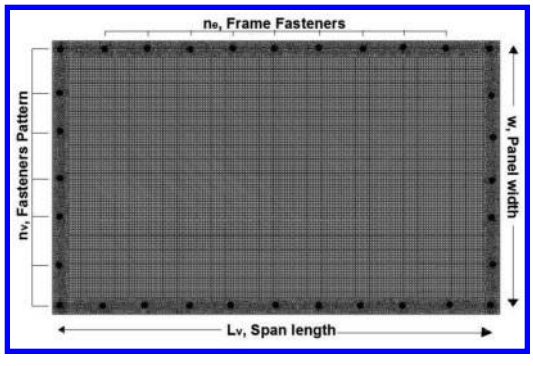

Figure 3. Discrete model of the connected flat plate.

where K_c is the connector stiffness and K_0 is the stiffness associated to plate deformations. Understanding this behaviour is essential when assessing diaphragm in-plane shear stiffness of the fasteners with finite element models such as the one used in this studied. In particular, the evaluation of the panel area affected by the connector, which affects the stiffness K_0, requires careful calibration.

The test setup (Rogers and Tremblay, 2003) used to determine the shear stiffness of frame connectors is shown in Fig. 4a. These tests were reproduced using finite element analysis to characterize the panel deformations (Bakhti et al., 2012). In these tests, the specimens had lateral stiffeners, had a width of 70 mm and the deformations were measured over a gauge length of 100 mm. As shown, non-uniform tension and compression stresses (Fig 4b) and shear stresses (Fig. 4c) develop on either side of the fastener. For 0.91 mm thick steel panel, the results indicate that the elastic stiffness K_o is approximately equal to 150 kN/mm. Calibration was also performed using data from similar tests carried out by De Matheis (1998) on un-stiffened 50 mm wide coupons having the same thickness and the same 100 mm gauge length. In that case, the elastic stiffness K_o was found to be 124 kN/mm, i.e., 17% less than the value determined from Rogers and Tremblay tests.

In Fig. 6, the non-linear load *vs.* displacement curve of a single connection, including deck deformations at the connector vicinity can be represented by Curve 2. The initial elastic stiffness of the connection corresponds to the stiffness K_f assessed by the SDI method. For a linear analysis, the curve follows that elastic stiffness. Knowing K_0, the connector stiffness K_c

Behaviour at the connection of the connected flat plate (corner part of the diaphragm) [Stress: N/mm^2]: a) Tension (ts.) and compression (cp.) at the connection in the direction of loading, b) Ts. and cp. distribution at the connection in the perpendicular direction to the loading, c) Shear stress distribution at the connection.

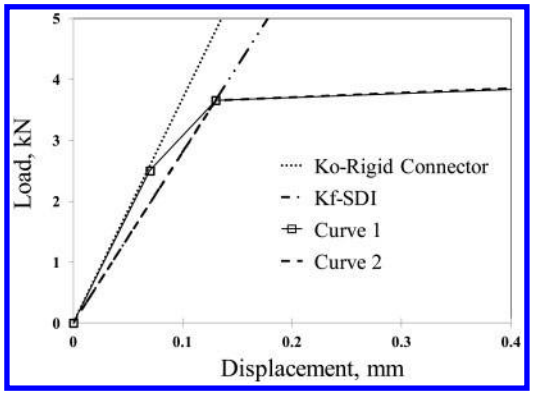

Figure 6. Typical curve for frame fastener calibration.

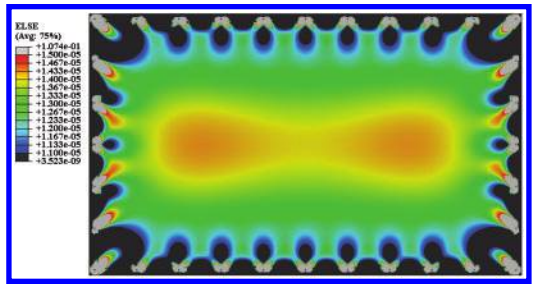

Figure 7. Elastic strain energy (N-mm) distribution on the connected thin flat plate.

can be back calculated using equation 3. The more realistic Curve 1, however, represents the non-linear behaviour of a single connection including the initial higher stiffness due to friction prior to connection slip (De Matheis, 1998). For diaphragms subjected to in-plane shear load with an internal force lower than the slip load, the connector deformation is assumed to be zero and the connection stiffness corresponds to K_0. Therefore, the discrete fixed flat plate is similar to the connected panel, due to the deformation of the plate at the fastener vicinity. For this reason, the stiffness of the connection K_f of the discrete fixed plate is equal to the elastic stiffness K_o of the deck.

For diaphragms with a fixed flat plate over the entire perimeter, the distribution of the shear stress is uniform everywhere on the plate. However, for diaphragms with discrete fasteners along the edges (Figs. 1 & 3), stress concentration occurs at the vicinity of the connectors and the distribution of the shear stress is not uniform (Fig. 5), which is significantly different from the first case. In the model, 5 mm diameter stiff regions representing the fastener shanks are used to represent more realistically this response. The behaviour at the connection during a numerical calibration of the fastener based on the test (Fig. 4) is very similar to the connection response in the connected flat plate (Fig. 5), except for the delimited area of the deformed plate at the connector vicinity, as discussed in Section 3.3.

3 ANALYSIS RESULTS

3.1 *Effect of the fastener configuration on the shear flexibility of the reduced plate*

This section explores plate areas potentially affected by the connector stiffness, pattern and spacing. The reduced plate (RPL) in Fig. 1 illustrates the zone not affected by the fastener stiffness, due to the distance from the connections. It is taken as the rectangular area having 40% of the area inside the fastener lines (912 × 1525 mm) of the entire plate EPL. In order to provide more information about the distribution of the shear in the plate, a parametric study was performed. In Fig. 7, non-uniform distribution of the element strain energy (ELSE) is shown, with the maximum values at the connections. The reduced plate RPL is located in the central zone for which the ELSE is approximately uniform.

For a shell element, the strain energy for elastic behaviour is defined as follows:

$$U_e = \frac{1}{2}\{\sigma\}^T\{\varepsilon\}tA_e \quad (4)$$

where $\{\sigma\}^T$ is the transpose stress vector, $\{\varepsilon\}$ deformation vector and A_e the area of the shell element. Therefore, the total strain energy of the reduced plate RPL is given by $U_{RPL} = \sum_{RPL} U_e$.

The elastic strain energy of a connector element is expressed as follows:

$$U_c = \frac{1}{2}K_c\delta_c^{\,2} \quad (1)$$

where δ_c is the slip connector. For the 912 × 1525 mm diaphragm with 0.91 mm deck thickness and 1 kN loading, the total elastic strain energy of the entire plate (EPLF) having continuous fixity to the edge members, U_{EPLF}, is equal to 4.34 N-mm. Therefore, the total elastic strain U_{RPL} of the reduced plate RPL with the 608 × 915 mm size depends only on the area ratio, i.e., $U_{RPL} = 40\%\ U_{EPLF}$.

Parametric studies on the connected plate under shear loading according to different connector stiffness K_c were performed. The fastener pattern and spacing was also varied. The ratio U_{RPL}/U_{EPLF} was first determined for the various fastener configurations. In Fig. 8, the U_{RPL} values for the discrete connected panels are always larger than 40% of U_{EPLF}. Larger elastic strain energy corresponds to larger shear deformations, indicating that the flexibility of the reduced plate region is higher than in the continuously fixed case. Examination of the results of the numerical simulations shows that at least 92% of the total strain energy of the reduced plate U_{RPL} is caused by shear stresses alone, meaning that the pure shear flexibility of the reduced plate far from the connectors is affected by the fastener configuration, even when the shear behaviour is nearly uniform. As expected, the

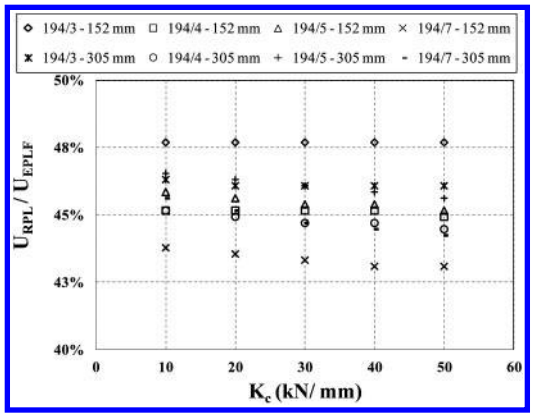

Figure 8. Connector stiffness impact on the shear deformation of the reduced plate.

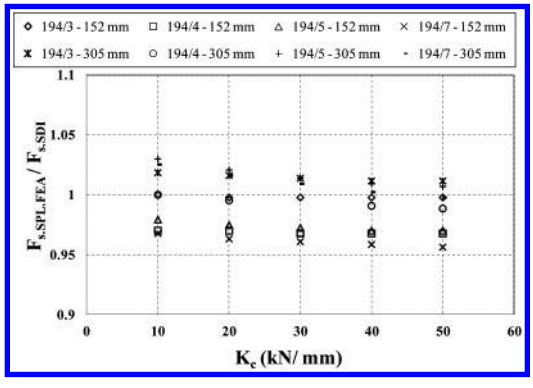

Figure 9. Connector stiffness impact on the shear flexibility.

U_{RPL}/U_{EPLF} ratios are not affected by K_c but they never reach the 40% value because of the discrete fastener arrangement.

3.2 *Effect of the fastener configuration on the shear flexibility*

This section presents the impact of the fasteners configuration with flexible connectors on the shear deformation. In order to avoid double counting the elastic stiffness, K_o, in both pure shear and connection flexibilities, and due to the uncertainty in defining the area at the connection, two trial zones were defined. In Fig. 1, the first is the affected plate zone (APL) containing all the connectors close to the edge of the entire plate. The APL may take into account all the deformed plate at the connector vicinity due to the stress concentrations. The second is the non-affected plate zone (SPL) that corresponds to entire plate area minus the APL zone. The SPL zone is 38 mm inset from the edge of the plate, i.e. 19 mm on either side of the fasteners, which resulted in an area 93% of the EPL area. This area was designed to take into account the shear deformation as the total strain energy dominated

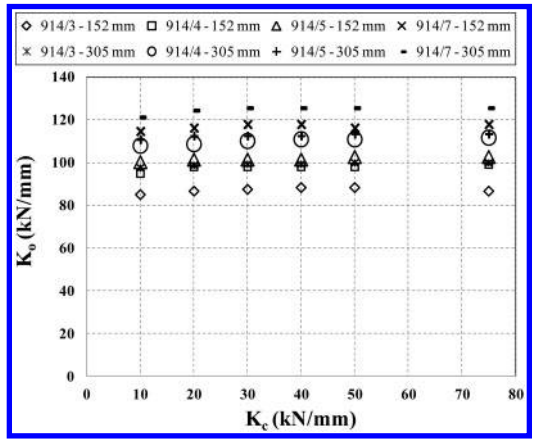

Figure 10. Impact of the connector spacing on the stiffness K_0.

by shear deformations. The corresponding shear flexibility for the SPL was computed using finite element analysis results using $F_{s.SPL.FEA} = 2U_{SPL}/P^2$. Figure 9 shows that $F_{s.SPL.FEA}$ is close to the shear flexibility from SDI, $F_{s.SDI}$, determined with equation 1. The ratio $F_{s.SPL.FEA}/F_{s.SDI}$ is generally not affected by K_c and varies only slightly with the fastener pattern and spacing.

3.3 *Effect of the fastener configuration on the slip flexibility*

The flexibility of the APL zone was obtained from $F_{s.APL.FEA} = 2U_{APL}/P^2$, where U_{APL} is the total strain energy from finite element analysis in APL. From this flexibility, the stiffness K_o was then deducted from equations 1 where K_f had been replaced by K_0. The results are shown in Fig. 10.

The stiffness K_o does not vary with K_c; however, it appears to be strongly affected by the connector spacing. The value of K_o varies between 80 and 120 kN/mm. A similar evaluation using an 60 mm wide affected plate zone (APL) revealed the same trend.

3.4 *Effect of the connector stiffness on the total flexibility*

In order to examine a possible interaction between shear and connection flexibilities, numerical simulations were performed to study the shear and the connector deformations together. The total flexibility, $F_{sc.FEA}$, from the analysis was compared with that calculated using the SDI method, $F_{sc.SDI}$. For the latter, the value of K_f was determined form equation 3 with the values of K_c assigned in the finite element analysis and $K_0 = 150$ kN/mm, reflecting the results of the numerical calibrations from individual connection tests. In Fig. 11, the flexibility assessed by the SDI method varies between approximately 92% and 100% of the values obtained numerically.

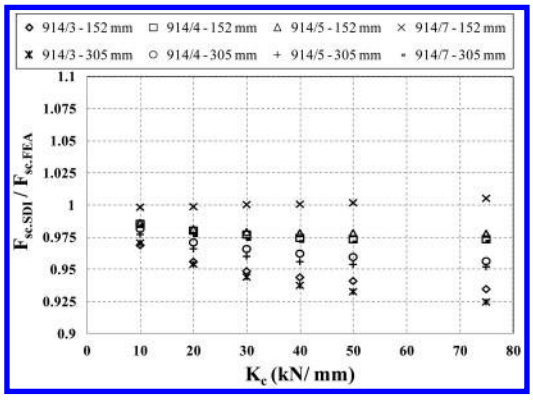

Figure 11. Impact of the connector stiffness on the total flexibility compared to the SDI method.

4 CONCLUSIONS

The main findings of this investigation can be summarized as follows:

1. The connection and the connector are two different concepts in term of shear behaviour. The connection includes the plates at the connector vicinity and the connector itself.
2. The determination of the delimited area of the deformed plate at the connection remains ambiguous. This area can be influenced by the connector spacing, which may affect the elastic stiffness K_o for elastic analysis.
3. The model studied was decomposed into three parts: the connectors, the affected plate zone and the non affected plate zone. The affected plate zone strongly interacts with the spacing and pattern of the fasteners. This gives evidence of a connections system being developed.
4. A non affected plate zone is defined to have a "pure" shear flexibility close to that assessed by the SDI method of the entire flat plate, regardless of the connectors spacing and stiffness. Hence, there is no interaction effect between the non affected plate zone and the connections.
5. The total in-plane shear flexibility of the connected plate based on the SDI method is between 92% and 100% of the values obtained from finite element analysis using K_o provided from the Rogers and Tremblay calibration tests, and is approximately 1% less than that obtained from the finite element analysis using De Matheis' calibration tests.
6. A good assessment of the total shear flexibility of the connected flat plate according to the SDI method is directly dependent on an accurate determination of the strain plate flexibility at the connector vicinity by individual fastener test calibration.

Further research is needed to obtain reliable information regarding the relationship between the interaction of shear and slip flexibilities considering the panel size and thickness.

ACKNOWLEDGEMENTS

Funding for this research was provided by the Natural Sciences and Engineering Research Council of Canada, the Vancouver Steel Deck Diaphragm Design Committee (VSDDC) and its many member companies, the Canadian Sheet Steel Building Institute, the Steel Deck Institute and Hilti Canada.

New experimental method for determining the stiffness and strength of steel storage rack floor connections

F. Roure, M.M. Pastor, M.R. Somalo & M. Casafont
REMM (Research group in Structures and Mechanics of Materials) – Universitat Politècnica de Catalunya, Spain

ABSTRACT: To analyse the down-aisle global stability of a rack structure it is necessary to know the moment – rotation characteristic of the beam to upright connection and of the upright to floor connection. In EN 15512, the moment – rotation characteristic of the upright to floor connection is recommended to be obtained experimentally, according to Annex A.2.7. There a test method is suggested, using two lengths of upright connected to opposite sides of a concrete block; but it is also said that "alternative test set-ups may be used, provided they accurately reproduce the real structural condition". In this paper an alternative test set-up is presented, using only one length of upright, connected to a concrete block. The concept is presented and the data collection and the calculation of the moment – rotation curve of the floor connection are exposed. Then the practical implementation of the test set-up is explained. A series of experimental results obtained by the new method are presented, and compared to the results obtained with the two lengths method. Finally the conclusions about the new testing method are presented.

1 INTRODUCTION

The detail of a typical pallet racking system is shown in Fig. 1. The basic structural elements of the system are: the beams, the uprights and the diagonals. The beams support directly the load of the pallets, and transmit them to the uprights. The diagonals are bolted to the uprights and form the frames that guarantee the cross-aisle stability. Most of the systems are unbraced in the down-aisle direction; in this case the down-aisle stability relies on the beam to upright connection and the upright to floor connection. The present paper deals with the behaviour of the upright to floor connection. The upright to floor connection has a non linear semi rigid behavior, and the codes usually recommend determining it experimentally. The behavior is dependent of the value of the axial force acting on the upright, so a complete characterization of the behavior of this connection requires testing at different levels, covering the usual range of axial loads.

2 HISTORICAL REVIEW

In 1996 the preNorm FEM 10.2.02 has proposed in Ap. 5.8 an experimental way of determining the ultimate moment, the design moment and the stiffness of the upright-base plate-floor connection. In 2009, EN 15512 has reproduced in Ap. A.2.7 the same procedure. It consists in testing, simultaneously two uprights and base plates, subjected to axial compression, acting in opposite faces of a concrete block.

Figure 1. Detail of a rack pallet system.

Different authors have studied the behavior of the upright to floor connection and its influence on the stability of the uprights and the rack structures, experimentally and by FE simulation: Godley, Beale & Feng

(1998), Beale & Godley (2003), Del Coz, García, Betegón & Fernández (2006).

Gilbert & Rasmussen (2011) have suggested a way to improve the results of the test arrangement proposed in EN 155512.

3 EN 15512 TWO UPRIGHT TEST PROCEDURE

3.1 *Test procedure*

The test arrangement proposed in EN 15512 is shown in Figure 2 and 3. After applying an axial preload and setting the transducers to zero, the desired axial load is applied, and then the transversal load is increased progressively until failure of the connections. With the value of forces and displacements registered, the moment and rotation are calculated. with equation 1 for each of the two connections. It is supposed that the transversal force F_2 is absorbed

$$M = (F_2/2) \cdot L + F_1 \cdot (d_5 + d_6)/2 \qquad \theta = \frac{d_2 - d_3}{d_{23}} \qquad (1)$$

symmetrically bye the two lengths of uprights. The test is repeated for the different axial loads desired.

3.2 *The drawbacks of this procedure*

When applied in practice this procedure has several drawbacks:

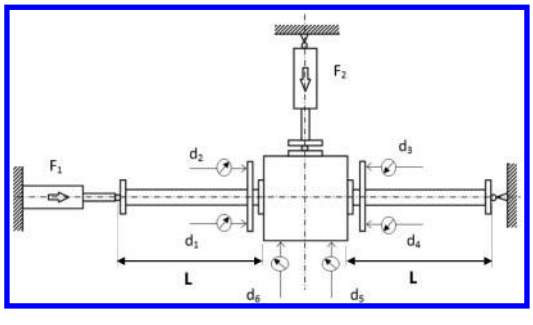

Figure 2. EN 15512 two uprights test arrangement.

Figure 3. EN 15512 two uprights test arrangement.

- it is very difficult to align correctly all the components.
- when the first uprights fails, the symmetry is loosen and there is no guarantee that the transversal force and the moment are still symmetrically distributed, and that equation [1] is still valid.

4 NEW PROPOSAL: SINGLE UPRIGHT TEST

4.1 *New test arrangement*

In A.2.7.2 of EN 15512 it is said that "alternatives may be used, provided they accurately model the real structure condition". Here an alternative method is proposed, that verifies these condition. Figures 4 and 5 show the test arrangement proposed. The concrete block is completely fixed. A single upright sample of 600 mm length with the base-plate is fixed to it (with or without anchorages, as the case may be), and at the head of the upright the axial and the transversal forces are applied.

The two force actuators, axial and transversal, are pinned at both ends. The head of the upright must be guided so that the axial and transversal displacements and the rotation around the vertical axis are free, and all the others degrees of freedom (vertical displacement and rotations around the axial and transversal axis) are restrained. The joint in the head of the upright has to guarantee that the rotations around the vertical axis of the axial force, of the transversal force and of the section of the upright are free and independent (see figure 6).

4.2 *Test procedure*

An axial pre-load is applied and the sense of the initial transversal displacement is noted. Load is released, transducers set to zero, and the desired level of axial load is applied. Then the transversal load is applied, in the same sense as the initial displacement, and is increased until failure of the connection.

Forces and displacements are continuously registered and moment and rotation are then calculated with the equations 2 and 3 (see Fig. 7):

$$M_b = (F_2 + F_1 \cdot \sin\beta) \cdot L + (F_1 \cdot \cos\beta) \cdot d_1 \qquad (2)$$

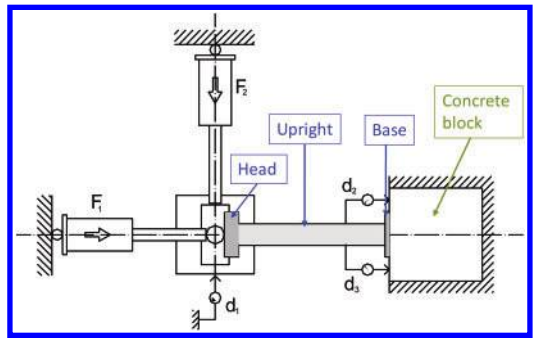

Figure 4. New proposal: single upright test arrangement.

Figure 5. Single uprights test arrangement.

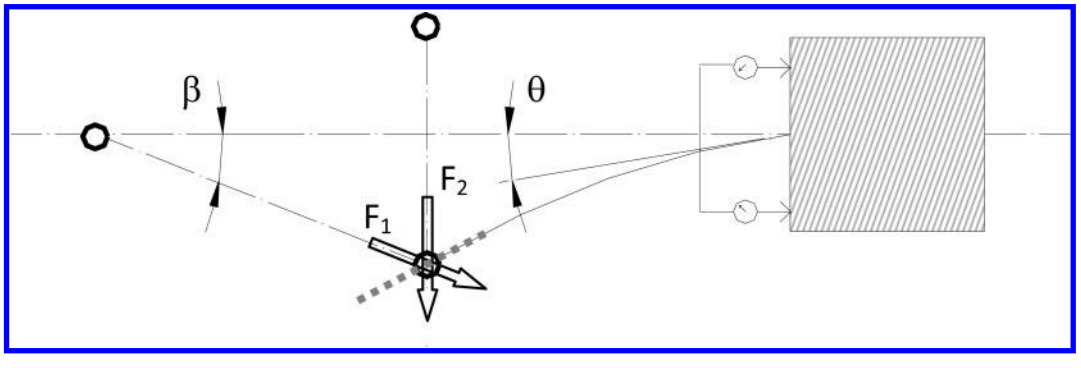

Figure 6. Free and independent rotations at the joint of the head of the upright.

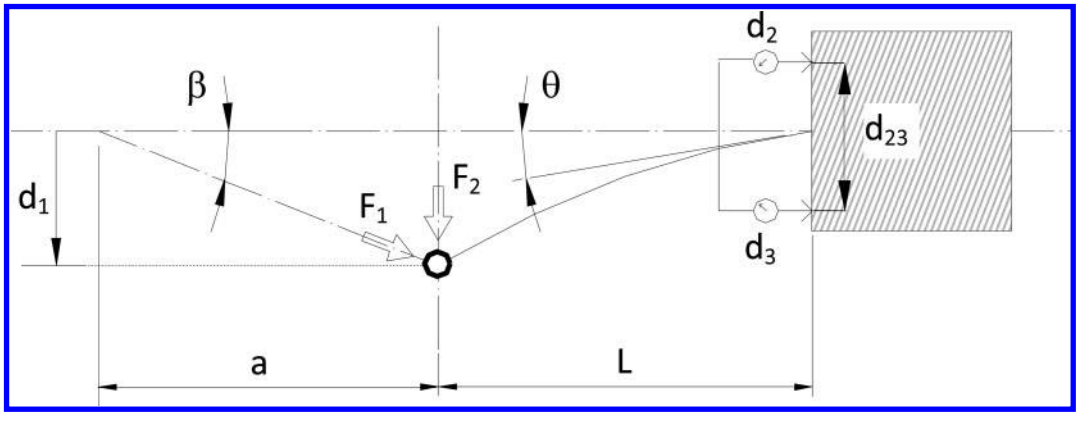

Figure 7. Single uprights test notation.

M_b: moment applied to the base plate.
F_1: axial load applied on the upright.
F_2: transversal load applied on the upright.
L: distance between the joint and the upright base.
d_1: transversal displacement sensor.
β: angle of axial load ($\beta = \text{atan}(d_1/a)$)
a: distance between pivot an joint.

$$\theta_b = \frac{d_2 - d_3}{d_{23}} \quad (3)$$

θ_b: rotation of the base plate.
d_2: displacement sensor 2.
d_3: displacement sensor 3.
d_{23}: distance between sensors 2 and 3.

4.3 *Advantages of the new test arrangement*

Compared to the arrangement proposed in EN 15512 the new test arrangement has several advantages:

- easier to implement (alignment of only one upright)
- it always allows full development of the failure
- gives consistent series of results
- needs only one sample per test

5 DISCUSSION OF RESULTS

5.1 *M – θ curves*

One type of medium load upright and its base plate have been tested with both methods, at different levels of axial load. One example of the M – θ curves obtained with the two upright and the single upright arrangement, for the same axial load level, are shown in Figures 7 and 8, respectively.

In the code it is recommended to do tests at least at 6 different axial load levels, and to do a minimum of 2 tests at each level. With these 12 results (M_{ti}) a suitable algebraic expression, by using a least square curve fitting process, is chosen to represent the ultimate moment M_b as a function of the axial load (see Fig. 10).

The M - θ curve, at each axial load level can be approximated by a bilinear curve. The two parameters that define it are the design moment M_{rd} and the stiffness K (see Fig. 10). To define the value of M_{rd} the process is.

- normalize the ultimate moments of each axial load level (M_{ti}/M_t)
- calculate the standard deviation s of all the normalized moments
- calculate the characteristic moment of each axial load level:

$$M_k = M_t\,(1 - k_s \cdot s) \quad (4)$$

where $k_s = 1{,}88$ for $n = 12$

- calculate the design moment of each axial load level:

$$M_{rd} = \eta \frac{M_k}{\gamma_M} \quad (5)$$

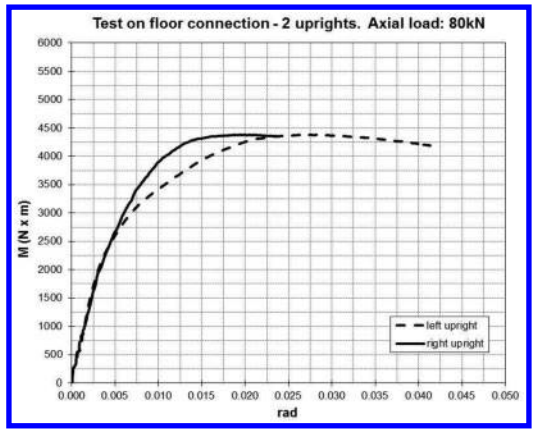

Figure 8. M – θ curve obtained with the two upright test arrangement.

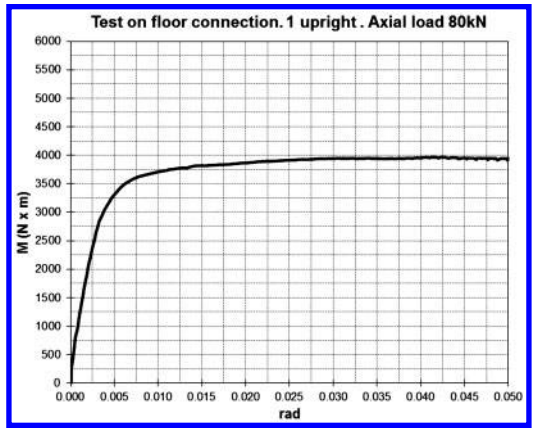

Figure 9. M – θ curve obtained with the single upright test arrangement.

where $\gamma_M = 1{,}1$ (according to 7.5 of EN15512)
$\eta \leq 1$ reduction factor to achieve a higher stiffness

In Fig. 10 two different bilinear approximations of the M – θ curve are shown, obtained with different values of η.

5.2 *M_b and K function of axial load*

In Figure 11 the ultimate moments of each test (M_{ti}) for the 6 axial load levels and the fitted curve (M_b), obtained with both test methods, are presented. The values obtained with both methods are very similar. The stiffness K at each axial load level has been calculated and is represented in Figure 12 as function of axial load. For both methods the same design moment M_{rd} has been used. The scatter of the single results obtained with the two uprights arrangement is clearly higher than with the single upright arrangement. The stiffness values obtained with the single upright arrangement are higher

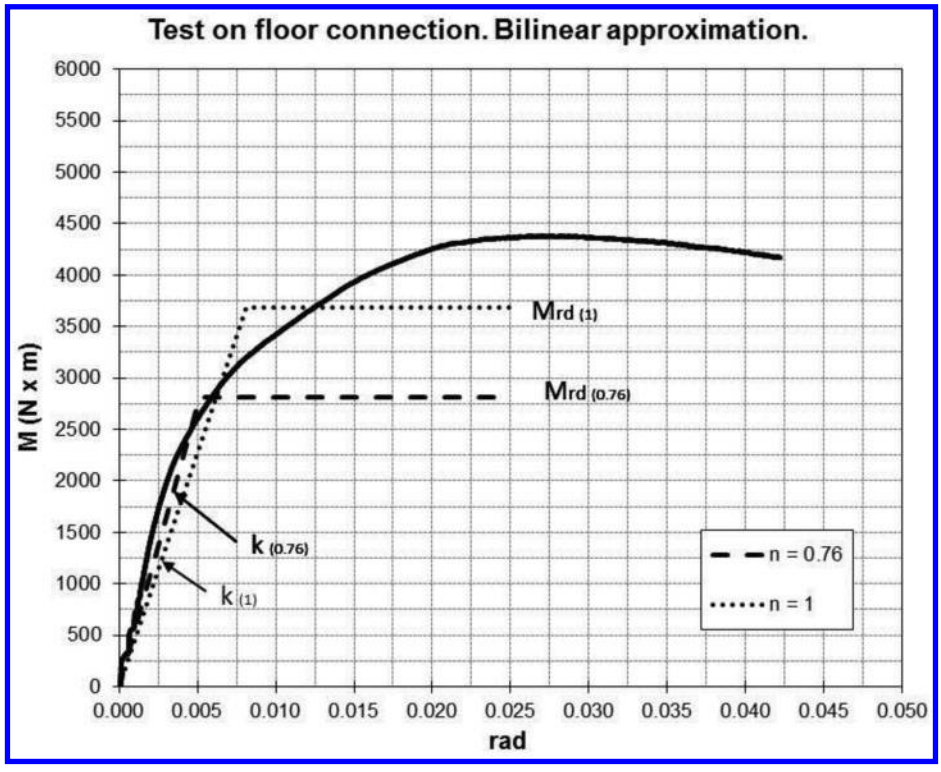

Figure 10. Bilinear approximation of the M – θ curve.

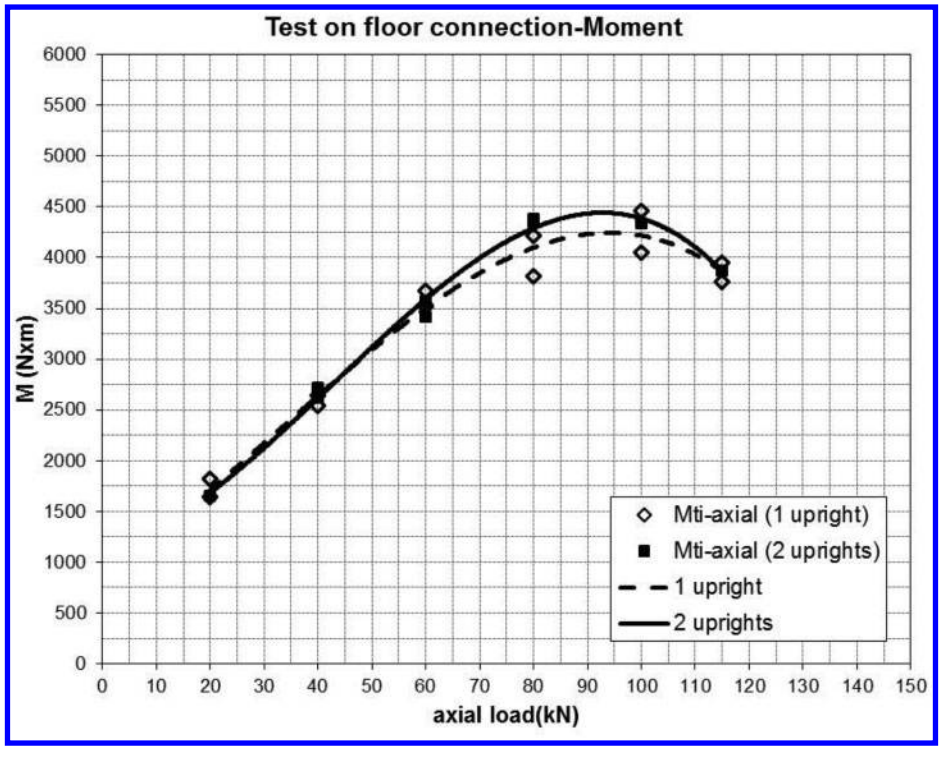

Figure 11. Ultimate moment as function of the axial load.

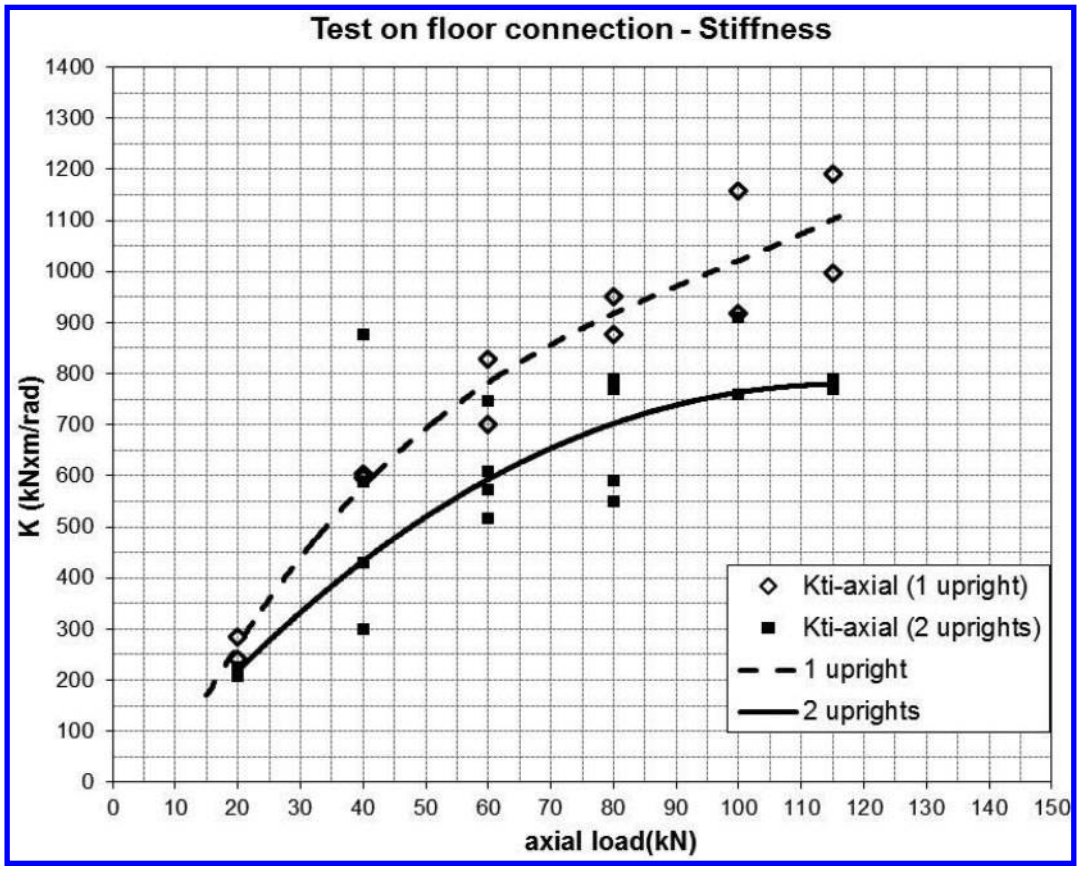

Figure 12. Stiffness as function of the axial load.

6 CONCLUSIONS

After using both test arrangements and comparing the results obtained, it can be concluded that:

- The new test arrangement is easier to implement (only one upright has to be aligned)
- It always allows full development of the failure
- The scatter in the results is lower
- Needs only one sample per test
- The values of the ultimate moments obtained with both methods are equal
- The values of the stiffness obtained with the single upright test are higher.

Seismic behaviour of welded and bolted I-beam to box column connections

Qian-Yi Song, Amin Heidarpour & Xiao-Ling Zhao
Department of Civil Engineering, Monash University, Melbourne, Australia

ABSTRACT: The secondary disasters, as fire, colliding, explosion and so on, usually occur following an earthquake. The subsequent actions would be more destructive. In order to investigate structure behaviour after an earthquake, it's important to interpret seismic behaviour of structures and evaluate damage levers induced by various earthquake intensities. This paper presents a preliminary work on investigating behaviour of steel connections under seismic loading, focusing on test and analysis of popular used welded and bolted I-beam to hollow box column connections under cyclic loading. 4 connections, including 2 fully welded connections and 2 double-angle bolted connections were tested in the lab under cyclic loading. The load vs. deformation relationship, strength and dissipated energy were measured during the test, meanwhile deformation, fracture and final failure phenomena were observed. Ductility and earthquake induced damage based on test results are described and evaluated preliminarily. Test results could be useful for further investigation and analysis on pre-damaged connections under various possible post- earthquake actions.

1 GENERAL INSTRUCTIONS

The heavy ground motion in an earthquake often causes huge damages and loss of lives and properties. Moreover, the secondary disasters induced by the earthquake would cause more severe damages. Considering structures are subjected to earthquake induced secondary actions, researches on the behavior of structures under these extreme conditions are significantly necessary.

Damage evaluation after earthquake is basis as for above mentioned investigation. Several damage models can be found to define structure's damage degree after an earthquake. Castiglioni & Pucinotti (2009) summarised failure criteria and cumulative damage models for steel components under cyclc loading. So far, There are few published investigations on the residual capacity of steel components under various secondary actions after an earthquake.

Welded I-beam to hollow box column connection and bolted double-angle connection are the simplest configurations, usually used in low-rise and middle-rise buildings as framing connection. Although with limited seismic resisting ability, they are designed for the experimental investigation in this paper, which avoid complicated analysis with lots of parameters, while the load vs. resisting mechanism could be analysed clearly and generally.

There are several published research works on these two types of connections. Static tests were carried out by Sherman (1995) on the double-angle I-beam to box column bolted connections. The observed failure of double-angle connection was on the weld. It was proposed that the only limit state which should be considered for HSS column wall is the through-thickness shear rupture. The possible limit states for double angle I-beam to HSS connections were listed by Sherman (1996). Gong (2008) presented a static experimental study on double angle shear connections using small-size hollow section columns. Fully welded I-beam to box column connections can be considered as connections with two transverse plates conservatively, as mentioned in EC3-part8 (CEN, 2005). Shear strength of double angle connections is given in AISC steel construction manual (AISC-325, 2005).

This paper presents test results of I-beam to box-column connections under cyclic loading, which focuses on investigating damages induced by earthquakes. Main parameters as load vs. displacement relationship, energy dissipation and residual deformation after loading cycles were measured and analyzed. This research provides benchmark data for further investigation on connections behaviour under post-earthquake fire which is currently being developed at Monash University.

2 CONNECTION DETAILS AND TEST PLAN

2.1 *Connection specimens*

There are two types of connections investigated in the research work. One is fully welded tubular connection which assembled using an I-beam and a hollow box column through welding. Another type of connection is bolted double-angle tubular connection. The I-beam of bolted connection is bolted to two pieces of angle steel which are welded to column face, and

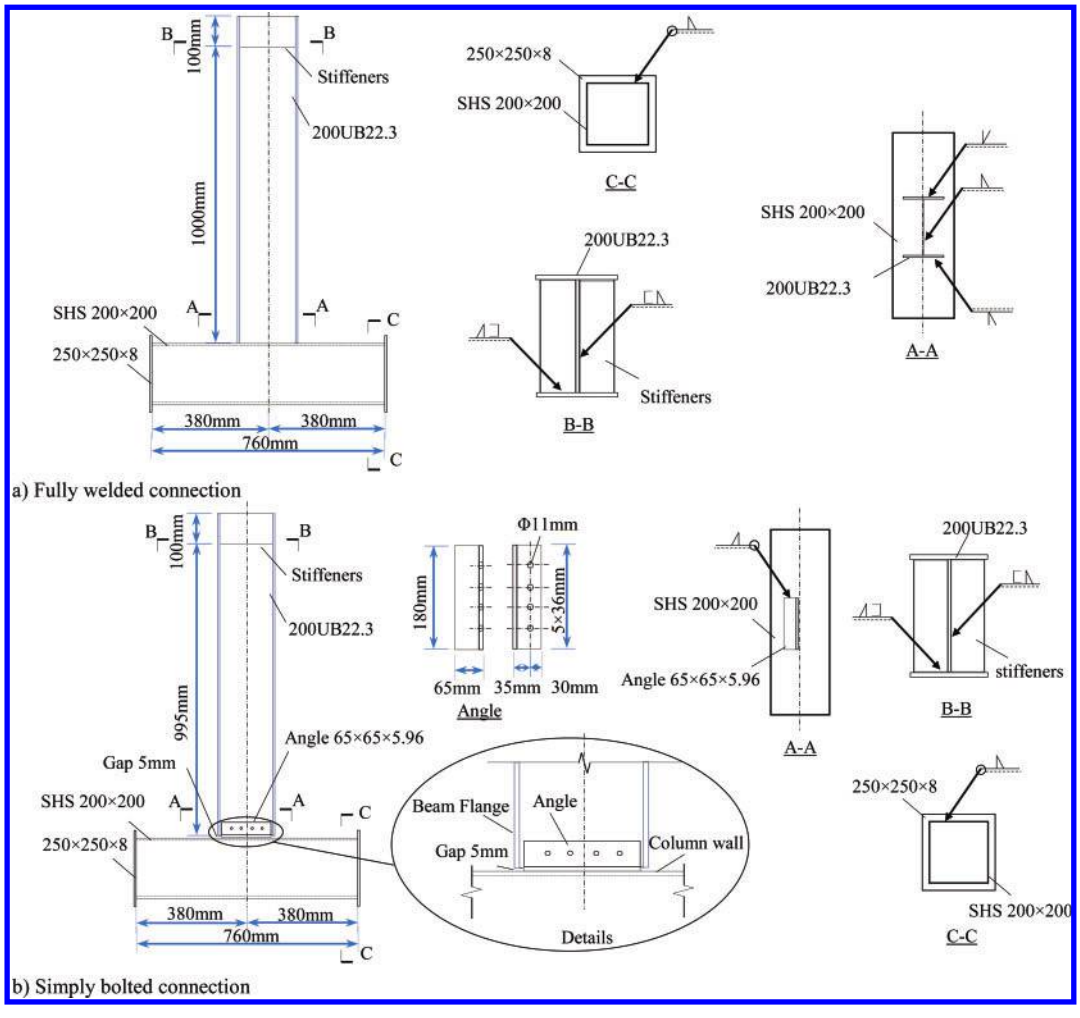

Figure 1. Component and configuration details of designed connections.

there is a small gap between I-beam with column face. The designed lengths of column and I-beam are the same, but columns with two different thicknesses, namely 4.76 mm and 8.75 mm, are used. All the I-beams used in the test are 200UB22.3 (Onesteel, 2003). The geometrical details of connections are listed in Table 1. All the bolts are G8.8M10, and angle section is 65 × 65 × 5.96 (unit: mm), with length of 180mm. Connection configuration details are shown in Figure 1a, b.

Table 1. Geometric properties of specimens.

	Column (mm)		Beam(mm)		
No.	B	t_c	Section	t_f	t_w
CWH1C	200 × 200	4.76	203.0 × 131.6	6.64	5.14
CWH2C		8.75			
CBH1C		4.76			
CBH2C		8.75			

Note: In the specimen number, the meaning of characters is as following: C-connection, W-welded, B-bolted, H-hollow section box column, the last C-cyclic loading.

2.2 *Boundary conditions and loading protocol*

The bottom end of column is fixed, while another side of the column is only axially movable and supported by a lateral triangular frame. A small constant axial load of 50kN is exerted on the column during the test. Cyclic loading is applied on the beam, 1 meter away from column face using displacement controlling. Test setups are shown in Figure 2. Compressing the beam towards ground is taken as positive loading direction. In the test, AISC-341 (AISC-341, 2005) cyclic loading protocol is adopted, shown in Figure 3. Cyclic test stops until the connection fails or the maximum travel displacement achieves.

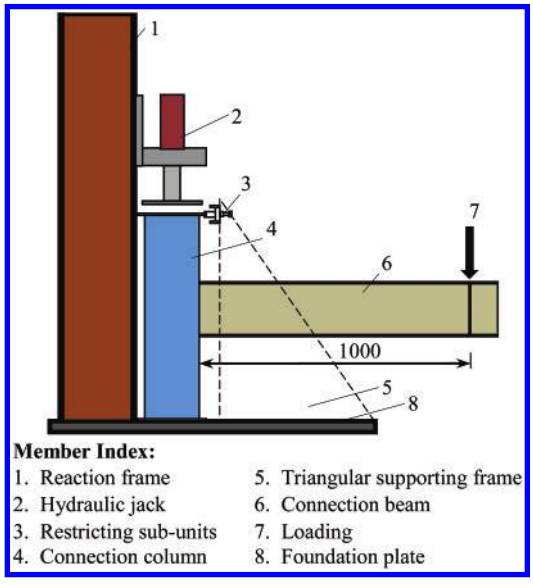

Figure 2. Loading setups.

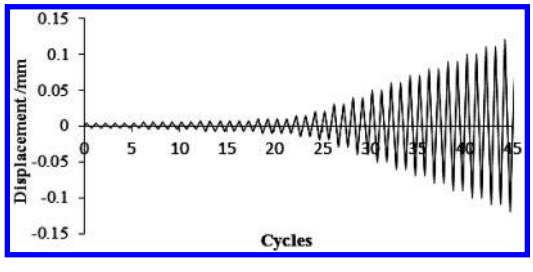

Figure 3. Cyclic Loading protocol (AISC-341, 2005).

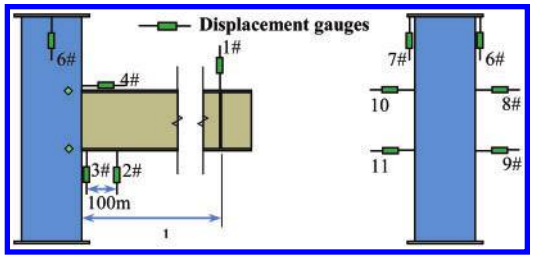

Figure 4. Arrangement of displacement gauges.

2.3 *Gauges and material properties*

The arrangement of displacement gauges are shown in Figure 4. Material properties as yielding strength f_y, ultimate strength f_u, initial elastic modulus E_s, yielding strain ε_y and the Poisson ratio ν_s, obtained from tensile coupon tests, are listed in Table 2.

3 EXPERIMENTAL RESULTS AND ANALYSIS

3.1 *Test results*

Figure 5 shows typical load vs. displacement relationships for tested welded and bolted connections.

Table 2. Material properties.

Properties	t (mm)	tf_y (MPa)	f_u (MPa)	E_s (MPa)	ε_y ($\mu\varepsilon$)
Column	4.76	359.32	448.82	181200	1983

Bolt	–	1042.8	1164.1	235392	4430

Note: Poisson's ratio (ν_s) is 0.293.

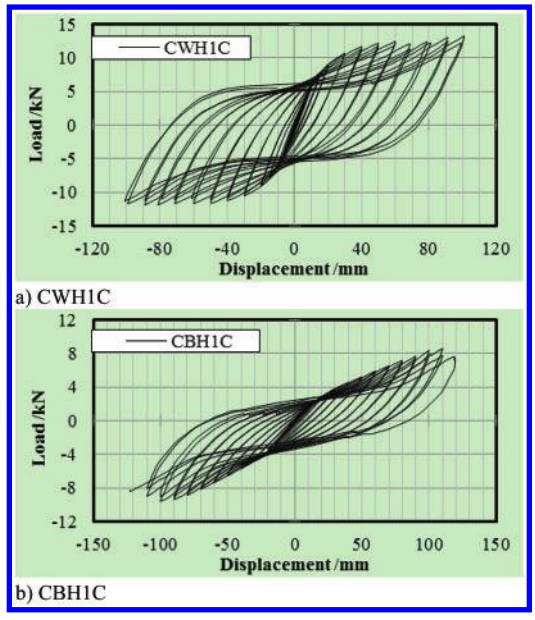

Figure 5. Load vs. displacement relationships.

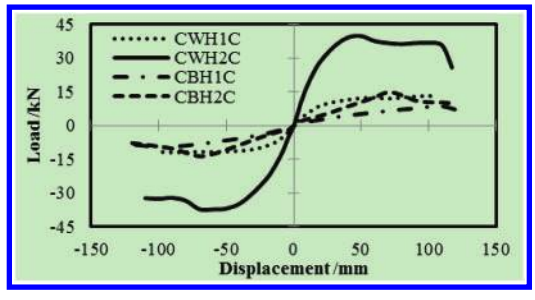

Figure 6. Skeleton curves of connections.

Skeleton curves are shown in Figure 6, which reflect the strength and ductility performance of connections under cyclic loading. As connections could be subjected to several cycles under the same displacement amplitude, the shown skeleton curve connects peak points of the first cycle. The determination of yielding strength F_y, ultimate strength F_u, the failure strength

F_f with associated displacements δ_y, δ_u, δ_f and the maximum displacement δ_{max} are given in Figure 7.

Main results of connections under cyclic loading tests are summarized in Tables 3 to 5. Table 3 shows the measured yielding strength F_y, ultimate strength F_u and related displacement δ_y, δ_u and the maximum loading deformation amplitude δ_{max} under both positive and negative directions. The total loading cycles, failure mode with the cycle number at which initial failure occurs are listed in Table 4. The failure displacement δ_f and displacement ductility coefficient $\mu(=\delta_f/\delta_y)$ in positive and negative direction and the average displacement ductility coefficient $\bar{\mu}$ are listed in Table 5. Due to loading travel capacity of equipment, the failure load F_f may be still higher than $0.85F_u$ at the end of the test, thus it is conservatively assumed that $\delta_f = \delta_{max}$ in calculating the ductility coefficient.

Dissipated energy during cyclic loading test can be calculated by the enclosed area of a single cycle from the load vs. displacement relationship, which of connections is shown in Figure 8.

3.1.1 *Fully welded connections*

The welded connection CWH1C was totally subjected to 42 cyclic loading cycles. Cracks at column face around tensile beam flange tips initially occurred after about 25 cycles with displacement amplitude of 20 mm. Then cracks were developed when the load increased. As both the top and bottom beam flanges were subjected to tensile load due to repeated loading, cracks at column face were symmetrical around all beam flange tips. The typical initial crack is shown in Figure 9a. It was developed through the column wall thickness quickly after several more cycles.

The test of CWH1C stopped when punching shear fracture extending towards the middle of column wall along the beam flange (Fig. 9a), when the maximum loading amplitude achieved 100mm. Due to setup arrangements, although fracture was still developing at the end of the test, there was no significant load drop. The maximum positive resisting strength

Table 4. Observed failure characteristics.

Specimen	Total cycles	Failure phenomena	Cycle of initial failure
CWH1C	42	Column wall punching shear	25
CWH2C	44	Beam flange tearing with punching shear of middle column wall	26
CBH1C	45	Angle web tearing symmetrically at top and bottom corner	37
CBH2C	46	Angle welding tearing at top-side and angle web tearing at bottom-side	34

is 13.21 kN during the 41st loading cycle at displacement of 100.8 mm. The maximum negative resisting strength is −11.91 kN during the 39th loading cycle at displacement of −88.8 mm. Under the same displacement amplitude, strength of the second loading cycle is usually lower than the first cycle for damages caused in previous loading cycle.

Specimen CWH2C is stronger than CWH1C, and is the strongest connection among the 4 tested connections. Before the last loading cycle to the amplitude of 120 mm, it had been subjected to 44 loading cycles. The maximum positive resisting strength is 39.83 kN during the 31st loading cycle at the displacement of 50.0 mm. The maximum negative resisting strength is −37.28 kN during the 33rd loading cycle at displacement of −60.0 mm. The resisting strength of following cycles decreases a little. The test stopped with a load dropping of 15% at the 45th cycle. Because of asymmetrical tearing damages at the top and bottom beam flange tips, the positive half of loading cycles looks fuller than the negative part of cycles. The initial fracture occurred at about 26th cycle with the amplitude of 20 mm, which is at the tensile beam flange tips (Fig. 9a). The fracture then developed slantwise direct to column wall, and finally punching shear occurred at the middle of the column wall (Fig. 9a).

3.1.2 *Bolted connections*

Bolted connections are usually pin connections with negligible moment resisting capacity. It is obvious that the typical hysteretic curve shape of bolted connection is thinner compared with welded connections (Fig. 5). Moreover, the initial stiffness of bolted connections is much small as well.

CBH1C is a double-angle bolted connection with column wall thickness of 4.76 mm. It was subjected to 45 loading cycles totally during the test, which achieves 120 mm in the positive loading direction. The maximum positive resisting strength is 8.60 kN in the 43rd loading cycle at the displacement of 110.0 mm. The maximum negative resisting strength is −9.59 kN in the 41st loading cycle at displacement of −99.9 mm. The load amplitude of the last cycle dropped down obviously due to the tearing fracture of angle webs, which occurred initially at about the 37th cycle with loading amplitude of 80 mm symmetrically on the top and bottom. The typical failure phenomena are shown in Figure 9b.

CBH2C is another bolted connection with column wall thickness of 8.75 mm. It was totally subjected to 46 loading cycles. The maximum positive resisting strength is 14.99 kN during the 37th loading cycle at the displacement of 74.5 mm. The maximum negative resisting strength is −13.76 kN during the 37st loading cycle at displacement of −69.2 mm. The load dropped down obviously due to the tearing fracture of angle webs at bottom side and the fracture of welding lines at top side. Fracture damages occurred initially at about the 34th cycle with displacement amplitude of 60mm. The typical failure phenomena are shown in Figure 9b.

3.2 *Analysis*

Due to different configuration details, connections show various performances under cyclic loading test procedure. Fully welded connections are normally stronger than simple bolted connections, due to the fact that they can hold big enough moment while bolted connections are usually considered as shear connections with negligible moment resisting capacity. The positive displacement corresponding to ultimate load of CWH1C and CBH1C are 100.8 mm and 110.0 mm while CWH2C and CBH2C are only 50 mm and 74.5 mm respectively. The displacement corresponding to ultimate load in negative direction of CWH1C and CBH1C are bigger than those of CWH2C and CBH2C as well. This indicates that connections with thinner column wall thickness are of better flexible

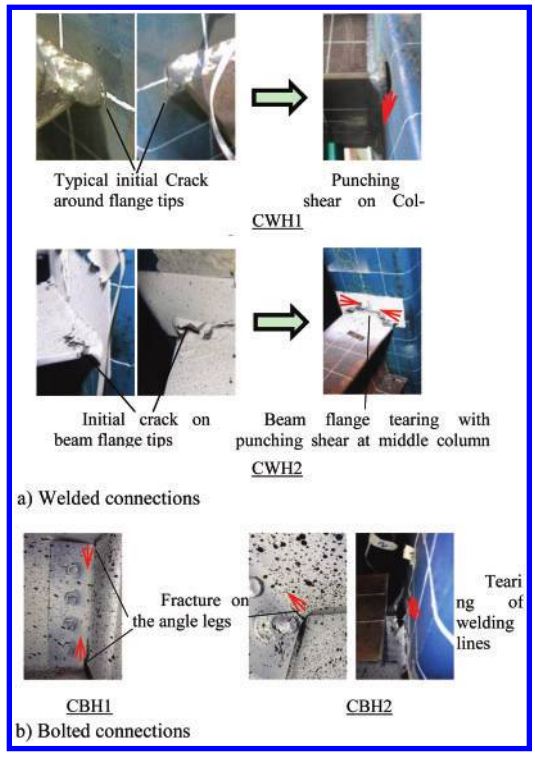

Figure 9. Failure phenomena of welded specimens.

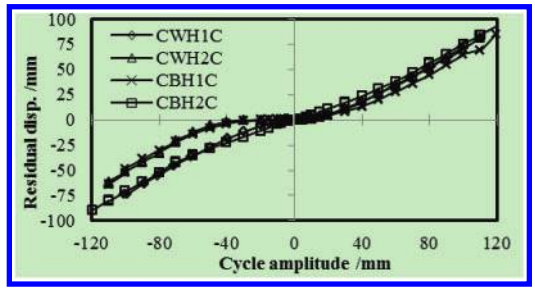

Figure 10. Residual displacement of connections.

capacities, although their bearing abilities are usually lower. The calculated average displacement ductility coefficient of CWH1C is at least 5.30, as shown in Table 4, while that of CWH2C, CBH1C and CBH2C are 4.68, 2.18 and 2.69, respectively. This indicates welded connections CWH1C and CWH2C are more ductile than bolted connections CBH1C and CBH2C.

From Figure 8, we can see that the energy dissipated by hysteretic loops increases with the increase of displacement amplitude. Cyclic Loading is carrying on by double cycles with the same displacement amplitude after 22 cycles, before which the dissipated energy of cycles is not apparent. From the 23th loading cycle, the energy dissipation keeps increasing obviously and that of the second cycle is usually lower than the previous one under the same amplitude. It indicates that before the 22nd loading cycle, all the connections are in elastic stage, after it due to inelastic behaviour caused by material plasticity, crack and column wall buckling, the plastic response becomes obvious. The energy dissipation capacity of CWH2C is the best, followed by CWH1C, CBH2C and CBH1C. Residual displacements also become bigger at the end of every loading cycle, compared with the original zero point. The measured residual deformation of each connection at the 0 load point is shown in Figure 10. The shown 0 load associated residual displacements of the 4 connections are very close after the same loading cycles.

As all the tested connections show obvious damage accumulation under cyclic loading, damage after different loading cycles can be assumed as damages induced by various earthquake intensities, which is concerned for the proposed investigation on connection behaviour under post-earthquake fire. The connection damage status after different loading cycles can be evaluated by several methods based on ductility and dissipated energy, as damage index (Newmark & Rosenblueth, 1974), cumulative plastic deformation index or cumulative ductility index (Krawinkler, 1987) and cumulative energy reduction index(Calado, et al., 2000). The evaluation and analysis work on these connections are currently under process at Monash University.

4 CONCLUSIONS AND FURTHER WORK

Totally 4 connections with different configurations including fully welded connection and double-angle bolted connection were tested under cyclic loading at ambient temperature. Load vs. deformation relationships and strength were measured during the test, together with observation on specimen deformations and the failure phenomena. Ductility and earthquake induced damage based on test results were analysed preliminarily.

The presented seismic test results form benchmark data for subsequent investigation work on connection behaviour under post-earthquake fire. Based on the theoretical classification and evaluation of the cyclic loading results, fire tests are currently performed using pre-damaged connections damaged by various cyclic loading cycles, which are used to simulate different earthquake intensity.

ACKNOWLEDGEMENT

The research work presented in this paper was supported by Australian Research Council through a Discovery Project (DP1096454) awarded to the second author. Moreover, I would like to express gratitude to the lab technicians Jeff Doddrell who made the specimens, Kevin Nievaart who made the laboratory equipment easily available and all others who worked for the project.

ABSTRACT: This paper presents an analytical study on bolted in a T-Stub, subjected to static loading. These assemblies are tested for modeling the tensile part of an assembly of the type beam-column bolted with end plate extended. The originality of this work is the study of the influence of the second row of bolts, which is not treated in the literature. This configuration is commonly found in different countries of Europe and in particular Germany, where this configuration is standardized. The analogy between the tensile zone in an assembly and a T-Stub based on the Eurocode3 Part 1.8 has enabled to establish a simple mathematical formulation for the determination of the main characteristics, such as strength and stiffness, in order to put in evidence the influence of each parameter. In this study the thickness of the plate (flange of T-Stub) is the main parameter, as well as the number of bolts rows and the effect of the lever's force. The obtained results allow to proof the value of having another bolts rows and the role of the thickness of the plate, on the failure's modes that can occur during the application of the load to the state limit ultimate. A comparison is made between the experimental results, analytical results and results from the literature.

Keywords: Eurocode3, assembly, T-stub, bolt, stiffness, strength

NOMENCLATURE

L_{eff}: effective length
e_{pl}: plate thickness
fy: yield stress of steel
m: distance from the bolt axes to the weld edge
n_1: distance from the bolt axes to plate edge
n_2: distance between two bolts axes
d: diameter of the bolt
A: net area of the bolt
d_w: diameter of the washer
F_{Ri}: design strength of a T-stub equivalent to each failure mode
M_{pl}: plastic moment
N_{pl}: plastic resistance of the bolt
Fub_0: ultimate strength of bolt
K_{init}: initial stiffness of T-Stub
F_{el}: elastic load applied
F: load applied
Q, B: reactions

1 INTRODUCTION

Steel structures are usually made of columns and beams joined together by assemblage that have an influence on the overall behavior of the structure. Steel construction uses two main types of joints: the welded and bolted connections. However, the bolted assembly with end plate is widely used in steel structures. Generally, in practice the bolted end plate has various geometric configurations due to the variation in the number bolts per rows, the space between bolts axes, the dimensions of the end plate which may be flowing or not, the size of columns and beams (thickness of the flange and the web considered), the prestressed force in the bolts, the mechanical properties of the steel and the contact surfaces.

Bolted connections have recently attracted new research efforts after the unexpected failures of welded joints during earthquakes. Criteria and formulations to predict the stiffness and strength in static loading conditions, typologies of the most common joints were codified by the Eurocode3, which is based on the so-called components.

Eurocode3 retained the components method to characterize the behavior of beam-column assembly, considering that the assembly is a set of basic components.

In this study, we are interested in the analysis of the behavior of T-stub with two rows of bolts and

to confront the assembly of four rows of bolts vertically arranged, for which no recommendation appears in the current regulations (Eurocode3 , CCM97), and which are the principal components in the assembly. The behavior of the T-stub is more or less complex. The Simplification of the design formulas associated are then different. The effect of some parameters such as plate thickness, number of bolts, and the lever force play a very important role in determining the strength and stiffness of the beam-column assemblies.

2 COMPONENTS METHOD

In the spirit of Eurocode3, every assembly must be regarded as a set of elements, called "components", which all contribute in a manner more or less important to the strength and the stiffness of this assembly.

The "component" that immediately comes to mind in the case of a bolted assembly is obviously the bolt, or rather each of the bolt's assembly.

The method of components considers any assembly as a set of individual elementary components. The basic concept, upon which this method is based, has the following steps:

- Identification of all basic components of the assembly;
- Evaluation of characteristics (strength and stiffness) of these components;
- Association of components to obtain strength and rigidity of the entire assembly.

For an assembly with extended end plate and bolted, subjected to bending, several basic components can be identified, depending on the type of solicitations they are subjected to (Eurocode3, Aribert 1999)

Once the behavior of the main components of the assembly is determined, each one is modeled by a spring (Eurocode3). The assembly is effectively represented by a system of springs. The external forces are then applied to it and the response of the entire assembly is deduced from the study of the spring system, based on physical principles, such as equilibrium of forces, compatibility of displacements, respect of strength, ductility respect. . .

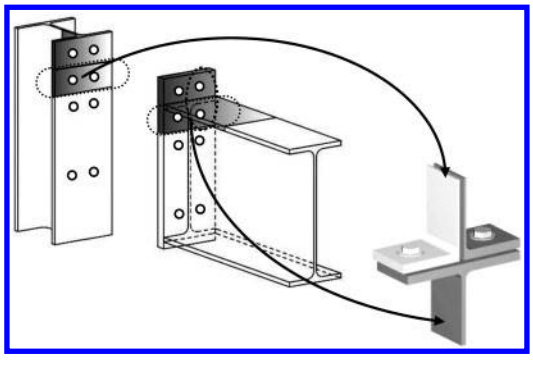

Figure 1. Theoretical model of a T-stub.

3 MODELLING OF TENSILE ZONE

The bolted connections beam to column with end plate can be classified according to their strength as, articulated, semi-rigid and rigid. In terms of bending's strength, they can be classified as rigid, partial strength and full strength.

The resistance of the T-stub (Fig. 1) is governed by the equivalent resistance of the plate (flange), bolts, web and the weld of web-flange (in the case of a welded T-stub).

4 CALCULATION OF T-STUB ASSEMBLY SUBJECTED TO TENSION

Eurocode3 adopts a modeling of the behavior of semi-rigid steel assemblies of the type beam-column bolted with end plate (Eurocode3, Aribert 1999). In our study, we only model the behavior of the column's flange and the end plate, by using a T-stub represented as a continuous beam, supported on ordinary bolts and taking into account the effect of lever due to longitudinal deformation of the plate (Aribert 1999).

4.1 *Modeling a T-stub with two bolts per row (Eurocode3, Aribert 1999, Mimoune 2003, 2008, Ana 2004, Al-Khatab 2007)*

According to Eurocode3, in order to calculate the initial stiffness of the T-stub for a single row of bolt vertical arranged, we cumulate the contribution of the column flange (first T-stub) and the end plate (second T-tub) and the bolts with their stiffness coefficients in series. An increase in thickness of the plate, does not allow the bending of the plate, and this was reflected by the increase of the effort applied right to the bolts due to the total load and the effect of lever force. A failure mode corresponds to the third category, which is the destruction of the bolts.

The theoretical model proposed by Aribert et al is the study of beam on four (04) supports subjected to a tensile force due to a gravity load type soliciting the beam (Fig. 2).

When the force F exceeds F_{el}, the deformation of the column flange (the plate) changes from domain elastic to domain elasto-plastic until failure obtained by the following three modes:

$$F_{R1} = \frac{4.M_{pl}}{m}\text{; mode1} \qquad (1)$$

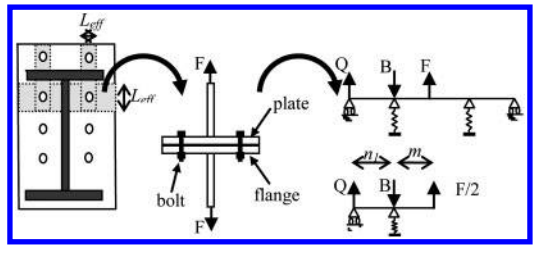

Figure 2. Model of the spring for T-sub (2 bolts per row).

with: $M_{pl} = 0.25 L_{eff} e_{pl}^2 f_y$

$$F_{R2} = \frac{2.(M_{pl} + n_1.N_{pl})}{n_1 + m}\text{; mode 2} \quad (2)$$

with: $N_{pl} = 0,675.fub_0 A$

$$F_{R3} = 2.N_{pl}\text{; mode 3} \quad (3)$$

When lever force may appear, it is convenient that the design strength of tension F_R of a T-stub, is taken equal to the smallest of the three possible failure modes according to Table 6-2 (Eurocode3).

The possible failure modes of the T-stub equivalent (Fig. 3) can be supposed to be similar to those provided in the Eurocode3. This classification is identified in Eurocode 3 and the literature (Aribert 1999, Mimoune 2003, 2008,. . .).

Tests were performed in the laboratory LMSS, Faculty of Engineering, University of Constantine, Algeria (Mimoune 2003, 2008). We can classify the failure modes observed in three categories:

- ruin of the end plate;
- ruin of the plate and destruction of the bolts;
- destruction of the bolts.

Regarding the first category, which corresponds to thin plates, the assembly continued to resist even with large deformation, the bolt failure is excluded. It was observed that the total ruin of the specimen comes with the breaking of the plate right next to the welded cords, which they have well resisted. Very important deformations were recorded at the holes also. The second category of failure mode, which corresponds to the plasticizing of the plate and the bolts destruction, was observed for assemblies of medium thickness. An important deviation right to the bolts is recorded at the beginning of loading; the destruction of assembly is reached after the deformation of the plate and the destruction of the bolts. Finally, the third mode is done by complete rupture of the bolt (Fig. 4).

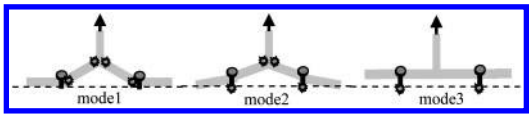

Figure 3. Failure modes observed for a T-sub with two bolts per row (Eurocode3).

Figure 4. T-stub tested (two bolts per row).

4.2 *Modeling a T-stub with four bolts per row:*

The analogy between the tensile zone of the beam-column assembly and the T-stub has enabled to establish simple mathematical formulations (Mehidi 2010, 2011) based the strength of materials methods, to determine the main characteristics such as strength and rigidity. These formulations easy to use in practice are not retained by the Eurocode3 or by CCM97.

We propose a new spring model of a T-stub relative to the end plate (column's flange) which is represented as a continuous beam rests on six supports in order to study the behavior of the end plate in the point of view strength, stiffness and the observed failure modes (Fig. 5).

Depending on the thickness of the end plate, the deviation between axes of the bolts, and when the tensile force F exceeds F_{el}, the plate is deformed in the domain of elasto-plastic until stage of ruin obtained (Fig. 6):

- by plasticization of the total plate (mode1);
- by plasticization the plate and ruin of intermediate bolts B2 (mode 2-1);
- by ruin of intermediate bolts B2 and plasticization total of the plate (Mode 2-2);
- either by formation of plastic hinges and bolts ruin (mode 2-3);
- either by breaking of all the bolts (mode 3).

Ultimate strength for each mode can be determined using the cinematic method which gives us:

$$F_{R1} = \frac{4.M_{pl}}{m}\text{; mode1} \quad (4)$$

$$F_{R2-1} = \frac{2(M_{pl} + N_{Pl}.n_2)}{m + n_2}\text{; mode2-1} \quad (5)$$

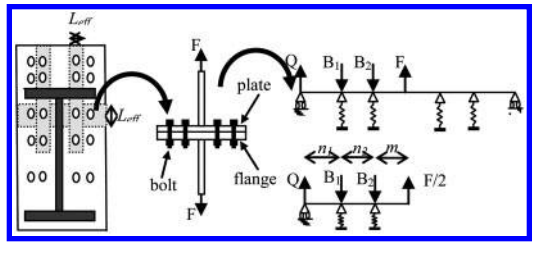

Figure 5. Spring Model proposed of the T-stub (four bolts per row).

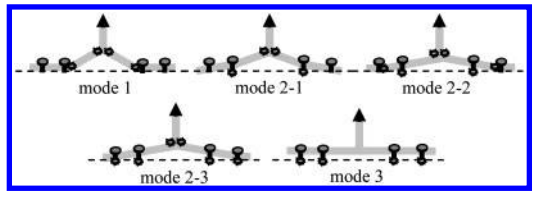

Figure 6. Failure modes observed for a T-stub with four bolts per row.

$$F_{R2-2} = \frac{4.M_{pl} + 2.N_{pl}.n_2}{m + n_2} \text{;mode2-2} \quad (6)$$

$$F_{R2-3} = \frac{2M_{pl} + N_{pl}.(4.n_1 + 2.n_2)}{m + n_2 + n_1} \text{;mode2-3} \quad (7)$$

$$F_{R3} = 4.N_{pl} \text{;mode3} \quad (8)$$

In the same context, tests have been made in the laboratory LMSS, Faculty of Engineering, University of Constantine, Algeria, allow the observed different failure modes mentioned above (Fig. 7).

When lever force may appear, it is convenient that the design strength of tension F_R of a T-stub is taken equal to the smallest of the five possible failure modes (Table 1). Eurocode3 proposed two formulas, the first simple (method 1) and the second alternative (table 6.2 .Eurocode3). For T-stub 2 bolts per row, $n_1 \leq 1.25\,m$, and for the T-stub with four bolts per row, $n1 + n2 \leq 1.25\,m$ (Demonceau 2011).

It should be noted that the effective length L_{eff} corresponding to each failure mode (Table 6.4 Eurocode3) is not taken into account in this study.

Figure 7. T-stub tested (four bolts per row).

5 PARAMETRIC ANALYSES

A parametric study has been initiated to study the sensitivity of different geometric parameters in order to determine the limits of applicability of the analytical formulas and evaluate the simplifications adopted. In this context, we analyze on the basis of analytical formulas (Eurocode3, Aribert 1999, Mehidi 2010, 2011) the evolution of the stiffness, the strength, and the lever force that acts upon the T-stub in function of the plate thickness (e_{pl}), curvature at the point of application of the load (displacement), and the position of the lever force resulting (n_1). The used values for either (e_{pl}) or (n_1) are more than those proposed by the Eurocode3 in a way to see its influence in a sufficient large domain.

In this analysis, we seek to confirm the new model mentioned above by comparing it with that given by Eurocode3 and the one in the literature (Demonceau 2011, Jiménez 2011). A computer program was carried out to study the role and influence of each component, in particular the effect of the fourth line of the bolts vertically disposed. The results obtained show that the simultaneous increase of the thickness of the end plate, diameter (d) and the number of bolts, have a considerable influence on the value of the strength, stiffness, and failure mode.

We show the main results of this analysis in the following paragraphs.

5.1 *Evolution of the initial stiffness in function (e_{pl}) and (n_1):*

Figure 8 shows the evolution of the initial stiffness in function of the thickness of the plate (e_{pl}) for both

Table 1. Summary of the strengths of T-stub.

Failure modes	T-stub with 2 bolts per row	T-stub with 4 bolts per row	
	Eurocode 3, méthode 1 , Table 6.2	Proposed model	(Demonceau 2011, Jiménez 2011) alternative Méthode
Mode 1	$F_{R1} = \frac{4.M_{pl}}{m}$	$F_{R1} = \frac{4.M_{pl}}{m}$	$F_{R1} = \frac{(8n_2 - 2d_w)M_{pl}}{2mn_2 - \frac{d_w}{2}(m + n_2)}$
Mode 2	$F_{R2} = \frac{2(M_{pl} + N_{Pl}.n_1)}{m + n_1}$	$F_{R2-1} = \frac{2(M_{pl} + N_{Pl}.n_2)}{m + n_2}$ $F_{R2-2} = \frac{4.M_{pl} + 2.N_{pl}.n_2}{m + n_2}$ $F_{R2-3} = \frac{2M_{pl} + N_{pl}.(4.n_1 + 2.n_2}{m + n_2 + n_1}$	$F_{R2} = \min(F_{R2,p}, F_{R2,np})$ $F_{R2,p} = \frac{2M_{pl} + 2N_{pl}(n_2{}^2 + 2n_1^2 + 2n_1n_2)}{(m + n_1 + n_2)}$ $F_{R2,np} = \frac{2M_{pl} + 2N_{pl}n_2}{(m + n_2)}$
Mode 3	$F_{R3} = 2.N_{pl}$	$F_{R3} = 4.N_{pl}$	$F_{R3} = 4N_{pl}$

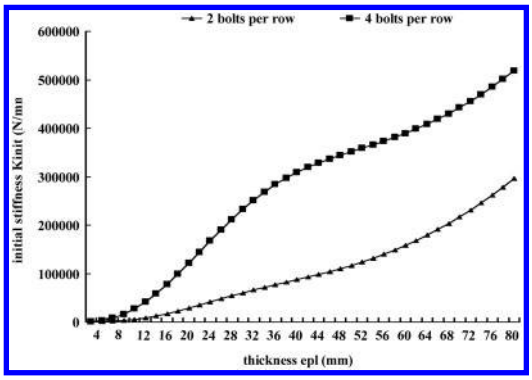

Figure 8. Variation of the initial stiffness depending on the thickness of the plate (e_{pl}).

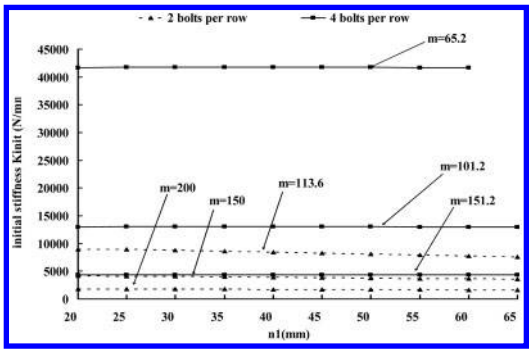

Figure 9. Variation of the initial stiffness based of (n_1) and (m) to thickness $e_{pl} = 14$ mm.

models 2 and 4 bolts per row, taking account of (m) between the bolt axis and the appearance of the first plastic hinge of the first model, is equal to the sum of (m) and (n_2) of the second model for a better taking into account the added row bolts. We observe that there is a slight difference for relatively thin plate, contrary the deviation is remarkable whenever the thickness increase. Generally, the model with 4 bolts per row gives initial stiffness always greater and becomes very significant compared to the first model with 2 bolts per row, which reflect the interest of the new model obtained and the appropriate business.

For the same values (n_1) given and (m) different, for example $n_1 = 20$ mm, the initial stiffness of the T-stub with two bolts per row, is less than the one with 4 bolts per row (Fig. 9). It is observed that the results of stiffness obtained, are very low due to the important value of (m), which causes a certain flexibility to the assembly; the T-stub with $m = 65.2$ mm, is stiffer than the one with $m = 101.2$ mm. The significance of the change of (n_1) is not shown by curves of figure 9, this is due to the values of the distance between the welding cord and the bolt axis which are important and that the T-stub has a flexibility, which at the same time reduces the transmission effect of the force applied to the position of the lever force.

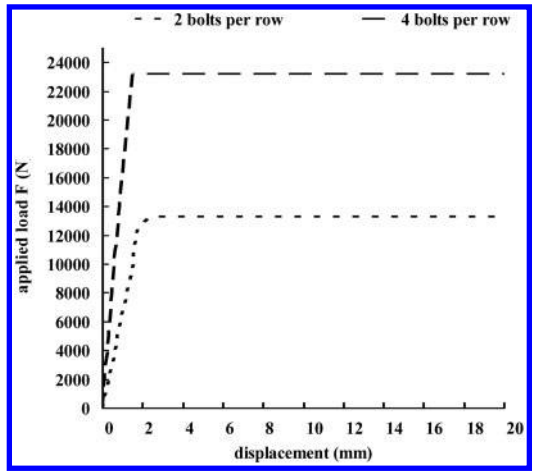

Figure 10. Variations of the load applied as a function of displacement of the plate- $e_{pl} = 10$ mm and $n_1 = 35$ mm.

5.2 *Evolution of strength versus (epl):*

Figures 10 show the variation of the applied load F versus displacement, right to the load application for plate $e_{pl} = 10$ mm. By varying the number of bolt rows; the distance between tow axis of the first row of the bolt and the welded web-flange decrease, we note that the strength will be almost doubled and the displacement (deviation) will decrease.

5.3 *Evolution of the force versus the lever (n1)*

Figure 11 shows a comparison between different T-stub reflecting the effect of thickness on the lever force, witch is not significant due to the simultaneous influence of several parameters such as, the number of bolts axis , the values of (m) and (n_2), and the force applied, giving by the end a very complex behavior of the assembly. For the first model, we notice that the contact between the plates done for thin and while we relatively thick ones. By contrary, the lever force decreases with the increase thickness for relatively thick plates, which reflects the deviation between the two plates without contacts. For the second model, is the opposite case of the first, with low values of lever force. We also attempt to know the evolution of the lever effort according to the external force applied by varying the position of the lever (n_1) (Fig. 12). Ratio of obtained values is 0.5 for T-stub with 2 bolts per row, this is due to large values of (m) compared to (n_1), which reflects the full transmission of the force applied at the lever force and which indicates that the spring model (Eurocode3, Al-Khatab 2007) has a large dilatation at the bolts level. This case will be resolved when we increases the diameter of the bolts (bolt becomes more rigid) or by adding another row of bolts that gives a ratio of about 0.06 which will be the case of a T-stub with four bolts per row.

After a plastic analysis of continuous beams on six supports, it reached the ruin in function of the number

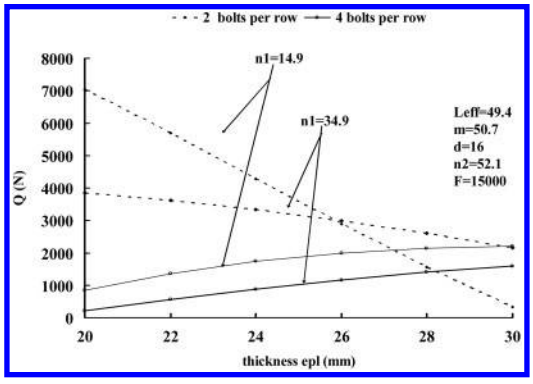

Figure 11. Variation in the lever force according to the thickness of the plate.

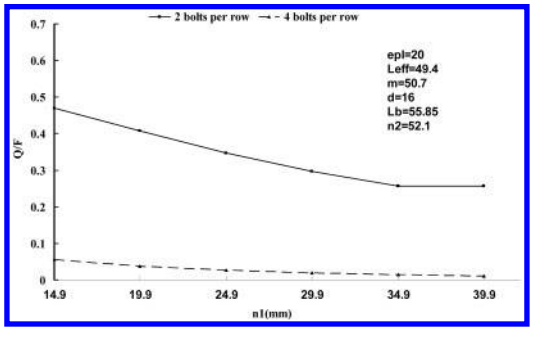

Figure 12. Variations in the ratio of lever force- applied load by the values of *nl*.

of hinges that appear, to say that a Mechanism. Therefore, the comparison can be made with (Demonceau 2011) is significant, except for failure mode 2, and contrary to the other (mode 1 and 3) have the same results.

6 CONCLUSIONS

In this article, we presented the principles of the component method adopted by the Eurocode3; to characterize the behavior of assemblies.

Then, we also analyzed the behavior of T-stub which conducted major components in the tensile zone assemblies, subjected to bending. In this context, we varied several geometrical parameters of the T-stub in order to see the sensitivity of the initial stiffness, the lever effort and strength depending on, thickness of the plate, the position of the resulting lever force and the number of the bolt per row (number of row arranged vertically).

At the end of this study, it can be argued the following conclusions:

– Increasing the thickness of the plate (flange) will increase stiffness for both models, but leads to a better decreasing of displacement and delay the appearance of the first plastic hinge for the new model with four rows of bolt;
– The addition of another row of bolt vertically arranged, has an influence on the value of the total force applied, compared with the same original T-stub.
– The geometrical dimensions as position of lever force, the distance between the bolt axis and welded cord, play an important role in determining the behavior of the plate (deformation) as well as the amplification of lever force.

The comparison of these results with those of the literature and experimental, we can confirm that the analysis of this new model offers the advantage of studying the tensile part of the bolted assembly beam-column with end plate. The behavior of assemblies with four or more lines arranged vertically (four bolts per row or more) and the obtained results are used to solve some problems in the design of steel frame nodes, as reducing the curvature of the plate (Demonceau 2011); the stiffness and strength in this case will be amplified in a non negligible manner.

Axial capacity of transverse branch plate-to-CHS T-joints

A. A. Shaat
Lecturer, German University in Cairo – Assistant Professor (on leave), Ain Shams University, Egypt

ABSTRACT: The current international design guidelines estimate the axial capacity of transverse branch plate-to-CHS T-joints using a single formula for both tension and compression loads. In fact, the behavior of CHS under branch compressive loads is completely different from their behavior under tensile loads. A parametric numerical finite element study is undertaken to accurately assess the variation in joint capacity under both compression and tension loading cases. Various geometric and material properties are modeled and analyzed using commercially available software, ANSYS. An evaluation of the current CIDECT and AISC strength predictions concluded that general underestimation of the T-joint capacity exists specially when the branch plate is loaded in tension. New design strength functions associated with their valid ranges are proposed based on a nonlinear regression analysis of both the finite element results and previous research data.

1 INTRODUCTION

Steel hollow sections are extensively used in both offshore and onshore structures for their inherent strength and efficiency. In these structures, the hollow section chord members are either welded directly to the brace members or welded to a branch plate that is connected at its other end to the brace member, as shown in Figure 1. The branch plates could be welded at the longitudinal direction of the chord member or at its transverse direction. The behavior of these welded branch plates to either Rectangular Hollow Sections (RHS) or Circular Hollow Sections (CHS) has been studied in many research programs such as Cao et al. (1998), Kosteski et al. (2003), Wardenier et al. (2009), and Voth and Packer (2012a and 2012b). Design equations that predict the axial load capacity of these branch plates can be found in the Comité International pour le Développement et l'Etude de la Construction Tubulaire (CIDECT) Design Guide No. 1 (Wardenier et al., 2008a) and the American Institute of Steel Construction (AISC) Design Guide No. 24 (Packer et al. 2010).

Figure 1. Example of transverse plate-to-CHS joint.

Lu et al. (1994) proposed an ultimate deformation limit that can be used for hollow structural joints based on both experimental and numerical results. This deformation limit is estimated at 3% of the chord member breadth (b_0) in the case of RHS or the chord member diameter (d_0) in the case of CHS. The applicability of this limit was further validated by Zhao (2000). This deformation value is the most widely limit state used by both researchers and designers to determine the hollow section joint strength.

The following general format was established for calculating the axial capacity (N_1) of branch plate-to-CHS joint since its first development.

$$N_1 = Q_u \cdot Q_f \cdot f_{y0}\, t_0^2 \quad (1)$$

Where, Q_u = partial design strength function, Q_f = chord stress function, f_{y0} = yield strength of the chord member, and t_0 = thickness of the chord member.

The development of the partial design strength function (Q_u) for the transverse plate-to-CHS T-joint is briefly reported herein. First, Kurobane et al. (1976) developed the following formula;

$$Q_u = 6.43\,(1 + 4.60\,\beta^2) \quad (2)$$

Where, β = joint width ratio = b_1/d_0, and b_1 = transverse plate width.

Wardenier (1982) modified the coefficients of the previous equation to account for experimental results of subsequent research programs, as follows;

$$Q_u = 4.20\ (1 + 5.07\ \beta^2) \tag{3}$$

The 1st edition of CIDECT design guide No. 1 (Wardenier et al., 1991) implemented further simplified modifications to the previous design strength function as follows;

$$Q_u = 4.00\ (1 + 5.00\ \beta^2) \tag{4}$$

All the previous expressions have been originally derived based on the assumption of CHS-to-CHS T-joints. Subsequent modifications to the partial design strength function have been reported to account for the effect of the branch plate thickness (t_1) as well as the slenderness of the chord member (γ) (Wardenier et al., 2008b), as follows;

$$Q_u = 2.60\ (1 + 6.80\ \beta^2)\ \ (1 + 0.25\ \eta)\ \gamma^{0.2} \tag{5}$$

Where, γ = chord radius-to-thickness ratio = $d_0/2t_0$, and η = branch plate thickness-to-chord diameter ratio = t_1/d_0.

Based on reanalysis of existing numerical and experimental results for transverse branch plate-to-CHS joints, Wardenier et al. (2008b) adopted further modifications to Equation 5, as follows;

$$Q_u = 2.20\ (1 + 6.80\ \beta^2)\ \ (1 + 0.40\ \eta)\ \gamma^{0.2} \tag{6}$$

IIW sub-commission XV-E and the 2nd edition of CIDECT design guide No. 1 (Wardenier et al., 2008a) have assumed that the value of η is very small and close to zero for transverse branch plate T-joints. Therefore, further simplifications can be implemented to the partial design strength function as follows;

$$Q_u = 2.20\ (1 + 6.80\ \beta^2)\ \ \gamma^{0.2} \tag{7}$$

On the other hand, AISC steel design guide No. 24 (Packer et al., 2010) adopted one common equation for the strength function of both T- and X- types of joints, as follows;

$$Q_u = 5.50\ /\ (1 - 0.81\ \beta) \tag{8}$$

Exploring the development history of the axial capacity of the transverse branch plate-to-CHS joints (Equations 1 to 8) refers to one common approach that does not differentiate between the loading directions of the branch plate; whether tension or compression.

An experimental program consisting of 12 branch and through plate-to-CHS joints under both tension and compression loading was carried out by Voth and Packer (2012a). The experimental results revealed that the behavior of branch plate-to-CHS T-joints tested in tension and compression is significantly different. Using regression analysis that incorporates the results of both experimental and finite element model (FEM) analyses individual formula for each loading case is introduced by Voth and Packer (2012b), as follows;

$$\text{Compression} : Q_u = 2.90\ \zeta\ (1 + 3.0\ \beta^2)\ \gamma^{0.35} \tag{9}$$

$$\text{Tension} : Q_u = 2.60\ \zeta\ (1 + 2.5\ \beta^2)\ \gamma^{0.55} \tag{10}$$

Where, ζ is a reduction factor with a lower bound value of 0.85.

Two main factors were ignored while developing the design equations by Voth and Packer (2012b), which are;

1. The branch plates were assumed relatively thin (i.e. η = zero), while the large weld size (13.43 mm) in addition to the branch plate thickness (19.05 mm) used in their numerical analysis imply η ratio of 0.21. This large value of η will have a considerable impact on the regression analysis of the design equations.
2. The large values of β (i.e. $\beta > 0.85$) prevent the CHS chord member from reaching the predefined deformation limit of 3% of the chord member. This is mainly due to the stiffening effect of the wide transverse branch plate. Therefore, splitting each design equation into two equations with a limiting validation β ratio may provide more accurate strength predictions.

This paper introduces a FEM that captures the variation in strength of transverse plate-to-CHS joints under tension and compression loading. After verifying the model against the test results of Voth and Packer (2012a), a comprehensive parametric study was carried out to examine the validity of Equations 9 & 10 against a wider range of parameters. The following sections introduce the FEM details, verification against the test results, and the detailed parametric study. Finally, a regression analysis was carried out to propose new design equations that predict both compressive and tensile capacities of transverse branch plate-to-CHS joints.

2 FINITE ELEMENT MODELING

This section introduces the details of the FEM and methodology adopted for the branch plate-to-CHS T-joints, including element type, mesh density, boundary conditions, and material modeling. Commercially available finite element program ANSYS has been employed.

2.1 *Shell element and mesh size*

The symmetric geometry of the T-type specimens about two vertical planes allowed modeling only one quarter of the specimens, as shown in Figure 2.

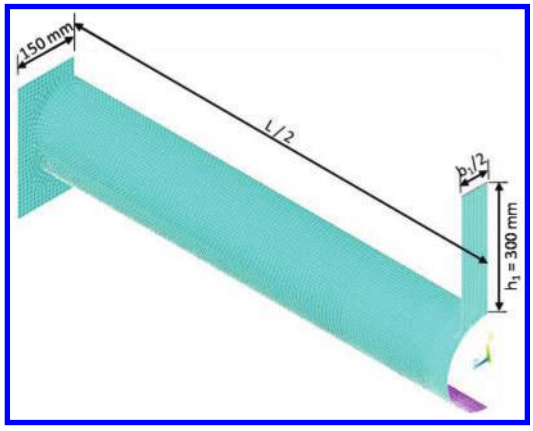

Figure 2. One quarter of the FEM.

Symmetric boundary conditions are applied at the specimen cut edges. Nominal center line dimensions are used to model the specimens. A 3-D SHELL181 element is used to model all components of the specimen including, the CHS chord, branch plate, chord end plates, and welding material between the branch plate and chord member. SHELL181 is suitable for analyzing thin to moderately thick shell structures. It is a 4-node element with six degrees of freedom at each node: three translations in the x, y, and z directions, and three rotations about the x, y, and z-axes. In the model, the element size is varied in such a way that relatively smaller elements with a size of 5 mm are used at the vicinity of the intersection between the branch plate and chord member where the stress gradient is more critical. The mesh density decreased towards the ends where size of elements reaches 10 mm.

2.2 *Material modeling*

Multi-linear isotropic hardening material model was used to model all components of the specimens. This model captures quite accurately the stress–strain curves obtained from coupons tests by Voth and Packer (2012a). The welds were assumed to have the same material properties as the base metal.

2.3 *Loading and boundary conditions*

Uniformly distributed pressure is applied at the top edge of the branch plate. End plate (20 mm thick) is modeled at the end of the chord member with complete fixity to the chord nodes. All nodes of the end plate are restrained in the x, y, and z translational degrees of freedom.

2.4 *Finite element model validation*

The finite element model is validated using the results of eight specimens tested by Voth and Packer (2012a). All specimens had the same chord size of (219 × 4.8) and yield strength of 389 MPa, which is outside the validity range for Equation 8. The design provisions of Eurocode 3 specify the limits for the diameter-to-thickness ratio (d/t) equal to ($11750/f_y$), ($16450/f_y$), and ($21150/f_y$) for classes 1, 2, and 3, respectively. Accordingly, specimens tested by Voth and Packer (2012a) are classified as class 3, which is outside the validity range of Equation 7. The tested parameters included different configurations such as the plate orientation (longitudinal or transverse), method of plate attachment (branch or through), and the type of loading (tension or compression). Table 1 lists a comparison between the experimental and FEM loads, where the load is measured at the 3% deformation of the chord diameter as a criterion for the joints capacities. Table 1 indicates an average value for the ratio between the FEM and experimental loads of 0.98 with a standard deviation of 0.06. The model is deemed suitable and reliable for the parametric study that follows.

3 PARAMETRIC STUDY

The validated model is used to carry out an extensive parametric study to examine the validity of Equations 9 and 10 in predicting the tensile or compressive capacities of transverse branch plate-to-CHS T-joints. All specimens had the same chord diameter (219 x t_0). A chord effective length parameter (α) is taken equal to 20 as per the recommendations of van der Vegte and Makino (2006). The prescribed value of α resulted in a total length of chord member equal to 2200 mm. The branch plate thickness is taken equal to 20 mm and is kept constant throughout the parametric study.

A total of 64 specimens are examined in this research program to study the following parameters:

1. Chord sizes are 219 × 6.4, 8.0, 9.5, and 11, which are equivalent to chord thicknesses of 6.35 mm, 7.95 mm, 9.53 mm, and 11.13 mm, respectively.
2. Branch plate widths of 100 mm, 140 mm, 180 mm, and 200 mm, which are equivalent to β ratios of 0.49, 0.67, 0.84, and 0.94, respectively. It should be noted that the calculations of β ratios have accounted for the footprint of the branch plate including its weld sizes.

4 RESULTS

Tables 2 and 3 list the results of the finite element analysis in terms of the joint compressive and tensile capacities (N_{FEM}), respectively. The tables also list the joints capacities (N_1) as calculated using the formulae given in Equations 1, and 7 to 10 as well as a comparison between these values and the FEM results.

The results show large discrepancy between the FEM results and the values given using Equations 7 to 10. Table 2 indicates that using Equation 7 (Wardenier et al., 2008a) and Equation 8 (Packer et al., 2010) to calculate the compressive strength of branch plate-to-CHS T-joints give conservative results with average differences of 10% and 23% lower than the FEM results. Equation 9 introduced by Voth and Packer (2012b) for the compressive strength of joints gives also conservative results with 10% lower than the FEM results. However, Equation 9 has a lower standard deviation of 7% compared with 14% and 22% for Equations 7 and 8, respectively.

Table 3 proves that using the same Equations 7 and 8 to calculate the tensile strength of the joints is way below their real capacities. Equations 7 and 8 underestimate the tensile strength of transverse branch plate-to-CHS T-joints by 47% and 63%, respectively. Equation 10 introduced by Voth and Packer (2012b) for the tensile strength of joints gives better results with an average of only 6% lower than the FEM results. Yet, Equations 7, 8, and 10 have large standard deviation values of 38%, 50%, and 15%, respectively.

5 NEW PROPOSED DESIGN EQUATIONS

A non-linear regression analysis is performed using the general format of partial design strength predictions (i.e. similar to Equations 5 and 6) that account for

*Specimens failed prior to reaching the 3% d_0.

the effect of branch plate thickness. The finite element results of Voth (2010) are included in the regression analysis to have more reliable predictions. A limiting β ratio of 0.85 is adopted to exclude the specimens that failed prior to reaching the deformation limit of 3% d_0. It should be noted that two specimens out of the 16 specimens with β equal to 0.83 failed at a lower deformation limit. This small number of specimens was assumed insignificant to change the equations limit ($\beta = 0.85$). The proposed design equations are summarized as follows;

Compressive strength:

$$Q_u = 2.40\,(1 + 2.21\,\beta^2)\,(1 + 1.08\,\eta)\;\gamma^{0.40} \quad \text{for } \beta < 0.85 \tag{11}$$

$$Q_u = 10.81\,\beta^{3.34}\eta^{0.20}\,\gamma^{0.54} \quad \text{for } \beta \geq 0.85 \tag{12}$$

Tensile strength:

$$Q_u = 2.14\,(1 + 1.50\,\beta^2)\;\;(1 + 0.95\,\eta)\;\;\gamma^{0.64} \quad \text{for } \beta < 0.85 \tag{13}$$

$$Q_u = 26.90\,\beta^{3.13}\eta^{1.13}\,\gamma^{0.88} \quad \text{for } \beta \geq 0.85 \tag{14}$$

The strength ratio between the numerical results and the proposed equations' values ($N_{FEM}/N_{roposed}$) has average values of 0.99, 1.00, 0.99, and 1.02 for Equations 11 to 14, respectively. The previous strength Equations 11 to 14 have correlation coefficients of 0.996, 0.998, 0.991, and 0.987, respectively.

6 CONCLUSIONS

Evaluation of the current design guidelines, for transverse branch plate-to-CHS T-joints, has been undertaken using a numerical finite element parametric

study consisting of 64 specimens, under both tension and compression branch plate loading. The study has proved that the current international design guides (CIDECT Design Guide No. 1 and the AISC Design Guide No. 24) are generally conservative for transverse branch plate-to-CHS T-joints and under-utilize their capacities especially when the branches are loaded in tension. Based on regression analysis, of the FEM results as well as research data by Voth (2010), improved partial design strength functions are proposed to accurately predict the axial capacity of transverse branch plate-to-CHS joints.

Sustainable composite beams with deconstructable bolted shear connectors

S.S.M. Lee & M.A. Bradford
Centre of Infrastructure Engineering and Safety, School of Civil and Environmental Engineering, The University of New South Wales, NSW Sydney, Australia

ABSTRACT: Composite structures using steel joists mechanically connected to concrete slabs serving as the flooring and decking systems are commonly used in buildings and bridges respectively. The use of the state-of-art sustainable geopolymer concrete and innovative deconstructable pretensioned bolts under service loads in composite beam design can reduce CO_2 emission by enhancing the sustainability of, and recyclability in, the construction industry by enabling deconstructability. Most previous research has been conducted on composite beams with welded shear studs with conventional concrete using ordinary Portland cement, with limited studies on beams with pretensioned bolted shear connectors being reported. This paper describes the results of five preliminary push tests that have been conducted to establish the strength and stiffness characteristics of pretensioned bolted shear connectors. The effects of the size of the clearance holes, the diameter of the bolts and the pretension force are also investigated. It is shown that the shear connectors can induce three types of shear interaction along a beam: viz. a region of "full interaction", a region of "zero interaction" and a region of "partial interaction", that are delineated by the shear flow force at the interface, by the coefficient of friction at the interface and bolt pretension, and by the size of the clearance hole relative to the diameter of the bolt. A mechanics-based model that can capture the beam behaviour based on the push test results is described.

1 INTRODUCTION

Composite structures using steel joists mechanically connected to concrete slabs are commonplace in buildings and bridges. Concrete is normally strong in compression but weak in tension, whilst steel in compression is prone to buckling effects, and so their symbiotic attributes in composite beams make the composite beam an efficient member. The mechanical shear connectors are designed to bring about composite action in these complementary materials to increase the strength, ductility and stiffness of composite beams above those of the individual materials themselves. Normally, the weakest component governs the strength of the composite structure.

Ordinary Portland cement (OPC) has been traditionally used as a paste to produce concrete for many years. It is widely-known that OPC is a major contributor to anthropogenic greenhouse gas production, with large CO_2 emissions being associated with the manufacture of OPC, with one tonne of OPC producing approximately one tonne of CO_2 (Davidovits 1994). The use of geopolymer concrete (GPC) as a replacement for OPC is seen as one means of mitigating the excessive CO_2 emissions associated with OPC, and is a topic of current research in cementitious materials science. Fly ash is a waste material from coal burning power stations around the world, and has been used and experimentally tested as a source of geopolymer for GPC that is reported to exhibit comparable if not better material properties to OPC-based concrete (Hardjito et al. 2004). The use of a waste material such as fly ash to replace OPC to produce high strength GPC is producing a new era of more sustainable concrete industry. However, GPC is not readily batched on-site by comparison to concrete based on OPC, and so its use in precast applications is an important research issue. The slab systems considered in this paper are precast GPC ones.

There are many types of mechanical shear connectors (Oehlers and Bradford 1995) as shown in Figure 1, but the most commonly used ones are the stud connectors normally welded to the top flanges of the steel joists before casting the concrete slabs (solid or profiled with steel sheeting) because they are economical and easy to install. Clearly the welding and casting of the concrete around headed stud connectors is highly problematic in formulating deconstructability and

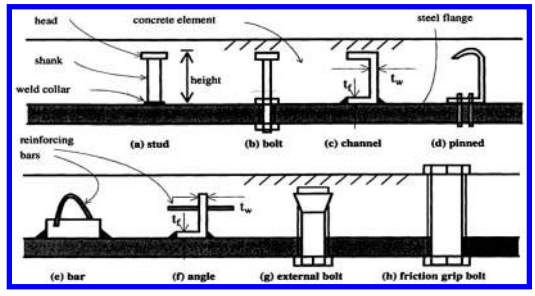

Figure 1. Mechanical shear connectors.

recycling technologies for composite beams. High-strength bolted steel shear connectors (Figure 1(h)) provide a viable alternative to headed connectors in terms of deconstructability. Despite this, and despite the potential for retrofitting composite bridge beams whose studs have failed under fatigue loading, surprisingly little has been reported in the open literature on high-strength bolts as shear connectors.

Most of the previous research of composite beams has been based on stud shear connectors for normal steel joists and with OPC slabs. Of the limited studies on bolted shear connectors in composite steel-concrete beams, Dallam (1968) and Dallam and Harpster (1968) reported push tests and beam tests undertaken with bolts embedded in the concrete, Marshall et al. (1971) undertook tests on embedded and post-installed bolts and recently Kwon et al. (2010) investigated the use of post-installed shear connectors under static and fatigue loading. However, none of those studies offered a complete understanding of the structural behaviour of these types of structures nor considered the issues of deconstructability and sustainability. Therefore, more detailed investigations of the structural behaviour of bolted shear connectors, bolted steel joists and precast GPC slabs, all of which can be recycled at the life end of a structure, is much-needed. The use of push tests and the potential of applying the push test data to predict the structural response of full-scale sustainable composite beams with deconstructable bolted shear connectors is the subject of this paper.

2 EXPERIMENTAL PROGRAM

Five push tests were conducted to obtain the load-slip characteristics of the pretensioned bolted shear connectors, with an aim to study the effects of the pretension, the size of the holes in the concrete panels, the diameter of the bolts and the number of bolts on the strength and stiffness of these types of shear connectors, and to provide data to model the response of composite beams theoretically. The key push test parameters are summarised in Table 1.

Two different sizes of high strength structural bolts were used, viz. M20 8.8 and M16 8.8 bolts pretensioned to their specified loads of 145 kN and 95 kN respectively. A smaller pretension of 80 kN was also applied in one of the push tests. Two sizes of holes were prepared for the push test specimens viz. 24.0 mm and 28.0 mm in diameters which gave clearances between the pretensioned bolt and the hole in the concrete panels of 2 mm and 4 mm all around respectively. Figure 2 outlines the precast slab dimensioning and the location of the holes.

The geopolymer concrete push test panels were prepared and cast by ZeoBond (E-crete) based in Melbourne, Australia. The details of the steel mesh reinforced concrete panels are shown in Figure 3. The precast concrete panels and 10 standard cylinders were cured with plastic cover at room temperature for 7, 14, 28 and 90 days and the strengths of the concrete at these ages were tested. Special bushes were made to align the centres of the holes in the steel flange and the concrete panels before drilling the holes through the steel flange. The bolts were then pretensioned using squirter (with orange colour squirts) washers which had been calibrated to give precise pretensions of 145 kN and 95 kN to the M20 8.8 and M16 8.8 bolts respectively

Table 1. Summary of test parameters and results.

Specimen	Bolt dia. (mm)	Hole dia. (mm)	No. of bolts	No. of panels	Pretension per bolt (kN)
001	20	24	4	2	145
002	20	28	4	2	80
003	16	24	4	2	95
004	20	24	4	2	145
005	20	28	8	4	145

Figure 3. Push test preparation and test set-up process.

using an electric torque control wrench. The final positions of the pretensioned bolts were marked before loading in each push test. The push test specimens were then installed with two linearly varying displacement transducers (LVDT)s to measure the slips at the steel-concrete interface and a third LVDT was used to monitor the horizontal movements during the tests. Rollers were placed at one of the supports and the push test specimens were loaded using a displacement controlled Instron test rig in the Heavy Structures Research Laboratory at the University of New South Wales. During each push test, the test specimen was cycled 25 times between approximately 5% and 40% of the estimated failure load as per the EC4 push test procedure before loading it to failure.

3 RESULTS

The results of Push test 001 show that there are three distinctive stages of the load-slip curves, shown in Figure 4.

During the first stage of interaction, the friction created by the pretension of the bolts at the steel-concrete interface resisted slip at the interface giving rise to a very stiff or "near full" shear interaction. Towards the end of this stage, a loud "bang" was heard when the increasing applied vertical load finally overcame the friction at the interface. Once this friction was overcome at around 283 kN, slip started to occur during the second stage of interaction, and the shear connection became much more flexible under displacement control resulting in a "near zero shear interaction". The coefficient of friction was calculated to be 0.49 which is comparable to figures of 0.47 to 0.479 quoted in the work of Marshall et al. (1971) on push tests between their steel beam and precast slabs. It was possible that one of the bolts was slightly under pretensioned as indicated by the LVDT in the north-side, as not all orange coloured squirters came out after closer examination during the test. This explained why LVDT N showed an earlier slip than LVDT S, and so the coefficient of friction of 0.49 is an upper bound.

Under displacement control, the slipping continued to increase to a critical value which is consistent with the clearances between the pretensioned bolts and the circumferences of the holes in the precast concrete panels. In this case, it can be seen from Figure 4 that this value was very close to 4 mm, i.e. twice the hole clearance all around as would be expected as the bolts were located concentrically in the holes. Once this critical slip value (which depends on the clearance between the bolts and the circumference of the holes in the precast concrete panels) was exceeded, the bolts started to bear on the concrete producing a stiffer partial shear interaction response with increasing load until around 600 kN when there was indication of strain hardening with increased ductility during this third stage of shear interaction. The failure load was 866 kN (3.06 times the load at first slip; c.f. Marshall's equivalent value of 2.63) with all bolts fully

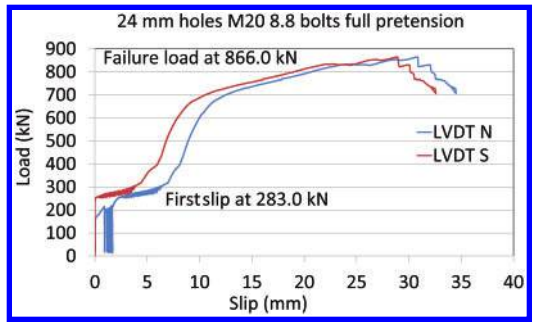

Figure 4. Load-slip evolution for specimen 001.

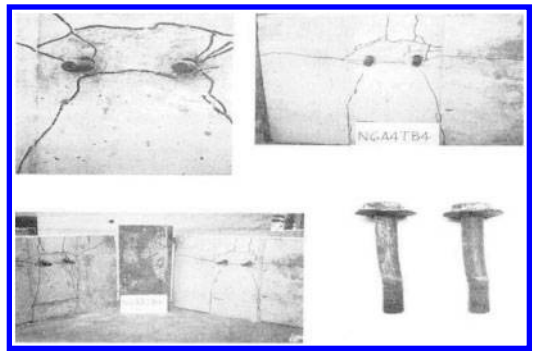

Figure 5. Dallam's push-test failure mechanism.

yielded and a block shear failure in the concrete resulting in a maximum slip of 30.8 mm and an ultimate shear stress of 689 N/mm^2 (c.f. Marshall's equivalent value of 607 N/mm^2). Closer examination of the failed test specimens shows evidence of friction with noticeable scuffing being overcome and the scale of scuffing which is broadly proportional to the applied pretension and also bearing on the concrete at the steel interface. This failure mechanism appears to be consistent with that in Dallam's push tests (Dallam 1968), as shown in Figure 5.

The second push test 002 was carried out at a 90 day concrete strength with an increase in the diameter of the holes from 24 mm to 28 mm and a smaller pretension of 80 kN (about half of that for specimen 001). The load-slip curves show a similar trend and failure mechanism as depicted in those of push test 001, as shown in Figure 6. A lower load of 80 kN at first slip was recorded as a result of smaller pretension of the bolts and the critical slip value was consistent with the size of the holes before bearing on the concrete occurred. A lower failure load of 808 kN, as a result of reduced the pretension (c.f. Marshall's similar observation) was measured with a maximum slip of 26 mm, indicating a high degree of ductility. The lower pretension gave rise to a lower coefficient of friction of 0.25 and this requires further investigation. The load-slip curve of a single 22 mm pretensioned shear connector from the push tests of Kwon et al. (2010) is very similar to that of Figure 6.

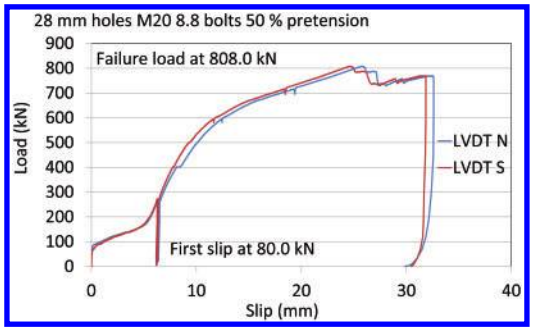

Figure 6. Load-slip evolution for specimen 002.

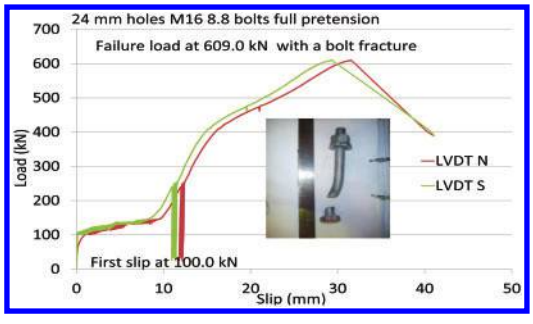

Figure 7. Load-slip evolution for specimen 003.

The third push test 003 involved the use of a smaller size of bolts, i.e. M16 8.8 pretensioned to 95 kN and the results are shown in Figure 7. Again, the load slip curves confirm the occurrence of three different stages of shear connector load-slip behaviour, i.e. changing stiffness as observed in two previous push tests. The lower pretension gave a similar load of 80.0 kN at first slip and the critical slip value recorded during the second stage of "near zero" shear interaction was consistent with the clearance between the pretensioned bolts and the holes in the precast concrete panels, i.e. 8.0 mm. The push test specimen failed at 609 kN with a maximum slip of 31.5 mm and with bolt fracture in addition to shear cracks in the concrete and three fully-yielded bolts.

The fourth push test was a repeated test of push test 001 and, as would be expected, the load slip curves show similar pattern to that of push test 001 as shown in Figure 9. The test specimen started to slip at a slightly lower value of 263.0 kN but failed by a bolt fracture in addition to shear cracks in concrete and three fully yielded bolts at a higher load of 890 kN with a maximum slip of 24.8 mm. During this test, the bolts were deconstructed at a service load between after the first slip and before the bolts started to bear on the concrete. The deconstructability of the bolts under service loads was confirmed. The bolts were then unloaded and then re-pretensioned and reloaded to failure. The test specimen failed at 890 kN with a maximum slip of 24.8 mm with a bolt fracture in addition to shear cracks in the concrete and three fully yielded bolts. One of the possible reasons that it failed at a higher load with a bolt

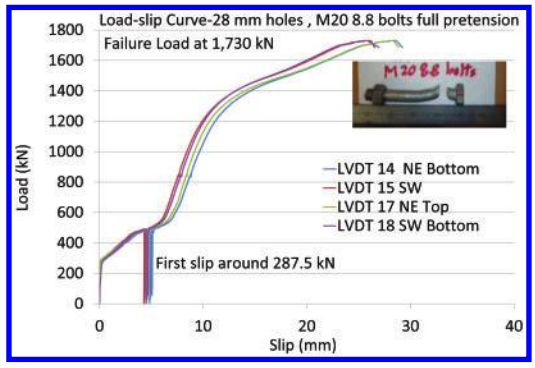

Figure 8. Load-slip evolution for specimen 005.

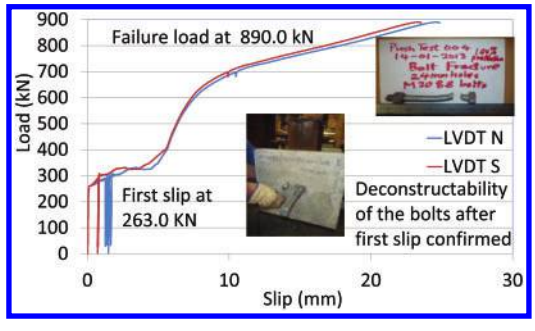

Figure 9. Load-slip evolution for specimen 004.

fracture could be due to the increased concrete strength to 48 MPa at 90 days rather than 43 MPa at 21 days.

The last of the push test series, push test 005, was a test in which the number of bolts and concrete panels was increased two-fold by stacking up two single panels on each side of the push test specimen, and the results are shown in Figure 8. This replicates more closely a full-scale test beam situation in which several precast panels are juxtaposed on the top flange of a steel joist.

The load slip curves and the failure mechanism are slightly different from the other four push tests, except push test 002. The second stage of the "near to zero interaction" appears to be replaced by some level of "semi-partial interaction" with a finite stiffness. There was evidence that some bolts slipped earlier than the others resulting in a situation where some bolts were still slipping while the others were already bearing on the concrete. This gave a combined overall "semi-partial" stiffness of the push test specimen. In the case of a simply supported beam under a distributed load, the varying shear flow along the span will cause the bolts to slip or bear on the concrete at different stages of the loading after the initial overcoming of the friction at the steel-concrete interface produced by the pretension. The failure load recorded was 1730 kN as predicted, being around twice of that in push test 004 single panel push test.

The key push test results are summarised in Table 2, while Figure 11 indicates some failure modes.

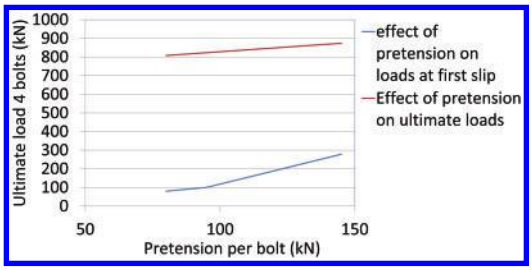

Figure 10. Effect of pretension on loads.

Table 2. Key push test results.

Test	P_{sp} (kN)	P_u (kN)	μ	s_b (mm)	s_u (mm)
001	283	866	0.49	4	30.8
002	80	808	0.25	6	25.8
003	100	609	0.26	8	31.5
004	263	890	0.45	4	24.8
005	288	1730	0.50	8	28.6

P_{sp} = load for first slip; P_u = ultimate load; μ = coefficient of friction; s_b = slip at first bearing; s_u = ultimate slip.

Figure 11. Failure modes.

The effect of the pretension on the loads at first slip and the ultimate loads is shown in Figure 10. It can be seen that, similar to the push tests of Marshall et al. (1971), pretension appears to have an increasing effect on the loads at first slip and the ultimate loads in specimens with pretensioned bolted shear connectors.

4 FRAMEWORK OF THEORETICAL MODEL

A theoretical model of the response of a beam with pretensioned bolted shear connectors at service loading can be developed, which uses the empirical results from the push testing (Rowe & Bradford 2013). This can be illustrated with reference to a simply-supported geometrically symmetrical beam of length L under a monotonically increasing uniformly distributed load

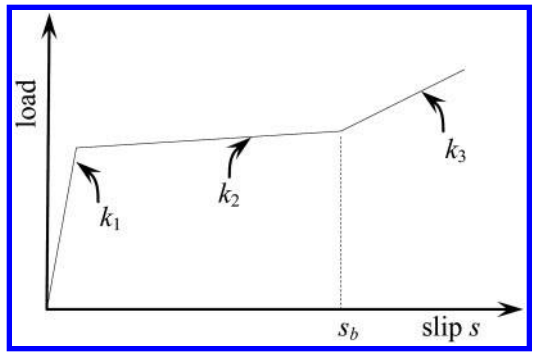

Figure 12. Idealised response in elastic range.

q, for which the shear flow force at the interface is $V = qx \cdot B/I$, where B is the first moment of area of the slab above the interface, I is the second moment of area of the composite beam with full shear interaction (both determined from transformed area principles) and x is the longitudinal coordinate measured from mid-span. The shear connection can be considered as continuous and distributed uniformly lengthwise.

Initially, the beam has full interaction because of the prestress provided by the bolts, which has a capacity of $p = \mu n P/L$, where P is the prestress in each of the n bolts and μ is the coefficient of friction. When the shear flow force at the ends of the beam $(1/2qLB/I)$ reach p, the bolts in that location start to slip, i.e. when $q = q_1 = 2pI/(LB)$. As q increases from q_1, the bolts slip in the region defined by $[-L/2, -a] \cup [a, L/2]$ where $a = (p/q) \cdot (I/B)$ until the slip at the ends of this region reach a limiting value s_b at $q = q_2$, where s_b is the slip at first bearing. The region then defined by $[-L/2, -b] \cup [b, L/2]$ experiences partial interaction, with the bolts bearing against the GPC slab. As q increases above q_2, the values of a and b decrease, and so the beam has five distinct regions of shear connection, viz. Γ_1: $[-a, a]$; Γ_2: $[-b, -a] \cup [a, b]$ and; Γ_3: $[-L/2, -b] \cup [b, L/2]$.

The regions of shear connection Γ_1, Γ_2 and Γ_3 are illustrated by the load-slip relationship shown in Figure 12, for which the slip moduli can be determined from the push test results. As an approximation from these, $k_1 \approx \infty$, $k_2 \approx 0$ and k_3 must be determined empirically. A beam-type finite element model (Ranzi et al. 2004) can be cast in an adaptive mode, with the element boundaries defined by a and b changing with an increase of q.

5 CONCLUSIONS AND ONGOING RESEARCH

This paper has described five push tests undertaken on precast GPC slabs connected to steel I-sections with high strength pretensioned bolts acting as shear connectors. The push test data confirmed one of the study's research hypotheses, in which three distinctive stages of the load-slip characteristics of the pretensioned

bolted shear connection at the steel-GPC interface occurred were observed. These are "near-to-full interaction" followed by "near-to-no interaction" and then finally "partial interaction", with some evidence of strain hardening resulting in the significant ductility of these types of deconstructable shear connectors. The potential of deconstructability of the bolts under service loads was explored and confirmed, with the bolts being removable. The push tests show that the pretension has an increasing effect on the loads to cause first slip and to some extent on the ultimate loads.

In a beam situation, it is likely that regions with these different stages of shear interaction will occur simultaneously, depending on the interface shear flow forces given other parameters being constant. The framework of a simply supported quasi-elastic bolted shear connection composite model under uniformly distributed loading has been described, which uses empirical results obtained from the push testing. Based on the push tests, further experimental work will be undertaken on full-scale beam specimens.

ACKNOWLEDGEMENTS

The work in this paper was supported by the Australian Research Council through an Australian Laureate Fellowship. Zeobond provided the GPC and Hobson Engineering Pty Ltd provided technical advice on the bolt installation. The support of the technical staff in the UNSW Heavy Structures Research Laboratory is acknowledged with thanks.

Numerical simulations of concrete-composite-slabs with perforated metal sheets

S. Pirringer & J. Kollegger
Vienna University of Technology, Vienna, Austria

ABSTRACT: A new approach for composite slabs, using perforated metal sheets as reinforcement, is currently under development at Vienna University of Technology. Compared to common composite slabs with profiled metal sheets, this new design allows a reduction of the slab thickness and two-way slab action. Thereby the transmission of the shear load across the interface between the steel sheet and the concrete is established by the concrete that fills the punched holes of the perforated metal sheet during the concreting process. This new approach of sustainable composite slabs can be used for small sized, structural elements, as for example covers for cable channels, deck slabs for pedestrian bridges and prefabricated parts for short spans. The aim of the research project is the investigation of the structural behavior of the slab and the bond between the concrete and the metal sheet by numerical simulations with ABAQUS and full-scale tests.

1 INTRODUCTION

There is a wide range of areas of application for small reinforced concrete slabs. Covers for cable channels, for example in tunnels and on bridges, is one of the common fields of application, and there-fore a matter of prefabricated, mass-produced articles.

For short spans both reinforced concrete slabs as well as composite slabs with profiled metal sheets show major disadvantages. On the one hand, reinforced concrete slabs need a concrete cover to activate the mild steel reinforcement and to reach the projected bearing capacity. In small concrete slabs this coverage can amount to 10 to 20% of the overall weight and material consumption. On the other hand, the minimum thickness of common one-way composite slabs is limited by the construction height of the profiled metal sheet.

With an approach that is currently under development at Vienna University of Technology the disadvantages mentioned above can be avoided. By using a perforated metal sheet (Fig. 1), it is possible not only to reduce thickness and weight and thus the CO_2 emissions during the manufacture and the costs of the slab, but also to offer a two-way slab action with a minimized effort and complexity of the formwork. The bond between the two basic materials of the metal-concrete-composite-slab (MCC slab) is established by the concrete filling the punched holes of the perforated metal sheet which is placed on the bottom side of the slab.

For a proper fabrication of the slabs, the metal sheet can simply be put on the bottom of the form-work. Another advantage of this system is the possibility of using commercially available metal sheets without any further treatment. Moreover, the costs of recycling are estimated to be low.

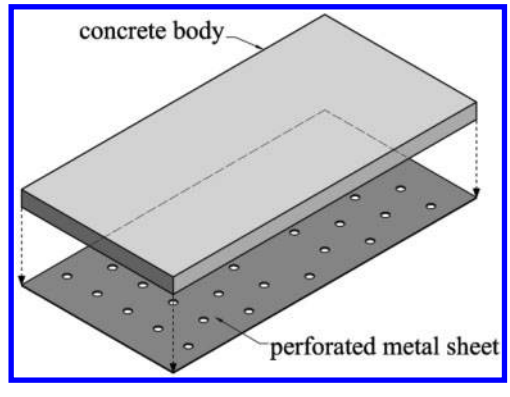

Figure 1. Schematic assembly of a MCC-slab.

2 TECHNICAL BACKGROUND

In contrast to common composite slabs, this approach means working without any of the usual mild steel reinforcement, and using only a perforated metal sheet instead. Since this method tends to be only used for small slabs with thicknesses down to 50 to 100 millimeters or even less, the end anchor-age poses the major problem. Due to the low construction height no end anchorage as known from common composite slabs, e.g. shear studs and/or dovetailed deformations of the profiled (trapezoidal) sheet at the bearing, can be used. Therefore, the whole anchorage has to be accomplished just by the load transfer through the shear

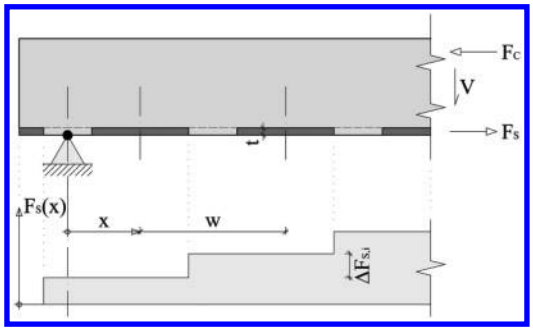

Figure 2. Schematically, longitudinal cut of a MCC-slab.

connectors (concrete dowels) placed in the perforation of the metal sheet (Fig. 2). Besides proving the resistance to bending and shear force, the structural stability of these concrete dowels plays a significant role. For a proper design of the composite slab their ultimate load needs to be known and predictable in advance.

On the one hand, the load bearing capacity of the concrete dowels P_{CD} was approximately calculated by formulas based upon the bearing pressure of holes (Berger 1994) assuming a sinus-shaped distribution of the contact pressure (Fig. 3). On the other hand, it was calculated by the bending stresses that result from the bending moment due to an offset $t/2$ of the dowel force $\Delta F_{s,i}$.

$$P_{CD,calc}(f_c) = \frac{f_c \pi \emptyset t}{4} \quad (1)$$

$$P_{CD,calc}(f_{ct}) = \frac{f_{ct} \pi \emptyset^3}{16t} \quad (2)$$

Where f_c = concrete (or mortar) compressive strength; f_{ct} = concrete (or mortar) tensile strength; $\emptyset$ = diameter of hole; and t = perforated metal sheet thickness.

Based on these approaches for the limit states of the concrete dowels, a threshold ratio $(\emptyset/t)_{lim}$, that considers the concrete compressive and tensile strength, can be derived by equating Equation 1 and 2.

$$P_{CD,calc}(f_c) = P_{CD,calc}(f_{ct}) \rightarrow \left(\frac{\emptyset}{t}\right)_{lim} = 2\sqrt{\frac{f_c}{f_{ct}}} \quad (3)$$

Thus, for known material properties and given parameters $\emptyset$ and t of the perforated metal sheet, this ratio theoretically serves as a parameter for the failure mode of the concrete dowel:

- $\emptyset/t > (\emptyset/t)_{lim} \rightarrow$ failure by exceeding the compressive strength of the dowel material
- $\emptyset/t < (\emptyset/t)_{lim} \rightarrow$ more brittle behavior expected and failure by exceeding the tensile strength of the dowel material

Taking these considerations into account, a $\emptyset/t$-ratio above the threshold ratio would be the best choice.

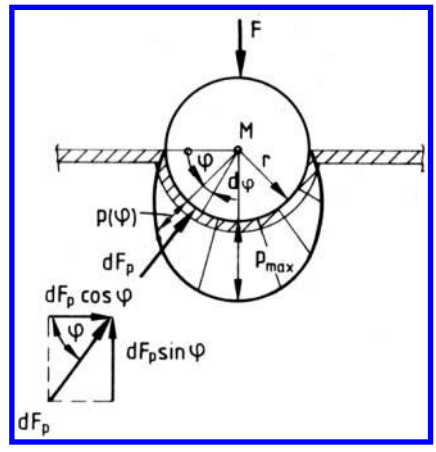

Figure 3. Bearing pressure of holes (Berger 1994).

3 LOAD TESTS ON MCC-SLABS AND THE BOND BEHAVIOR

3.1 *Load tests on MCC-slabs*

Up to now, a preliminary series of 5 specimens as well as 9 series (3 specimens per series) of 4-point bending tests on composite slabs by this approach were carried out. In all of those bending tests metal sheets with circular perforations, arranged in a constant, rectangular grid, have been combined with a concrete body made of self-compacting concrete.

The bending tests proved, that with the correct selection of size (diameter) and layout of the concrete dowels, in short the perforation of the metal sheet, the bond within the MCC-slab is strong enough to resist loads up to the bending load capacity according to Eurocode 2 and to cause a ductile behavior. Series that were designed to collapse due to exceedance of the shear resistance or the load capacity of the shear connectors collapsed at ultimate loads close to values calculated in advance.

3.2 *Load tests on the bond behavior*

For a validation of the calculated dowel capacity, separate tests on the bond behavior were carried out in addition to the 4-point bending tests (Pirringer & Kollegger 2012). Due to the geometry of the whole system and its concrete dowels, the standard shear test as described in Eurocode 4 (appendix B) could not be performed. A new test set-up, basically in accordance to EC 4, was developed for the investigation of the concrete dowel capacity.

Sendzimir galvanized, partly perforated metal sheets with an arrangement of cylindrical holes in a rectangular grid, and a concrete body in two different sizes ($100 \times 100 \times 50$ mm, $150 \times 100 \times 50$ mm) were used for all specimens (Fig. 4). In these experiments either self-compacting concrete (SCC) or grouting mortar was used for the concrete body of the specimens.

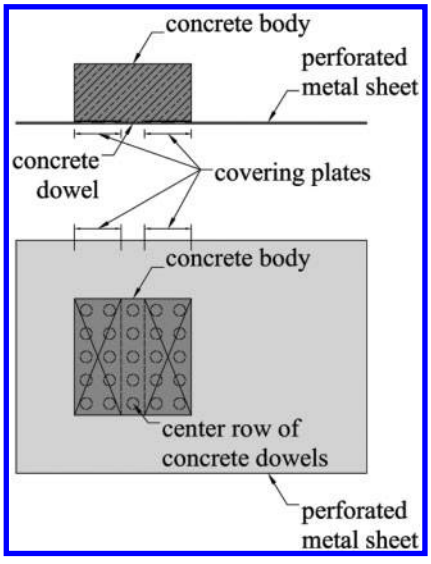

Figure 4. Specimen for shear tests.

3.2.1 *Test set-up*

The whole test set-up was designed in such a way that a shear force F_S as well as a lateral, normal force $F_L \geq 0$ can be applied by a hydraulic testing machine, to simulate the area of the composite slab close to the support (Fig. 5).

The displacement-controlled shear force F_S that was applied with a hydraulic jack, has been gauged with a load cell during the test. Simultaneously, the relative displacement in the direction of load be-tween the concrete body and the steel sheet (slip) has been measured with two displacement transducers on both sides of the concrete body.

Even for tests without a planned lateral loading, the hydraulic testing machine was put against the specimen with a low force of about 0,2–0,3 kN. Thus, a raising and detaching of the concrete body, caused by the resulting moment due to the offset between the applied shear force and the restraining force, should be prevented.

3.2.2 *Series of tests & test parameters*

So far 24 different sets of parameters – a total of 120 specimens, 5 specimens for each set of parameters – were investigated under static loading. A static, displacement-controlled test with a constant displacement-rate of 0,2 mm/min until failure of the concrete dowels was carried out for all specimens.

The resulting dowel capacity $P_{CD,test}$ had to be calculated from the measured shear force F_S. There-fore the friction in the composite joint between the covering plates as well as the concrete and the perforated metal sheet was taken into account.

Beside the material properties the following geometrical parameters of the perforated metal sheet have been of interest for the actual test series:

– Diameter of holes *Ø*
– Center-to-center distance of holes *w*

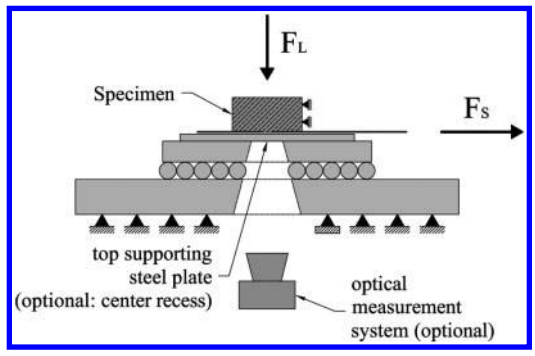

Figure 5. Schematic assembly of the test set-up for tests on the bond behavior with adjustable lateral loading ($F_L \geq 0$) and optional optical measuring.

– Metal sheet thickness *t*
– single or multiple rows of concrete dowels in the direction of the horizontal shear load F_S

For the tests on the concrete dowel capacity neither the tensile strength nor the modulus of elasticity of the metal sheet has been of relevance.

In several series also the influence of different lateral loadings F_L on the concrete dowel capacity was investigated, whereat the lateral load had to be limited to 45 kN because of structural reasons regarding the test set-up.

3.2.3 *Results and conclusion of the tests*

The resulting mean values of the concrete dowel capacities $P_{CD,test}$ were determined considering the overall number of concrete dowels from the ultimate shear force after deducing the calculated friction. The measured values were evaluated for the time of the maximum applied shear force F_S, equivalent to the ultimate dowel load, and were compared to the decisive value $P_{CD,calc}$ calculated according to Equation 1 and 2.

In general, the results of the tests showed a good correlation to the values calculated according to Equations 1 and 2, which are based upon simple mechanical aspects.

4 NUMERICAL SIMULATION OF THE BOND BEHAVIOR

As stated before, very useful information on the bearing capacity of the shear connectors, as well as the slip between the concrete body and the metal sheet, could be gained by the bending tests and the tests on the bond behavior. However, for finding a generally valid design method for this new approach of composite slabs, also detailed information on the distribution of strains and stresses within its individual components – especially the concrete dowel – will be needed.

Therefore, the Finite Element Method (FEM) offers a suitable tool for solving such highly nonlinear problems. For a validation of the tests on the bond behavior, the finite element program ABAQUS was used for calculations of the concrete dowel.

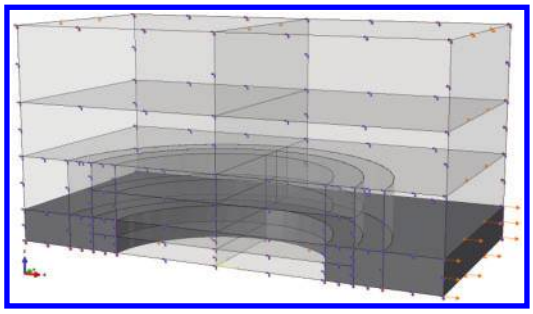

Figure 6. Model for numerical simulations in ABAQUS and zoning for mesh refinement (concrete body – light grey, transparent, steel sheet – dark grey). The arrows at the front side of the steel sheet symbolize the applied displacement-controlled shear load as a boundary condition.

4.1 *Modeling of the geometry*

For a first series of calculations, concrete dowels with the following dimensions were investigated:

- $\varnothing = 10$ mm
- $w = 20$ mm
- $t = 1.5$ mm

These settings were used in multiple test series and offer a good basis for comparisons.

For saving computational costs, only a single concrete dowel, by taking advantage of the concrete dowels symmetry, was modeled. Instead of the total height of the test specimens of 50 mm, also the model's height was reduced to 10 mm (including the perforated metal sheet thickness). By these simplifications, the total size of the model was downsized to 20 × 10 × 10 mm (Fig. 6).

For a practical mesh refinement of the whole model, the concrete part as well as the steel part of the model was separated into several, smaller parts. Parts of the same material were connected with *TieConstraints* among each other, and thus rebuilt the 2 major parts of the model – the concrete body and the perforated metal sheet. This partition was conducted in a manner that enabled the finest mesh at the changeover from the circular concrete dowel to the rest of the concrete body (Fig. 6).

4.2 *Material properties*

For both materials a nonlinear stress-strain relationship was chosen. Whereas a simple elastic-plastic model was chosen for the metal sheet, the self-compacting concrete was described by a *Concrete Damaged Plasticity* model with default values for the *Plasticity* parameters. The underlying material model for the compressive stresses, and all of its parameters, was adopted directly from Eurocode 2:

$$\frac{\sigma_c}{f_{cm}} = \frac{k\eta - \eta^2}{1 + (k-2)\eta} \tag{4}$$

Where σ_c = compressive stress; $\eta = \varepsilon_c / \varepsilon_{c1}$; ε_{c1} = compressive strain at highest compressive stress of concrete; $k = 1.05\, E_{cm} \cdot |\varepsilon_{c1}| / f_{cm}$

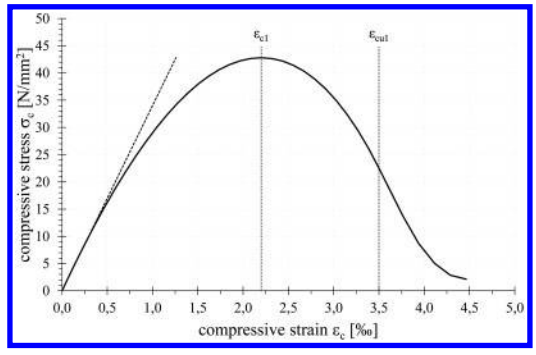

Figure 7. Concrete stress-strain relationship used for numerical simulation in ABAQUS.

Table 1. Material properties.

Material	f_{cm}/f_{ym} [N/mm²]	f_{ctm}/f_{ym} [N/mm²]	E_{cm}/E_{ym} [N/mm²]	ν [–]
Concrete	42.8	2.9	34,000	0.2
Steel	235.0	235.0	210,000	0.3

For strains exceeding the strain of failure ε_{c1u}, a linear decline of stresses with the gradient at failure strain was assumed. In separate calculations a better convergence of the calculation could be achieved with a rounded out stress-strain relationship for post-cracking stresses at the changeover to a stress-free state. A residual compressive stress of the post-cracking stresses also showed a beneficial convergence behavior of the calculation (Fig. 7).

The tensile behavior of the concrete after crack initiation was defined by an exponential stress-displacement relationship based upon the fracture energy G_F (Hordijk 1991):

$$\frac{\sigma_t}{f_{ctm}} = \left\{1 + \left(c_1 \frac{w}{w_c}\right)^3\right\} e^{-c_2 \frac{w}{w_c}} - \frac{w}{w_c}(1 + {c_1}^3) e^{-c_2} \tag{5}$$

Where σ_t = tensile stress; w = crack opening, $w_c = 5.14 G_F / f_{ctm}$ = the crack opening at the complete stress-free state; c1 = 3; c2 = 6.93.

The fracture energy G_F was calculated according to *fib* Model Code 2010:

$$G_F = 73 \cdot {f_{cm}}^{0,18} \tag{6}$$

The basic material properties are listed in Table 1.

4.3 *Mesh*

During the actual calculations different mesh densities have been tested and used for comparisons.

Models with a constant element size as well as models with different mesh densities with a fine mesh for the shear connector were investigated. The used mesh densities varied from very coarse meshes of 1 mm for regions of low stresses to fine meshes of 0.125 mm for regions around the concrete dowel. For models

with variable mesh densities the individual parts of the model were meshed with 4 different element sizes.

Quadratic elements often led to a poor convergence behavior wherefore mostly linear elements were used in the actual calculations (partly with reduced integration).

4.4 *Boundary conditions, constraints and loading*

The primary boundary condition to prevent displacements in vertical direction is defined in the bottom surface of the steel sheet which represents the top supporting steel plate of the test set-up in Figure 5. The top surface of the concrete body is fixed in vertical direction as well to prevent a rising of the concrete part as it is done by the hydraulic testing machine. In the actual simulations the bottom surface of the concrete dowel is not restrained in any degree of freedom to prevent nonexistent tensile stresses due to deformations of the dowel during the load step.

The shear load is applied as a displacement-controlled boundary condition at the front side of the steel sheet and is linearly increased during the load step. The front side of the concrete part acts as bearing for the applied shear load and is restrained in the same direction (Fig. 6).

In horizontal direction, perpendicular to the direction of the shear load, the whole model is fixed on both sides over its whole cross-section via boundary conditions for symmetry planes.

In simulations that have been carried out using *ABAQUS/Standard,* between all surfaces of the concrete and steel parts that may come into contact, a frictionless, *Hard-Contact*, *Contact Pair* Interaction was defined. Furthermore, in some models a *Contact Control* with a defined automatic stabilization and an adjustment to remove overclosures between parts in contact was added to obtain a better convergence behavior. In simulations that have been carried out using *ABAQUS/Explicit* a default *General Contact* was defined.

4.5 *Calculation method*

The numerical simulation of the shear connector was accomplished by different approaches. Thereby the load step was defined as one of the following step types:

- Static, General (SG)
- Dynamic, Implicit (DI)
- Dynamic, Explicit (DE)

In each case a step-duration of 1 second was chosen to apply the shear load. Mass scaling was used to accelerate the calculation in case of *Dynamic, Explicit* simulations.

The biggest problem during the calculations, independent of the chosen step type, was the convergence behavior in the post peak behavior of the concrete dowel.

5 RESULTS OF THE NUMERICAL SIMULATIONS

In the following, some of the carried out calculations will be presented and discussed. The investigated calculations and their varying model parameters are summed up and shown in Table 2.

Because of the used mass scaling, in series S9 to S14 the kinetic energy (*ALLKE*) as well as the internal energy (*ALLIE*) of the whole model was monitored and compared. In all cases the kinetic energy accounts for less than 1% of the internal energy, and therefore can be considered to be an appropriate choice.

In Figure 8 the several distributions of the reaction force F, measured at the front side of the concrete part, are shown as a function of the applied displacement in the steel sheet (simulation S1, S2 and S7 show an almost identical distribution).

In all suitable simulations, the reaction force of the whole dowel was underestimated in comparison to the decisive value calculated by Equation 1 and 2 (504 N) and the measured results of the load tests (609 N).

5.1 *Influence of the element size and type*

A comparison of simulation S1 and S6 as well as between S11 up to S14 shows that a mesh refinement has a major influence on the quantitative results of the simulation. Thereby, the qualitative progression of the distribution of the reaction force remains more or less unaffected.

In general, the maximum reaction force (F_{max}) decreases significantly due to a mesh refinement. In the actual calculations the effect was more pronounced in *DE*-steps:

- $F_{max,S6}/F_{max,S1} = 125.7\%$
- $F_{max,S11}/F_{max,S13} = 152.3\%$

The choice between linear elements with reduced and full integration showed a deviation of about 3% to 4% (S1/S3, S7/S8, S9/S13). In all cases the value of the maximum reaction force was higher when calculated with full integration.

5.2 *Influence of contact stabilization control*

As it can be seen in a direct comparison of S4 up to S6, the choice of the stabilization factor of the contact controls has a major influence on the simulation as well. A comparison between the energy dissipated by viscous damping (*ALLSD*) and the internal energy (*ALLIE*) can be used as an indicator, whether a reasonable value for the stabilization has been chosen. In case of S1 and S2 the ratio between those energies is on average below 1%, with the consequence that both distributions of the reaction force are almost identical. In case of S4 and S5 the ratio is bigger than 50% respectively 5% and thus the stabilization factor should be further reduced.

Table 2. Overview of the parameters used for the numerical simulations.

Simulation series	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14

6 CONCLUSION

At the present moment the calculations offer a basis for further investigations and calculations, but do not represent and describe the measured, quantitative results of the load tests realistically.

The convergence behavior still marks the major problem when using the *Concrete Damaged Plasticity* material model. Moreover, the contact behavior does not seem to cause computational problems as shown in accompanying simulations with purely, linear elastic material properties. Furthermore, the most computational costs seem to be a result of the used concrete material model, especially when reaching the post-cracked state.

Another problem to cause a poor convergence behavior might be exceeding deformations at the contact area during the loading process right at the changeover from the circular concrete dowel to the rest of the concrete body. In this area an addition of cohesive elements, element deletion and/or XFEM could lead to thoroughly stable simulations.

Apart from further load tests, the implementation of the above mentioned methods for improving the numerical simulations is one of the next objectives to be carried out in near future.

A computer method for design and M-N-Φ analysis of composite steel-concrete cross-sections

C.G. Chiorean, A. Chira & M. Buru
Technical University of Cluj-Napoca, Faculty of Civil Engineering, Cluj-Napoca, Romania

ABSTRACT: This paper presents a general method for the rapid design, moment-curvature analysis and ultimate strength capacity evaluation of arbitrary-shaped composite steel-concrete cross-sections that are subjected to biaxial bending and axial force. The procedure may be used to assess the main features of elasto-plastic behaviour: multiple yielding points, flexural and axial rigidity, moment-curvature relationship, curvature ductility, and 3D interaction domains. The procedure allows cross-sections to be designed by solving directly for the reinforcement required to provide a cross-section with adequate strength. A computer program was developed, aimed at obtaining the ultimate strength capacity, moment-curvature relationships and reinforcement required by composite cross-sections subjected to combined biaxial bending and axial load. In order to illustrate the proposed method and its accuracy and efficiency, this program was used to study several representative examples, which have been studied previously by other researchers.

1 INTRODUCTION AND RESEARCH SIGNIFICANCE

The inelastic response of cross-sections can be represented by either moment-curvature diagrams for fixed values of axial force (M-N-Φ) or interaction diagrams that express, at failure, the interaction between the axial load and bending moments about major and minor principal axes of the cross-section. These analyses are based on assumption that all structural and reinforcement parameters are specified and, under given external loads either the cross section reach its failure (*ultimate strength analysis*) or inelastic behavior of cross-section is revealed (*moment-curvature analysis*). On the other hand, procedures for solving directly for the reinforcement required to provide a cross-section with adequate strength (*sectional design analysis*) are essential in practical design.

Some methods have been presented in literature for the ultimate strength analysis and design of various concrete and composite steel-concrete sections (Dundar & Sahin 1993; Rodrigues & Ochoa 1999; Chen et al. 2001; Rosati et al. 2008; Palares et al. 2009; Chiorean 2010). The method proposed herein, for design of cross-sections, consists of computing the required reinforcement area (A_{tot}) supposing that all structural parameters are specified and, under given external loads, the cross section reaches its failure either in tension or compression. The method proposed herein, for moment-curvature analysis, adopts Newton-Raphson procedure and the arc-length constraint equation to determine the moment-curvature diagrams for fixed values of axial force (M-N-ϕ) of an arbitrary composite steel-concrete cross-section. Residual stresses in structural steel component are due to uneven cooling of component parts during the rolling process. However, only a few works available in the literature have addressed this effect on the carrying capacity of composite steel-concrete cross-sections (Skrabek & Mirza 1990). For this reason, residual stresses were accounted for in encased steel sections used for the ultimate strength capacity evaluation of composite steel-concrete cross-sections and two types of residual stress patterns, EC2 and AISC-LRFD distribution, can be taken into account in the present formulation.

2 MATHEMATICAL FORMULATION

2.1 *Basic assumptions and constitutive material models*

Consider the cross-section subjected to the action of the external bending moments about both global axes and axial force as shown in Figure 1.

The cross-section may assume any shape with multiple polygonal or circular openings. It is assumed that plane section remains plane after deformation. Thus the resultant strain distribution corresponding to the curvatures about global axes $\mathbf{\Phi} = \{\phi_x, \phi_y\}$ and the axial compressive strain ε_0 can be expressed at a generic point, in concrete matrix, fiber of structural steel or ordinary reinforced bars, of coordinates (x, y) in a linear form as:

$$\varepsilon = \varepsilon_0 + \phi_x y + \phi_y x \tag{1}$$

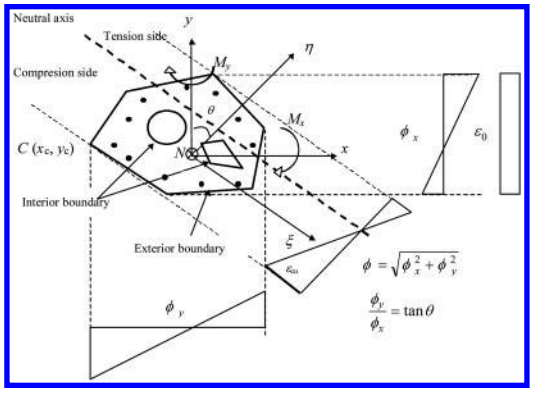

Figure 1. Model of arbitrary composite cross-section.

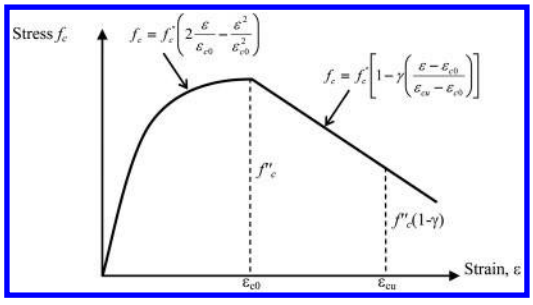

Figure 2. Stress-strain relationships for concrete in compression.

The constitutive relation to model the concrete under compression is represented by a combination of a second-degree parabola (for ascending part) and a straight line (for descending part), as depicted in Figure 2, where γ represents the degree of confinement in the concrete. Multi-linear elastic-plastic stress-strain relationships, both in tension and in compression, is assumed for the structural steel and the conventional reinforcing bars. Residual stresses may be incorporated in the analysis. The magnitude and distribution of residual stresses in hot-rolled members depend on the type of cross-section and manufacturing processes and different patterns are proposed. In the US, the residual stress is considered constant in the web although when the depth of a wide flange section is large, it varies more or less parabolically. Another possible residual stress pattern in the web is the one simplified by a linear variation as used in European calibration frames (Fig. 3).

Assuming that the residual strain can be linearized for individual zones in the steel section the total strain in a point can be computed as:

$$\varepsilon = \varepsilon_0 + \phi_x y + \phi_y x + \varepsilon_r \qquad (2)$$

where ε_r represents a linear residual strain field.

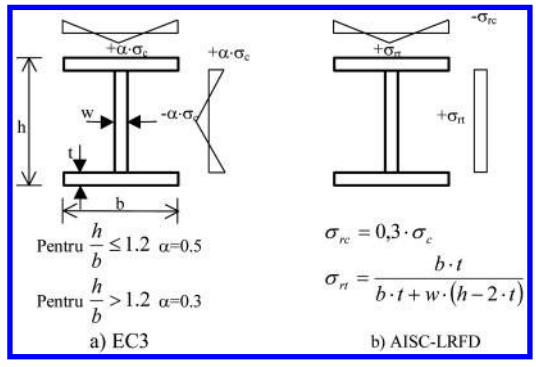

Figure 3. Residual stress patterns.

2.2 *Formulation of the proposed design procedure*

The method proposed herein consists of computing the required conventional reinforcement area (A_{tot}) supposing that all structural parameters are specified and, under given external loads (N, Mx, My), the cross section reach its failure either to maximum strains attained at the outer compressed point of the concrete section or to maximum strains attained in the most tensioned steel fibre. Consider an irregular composite section as shown in Figure 1 subjected to axial force and biaxial bending moments. The conventional reinforcement layout is given as percentage (α_i) of the total reinforcement steel area (A_{tot}) in each location. At ultimate strength capacity the equilibrium is satisfied when the external forces are equal to the internal ones and either in the most compressed or tensioned steel fibre the ultimate strain is attained. These conditions can be represented mathematically in terms of the following nonlinear system of equations as:

$$\begin{cases} \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0,\phi_x,\phi_y\right)\right)dA_{cs} + A_{tot}\sum_{i=1}^{N_{rs}} \sigma\left(\varepsilon_i\left(\varepsilon_0,\phi_x,\phi_y\right)\right)\alpha_i - N = 0 \\ \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0,\phi_x,\phi_y\right)\right)y dA_{cs} + A_{tot}\sum_{i=1}^{N_{rs}} \sigma\left(\varepsilon_i\left(\varepsilon_0,\phi_x,\phi_y\right)\right)y_i\alpha_i - M_x = 0 \\ \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0,\phi_x,\phi_y\right)\right)x dA_{cs} + A_{tot}\sum_{i=1}^{N_{rs}} \sigma\left(\varepsilon_i\left(\varepsilon_0,\phi_x,\phi_y\right)\right)x_i\alpha_i - M_y = 0 \\ \varepsilon_0 + \phi_x y_c\left(\phi_x,\phi_y\right) + \phi_y x_c\left(\phi_x,\phi_y\right) - \varepsilon_u = 0 \end{cases} \qquad (3)$$

in which A_{tot}, ε_0, ϕ_x, ϕ_y represent the unknowns, the surface integral is extended over concrete and structural steel areas (A_{cs}), N_{rs} represents the number of conventional steel reinforcement bars. In the above equations the first three relations represent the basic equations of equilibrium for the axial load N and the biaxial bending moments M_x, M_y respectively. The last equation represents the ultimate strength capacity condition, that is, in the most compressed or most tensioned point the ultimate strain is attained; in this equation $x_c(\phi_x, \phi_y)$ and $y_c(\phi_x, \phi_y)$ represent the

coordinates of the point in which this condition is imposed:

$$\varepsilon(\phi_x,\phi_y)=\varepsilon_u+\phi_x(y-y_c)+\phi_y(x-x_c) \tag{4}$$

In this way, substituting the strain distribution given by the Eq. (4) in the basic equations of equilibrium, the unknown $\varepsilon_0$together with the failure constraint equation can be eliminated from the nonlinear system (3). Thus, the nonlinear system of equations (3) is reduced to an only three basic equations of equilibrium in which the unknowns, total reinforcement steel area A_{tot}, and the ultimate sectional curvatures ϕ_x and ϕ_y, can be obtained iteratively following the procedure described in (Chiorean 2013).

2.3 *Moment-curvature (M-N-Φ) analysis procedure*

Consider an composite cross-section with arbitrary shape as shown in Figure 1 subjected to biaxial bending moments (M_{x0}, M_{y0}) and axial force (N_0). The equilibrium is satisfied when the external forces (N_0, M_{x0}, M_{y0}) are equal to the internal ones. These conditions can be represented mathematically in terms of the following nonlinear system of equations as:

$$\begin{cases}\int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))dA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))A_{rsi}-N_0=0\\ \int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))ydA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))y_iA_{rsi}-M_{x0}=0\\ \int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))xdA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))x_iA_{rsi}-M_{y0}=0\end{cases} \tag{5}$$

where A_{rsi} $(i=1,N_{rs})$ denotes the area of conventional steel reinforcements, and in which $\varepsilon_0,\phi_x,\phi_y$ represent the unknowns. The above system can be solved numerically using, for instance, the load-controlled Newton method and taking into account the fact that the stresses are implicit functions of the axial compressive strain and curvatures through the resultant strain distribution given by the Eq. (1). Regarding the automatic drawing of the moment–curvature diagram, the strategy is as follows. Scaling the bending moments through the load factor λ and keeping the axial force constant $N=N_0$, the complete moment-curvature diagram can be obtained, under constant axial force by solving the system of equations (Eq. 6), where the axial compressive strain ε_0, the curvatures ϕ_x and ϕ_y and the load amplifier factor λ represent the unknowns.

$$\begin{cases}\int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))dA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))A_{rsi}-N_0=0\\ \int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))ydA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))y_iA_{rsi}-\lambda M_{x0}=0\\ \int_{A_{cs}}\sigma(\varepsilon(\varepsilon_0,\phi_x,\phi_y))xdA_{cs}+\sum_{i=1}^{N_{rs}}\sigma(\varepsilon_i(\varepsilon_0,\phi_x,\phi_y))x_iA_{rsi}-\lambda M_{y0}=0\end{cases} \tag{6}$$

This system can be rewritten in terms of non-linear system of equations in the following general form:

$$\mathbf{F}(\lambda,\mathbf{X})=\mathbf{f}^{\text{int}}-\mathbf{f}^{ext}=\mathbf{0} \tag{7}$$

where $\mathbf{X}=[\varepsilon_0\ \phi_x\ \phi_y]^T$ In this case, maintaining the axial force N_0 constant and scaling just the bending moments, we are in the situation of the non-proportionally applied loading, which involves two loading vectors, one that will be scaled and one fixed. The external loading can then be represented by:

$$\mathbf{f}^{ext}=\begin{bmatrix}N_0\\0\\0\end{bmatrix}+\lambda\begin{bmatrix}0\\M_{x0}\\M_{y0}\end{bmatrix}=\mathbf{f}^{ext}_{fixed}+\lambda\mathbf{f}^{ext}_{scaled} \tag{8}$$

so that the out of balance force vector becomes:

$$\mathbf{F}(\lambda,\mathbf{X})=\mathbf{f}^{\text{int}}-\mathbf{f}^{ext}_{fixed}-\lambda\mathbf{f}^{ext}_{scaled} \tag{9}$$

To obtain the equilibrium path, a proper parametrization is needed. A common setting of a continuation process is to augment the equilibrium equations (9) with a constraint (Crisfield 1991). In this procedure, commonly called arc-length method, these equations are solved in a series of steps or increments, usually starting from the unloaded state ($\lambda=0$). An indirect solution scheme for the constraint equation may be introduced. This procedure is iterated until convergence with respect to a suitable norm is attained. Assuming that a point (${}^{\tau}\mathbf{X}$, ${}^{\tau}\lambda$) of the equilibrium path has been reached, the next point (${}^{\tau+\Delta\tau}\mathbf{X}$, ${}^{\tau+\Delta\tau}\lambda$) of the equilibrium path is then computed updating the loading factor, axial compressive strain ε_0 and the curvatures ϕ_x and ϕ_y as:

$$\begin{aligned}{}^{\tau+\Delta\tau}\lambda&={}^{\tau}\lambda+\Delta\lambda_{k+1}\\ {}^{\tau+\Delta\tau}\mathbf{X}&={}^{\tau}\mathbf{X}+\Delta\mathbf{X}_{k+1}\end{aligned} \tag{10}$$

Adopting an automatic step length adaptation scheme (Crisfield 1991) for the loading factor, the entire moment-curvature interaction diagram of the cross section can be constructed for a given axial force.

2.4 *Evaluation of tangent stiffness and stress resultant*

Based on Green's theorem, the integration of the stress resultant and stiffness coefficients over the cross-section will be transformed into line integrals along the perimeter of the cross-section (Chiorean 2010). In order to perform the integral on a determined side of the contour (L_i), polygonal or circular, of the integration area, an adaptive interpolatory Gauss-Lobatto method is used (Chiorean 2010). The conventional steel reinforcements are assumed to be discrete points with effective area, co-ordinates and stresses. The effect of residual stresses may be included in the analysis providing that the residual stress can be linearized for individual zones in the steel section associated to variations of residual stresses throughout the height of cross-section (Chiorean 2013).

3 COMPUTATIONAL EXAMPLES

The accuracy and computational advantages of the numerical procedures developed here has been evaluated using several selected benchmark problems analysed previously by other researchers using different numerical methods. Furthermore new parametric studies and computational examples are given in order to demonstrate the effectiveness of the ultimate strength capacity evaluation procedure described in (Chiorean 2010).

3.1 *Composite steel-concrete cross-section with arbitrary shape*

The composite steel-concrete cross-section depicted in Figure 4, consists of the concrete matrix, fifteen reinforcement bars of diameter 18 mm, a structural steel element and a circular opening.

Characteristic strengths for concrete, structural steel and reinforcement bars are $f_c'' = 30$ Mpa, $f_{st} = 355$ Mpa and $f_s = 460$ Mpa, respectively. These characteristic strengths are reduced by dividing them with the corresponding safety factors $\gamma_c = 1.50$, $\gamma_{st} = 1.10$ and $\gamma_s = 1.15$. The crushing strain $\varepsilon_0 = 0.002$ and ultimate strain $\varepsilon_{cu} = 0.0035$ have been used. The Young modulus for all steel sections was 200 GPa. A bi-linear elasto-perfect plastic stress-strain relationship for the reinforcement bars and structural steel, both in tension and in compression, is assumed. This is an example proposed and analysed by Chen et al. (2001) and later studied by Rosati et al. (2008) and others.

The effects of confinement in the concrete were investigated for different values of degree of confinement γ. As it can be seen in Figure 5 by reducing the confinement in the concrete the interaction curves indicate lower capacities and the non-convexity of the diagrams is more pronounced. The bending moments are computed about the geometric centroidal axes for a compressive axial force $N = 10000$ kN. Figure 6 shows the bending moment-curvature diagrams of cross-section, considering uniaxial bending about X-axis with a compressive axial force $N = 8000$ kN and for different values of degree of confinement ($\gamma = 0;0.15;0.30;0.50$). As it can be seen, the strain softening effect exhibited by the concrete in compression ($\gamma > 0$) indicates lower bending capacity of cross section an also "snap-back" behaviour; this effect is more accentuated as degree in confinement is decreased.

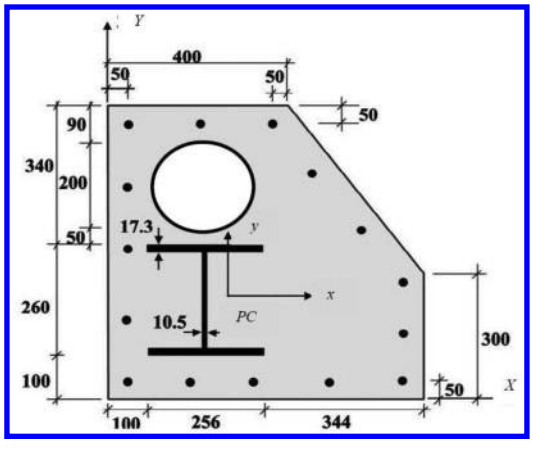

Figure 4. Composite steel-concrete cross-section.

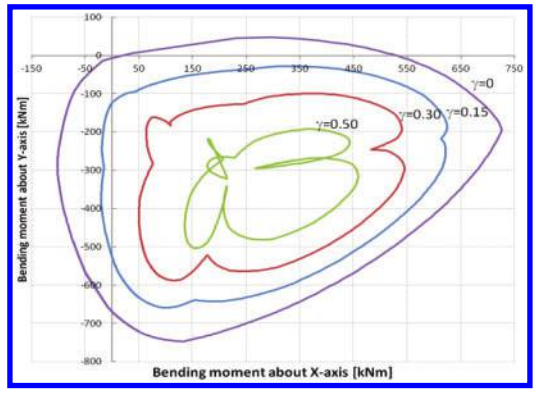

Figure 5. Moment capacity contours with compressive axial load $N = 10000$ kN: influence of degree of confinement.

Table 1. Influence of residual stresses over total reinforcement steel area ($M_x = 210.5$ kNm and $M_y = 863.5$ kNm).

N [kN]	A_{tot} [cm^2] (without residual stresses)	A_{tot} [cm^2] (EC3 distribution)	A_{tot} [cm^2] (AISC-LRFD distribution)
1000	58.82	58.28	57.69
3000	41.55	42.47	42.18
5000	31.19	41.85	36.64
6000	33.41	50.83	42.37
8000	61.01	86.60	71.25
9000	84.16	110.38	93.57
10000	110.43	136.37	118.83

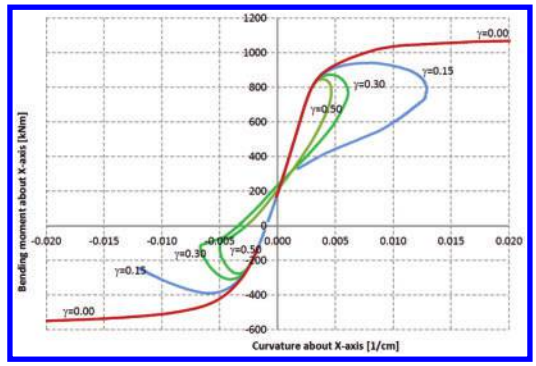

Figure 6. Moment curvature diagrams for different values of degree of confinement and compressive axial force $N = 8000$ kN

Let us consider this cross-section subjected to biaxial bending to carry the following design loads: $N = 4120$ kN, $M_x = 210.5$ kNm and $M_y = 863.5$ kNm. The distribution of the steel reinforcing bars are shown in Fig. 4, and we consider that all rebars have the same diameter. The iterative process of design was started with $\phi_x = 0$ and $\phi_y = 0$, and $A_{tot} = 0.005 A_g = 215$ cm^2. The equilibrium tolerance has been taken as $1E$-4. After only five iterations, the total area required of the rebars was found to be $A_{tot} = 34.347$ cm^2. Consequently, the required diameter of the selected rebar is $\Phi_{req} = 2\sqrt{\frac{A_{tot}}{N_b \pi}} = 1.71\ cm$ which compare very well with the required bar diameter reported by Chen *et al.* (2001), $\Phi_{req} = 1.78$ cm. In the above computational example, the axial force and bending moments are represented about the plastic centroidal axes of the cross-section. When the design loads are represented about the geometric centroid the total area required of the rebars was found to be $A_{tot} = 15.674$ cm^2. This result has been obtained after only six iterations. Table 1 presents the variations of total reinforcement area considering different values of compressive axial load and two types of residual stress patterns, EC3 and AISC-LRFD respectively, for structural steel element. As it can be seen the presence of residual stresses increases the total reinforcement steel area as axial compressive load is increased.

3.2 *Rectangular composite steel-concrete section. Influence of residual stresses*

In order to evaluate the effects of residual stresses over ultimate strength capacity, deformability and flexural rigidity of composite steel-concrete cross section, the moment-capacity contours and moment-curvature diagrams are determined for a very common composite cross- section under biaxial loading: rectangular cross-section with symmetrically placed structural steel. The cross-section consists of a concrete core and a symmetrically placed USA wide flange section W12 × 120 (Fig. 7). Characteristic strength for concrete in compression is $f_c'' = 20$ MPa and the stress-strain curve which consists of a parabolic and linear part was used in the calculation with crushing strain $\varepsilon_0 = 0.002$, ultimate strain $\varepsilon_{cu} = 0.0035$.

The strain softening of concrete is taken into account with $\gamma = 0.15$. The Young modulus for encased structural steel and reinforcements is 200 GPa. A bi-linear elasto-perfect plastic stress-strain relationship for the reinforcement bars and structural steel, both in tension and in compression, is assumed with the yield strength $f_y = 300$ MPa. Figures 8 and 9 shows the comparative bending moment-curvature diagrams of cross-section, considering uniaxial bending about X-axis (strong) and Y-axis (weak) respectively under several compressive axial loads and with and without residual stress effect. The effect of residual stresses is taken into account considering two types of residual stress patterns, EC3 and AISC-LRFD (Fig. 3), respectively, for structural steel element. The comparisons reveal that the influences of residual stresses play an important role on both carrying capacity and inelastic behaviour, during the loading process, on composite cross section and this effect becomes more effective with higher compressive axial load. Figure 10 presents

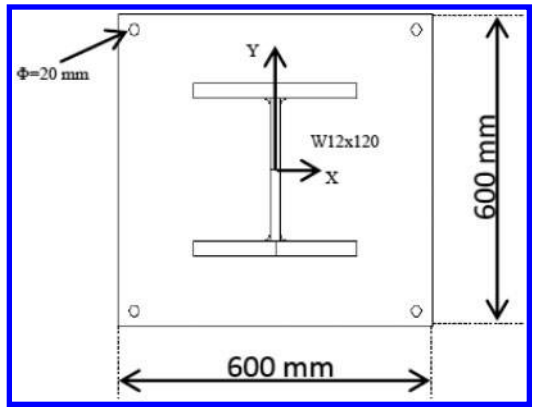

Figure 7. Rectangular composite steel-concrete cross-section.

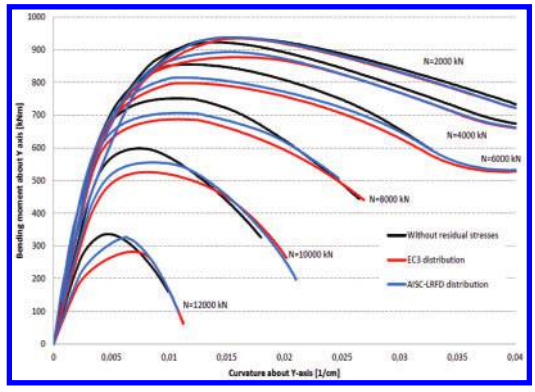

Figure 8. Moment-curvature analysis for different values of compressive axial loads: weak axis bending.

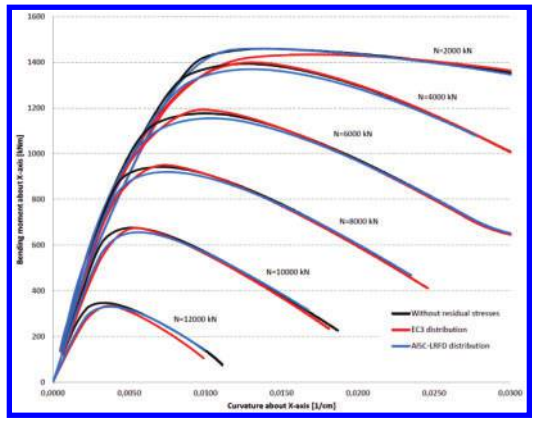

Figure 9. Moment-curvature analysis for different values of compressive axial loads: strong axis bending.

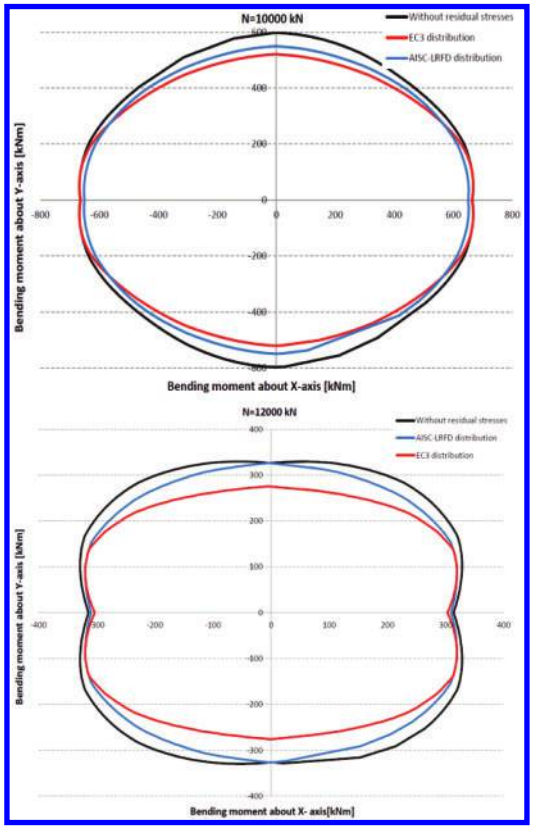

Figure 10. Moment capacity contours with different values of axial compressive load and different residual stress patterns for encased steel section.

the moment capacity contours for different values of axial compressive load with and without the presence of residual stresses. As it can be seen the residual stresses indicates lower capacity of cross section, and this effect is more pronounced as axial load increases especially in the case of EC3 distribution for residual stresses.

4 CONCLUSIONS

A new computer method has been developed for the rapid design, moment-curvature analysis and ultimate strength capacity evaluation of composite steel-concrete cross-sections subjected to axial force and biaxial bending. The iterative algorithm, proposed herein, to design the steel reinforcement of composite steel-concrete sections under biaxial bending and axial force, as compared to other iterative methods, is very stable and the convergence is very fast. The moment-curvature diagrams for fixed values of axial force are obtained by an incremental-iterative arc-length procedure, and the proposed approach has been found to be extremely powerful and efficient. Due to presence of residual stresses, for encased steel section, a reduction of capacity strength of composite steel-concrete cross-section was observed. The influence of residual stresses on the carrying capacity of cross- sections is most effective with higher axial load levels. From the numerical tests it may be concluded that the influence of the residual stress on the carrying capacity and inelastic behavior during the loading process is important and must be considered in the valuable advanced analysis of composite cross-sections. It can be concluded that the proposed numerical method proves to be reliable and accurate for practical applications in the design of composite steel-concrete beam-columns and can be implemented in the advanced analysis techniques of 3D composite frame structures.

Load-carrying capacity of steel and high-strength concrete composite columns

M. Karmazínová & J.J. Melcher
Brno University of Technology, Brno, Czech Republic

ABSTRACT: The paper deals with the problems of the buckling compression of steel-concrete composite columns. The paper presents some selected results of the more extensive research realized on the author's workplace and oriented to the utilization of high-strength steels and concretes in steel structural members and composite structural members composed of steel and concrete. This paper is directed towards one part of this research only that means theoretical analysis of the buckling resistance and experimental verification of the objective buckling resistance of columns in connection with the actual behaviour and corresponding relevant failure mechanism. Within the framework of the buckling resistance analysis two basic cross-section column types have been investigated: (i) steel HEA cross-sections of the dimensions in the range from HEA 140 up to HEA 200, encased by concrete between flanges, and (ii) steel circular tubes of the diameter in the range from 133 to 168 mm and thickness from 4 to 5 mm, filled by concrete; the buckling length of investigated columns was 3 m. Materials of investigated columns were as follows: steel grade in the range from S 235 to S 420 mostly, but in several cases even up to S 460 and S 700; concrete class in the range from C 20/25 to C 80/90. Within the experimental research, so far 56 specimens subjected to compression force have been tested in total, i.e. 29 HEA cross-section columns with concrete encasement and 27 tubes filled by concrete. Within the experimental investigation, also the material tests and their evaluation, as well as the measurement of actual geometrical imperfections, have been performed to verify the results obtained from theoretical studies. The attention has been mainly paid to the following significant problems: the efficiency of the usage of high-strength materials in steel-concrete composite columns; the effectiveness of concrete contribution to the buckling resistance of steel-concrete columns; the evaluation of the test results aimed to determine the design buckling resistance. This paper namely presents the results of the verification of the buckling resistance of HEA cross-sections with high-strength concrete, with accent to its contribution to the load-carrying capacity.

1 INTRODUCTION

The particular problem of the load-carrying capacity of composite columns composed of high-strength steels and concretes has been experimentally and theoretically investigated on the several groups of structural members simulating the typical building columns, from the viewpoint of their geometry and usual dimensions. According to this condition, the columns of 3 m length of two basic HEA cross-sections, HE 140A and HE 160A, have been chosen for the experimental and theoretical analysis. The attention was mainly paid to the influence of high-strength concrete on the buckling resistance. Steel and steel-concrete columns of the following material properties have been investigated: steel grades S 235 and S 355; concrete classes C 20/25 and C 80/95 for the first cross-section and C 50/60 and C 70/85 for the second one, in accordance with the overview of the investigated column types presented in Table 1.

Table 1. Overview of investigated column types

Cross-section	column group	steel grade	concrete class
HE 140A	TS 1	S 355	steel only
	TS 2	S 355	C 20/25
	TS 3	S 355	C 80/95
HE 160A	TS 4	S 235	steel only
	TS 5	S 235	C 50/60
	TS 6	S 235	C 70/85
HE 160A	TS 7	S 355	steel only
	TS 8	S 355	C 50/60
	TS 9	S 355	C 70/85

For investigation, the columns with such cross-section configurations and material combinations, for which the highest ratio of the buckling capacity to full-plastic capacity has been calculated. Table 1 shows the first two groups of specimens only, which have been

already tested; next test specimens have been produced and recently are preparing for testing.

2 CALCULATIONS OF BUCKLING LOAD-CARRYING CAPACITY

The buckling load-carrying capacity of the composite steel-concrete column, calculated using simplified methods given in EN 1993-1-1, EN 1994-1-1 (also Kuranovas, Liang, Yu) is usually written as

$$N_b = \chi N_{pl}, \tag{1}$$

where, for the column composed of open steel cross-section with concrete encasement, the full-plastic section load-carrying capacity (without buckling) N_{pl} is usually given in the form

$$N_{pl} = A_a \cdot f_y + 0.85 \cdot A_c \cdot f_c \tag{2}$$

with steel and concrete cross-section areas A_a, A_c, yield strength f_y and cylindrical concrete strength f_c. The reduction buckling factor χ depends on the non-dimensional slenderness $\bar{\lambda}$ known as

$$\bar{\lambda} = \sqrt{N_{pl} / N_{cr}}, \tag{3}$$

where the critical force N_{cr} is

$$N_{cr} = \pi^2 \cdot (EI)_{eff} / L_{cr}^2, \tag{4}$$

the effective flexural stiffness is

$$(EI)_{eff} = E_a I_a + 0.6 \cdot E_c I_c \tag{5}$$

with steel and concrete Young's modulus of elasticity E_a, E_c and corresponding second moments of area I_a, I_c. Then, the buckling reduction factor χ can be written as

$$\chi = \frac{1}{\phi + \sqrt{\phi^2 - \bar{\lambda}^2}}, \tag{6}$$

if the coefficient ϕ is

$$\phi = 0.5 \cdot \left[1 + \alpha_1 \cdot (\bar{\lambda} - 0.2) + \bar{\lambda}^2\right] \tag{7}$$

where the buckling curve (EN 1994-1-1) of "c" with the imperfection factor value of $\alpha_1 = 0.49$ is applied for I or H cross-sections encased between flanges.

Within the particular theoretical analysis, the expected buckling load-carrying capacities have been calculated for steel and steel-concrete columns with material specifications mentioned above, using formulas (1) to (7). The calculations have been performed with the characteristic values of concrete cylindrical strength and nominal values of steel yield strength, to obtain buckling load-carrying capacities corresponding with the predicted ultimate capacities. The capacity values have been determined for the buckling lengths, which are usually used for the columns of building constructions, i.e. in the range of about from $L_{cr} =$ 3 m up to $L_{cr} =$ 5 m, and also for the buckling length of $L_{cr} = 0$ m (pure compression), to compare the full-plastic load-carrying capacity N_{pl} and the buckling load-carrying capacity $N_b = \chi N_{pl}$ and to obtain the dependence of the capacity on the compression strength and Young's modulus of elasticity of concrete.

3 EXPERIMENTAL VERIFICATION OF BUCKLING LOAD-CARRYING CAPACITY

To verify the actual behaviour of steel and steel-concrete columns and to evaluate the contribution of concrete to the buckling capacity, the test specimens of geometrical and material parameters corresponding with ones mentioned above have been experimentally verified. The overview of 77 specimen groups accordant to described column types is shown in Table 2, together with the mean values of measured physical-mechanical properties.

The illustrations of the test arrangement and test realization are depicted in Figs. 1 and 2. The photos show the testing equipment, the test specimen on the beginning loading process and failed test specimen.

The experimental verification has been realized in two basic phases. The first phase has been oriented to the comparison of the buckling load-carrying capacity of steel columns (column group TS 1) with the capacity of steel-concrete columns with normal-strength concrete (column group TS 2) and high-strength concrete (column group TS 3).

The European Standard rules are useable for steel grade up to S 460 and for concrete strength class up to C 60/75, but for higher strengths it cannot be used without other verification. In the first phase of this research

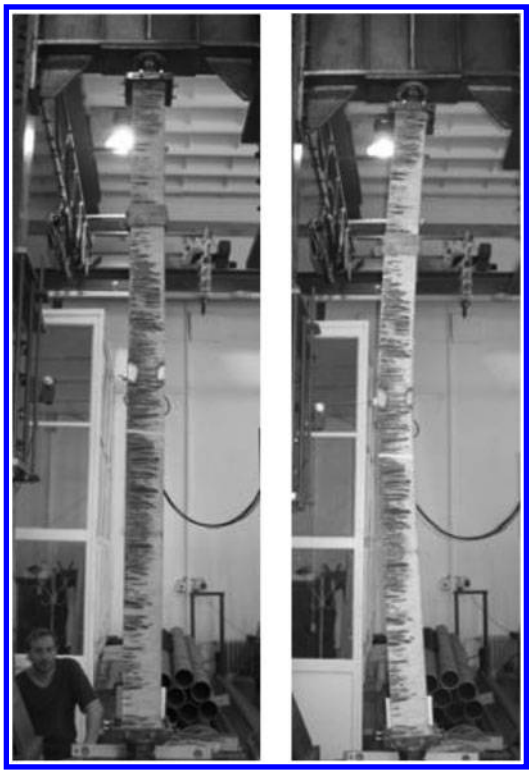

Figure 1. Illustration of test arrangement and test performance.

Figure 2. Strain gauges on test specimens and failed specimen.

it was verified, that the usage of high-strength concrete is effective because it gives increasing in load-carrying capacity, which corresponds with the assumed values calculated according to the standards. In both phases,

the influence of particular concrete properties has been investigated in detail.

The buckling load-carrying capacities obtained from the loading tests in comparison with the expected capacities calculated, are listed in Table 3. The theoretical values have been calculated according to the procedure mentioned above, with the actual material properties.

Mechanical properties used for theoretical values calculation, have been measured helping the material test specimens cut from the failed specimens after

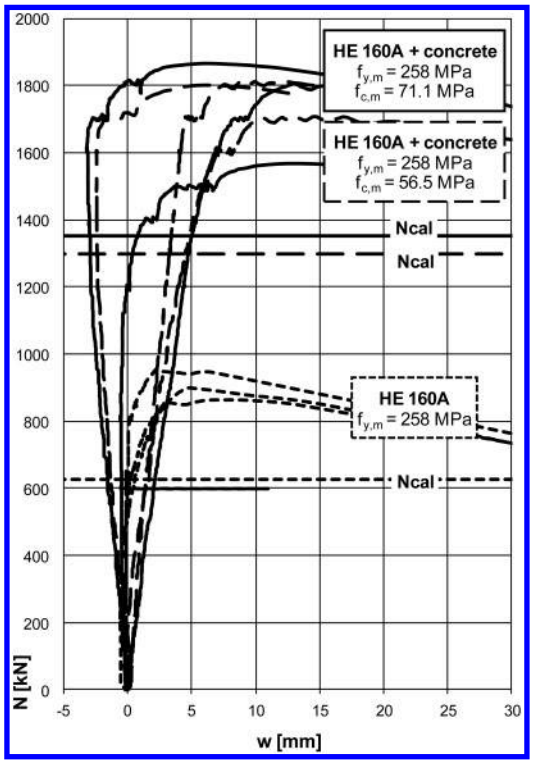

Figure 4. "*N*–*w*" diagrams: column groups TS 4, TS 5, TS 6 – HE 160A, steel grade S 235, concrete classes C50/60, C70/85.

loading test finishing. For the comparison, the average ratio of the test capacity to the calculated values is added to Table 3, too.

In Figs. 3, 4 and 5 the basic relationships of the buckling capacity N_{test} and deflections w at the mid-length are drawn for steel columns (TS 1, TS 4, TS 7), for steel-concrete columns with normal-strength concrete (TS 2) and for steel-concrete column with two different qualities of high-strength concrete (TS 5, TS 6, TS 8). For the comparison, the calculated values of the buckling load-carrying capacity are added to the graphs in Figs. 3, 4, 5, too.

From Figs. 3, 4 and 5 it is seen in general encasement between flanges using concrete of mentioned material properties can increase the buckling compression load-carrying capacity even up to about two times in comparison with steel columns; the actual buckling capacity of steel-concrete columns obtained from the tests very good corresponds with the buckling capacity calculated by standard rules (see e.g. Karmazínová et al. 2009, 2010, 2011); they are higher approximately by 30 % (TS 5, TS 6) and by 17 %, respectively (TS 8); in this case, the buckling capacities of the members with concrete C 50/60 and C 70/85 are about the same (TS 5, TS 6), although the measured parameters of both concretes very good correspond with the assumed properties, but the Young's modulus of concrete C 50/60 measured has been obtained much more than normally assumed; the actual buckling load-carrying capacities of specimens TS 7, TS 8 are higher by 17 % only, because (probably) yield strength has been measured for very small number of material test specimens, so that the value can be influenced by that fact.

4 CONCLUSIONS

From particular results verified experimentally, for steel-concrete columns composed of H cross-section encased by high-strength concrete between flanges the following partial conclusions may be deducted:

- Buckling load-carrying capacity in compression can be calculated using the usual procedure given by European Standard rules, like as for the column with normal concrete.
- Actual values of buckling load-carrying capacity are approximately by 30 % higher than the values calculated with measured properties.
- As expected, from test results of column groups TS 5 and TS 6 it is seen, that the influence of Young's modulus is understandably more significant than the influence of concrete strength. One of the effective methods how to evaluate the importance of the influence of particular parameters, is sensitivity analysis (Kala et al. 2009, 2010, Melcher et al. 2009b), which

is continuously utilized in parallel with the loading tests realization and test results evaluation.
- For more correct evaluation the larger test number with specimens of different material and geometrical properties is needed. The research is continuing and new specimens prepared to test.

ABSTRACT: This paper utilised experimental tests to provide further information and conclusions regarding composite steel-concrete beam specimens by examining the behaviour of multi-span composite steel-concrete beams which are subjected to combined actions of torsion and flexure for both full and partial shear connection and comparing the disparity in the varying degrees of shear connection. Generally, it was found that in the presence of torsion, there is no increase in the flexural capacity of a multi-span composite steel-concrete beam regardless of the degree of shear connection. Furthermore, there was no increase in the torsional capacity when flexure was present. In regards to shear connection, partial shear connection multi-span composite steel-concrete beam specimens attained nearly the same capacities in terms of both flexure and torsion as the full shear connection multi-span composite steel-concrete beam specimens. Additionally, it was discovered that the multi-span composite steel-concrete beam specimens achieved almost double the flexural capacities of similar single span composite steel-concrete beams. However, in terms of torsional capacity, there is a larger difference between multi-span composite steel-concrete beam specimens and single span composite steel-concrete beam specimens with multi-span composite steel-concrete beam specimens achieving more than three times the capacities of the single span specimens in certain cases.

1 INTRODUCTION

A great deal of research has been carried out in the field of composite steel-concrete beams. Yet, certain topics have been neglected or ignored in these researches. One of these issues is the behaviour of composite steel-concrete beams that are subjected to combined flexure and torsion. This topic has been researched by Ray and Mallick (1980), Nie et al. (2000), Thevendran et al. (2000) and Tan & Uy (2009a, b & 2011). However, the Australian Standard for composite members AS 2371.1 (Standards Australia, 2003) or other international standards on composite steel-concrete construction such as Euro-Code 4 (EN 1994-1-1, 2006), British Standard 5950 (BS 5950, 2000) or the American Institute of Steel Construction (AISC, 2006) does not cover this load combination.

Furthermore, much of the research and experiments on composite members has only considered full shear connection without looking at the effects of partial shear connection. This is a critical issue as partial shear connection composite beams have been shown to exhibit similar strength characteristics to full shear connection composite beams with increased ductility albeit at a reduced cost. Additional research into partial shear connections could produce further evidence that solidifies the fact that partial shear connection composite beams exhibit almost the same strength as full shear connection composite beams except at a fraction of the price.

Finally, more research needs to be performed on multi-span composite steel-concrete beams. The behaviour of multi-span composite beams is still largely unknown since the vast majority of research on composite steel-concrete beams has been carried out on single span members. Multi-span members are commonly used for bridges and highway interchanges and further knowledge on the behaviour of these members could vastly improve design techniques for these critical forms of infrastructure. Hence, multi-span composite steel-concrete beams will be examined for this paper.

The aim of this paper is to investigate the overall behaviour of multi-span composite steel-concrete beams subjected to combined flexure and torsion. This paper will aim to examine the characteristics and behaviours of multi-span composite steel-concrete beams, when the beams are subjected to varying

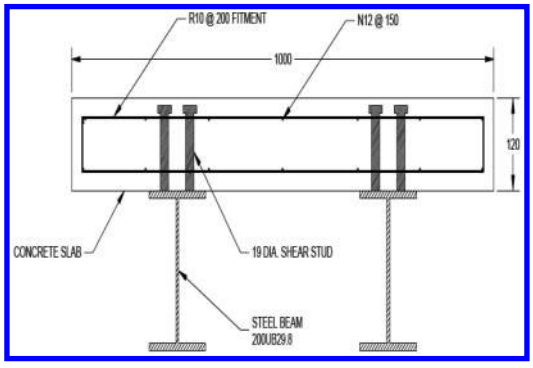

Figure 1. Typical Cross sectional view for multi-span composite steel-concrete beam.

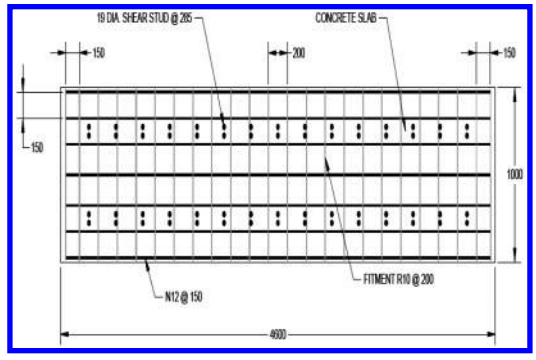

Figure 2. Typical plan view for multi-span composite steel-concrete beam.

degrees of flexure and torsion, by inspecting such traits as strength, torsional capacity, flexural capacity, deflection, interface slip, twist and failure modes. This paper will also investigate the main disparity between full shear and partial shear connection and their effects on multi-span composite steel-concrete beams and the difference between multi-span composite steel-concrete beams and single span composite steel-concrete beams. Finally, the interaction of torsion and flexure for multi-span composite steel-concrete composite beams will also be investigated.

2 EXPERIMENTAL PROGRAMME

2.1 *Details of test specimens*

A total of eight multi-span composite steel-concrete beam specimens were used in the experimental phase of this research. These included four beams with partial shear connection and four beams with full shear connection. All of the beams were 4600 mm in length with a simply supported span of 4000 mm. The beams were multi-span beams and consisted of two steel beams attached to one concrete slab for all the beams tested, for both full and partial shear connection.

The concrete slab for each composite beam was 1000 mm in width and 120 mm thick with a nominal compressive strength of 32 N/mm^2 for the concrete. As for the steel beam, a 200UB29.8 section was selected that encompasses a depth of 207 mm and a flange width of 134 mm. For each composite beam, 2 steel beams will be connected to the concrete slab as shown in Figure 1 and 2. Table 1 also highlights the details of all the multi-span composite beam specimens with their type of applied loading.

Table 1. Details of the test specimens.

Specimen	Shear connection (%)	Type of applied loading
MCBF1	100	Pure flexure
MCBF2		Low flexure & high torsion
MCBF3		Medium flexure & medium torsion
MCBF4		High flexure & low torsion
MCBP1	50	Pure flexure
MCBP2		Low flexure & high torsion
MCBP3		Medium flexure & medium torsion
MCBP4		High flexure & low torsion

2.2 *Experimental setup and procedure*

The test rig used for all of the experiments carried out on the multi-span composite steel-concrete beams was the INSTRON 1000 kN testing rig. The test rig has a maximum capacity of applying a total of 1000 kN. For different loading cases, the test rig was adjusted slightly to accommodate for the changes.

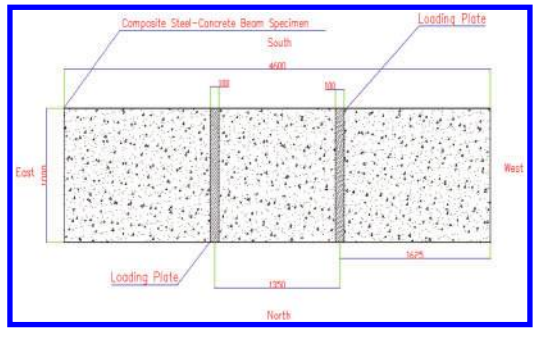

Figure 3. Loading setup for MCBF1 and MCBP1.

For each test, the beams were loading differently according to their type of applied loading. For MCBF1 and MCBP1, the loading plates were 100 mm wide and spanned the entire width of the concrete beam. Each loading plate was positioned 675 mm from the centre of the composite beam specimen which provided a loading span of 1350 mm as shown in Figure 3 and 4.

As for those beams such as MCBF2-4 and MCBP2-4 that required applied torque, the loading plate was positioned at a distance from the centre of the composite steel-concrete beam. An example for MCBF2 and MCBP2 which required low flexural and high torsional loading is showed in Figure 5 and 6.

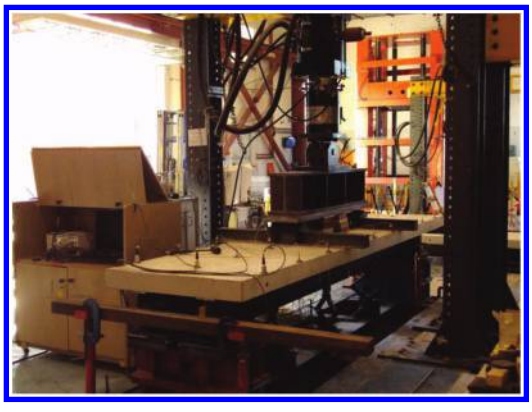

Figure 4. Test setup for MCBF1.

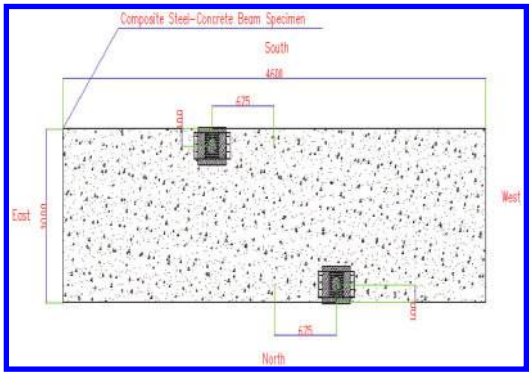

Figure 5. Loading setup for MCBF2 and MCBP3.

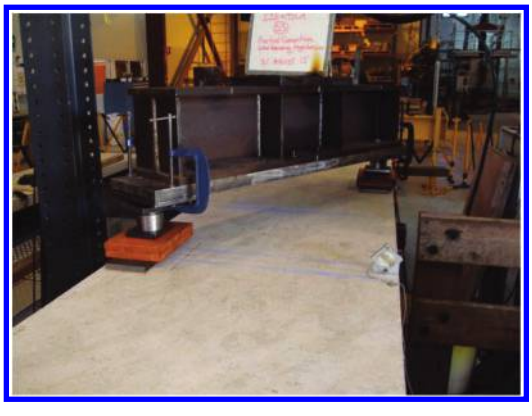

Figure 6. Test setup for MCBF2.

3 RESULTS AND DISCUSSION

3.1 *Flexural strength*

Table 2 shows the ultimate moment and the maximum mid-span deflection achieved by each composite beam specimen that was tested. As expected, the composite beam specimens that were subjected to higher degrees of flexure achieved a higher ultimate moment than the specimens that were subjected to higher degrees of torsion.

Table 2. Summary of ultimate moment and maximum mid-span deflection of all the beam specimens.

Specimen	Ultimate Load (kN)	Ultimate Moment (kNm)	Maximum mid-span deflection (mm)
MCBF1	646	428	114
MCBF2	415	275	20
MCBF3	522	346	45
MCBF4	597	395	60
MCBP1	591	392	150
MCBP2	372	247	17
MCBP3	512	339	71
MCBP4	577	382	94

Overall, the partial shear connection multi-span composite steel-concrete beam specimens achieved an average of 94% of the ultimate moment attained by the full shear connection multi-span composite steel-concrete beam specimens. The partial shear connection composite steel-concrete beam specimens demonstrated very high ultimate moments and applied loads when considering that they possess half the shear studs present in the full shear connection composite steel-concrete beam specimens. Especially when there was a combined action of flexure and torsion and the flexure induced was equal to or higher than the torque, the partial shear connection composite steel-concrete beam specimens attained almost the same strength as the full shear connection composite steel-concrete beam specimens albeit a difference of 2 or 3%.

Finally, by examining the results, it can be determined that in the presence of torsion, there is no increase in the flexural capacity of a multi-span composite steel-concrete beam. Furthermore, failure of the beam specimens arrives at an earlier stage when torsion is present since the beams fail in torsion in these cases and not by flexure. While, under higher levels of flexure, the beams failed by crushing of the concrete (flexural failure) and were able to achieve a higher applied load than the specimens that were loaded under higher levels of torsion.

3.2 *Torsional strength*

From Table 3, a total of six of the eight beams tested were subjected to some degree of torsion. After analysing the results, it is clear that the composite beam specimens that were subjected to higher degrees of torsion attained a higher torsional capacity than the composite beam specimens that were subjected to higher degrees of flexure. The only exception was beam MCBP3 which was subjected to medium torsion and medium flexure yet managed to attain a higher torsional strength than the partial shear connection composite beam specimen loaded under high torsion and low flexure, MCBP2. Additionally, regardless of

Table 3. Summary of ultimate torque and maximum twist of all the beam specimens.

Specimen	Ultimate Load (kN)	Ultimate Moment (kNm)	Maximum twist (mRad)
MCBF2	415	83	15
MCBF3	522	78	26
MCBF4	597	60	26
MCBP2	372	75	78
MCBP3	512	77	27
MCBP4	577	58	28

how high the amount of torque induced in the specimen was, the twist remained relatively low indicating that the beams only twisted slightly under the applied loads.

Overall, the partial shear connection multi-span composite steel-concrete beam specimens exhibited higher twist that the full shear connection multi-span composite steel-concrete beam specimens, except in the case of high torsion and low flexure. The beams loaded in this arrangement of high torsion and low flexure, MCBF2 and MCBP2, did not conform to this as the partial shear connection multi-span composite steel-concrete beam specimen, MCBP2, experienced a lower twist than the full shear connection multi-span composite steel-concrete beam specimen, MCBF2.

Furthermore, the presence of flexure did not cause any increase in the torsional strength. Overall, the partial shear connection composite steel-concrete beam specimens as well as the full shear connection composite steel-concrete beam specimens attained similar values of ultimate torque.

3.3 *Interface steel-concrete slip*

Overall, the interface slip between the concrete and the steel beams was greater for the partial shear connection multi-span composite steel-concrete beam specimens than for the full shear connection multi-span composite steel-concrete beam specimens as showed in Table 4. This was expected since the lower number of shear connector studs would obviously result in greater slip between the concrete-steel interface. Furthermore, the interface slip was greater in the specimens that were exposed to higher levels of flexure than the specimens that were exposed to higher levels of torsion. This leads to the conclusion that high flexure (or even pure flexure) will result in higher interface slip, while high torsion leads to lower values of interface slip.

3.4 *Crack patterns and failure modes*

The crack patterns and failure modes depended heavily on the type of loading the beam was subjected to rather than the degree of shear connection. The specimens subjected to pure flexure, MCBF1 and MCBP1, failed by flexure due to crushing of the concrete. This

Table 4. Summary of maximum interface slip of all the beam specimens.

Specimen	Maximum interface slip (mm)
MCBF1	1
MCBF2	4
MCBF3	0.7
MCBF4	0.8
MCBP1	1
MCBP2	3.1
MCBP3	1
MCBP4	1.7

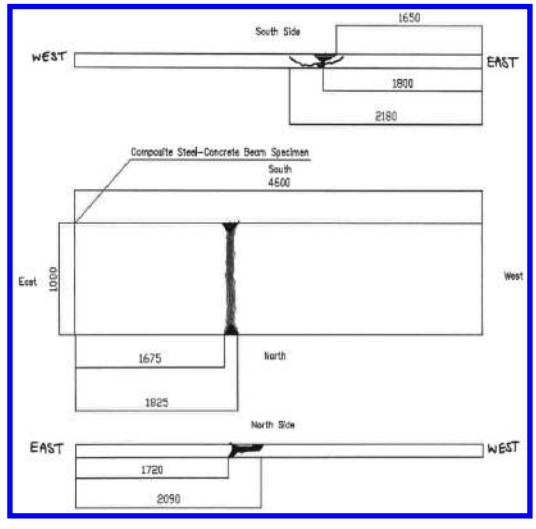

Figure 7. Crack patterns for MCBF1.

is evident in Figure 7 where it is visible that the cracking and crushing of the concrete occurred in the areas where the loading plates where located for MCBF1.

Beams MCBF2 and MCBP2, both loaded under medium torsion and medium flexure, failed in the same manner as beams MCBF3 and MCBP3 which was torsional failure. This can be clearly seen in Figure 8 as the cracks in MCBF3 developed all over the top surface of the concrete and numerous slightly horizontal cracks occurred on the North and South sides as well. Furthermore, beams MCBF3 and MCBP3 developed cracks on the bottom side of the concrete slab as well.

Finally, the beams loaded under high flexure and low torsion, MCBF4 and MCBP4, failed by crushing of concrete (flexural failure) similar to beams MCBF1 and MCBP1. The cracking of these two beams was localised in the area between where the two loading plates were located and consisted of deep cracks.

3.5 *Interaction flexure-torsion diagram*

Figure 9 illustrate the interaction diagram for the full and partial shear connection multi-span composite

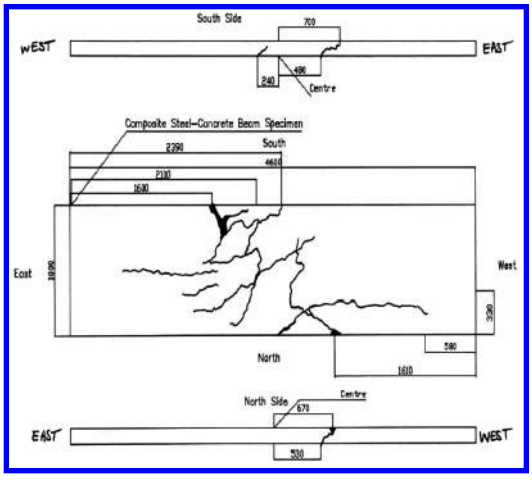

Figure 8. Crack patterns for MCBF3.

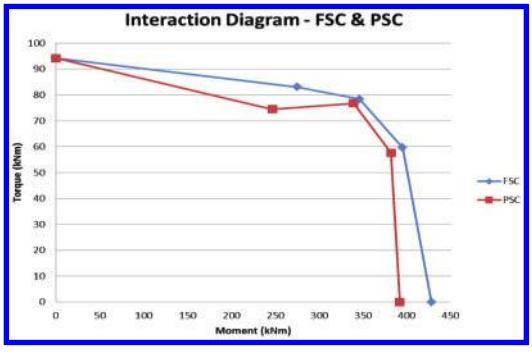

Figure 9. Interaction flexure-torsion diagram.

steel-concrete beam specimens. A point for each beam specimen is plotted on the graph (torque against moment). As one can deduce from Figure 9, the strength characteristics of the partial shear connection multi-span composite steel-concrete beam specimens is almost similar to the full shear connection multi-span composite steel-concrete beam specimens especially in the cases of medium flexure and medium torsion as well as high flexure and low torsion loading cases.

3.6 *Comparison with single span beams*

Similar to the research carried out for this paper, Tan & Uy (2009a) conducted experiments on straight composite steel-concrete beams subjected to combined flexure and torsion. The only distinction between this research and Tan & Uy (2009a) would have to be the size of the beam specimens and the number steel beams utilised.

From Figure 10, the ultimate moment attained by the multi-span composite steel-concrete beam specimens in this paper was larger than that of the single span composite steel-concrete beam. This was expected since the composite beam specimens tested

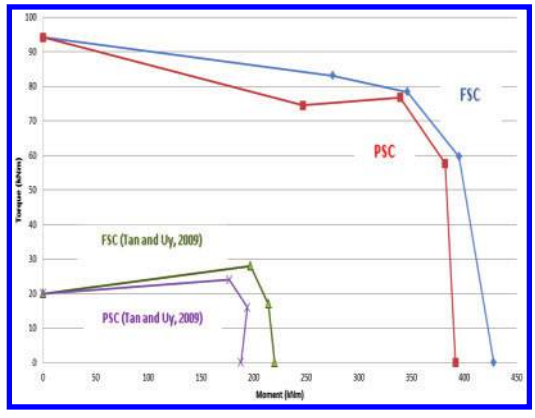

Figure 10. Comparison between the interaction flexure-torsion diagrams for multi and single span beams.

for this research were double the size of the specimens utilised in the experiments by Tan & Uy (2009a). For the specimens subjected to pure flexure, CBF-1 attained 51% of the flexural capacity of MCBF1, while CBP-1 attained 48% of the flexural capacity of MCBP1. This demonstrates that when loaded under pure flexure, the multi-span composite steel-concrete composite beams attain a flexural capacity roughly twice that of a single span composite steel-concrete beam. When considering the beams loaded under high flexure and low torsion, the same conlusion can be made since CBF-2 attained 54% of the flexural capacity of MCBF4 and CBP-1 attained 50% of the flexural capacity of MCBP4, the multi-span composite steel-concrete beam specimens achieve roughly double the flexural capacity of the single span beams for both full and partial shear connection.

However, when examining the specimens that were loaded under high torsion and low flexure, it is evident that CBF-3 achieved 72% of the flexural capacity of MCBF2 while CBP-3 achieved 72% of the flexural capacity of MCBP2. This demonstrates that the single span composite beam specimens obtained roughly 72 % of the flexural strength of the multi-span composite beam specimens.

4 CONCLUSIONS

In conclusion, in the presence of torsion, there is no increase in the flexural capacity of a multi-span composite steel-concrete beam, whilst in the presence of flexure did not cause any increase in the torsional capacity in the multi-span composite steel-concrete beam specimens.

In terms of failure modes, multi-span composite steel-concrete beams loaded under high flexure failed due to the crushing of the concrete while the multi-span composite steel-concrete beams loaded under higher levels of torsion failed due to shear torsional failure.

Multi-span composite steel-concrete beams subjected to higher degrees of torsion attained a higher torsional capacity than the specimens that were subjected to higher degrees of flexure.

Regardless of how high the amount of torsion was induced in the specimen, the twist remained relatively low indicating that the multi-span composite steel-concrete beams only twisted slightly under the applied loads. The twist of a multi-span composite beam specimen, when subjected to torsion, will be relatively similar regardless of the degree of shear connection.

The flexural capacity of partial shear connection multi-span composite steel-concrete beams is roughly similar to that of the full shear connection multi-span composite steel-concrete beams. This is especially true in the case of high flexure.

When a high degree of flexure was present, the multi-span composite steel-concrete beam specimens actually attained higher values of twist than the specimens that were exposed to high torsion. Overall, the partial shear connection multi-span composite steel-concrete beam specimens exhibited higher twist that the full shear connection multi-span composite steel-concrete beam specimens, except in the case of high torsion and low flexure loading.

The interface slip between the concrete and the steel was greater for the partial shear connection multi-span composite steel-concrete beam specimens than for the full shear connection multi-span composite steel-concrete beam specimens.

The disparity in flexural strength between full shear and partial shear specimens is lower in multi-span composite steel-concrete beams than in single span composite steel-concrete beams. Additionally, the degree of shear connection has a lower effect on flexural strength when considering multi-span composite steel-concrete beams than when considering single span composite steel-concrete beams.

ABSTRACT: This paper deals with the service behaviour of composite steel-concrete bridges, with particular attention devoted to how this is influenced by the time-dependent behaviour of the concrete, such as creep and shrinkage. The paper outlines some of the main aspects which need to be addressed in service design, which include the evaluation of the influence of creep and shrinkage on the stress state and deformations induced in the concrete slab and steel girder, and how these vary with time when the composite bridge is subjected to external static loads, geometrical actions and shrinkage effects. Considerations are also provided on how shear-lag effects, the shear deformability of the steel girder and different casting sequences specified during construction affect the deformations and stress distributions of a composite steel-concrete bridge over time.

1 INTRODUCTION

Composite steel-concrete construction represents a widely used form of construction for bridge applications thanks to its ability to well combine the advantages of both steel and concrete. In fact, composite members exhibit enhanced strength and stiffness when compared to the contribution of their components acting separately. The composite action is provided by means of shear connectors, welded to the top flange of the steel and embedded in the concrete during casting. The composite response at service condition is highly dependent on the deformability of the shear connectors, which enables relative movements to occur between the slab and the steel beam. This kinematic behaviour, in which slip can occur between the two components, is usually referred to as partial shear interaction.

This paper outlines some important considerations related to the service behaviour of composite bridges, with particular attention devoted to how this is influenced by the time-dependent behaviour of the concrete, such as creep and shrinkage. Extensive work has been carried out to date in this area. Despite this, it is beyond the scope of this paper to provide a review of the current state of the art in this area and, for this purpose, reference should be made to (Ranzi et al. 2013). In particular, this paper describes how time effects influence the deformations and internal stresses in composite bridges when subjected to external static loads, geometrical actions, shrinkage effects, and how the time-dependent composite response is affected by shear-lag effects, by the shear deformability of the steel girder and by different casting sequences specified during construction.

2 STATIC ACTIONS

Composite beams subjected to static actions exhibit an increase in deflections and deformations over time as well as a redistribution of stresses between steel beam and slab due to cross-section heterogeneity. This is illustrated in Figure 1 for a typical two-span continuous beam subjected to a uniformly distributed load. (Dezi & Tarantino 1993, Bradford & Gilbert 1992, Amadio & Fragiacomo 1993, Gilbert & Ranzi 2011)

Considering the applied external actions to remain constant with time, the resultant bending moment $M(z,t)$ (Figure 2b) does not undergo significant changes, as can also be highlighted in Figure 2d by the variation in time of the reaction at the inner support (R) is plotted. Theoretically, these differences

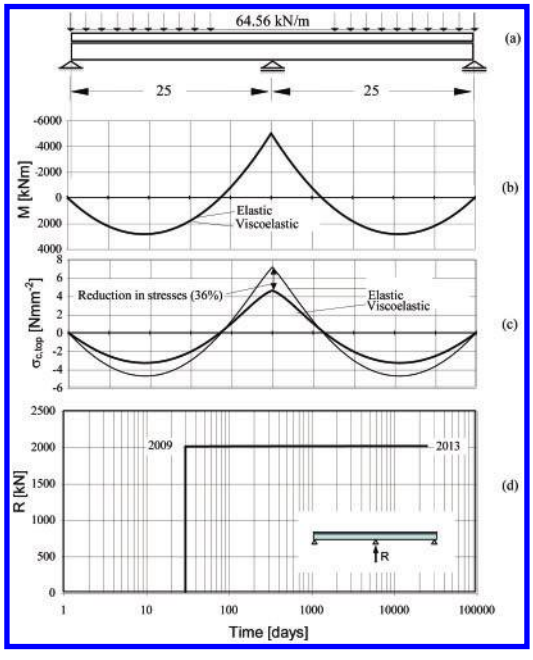

Figure 1. Effects of static actions on composite girders.

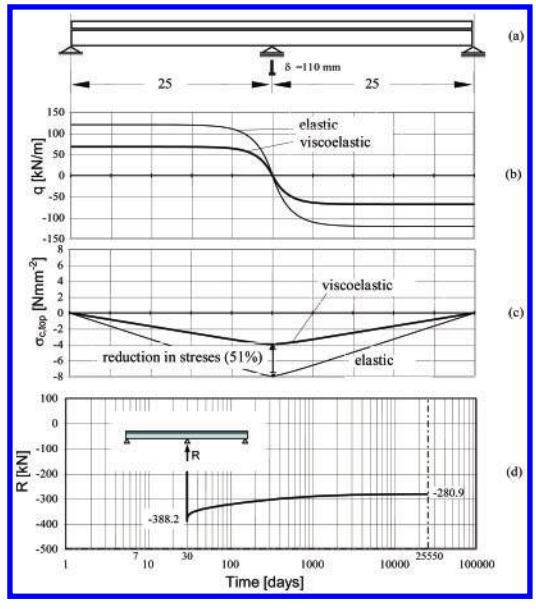

Figure 2. Effects of geometrical actions on composite girders.

become negligible for composite beams with stiff shear connections and where the only stress redistributions taking place are those between the concrete slab and the steel girder, with slab unloading over time and redistributing its stresses to the steel component. Under these ideal conditions, it could be possible to describe this time-dependent composite behaviour relying on the first theorem of linear visco-elasticity (CEB 1988, Dezi & Tarantino 1993) as follows: in composite steel-concrete prismatic beams with stiff connection and rigid restraints, subjected to static actions (also varying in time), the reactions and, consequently, the resultant bending-moment distribution coincide with those calculated with a purely elastic analysis. On the other hand, internal stresses, strains and displacements must be evaluated by summing the effects induced by creep to the corresponding elastic quantities.

For practical applications, negligible errors are made by evaluating the redundant restraint reactions under the assumption of stiff connection, while displacements should be calculated taking into account the flexibility of the shear connection.

3 GEOMETRICAL ACTIONS

Geometrical actions, such as support settlements, lead to a time-dependent response well represented by the classical relaxation behaviour, which produce a reduction in time of the self-equilibrated reaction forces and of the stress state in the concrete slab. Assuming the geometrical actions to remain constant in time, the displacements calculated in each cross-section of a bridge do not vary sensibly with time and, theoretically, vanish when specifying a stiff shear connection. It is possible to describe this trend following the second theorem of linear visco-elasticity as (CEB 1988, Dezi & Tarantino 1993): in composite steel-concrete prismatic beams with stiff shear connection and rigid restraints, and subjected to geometrical actions (also varying in time), the rotations and the displacements coincide with those calculated with a purely elastic analysis. On the other hand, internal strains, stresses and reactions must be evaluated combining the effects induced by creep to those obtained from the elastic response.

Suitable settlements are often imposed in order to control the tension of the slab in the hogging moment regions. An example related to a two-span composite beam is provided in Figure 2. For shear connection rigidities in the range of practical interest, the longitudinal normal stress (σ_c) is almost halved over time due to creep effects as shown in Figure 2c, therefore considerably reducing in time the benefits provided to the structure by this prestressing technique.

4 SHRINKAGE

Shrinkage is the result of the concrete volume reduction which takes place over time and is independent from applied loads. (CEB 1988, Gilbert & Ranzi 2011) In composite beams, the presence of the shear connection prevents the free shortening of the slab so that a distribution of shear forces takes place over time at the interface. In particular, the distribution of the shear force (q) is characterised by peaks at the beam ends, which are strongly influenced by the shear connection

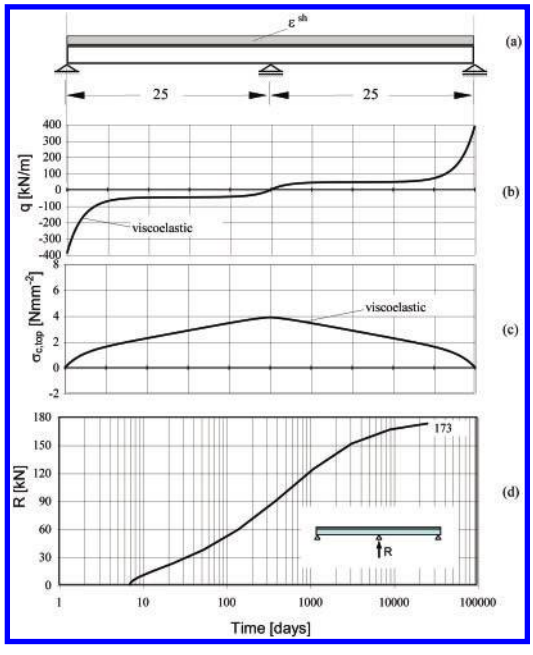

Figure 3. Effects of shrinkage on composite girders.

stiffness. This trend is outlined in Figure 3 for the case of a two-span composite beam. In statically indeterminate structures, a self-equilibrated system of reactions develops in time due to shrinkage effects, as depicted in Figure 3d considering the reaction of the internal support.

The distributions of internal actions, induced by concrete shrinkage and evaluated for different values of the shear connection stiffness, produce differences only at the ends of the spans. Under the assumption of stiff shear connection, it is possible to obtain acceptable results at locations away from the beam ends and from the internal supports. However, this approach does not allow for evaluation of the peak values exhibited for the shear force transmitted at the shear connection (Dezi 1994). Shrinkage also occurs and influences the time-dependent deflections and deformations of composite beams. Its effects are generally more pronounced than those observed in reinforced concrete structures due to the eccentricity of the concrete slab with respect to the overall cross-section.

5 SHEAR-LAG EFFECTS AND CONCRETE SLAB EFFECTIVE WIDTH

When a composite beam is subjected to external loads or deformations, the slab cross-section looses its planarity due to the concentrated forces induced by the shear connectors. This behaviour tends to produce higher longitudinal deformations within the slab in the vicinity of the connectors' line which decrease when moving away from the steel beam. This warping effect

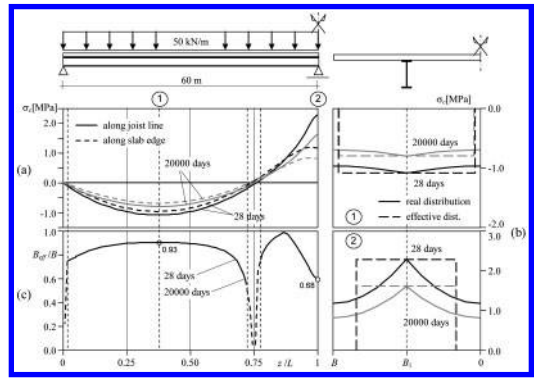

Figure 4. Uniformly distributed load: (a) stress distribution along the bridge axis; (b) stresses at the slab mid-height at two locations; (c) variation of the effective width along the bridge axis.

is usually referred to as shear-lag and its magnitude is dependent upon the type of applied action and support conditions.

From a design viewpoint, it is usually more convenient to remain within Bernoulli beam theory simplifying the analysis with the effective width method, in which plane sections remain plane after deformation and a constant stress is assumed over a modified effective slab width. This approach makes possible to obtain results 'equivalent' to those calculated with rigorous analyses reducing the width of the slab to the effective one. Work carried out to date on the influence of the time dependent response of concrete on the effective width values highlighted how the latter do not vary with time when considering static actions and geometric settlements. As a consequence, the effective width expressions adopted for the instantaneous cases can be applied also when accounting for time effects. In the case of prestressing, it was observed that there is a time-dependent decrease of the effective width and that areas in the vicinity of the prestressing anchorages are heavily affected by shear-lag, e.g. (Dezi et al. 2006a).

Typical results observed for two-span continuous composite bridges are depicted in Figures 4 and 5 for the cases of a uniformly distributed load applied at 28 days from concrete casting and of the settlement of the internal support. In both cases, stresses and effective width values calculated from the instantaneous (at 28 days) and time-dependent (at 20000 days) analyses are provided. To emphasise the occurrence of shear-lag effects, values plotted in the figures show variations along the slab edge and along the joist's line. For example, Figures 4a-b highlight how the edge stresses are typically smaller than those produced above the steel joist and these variations become more pronounced at the internal support (Gara et al. 2008). Considering the cross-sections of maximum positive and negative moments, i.e. located at about 0.375 L and L from the bridge end, respectively (where L is the length of one span), it can be observed that while the stress magnitudes vary with time, their actual trend

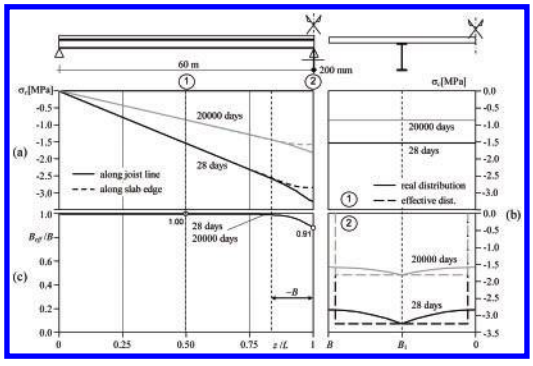

Figure 5. Support settlement: (a) stress distribution along the bridge axis; (b) stresses at the slab mid-height at two locations; (c) variation of the effective width along the bridge axis.

remains constant (Figure 4b). The consequence of this behaviour is that the effective width does not vary with time, as shown in Figure 4c. Considering the trend of the effective width, a linear variation is attained close to the internal support whereas, in sagging regions, it is almost constant. It is worth noting that for sections located in the regions where the bending moment is about zero, the calculated effective widths approach zero because of the low stresses in the vicinity of the contraflexure points: these values are not significant from a design viewpoint.

Similarly to the case of concentrated transverse forces, settlements of the supports produce shear force resultants varying stepwise at the location of the support. Under these loading conditions, the warping due to shear is constant along the member axis, except in the vicinity of the supports in accordance with Saint Venant's conditions. Even if the warping is non zero, the distribution of longitudinal stresses within the concrete slab is uniform and the effective width coincides with the geometric width. This trend is reflected by the results plotted in Figure 5.

6 SHEAR DEFORMABILITY OF THE STEEL GIRDER

The shear deformability of the steel girder significantly influences the magnitude of deformations and displacements exhibited by a composite bridge, especially when considering the relatively high plate element slenderness commonly specified in real applications.

The influence of the shear deformability of the steel girder on the structural response is outlined in Figure 6 based on the results of an extensive parametric study carried out on 200 realistic composite steel-concrete bridge arrangements designed with Australian guidelines (Rapattoni et al. 1998). These include both simply-supported and three-span continuous systems subjected to a uniformly distributed load (Ranzi & Zona 2007). For the shear connection rigidity, two limit cases have been considered with consist

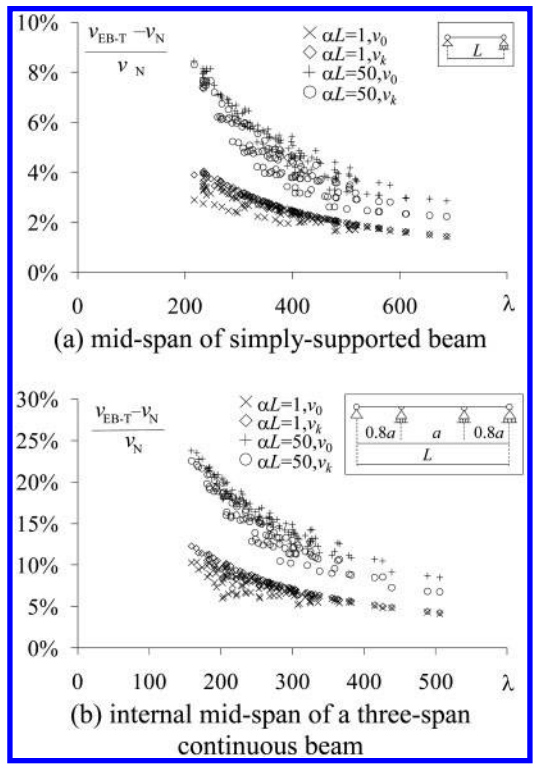

Figure 6. Differences between values calculated with the EB-T (v_{EB-T}) and Newmark (v_N) models.

of low ($\alpha L = 1$) and high ($\alpha L = 50$) shear connection stiffness, where αL is a dimensionless parameter commonly used in the literature.

The analytical model accounting for the shear deformability of the steel beam is derived coupling a Euler-Bernoulli beam model for the concrete slab with a Timoshenko beam model for the steel girder (referred to as EB-T model). Its results are compared with the classical Newmark model which considered two Euler-Bernoulli beams for the slab and steel beam. In this case, the analytical representations accounts for only the flexural deformations of the two components.

Based on these two models, the variations between the mid-span deflections calculated for the simply-supported bridges are outlined in Figure 6a, as a function of a dimensionless parameter λ which accounts for the flexural rigidity of the steel, its shear rigidity and bridge span. The shear connection stiffness significantly affects the discrepancy between these results. For low values of shear connection stiffness, the maximum difference between the two models remains within 4%, while this more than doubles for high shear connection rigidities, i.e. with maximum differences slightly greater than 8%. The concrete time-dependent behaviour tends to decrease these variations for high levels of shear connection stiffness while an opposite trend is noted with low stiffness. For clarity, t_0 and t have been introduced to denote the instant in time of

first loading and the one of interest in the time domain, respectively.

Similar trends can be observed for the three-span beam configurations (Figure 6b), even if the differences obtained for the indeterminate structure is significantly increased. Long-term effects tend to reduce these differences for high levels of shear connection stiffness while leading to an opposite result for low connection stiffness. This increase is justified by the consideration that shear deformations are not reduced by the continuity of a beam, as it occurs for flexural deformations.

7 EFFECTS OF EARLY AGE SHRINKAGE AND CONSTRUCTION PHASES

The behaviour of the early age concrete and the planning of the casting sequences have an important role in the concrete cracking phenomenon during construction of continuous steel-concrete composite bridge decks. In fact, in the case of long viaducts, the slab needs to be poured on unpropped steel beams fractionating the casting process. The weights of the concrete and of the travelling formworks may induce tensile stresses in the slab sections which have already hardened, e.g. (Ducret & Lebet 1999, Mari et al. 2003, Dezi et al. 2006b).

The behaviour of early age concrete characterised by significant shrinkage effects such as endogenous chemical shrinkage, thermal shrinkage due to cooling of the hardened concrete and drying shrinkage, is responsible for inducing further tensile stresses. The early cracking may affect not only the hogging regions but even the sagging regions which are usually considered uncracked. The phenomenon can be controlled by optimising the concrete pouring sequences by casting the slab sections first in the centre of each span and then over the interior supports. A basic role is played by the rheology of the early age concrete; in fact, tensile creep is involved in the incipient cracking mechanism and non linear phenomena are expected since tensile stresses are almost equal to the relevant strength.

The influence of different casting sequences is outlined considering case study of a 12 span continuous steel-concrete composite bridge with span lengths varying from a minimum of 55 m (for the external spans) to a maximum of 120 m (for the central span) for a total length of about 1 km. The slab is poured on precast-deck elements used as formworks. With reference to the longitudinal direction, a casting speed of 43 m/day is considered in the calculation. It is assumed that the concrete setting ends at 12 hours from pouring and that the curing duration is two days. Three casting schemes are considered: a continuous sequence from one end to the other end of the deck, referred to as scheme (a), and two fractionated sequences consisting in alternating the casting of a sagging segment to that of a hogging segment, denoted as schemes (b) and (c). Scheme (b) differs from scheme (c) for the length

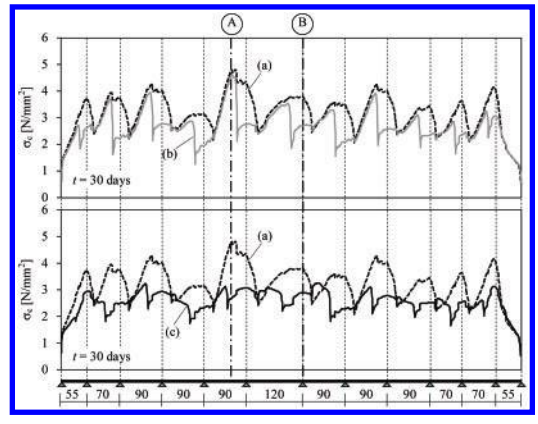

Figure 7. Concrete stresses at the end of constructive phases ($t = 30$ days).

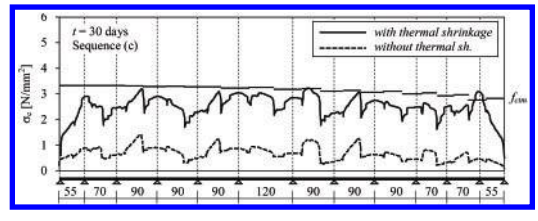

Figure 8. Influence of the thermal shrinkage on the tensile stress state.

of the various segments: in the first case sagging and hogging segments are chosen so as to be symmetric with respect to the axes of the relative spans (for sagging segments) and supports (for hogging segments); in the second case the sagging sections are reduced and the hogging section enlarged in a non-symmetric way.

Figure 7 shows the stresses, measured at the concrete slab mid-plane at the end of the slab construction, produced by the continuous and fractionated castings. All the slab segments are affected by tensile stresses for both cases of continuous and fractionated casting: in the case of continuous casting the maximum stresses are observed to occur in the hogging moment regions while in the fractionated castings these take place in the sagging moment regions. The differences between the two fractionated sequences can be summarised as follows: sequence (b) is not effective in limiting concrete tractions because the same stress levels of sequence (a) are achieved in the sagging moment regions despite the significant stress reduction produced in the hogging moment regions; on the contrary, sequence (c), obtained with non-symmetric sections, permits a sensible reduction of the stresses.

Figure 8 shows the importance of the thermal shrinkage and demonstrates that it is responsible for more than 50% of the tensile stresses at the end of casting (30 days). Structural analyses would be strongly not realistic and non conservative in predicting the bridge cracking tendency if thermal shrinkage was neglected.

8 CONCLUSIONS

This paper presented some of the main aspects to be considered in the design at service conditions of composite steel-concrete bridges. The main focus has been related to the influence of the time-dependent behaviour of the concrete on the stress state and deformations induced in the composite member. Particular considerations have been provided on how time effects influence the composite response when subjected to external static loads, geometrical actions and shrinkage effects, and how this is affected by shear-lag effects, by the shear deformability of the steel girder and by different casting sequences specified during construction affect the deformations and stress distributions of a composite steel-concrete bridge over time.

Nonlinear inelastic analysis of 3D composite steel-concrete frameworks

C.G. Chiorean, M. Buru, A. Chira & I. Marchis
Technical University of Cluj-Napoca, Faculty of Civil Engineering, Cluj-Napoca, Romania

ABSTRACT: This paper presents an efficient computer method for nonlinear inelastic analysis of three-dimensional composite steel-concrete frameworks. The proposed formulation is intended to model the geometrically nonlinear inelastic behaviour of composite frame elements using only one element per physical member. The behaviour model accounts for material inelasticity due to combined bi-axial bending and axial force, gradual yielding is described through basic equilibrium, compatibility and material nonlinear constitutive equations. Tangent flexural rigidity of cross-section is derived and then using the flexibility approach the elasto-plastic tangent stiffness matrix and equivalent nodal loads vector of 3-D beam-column element is developed. The proposed nonlinear analysis formulation has been implemented in a general nonlinear static purpose computer program. A computational example is given to validate the effectiveness of the proposed method and the reliability of the code.

1 INTRODUCTION AND RESEARCH SIGNIFICANCE

In recent years, have witnessed significant advances in nonlinear inelastic analysis methods for steel and composite steel-concrete framed structures and integrate them into the new and more rational advanced analysis and design procedures (Li & Li 2007). Reliable nonlinear analysis tools are, for instance, essential in performance-based earthquake engineering, and advanced analysis methodologies, that involves accurate predictions of inelastic limit states up or beyond to structural collapse. There currently exist several methods and computer programs concerning the nonlinear inelastic analysis that calculate strength limit states of steel and composite steel-concrete frame structures. At one extreme, two- and three dimensional finite elements enhanced with advanced material constitutive laws were used to investigate the nonlinear response of steel and composite steel-concrete frame members. Currently the available tools for such analysis are general purpose FE programs that require very fine-grained modelling that is often impractical to the structural engineer. At the other extreme, the line elements approach in conjunction with either distributed or concentrated plasticity models, have been devoted to the development of nonlinear analysis tools for frames that provide a desirable balance between accuracy and computational efficiency (Ngo-Huu & Kim, 2012; Iu et al. 2009; Izzudin et al. 2002, Chiorean 2009). In spite of the availability of such nonlinear inelastic algorithms and powerful computer programs, the nonlinear inelastic analysis of real large-scale frame structures still posses huge demands on the most powerful of available computers and still represents unpractical tasks to most designers.

The present work attempts to develop accurate yet computational efficient tools for the nonlinear inelastic analysis of real large-scale 3D composite steel-concrete frameworks fulfilling the practical and advanced analysis requirements. Essentially, nonlinear inelastic analysis employed herein uses the accuracy of the fiber elements approach for inelastic frame analysis and address its efficiency and modelling shortcomings both to element level, through the use of only one element to model each physical member of the frame, and to cross-sectional level through the use of path integral approach to numerical integration of the cross-sectional nonlinear characteristics.

2 MATHEMATICAL FORMULATION

2.1 *Basic assumptions and constitutive material models*

The following assumptions are adopted in the formulation of analytical model: (1) plane section remain plane after flexural deformation; no slip occurs at the steel-concrete interface, full composite action is considered (2) warping and cross-section distortion are not considered; (2) torsional buckling do not occur; (3) small strain but arbitrarily large displacements and rotations are considered. The proposed approach is based on the most refined type of second order inelastic analysis, distributed plasticity model, where elasto-plastic behaviour is modelled accounting for spread-of plasticity effect in sections and along the element and employs modelling of structures with only one line element per member, which reduces the number of degree of freedom involved and the computational time. Consider the cross-section subjected to the action of the

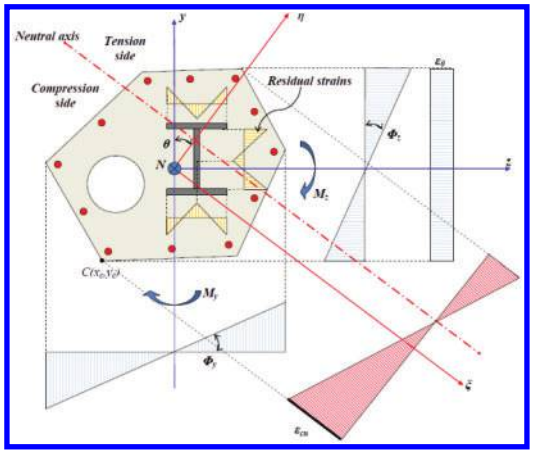

Figure 1. Model of arbitrary composite cross-section.

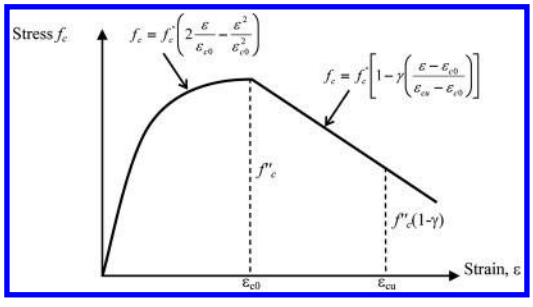

Figure 2. Stress-strain relationships for concrete in compression.

external bending moments about both global axes and axial force as shown in Figure 1.

The cross-section may assume any shape with multiple polygonal or circular openings. The constitutive relation to model the concrete under compression is represented by a combination of a second-degree parabola (for ascending part) and a straight line (for descending part), as depicted in Figure 2, where γ represents the degree of confinement in the concrete. Multi-linear elastic-plastic stress-strain relationships, both in tension and in compression, is assumed for the structural steel and the conventional reinforcing bars.

2.2 *Elasto-plastic flexural rigidity of cross-section*

Considering the cross-section subjected to the action of the external bending moments (M_y, M_z) about each global axes and axial force (N) as shown in Figure 1. The origin of the reference axis is usually considered in the geometric centroid of the cross-section. Under the above assumptions the resultant strain distribution corresponding to the curvatures about global axes $\mathbf{\Phi} = [\Phi_y \quad \Phi_z]$ and the axial strain ε_0 can be expressed in point $\mathbf{r} = [y \quad z]$ in a linear form as:

$$\varepsilon = \varepsilon_0 + \Phi_y z + \Phi_z y + \varepsilon_r = \varepsilon_0 + \mathbf{\Phi}\mathbf{r}^T + \varepsilon_r \qquad (1)$$

where ε_r represents the initial deformation produced by residual stresses, and is taken into account inabove equation only for the structural steel. The equilibrium is satisfied when the external forces (N, M_y, M_z) are equal to the internal ones. These conditions can be represented mathematically in terms of the following nonlinear system of equations as:

$$\begin{cases} \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0, \phi_y, \phi_z\right)\right) dA_{cs} - N = 0 \\ \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0, \phi_y, \phi_z\right)\right) z dA_{cs} - M_y = 0 \\ \int_{A_{cs}} \sigma\left(\varepsilon\left(\varepsilon_0, \phi_y, \phi_z\right)\right) y dA_{cs} - M_z = 0 \end{cases} \qquad (2)$$

in which $\varepsilon_0, \phi_y, \phi_z$ represent the unknowns and the surface integral is extended over concrete and structural steel areas (A_{cs}). The above system can be solved numerically using, for instance, the load-controlled Newton method and taking into account the fact that the stresses are implicit functions of the axial strain and curvatures through the resultant strain distribution given by the Equation (1). The tangent stiffness matrix for the cross section relates small changes in the deformations to small changes in the actions sustained. The incremental relationships between incremental efforts and incremental deformations can be expressed as:

$$\begin{bmatrix} k_{11} & k_{12} & k_{13} \\ k_{21} & k_{22} & k_{23} \\ k_{31} & k_{32} & k_{33} \end{bmatrix} \cdot \begin{bmatrix} \Delta\varepsilon_0 \\ \Delta\phi_y \\ \Delta\phi_z \end{bmatrix} = \begin{bmatrix} \Delta N \\ \Delta M_y \\ \Delta M_z \end{bmatrix} \qquad (3)$$

where the coefficients of the tangent stiffness matrix k_{ij} are evaluated considering the strains and stresses at equilibrium for given external actions. Tangent flexural rigidities for major and minor axis bending under conditions of constant axial load are evaluated by inverting the cross-section tangent stiffness matrix, imposing the condition of constant axial load to obtain a flexural flexibility matrix and inverting this to find the tangent flexural rigidities, about each principal axis, at constant axial load:

$$\begin{aligned} EI_{tz} &= \frac{k_{11}k_{22}k_{33} - k_{11}k_{23}^2 - k_{33}k_{12}^2 + 2k_{12}k_{13}k_{23} - k_{22}k_{13}^2}{k_{11}k_{33} - k_{13}^2} \\ EI_{ty} &= \frac{k_{11}k_{22}k_{33} - k_{11}k_{23}^2 - k_{33}k_{12}^2 + 2k_{12}k_{13}k_{23} - k_{22}k_{13}^2}{k_{11}k_{22} - k_{12}^2} \end{aligned} \qquad (4)$$

where stiffness coefficients k_{ij} ($k_{ij} = k_{ji}$) are given in Eqs. (4):

$$\begin{aligned} k_{11} &= \int_{A_{cs}} E_T dA_{cs}\,;\; k_{12} = \int_{A_{cs}} E_T z dA_{cs}\,;\; k_{13} = \int_{A_{cs}} E_T y dA_{cs}\,; \\ k_{22} &= \int_{A_{cs}} E_T z^2 dA_{cs}\,; k_{23} = \int_{A_{cs}} E_T yz dA_{cs}\,;\; k_{33} = \int_{A_{cs}} E_T y^2 dA_{cs} \end{aligned} \qquad (5)$$

and where the surface integral is extended over concrete and steel area (A_{cs}). The tangent axial rigidity

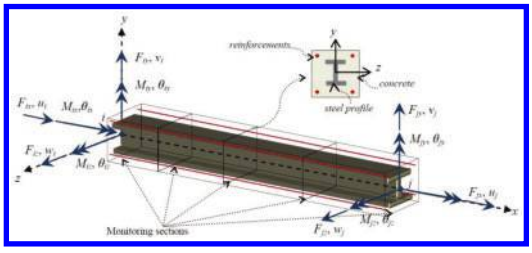

Figure 3. Beam column element with 12 DOF.

is computed as $EA_t = \int_{A_{cs}} E_T dA_{cs}$. Based on Green's integration formula according to which the domain integrals appearing in the evaluation of internal resultant efforts and tangent stiffness matrix coefficients of the section can be evaluated in terms of boundary integral. This approach is extremely rapid because stress integrals need only be evaluated at a small number of points on the section boundary and rapid convergence is assured by the inclusion of exactly determined tangent stiffnesses and, of great importance, it is assure convergence for any load case.

2.3 *Flexibility based derivation. Member analysis*

Flexibility-based method is used to formulate the distributed plasticity model of a 3D frame element (12 DOF) under the above assumptions. An element is represented by several cross sections (i.e. stations) that are located at the numerical integration scheme points (Fig. 3). The spread of inelastic zones within an element is captured considering the variable section flexural EI_y and EI_z and axial EA rigidity along the member length, depending on the bending moments and axial force level, cross-sectional shape and nonlinear constitutive relationships as already described. Figure 4 shows the deformed shape of a 3D beam-column element in local system attached to the initially straight center line, with the rigid body modes removed. Non-linear analysis by the stiffness method requires incremental loading, i.e. the inelastic behaviour is approximated by a series of elastic analysis. The element incremental flexibility matrix f_r which relates the end displacements to the actions $\Delta \mathbf{s}_r$ can be derived directly from energetic principles.

Assuming elastic behaviour within a load increment, and no coupling of axial and flexural responses at the section level, the increment of the strain energy ΔW can be written as follows, including the additional shear and torsional deformations:

$$\Delta W = \frac{L}{2}\int_0^1 \frac{N^2}{EA(\xi)}d\xi + \frac{L}{2}\int_0^1 \frac{M_z^2(\xi)}{EI_z(\xi)}d\xi + \frac{L}{2}\int_0^1 \frac{M_y^2(\xi)}{EI_y(\xi)}d\xi + \frac{L}{2}\int_0^1 \frac{M_x^2}{GI_t(\xi)}d\xi + \frac{L}{2}\int_0^1 \frac{T_y^2(\xi)}{GA_y(\xi)}d\xi + \frac{L}{2}\int_0^1 \frac{T_z^2(\xi)}{GA_z(\xi)} \quad (6)$$

in which the bending moments and shear forces are given by the following equations, supposing that the element is subjected to uniform distributed loads $q_{y(z)}$:

$$M_{y(z)}(\xi) = M_{iy(z)}(\xi - 1) + M_{jy(z)}\xi + \frac{q_{y(z)}L^2\xi(\xi-1)}{2}$$
$$T_{y(z)}(\xi) = \frac{dM_{y(z)}(\xi)}{d\xi} = \frac{M_{iy(z)} + M_{jy(z)}}{L} + \frac{q_{y(z)}L^2(2\xi-1)}{2} \quad (7)$$

Using the second theorem of Castigliano the relationship between incremental deformations and efforts can be readily calculated and partitioned as follows:

$$\begin{bmatrix} u \\ \theta_{iy} \\ \theta_{jy} \\ \theta_{iz} \\ \theta_{jz} \\ \theta_x \end{bmatrix} = \begin{bmatrix} \frac{\partial \Delta W}{\partial N} \\ \frac{\partial \Delta W}{\partial M_{iy}} \\ \frac{\partial \Delta W}{\partial M_{jy}} \\ \frac{\partial \Delta W}{\partial M_{iz}} \\ \frac{\partial \Delta W}{\partial M_{jz}} \\ \frac{\partial \Delta W}{\partial M_x} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{1(3x3)} & \mathbf{0}_{(3x3)} \\ \mathbf{0}_{(3x3)} & \mathbf{f}_{2(3x3)} \end{bmatrix} \cdot \begin{bmatrix} N \\ M_{iy} \\ M_{jy} \\ M_{iz} \\ M_{jz} \\ M_x \end{bmatrix} + \begin{bmatrix} 0 \\ \delta_{iy} \\ \delta_{jy} \\ \delta_{iz} \\ \delta_{jz} \\ 0 \end{bmatrix} \quad (8)$$

or in a condensed form:

$$\Delta \mathbf{u}_r = \mathbf{f}_r \cdot \Delta \mathbf{s}_r + \boldsymbol{\delta}_r \quad (9)$$

where $\mathbf{f}_r$ represents the incremental flexibility matrix of the beam-column element without rigid body modes, and $\boldsymbol{\delta}_r$ is a term resulting from loading actions (Chiorean 2009).

To produce the deformational-stiffness relation, the Equation (7) is inverted, resulting the following deformational-stiffness equation:

$$\Delta \mathbf{s}_r = \mathbf{k}_r \cdot \Delta \mathbf{u}_r - \mathbf{q}_r \quad (10)$$

where the vector $\mathbf{q}_r$ is the equivalent load vector, whereas k_r represents the instantaneous element stiffness matrix of the beam-column element without rigid body modes, determined by matrix inversion of the flexural matrix f_r:

$$\mathbf{k}_{r(6x6)} = \mathbf{f}_r^{-1} = \begin{bmatrix} \mathbf{f}_1^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{f}_2^{-1} \end{bmatrix} = \begin{bmatrix} \mathbf{k}_{1(3x3)} & \mathbf{0}_{(3x3)} \\ \mathbf{0}_{(3x3)} & \mathbf{k}_{2(3x3)} \end{bmatrix} \quad (11)$$
$$\mathbf{q}_r = \mathbf{k}_r \boldsymbol{\delta}_r$$

The resulting element stiffness matrix is a 6×6 matrix. To include rigid body modes, the stiffness matrix is pre- and post multiplied by a transformation matrix to result in the required 12×12 matrix. The geometrical nonlinear effects for each element are taken into account in the present analysis, in a beam column approach, by the use of the inelastic stability stiffness functions and updating at each load increment the length, axial force and the flexural rigidity about of each principal axes of the element. This way minimizes modeling and solution time, generally only one or two elements are needed per member. The element force fields are described by the second order transfer matrix

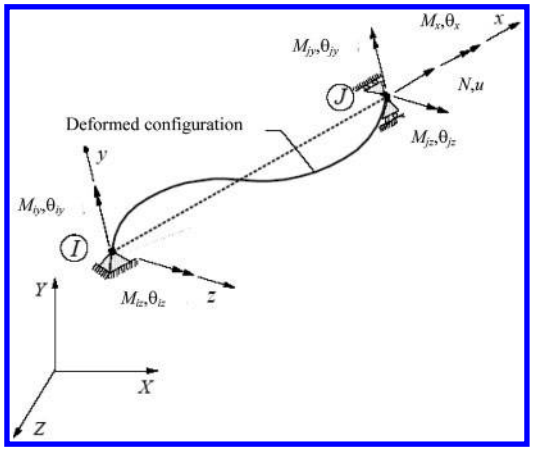

Figure 4. Beam column element with rigid body modes removed.

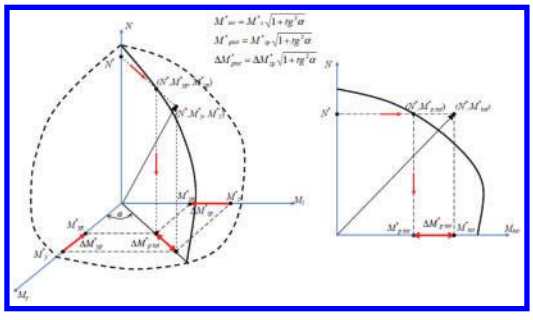

Figure 5. Interaction diagram for given bending moment's ratio. The plastic surface requirements.

as function of the nodal element forces (Chiorean 2009). If the state of forces at any cross-section along the beam column element equals or exceeds the plastic section capacity, the flexural stiffness at the respective location approaches zero. This effect is reflected in the tangent stiffness matrix coefficients given by the equations (9). Once the member forces get to the full plastic surface they are assumed to move on the plastic surface at the following loading step. Therefore, when the axial force of a member increases at the following loading step, the incremental force-displacement relationships at the element level has to be modified such that the loading result in motion along the interaction surfaces and the plastic strength surface requirement of the full plastified sections is always satisfied. Assuming that at the end of a loading step, at a cross-section, the forces violates the plastic surface, the bending moment is adjusted to be reduced, considering the member loaded by the correction bending moment ΔM_p, where ΔM_p is the change in the plastic moment capacity at the respective cross section as axial force changes (Fig. 5). The correction plastic bending moments are determined as follows. Let us consider that at the current loading step in a specified location the forces exceed the plastic surface, this means that for that loads the maximum strain in most compressed or tensioned fiber of the cross-section exceeds the assumed ultimate strain. For given value of axial force N^* the iterative procedure described in (Chiorean 2010) is applied in order to determine the ultimate bending moments (M_{yp}^*, M_{zp}^*) for a given bending moment ratio ($\tan\alpha = M_{zp}^*/M_{yp}^*$). Next the correction plastic bending moment is determined as:

$$\begin{aligned}\Delta M_{yp}^* &= M_y^* - M_{yp}^* \\ \Delta M_{zp}^* &= M_z^* - M_{zp}^*\end{aligned} \tag{12}$$

The additional incremental moments are applied as loadings on the element and are considered through equivalent nodal forces (Chiorean 2013). Since the force-point movement remains on the plastic strength surface of a member, the plastic strength surface requirement of a section is not violated by the change of member forces after the full plastic strength of cross-section is reached.

2.4 *Geometry updating and analysis algorithm*

In order to trace the equilibrium path, for proportionally and non-proportionally applied loads, the proposed model has been implemented in a simple incremental matrix structural-analysis program. In this approach the simple Euler stepping algorithm is used in conjunction with constant work-load increments. Using an updated Lagrangian formulation (UL) the nonlinear geometrical effects are considered updating the element forces and geometry configurations at each load increment. The natural deformation approach (NDA) in conjunction with the geometrical "rigid body qualified" stiffness matrix is adopted for the element force recovery and the web plane vector approach is effectively used to update the frame element coordinates (Chiorean 2009).

3 COMPUTATIONAL EXAMPLE

The Orbison's six story rigid space frame, studied previously by other researchers, has been modified and included in this verification study (Fig. 6). In order to demonstrate the effectiveness of the numerical procedure developed here, this example converts the pure steel frame to a composite frame (Iu et al. 2009). The steel beams in the frame rigidly support the concrete floor slab, and the steel columns are partially encased in the concrete (Fig. 6). The yield strength of all steel members is 250 MPa, Young's modulus is $E = 20700$ MPa and shear modulus $G = 79293$ MPa. The compressive yield stress of concrete is 16 MPa and the stress-strain curve which consists of a parabolic and linear part was used in the calculation, with crushing strain $\varepsilon_0 = 0.002$ and ultimate strain $\varepsilon_{cu} = 0.0035$. The strain softening of concrete is not taken into account ($\gamma = 0$). The frame is subjected to the combined action of gravity and lateral loads acting in

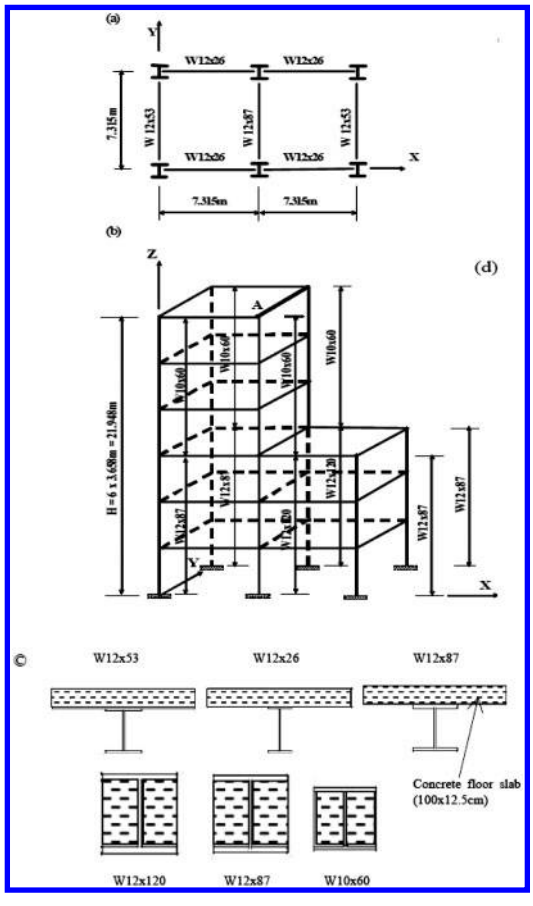

Figure 6. Orbison's six story rigid space frame.

the Y-direction. Uniform floor pressure is 9.6 kN/m^2 (simulated here as uniform distributed loads on each beam) and the wind loads are simulated by point loads of 53.376 kN in the Y direction at every beam-column joints. The inelastic behaviour represented by the load-deflections curves at node A in X and Y directions calculated by the proposed approach and those given in the literature is compared in the Figure 7. A refined plastic hinge model for composite elements was employed in (Iu et al. 2009), whereas a fiber finite element approach for pure steel elements was included in (Jiang et al 2002). Good correlation of the numerical results can be observed. However in the case of full composite frame (beams and columns) the proposed approach indicates the ultimate load factor 1.25 which is slightly higher than ultimate load factor obtained by Iu et al (1.17) (Iu et al. 2009) using a refined plastic hinge approach. Some differences can be observed also over the lateral stiffness of the frame. In the analysis of frame while considering the composite beams and columns the ultimate load factor is slightly higher than in the case of steel frame with composite beams only, in the last case the ultimate load factor resulting 1.19. As it can be seen the lateral stiffness of the frame slightly increases for full composite case (beams

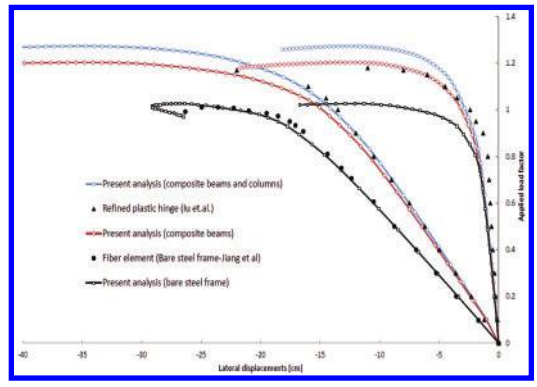

Figure 7. Load-deflection curves at node A in X and Y directions.

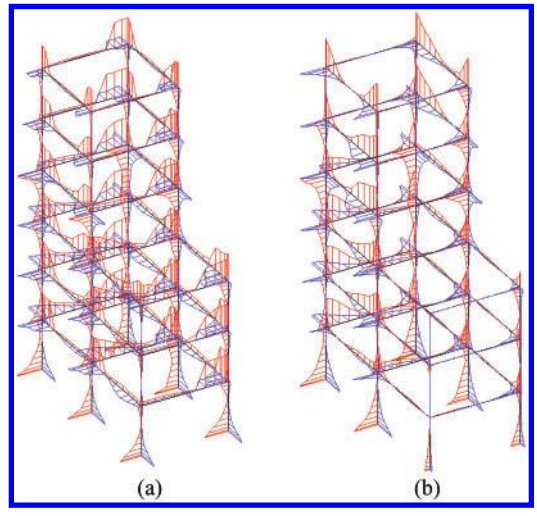

Figure 8. Tangent flexural rigidity distribution along the member's length at ultimate load factor: (a) Composite frame; (b) Pure steel frame.

and columns) as compared with the case in which the composite action is taken into account only for beams. Figure 8 shows the variation of flexural rigidities along the member lengths, at the ultimate load factor, for the pure steel frame and for the composite steel-concrete frame. It can be clearly observed the flexural stiffness degradation for beams and columns in these cases.

4 CONCLUSIONS

A reliable and robust nonlinear inelastic analysis method for composite steel-concrete space frames has been developed. The proposed model is based on the most refined type of second order inelastic analysis, the plastic zone analysis. Gradual yielding is described through basic equilibrium, compatibility and material nonlinear constitutive equations and path integral approach is applied to numerical integration of the cross-sectional nonlinear characteristics.

The proposed analysis can practically account for major factors influencing nonlinear composite steel-concrete space frame behaviour: gradual and distributed yielding associated with biaxial bending and axial force, stress-strain relationships for concrete in compression, residual stress distribution in encased steel elements, shear deformations, local and global second order effects with computational efficiency, and the necessary degree of accuracy, usually only one element per member is necessary to analyze. Lateral loads acting along the member length can be directly input into the analysis without the need to divide a member into several elements, leading to a consistency in the linear and nonlinear structural models.

The model has been implemented in a simple incremental matrix structural analysis program and allows proportionally and non-proportionally loading, and has been verified by comparing the predicted results with the established results available from the literature. The studies show that the proposed analysis compares very well to finite fibre element solution with much less computational effort. The proposed software is presented as an efficient, reliable tool ready to be implemented into design practice for advanced analysis and pushover analysis of spatial composite steel-concrete frame structures.

Square concrete filled steel hollow columns

M. Dundu
University of Johannesburg, Johannesburg, South Africa

ABSTRACT: The behaviour of 12 square concrete-filled steel tubes (CFSTs) under concentric axial compression is investigated. The hollow steel sections are 102 × 102 × 3.0 mm, 120 × 120 × 3.5mm and 150 × 150 × 3.5mm and are filled with Grade 30 concrete. For each section size, the lengths tested are 1.0 m, 1.5 m, 2.0 m and 2.5 m. These lengths provide a range of columns, from relatively short to slender composite columns. The slenderness ratio (L/b) range from 6.67 to 24.61 and the depth-to-wall thickness (b/t) range from as 33.87 to 42.86. The compressive resistance of the composite columns are compared with the design strengths predicted by the South African standard (SANS 10162-1), as well as the European design standard (Eurocode 4). The test results of the slender members are found to be at variance with the codes.

1 INTRODUCTION

It is common knowledge in composite construction that the compressive resistance, ductility, and the energy absorption of square concrete filled steel tube CFST columns is lower than that of circular CFST columns. This is caused by the little concrete confinement exhibited by the square CFST columns. In spite of this huge disadvantage over its circular counterpart, square CFST are increasingly becoming more popular columns in the construction of high-rise buildings. This situation is necessitated by the cross-sectional shape of the member, which in most cases suits the plan of the buildings. The effect of this is that the beam–column joints are easy and less expensive to construct. The large moment of inertia of the square cross-section leads to higher capacity of resisting lateral load.

Although numerous publications of square CFST are available in literature, most of the investigations were performed on short columns, which failed in local buckling and crushing of the concrete only. This investigation is carried out to determine the behaviour of square composite columns, over a wider range of cross-sectional sizes and lengths. The experimental test strengths are compared to the strengths specified by SANS 10162-1 (2005) and Eurocode 4 (2004). Eurocode 4 (2004) is abbreviated as EC4 (2004) in this paper. Note that SANS10162-1 (2005) is based on the Canadian steel code (CAN/CSA-S160-01 (2001)).

2 TESTING PROGRAMMES

2.1 *Material properties*

Steel properties were established by carrying out tensile tests on steel coupons, cut from the square hollow sections (SHS) under consideration. All coupons were machined and tested according to the guidelines provided by the British Standard, BS 18 (1987). The yield strength (f_y), ultimate strength (f_u) and elastic modulus (E_s) of the steel tubes are given in Table 1. Grade 30 MPa concrete was specified for use in the composite columns. A total number of 6 concrete cubes, 100 mm × 100 mm × 100 mm, were cast from the same mix prepared for the composite columns. After 28 days the concrete cubes were tested according to SANS 5861-1 (2006), to give the concrete results in Table 1. In order to apply EC4 (2004), the cube strength of the concrete (f_{cu}) is converted into a cylinder strength (f'_{cu}), as required by the code.

Table 1. Average tensile coupon test results

	Steel tube			Concrete		
SHS size (mm)	f_y MPa	f_u MPa	E_s GPa	f_{cu} MPa	f'_u MPa	E GPa
102 × 102 × 3.0	483.9	552.7	204.7	31.2	25.0	28.3
120 × 120 × 3.5	401.0	456.5	205.8			
150 × 150 × 3.5	405.0	481.1	203.7			

2.2 *Specimen preparation*

A total number of 12 square composite columns were prepared for testing. These columns varied in lengths and cross-sectional areas. The column lengths chosen for this investigation are 1.0 m, 1.5 m, 2.0 m and 2.5 m and the size of the square tubes are 102 × 102 × 3.0 mm, 120 × 120 × 3.5 mm and 150 × 150 × 3.5 mm. All columns were filled with grade 30 concrete. A 5 mm thick end-plate was tack-welded to the bottom of each column to contain the

concrete during casting. The concrete was placed in 5 layers and compacted with a vibrator to remove air pockets. The top part of the specimens was covered with plastic sheeting to prevent moisture from evaporating for a period of 28 days. This was done to ensure that the concrete achieves its 28-day strength. After 28 days, the plastic sheeting was removed from each column and the top surfaces were levelled with an angle grinder to ensure uniform load distribution over the top surface.

2.3 *Test set-up and procedure*

The Moog machine, with a capacity of 2500k N, was used to test the composite columns. The specimens were loaded at a rate of 2 mm/min until failure to ensure that the behaviour was carefully observed. At the bottom of each specimen, pinned end conditions were simulated by placing a steel ball between two plates with grooves at the centre. Only one groove plate was used at the top of the specimens since the head of the machine had a socket. The columns were concentrically loaded to avoid end moments. Figure 1 shows the typical test set-up.

A linear variable displacement transducer (LVDT) was used to measure axial shortenings. The Moog machine is equipped with this LVDT, which automatically measures the axial deformation as the load is applied. Strain gauges were attached at mid-height, on two opposite sides of each column, to measure circumferential surface strains. Both strain gauge and LVDT readings were recorded on a computer connected to the machine.

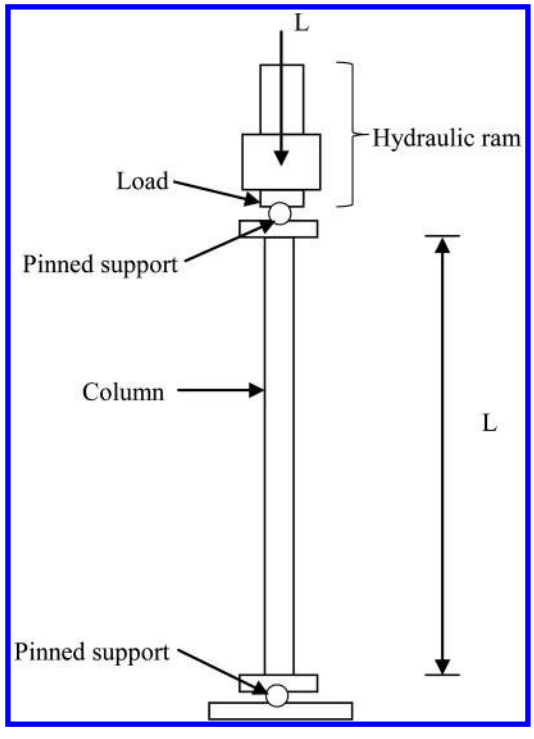

Figure 1. Schematic test setups.

3 FAILURE MODES

The general failure mode observed in the specimens was overall member buckling. All the 1.5 m to 2.5 m columns failed by overall buckling (Figure 2(b)). Overall instability was promoted by the large slenderness ratio. In addition to overall member buckling the shorter columns, typically 1 m of the larger sections ($150 \times 150 \times 3.5$), exhibited bulging (local buckling) behaviour at the centre and near the top end (Figure 2(a)). The other sections displayed local buckling away from the centre, at about a quarter of the column length from the top of the column. In both columns the concrete forced the steel tube to buckle outwards. Specimens with high b/t ratios had more local buckling or bulging compared to those with small b/t ratios. Bulging was characterised by plastic flow of concrete to fill up the sections where the steel buckled outwards.

4 ANALYSIS OF TEST RESULTS

SANS10162-1 (2005) and EC4 (2004) prescribes different limits about the compressive strength of concrete, steel yield strength and diameter-to-thickness ratio that must be used in composite columns. The limits are given in Table 2, where parameters b, L and t represent the outside width, length and thickness of the square hollow steel sections. SANS10162-1 (2005) requires the concrete strength to range from 25 MPa to 100 MPa for axially loaded CFST columns and limits the specified yield stress (f_y) of the steel to 700 MPa, to promote ductility. The characteristic concrete cylinder strength (f_{cu}) and the yield stress (f_y) of the steel ranges from 20 MPa to 50 MPa and 235 MPa to 360 MPa, respectively, in EC4 (2004). As shown in Table 1, concrete requirements satisfy both SANS10162-1 (2005) and EC4 (2004), however, the steel satisfies SANS10162-1 (2005) only, and not EC4 (2004). The slenderness ratio (L/b) of the composite column ranges from 6 to 25. This classifies the columns as intermediate to slender (Kuranovas et al (2009)), reflecting the lengths of that can be expected in practice.

The width-to-thickness ratio (b/t) of the columns ranges from 33.87 to 42.86. SANS 10162-1 (2005) and EC4 (2004) recommends that the outside width-to-thickness ratios of square hollow structural sections in compression be limited to $b/t \leq 1350/\sqrt{f_y}$ and $b/t \leq 52\sqrt{235/f_y}$, respectively (Table 2). These limits suggest that local buckling will not be the critical failure mode. A comparison of the provision from these codes shows that EC4 (2004) has more stringent requirements than SANS 10162-1 (2005).

Table 3 shows a comparison of the experimental results of square concrete-filled steel tube columns

Figure 2. Typical failure modes.

with the predicted compressive resistance calculated using SANS10162-1 (2005) and EC4 (2004). In this table N_{TEST} is the maximum applied load from the concrete filled SHS, N_{SANS} is the compressive resistance concrete filled SHS, calculated using SANS10162-1 (2005) and N_{EC4} is the compressive resistance of the concrete filled CFST, calculated using EC4 (2004). It should be noted that both codes do not consider confinement in determining the compressive resistance

Table 3. Test and predicted strengths columns

SHS size mm	L m	N_{TEST} (kN)	N_{SANS} (kN)	N_{EC4} (kN)	N_{TEST}/N_{SANS}	N_{TEST}/N_{EC4}
102 × 102 × 3.0	1.0	710.3	752.5	763.2	0.94	0.93

150 × 150 × 3.5	1.0	1447.7	1259.9	1324.7	1.15	1.09
150 × 150 × 3.5	1.5	1323.3	1245.0	1283.8	1.06	1.03
150 × 150 × 3.5	2.0	1287.0	1211.7	1235.2	1.06	1.04
150 × 150 × 3.5	2.5	1183.9	1154.4	1173.6	1.03	1.01

of square CFSTs. As expected the compressive resistance of all columns decreases with increase in length of columns (Table 3).

It can be observed from the Table 3 that the strengths predicted by SANS 10162-1 (2005) are almost the same with those predicted by EC4 (2004). The result of this is that the ratios of the test strength to the code values are also the same. Both codes overestimate the strengths of 102 × 102 × 3 square composite columns. For the 102 × 102 × 3.0 section of 1 m length, both standards overestimate the test values by an average of 6.5%. This percentage increases to 20% for a 2.5 m length of the same cross-sectional size. On average, both codes overestimated the composite column capacity of this section by 11%. All the columns in this group are much slender than the other groups, and failed by overall flexural buckling. No evidence of confinement is observed in this group. The wall of the square tube resisted the concrete pressure by plate bending, instead of the membrane-type hoop stresses (Tomii et al. (1977)).

In the case of the 120 × 120 × 3.5 section the two codes overestimated the 1 m column by 23–25%. For the same length, the codes also overestimated the 150 × 150 × 3.5 section by 9–15%. This can be interpreted to imply that the stockier sections of larger b/t ratios possess some confinement. A previous study found the corner regions in square concrete filled tubes to generate some confinement, however, the confinement quickly diminished beyond the corners and vanished completely at the center of the side walls (Zhang (1989)). Thus the confining pressure is not sufficient to overcome the effect of concrete degradation. Although the codes could not predict the strength of the 1 m column accurately enough, they were able to predict the other lengths of the 120 × 120 × 3.5 and 150 × 150 × 3.5 sections. This seems to indicate that the codes are able to predict the strength of practical sized square composite columns reasonably well.

A clear trend is also shown in Table 3; the ratio of the test strength to the predicted decreases with increase in slenderness ratio. A probably cause of this is that the confinement effect is reduced with increasing length

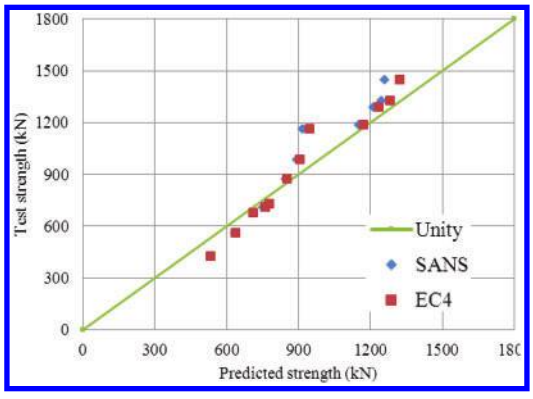

Figure 3. Test vs code predicted strength.

of the column, since the lateral deflection prior to failure increases the bending moment and reduces the mean compressive strain in the concrete. This trend means that both codes are not able to predict composite columns of different length or slenderness ratio at the same level of accuracy. Stockier test columns tend to have larger strength than slender sections.

A plot of the test strength as a function of code predicted loads is shown in Figure 3. In this figure, the points above the line are regarded as safe and those below the line are regarded as unsafe. As can be seen from the figure, all points for the $102 \times 102 \times 3.0$ are on the unsafe side. For the $120.0 \times 120.0 \times 3.5$, only the 2.5 length composite column data point is on the unsafe side. The figure also shows that the codes tend to underestimate the test strengths for the short columns.

5 LOAD-AXIAL SHORTENING

Figures 4 to 6 show the relationship between the axial load applied to the columns and the corresponding axial shortening. The graphs are linear-elastic, followed progressively by an inelastic portion, as the steel started yielding. From these graphs it can be seen that the shorter CFST columns has a higher stiffness and load carrying capacity than the longer columns. Generally, the stiffness decreases with increase in length of all columns. For constant compressive strength of the concrete, and constant thickness and yield stress of the circular hollow section, the stiffness increases with increase in the diameter of the CFST columns. As the length of the composite columns increases, the load carrying capacity decreases.

Composite columns with larger widths and steel thicknesses exhibited far much more inelasticity than the composite columns with smaller diameters and thicknesses. This is shown by a relatively flat graph at ultimate load, implying that local buckling occurred after achieving the yield strength (see Table 3 and Figure 6). The graphs also show that thicker tubes exhibited higher axial deformations just before local wall buckling. Smaller sized sections rapidly shaded

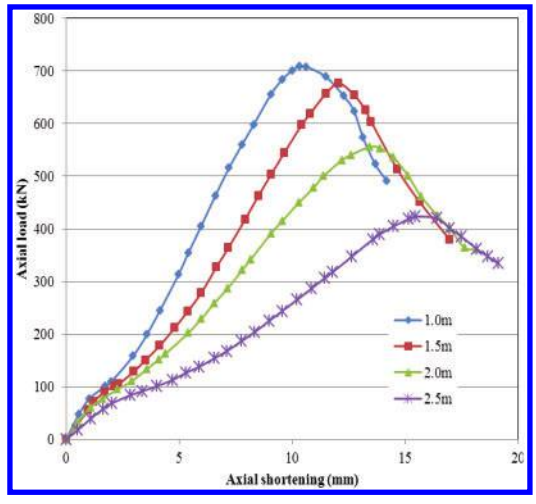

Figure 4. $102 \times 102 \times 3.0$ mm composite columns.

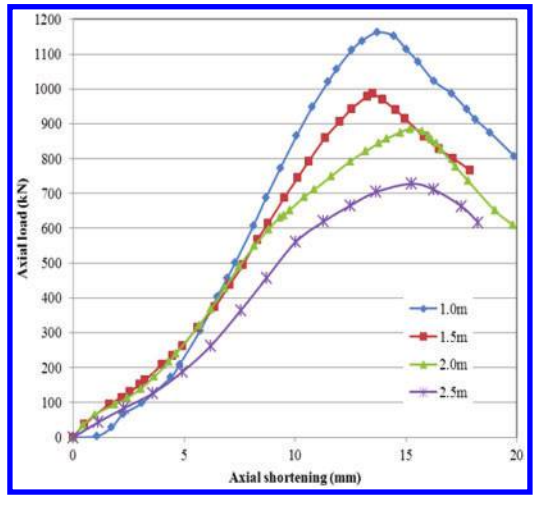

Figure 5. $120 \times 120 \times 3.5$ mm composite columns.

their load once the maximum load was attained (Figure 4 and 5). Once the composite column has reached the yield value the square tube walls fail to provide confinement of the concrete core. The load-displacement graph of the $150 \times 150 \times 3.5$ mm, 2.5 m long composite column was not included because of additional deformation of 30 mm thick end-plates initially used in the tests.

6 CONCLUSION

The failure mode observed in most specimens was overall member buckling. Overall buckling was observed in 1.5 m to 2.5 m length columns, whilst the shorter columns (typically 1 m of larger sections ($150 \times 150 \times 3.5$)) experienced both overall buckling of the member and local buckling at the centre and near the top end. Specimens with high b/t ratios had

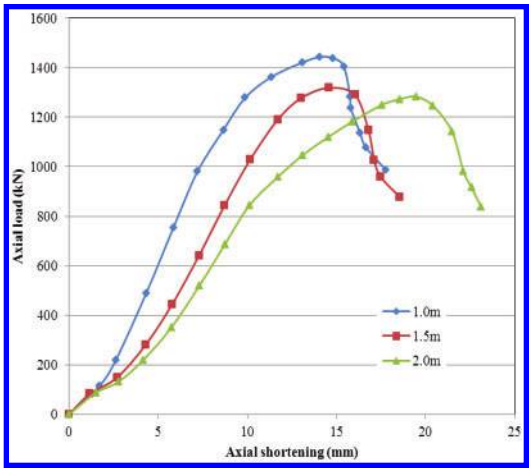

Figure 6. 150 × 150 × 3.5 mm composite columns.

more local buckling or bulging compared to those with small b/t ratios. All square concrete-filled tubes experienced a reduction in strength with an increase in slenderness ratio of the steel tube. The load-axial deflection curves showed that all specimens behaved in an inelastic manner; however, stockier sections were more inelastic than the slender sections.

Both codes overestimated the strengths of 102 × 102 × 3.0 square composite columns. On average, the codes overestimated the capacity of these composite columns by 11%. The two codes underestimated the stockier members of the 120 × 120 × 3.5 and 150 × 150 × 3.5 sections by 23–25% and 9–15%, respectively. These sections were found to possess some confinement; however, the confining pressure is not sufficient to overcome the effect of concrete degradation. The codes were able to predict the strength of 1.5 m–2.5 m of the 120 × 120 × 3.5 and 150 × 150 × 3.5 sections, implying that the codes are able to predict the strength of practical sized square composite columns reasonably well.

Transverse strains recorded at mid-heights of the specimens were very small. As a result, it was concluded that square concrete-filled steel tubes do not provide confinement of the concrete core.

ABSTRACT: The vertical loading transfer mechanism of beam-column connection with internal stiff ring in large-dimension CFT column was studied. Two specimens which prototype was from a super-high rise building were tested. A finite element model was employed to simulate the behavior of the specimens and the result showed good agreement with experimental test. By both the test and FE analysis, it indicates that shear force on beam transfers to both steel tube and core concrete of CFT column, while for the latter the main path is through internal stiff rings and vertical ribs in the joint zone. The internal stiff ring is also key element to distribute vertical loads of above floors between steel tube and core concrete. The study shows that the ring with a width of 1/10 diameter of the steel tube could meet the requirement well, rather than the previously suggested size of 1/4 tube diameter by technical handbook, and adopting the new size can save quite a lot steel in super-high rise building structure.

1 INTRODUCTION

In concrete-filled tube (CFT) member, two materials, the concrete in-filled and steel tube outside, multiply the stiffness and strength of the CFT member: the concrete not only provides the strength, but also reduces the potential risk of the local buckling for steel tube, and the steel tube confines the concrete to efficiently resist compression, bending moment, and shear. Due to the composite action between steel and concrete, CFT member has large loading capacity and other good structural performances, such as high ductility and stable energy dissipation ability. Because of its excellent static and seismic performance, CFT has been generally used as columns in buildings, especially in super-high rise building where the CFT columns are usually with large dimensions due to the requirement for huge loading capacity.

There have been lots of researches conducted for investigation of the behavior of CFT column with common dimension under axial load alone or combined both axial load and moment.[Chol, Ge, Gupta] However, few studies have been carried out to investigate the behavior of those with large dimension. CFT columns offer advantages over either pure steel or concrete members, however, the structural benefits require stress transfer between the steel and the concrete. Although bond stress transfer is not well understood, it is considered as one of important measure to meet the requirement. Aim to improve the interaction, other measures has been used, including shear connectors on the inside of the tubes such as internal stiff ring.[Han, Kang, Zhang] However, in the background project of this research the structural engineers face new challenge. The project is a super-high rise building with 88 stories and the height of 438 meters above ground. The diameter of huge CFT columns is 3 meters. The designers consider the two issues. First, in the large diameter CFT column, which countermeasure is most efficient to transfer load from steel tube to core concrete? The studs densely arranged in the inner surface of steel tube, or the internal stiff ring with vertical rib which is designed in the beam-column connection location. Second, how to set the detailed sizes of the stiffeners rationally According to the previous constructional handbook, the recommended width of internal ring should be one fourth of the steel tubes. Considering the 88 stories and 3 meter diameter, the amount of steel for the internal ring shall be a big consumption.

The research conducted by the authors includes the following contents. An experiment was conducted through two specimens. Then a finite element model is established to simulate behavior of the experimental specimen. The model is then employed to investigate the distribution of stress and strain in steel tube and core concrete. Finally, the transfer mechanism of large-dimension CFT is analyzed combining the result of experiment and numerical simulating. The objectives of this study are: (1) investigating the path of the load transferring from steel beam to the core concrete; (2) studying the loading ratio share by steel tube and core

concrete; (3) checking the rational size of internal stiff ring which is smaller than the one recommended by the existed technical handbook.

2 EXPERIMENTAL PROGRAM

2.1 *Specimen Details*

Two specimens with connections consisted of internal stiff ring were designed and tested in this experimental program.

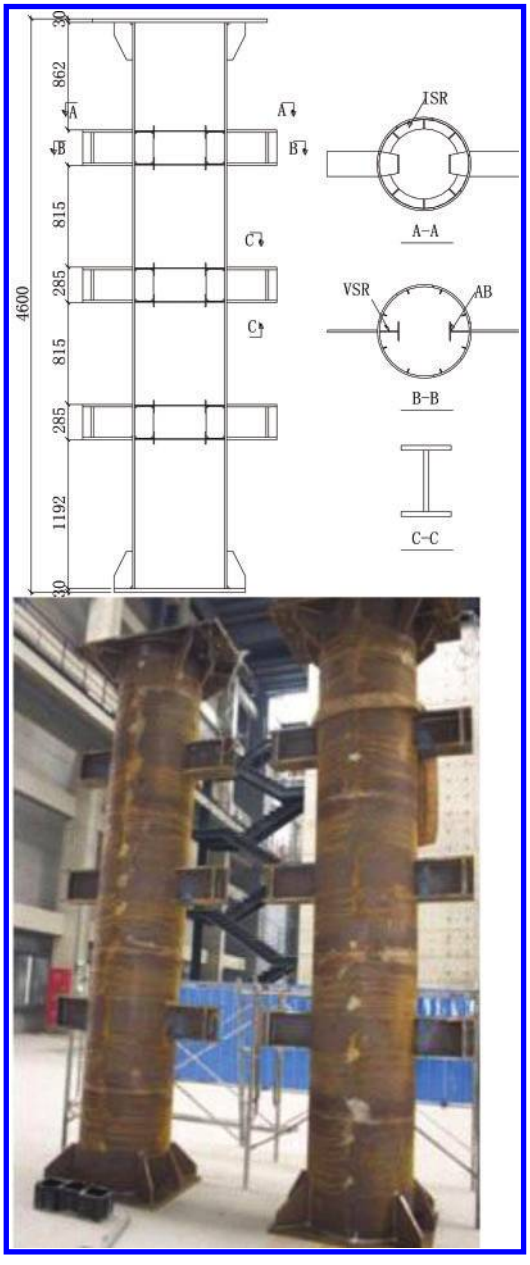

Figure 1. Overall dimension of specimen.

Due to the limit capacity of the testing rig and actuator, one-fourth scaled specimens were designed. The discreteness of the property of concrete was taken into account, so the two specimens were identical both in dimension and materials. The main body of the specimens was 4.6 meter long CFT column to which six 0.4 meter long steel I-beams were welded on both sides. Figure 1 and Table 1 show dimensions and details of the specimens. The beam-column connection of specimens consisted of internal stiff ring (ISR), vertical stiff rib (VSR) and anchorage board (AB). The width of the internal stiff ring was the main parameter, which was suggested as one-fourth of the diameter of the tube in Chinese technical handbook. However, by pre-analysis, it was found that one tenth of the tube diameter was enough for loading transferring and stiffening the joint zone. So in the test, the new size was adopted. The boards acted as an anchor to transfer horizontal force transferred from the flange of the beam.

For all specimens, steel components were fabricated first and the column was then filled and frequency vibrator was used to consolidate the concrete. The specimen was left to cure in the ambient temperature and humidity of the structures laboratory. The structural steel used in these specimens was Q345. Table 2 shows the mechanical properties of the steel in various part of the specimen. The strength of in-filled concrete was C70, and the actual strength was 68.7 N/mm^2.

2.2 *Test setup and specimen*

Figure 2 shows a photograph of the test setup with the specimen.

Table 1. Dimensions of specimen.

Item		Prototype (mm)	Specimen (mm)
Steel tube		3000×60	750×16
Joint Zone	Internal stiff ring	300×300×20	75×75×6
	Vertical stiff rib	1020×300×20	255×75×6
	Anchorage board	600×400×30	150×100×8
Steel Beam		H1100×600×18×40	H285×200×20×20
Stud		L = 120,φ19@ 300	L = 30, φ6@75
Reinforcement	Longitudinal bar	26φ20	16φ6
	Hoop	10@120	4@80

Table 2. Measured material properties.

	Yield strength (N/mm2)	Ultimate strength (N/mm2)	Elongation (%)
VSR	390	525	27.9
Steel tube	376	502	25.7
Steel beam	420	580	23.5

The bottom of the column was fixed in the shelf balanced reaction frame by eight M30 bolts. The column was subjected to a constant axial load on its top, which was provided by two 6000 kN jacks, representing the load received from above floors. Four beams were subjected to identical load by 1000 kN jack respectively, and another two beams were loaded by 1600 kN jacks. The beam loads were supposed to simulate the loads of corresponding floor in the building.

Figure 2. Test setup.

There were three loading modes programmed: (1) axial load on CFT column top alone, the column load was gradually applied until it reached the intended value; (2) only beam end loads; (3) both column and beam end loads, the column load was applied first until it reached the intended value and was kept constant during the rest of the test, then the beam loads were applied gradually until it reached the ultimate capacity of the jacks.

Figure 3 shows the layout of instruments to measure displacements and strains of the specimens. LVDT were employed at the top and bottom of the column

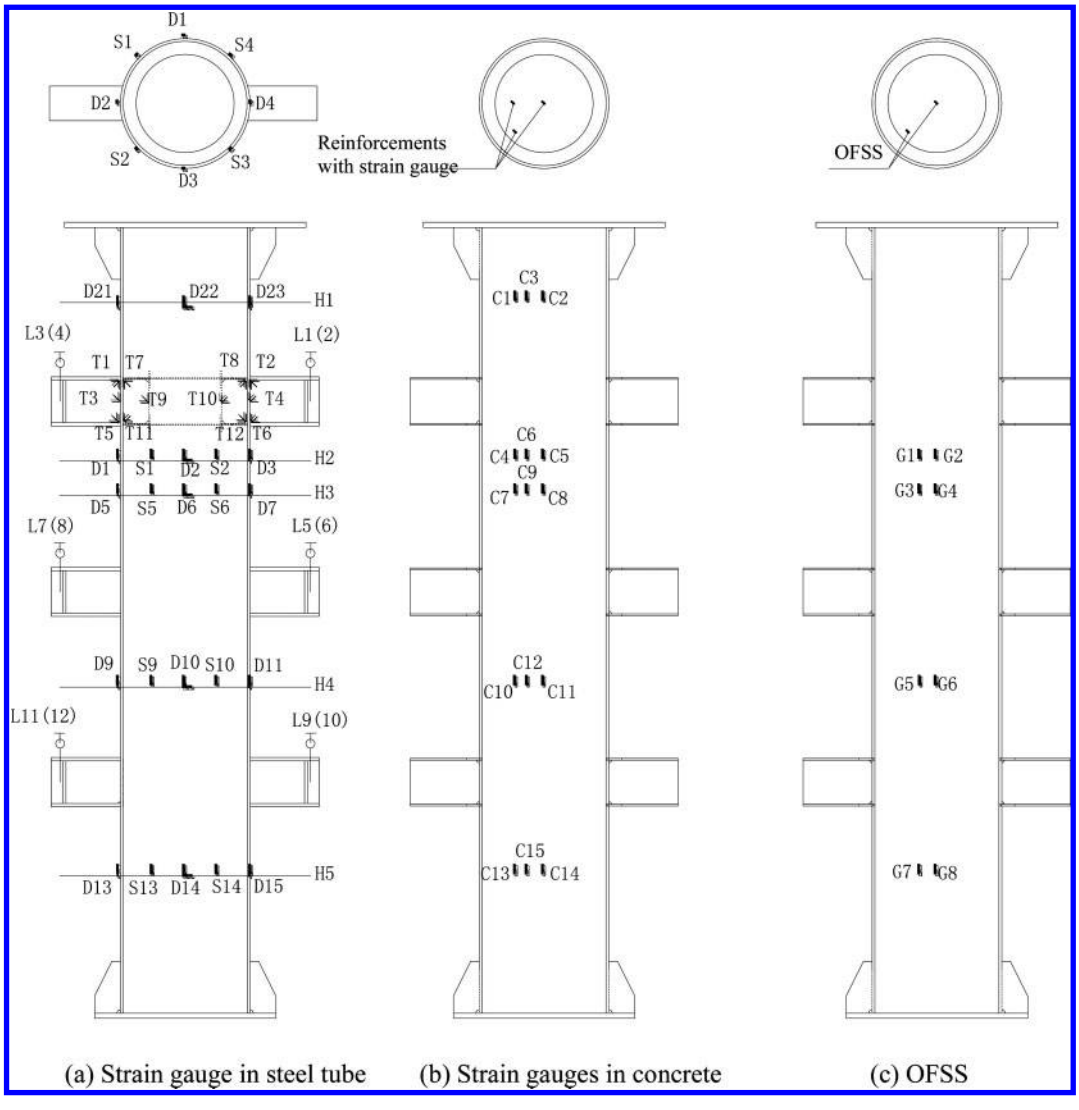

Figure 3. Location of strain gauges and displacement.

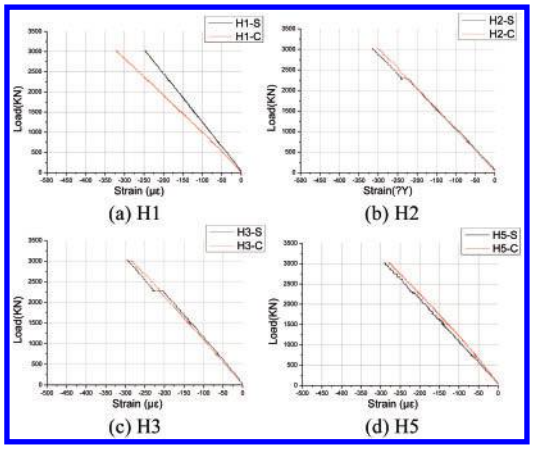

Figure 4. Load-strain curve under axial load.

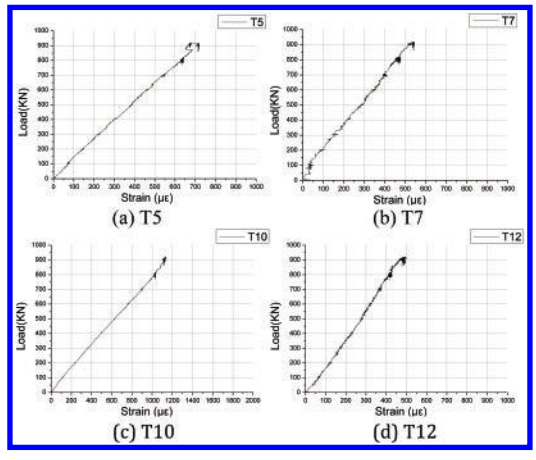

Figure 5. Load-strain curve of steel beam and rib in the case of beam load alone.

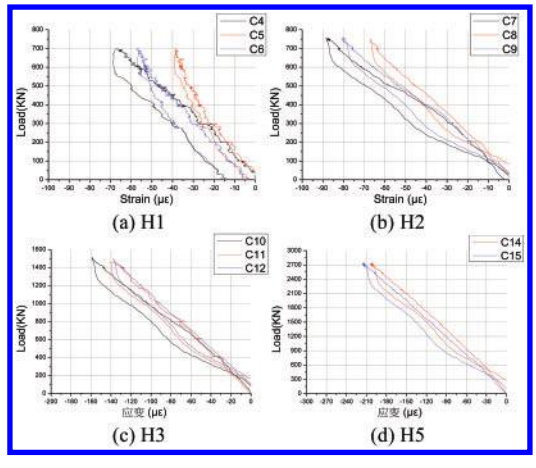

Figure 6. Load-strain curve of concrete in the case of beam load alone.

and ends of beams. Strain gauges were employed to measure the strain in the steel tube and beams. In the concrete, strain gauges were attached to steel reinforcement based on the hypothesis that the steel reinforcement and concrete have the same strain. Besides, nine optical fiber strain sensors (OFSS) were embedded into the core concrete to measure the compressive strain of concrete directly. In Figure 3, the symbol L denotes the LVDT, S, D and T denote the strain gauges with single, double and three directions respectively, C denotes the strain gauge in the concrete, and G denotes OFSS. Five sections corresponding to the location of strain gauge were denoted as H1 to H5.

2.3 *Specimen behavior*

Though there is unavoidable discreteness of concrete in-filled, no obvious difference of the specimen behavior was showed by test data and observation, so the data shown following are those from one specimen. The general behavior of the specimen is described in terms of load–displacement curve and load-strain curve.

Figure 4 shows the load-strain curves of the steel tube and the concrete in-filled in the case of axial load on column top alone. In the Figure, the strains are the average values of steel tube and concrete in the located section respectively. The linearity of the curves means that steel tube and concrete had not reached yielding strength. Except of the section H1, the curve of concrete strain almost overlaps with the one of steel strain, which implies that the existence of internal stiff ring and rib play important role in redistribution of axial load between steel tube and concrete, making the uniformity of the axial strain among the two materials. The other observation is the good agreement on strain value obtained from traditional strain gauges and OFSS.

Figure 5 shows the load-strain curves of tri-axial strain gauges arranged at the web of beam and vertical stiff rib in the case of beam load alone. The strain value is the result of the equivalent one. The value of strain in vertical stiff rib is grate larger than the one of stiff ring and near to the one of strain gauges at the corresponding position of beam web, these indicate that the beam load transfers from web of beam to steel tube then to VSR. Figure 6 shows the load-strain curve of the concrete in-filled in the same load case. It is found that the value of the strain gauge nearby ISR is generally larger than the one far away from ISR, which means the beam load sustained by concrete transfer from ISR to core concrete.

Table 3 shows the ratio of load sustained by steel tube under column top load and beam loads. The theoretical ratio is an ideal ratio based on the hypothesis that steel tube and concrete in-filled have identical strain. It seems that the steel tube shares the load a little larger than theoretical expectation in most sections expect H1. By comparing with the ratio by H1 and others in the case of column top load alone, we can see that the function of ISR in transferring axial load. Looking at the other ratios from H2 to H5, we can notice that the ratio has no big change. Thus we can deduce that the stud on the inner surface of tube contributes little to transfer the vertical load. Moving

Table 3. Ratio of load sustained by steel tube.

Section	Column Top Load	Beam Load	Theoretical Ratio
H1	31%	N/A	33%
H2	40%	40.37%	
H3	37%	34.33%	
H4	41%	30.99%	
H5	37%	38.42%	

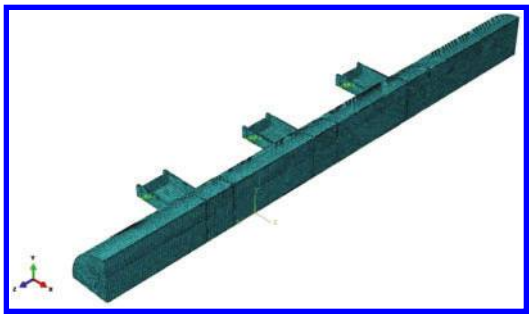

Figure 7. FEA model.

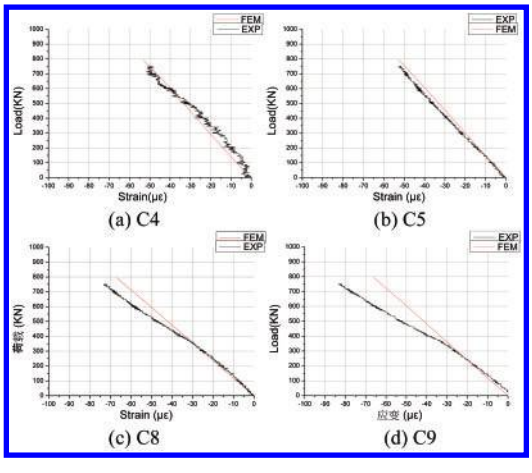

Figure 8. Comparison of strain of concrete between analysis and experiment.

to the data of beam load action, we found the identical fact.

3 NUMERICAL STUDY

3.1 *FEA model*

Numerical simulation has become an increasingly important measure to investigate the behavior of CFT column and connection. The commercial FEA package, ABAQUS, was employed in this numerical analysis. This study aimed to simulate the flexural behavior of the specimen and interaction of concrete and steel, and finally to find out the transfer mechanism of load

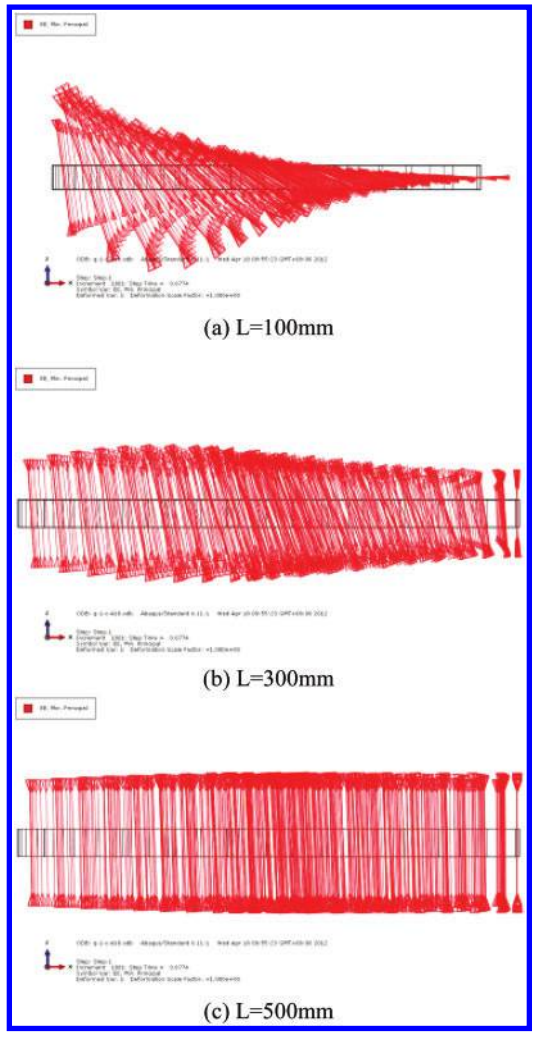

Figure 9. Distribution of strain of concrete.

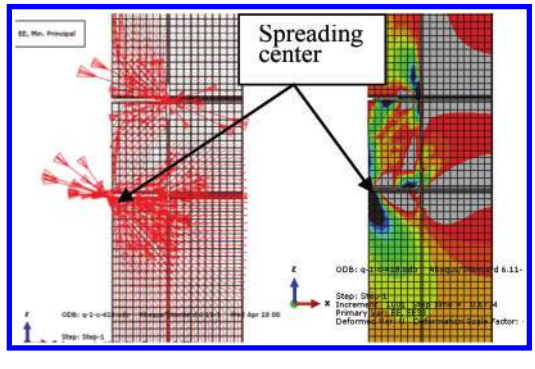

Figure 10. Spreading center.

in large-dimension CFT under column top load and beam load.

Owing to the symmetry of specimen and boundary conditions, only 1/4 of the specimen was taken

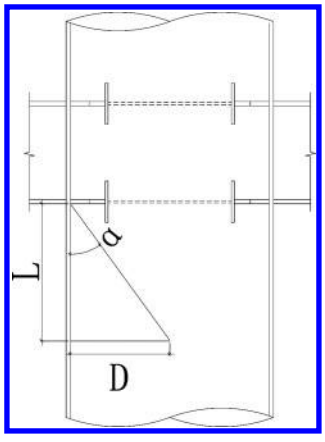

Figure 11. Diffusion angle.

with symmetric boundary conditions to establish a simulation model. The core concrete and steel tube were modeled by a reduced- integration 3D hexahedral solid element (C3D8R). The contact interaction model of ABAQUS was used to simulate the interaction of steel and concrete in CFT specimen. The model is capable of simulating the mechanical interaction of two parts at the interface. The mechanical property of the contact interaction was defined along normal and tangential respectively. The 'hard contact' relation was employed as normal mechanical property. The tangentia11 mechanical property of the contact interaction was simulated by an isotropic Coulomb friction model and the friction coefficient of 0.25 was assigned in the model. The FEA model is shown Figure 7.

3.2 *Numerical analysis results and comparison with tests*

Figure 8 shows the comparison of measured strain in core concrete and computed one. It indicates good agreement between the experimental and analytical results. Figure 9 displays the approximate distribution of axial strain of core concrete when the beam load is 1200 kN. The L represents the distance of strain section from the bottom of internal stiff ring. It is obvious that with increasing of the distance, the distribution of strain at section is more homogeneous. Strain of the section with distance of 500 mm has an almost uniform distribution. Comparing to the specimen in which transfer of load rely on bond purely, the existence of stiffeners is useful for transfer of stress.

According to Figure 10, the intersection point of ISR, VSR and steel tube is the point where the stress spreads distinguished, highlighted in the Figure 10. As is illustrated in the Figure 11, α is defined as spreading angle. D is the radius of tube and L represents the distance from bottom of ISR to uniform strain section. In the study case α is 51.3° $\alpha = \arctan(D/L)$ under the beam load.

4 CONCLUSION

The vertical load on beam mainly transfers from web of beam to steel tube, VSR and ISR and then to the concrete in-filled at last. During the transferring path from steel tube to core concrete, the main actor is the VSR and ISR, rather than studs. The existence of ISR and VSR also acts as main conductor transferring the above floor loads.

Almost uniform distribution of axial strain in core concrete can be obtained at the section with a certain distance from the bottom of ISR. In the studied case, we can set a stress spreading angle approximately equal to 51° corresponding to the vertical load transferring by beam.

The width of one tenth of ISR is enough to transfer vertical load on beam and above floors, from steel tube to core concrete. But it should be noticed that in this study, the conclusion relates to the existence of component VSR and AB. This conclusion was also withdrawn from a test where the beam end was mainly subjected moment.

Connections by adherence – a numerical analysis of preliminary push-out tests

H.J.F. Diógenes, A.L.H.C. El Debs, & M.K. El Debs
University of Sao Paulo, Sao Carlos, Brazil

ABSTRACT: The process of building or retrofitting structures is affected by the speed of construction, not only in the cost, but also due to the potential of injury that it can produce (noise, pollution, traffic problems etc.). Thus, it is wanted a construction time as short as possible, especially in the case of bridges construction. The steel-concrete composite structures satisfy these requirements since steel and concrete members can be prefabricated, and only the structural assembly needs to be performed on site. Currently, however, the steel-concrete composite connections are not well adapted for using prefabricated slabs, which reduces the construction time and improves building durability. In this way, the development of new types of connections is clearly necessary. Looking for a practical, economical and fast solution for connections in steel-concrete composite structures, connections by adherence are themselves quite promising. This paper presents a numerical analysis performed with FEM based software Diana® simulating preliminary Push-Out tests of connections by adherence. To improve the performance of the steel-concrete interface, it is proposed a mechanical treatment on the involved interfaces, associated to the use of a high performance mortar connecting the elements. The numerical results demonstrated a high approach with experimental values, mainly in terms of load capacity prevision.

1 INTRODUCTION

1.1 *Generalities*

According to the fib Model Code (2010), the use of cast *in situ* concrete is, most of the times, the cheapest solution for conventional constructions. However, the prefabrication has the advantage of providing a rapid implementation and a better quality of structural elements, among others. Aiming industrialization of construction, the combination of precast concrete and composite structures can result in a system with good quality, executed with high speed and economy.

Composite structures made by steel and concrete are perfectly adaptable to the process of prefabrication, with a building system in which the whole structure or part of it can be made outside of the construction site. The main obstacle to the use of composite structures is to provide a full interaction among the structural elements.

In this way, connections are the most important part in the project of precast concrete and composite structures, affecting the whole production process. The most common connections, the pinned ones, lead to structures subjected to higher bending moments. On the other hand, connections that tend to reproduce the behavior of monolithic concrete structures reduce some of the advantages of prefabrication, mainly the speed of construction.

The process of building or retrofitting structures is affected by the speed of construction not only in the cost, but also due to the potential injury it can produce (noise, pollution, traffic problems etc.). Therefore, it is wanted a construction time as short as possible, especially in the case of bridges construction. The steel-concrete composite structures satisfy these requirements, since steel and concrete members can be prefabricated and only the structural assembly needs to be performed on site.

Currently, however, the steel-concrete composite connections are not completely adapted for using prefabricated slabs, which reduces the construction time and improves the building durability. In this way, the development of new types of connections is clearly necessary.

Looking for practical, economical and fast solutions for connections in steel-concrete composite structures, connections by adherence are themselves quite promising.

To improve the performance of steel-concrete interface, this paper proposes a mechanical treatment at the interfaces, associated to the utilization of a high performance grout connecting these materials.

1.2 *Brief review*

The study of connections by adherence, as well as the study of composite beams using this type of connection, can be divided into two fields. The first field concerns to the study of shear interfaces, and the second is related to the possible arrangements to be used

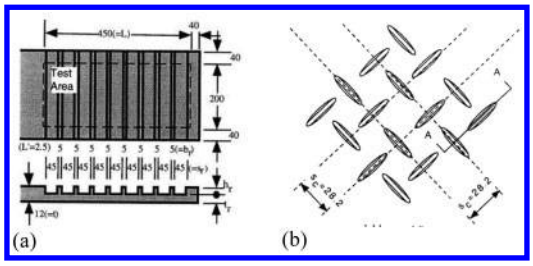

Figure 1. Grooves: (a) Parallel (ribbed plates), (b) Oblique (checkered plates).

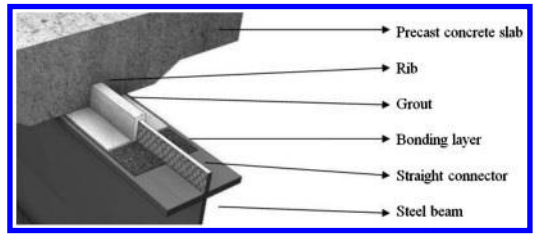

Figure 2. Connection by adherence (Thomann, 2005).

in the connection between steel beams and precast concrete slabs.

Numerous surveys have been carried out under the shear behavior of steel elements embedded in concrete, more significantly related to steel bars. Such studies are limited to a specific geometry (plain or ribbed bars) and concrete. However, some studies, although few, have sought to understand the interaction between a steel plate and cement-based materials, such as concrete and grout.

Studies related to the resistance of steel-concrete interface, when the steel surface has a roughness, are dated from the late '90s, although the idea of applying a certain roughness to the interfaces is even older. Kitoh & Sonoda (1996) studied the shear strength of the interface between concrete and a steel plate with grooves perpendicular to the direction of shear (ribbed plates – Figure 1 – (a)). Sonoda, Kitoh & Uenaka (2000) performed the same study, however for discontinuous oblique grooves, a type of surface called checkered plates (Figure 1 – (b)). Studies by Kitoh & Sonoda (1996) and Sonoda, Kitoh & Uenaka (2000) were strictly experimental, with no theoretical models being proposed for evaluating the steel-concrete interfaces proposed by the authors.

Few studies have considered the geometry of the interface as a parameter. Most researches have focused on specific geometry and materials. A more detailed understanding of shear behavior of interfaces, explicitly considering the geometry and materials (steel, concrete, mortar and a bonding layer), is therefore still quite scarce.

Thomann (2005), until then, represented the most extensive research on interface shear, considering the influence of geometry and materials. The purpose was to make a connection between steel beams and prefabricated concrete slabs to be used in steel-concrete composite bridges.

The second field is related to the development of new arrangements to connect precast concrete slabs and steel beams. Precast slabs provided with a longitudinal rib on the bottom were used to develop different connection systems. Among the most interesting researches using these systems, worth being mentioned those of Yamane et al. (1998), Shim, Lee e Chang (2001), Schmidt et al. (2004), Thomann (2005), Bouazoui et al. (2008), Hegger, Rauscher, and Gallwoszus (2010), Papastergiou (2012) and Diogenes, El Debs & El Debs (2012).

One advantage of using this type of connector is that straight connectors are characterized by the continuous transfer of forces along the interface, whereas connectors in the form of studs produce stress concentration. Straight connectors minimize stress concentration and also its consequences, such as cracking.

Since its inception, in the late 80's, the straight connectors were associated with composite connections using cast *in situ* concrete. Only from the last decade, composite connections with precast concrete have been used, producing what we now call **connections by adherence**.

This term refers to a connection based on the contact between interfaces, whose resistance is not associated to the compression of the concrete against a punctual connector. In this case, the connection is achieved through the shear between interfaces involving precast concrete slab and steel beam. The connection studied in this work was first proposed by Dauner & Antille (2002) and later studied by Thomann (2005) and Papastergiou (2012). Figure 2 shows a sketch of the mentioned connection.

By chemical or mechanical means, a certain roughening is introduced on the surface of the slab in contact with grout. After prestressing the precast slabs, grout is injected between the concrete slab and the steel beam.

Thomann (2005), as already outlined, did an extensive experimental research presenting data from push-out tests, direct shear, pull-out, and composite beams. He was able to demonstrate the viability of the new connection system, also proposing requirements for a specific geometry of grooves. It should be noted that the work of Thomann (2005) envisioned the use of this type of connection in composite bridges of concrete and steel structures, which are necessarily subject to fatigue.

Continuing the work of Thomann (2005), Papastergiou (2012) evaluated the same connection, now in terms of fatigue behavior, concluding that the connection by adherence also satisfies the limits set by the Swiss standard for fatigue behavior.

2 EXPERIMENTAL PROGRAM

This section describes the exploratory push-out samples tested by Diógenes, El Debs & El Debs (2012).

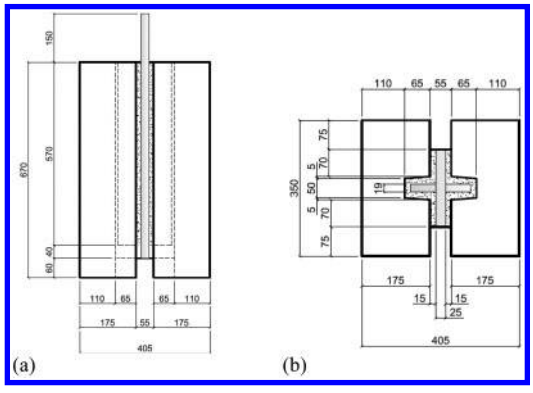

Figure 3. Dimensions of standard specimen: (a) View; (b) Cross section.

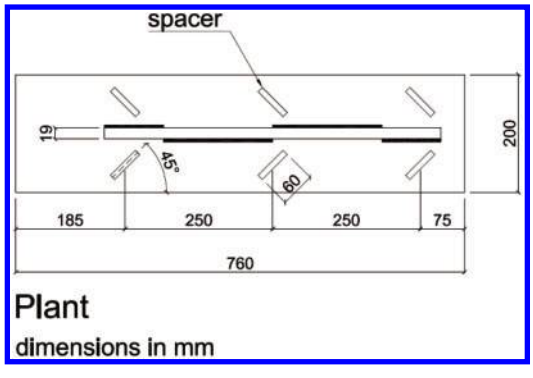

Figure 4. Standard dimensions of connectors.

2.1 *Samples description*

The tests were performed in pairs for each type of analyzed connector, totaling six specimens. At this stage of the work, only monotonic tests were performed. The trial data were the ultimate strength of the connection, the vertical displacement (slip) and the opening of the model (uplift).

The sample consisted of two blocks of plain concrete, subjected to a priming roughness of their surfaces and arranged to receive between the recesses a metallic element composed by a reaction plate and two opposing linear connectors welded in the faces. The merger between the elements was made with grouting. In all connectors, 12.5 mm bars were welded on the surface of the reaction plate, in order to serve as spacers and simulating the shear keys.

The differentiation among the connectors is a function of their surfaces. The L-type connector did not receive any type of mechanical treatment, as shown in Figure 6 – (a).

In contrast to the L connector, the R-type connector (Figure 6 – (b)) received a mechanical treatment (grooves to 45 degrees with 2 mm of depth and 10 mm of width) to improve the mechanism of transfer shear stresses.

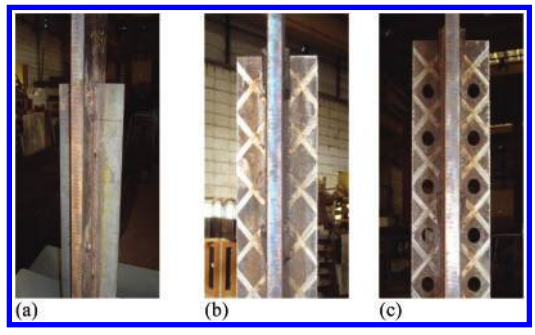

Figure 5. Connectors tested: (a) Connector L; (b) Connector R; (c) Connector RP.

Figure 6. Details of produced surface.

Besides, a variation of the R-type connector was also proposed. The RP-type connector (Figure 6 – (c)) is a composition of two others, the Perfobond proposed by Leonhardt et.al (1987) and the R connectors proposed by Thomann (2005). It is intended that the holes can generate a "dowel effect" and improve the adherence.

Once a mechanical treatment was performed on the steel surface, a roughness was designed in the concrete blocks in order to improve the transfer of forces between the interfaces, considering that, without "printing" the roughness on the concrete block, the connection failure should occur at the grout-concrete interface.

The collage of a rough blanket at the bottom of the formwork produced the printed roughness. Figure 7 shows the results produced by this procedure.

The option for a "printed" roughness was made in order to provide a greater uniformity of surface, once the use of retarders do not provide a homogeneous rough surface. The used blanket had a nominal depth of 1.2 mm.

2.2 *Materials properties*

Table 1 presents all data concerning the characterization of materials.

Table 1. Materials properties.

Model		P01	P02	P03	P04	P05	P06
Concrete	f_c	54.4	54.4	45.2	45.2	47.7	47.7
[N/mm^2]	f_{ct}	3.8	3.8	2.7	2.7	3.0	3.0
HPM	f_c	75.9	75.9	75.9	75.9	87.2	87.2
[N/mm^2]	f_{ct}	3.1	3.1	3.1	3.1	3.0	3.0
Connector		L	L	R	R	RP	RP
Steel		ASTM A-36					
[N/mm^2]		$f_y = 250$ N/mm^2 ; $f_t = 400$ N/mm^2					

The used grout admixtures were based on Vanderlei (2004), whose work was devoted to the study of Powder Reactive Concretes (PRC). PRC are basically composed of powders (quartz sand, cement common quartz powder and silica fume), small steel fibers, superplasticizer and water, where the solids are smaller than 2 mm. The PRC was manufactured under similar conditions of conventional concrete, but with very low water / cement ratio – around 0.15.

In order to obtain a mortar with compressive strength about 80 MPa, it was developed a mixture of PRC using fine quartz sand, Portland cement, superplasticizer, quartz powder and silica fume. This mortar was called high performance mortar (HPM), since the usual water/cement ratio (w/c = 0.5) was not compatible with the w/c ratio of a PRC. It is noteworthy that HPM must have sufficient fluidity and workability to permit its injection in openings about 15–20 mm wide.

3 NUMERICAL ANALYSIS

The numerical analysis reported in this work represents a preliminary numerical study of exploratory push-out tests performed by Diógenes, El Debs & El Debs (2012) and described at section 2. The analysis was performed using computational package Fx + DIANA v 9.4.4, based on finite element method.

3.1 *Finite elements adopted*

Solid elements were used to simulate steel and concrete, while surface elements modeled the steel-concrete interface.

The solid element adopted was the HX24L (Figure 8), which is an isoparametric finite element with 8-nodes and linear approximation for displacements.

Regarding the steel-concrete interface modeling, it was used the finite element Q24IF (Figure 9). This is an interface element between two planes in a three-dimensional configuration with linear interpolation.

3.2 *Hypothesis adopted*

To represent the experimental samples, it was developed a numerical model using symmetry with the presence of a single interface, which should be able to represent de structural behavior of the sample.

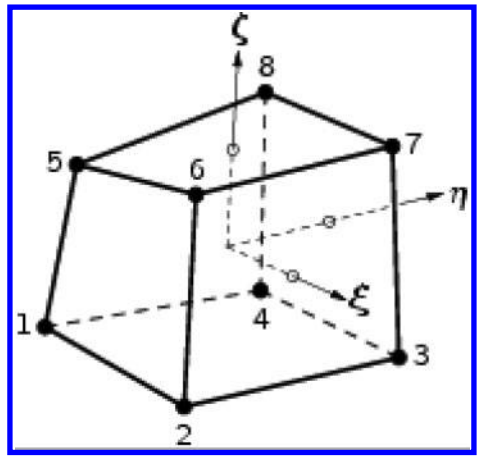

Figure 7. HX24L finite element (DIANA, 2012).

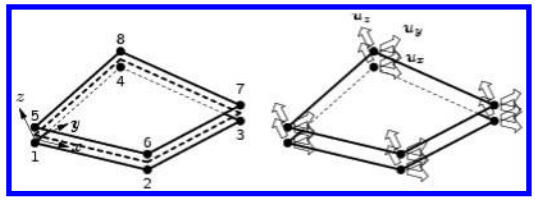

Figure 8. Q24IF finite element, typology and displacements (DIANA, 2012).

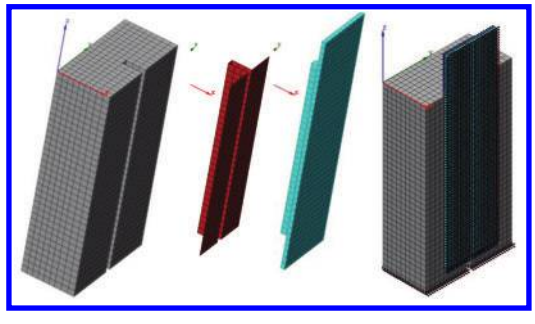

Figure 9. Numerical model overview.

So, the numerical model that represented the experimental sample did not show the region of HPM, i.e., the interface had zero thickness and the concrete block was placed directly over the connector. In Figure 10 are presented the elements of the numerical model individually.

Regarding the boundary conditions, the nodes at the bottom of the concrete block had its translation in Z restricted and the nodes of reaction plate restricted at X and Y translations in order to apply the symmetry condition.

3.3 *Materials models*

Concerning the interface behavior, a Bond-slip model was chosen. From the Bond-slip models available in DIANA, the Cubic Law was used. The Cubic law

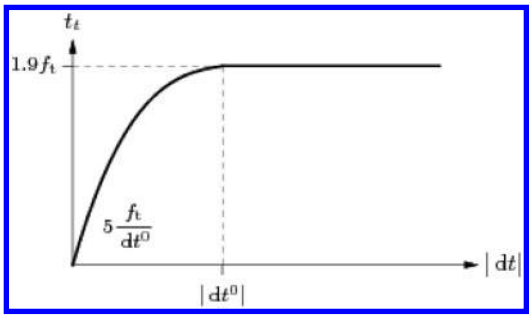

Figure 10. Bond-slip model for interface (DIANA, 2012).

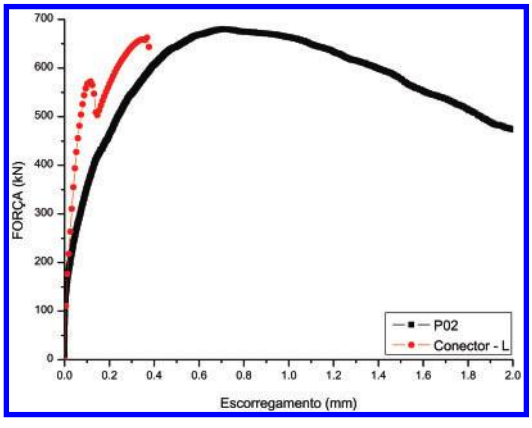

Figure 11. Numerical × Experimental result – L-type.

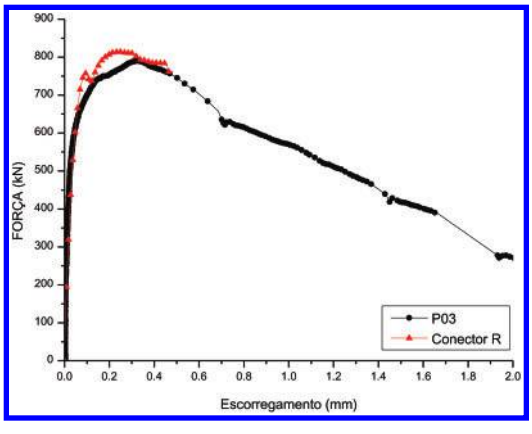

Figure 12. Numerical × Experimental result – R-type.

model represents a polynomial relation between shear traction and slip which shows a limit if the slip is larger than a certain value $\mathbf{d}_{to}$. This model requires that the tangential and normal stiffness to the interface be provided, beyond the parameters **C** and $\mathbf{d}_{to}$.

About the constitutive model for the concrete, a model based on total strain, also called 'Total Strain crack models' was used. These models describe the tensile and compressive behavior of a material with one stress-strain relationship. The tensile fracture energy was calculated according CEB Model Code 1990.

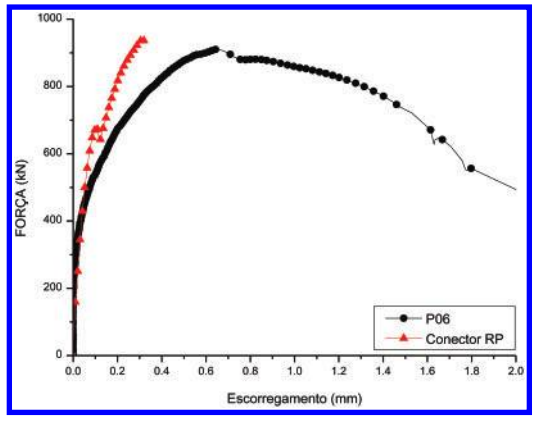

Figure 13. Numerical × Experimental result – RP-type.

Table 2. Strength – Experimental × Numerical.

	Ultimate strength		
Model	Experimental (kN)	Numerical (kN)	Difference (%)
L	680.14	658.81	+3.1
R	790.33	814.57	−3.1
RP	911.20	936.30	−2.8

Table 3. DIANA input parameters.

Parameter	**Value**

Compression curve name	PARABO
Tensile fracture energy (Gf)	CEB Model Code 1990
Compressive fracture energy	100 × Gf
Reduction due to lateral cracking	VC 1993
Shear retention function name	CONSTA
Shear retention	0.5
Interface	
Tangential Stiffness	*1 N/mm²/mm*
Normal Stiffness	10^{-4} *N/mm²/mm*
Parameters bond-slip model – **C**	0.95 (L-type); 1.1 (R-type); 1.25 (RP-type)
Parameters bond-slip model – $\mathbf{d}_{to}$	0.55 (L-type); 0.15 (R-type); 0.55 (RP-type)

To describe the steel behavior, Von Mises yield criterion was adopted.

4 RESULTS

Figures 12, 13 and 14 present de comparisons among de experimental and numerical curves obtained from the tests.

As it can be seen, the numerical model approximates the connection capacity relatively well, and in some cases also presents a reasonable approximation of slip (connector R-type). However, the numerical model is not able to reproduce the descending part of the experimental curve, which was expected, since the Bond-slip model is a failure criterion.

Table 2 presents the numerical values for the maximum strength obtained from the numerical simulation, compared to experimental values.

Finally, Table 3 shows the input values for the DIANA parameters which achieved those results.

5 CONCLUSION

The numerical model developed in this work demonstrated being adequate to describe the behavior of the connection, despite considering a single interface. However, the post peak behavior could not be obtained. It is believed that deviations of slip presented by numerical model response are due to the simplified option made.

Finally, it is worth noting that the numerical models were stiffer than the experimental prototypes, which might be corrected with the implementation of multi-linear models describing individually the various interfaces involved.

Constitutive equations for stainless steels: experimental tests and new proposal

I. Arrayago, E. Real, & E. Mirambell
Department of Construction Engineering, Universitat Politècnica de Catalunya, UPC. Barcelona, Spain

ABSTRACT: During last decades some material models to reproduce the stainless steel behaviour have been developed. Recent studies have demonstrated that some current formulations to model stress-strain curves for stainless steel, such as the formulation presented in EN 1993-1-4, do not provide good estimations for ferritic alloys so new stress-strain relationships are required. A total of 14 tensile coupon tests on ferritic (1.4016), 14 on austenitic (1.4301) and 14 on duplex (1.4462) stainless steels have been conducted in order to obtain suitable parameters for different stainless steel grades. All coupons have come from the same steel producer and will have been tested in the same machine, in order to reduce the scattering of the experimental results (Young's modulus, 0.2% proof stress, 1.0% proof stress, ultimate stress and nonlinear parameters n and m). Therefore, new analytical expressions to determine these parameters are proposed for austenitic, ferritic and duplex stainless steels.

1 INTRODUCTION

The use of stainless steel elements has been increasing in last decades in structural applications, due to its corrosion resistance and material properties. It presents an important nonlinear stress-strain behaviour that makes it different from carbon steel. This behaviour can be analytically described by different material models available in the literature, which have derived from the expression originally proposed by Ramberg & Osgood (1943) and modified by Hill (1944).

Those material models use some parameters, obtained from experimental tests, which show a great variability between different stainless steel grades and are also different from the ones proposed in Standards. Hence, it is necessary to conduct some tensile tests and collect existing experimental data in order to correctly determine these parameters.

This paper presents the tensile tests conducted in annealed austenitic (1.4301), ferritic (1.4016) and duplex (1.4462) stainless steel coupons and the later result analysis. The expressions gathered in Standards and previous works, presented by Real et al. (2012), for the determination of the different parameters are checked herein and some new analytical expressions are also proposed.

2 MATERIAL MODELS

2.1 *Existing material models*

In last decades various material models reproducing stainless steel behaviour have been developed. All these models derived from the general expression shown in (1).

$$\varepsilon = \frac{\sigma}{E_0} + 0.002\left(\frac{\sigma}{\sigma_{0.2}}\right)^n \qquad (1)$$

whereE_0 is the initial Young's modulus, $\sigma_{0.2}$, conventionally considered as the yield stress, is the proof stress corresponding to a 0.2% plastic strain and $n$represents the nonlinear parameter. This expression is not accurate enough for stresses over the yield stress, so Mirambell & Real (2000) proposed a two stage model in order to describe stainless steel behaviour for higher stresses. The second stage is described by (2) for stresses over the 0.2% proof stress with a different nonlinear parameter m.

$$\varepsilon = \frac{\sigma-\sigma_{0.2}}{E_{0.2}} + \left(\varepsilon_u - \varepsilon_{0.2} - \frac{\sigma_u-\sigma_{0.2}}{E_{0.2}}\right)\left(\frac{\sigma-\sigma_{0.2}}{\sigma_u-\sigma_{0.2}}\right)^m + \varepsilon_{0.2} \qquad (2)$$

where $E_{0.2}$ is the elastic tangent modulus at 0.2% proof stress, σ_u and $\varepsilon_u$are the ultimate stress and strain respectively and $\varepsilon_{0.2}$is the total strain at the 0.2% proof stress.

This model was revised by Rasmussen (2003), assuming that the ultimate plastic strain is equal to the total ultimate strain and proposing some simplifications shown in (3) to (6) in order to reduce the number of parameters needed to define the material model. Afterwards, Gardner (2004) proposed some modifications to have a more consistent model for compression, ending the second stage at the 1% proof stress and providing excellent predictions for both tension and compression.

However, as advanced numerical modelling techniques require a better fit of the stress-strain curve up to high strains, some three stage models have been proposed by Quach (2008) and Hradil et al. (2012). Both models use three basic Ramberg-Osgood curves but with three different reference systems for different stress ranges. A more detailled description of the evolution of the material models in the literature can be found in Real et al. (2012).

$$\frac{\sigma_{0.2}}{\sigma_u} = \begin{cases} 0.2 + 185\frac{\sigma_{0.2}}{E_0} & \text{for austenitic and duplex} \quad (3a) \\ \frac{0.2 + 185\frac{\sigma_{0.2}}{E_0}}{1 - 0.0375(n-5)} & \text{for all stainless steel alloys} \quad (3b) \end{cases}$$

2.2 *EN 1993-1-4*

EN 1993-1-4, Annex C (2006) proposal for the description of the analytical curve of the stainless steel behaviour is based on the Rasmussen material model, using some of the expressions described in Rasmussen (2003) and presented in equations (4) to (6) for the determination of the material parameters. Values for $\sigma_{0.2}$, σ_u and E_0 are proposed in Table 2.1 and section 2.1.3 in EN 1993-1-4.

$$n = \frac{\ln(20)}{\ln\left(\frac{\sigma_{0.2}}{\sigma_{0.01}}\right)} \quad (4)$$

$$m = 1 + 3.5\frac{\sigma_{0.2}}{\sigma_u} \quad (5)$$

$$\varepsilon_u = 1 - \frac{\sigma_{0.2}}{\sigma_u} \quad (6)$$

2.3 *Modification proposal for EN 1993-1-4*

Some modification proposals for the expressions (3) to (5) were presented in Real et al. (2012) after analysing some gathered experimental stress-strain curves in ferritic and austenitic stainless steels. These modifications are summarized herein.

$$n = \frac{\ln(4)}{\ln\left(\frac{\sigma_{0.2}}{\sigma_{0.05}}\right)} \quad (7)$$

$$m = 1 + 2.3\frac{\sigma_{0.2}}{\sigma_u} \quad \text{for austenitic} \quad (8a)$$

$$m = 1 + \frac{\sigma_{0.2}}{\sigma_u} \quad \text{for ferritic} \quad (8b)$$

$$\frac{\sigma_{0.2}}{\sigma_u} = 0.46 + 145\frac{\sigma_{0.2}}{E_0} \quad \text{for ferritic} \quad (9)$$

The aim of the work presented in this paper is to validate the original expressions and the new proposals with the experimental data obtained from the conducted tensile tests and to study their applicability to duplex stainless steels.

3 TENSILE COUPON TESTS

Tensile coupon tests have been conducted in order to determine the material properties of the studied stainless steel grades. These coupons were cut and mechanized from an annealed sheet by the steel producer and were tested in the longitudinal direction. A total of 42 tensile tests were conducted, 14 in austenitic grade 1.4301, 14 in ferritic grade 1.4016 and 14 in duplex grade 1.4462 (see Fig. 1). Material properties including initial Young's modulus E_0, different proof stresses ($\sigma_{0.01}$, $\sigma_{0.05}$, $\sigma_{0.2}$ and σ_u) and ultimate strains were measured.

Figure 1. Austenitic stainless steel coupons before and after testing.

Figure 2. Coupon in the testing INSTRON machine.

Tested coupons were necked in accordance with ISO 6892-1 (2009) and were 12 mm wide with a gauge length of 50 mm. The coupons were tested in an INSTRON 8805 500 kN machine (see Fig. 2), driven by strain control. The strain rate was determined according to ISO 6892-1, and the adopted strain rates were 0.1 mm/min for the initial part of the stress-strain curves up to 1% strains and increased to 2.2 mm/min in the plastic range.

Longitudinal strain was measured by a two point contact MTS extensometer, with a gauge length of 50 mm, mounted directly onto the specimen. Additionally, two linear electrical resistance strain gauges were attached to the centre part of both faces of each coupon in order to accurately determine the initial Young's modulus and verify the accuracy of the data provided by the extensometer in the initial part of the stress-strain curves. Every specimen showed a necking effect at the mid-length as it is shown in Figure 1.

Tables 1 to 3 show the most important material parameter values obtained for the conducted tests. An example of a measured experimental stress-strain curve for each of the studied stainless steel grades can be seen in Figure 3.

4 ANALYSIS OF RESULTS

The different expressions suggested in Real et al. (2012) and summarized in section 2.3 for the determination of some of the parameters needed for the analytical description of the stainless steel behaviour are checked herein, such as n, m, ε_u and σ_u. In addition, the applicability of those expressions to duplex stainless steels is also analysed.

The calculation of the initial elastic modulus E_0 is performed by a linear regression on a set of representative points. The main material parameters and the optimum nonlinear parameters (n,m) for the different material models presented before are determined by using an interactive program. A more detailed description of the program can be found in Real et al. (2012).

The nonlinear parameters are optimized in order to provide the best curve fitting between the experimental curve and the analytical models from a least square adjustment by minimizing the error between both curves. The optimization range has been defined for strains up to 1%, an adequate range for structural purposes. An error expression involving both stress and strain terms has been defined for the optimization and different data density along different strain values due to changes in test rates has been considered including different weights.

In this work nonlinear parameters n and m obtained when fitting Rasmussen material model are considered. This model needs only 3 material parameters, the stress-strain equation is the same as the one proposed in EN 1993-1-4, Annex C and exhibits good agreement with experimental results for stresses up to 1% proof stress.

4.1 *Expressions for the nonlinear parameter n*

The classical expression (4) was originally proposed for alloys with a less rounded shape than the stainless steels analysed herein so a new expression (see eq. (7)) was suggested in Real et al. (2012). The accuracy of the classical expression and the new proposed one are

checked herein. Tables 4 to 6 compare the optimized nonlinear parameter n with the ones obtained with eq. (3) and eq. (6). A better agreement for the new proposal for the three stainless steel types is shown.

4.2 *Expressions for the nonlinear parameter m*

The applicability of the original expression for the calculation of the second nonlinear parameter m (5), proposed in EN 1993-1-4 Annex C, is checked herein and those results are compared with the ones derived from (8a) and (8b) proposals. As Tables 7 to 9 show, equation (4) provides inaccurate results for all the studied grades. However, the equation (8a) proposed in Real et al. (2012) for austenitics seems a good alternative for both austenitic and duplex stainless steels. Although equation (8b) seemed to correctly predict m values for the ferritic coupons studied in Real et al. (2012), Table 8 shows that the results obtained for this study are not accurate enough but expression (8a), originally proposed for austenitic grades, provides good results.

4.3 *Expressions for the ultimate stain ε_u*

The expression for the determination of the ultimate strain ε_u proposed in EN 1993-1-4 Annex C, (6), provides accurate results for the studied austenitic and

duplex coupons, as it is shown in Table 10 for the austenitic specimens and in Table 12 for the duplex ones. However, this equation was not calibrated for ferritic stainless steels and as these show a stress-strain behaviour with a considerably lower ductility than austenitic and duplex grades, (6) provides inaccurate predictions of ε_u for ferritic stainless steels (see Table 11). Consequently, a new expression for the determination of the ultimate strain for ferritics, described by (10) and providing more accurate results, is suggested.

$$\varepsilon_u = 1 - 1.35\frac{\sigma_{0.2}}{\sigma_u} \qquad \textit{for ferritic} \qquad (10)$$

4.4 *Expressions for the ultimate strength σ_u*

Comparing the ultimate strength values obtained in the tensile tests with the ones predicted by the original expressions and the new proposals, different conclusions can be drawn. Table 10 shows that the original expression (3a) suggested in Rasmussen (2003) provides accurate ultimate strength predictions for austenitic stainless steels.

The original expressions for ferritic stainless steels (3b), and duplex (3a), do not correctly predict σ_u values so some new equations need to be proposed. A new proposal was suggested in Real et al. (2012), described by (9), for ferritic grades and this expression also provides good predictions for the coupons tested in this study, as it is shown in Table 11.

However, as duplex coupons were not studied in Real et al. (2012), no equation was given for these grades so a new proposal, described by (11), is suggested. Results obtained with this new equation can be seen in Table 12.

$$\frac{\sigma_{0.2}}{\sigma_u} = 0.76 + 0.0023\frac{\sigma_{0.2}}{E_0} \qquad \textit{for duplex} \qquad (11)$$

A summary of the expressions that more accurately predict the studied material parameters is presented in Table 13.

5 CONCLUSIONS

This paper presents and analyses the results of tensile tests conducted in annealed coupons on austenitic, ferritic and duplex stainless steels in order to more accurately characterize their main material parameters. The optimum nonlinear parameters n and m that better fit experimental data for Rasmussen material model, proposed in EN 1993-1-4, have been obtained.

The applicability and accuracy of some expressions proposed in EN 1993-1-4 for the determination of the material parameters and some modifications and new proposals have been checked herein. The accuracy of the most of the expressions has been confirmed with the conducted tensile tests and some new proposals have been suggested when needed.

These new proposals have been obtained from a limited number of test data, so further research needs to be done in order to adjust those proposals and extend their applicability to cold-formed stainless steel.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the Ministerio de Ciencia e Innovación (Spain) under the Project BIA 2012-36373. The first author also wants to knowledge the financial support given by UPC. The authors also want to thank Acerinox for providing the coupons and Francisco Gonzalez for his collaboration during the tests.

Direct strength method and continuous strength method for cold-formed lean duplex stainless steel columns

Y. Huang & B. Young
Department of Civil Engineering, The University of Hong Kong, Hong Kong, China

ABSTRACT: The direct strength method and continuous strength method are gaining increasing acceptance in design of stainless steel columns. This study investigates the applicability of these design methods for cold-formed lean duplex stainless steel columns, which is a relatively new high strength material with low nickel content. Available data were collected and compared with design strengths calculated from the direct strength method for stainless steel and carbon steel columns as well as the continuous strength method. It is shown that these design methods are generally conservative to predict the column strengths. The direct strength method for stainless steel using tangent modulus approach to determine the column buckling strength provides accurate predictions, but this method involves iterative process in the calculation. Modified direct strength method for stainless steel using explicit strength method to determine the column buckling strength is proposed in this paper. It is shown that the modified direct strength method is capable of predicting the column strengths accurately with a relatively simple calculation procedure.

1 INTRODUCTION

Cold-formed stainless steel structures have been increasingly used, due to its structural and architectural advantages. However, the high cost of stainless steel material restricts its application in construction projects. In recent years, a relatively new type of lean duplex stainless steel of grade EN 1.4162 with high strength and low nickel content has been developed. The structural and economical advantages of lean duplex stainless steel offer great potential for the use of its material by structural engineers and architects. Previous researches on the design of column members mainly focused on austenitic stainless steel grades EN 1.4301 (AISI 304) and EN 1.4401 (AISI 316) as well as duplex stainless steel grade EN 1.4462. However, investigation on columns of lean duplex stainless steel is limited. A series of stub and pin-ended column tests as well as a wide range of parametric study using finite element analysis (FEA) on lean duplex stainless steel square hollow section (SHS) and rectangular hollow section (RHS) were conducted by Huang & Young (2012a,b, 2013). It was found that the existing design specifications are generally conservative for columns. Design rules for compression members in the Australian/New Zealand Standard (AS/NZS 2001) and European Code (EC3 2006) as well as direct strength method (DSM) for carbon steel were modified. It is shown that the modified design rules generally provide more accurate and less scatter predictions. In addition, Huang & Young (2013) also proposed a new design approach for lean duplex stainless steel columns using stub column properties and full cross-sectional area. Experimental and numerical investigations on stub columns and pin-ended columns of lean duplex stainless steel SHS and RHS columns were carried out by Theofanous & Gardner (2009). It is suggested that the class 3 limit ($c/t\varepsilon$) be relaxed from 30.7 to 37.0, and a new effective width equation has been proposed.

Generally, current design specifications require calculation of effective width, which is not easy to calculate for section with complicated shape. Therefore, the DSM and continuous strength method (CSM) that use full area instead of effective area are gaining increasing acceptance in design. The DSM for carbon steel columns has been developed by Schafer (2002) and included in the North American Specification and the Australian/New Zealand Standard. The DSM for stainless steel columns has been proposed by Becque et al. (2008). The CSM for stainless steel stub column strengths, which uses cross-section deformation capacity and utilizes the strain hardening in stainless steel has been developed by Afshan & Gardner (2012).

The objective of this study is to assess the suitability of DSM and CSM in predicting the cold-formed lean duplex stainless steel columns. A total of 259 available column strengths were compared with design strengths calculated by the DSM for stainless steel (Becque et al. 2008), DSM for carbon steel (AISI 2007) and CSM for stainless steel (Afshan & Gardner 2012). The suitability of each design rule is discussed, based on which modification of DSM for stainless steel columns is proposed. The available column strengths are compared with design strengths obtained by the modified

DSM. It is shown that the modified DSM is able to provide more accurate and less scattered predictions with relatively simple calculation procedure comparing to the other design rules, and thus is recommended to be used in designing lean duplex stainless steel columns.

2 EXISTING DESIGN RULES & COMPARISON WITH COLUMN STRENGTHS

2.1 *General*

The suitability of existing DSM and CSM to lean duplex stainless steel columns are assessed by comparing the available column strengths with the design values. A large data pool of 259 lean duplex stainless steel pin-ended and fixed-ended columns that obtained from previous researches is used. Table 1 summarises the available experimental and numerical data on lean duplex stainless steel column strengths. The pin-ended columns included short and long columns, whereas the fixed-ended columns only consisted of stub columns. Reliability analysis was performed on the existing design rules.

The unfactored design strengths (nominal strength) were calculated using various design rules described in this paper. It should be noted that the lean duplex stainless steel is not covered in the existing design specifications and the DSM. The comparison of the column strengths with the design strengths is shown in Tables 2–3. The reliability of the column design rules is evaluated using reliability analysis, as detailed in the Commentary of the ASCE Specifications (ASCE 2002). The design rules are considered to be reliable if the reliability index (β_0) is greater than 2.5. For the purpose of direct comparison, a constant resistant factor (ϕ_1) of 0.85 and a load combination of 1.2DL+1.6LL as specified in the American Specifications (ASCE 2002) were used to calculate the reliability index (β_1). The calculation procedure for the reliability index in this study is identical to that in Huang and Young (2012b). The mean value (P_m), coefficient of variation (COV) of tests and FEA to design predictions load ratio (V_P), resistance factors (ϕ_0 and ϕ_1) and reliability indices (β_0 and β_1) are shown in Tables 2–3.

2.2 *Direct strength method for stainless steel*

The direct strength method (DSM) for stainless steel (Becque et al. 2008) was used to calculate the design strengths of lean duplex stainless steel columns in this study. It should be noted that all of the available 259 data are consisted of RHS and SHS, where distortional buckling will not occur. Therefore, the determination of distortion buckling is not considered in this study. The critical column elastic local buckling stress (f_{ol}) of the cross-section was obtained from a rational elastic finite strip buckling analysis (Papangelis & Hancock 1995) with a 5 mm half-wave length interval.

There are three different approaches to calculate the column design strengths using DSM for stainless steel (Becque et al. 2008), where the overall buckling strength (N_{ce}) is determined from (i) the explicit strength method in AS/NZS (1st approach),

(ii) the tangent modulus approach (2nd approach) and (iii) European Code (3rd approach). In the DSM, the column design strengths were determined by the minimum of the overall buckling strength (N_{ce}) and local buckling strength (N_{cl}).

For the explicit strength method (1st approach), Eqs (1) – (3) proposed by Becque et al. (2008) were used to calculate the member capacity for local buckling (N_{cl}), which is the column design strength, where A is the full section area. Determination of parameters (α, β, λ_0, λ_1) is required in this approach. It should be noted that the lean duplex stainless steel is not covered in the current AS/NZS (2001). In calculating the column design strengths, three different ways were used to obtain the parameters (α, β, λ_0, λ_1), such as (i) the existing parameters for S31803 (duplex) in AS/NZS, (ii) equations proposed by Rasmussen & Rondal (1997) and (iii) modified parameters for lean duplex stainless steel proposed by Huang & Young (2012b). The column design strengths calculated by these three ways are represented by $N_{DSM,explicit}$, $N^{*}_{DSM,explicit}$ *and* $N^{\wedge}_{DSM,explicit}$, respectively, as show in Table 2. Comparison of the available column strengths with $N_{DSM,explicit}$ is shown in Table 2 and Fig. 1. The direct strength method for stainless steel using explicit strength method (1st approach) is conservative. The mean value of the column strengths (N_u) over the design strengths ($N_{DSM,explicit}$) ratio is equal to 1.19 with the COV equals to 0.107, and the reliability indices (β_o and β_1) equal to 2.86 and 3.27, which are higher than the target value of 2.5. However, the design rules, when the parameters (α, β, λ_0, λ_1) are determined from the equations proposed by Rasmussen & Rondal (1997) and using the modified parameters for lean duplex stainless steel (Huang & Young 2012b), are less conservative. The mean values of $N_u/N^{*}_{DSM,explicit}$ and $N_u/N^{\wedge}_{DSM,explicit}$ equal to 1.13 and 1.13, with COV of 0.105 and 0.095, and the reliability index (β_o) equal to 2.67 and 2.71, respectively.

$$N_{cl} = \begin{cases} N_{ce} & \text{for } \lambda_l \le 0.474 \\ \left(\dfrac{0.95}{\lambda_l^{0.8}} - \dfrac{0.22}{\lambda_l^{1.6}}\right) N_{ce} & \text{for } \lambda_l > 0.474 \end{cases} \quad (1)$$

where

$$\lambda_l = \sqrt{\frac{N_{ce}}{N_{ol}}} \quad (2)$$

$$N_{ol} = Af_{ol} \quad (3)$$

Eq. (4) proposed by Becque et al. (2008) was used when N_{ce} is determined from the tangent modulus approach (2nd approach), and design strength is represented by $N_{DSM,tangent}$ in this study, as shown in Table 3. Comparison of available column strengths with $N_{DSM,tangent}$ is shown in Table 3 and Fig. 2. The direct strength method for stainless steel using tangent modulus approach (2nd approach) provides a less conservative yet more scattered predictions comparing with the DSM for stainless steel using explicit strength method (1st approach). The mean value of the available column strengths (N_u) over the design strengths ($N_{DSM,tangent}$) ratio is equal to 1.06 with the COV equals

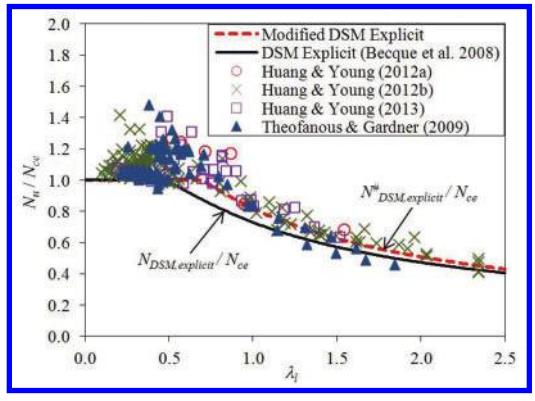

Figure 1. Comparison of column strengths with design strengths by existing and modified DSM using explicit strength method.

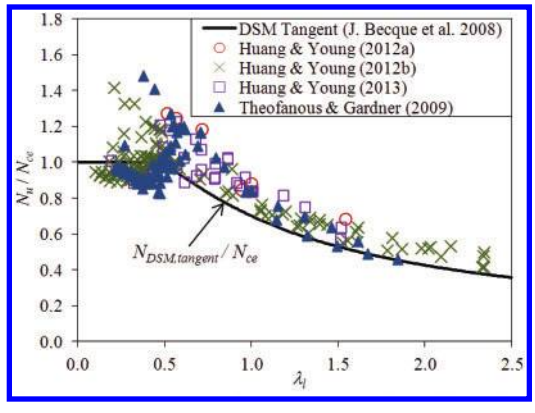

Figure 2. Comparison of column strengths with design strengths by DSM using tangent modulus approach.

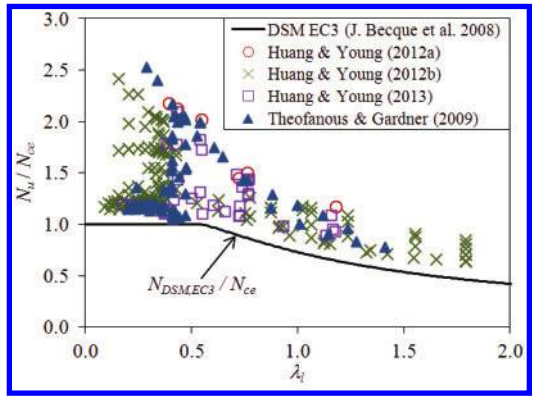

Figure 3. Comparison of column strengths with design strengths by DSM where the overall buckling strength was calculated in according to European Code.

to 0.130, as shown in Table 3. The reliability index (β_o) equal to 2.33, which is smaller than the target value 2.5. However, the method is considered reliable when the resistance factor (ϕ_1) of 0.85 is used, and the reliability index (β_1) is equal to 2.72.

$$N_{cl} = \begin{cases} N_{ce} & \text{for } \lambda_l \le 0.463 \\ \left(\frac{0.9}{\lambda_l^{0.9}} - \frac{0.2}{\lambda_l^{1.8}}\right) N_{ce} & \text{for } \lambda_l > 0.463 \end{cases} \quad (4)$$

Eq. (5) proposed by Becque et al. (2008) was used when N_{ce} is determined from European Code (3rd approach), and the design strength is represented by $N_{DSM,EC3}$, as shown in Table 3. Comparison of available column strengths with $N_{DSM,EC3}$ is shown in Table 3 and Fig. 3. The direct strength method for stainless steel using the European Code to determine the overall buckling strength (N_{ce}) provides quite conservative and scattered predictions comparing with the DSM for stainless steel using the other two approaches, especially for members with slenderness $\lambda_l \le 0.55$, as shown in Fig. 3. The mean value of the available column strengths (N_u) over the design strengths ($N_{DSM,EC3}$) ratio is equal to 1.46 with the COV equals to 0.214. The reliability indices (β_o and β_1) equal to 2.96 and 3.29, which are higher than the target value of 2.5.

$$N_{cl} = \begin{cases} N_{ce} & \text{for } \lambda_l \le 0.55 \\ \left(\frac{0.95}{\lambda_l} - \frac{0.22}{\lambda_l^2}\right) N_{ce} & \text{for } \lambda_l > 0.55 \end{cases} \quad (5)$$

2.3 *Direct strength method for carbon steel*

The direct strength method (DSM) for carbon steel was developed by Schafer (2002), and the DSM is shown in clause 1.2.1.1 of Appendix 1 in the AISI S100 Specification (AISI 2007) for the design of cold-formed carbon steel structural members. According to clause 1.2.1.1, the nominal member capacity in compression shall be the minimum of the nominal member capacity of a member in compression for flexural, torsional or flexural-torsional buckling (N_{ne}) and member in compression for local buckling (N_{nl}), as shown in Eqs. (6) and (7), respectively, where N_y is the nominal yield capacity of the member in compression, λ_c is the non-dimensional slenderness for N_{ne}, λ_l is the non-dimensional slenderness for N_{nl}, and N_{crl} is the critical column elastic local buckling load. Similar to the direct strength method for stainless steel, the determination of distortion buckling is not considered as distortional buckling will not occur for the RHS and SHS in this study. The design strength is represented by $N_{DSM,AISI}$, as shown in Table 3 and Fig. 4.

It is observed from Table 3 and Fig. 4 that the direct strength method for carbon steel provides conservative and scattered predictions for lean duplex stainless steel columns, especially for members with slenderness $\lambda_l \le 0.776$. The results are expected as the current direct strength method was developed based on cold-formed carbon steel members instead of stainless steel members. The mean value of $N_u/N_{DSM,AISI}$ equals to 1.25 with COV of 0.233. The current DSM for carbon steel is considered to be reliable, as the reliability indices (β_0 and β_1) of 2.69 are greater than the target value 2.5.

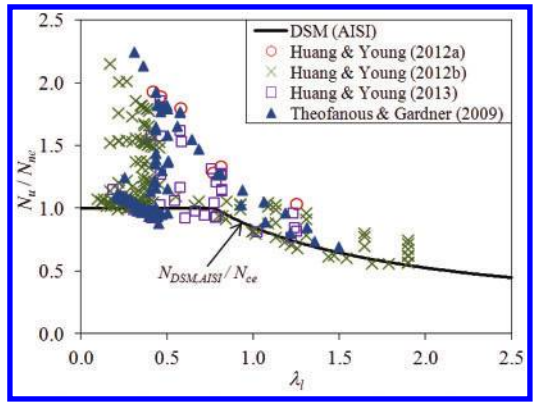

Figure 4. Comparison of column strengths with design strengths by DSM for carbon steel.

$$N_{ne} = \begin{cases} \left(0.658^{\lambda_c^2}\right) N_y & \text{for } \lambda_c \le 1.5 \\ \left(\frac{0.877}{\lambda_c^2}\right) N_y & \text{for } \lambda_c > 1.5 \end{cases} \quad (6)$$

$$N_{nl} = \begin{cases} N_{ne} & \text{for } \lambda_l \le 0.776 \\ \left[1 - 0.15\left(\frac{N_{crl}}{N_{ne}}\right)^{0.4}\right]\left(\frac{N_{crl}}{N_{ne}}\right)^{0.4} N_{ne} & \text{for } \lambda_l > 0.776 \end{cases} \quad (7)$$

2.4 *Continuous strength method for stainless steel*

The continuous strength method (CSM) (Afshan & Gardner 2012) that utilize the strain hardening of stainless steel is assessed by 39 available lean duplex stainless steel stub columns in this study. It should be noted that 10 specimens fall beyond the limit of applicability of the CSM (i.e. $\bar{\lambda}_p \le 0.68$), thus only 29 column strengths are compared with the design predictions, as shown in Table 3. The design strength is represented by N_{CSM} in this study, as shown in Table 3. The ultimate strength (f_u) and strain at ultimate strength (ε_u) are required in the calculation of design strengths.

The CSM for stainless steel is capable of predicting the stub column strengths of lean duplex stainless steel with the mean value of the available column strengths (N_u) over the design strengths (N_{CSM}) ratio equal to 1.10 and COV of 0.066. The design rule is considered to be reliable with the reliability indices (β_o and β_1) equal to 2.67 and 3.10, which are higher than the target value. Considering the relatively simple calculation procedure as well as accurate and reliable predictions, it is recommended that CSM be used for cold-formed lean duplex stainless steel sectional capacities.

3 MODIFIED DSM & COMPARISON WITH COLUMN STRENGTHS

Among various DSM discussed earlier, the DSM for stainless steel using tangent modulus approach ($N_{DSM,tangent}$) provides the most accurate predictions to lean duplex stainless steel columns, but the calculation is tedious due to the iterative process when compared to the other design rules. The DSM for stainless steel using explicit strength method (1st approach) with the existing parameters in AS/NZS ($N_{DSM,explicit}$), the DSM when N_{ce} is determined from European Code (3^{rd} approach), and the DSM for carbon steel base on AISI ($N_{DSM,AISI}$) provide quite conservative predictions. The DSM using explicit strength method with parameters obtained from equations proposed by Rasmussen & Rondal (1997) ($N^{*}_{DSM,explicit}$), and modified parameters for lean duplex stainless steel proposed by Huang & Young (2012b) ($N^{\wedge}_{DSM,explicit}$) are relatively less conservative than the aforementioned design rules.

The existing DSM are either conservative or tedious in the calculation process, therefore, modification to the DSM for stainless steel using explicit strength method (1^{st} approach) is proposed. It is suggested that the Eq. (1) to be modified to Eq. (8) as follows,

$$N_{cl} = \begin{cases} N_{ce} & \text{for } \lambda_l \le 0.7 \\ \left(\dfrac{0.96}{\lambda_l^{0.82}} - \dfrac{0.14}{\lambda_l^{2}}\right) N_{ce} & \text{for } \lambda_l > 0.7 \end{cases} \quad (8)$$

The N_{ce} is calculated using the explicit strength method and modified parameters for lean duplex stainless steel proposed by Huang & Young (2012b). The design strength determined from the modified DSM base on explicit strength method is represented by $N^{\#}_{DSM,explicit}$ in this study, as shown in Table 2.

The comparison results with the available column strengths are shown in Table 2 and Fig. 1. The mean value of $N_u/N^{\#}_{DSM,explicit}$ equals to 1.09 with COV of 0.090. It is shown that the modified DSM base on explicit strength method provides a more accurate and less scatter predictions than the existing DSM for stainless steel. For example, the mean value of $N_u/N_{DSM,explicit}$ equals to 1.19 with COV of 0.107. The modified DSM is reliable, where the reliability indices (β_o and β_1) equal to 2.58 and 3.00, which are greater than the target value of 2.5. The calculation procedure of the modified DSM for stainless steel is simple, since the iterative process and calculation of effective width are not required.

4 CONCLUSIONS

A total of 259 lean duplex stainless steel column strengths available in the literature were used to compare with the design strengths obtained from the direct strength method for stainless steel (Becque et al. 2008), direct strength method for carbon steel (AISI 2007) and continuous strength method (Afshan & Gardner 2012). It is shown that the design strengths calculated from the DSM for stainless steel using explicit strength method, the DSM for stainless steel when the overall buckling strength is determined from European Code, and the DSM for carbon steel are quite conservative in predicting the cold-formed lean duplex stainless steel column strengths. The DSM for stainless steel using tangent modulus approach is capable of providing accurate predictions, but the calculation is tedious due to the iterative process. The continuous strength method is able to provide good predictions to lean duplex stainless steel stub columns in this study, and the calculation procedure is relatively simple.

Modified DSM for stainless steel base on explicit strength method with modified parameters by Huang & Young (2012b) is proposed in this study. The modified DSM is proven to provide more accurate and less scatter predictions for cold-formed lean duplex stainless steel columns. Considering the accuracy, reliability and the simplicity of calculation, it is recommended that the modified DSM and the CSM be used in designing cold-formed lean duplex stainless steel members and sectional capacities, respectively. The modified DSM proposed in this study is capable of producing reliable limit state designs when calibrated with a resistance factor of 0.9.

ACKNOWLEDGEMENT

N. Silvestre
Department of Civil Engineering, ICIST/IST, TU Lisbon, Lisboa, Portugal

ABSTRACT: The behaviour and ultimate strength of lean duplex stainless steel plate girders under bending are studied in this paper. Lean duplex stainless steel I-section plate girders (LDIPGs) with stocky flanges and slender unstiffened webs are prone to several buckling phenomena (local, lateral-torsional) and, in particular, to Lateral-Distortional buckling (LD). Firstly, shell Finite Element (FE) models are validated by means of comparison with experimental test results available in the literature. Secondly, these models are used to unveil the structural behavior and ultimate strength of LDIPGs subjected to uniform bending. After that, the LDIPGs are selected on the basis of three key parameters: the radius of gyration of the compression flange, the section modulus and the unbraced length. Finally, the numerical results are compared with predictions given by AS4100 and EC3. It is found that the EC3 provides conservative predictions for the LDIPGs under bending, with a relatively high margin of safety. In order to reduce this difference, the imperfection factor associated to buckling curve (c) is recommended to be used in the scope of the design method provided by EN 1993-1-4.

1 INTRODUCTION

The interest in metallic corrosion resistant materials for the structural application has significantly been increasing over recent decades. Most of these materials are stainless steel alloys, which combine high strength, durability, weldability and an aesthetically clean surface with high corrosion resistance. Lean duplex stainless steels with reduced nickel content are very competitive within the stainless steel grades due to the strong fluctuations in nickel price and better mechanical properties than those with austenitic alloys. The lean duplex grade EN 1.4162, for instance, contains a relatively low nickel content of about 1.5% of its alloy composition. Examples for the structural applications of lean duplex grade EN 1.4162 include the Likholefossen Bridge in Norway and Siena Footbridge in Italy. However, most design codes treat them in the same way as austenitic steels because most of the existing numerical and experimental results come from austenitic or duplex alloys. The behaviour of stainless steel material in fact differs from that of carbon steels (Gardner 2005, Baddoo 2008). Stainless steels have a rounded stress-strain curve with no yield plateau and low proportional limit stress compared to carbon steel ones. Nevertheless little information specifically dedicated to lean duplex grades is available in the literature whereas austenitic grades are much more covered. On the other hand, I-section plate girders (IPGs) are nowadays main elements in many industrial areas such as aerospace, shipbuilding, bridges, industrial buildings and offshore structures. They are regularly made of lightweight and/or high strength materials and are joined by modern welding techniques. Their behaviour depends on the structural response of the plate elements that are subjected mainly to in-plane loading. Steel design standards (e.g. AISC 2010) normally define the flexural resistance of IPGs based on the consideration of local buckling (L) and lateral-torsional buckling (LT) limit states. In general, local buckling of IPGs is defined as a mode involving deformations of their individual plates without the translation of the intersection lines of the adjacent plate elements. Accordingly, the local buckling depends on the slenderness ratios of flange and web elements as well as the applied compressive stress ratio (stress gradient). Conversely, the LT is characterized by a rigid-body lateral translation and twist of the cross-section and highly depends on the unbraced length. On the other hand, it is common fact (e.g Hancock et al. 1980) that IPGs with slender webs fail in a mode characterized by web distortion, which is commonly known as the lateral-distortional buckling (LD) mode. There has been much research work reported in the literature on the LD concentrating on the carbon steel beams. Hence, the flexural strength of lean duplex stainless steel I-section plate girders of Grade EN 1.4162 (LDIPGs) is presented in this paper. To the authors' knowledge, the LD of LDIPGs has never been studied.

2 FE MODEL AND VALIDATION

Before studying the behaviour of LDIPGs, it is essential to validate the numerical model. Since there are no experimental studies on LD and LT of LDIPGs, we consider the tests recently carried out by Saliba and Gardner (2013) on the local buckling (LB) of lean duplex stainless steel I-section beams. Regarding the geometry, four beams under three-point bending were analysed. The I-section dimensions are h_w (web depth), b_f (flange width), t_f (flange thickness) and t_w (web thickness). The I-sections have the following labeling (adopted from Saliba and Gardner 2013): $I-200\times140\times6\times6-1$, $I-200\times140\times8\times6-1$, $I-200\times140\times10\times8-1$ and $I-200\times140\times12\times8-1$ ($h_w\times b_f\times t_f\times t_w$). The length $L=2.8$ m is the same for the four beam specimens. The numerical model was used four-node isoparametric thin shell element with reduced integration S4R. A mesh size of 10 mm was found appropriate for the purpose of this validation task. In order to have physical reality, geometric imperfections were included in the FE model. The actual initial imperfection measured in Saliba and Gardner (2013), obtained herein from the first eigenmode of the beam, was added to the perfect geometry. This task requires the performance of a preliminary elastic buckling analysis to determine the buckling mode shape, and then, the consideration of its shape and amplitude as input to the non-linear analysis. The effect of the residual stresses on the behaviour of the beam was not taken into account because Saliba and Gardner (2013) found it was negligible. The boundary and loading conditions considered herein are similar to those adopted in the experimental tests (Saliba and Gardner 2013). Regarding the global rotations and in-plane displacements at the supports, simply supported boundary conditions were applied to end sections. Additionally, lateral restraints were provided at the load points and supports, typical to the experimental setup in Saliba and Gardner (2013), to prevent LTB. In order to avoid web crushing due to concentrated forces (load and reactions), three plates (transverse stiffeners) were considered, two at the supports and one at the mid-span section. Regarding the loading, each beam is acted by a vertical load at the mid-span section, above the top flange. Thus, the most stressed zone of the beams is the mid-span section. The stainless steel material relationship has been modelled as a Von Mises material with isotropic hardening. Therefore two-stage version of expressing the full-range stress-strain material behaviour of stainless steel was developed by Rasmussen (2003). In this respect, Rasmussen (2003) proposed the use of the expression:

$$\varepsilon=\begin{cases}\dfrac{\sigma}{E_0}+0.002\left(\dfrac{\sigma}{\sigma_{0.2}}\right)^{n} & \text{for } \sigma\le\sigma_{0.2}\\[2ex] \dfrac{\sigma-\sigma_{0.2}}{E_{0.2}}+\varepsilon_u\left(\dfrac{\sigma-\sigma_{0.2}}{\sigma_u-\sigma_{0.2}}\right)^{m}+\varepsilon_{0.2} & \text{for } \sigma>\sigma_{0.2}\end{cases} \quad (1)$$

Table 1. Average properties (Saliba and Gardner 2013).

t [mm]	E_0 [GPa]	$\sigma_{0.2}$ [MPa]	σ_u [MPa]	n
6	202	524	728	9.9
8	206	518	728	10.2
10	206	493	769	8.9
12	201	468	723	8.7

for the complete stress-strain curve for stainless steel alloys. where E_0 is the initial modulus of elasticity, $\sigma_{0.2}$ is the 0.2% proof stress, and n is the nonlinearity index. This index is a measure of the non-linearity of the stress-strain behaviour – note that lower n values imply higher non-linearity. The degree of non-linearity varies among different grades of stainless steel. As the value of n increases the material behaviour tends to converge to the elasto-plastic behaviour of carbon steel (elastic-perfectly plastic behaviour for $n=\infty$). In Eq. 1, $E_{0.2}$ is the tangent modulus of the stress-strain curve at the 0.2% proof stress, given by

$$E_{0.2}=\frac{E_0}{1+0.002n/e} \quad (2)$$

where $e=\sigma_{0.2}/E_0$ is the non-dimensional proof stress and $m=1+3.5(\sigma_{0.2}/\sigma_u)$. The expression (Eq. 1) involves the conventional Ramberg-Osgood parameters (n, $\sigma_{0.2}$, E_0) as well as the ultimate tensile strength (σ_u) and strain (ε_u). The expressions have been shown to produce stress-strain curves which are in good agreement with tests over the full range of strains up to the ultimate tensile strain. Therefore, Eq. 1 is used in the current investigation to generate the stress-strain curve of the lean duplex stainless steel material Grade EN 1.4162. The material behaviour provided by ABAQUS allows for a multi-linear stress-strain curve to be used. The first part of the multi-linear curve represents the elastic part up to the proportional limit stress with measured Young's modulus. In this validation study, we adopted the average measured properties obtained by Saliba and Gardner (2013) of those obtained from the six coupon tests for each material thickness (two longitudinal tensile, two longitudinal compressive and two transverse compressive coupons). Table 1 provides the measured material properties for different thicknesses (Poisson's ratio $\nu=0.3$ was considered).

The results shown here comprise (i) moment-rotation curves, (ii) failure modes and (iii) ultimate strength values. Figure 1 shows the moment-rotation curves obtained for the four beam specimens. In these curves, the white rectangles represent the experimental values while the black rectangles denote the numerical ones (note that the vertical axis is normalized against the plastic moment M_p while the horizontal axis is normalized against the cross-section flexural rotation at the onset of plastic failure). Generally speaking, the numerical curves agree well with those

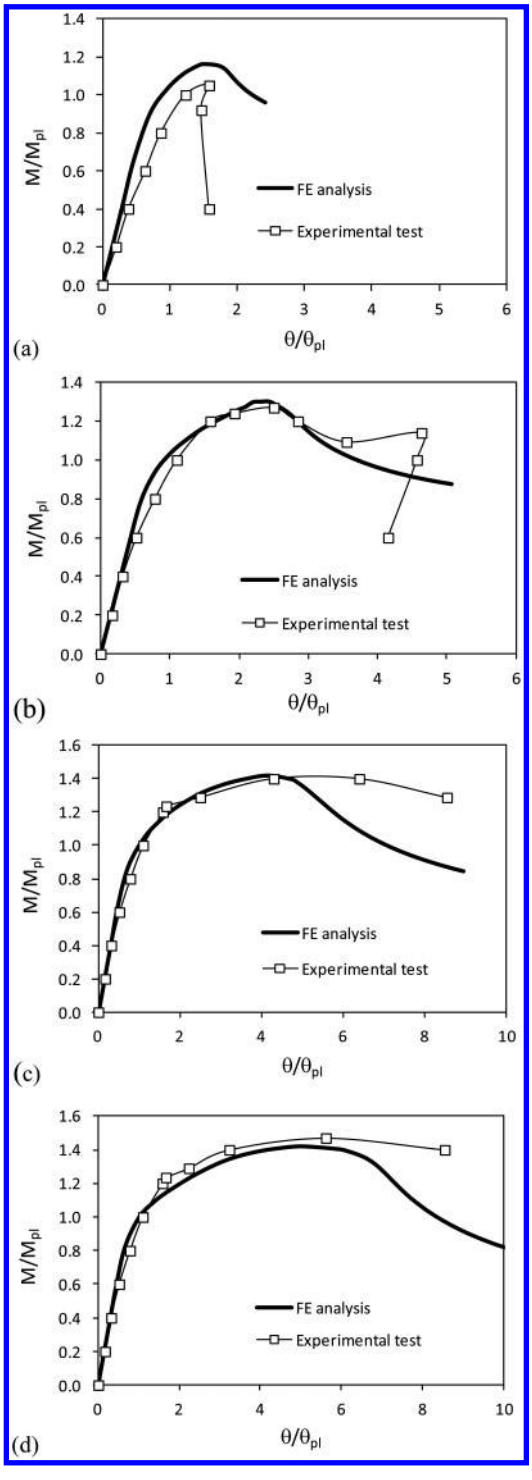

Figure 1. Moment-rotation curves of the lean duplex stainless steel I-section beams: (a) I – 200 × 140 × 6 × 6 – 1, (b) I – 200 × 140 × 8 × 6 – 1, (c) I – 200 × 140 × 10 × 8 – 1, (d) *I* – 200 × 140 × 12 × 8 – 1.

Table 2. Comparison between test and numerical results.

Beams	$M_{ul,Test}$ [kN.m]	$M_{ul,FE}$ [kN.m]	$\frac{M_{ul,FE}}{M_{ul,Test}}$
200 × 140 × 6 × 6 – 1	134	142	1.06
200 × 140 × 8 × 6 – 1	195	197	1.01
200 × 140 × 10 × 8 – 1	264	264	1.00
200 × 140 × 12 × 8 – 1	305	296	0.97

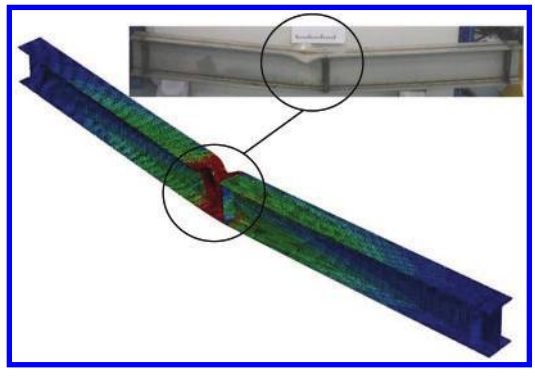

Figure 2. Failure modes of I – 200 × 140 × 6 × 6 – 1 beam under 3-point bending obtained from: (a) numerical analysis and (b) experimental test (courtesy of Saliba and Gardner 2013).

obtained experimentally, especially for the ascending branch of the curves. Regarding the beam strength, it is seen that the ultimate moments obtained numerically and experimentally compare fairly well (see Table 2). The percentage differences between the moments obtained experimentally ($M_{Test,ul}$) and numerically ($M_{FE,ul}$) are 6% (I – 200 × 140 × 6 × 6 – 1), 1% (I – 200 × 140 × 8 × 6 – 1), 0% (I – 200 × 140 × 10 × 8 – 1) and 3% (I – 200 × 140 × 12 × 8 – 1).

Finally, it is also interesting to note that the failure mode determined from the FE analysis compares very well with that obtained from experimental tests (Saliba and Gardner 2013). Figure 2 shows the failure mode of beam I – 200 × 140 × 6 × 6 – 1 determined from numerical analysis and experimental test. The formation of a plastic hinge at the left hand side of mid-span section is characterized by (i) local buckling of the top (compression) flange and (ii) yielding of the bottom (tensioned) flange.

3 PARAMETRIC STUDY

Since LDIPGs are frequently subjected to in-plane loading, it is important that design guidance takes into account several instability phenomena, such as local buckling and global buckling. The lean duplex stainless steel I-section beams previously studied failed by local buckling (L). However, it is probable that longer beams would fail either by lateral-distortional buckling (LD) or lateral-torsional buckling (LT). In order to

analyze the flexural behaviour of LDIPGs of Grade EN 1.4162 and unveil their structural behaviour, numerical analyses on full-scale plate I-section girders are conducted next. The input data are shown in the next paragraphs.

The cross-sectional dimensions of the LDIPGs were selected assuming compact flanges and slender webs. The overall dimensions h_w, b_f, t_f and t_w remain, but their values for the LDIPGs are quite different from their I-section counterparts. Table 3 shows the dimensions considered in this study. The FE analysis program consists of five groups (G1, G2, G3, G4 and G5), as it is seen in Table 3. The parameters covered herein are based upon the AISC (2010) recommendations:

- the radius of gyration of the compression flange (r_T) assumes three values (72.2 mm, 86.6 mm and 101 mm), and
- the section modulus referred to compression (S_{xc}) assumes three values (10582 cm^3, 13743 cm^3 and 17112 cm^3).

Based upon the r_T, S_{xc} and L_b variables, the study considers sections with flange width-to-web depth ratio (b_f/h_w) that varies between 0.20 and 0.39. The flange-to-web thickness ratio defined by t_f/t_w was fixed to 3. The flange dimensions are assigned a b_f/t_f ratio that ranges from 8.33 to 11.67. Meanwhile, web plate slenderness is characterized by web height to web thickness (h_w/t_w) values that vary between 89 and 150. Since the unbraced length (L) assumes nine values (3, 5, 7, 9, 11, 13, 15, 17, 19 m), 45 LDIPGs are considered in this study. The LDIPGs are labelled herein such that the group number could be identified from the label followed by their unbraced lengths. For example, the label "G2-9" defines a girder of Group 2 with an unbraced length of 9m.

The structural behaviour of LDIPGs depends on the mechanical properties of the lean duplex stainless steel material. According to the EN 10088-4 (2009), the cold-formed lean duplex stainless steel Grade EN 1.4162 has a minimum 0.2% proof stress ($\sigma_{0.2}$) of 530 MPa and an ultimate tensile strength ranging from 700–900 MPa. The lower bound of the tensile strength (700 MPa) is considered in the present study. Furthermore, we considered the Young's modulus $E_0 = 200$ GPa, Poisson's ratio $\nu = 0.3$ and proportional limit $\sigma_{0.01} = 400$ MPa.

The numerical models adopted herein for the LDIPGs follow that previously validated for I-section

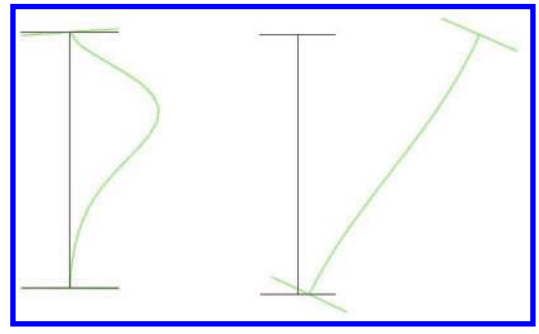

Figure 3. Local (L) and lateral-distortional (LD) buckling modes.

beams. As previously stated, the aim of this paper is to show some representative flexural strength results for the LDIPGs considering the key parameters affecting them; namely the radius of gyration of the compression flange (r_T), neglecting the contribution of the web, and the section modulus referred to compression (S_{xc}). As can be seen in Table 3, Groups 1-3 have very similar S_{xc}, while Groups 2 and 4-5 possess a typical value $r_T = 86.6$ cm. Thus, we have a total of 45 girders analysed herein. The yield bending moment ($M_y = S_{xc}f_y$) of the sections are provided in Table 3.

Both elastic (bifurcation) buckling and nonlinear FE analyses of LDIPGs were conducted and the critical moment (M_{cr}) and ultimate moment (M_{ul}) were then obtained from these analyses, respectively. The deformed shapes at the ultimate moments (M_{ul}) of the LDIPGs with different spans are examined herein to thoroughly monitor the different failure modes. Three failure modes were noticed in the current program, arising from local buckling (L – Figure 3), lateral-distortional buckling (LD – Figure 3) and lateral-torsional buckling (LT – Figure 3). Table 4 shows the distribution of buckling/failure modes for the 5 groups and 9 lengths. Table 5 shows the numerical results (M_{ul}/M_y) obtained for G1, G2, G3, G4 and G5. It is clearly shown that the girder length as well as the radius of gyration of the compression flange and the section modulus might affect the girder buckling/failure mode.

4 COMPARISON WITH DESIGN RESULTS

The numerical results shown before are now used to investigate the suitability of current design rules when

applied to estimate flexural strengths of the LDIPGs. The available design method of AS4100 (1998) and EN1993-1-4 (2006) do not account for web distortions in LDIPGs with stocky flanges and slender web. Accordingly, this section evaluates the lateral buckling predictions of both AS4100 (1998) andEN1993-1-4 (2006) for the use for the LDIPGs. It should be pointed out that the LT strength of IPGs in both elastic and inelastic ranges is defined in AS4100 (1998) and EN1993-1-4 (2006) by a single curve, not distinguishing elastic and inelastic strength. According to the AS4100 (1998), the strength of a laterally unrestrained girder subjected to major axis bending is estimated by the following formula:

$$M_{AS} = 0.6M_p\left[\sqrt{\bar{\lambda}_{LT}^{\,4}+3}-\bar{\lambda}_{LT}^{\,2}\right] \le M_p \qquad (3)$$

where $\lambda_{LT} = (M_y/M_{cr,LT})^{0.5}$ is the girder slenderness and M_p is the plastic moment of the section. According to the EN1993-1-4 (2006), the strength of a laterally unrestrained girder subjected to major axis bending is estimated by the following formula:

$$\chi_{LT} = \frac{1}{\Phi_{LT}+\sqrt{\Phi_{LT}^{\,2}-\bar{\lambda}_{LT}^{\,2}}} \le 1.0$$
$$\Phi_{LT} = 0.5\left[1+\alpha_{LT}\left(\bar{\lambda}_{LT}-0.4\right)+\bar{\lambda}_{LT}^{\,2}\right] \qquad (4)$$

where M_y is either (i) the yield bending moment of the effective cross-section ($M_{eff,y}$) if the cross-section is Class 4 or (ii) the yield bending moment of the gross cross-section ($M_{el,y}$) if the cross-section is Class 3. Additionally, χ_{LT} is the reduction factor for LT, α_{LT} is the imperfection factor (taken herein as 0.76 for welded open sections) and $\lambda_{LT} = (M_y/M_{cr,LT})^{0.5}$ is the girder slenderness. In the definition of the girder slenderness λ_{LT} for both AS4100 (1998) and EN1993-1-4 (2006), the elastic critical moment for LT ($M_{cr,LT}$) should be used. It is based upon the *gross* sectional properties and takes into account the loading conditions, the real moment distribution and the lateral restraint. The ultimate moments M_{ul} (or strengths) of the LDIPGs obtained from the FE nonlinear analyses, given indirectly in Table 5, are compared with the LT strengths predicted by the AS4100 (1998) and EN1993-1-4 (2006), shown in Tables 6 and 7. From Tables 6 and 7 it can be observed that the AS4100 (1998) predicts higher moments than numerical ones, while the EN1993-1-4 (2006) conservatively predicts such strengths. Pi and Trahair (2000) showed that the elastic LD moment ($M_{cr,LD}$) might be obtained from the Eq. 5. Their main idea suggests that a reduction in the warping stiffness due to web distortions should be taken into consideration in addition to a reduction in the torsional stiffness when calculating the LD moment of an I-beam with stocky flanges,

$$M_{cr,LD} = \frac{\pi}{kL}\sqrt{EI_y GJ_e\left(1+\frac{\pi^2}{(k_w L)^2}\frac{EC_{we}}{GJ_e}\right)}$$
$$GJ_e = \frac{(2GJ_f).(12D_w L^2/\pi^2 h_w)}{(2GJ_f)+(12D_w L^2/\pi^2 h_w)} \qquad D_w = \frac{Et_w^{\,3}}{12(1-\upsilon^2)} \qquad (5)$$
$$EC_{we} = \frac{EC_w}{1+r_{fw}^{\,3}.(h_w/12L_b).(1+b_f/h_w)}$$

where GJ_f is the torsional rigidity of the flange and r_{fw} is the smaller of t_f/t_w and 2. The elastic critical moment for LD ($M_{cr,LD}$) is now calculated using the *effective* torsional and warping rigidities (GJ_e and EC_{we}) proposed by Pi and Trahair (2000), and the ultimate strengths using $M_{cr,LD}$ are also shown in Tables 6 and 7. It can be seen from Tables 6 and 7 that the use of the *effective* torsional and warping rigidities in the context of AS4100 (1998) expression provides unconservative predictions for inelastic LD range, while it provides accurate results for the elastic LD range (long girders). However, utilizing such *effective* torsional and warping rigidities in the EN1993-1-4 (2006) equation provides higher conservative predictions of the LDIPG flexural strength than using the *gross* torsional and warping rigidities, for short unbraced lengths. Generally, it can be concluded that the design equation given by EN1993-1-4 (2006) (with *effective* torsional and warping rigidities) is suitable to be used in design.

Figure 4 shows the variation, with λ_{LT}, of the ratio between the ultimate moments obtained from numerical analyses (M_{ul}) and EC3 formulas (M_{EC3}). The current design approach is denoted by the black circles. It is seen that $M_{ul}/M_{EC3}>1.0$ and the mean value and standard deviation of M_{ul}/M_{EC3} are 1.24 and 0.04, respectively. This means that the EC3 design approach is too conservative and may cause economic losses. If we apply an imperfection factor α_{LT} of 0.49 rather than 0.76, which means that we use buckling curve (c) instead of curve (d), we get higher and less conservative M_{EC3} values. The results of the recommended design approach are denoted by the white circles in Figure 4.

It is seen that $M_{ul}/M_{EC3}>1.0$ but the mean value and standard deviation of M_{ul}/M_{EC3} are now 1.13 and 0.05, respectively – the mean error (13%) is now about one half of the mean error (24%) of the current EC3 approach.

5 CONCLUSION

The findings of a numerical investigation on the flexural behaviour of lean duplex stainless steel plate girders (LDIPGs) of Grade EN 1.4162 were presented. Firstly, the shell finite element model adopted in this study was validated by comparison with experimental results available in the literature. After that, the LDIPGs with compact flanges and slender unstiffened webs under the effect of uniform bending moments were considered. The obtained results were used to develop LD buckling design guidance for the LDIPGs. Several conclusions were drawn and described in the preceding section. For more details, the interested reader may refer to Hassanein and Silvestre (2013).

ABSTRACT: The Continuous Strength Method (CSM) was developed and calibrated against experimental and numerical results as a design approach, which allows for a rational exploitation of the significant strain-hardening exhibited by stocky stainless steel cross-sections, thereby leading to more economic design. In order to extend its scope of application beyond the fundamental loading cases of concentric compression and uniaxial bending, a comprehensive numerical parametric study has been conducted and the obtained numerical results have been utilized to determine suitable interaction equations for cross-sections subjected to combined loading. This paper focuses on the ultimate response of I-sections under combined loading and complements a recent relevant study on RHS under combined loading. It is concluded that the current design guidance for stainless steel cross-sections under combined compression and biaxial bending is overly conservative and significant gains can be made if the effect of strain-hardening on ultimate capacity is taken into account.

1 INTRODUCTION

The material response of stainless steels deviates significantly from the elastic-perfectly plastic model assumed in EN 1993-1-4 (2006), due to the absence of a yield plateau and the significant strain-hardening exhibited at relatively low strains. Failure to account for the actual material response and the adoption of the 0.2% proof stress as a nominal yield stress, as is conventionally specified in design regulations, leads to significant underestimation of the ultimate capacity of stainless steel cross-sections of low to intermediate slenderness, which can sustain stresses far beyond their nominal yield stress. The conservatism embedded in EN 1993-1-4 (2006) has been highlighted by numerous researchers (Burgan et al. 2000, Gardner & Theofanous 2008).

Given the high material cost of stainless steels, the development of more advanced design approaches that allow for a rational exploitation of the special merits of stainless steels in design is warranted. To this end, the Continuous Strength Method (CSM) was developed by Gardner & Nethercot (2004a, 2004b) and calibrated against experimental and numerical results as a strain-based design approach which rationally takes into account the significant strain-hardening exhibited by stocky stainless steel cross-sections. The method has also been adapted to aluminum alloys (Gardner & Ashraf 2006) and carbon steel (Gardner 2008). Recently the CSM was modified to incorporate the effect of interaction of the constituent plate elements on the cross-sectional capacity (Theofanous & Gardner 2012) by employing the concept of cross-sectional slenderness, as defined within the framework of the Direct Strength Method (Schafer 2008) in place of the plate slenderness of the most slender constituent plate element, which is assumed to relate to a cross-section's deformation capacity. Additional advancements of the method include its extension to stainless steel members failing by distortional buckling (Theofanous & Gardner 2012), as well as to stainless steel continuous beams (Theofanous et al. 2012a). Moreover, significant simplifications in design arise by departing from the accurate Ramberg-Osgood based material model originated by Mirambell & Real (2000) and further developed by Rasmussen (2003), and adopting a bilinear elastic-linear hardening material model (Gardner et al. 2011). A full account of the CSM for stainless steel design is given by Afshan and Gardner (in press).

Initially the scope of the method was limited only to stainless steel cross-sections subjected either to compression or uniaxial bending. Clearly, more general loading cases have to be considered if CSM is to become a viable alternative to existing design procedures. However the relevant research on stainless-steel components under combined loading is scarce and focuses mainly on beam-column members rather than cross-sections (Talja & Salmi 1995, Burgan et al. 2000, Greiner & Kettler 2008). This is also reflected in the lack of design rules for stainless steel cross-sections under combined loading in EN

1993-1-4 (2006), which refers the designer to the relevant carbon steel design rules given in EN 1993-1-1 (2005). To address the lack of relevant experimental and numerical data, an extensive parametric study on stainless steel RHS stub columns under combined compression and biaxial bending has been conducted and interaction equations for stainless steel RHS have been proposed by Theofanous et al. (2012b). The present paper extends that research by investigating the ultimate capacity of stainless steel I-section stub columns under combined loading. Based on an extensive finite element parametric study of I-section stub columns under combined compression and biaxial bending covering a wide range of cross-section geometries and slendernesses, interaction expressions are derived, which allow the application of the CSM to stainless steel components under general loading conditions. The numerical results are compared with the codified ultimate capacity predictions and with the CSM predictions demonstrating the superiority of the CSM in terms of both economic design and consistency of the predictions, particularly in the low slenderness region.

2 NUMERICAL MODELLING

The general purpose FE software ABAQUS (2010) has been utilized to model 20 I-section geometries subjected to a large number of loading cases. A full account of the basic modeling assumptions adopted herein is given in Theofanous & Gardner (2012a). All modelled cross-sections had a flange width of 100 mm and a flange thickness varying from 6 mm to 10 mm in increments of 1 mm, whilst two section aspect ratios equal to 1 and 2 and two flange to web thickness ratios equal to 1 and 0.6 were investigated, thus resulting in 20 cross-section geometries. The mid-surface of the cross-sections was modelled with a relatively fine uniform mesh of linear reduced integration finite strain shell elements S4R (ABAQUS 2010). The length of the modelled stub columns was set equal to three times the largest cross-section dimension. This length was deemed short enough to exclude member instabilities yet sufficiently long for local buckling to develop with little effect from the end restraints. All modelled stub columns failed by local buckling and the obtained ultimate capacity was assumed to represent the cross-sectional capacity of the modelled component.

A two-stage Ramberg-Osgood material law (Mirambell & Real 2000, Rasmussen 2003, Gardner & Nethercot 2004a) was employed to represent the material response of the modelled components. The adopted material properties correspond to a typical austenitic stainless steel (Groth & Johansson 1990) and are given in Table 1, where E is the Young's modulus, $f_{0.2}$ (or f_y) and $f_{1.0}$ are the stresses corresponding to 0.2% and 1% plastic strain respectively and n and $n_{0.2,1.0}$ are strain-hardening exponents.

The initial geometric imperfections assumed the shape of the lowest elastic buckling mode shape as determined by means of an eigenvalue buckling analysis for each component and load case considered. The amplitude of the initial geometric imperfection was determined by means of a predictive model (Dawson & Walker 1972) modified for stainless steel (Gardner & Nethercot 2004c). No residual stresses were included in the analysis due to the inherent uncertainty regarding their magnitude and distribution and due to the fact that they were shown to have an insignificant effect for stub columns (Gardner & Nethercot 2004c). A typical elastic buckling mode shape and a typical failure mode are shown in Figure 1.

Table 1. Adopted material properties.

E	$f_{0.2}$ (N/mm^2)	$f_{1.0}/f_{0.2}$	n	$n_{0.2,1.0}$	f_u (N/mm^2)
200000	306.1	1.2	5.6	2.7	614.7

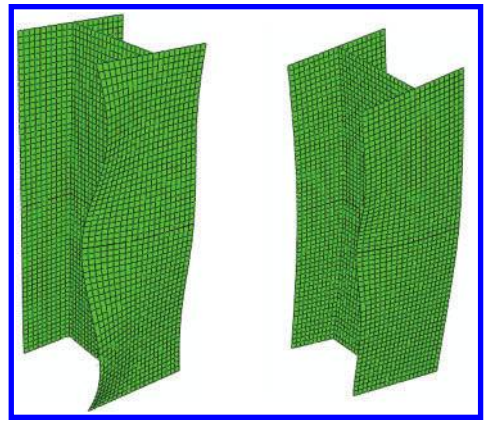

Figure 1. Lowest buckling mode shape and failure mode for a typical I-section subjected to compression and biaxial bending.

For each modelled component, 73 combinations of axial compression and biaxial bending about both principal axes were imposed, which contained the fundamental cases of pure compression and uniaxial bending about either axes. Moreover the interaction of axial force with uniaxial bending as well as the case of biaxial bending without a coexisting axial compression were also included as special cases. The loads were applied proportionally at the end cross-section of each component, which was constrained to displace and rotate as a rigid body, on which pin-ended boundary conditions were imposed.

Due to the large number of analyses performed, the computational cost was reduced by modelling half the length of each component and imposing appropriate symmetry boundary conditions. Scripting in Python was employed to utilize the parametric capabilities of ABAQUS (2010). Based on the obtained results, current design provisions are assessed in the following sections of the paper.

3 ASSESSMENT OF EN 1993-1-4

EN 1993-1-4 (2006) specifies special design provisions for stainless steel beam-column members, but refers to EN 1993-1-1 (2005) for cross-sectional checks, which allow for plasticity within a cross-section subjected to combined compression and biaxial bending, provided that the section is classified as Class 1 or 2. The codified interaction expressions of EN 1993-1-1 (2005) for a stocky (i.e. Class 1 or 2) I-section is given by Equation (1):

$$\left[\frac{M_{y,Ed}}{M_{N,y,Rd}}\right]^{2} + \left[\frac{M_{z,Ed}}{M_{N,z,Rd}}\right]^{5n} \leq 1 \qquad (1)$$

where $M_{y,Ed}$ and $M_{z,Ed}$ are the applied moments and $M_{N,y,Rd}$ and $M_{N,z,Rd}$ are the plastic moment resistances about the relevant axis, reduced due to the axial force N_{Ed} and $n = N_{Ed}/(Af_y)$. The design expressions for $M_{N,y,Rd}$ and $M_{N,z,Rd}$ are given in EN 1993-1-1 (2005). For Class 3 and Class 4 sections, the maximum longitudinal stress due to the applied loads should be limited to the yield stress f_y, which effectively results in a linear interaction equation.

For each modelled cross-section and load case, a triplet of axial force N_{Ed}, bending moment about the major axis $M_{Ed,y}$ and bending moment about the minor axis $M_{Ed,z}$ was obtained, thus enabling the determination of interaction surfaces in the (N_{Ed}, $M_{Ed,y}$, $M_{Ed,z}$) space and the assessment of current interaction equations.

In the following figures, $W_{pl,y}$, $W_{pl,z}$ are the section plastic moduli about the respective principal axes, A_{eff} is the effective cross-section area (gross area for Classes 1-3), $\beta_w = 1$ for Class 1 or 2 cross-sections, $\beta_w = W_{el}/W_{pl}$ for Class 3 cross-sections and $\beta_w = W_{eff}/W_{pl}$ and f_y is the nominal yield stress $f_{0.2}$. Figures 2-4 depict the comparison of numerical (normalized by codified resistance) and codified ultimate capacities for I-sections with an aspect ratio of 1 and a flange to web thickness ratio of unity for the special cases of compression and major axis bending (N-M_y), compression and minor axis bending (N-M_z) and biaxial bending respectively. All data points correspond to cross-sections classified either as Class 1 or 2 for which Equation 1 applies. As shown in Figures 2-4, the predictions of the Eurocode are overly conservative in all cases. The conservatism seems to increase with increasing slenderness, since the thicker cross-sections lie further away from the codified interaction curves. This suggests that the source of conservatism is the strain-hardening achieved by the stockier cross-sections which is not considered in the codified predictions.

Figures 5–7 depict the comparison of numerical and codified capacities for I-sections with an aspect ratio of 2 and a flange to web thickness ratio of 0.6. The classification of these cross-sections varies from Class 1 to Class 4 according to width to thickness ratio and applied loading, with all the cross-sections being Class 4 in pure compression, Class 1 or 2 for minor axis bending and Class 1 or 3 for major axis bending. It should be noted that this group of cross-sections is the most slender considered in this study, since the main focus of the paper is cross-sections of low to intermediate slenderness, for which the effect of strain-hardening is more pronounced.

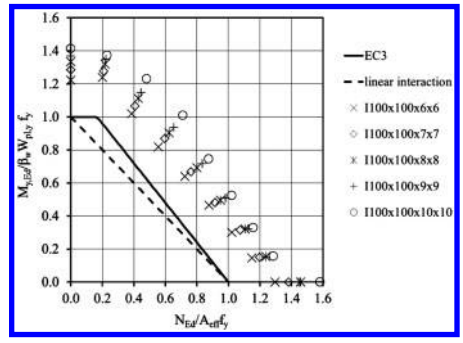

Figure 2. Interaction of axial compression and major axis bending (N_{Ed} + $M_{y,Ed}$, $M_{z,Ed} = 0$) for I-sections with aspect ratio 1.

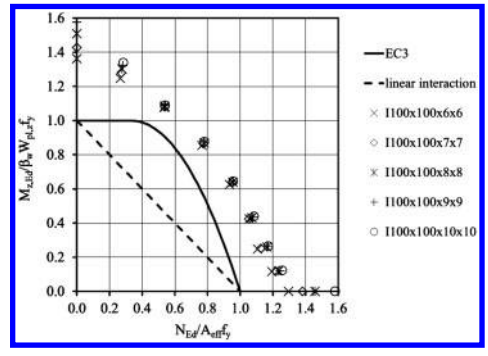

Figure 3. Interaction of axial compression and minor axis bending ($N_{Ed} + M_{z,Ed}$, $M_{y,Ed} = 0$) for I-sections with aspect ratio 1.

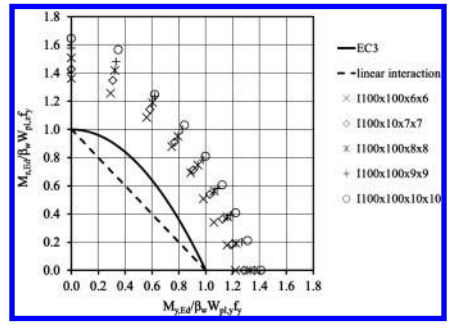

Figure 4. Interaction of minor axis and major axis bending ($N_{Ed} = 0$, $M_{y,Ed} + M_{z,Ed}$) for I-sections with aspect ratio 1.

Comparing Figures 5–7 to Figures 2–4 it can be observed that the level of conservatism of the codified predictions decreases with increased slenderness, due to the less pronounced effect of strain-hardening. However the codified predictions are still overly conservative. For the more general case of cross-sections subjected to compression and biaxial bending, similar

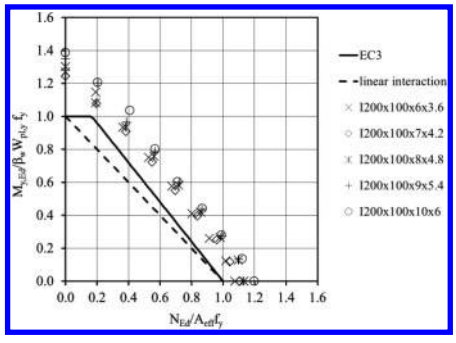

Figure 5. Interaction of axial compression and major axis bending ($N_{Ed} + M_{y,Ed}, M_{z,Ed} = 0$) for I-sections with aspect ratio 2.

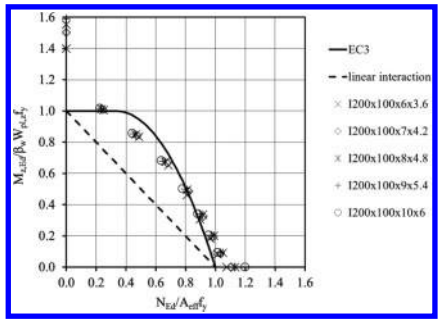

Figure 6. Interaction of axial compression and minor axis bending ($N_{Ed} + M_{z,Ed}, M_{y,Ed} = 0$) for I-sections with aspect ratio 2.

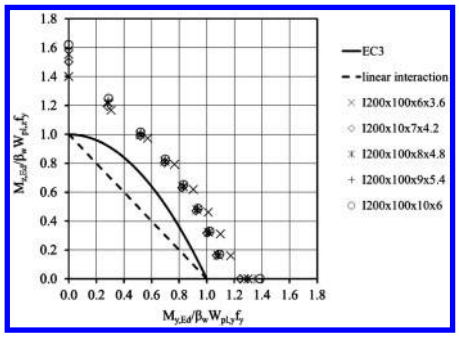

Figure 7. Interaction minor axis and major axis bending ($N_{Ed} = 0, M_{y,Ed} + M_{z,Ed}$) for I-sections with aspect ratio 2.

remarks on the conservatism and scatter of the predictions to the ones made for the more simplified loading cases previously hold. The numerically obtained interaction surfaces for $I100 \times 100 \times 10 \times 10$ and $I200 \times 100 \times 10 \times 6$ are shown in Figures 8 and 9. It can be observed the interaction surface of Figure 8 is more curved than the respective surface for Figure 9, due to the increased strain-hardening associated with the reduced slenderness.

A quantitative assessment of the accuracy of the predictions of EN 1993-1-4 (2006) and EN 1993-1-1 (2005) reveals that on average the Eurocode underestimates the numerically obtained capacities by 31%

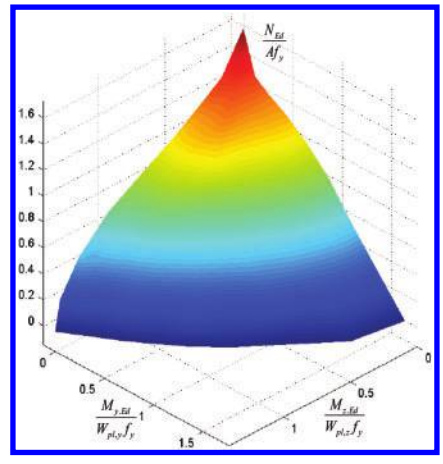

Figure 8. Interaction surface for $I100 \times 100 \times 10 \times 10$.

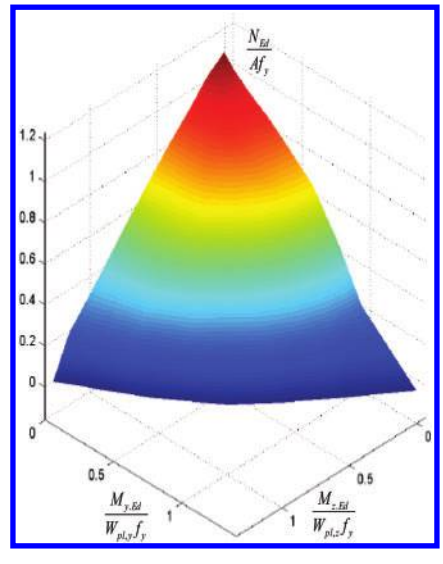

Figure 9. Interaction surface for $I200 \times 100 \times 10 \times 6$.

with a coefficient of variation (COV) of 0.158. The high COV is due to the different level of conservatism exhibited for cross-sections of different levels of slenderness; the embedded conservatism decreases with increasing slenderness. This is due to the effect of strain-hardening, which is more pronounced for stocky cross-sections and becomes insignificant with increasing slenderness.

4 THE CSM FOR COMBINED LOADING

The conservatism of the current design provisions highlighted in the previous section can be largely attributed to the inefficiency of current design provisions in determining the ultimate capacity for the fundamental loading cases acting in isolation for stocky cross-sections (i.e. the end points of the interaction surfaces). In this Section the numerically obtained

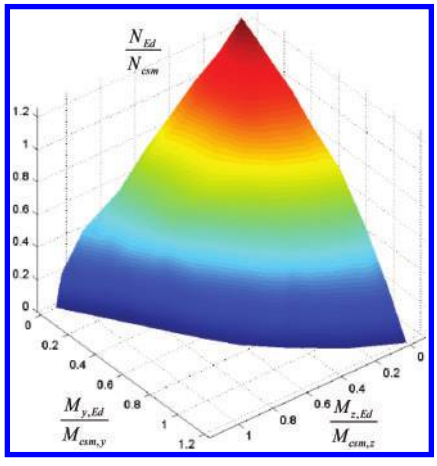

Figure 10. Interaction surface for I100 × 100 × 7 × 4.2.

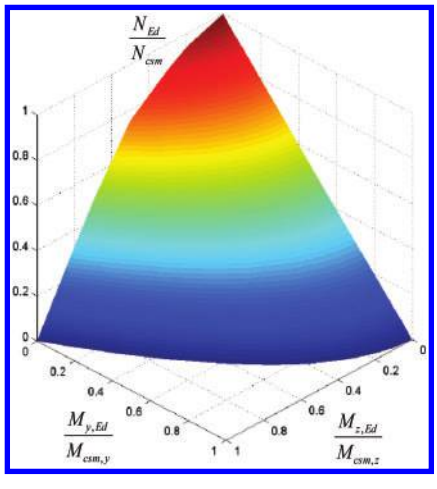

Figure 11. Interaction surface defined by Equation (4).

failure loads are normalized by the CSM predictions and an interaction equation which provides a best fit to the numerically obtained interaction surfaces is proposed, hence allowing the extension of the CSM to more general loading conditions.

A detailed account of the CSM is given in Afshan & Gardner (in press). In short, for each cross-section and load case considered, the corresponding elastic critical buckling stress f_{cr} is utilized to obtain the cross-sectional slenderness $\bar{\lambda}_p$ defined by Equation (2).

$$\bar{\lambda}_p = \sqrt{f_y / f_{cr}} \tag{2}$$

The maximum strain ε_{csm} that the section can attain (as limited by local buckling) is given by Equation (3):

$$\frac{\varepsilon_{csm}}{f_y/E} = \frac{0.25}{\bar{\lambda}_p^{3.6}} \le \min\left\{15; 0.1\frac{\varepsilon_u}{\varepsilon_y}\right\} \tag{3}$$

Having established the maximum strain that can be reached by the cross-section and assuming an elastic-linear hardening material model the axial and bending

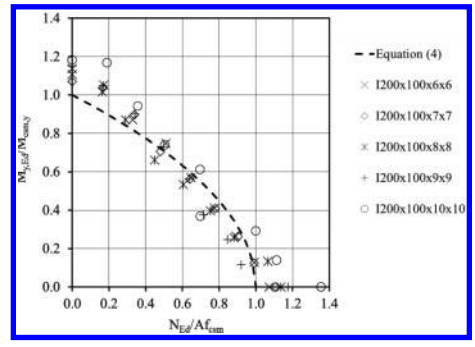

Figure 12. Interaction of axial compression and minor axis bending ($N_{Ed} + M_{y,Ed}$, $M_{z,Ed} = 0$) for I-sections with aspect ratio 2.

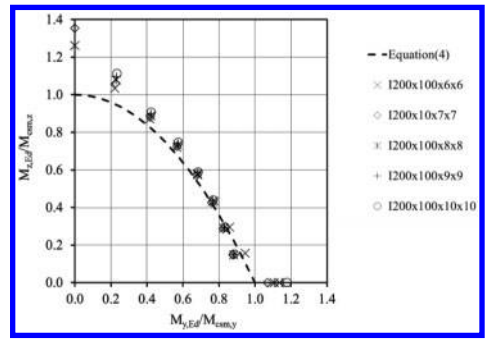

Figure 13. Interaction minor axis and major axis bending ($N_{Ed} = 0$, $M_{y,Ed} + M_{z,Ed}$) for I-sections with aspect ratio 2.

capacities according to CSM (i.e. N_{csm}, $M_{csm,y}$ and $M_{csm,z}$) can be obtained according to explicit equations (Gardner et al. 2011). The CSM allows for a rational exploitation of strain hardening up to strains 15 times larger than the elastic strain at f_y in accordance with codified ductility requirements (EN 1993-1-4 2006, EN 1993-1-1 2005). A further restriction pertaining to the CSM is the slenderness of the cross-sections at which it is applied, which is limited to $\bar{\lambda}_p \le 0.68$. From a total of 1460 obtained numerical results the CSM was not applicable only in 14 cases. For these cases the cross-sectional resistance was calculated according to the provisions of EN 1993-1-4 (2006).

Using the aforementioned procedure, the axial, minor axis bending and major axis bending capacities of all sections were determined. The numerical failure loads were normalized by the respective capacities and utilized to derive a suitable interaction curve that fits the data. A typical interaction surface is shown in Figure 10, whilst Equation (4) was shown to produce a slightly conservative but sufficiently accurate fit to the obtained results. Figure 11 depicts the interaction surface defined by Equation (4).

$$\frac{N_{Ed}}{N_{csm}} + \left(\frac{M_{y,Ed}}{M_{csm,y}}\right)^2 + \frac{M_{z,Ed}}{M_{csm,z}} \le 1 \tag{4}$$

The predictions of CSM in conjunction with Equation (4) are compared to the numerical results for the

special cases of axial compression and minor axis bending and biaxial in Figures 12 and 13 respectively for I-sections with an aspect ratio of 2 and a flange to web thickness ratio of 1. Generally, a good agreement between the proposed design approach and the numerical results can be observed. Finally, the accuracy of the proposed interaction equation is quantified in Table 2.

5 CONCLUSIONS

An extensive parametric study on stainless steel I-sections subjected to compression and biaxial bending has been reported and 1460 numerical results were extracted and utilized to assess the European design codes for stainless steel structures. As expected, the codified provisions are overly conservative since the strain-hardening exhibited by stocky I-sections is not allowed for. The CSM, which has been previously shown to offer improved ultimate capacity predictions for the fundamental load cases of axial compression and uniaxial bending in isolation, has been extended for I-sections under combined loading, by determining an appropriate interaction equation. Similarly to a recent study on RHS (Theofanous et al. 2012b), the CSM in conjunction with the proposed interaction equation, offers improved accuracy and design efficiency, particularly for stocky stainless steel cross-sections under general load cases likely to occur in practice.

Investigating the role of gradual yielding in stainless steel columns and beams by virtual testing

P. Hradil & A. Talja
VTT Technical Research Centre of Finland, Espoo, Finland

ABSTRACT: The metallic materials such as stainless steels are well known for the pronounced rounded shape of their stress-strain diagram. However, this material nonlinearity may change locally due to the fabrication, and therefore the load-displacement response of the structural member is not always the same as the stress-strain relation of the original material. The aim of this paper is to study the sensitivity of member resistance to the changes of gradual yielding rate in fabricated columns and beams. We used the automated finite element virtual experiments to demonstrate the effect of fabrication on the overall buckling of columns and beams.

1 INTRODUCTION

The buckling strength of members from metallic materials is, to some extent, governed by their nonlinear strain-hardening behavior (Rasmussen & Rondal 1997). Especially in the case of cold-formed stainless steels the large variety of stress-strain diagram shapes can be achieved by combining different material grades and fabrication methods. While the proper experimental investigation yields always credible results, it is long and expensive process. Numerical calculations can efficiently supplement the experimental program with additional data or completely replace it.

The nonlinear stress-strain relationship of stainless steels is usually described by formulas based on Ramberg-Osgood equation (Ramberg & Osgood 1943, Mirambell & Real 2000, Rasmussen 2003, Gardner & Ashraf 2006, Hradil et al. 2013). Such material models can vary in the complexity and number of required material parameters, however, only the basic nonlinear parameter n and the ratio of the ultimate and yield strength significantly affects the buckling behavior of columns and beams (Hradil & Talja 2012).

Fabrication of structural members introduces localized residual stresses and material changes that generally result in higher average strength and more rounded shape of load response diagram than expected (ECCS 1976). Even though the design codes offer the rules for the calculation of average section yield strength, the changes in nonlinear parameter n are not widely recognized.

2 SCOPE OF THE STUDY

The aim of our study is to investigate how significant is the gradual yielding in overall buckling of beams and columns, and how different fabrication methods affect the nonlinear factor n of the whole cross-section.

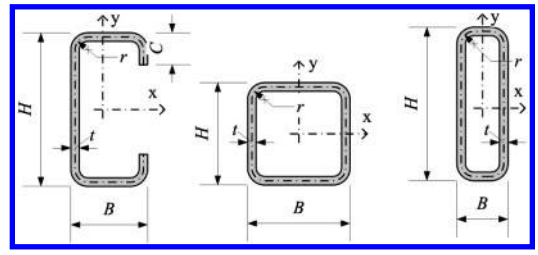

Figure 1. Studied cold-formed sections.

Table 1. Cold-formed sections, dimensions.

Section	*B* mm	*H* mm	*C* mm	*t* mm	*r* mm
C	36	72	15	4	6
SHS	48	48	–	4	6
RHS	24	72	–	4	6

2.1 *Cross-sections and tests*

Cold-formed open sections, hollow sections and welded open sections are the basic categories in Eurocode 3, Part 1–4. Therefore the study is based on cold-rolled RHS sections and press-braked C-sections (Fig. 1 and Table 1) where the effect of cold-forming may alter their nonlinear load response. Although the corner areas are not an issue in welded I-sections, we have included them in the study because of their membrane residual stresses due to fabrication (Fig. 2 and Table 2).

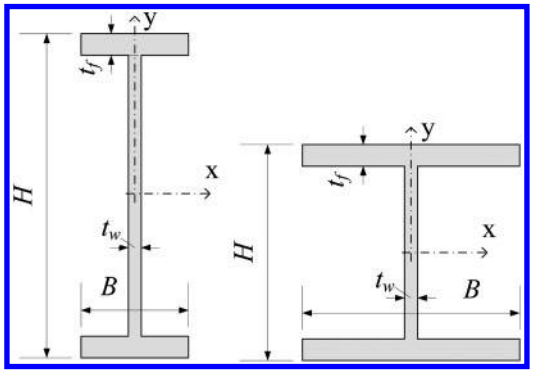

Figure 2. Studied welded sections.

Table 2. Welded sections, dimensions.

Section	B mm	H mm	t_f mm	t_w mm
I	50	150	10	5
H	100	100	10	5

The prediction of nonlinear factor degradation was validated by simulating full section tensile tests and the effect of this factor on member resistance was investigated in the cases of flexural buckling (FB), torsional-flexural buckling (TFB) and lateral-torsional buckling (LTB).

2.2 *Enhanced strength in corners*

The enhanced yield strength of press-braked open sections was applied in the corners according to Cruise & Gardner's model (2008). Assuming that the flat part strength of the channel section is 250 MPa, the predicted average strength results in 294 MPa with corner strengths 420 MPa (Fig. 3). Cold-rolled hollow sections have a larger area affected by the fabrication, which extends 2t from the corners to the flat parts. The current predictive models for the enhanced strength in corners and flat faces of hollow sections are based on the knowledge of virgin material yield strength. Moreover, the model proposed by Cruise & Gardner (2008) for hollow sections is limited to either low A/W or high f_u/f_y ratios, which was not acceptable in our study. Therefore we used Rossi's prediction (Rossi et al. 2009) with the virgin material yield strength 205 MPa that produced flat part strength of exactly 250 MPa and yield strength in the corners 290 MPa.

2.3 *Residual stresses*

Bending residual stresses of 36% of basic yield strength were inserted in corner areas and 15% of the basic strength in flats of press-braked open sections (Fig. 3), according to Gardner & Cruise (2009). In the case of hollow sections, the highest level of bending residual stresses in corners and flat parts was 37%

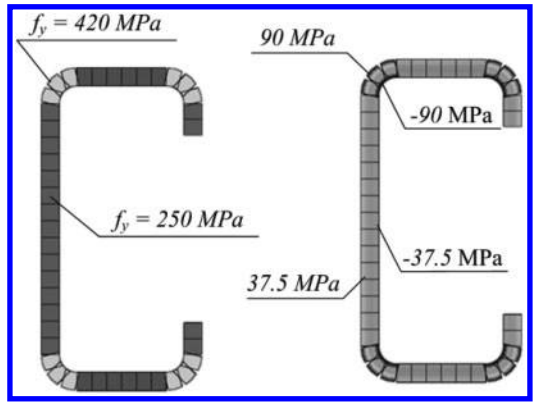

Figure 3. Example of finite element mesh with enhanced yield strength (left) and bending residual stresses (right) in the C-section.

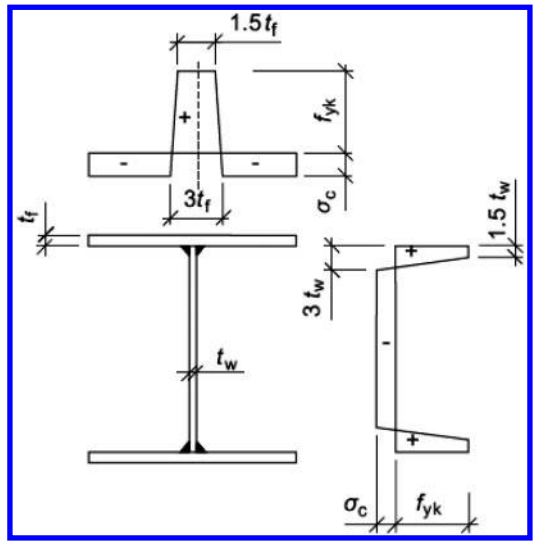

Figure 4. Distribution of membrane residual stresses according to BSK 99.

and 63% respectively. Membrane stresses are typically insignificant in such cross-sections, and therefore were neglected in our study.

The membrane stresses were, on the other hand, used in welded I-section models, where they play an important role. The model for carbon steels from the Swedish standard BSK 99, that was proposed by Gardner & Cruise (2009) for ferritic fabricated sections was used (Fig. 4). Then the compressive stress is calculated to maintain the equilibrium as described in the Equation 1.

$$\sigma_c = \frac{2.25(t_f + t_w)}{B + 0.5H - 2.25(t_f + t_w)} f_y \quad (1)$$

2.4 *Limitations*

The study is based on the current knowledge of material changes in the cold-formed cross sections and on

the existing predictive models for enhanced strength in corners. However, building complex numerical models with nonlinear material in corners requires the knowledge of all material parameters that define the shape of the stress-strain curve. In our study we assumed that parameters (excepting the material strength) remain unchanged if no suitable predictive model is available. The through-thickness distribution of bending residual stresses is fully plastic in our numerical calculations (Jandera et al. 2008) even though the latest studies showed that it is not always the most conservative case (Jandera & Macháček 2012).

3 METHODS

3.1 *Simple method for average material model prediction in cold-formed columns*

The prediction of n factor degradation was performed numerically with discrete strain increments. Simple Python script that iteratively calculates Ramberg-Osgood stress σ_{RO} for a given strain produced the average stress-strain diagram of the cross-section (Eqs. 2 to 5). Areas A_f and A_c are flats and corners sectional areas respectively.

$$\sigma = \frac{A_f\sigma_f + A_c\sigma_c}{A_f + A_c} \tag{2}$$

The total stress in flats σ_f or corner σ_c is composed of two parts with positive and negative residual components assuming that the residual stress has fully plastic through-thickness distribution (see Eq. 3). In the case of tensile residual stress, the unloading path is linear as described in Equation 5, where ε_R is the residual strain calculated by Ramberg-Osgood formula directly from the residual stress σ_R in flats and corners.

$$\sigma_{f(c)} = \frac{1}{2}\left(\sigma^{+}_{f(c)} + \sigma^{-}_{f(c)}\right) \tag{3}$$

$$\sigma^{+}_{f(c)} = \sigma_{RO(\varepsilon+\varepsilon_R)} \tag{4}$$

$$\sigma^{-}_{f(c)} = \begin{cases} E_0\varepsilon - \sigma_R & when\ \varepsilon < \sigma_R/E_0 \\ \sigma_{RO(\varepsilon-\sigma_R/E_0)} & else \end{cases} \tag{5}$$

The parameters of the overall cross-sectional material model were obtained by curve-fitting of Ramberg-Osgood equation to this diagram. The initial assumption was that both materials (in flats and corners) have the same n factor and initial modulus of elasticity E_0.

3.2 *Virtual experiments*

The finite element models were created and evaluated using the Abaqus plugin developed to simulate virtual testing of cold-formed steel members (Hradil et al. 2011). The plugin was designed to carry out the geometrically and materially nonlinear analysis with initial imperfections obtained from the linear eigenvalue analysis and scaled to the desired amplitude. The calculation usually stops after reaching the peak load or pre-defined deformation. The plugin was extended by the Python script that automatically executed series of models with variable member lengths, evaluated results and plotted buckling curves. With that level of automation a single buckling curve was calculated and plotted in less than hour on a common workstation with Intel core2 Duo CPU E8400 @ 3,00 GHz and 3.21 GB RAM. The same algorithm produced tensile test results of full cross sections. In that case no imperfections are needed and the eigenvalue analysis was turned off in the plugin settings.

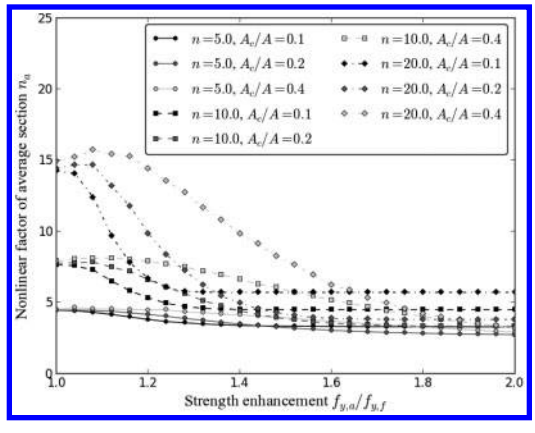

Figure 6. Nonlinear factor degradation due to enhanced corner properties in cold-rolled hollow sections.

4 RESULTS AND DISCUSSION

4.1 *Average material properties based on the simple method*

The predicted changes in nonlinear factor due to the strength enhancement and residual stresses are described in Figures 5–6. The degradation curves are

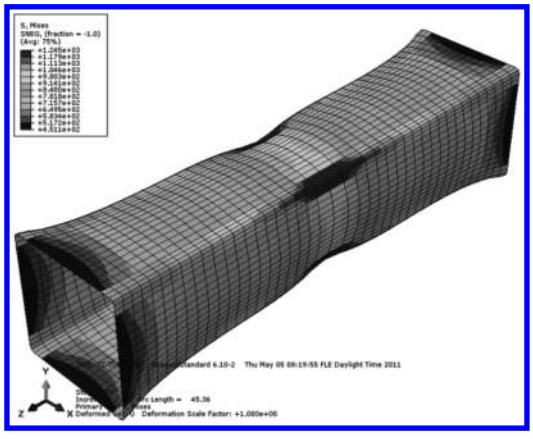

Figure 7. Square hollow section in tension.

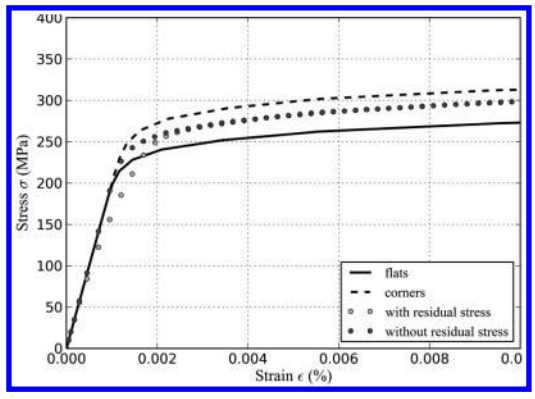

Figure 8. Example of stress-strain curve obtained from simulated tensile test of cold-rolled hollow section.

plotted for n factor 5, 10 and 20 and for the share of the corner area A_c/A equal to 10, 20 and 40%. The average yield strength and the flat parts yield strength are noted as $f_{y,a}$ and $f_{y,f}$ respectively.

The results show that the changes in nonlinearity are more significant with the increasing n of material. It can be also observed that increasing the average strength beyond a certain limit has no effect on the overall cross-section nonlinearity n_a. It stops decreasing at about $n_a = 5$, depending on the share of corner area A_c/A. Even if there is no strength enhancement ($f_{y,a}/f_{y,f} = 1.0$), the strong influence of residual stresses can be observed.

Table 3. Comparison of simply predicted n and the virtual tensile test results.

Section	A_c/A	$f_{y,a}/f_{y,f}$	n	n_a	$n_{a,TT}$
RHS	0.52	1.16	5	4.9	5.0
			10	8.2	7.6
			20	15.8	12.1
SHS	0.62	1.16	5	4.9	5.0
			10	8.3	7.5
			20	16.3	12.0
C	0.24	1.68	5	4.5	4.6
			10	7.9	8.0
			20	12.8	12.7

4.2 *Average material properties based on the virtual tensile tests*

Even though the method presented in the previous section is computationally very effective, it does not account for the interaction between corners and flats and gradual stress redistribution in the cross-section. To obtain more reliable results, the tensile load and displacement relation of the profiles was calculated by finite element models (Fig. 7). The load-displacement diagram of the profile served as the basis for stress-strain relation, as demonstrated in Figure 8. The material models of flats and corners were two-stage Ramberg-Osgood curves (Mirambell & Real 2000) with the second nonlinear factor m equal to 3 and the ultimate strain ε_u equal to 40%.

The regression analysis similar to the previous study was applied to the finite element results to produce nonlinear factor $n_{a,TT}$ of the cross-section. Results are compared to the predicted factors n_a in Table 3, which were produced by the simple method. This method was modified to take into account two-stage Mirambell and Real's material that was also used in finite element calculations.

It can be observed that the finite element analysis mostly resulted in lower n factor than the simple predictive method; however, both calculations showed the significant increase of nonlinearity in the full section loading response especially when the material n factor was high.

4.3 *Results of virtual buckling tests*

The cold-rolled hollow sections were studied in flexural buckling, press-braked open sections in flexural and torsional-flexural buckling, and welded open sections in flexural and lateral-torsional buckling. The dimensions of the cross sections are presented in Table 1. The main goal of this extensive study was to verify the current buckling curves in EN 1993-1-4 (Hradil & Talja 2012), and therefore only selected results are presented in this paper to demonstrate the effects of fabrication and material nonlinearity on the member buckling strength.

Figures 9–12 show the results of virtual buckling tests on various cross-sections, materials (parameter n) and overall buckling modes. In this comparison the ratio of ultimate and yield strength in flat parts (Equation 6) is 1.4.

$$\overline{\sigma} = f_u / f_y \tag{6}$$

Many experimental results are available for the flexural buckling of stainless steel hollow sections (Theofanous & Gardner 2009, Talja 2002, Ala-Outinen &

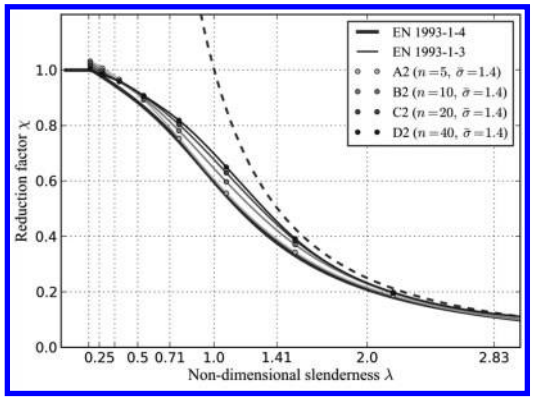

Figure 9. Calculated buckling curves of press-braked sections in torsional-flexural buckling.

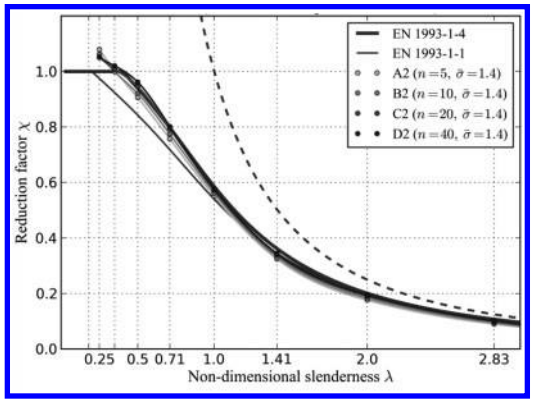

Figure 10. Calculated buckling curves of cold-rolled hollow sections in flexural buckling.

Oksanen 1997, Gardner & Nethercot 2004, Hyttinen 1994, Liu & Young 2003, Talja & Salmi 1995, Young & Liu 2003, Rasmussen & Hancock 1990, Ellobody & Young 2005). The example in Figure 13 shows collected results of major axis flexural buckling with n factor approximately 10 plotted against the predicted curve.

The interested reader may refer to the paper published in the proceedings of 4th International Experts Seminar (Hradil & Talja 2012) for more results of overall buckling.

5 SUMMARY

The computational tool was developed in VTT Technical Research Centre of Finland to simulate laboratory tests of cold-rolled, press-braked and welded members from metallic materials. Several predictive models for the effect of fabrication in form of enhanced material properties and residual stresses were included. The tool automatically generates finite element models for the geometrically and materially nonlinear analysis with initial imperfections (GMNIA), executes the calculation and evaluates the results provided by Abaqus solver. Therefore it is very suitable for parametric studies and optimization tasks.

We used this tool to predict buckling curves of cold-rolled hollow sections, press-braked lipped channels and welded I-sections in flexural, torsional-flexural

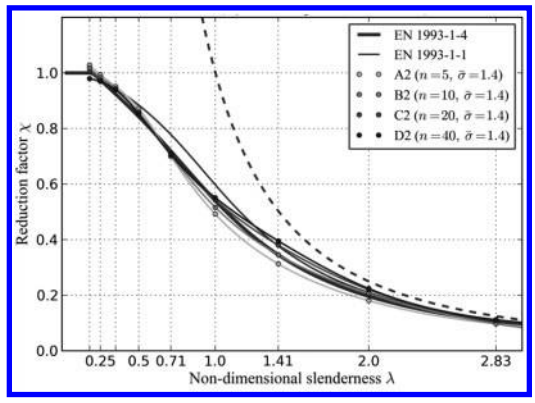

Figure 11. Calculated buckling curves of welded sections in flexural buckling.

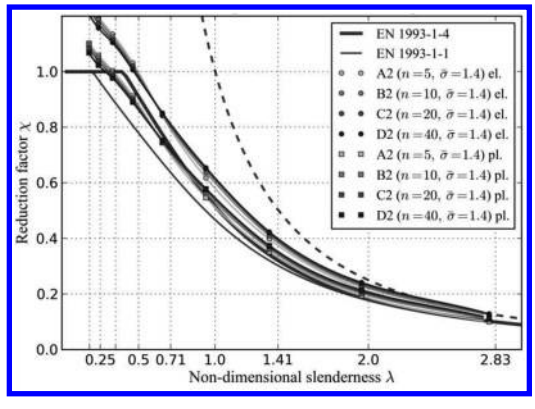

Figure 12. Calculated buckling curves of welded sections in lateral-torsional buckling (elastic and plastic design).

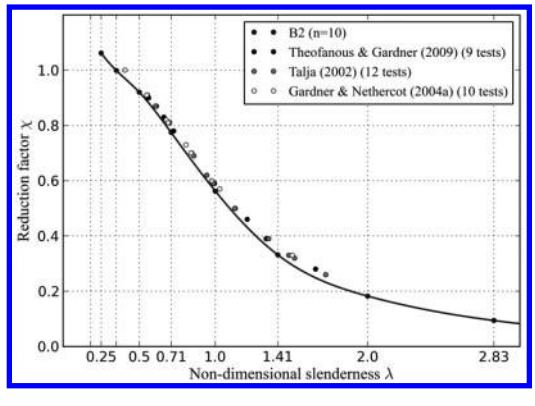

Figure 13. Experimental results of cold-rolled hollow sections in major axis flexural buckling and $n = 10$.

and lateral-torsional buckling. The curves generated by numerical calculations showed different levels of sensitivity to the variation of flat material's nonlinear factor *n*. The reasons for this behavior include the fabrication-related material changes in cold-formed corners and residual stresses from welding and forming. Currently, the finite element analysis is the only numerical method able to take this effect fully into account if the material changes and residual stress levels are correctly predicted.

The degradation curves of presented in this study can be a great source for the future development of predictive equations for the nonlinear factor *n* of the fabricated sections. Moreover, it was recognized that the material nonlinearity of sections that are not significantly affected by the fabrication can lead to different buckling curves for each *n*.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Community's Research Fund for Coal and Steel (RFCS) under Grant Agreement No. RFSR-CT-2010-00026, Structural Applications of Ferritic Stainless Steels.

Experiments on ferritic stainless steel columns in fire

B. Rossi & J.M. Franssen
University of Liège, Belgium

N. Tondini
University of Trento, Italy

ABSTRACT: This paper presents the performance of ferritic stainless steel 1.4003 hollow section columns when exposed to fire loading. Three column tests were carried out in the framework of the RFCS project named Structural Applications of Ferritic Stainless Steels (SAFSS, RFSR-CT-2010-00026). Tubular thin-walled members were considered in this study because structural applications of ferritic stainless steels generally incorporate such profiles. Two cross-section geometries were selected: a square hollow sections (SHS) $80 \times 80 \times 3$ mm (the columns having nominal lengths of 3000 mm and 2500 mm, respectively); and a Rectangular Hollow Section (RHS) $120 \times 80 \times 3$ mm, (2500 mm long). Fire loading was applied under a constant concentrically compressive load. Identical columns tests at room temperature are also reported.

1 INTRODUCTION

The Steel Construction Institute (SCI) is currently coordinating a three-year European study into the structural applications of ferritic stainless steels (SAFSS, RFSR-CT-2010-00026) with the aim of increasing their use in load-bearing structures. The other partners are AcerInox (Spain), Aperam (France), Arup (UK), Institute of Metals and Technology (IMT) (Slovenia), Outokumpu Stainless Oy (Finland), Universitat Politechnica de Catalunya (UPC) (Spain) and VTT Technical Research Centre of Finland (Finland), as well as University of Liège as a subcontractor. The project includes material and member testing as well as analytical and numerical studies. Three target applications most suited to ferritic stainless steels have been identified: lattice roof trussed and space frame structures, exposed decking in composite floor systems and signage and security structures. The final aim of the project is to provide design guidance to practitioners for the specification of ferritic stainless steels in structures. The work packages include studies into: (*i*) Mechanical properties; (*ii*) Structural performance of light gauge members; (*iii*) Structural performance of steel decking in composite floor systems; (*iv*) Structural performance at high temperatures; (*v*) Structural performance of bolted and screwed connections; (*vi*) Structural performance of welded connections; (*vii*) Corrosion resistance; (viii) Design guidance and implementation into Eurocode 3. The study focuses on five grades with varying levels of corrosion resistance: 1.4003, 1.4016 (AISI 430), 1.4509 (AISI 441), 1.4521 (AISI 444) and 1.4621.

Work package (*iv*) seeks to obtain information on the performance of structural members when exposed to fire loading. Strength and stiffness retention factors have been derived from tensile tests carried out under isothermal and anisothermal conditions (for temperatures ranging from 25°C to 1000°C). The test data obtained will be employed to establish stress-strain relationships in accordance with the stainless steel model in EN 1993-1-2 Annex C (2005). In addition, a number of loaded member tests subject to fire loading have been carried out in order to calibrate a numerical model. Trusses and space frames made of tubular thin-walled members are typical structural typologies where ferritic stainless steel is employed. As a result, the tests focused on profiles used in these types of structures, which were tested under concentric compressive load. Three fire tests on SHS and RHS columns of varying global slenderness were carried out. In order to fully identify the effects of fire loading, identical columns were also tested at room temperature. In addition, mechanical properties at room temperature were established by means of tensile tests on material coupons extracted from members.

During this project, numerical simulations will also be performed to reproduce the test results, perform parametric analyses and assess the level of reliability of codified and new predictive models such as Ng & Gardner (2007), Uppfeldt et al. (2008), Lopes et al. (2010) and Lopes et al. (2012), in which the results of tests and numerical models are analyzed and used to derive new design models for stainless steel columns and beams-columns in fire.

2 SPECIMEN GEOMETRY

Two cross-section dimensions were selected: a square hollow sections (SHS) $80 \times 80 \times 3$ mm and a rectangular hollow section (RHS) $120 \times 80 \times 3$ mm. The cross-section areas were calculated on the basis

Table 1. Cross-section dimensions.

#	1	2	3
Section [mm]	80 × 80 × 3	80 × 80 × 3	120 × 80 × 3
Cross-section measured dimensions [mm]	$t_{av} = 2.87$ $B = 79.6$ $H = 79.2$	$t_{av} = 2.82$ $B = 79.2$ $H = 79.8$	$t_{av} = 2.97$ $B = 79.4$ $H = 119.5$
A [cm^2]	8.5	8.4	11.2
Massivity factor [m^{-1}]	338	342	329

Table 2. Mill certificate data (from Stalatube).

Section	80 × 80 × 3	120 × 80 × 3
$\sigma_{0.2}$ [MPa]	336.0	329.0
$\sigma_{1.0}$ [MPa]	360.5	350.0
σ_{ult}[MPa]	484.5	468.0
ε_{ult}[%]	42.5	37.0

of an average measured corner internal radius R_i of 4.0 mm for the 80 × 80 × 3 sections and 3.86 mm for the 120 × 80 × 3 section (Table 1); where t_{av} is the average of the thicknesses of the four faces.

The material was the ferritic 1.4003 stainless steel grade. At room temperature, this grade exhibits mechanical properties similar to those of traditional carbon steel. The main room-temperature mechanical characteristics of this grade, according to EN 10088-2 (2005), are: (i) 0.2% proof strength $\sigma_{0.2\%} \geq 280$ MPa, (ii) elongation after fracture $\varepsilon_{ult} \geq 20\%$ and (iii) ultimate tensile strength $\sigma_{ult} = 450$ to 650 MPa. The specimens were supplied by the steelwork company Stalatube. The mill certificate data are provided in Table 2.

3 TESTS AT ROOM TEMPERATURE

3.1 *Tensile coupon tests*

The material mechanical behavior was tested at room temperature by the steelwork company Aperam. For each section size, three tensile coupon tests were performed in accordance with EN 10002 (2004). The coupons were extracted from each of the three faces: namely 90°, 180° and 270°, as illustrated in Figure 1. The face that included welding was excluded. The average tensile coupon tests characteristics are provided in Table 3.

The sections considered herein are manufactured at ambient temperature and hence undergo plastic deformations, which result in an increase in yield stress and a reduction in ductility. Square and rectangular hollow sections are first formed into a circular section that is subsequently crushed into a square or a rectangular cross-section. Materials, such as stainless steel, with nonlinear stress-strain behavior and significant strain

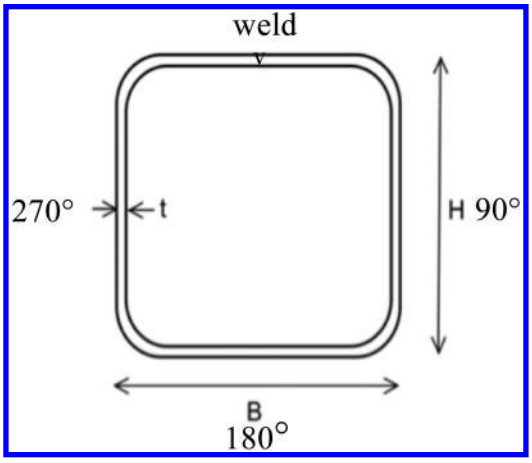

Figure 1. Notations for the cross-section dimensions.

Table 3. Average tensile coupon tests results.

Section	80 × 80 × 3	120 × 80 × 3
$\sigma_{0.2}$ [MPa]	458.7	437.2

E_0 (MPa)	193	194

hardening show a more pronounced response to cold working, Rossi et al. (2013). Presently, compared to the mill certificate data, the tensile coupon tests indicate that the flats experienced significant strain hardening.

3.2 *Column tests*

Firstly, three column tests were performed at room temperature in order to obtain the compressive axial capacities and the failure modes. The out-of-straightness of the four faces was also measured and this was the only indication of the initial global imperfection. It is worth pointing out that the maximum amplitude of the out-of-straightness was less than 1 mm for the three columns that were tested at ambient temperature.

In order to be fully in contact with the end plates of the testing machine, the specimen ends were machine cut; the total length of each column resulted: $L_{\#1} = 2962.5$ mm, $L_{\#2} = 2473.5$ mm, $L_{\#3} = 2475$ mm, respectively. Each column was concentrically loaded using a Schenk hydropolus, the maximum capacity of which is 2500 kN. The machined ends of the columns allowed for a perfect contact with the loading device. Full-restrained boundary condition is achieved during the tests. The loading was controlled by displacement with a speed of 0.5 mm/min. Both axial and transversal displacements were measured. The global flexural transversal displacements in two perpendicular directions were measured using extensometers placed at

mid-height of the column. These main features and the results of the tests are shown in Table 4. All the three columns failed in the same way, by combination of local buckling and global flexural buckling.

4 FIRE TESTS

4.1 *Elevated temperature material mechanical properties*

Elevated temperature material properties of stainless steel alloys are reported in the current provisions of EN 1993-1-2 (2005). A consistent review is also provided in Gardner et al. (2010): all available test data are analyzed and revised strength and stiffness reduction factors at elevated temperatures for a range of grades of stainless steel (including the ferritic grade 1.4003) have been proposed. In the frame of the aforementioned RFCS project, strength and stiffness retention factors will be derived from the results of tensile tests carried out under isothermal and anisothermal conditions. They will be made available in the final technical report of the project RFSR-CT-2010-00026.

4.2 *Specimen geometry, boundary conditions and loading protocol*

Three columns were selected and tested under fire in a vertical wall furnace (Figure 2): i) two square hollow sections (SHS) 80 × 80 × 3 mm having nominal lengths of 3000 mm and 2500 mm, respectively; and ii) a rectangular hollow section (RHS) 120 × 80 × 3 mm, 2500 mm long. This choice entailed the SHS to be classified as class 2 according to the EN1993-1-4 (2006) and the RHS as class 4.

From a behavior at elevated temperature viewpoint, the three columns have a massivity factor that is fairly the same and rather high (Table 1). The actual dimensions are reported in Table 1. For columns #1 and #2, the maximum out-of-straightness of the four faces was less than 1 mm. Only for column #3, a maximum amplitude of the out-of-straightness equaling 5.0 mm (i.e. about L/500) was detected at mid-height.

The specimens were welded to 20 mm thick end plates made of stainless steel grade 1.4307 and holes for bolts were allowed for to ensure a full degree of fixity at both column ends. The welding wire was made of

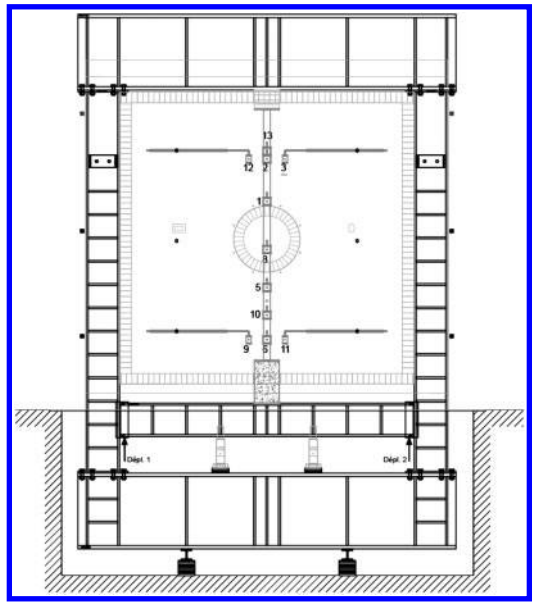

Figure 2. Schematic elevation of the vertical furnace.

1.4430 stainless steel grade. The depth of the welded lips was 5.0 mm thick. The interface between the plates and the concrete blocks on which the plates were bolted was filled with a fine grain temperature resistant plaster to guarantee an optimal contact with the plate. Full-restrained boundary conditions were imposed. The supports made of concrete were then covered with ceramic fiber. Therefore, the heated length reduced of approximately 50 mm (the fiber is 25 mm thick).

The distribution of the air temperature in the furnace was measured by using pyrometers (plate thermometers) located at 11 points around the column: 7 coming into the furnace through the closing wall and 4 located behind the column coming into the furnace through the brick wall where burners are located (Figure 2). They provided the air temperature at a distance of 100 mm from the steel surface. No thermocouples were installed on the specimens because it was reckoned that due to the small thicknesses, the temperature of steel at failure could be sensibly considered equal to that of air.

The load protocol followed the EN1363-1 provisions (2001), which entail to maintain the load constant at least during 15 minutes, time after which the ISO 834 heating curve was applied, with the load being maintained constant until failure.

In detail, the tests began by applying the static loading at ambient temperature until 30% of the design load $N_{b,Rd}$ calculated according to EN1993-1-4 (2006) (see Table 5).

In this table, the design load is calculated on the basis of a yield strength equal to 350MPa. After the static loading at ambient temperature was applied, the fire test began according to the ISO 834 fire curve. It is worth pointing out that, according to the EN1363-1 provisions (2001), *time zero* is taken as the time

Figure 3. Left to right – Seven pyrometers located at the front side of the column through the furnace closing device; four pyrometers located at the back side of the column.

Table 5. Applied static load at high temperature.

#	1	2	3
Calculated $N_{b,Rd}$ [kN]	239	260	336
Applied load [kN]	72	78	100

at which one pyrometer inside the furnace reaches 50°C. The failure time was defined from $t = 0$ to the time when the displacements increased with vertical asymptote.

It is important to mention that, as described before, a closing wall was necessary in order to seal the wall furnace during the tests (Figure 2). This means that a gradient of temperature may develop horizontally inside the furnace, causing the columns to get warmer on the side toward the hot bricks composing the furnace wall, the one in which the gas burners lay. This gradient may influence the direction of buckling and the overall behavior, Tondini et al. (2013).

4.3 *Main tests results*

In Figure 4, the main result in terms of Net vertical displacement versus time for column #1 is presented. It is possible to observe that the axial displacement was first positive owing to elastic shortening of the column at ambient temperature. Then, when the fire test began it became negative because of thermal expansion. The time of failure occurred at 12 min 9 s after *time zero* and at the air temperature of 709.4°C.

The failure mode involved the formation of a main plastic hinge at the column centre and, less developed, at about a quarter and at three quarters of the height. Thus, full *fixed-end* boundary conditions seemed to be achieved.

Similar considerations as those made for column #1 can be drawn for column #2 too. However, in this test the plastic hinge at the top of the column was

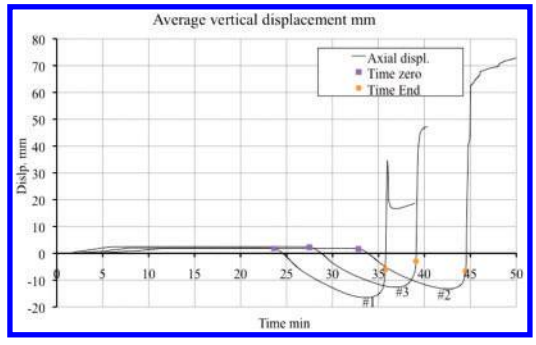

Figure 4. Average axial displacement versus time for column #1.

Figure 5. Failure mode for specimen #1 (3 m long).

more developed than in the previous test. The time of failure occurred at 12 min after *time zero* and at air temperature of 707.7°C.

For column #3 the time of failure occurred at 11 min 51 s after *time zero* and at the air temperature of 705°C. Thus, in terms of fire resistance it exhibited a similar behavior as the one experienced by column #1 and #2. As expected, it failed around its weak axis. The mode of failure was characterized by the formation of two clear plastic hinges (approximately at the top and at mid-height), as shown in Figure 6. The explanation of such a behavior is given in Section 4.4.

From the three tests it is possible to observe that the fire resistance was fairly the same, i.e. t_{tests}. This was expected since the massivity factors were very similar among the specimens (330–340 m^{-1}) as well as the applied load ratio ($0.3N_{b,Rd}$). Interesting to note that even though column #3 had the lowest massivity factor its fire resistance was the lowest. This is explicable because of a higher initial imperfection.

4.4 *Analysis of the effects of temperature gradients in the member and their influence on the failure mode*

In this experimental campaign, a *fixed-end* boundary conditions (no lateral displacements nor rotation

Figure 6. Failure mode for column #3.

and warping) was achieved. Theoretically, in full-restrained conditions, failure would occur with an almost simultaneous formation of three plastic hinges located at the top section, at the mid-height section and at the bottom section of the column. However, in the tests it was observed the formation of two plastic hinges – at the top section and at the mid-height section – rather than three. This could be due to the fact that full-restrained conditions were not achieved, above all at the base section where in every test no clear plastic hinge formed.

In fact, the main reason of the observed failure modes lies elsewhere. By analyzing the data of the

Table 7. Axial resistance at three sections along the height in the last 30s for each test.

#	1	2	3
Top section	80.5	81.2	98.8

Bottom section	97.9	97.1	121.4

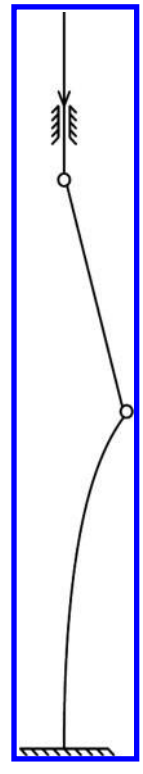

Figure 7. Failure mode of columns owing to a temperature gradient along the height of the column.

tests it was found that the temperature in the furnace was neither perfectly uniform along the height of the columns, nor in a horizontal plane, as already observed in Tondini et al. (2013).

In particular, the top of the column was, in all tests, warmer, whereas the bottom end was always colder with a temperature variation along the height of averagely 35°C–40°C in the last 30s of the test, i.e. close to failure.

In the horizontal plane, at the top, the face towards the brick wall was warmer of about 22°C–26°C than the face towards the closing wall; at mid-height basically no horizontal gradient appeared and; at the bottom, a difference of about 14°C–24°C between the brick wall side (hotter) and the closing wall side (colder) established.

On the basis of these measured temperatures, the reduction factors for yield strength of stainless steel according to EN1993-1-2 (2005) were computed at

the top, at mid-height and at the bottom sections of each column in the last 30s of each test for every faces composing the section. Each face was assumed at constant temperature based on the closest pyrometer. For the faces on the sides where no pyrometer was located the average temperature between the furnace wall face and closing wall face was taken. By doing this it was possible to estimate the axial resistance of the column at the three sections along its height by taking into account temperature gradients. The experimental yield strength was considered (see Table 3).

On the basis of these calculations, it was possible to observe that, owing to the colder temperature at the bottom end, the relative estimated average axial resistance in the last 30 s was significantly higher than the axial resistance at mid-height and even larger with respect to that at the top section, up to 23% higher for column #3. Moreover, the estimated axial resistances at the bottom end near failure were still well higher than the applied loads; whereas the axial resistances in the other sections were close to them. This means that the plastic hinge at base did not form and failure occurred due to the mechanism shown in Figure 7 owing to loss of resistance caused by elevated temperatures associated with second-order effects.

For column #1, the plastic hinge at the top did not clearly develop because the test was stopped soon after the first signs of instability whilst the others were pushed further.

5 CONCLUSIONS

Three fire tests on thin-walled columns made of ferritic stainless steel 1.4003 were performed. Two cross sections and two lengths were taken into account. All columns were loaded with a concentric axial compression up to 30% of the design $_{Nb.Rd}$ computed according to EN1993-1-4 (2006) and subsequently heated according to the ISO834 time-temperature curve. Full-restrained boundary conditions were imposed. Due to similar massivity factors and applied load ratios the fire resistance was fairly the same: about 12 minutes. The failure mode consisted of two plastic hinges and it was caused by the temperature gradient along the height developed inside the furnace

Buckling response of ferritic stainless steel columns at elevated temperatures

S. Afshan & L. Gardner
Imperial College London, London, UK

N.R. Baddoo
The Steel Construction Institute, Ascot, UK

ABSTRACT: This paper presents a numerical study on the buckling behaviour of ferritic stainless steel columns in fire. Finite element models were developed and validated against existing test results to predict the elevated temperature non-linear response of ferritic stainless steel columns. A total of nine austenitic and three ferritic stainless steel column tests were replicated using the finite element analysis package ABAQUS. Parametric studies were performed to investigate the effects of variation of load level and global slenderness on the elevated temperature buckling response of ferritic stainless steel columns, and to extend the range of structural performance data. Both the experimental and numerical parametric study results were compared with the current design rules in EN 1993-1-2 (2005) and recent proposed modifications thereof by Ng and Gardner (2007), Uppfeldt et al. (2008) and Lopes et al. (2010).

1 INTRODUCTION

The characteristics of stainless steel, such as inherent durability, good mechanical properties and ease of maintenance, make it ideally suited for many civil engineering applications. Austenitic stainless steels, containing 17–18% chromium and 8–11% nickel, are the most widely used grades. However, the price of the alloying elements, in particular nickel, represents a major disincentive as far as material selection is concerned.

Hence, stainless steel grades with chemical compositions that offer similar benefits to the austenitics, but with lower nickel content, have been developed. Ferritic stainless steels, with little or no nickel content, have found applications in the automotive industry, road and rail transport, power generation, and mining. However, ferritic stainless steels have scarcely been used in structural applications. The aim of this study is to explore the fire resistance of ferritic stainless steel columns and assess the suitability of the current design provisions to this family of stainless steel.

2 REVIEW OF FIRE TESTS ON FERRITIC STAINLESS STEELS

The Steel Construction Institute is co-ordinating an ongoing RFCS project called Structural Applications of Ferritic Stainless Steels (RFSR-CT-2010-00026). This project includes an investigation into the performance of ferritic stainless steel members in fire. Experimental studies, focusing on the buckling response of columns made of grade EN 1.4003 ferritic stainless steel in fire were carried out at the University of Liège (Rossi, 2013). Elevated temperature material tests were also conducted and are reported in Manninen and Säynäjäkanas (2012). These results are utilized herein for the development and validation of the numerical models.

2.1 *Material properties*

Isothermal tensile coupon tests on material cut from EN 1.4003 cold-rolled sheets were performed in the temperature range of 20–1000°C (Manninen and Säynäjäkanas, 2012). Elevated temperature material properties are expressed as a portion of the corresponding room temperature properties. This leads to the use of strength and stiffness reduction factors for key parameters i.e. the elevated temperature 0.2% proof stress, ultimate tensile stress and Young's modulus. The stiffness retention factor $k_{E,\theta}$ is defined as the elevated temperature initial tangent modulus E_θ, normalized by the initial tangent modulus at room temperature E. The strength retention factors $k_{0.2,\theta}$ and $k_{u,\theta}$ are defined as the elevated temperature 0.2% proof stress and ultimate tensile stress normalized by their respective room temperature values. The $k_{2,\theta}$ factor is also used for determining the material strength at 2% total strain $\sigma_{t2,\theta}$, as defined in Annex C of EN 1993-1-2 (2005). Figures 1–2 show the measured reduction factors for the 0.2% proof stress and the ultimate tensile stress, respectively. The corresponding EN 1993-1-2 (2005) reduction factors for grade EN 1.4003 stainless steel and structural carbon steel are also depicted. EN 1993-1-2 (2005) provides a single set of stiffness

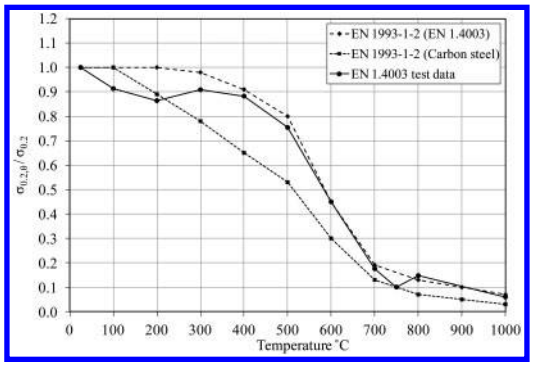

Figure 1. 0.2% proof stress reduction factor.

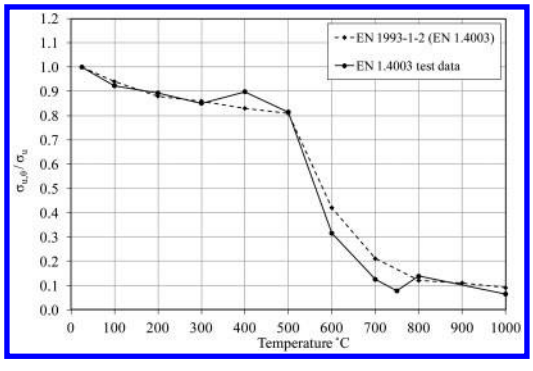

Figure 2. Ultimate tensile stress reduction factor.

reduction factors, common to all stainless steel grades. The test results obtained showed that in fact the elevated temperature stiffness of ferritic stainless steel (grade EN 1.4003) is somewhat in between that of the austenitics and structural carbon steel. The measured strength reduction factors are in good agreement with the EN 1.4003 codified values.

2.2 *Flexural buckling*

A total of three full scale fire tests on ferritic EN 1.4003 stainless steel tubular columns were conducted (Rossi, 2013). A summary of the test details, including nominal section size, specimen length, applied loads and critical furnace temperatures are provided in Tables 1. All columns were fixed at both ends. The manufacturing process of the tested columns involved cold-rolling into a circular tube followed by sizing into the final cross-section geometry. All fire tests were performed anisothermally, whereby the load – taken as approximately 30% of the specimen's codified room temperature buckling resistance – was applied at room temperature and maintained at a constant level while the temperature was increased, following the standard ISO-834 (2002) fire curve, until failure.

3 NUMERICAL MODELLING

The aim of this section is to develop and validate numerical models for predicting the resistance

Table 1. Summary of ferritic column fire tests.

Nominal section size	Length (mm)	Load (kN)	Critical furnace Temperature (°C)
SHS 80 × 80 × 3	3000	72	709.4
SHS 80 × 80 × 3	2500	78	707.7
RHS 120 × 80 × 3	3000	100	705.0

of stainless steel columns in fire. Fire test results from the literature on austenitic (EN 1.4301) stainless steel columns from Baddoo and Gardner (2000) and Ala-Outinen and Oksanen (1997) and ferritic stainless columns (Rossi, 2013) were gathered. These test results were used to validate the finite element models. The development of the numerical models leading into the results of parametric studies is described herein.

3.1 *Validation of numerical models*

3.1.1 *General*

The non-linear finite element analysis package ABAQUS, Version 6.10-1 (2010) was used to replicate the elevated temperature response of column tests from the literature. Shell elements were adopted to simulate the stainless steel tubular hollow section columns as is customary for modelling of thin-walled structures. The four-node doubly curved general-purpose shell element with reduced integration S4R, for the structural model, and D4S, for the thermal model, which has performed well in numerous similar applications (e.g. Ng & Gardner, 2007; To & Young, 2008) were used. A suitable mesh size, providing accurate results with practical computational times, with a minimum of ten elements across each plate was adopted.

The test boundary conditions were replicated by restraining suitable displacement and rotation degrees of freedom at the column ends. All boundary conditions were applied through reference points at the column ends. For the fixed column tests, all the six degrees of freedom of the lower reference point were restrained, while the upper reference point was allowed to move along the column axis and was fixed against all the other five degrees of freedom. To model the pinned end support condition, all degrees of freedom of the lower reference point, except rotation about the column minor axis, were fixed, while the upper reference point was free to displace along the column axis and rotate about the column minor axis. Measured geometric dimensions were used in each model to replicate the corresponding test behaviour.

3.1.2 *Elevated temperature material properties*

The performance of finite element models is highly sensitive to the prescribed material parameters, hence making an accurate representation of the material characteristics essential. In Baddoo and Gardner (2000), isothermal material tests at temperatures 20–1000°C were performed on the sheet material used to fabricate

the stainless steel sections. Ala-Outinen and Oksanen (1997) carried out anisothermal tensile tests on coupons cut from the flat faces of cold-rolled sections and the results were converted into stress-strain curves at temperatures 20–900°C. The measured material stress-strain curves at elevated temperatures were utilised in the development of the finite element models. For the ferritic column tests, the material model proposed by Gardner et al. (2010), along with the measured elevated temperature reduction factors, provided in Section 2, and the room room temperature material properties were used. ABAQUS requires that the material properties are specified in terms of true stress σ_{true} and log plastic strain ε^{p}_{ln}, which may be derived from the nominal engineering stress–strain curves as defined in Eqs. (1) and (2), respectively, where σ_{nom} and ε_{nom} are engineering stress and strain, respectively and E is the Young's modulus.

$$\sigma_{true} = \sigma_{nom}(1+\varepsilon_{nom}) \quad (1)$$

$$\varepsilon^{p}_{ln} = \ln(1+\varepsilon_{nom}) - \frac{\sigma_{true}}{E} \quad (2)$$

For austenitic stainless steel, the thermal properties from EN 1993-1-2 (2005) were incorporated in the models. The thermal properties of ferritic stainless steels are different from the austenitic stainless steels and are not covered in EN 1993-1-2 (2005). Thermal expansion data were sourced from EN 10088-1 (2005) and specific heat and thermal conductivity data were obtained from the StahlDat SX (2011) database.

3.1.3 *Corner material modelling*

Stainless steel exhibits a pronounced response to cold-work, resulting in the corner regions of cold-formed sections having significantly higher 0.2% proof strengths than the flat faces. For the ferritic column tests, corner material properties were measured at room temperature. For the austenitic stainless steel tests, where no corner material properties were reported, Cruise and Gardner's (2008) predictive equations for the strength enhancement in the corner regions of cold-rolled and press-braked stainless steel sections were used to determine the room temperature 0.2% proof strength of the corner regions.

The modified compound Ramberg-Osgood material model proposed by Gardner et al. (2010) was used to obtain a continuous prediction of the stress-strain response of the cold-worked corner regions at elevated temperatures. It has been shown that the beneficial effect of cold-work is lost at high temperatures of about 800°C and above (Ala-Outinen & Oksanen, 1997 and Chen & Young, 2006). Hence, in order to allow for this in the numerical models, the 0.2% proof strength reduction factors for temperatures of 800°C and above were reduced by 20% in relation to those used for the sheet material provided in EN 1993-1-2 (2005) as recommended by Gardner et al. (2010). The corner strength enhancement was confined to the corner region for the press-braked sections, while for the cold-rolled sections, a uniform strength enhancement for the corner region plus an extension of 2t, where t is the material thickness, beyond the corner radius into the flat faces of the section was used (Cruise & Gardner, 2008).

3.1.4 *Initial geometric imperfections*

Initial geometric imperfections are introduced into structural sections during production, fabrication and handling and can significantly influence structural behaviour. Imperfection shapes of the form of the lowest global and local buckling modes obtained from a linear elastic eigenvalue buckling analysis were utilized. A global imperfection amplitude of L/2000, where L is the column total length, was adopted for the austenitic stainless steel columns, while the test measured imperfection amplitudes were used for the ferritic stainless steel columns. The amplitude predicted by the Dawson and Walker model as adapted for stainless steel (Ashraf et al., 2006), given by Eq. (3) was used for the local imperfection amplitude w_0, where t is the plate thickness, $\sigma_{0.2}$ is the material 0.2% proof stress and σ_{cr} is the plate critical elastic buckling stress.

$$w_0 = 0.023t(\sigma_{0.2}/\sigma_{cr}) \quad (3)$$

3.1.5 *Analysis procedures*

Three types of numerical analyses were performed for each model – a linear elastic buckling analysis to determine the buckling mode shapes, and a heat transfer analysis to obtain the temperature development in the columns, were initially carried out. The results were subsequently incorporated into a geometrically and materially non-linear stress analysis. The non-linear stress analysis was performed in two steps to simulate the anisothermal loading condition of the column fire tests. In the first step, the load was applied to the top of the column, through its reference point, at room temperature. This load was maintained at a constant level during the second step while the evolution of the temperature with the fire exposure time was applied. For the case of the austenitic stainless steel columns, no heat transfer analysis were carried out, as the steel surface temperature was measured during the test and was directly imported into the models.

3.1.6 *Validation results*

A total of nine austenitic stainless steel columns and three ferritic stainless steel columns were modelled. The fire performance criteria set out in EN 1363-1 (1999) for vertically loaded members, stating that a column is deemed to have failed when both the vertical contraction and the rate of vertical contraction have exceeded L/100 mm and 3L/1000 mm/min, respectively, where L is initial column height in mm, were used to determine the critical failure temperature. A summary of the comparison between the test and FE results is provided in Table 2. For the austenitic stainless steel columns, the FE models give a mean FE/test critical temperature of 0.90 and a coefficient of variation of 0.03, and provide safe-side predictions of the fire resistance of the test column specimens.

Table 2. Comparison of critical temperatures between test and FE results.

Nominal section size	Classification	Critical temperature (°C) Test	FE	FE/Test
RHS 150 × 100 × 6	Class 1	801	757	0.91
RHS 150 × 75 × 6	Class 1	883	814	0.92
RHS 100 × 75 × 6	Class 1	806	744	0.92
SHS 40 × 40 × 4 (1)	Class 1	872	750	0.86
SHS 40 × 40 × 4 (2)	Class 1	579	502	0.87
SHS 40 × 40 × 4 (3)	Class 1	649	608	0.94
SHS 40 × 40 × 4 (4)	Class 1	710	646	0.91
SHS 40 × 40 × 4 (5)	Class 1	832	722	0.87
SHS 40 × 40 × 4 (7)	Class 1	766	681	0.89
SHS 80 × 80 × 3	Class 4	709	722	1.02
SHS 80 × 80 × 3	Class 4	708	713	1.01
RHS 120 × 80 × 3	Class 4	705	705	1.00

This under-prediction may be due to the application of uniform temperature through the thickness of the column section. In addition, all column tests were partially protected near the column ends to prevent the effect of sudden temperature variation at the start of the test, leaving a smaller exposed length than the full length used in the FE simulations. For the ferritic stainless steel columns, the FE and test results are in very good agreement with a mean FE/Test critical temperature of 1.01 and a coefficient of variation of 0.01. From the comparison of the test and FE results, it is concluded that the described FE models are capable of safely replicating the non-linear, large deflection response of the stainless steel columns in fire.

3.2 *Parametric studies*

Having validated the FE models, a series of parametric studies was performed to investigate the influence of variation of global slenderness and load level on the fire performance of ferritic stainless steel columns. Two section sizes, namely SHS 80 × 80 × 6 and RHS 120 × 80 × 6, were employed. The same modelling procedures as explained in the previous sections were employed. The global imperfection amplitude was taken as L/1000, where L is the column length, in accordance with the permitted out-of-straightness tolerance in EN 1090-2 (2008). The local imperfection amplitude was taken as that predicted by Eq. (3). All columns were pin-ended at both ends and were loaded anisothermally. Due to the symmetry in the geometry and the boundary conditions of the analyzed specimens, only half of the section, but over the full length, was modelled. The standard ISO-834 (2002) fire curve was applied to the specimens in the heat transfer model and the temperature development was simulated through the convection, conduction and radiation heat transfer mechanisms. The length of the column specimens was varied from 0.5 m to 3.0 m in order to cover a wide range of member slenderness values.

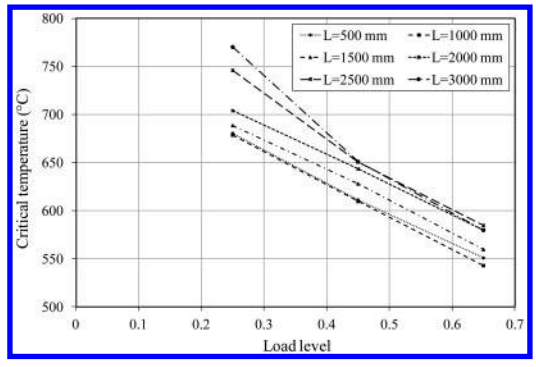

Figure 3. Effect of load level on the SHS 80 × 80 × 6 column critical temperature.

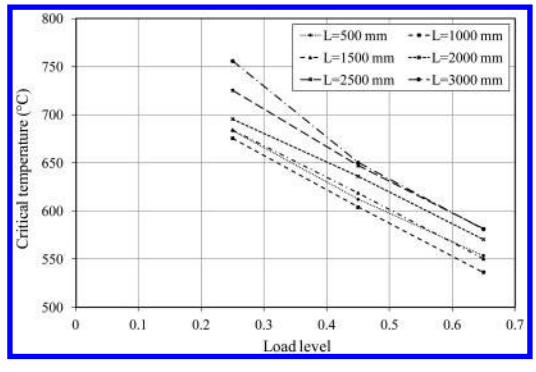

Figure 4. Effect of load level on the RHS 120 × 80 × 6 column critical temperature.

Three different load levels were applied to each column specimen: 25%, 45% and 65% of the room temperature minor axis buckling resistance, determined in accordance with EN 1993-1-4 (2006).

3.3 *Parametric results*

The effect of load level and member slenderness on the fire resistance of ferritic stainless steel columns, in terms of critical temperature, was studied, by fixing the cross-section size to SHS 80 × 80 × 6 and RHS 120 × 80 × 6. In order to focus on the member buckling behaviour, the thickness of the cross-sections was chosen such that both sections are Class 1. The column lengths of 0.5 m to 3.0 m provided a range of room temperature member slenderness $\bar{\lambda} = 0.25$–1.55. The obtained results are shown in Figures 3 and 4 for the SHS 80 × 80 × 6 and RHS 120 × 80 × 6 cross-sections, respectively. As anticipated, the column failure temperature reduces with increased load level. The variation of critical temperature with load level is also dependent on the member slenderness. This is expected as the member slenderness is dependent on the material strength and stiffness and its degradation with temperature.

4 ANALYSIS OF RESULTS AND DESIGN RECOMMENDATIONS

This section presents a comparison of the parametric study results with the existing design rules provided in EN 1993-1-2 (2005) and its modified versions proposed by Ng and Gardner (2007), Uppfeldt et al. (2008) and Lopes et al. (2010). Based on EN 1993-1-2, the design fire resistance of stainless steel structures, assuming a uniform temperature distribution, is based on the room temperature design resistance, supplied in EN 1993-1-4 (2006), modified to take account of the mechanical properties at elevated temperature and with a revised buckling curve. Since in fire situations higher strains than at room temperature are acceptable, EN 1993-1-2 uses the elevated temperature stress at 2% total stress, $\sigma_{t2.0,\theta}$ for the design of columns with Class 1, 2 and 3 cross-sections and the 0.2% proof stress $\sigma_{0.2,\theta}$ for Class 4 cross-sections. In classifying cross-sections, a reduced value for the strength parameter $\varepsilon = 0.85\ (235/f_y)^{0.5}$ is used to allow for variation of material strength with temperature. This definition is not consistent with its room temperature definition for stainless steel defined in EN 1993-1-4 (2006) as $\varepsilon = [(235/f_y)(E/210000)]^{0.5}$. Furthermore, it does not reflect the actual variation of strength and stiffness of stainless steel at elevated temperatures. EN 1993-1-2 (2005) also allows the effective section properties of Class 4 sections in fire to be based on room temperature design. Ng and Gardner (2007) recommended that the $\sigma_{0.2,\theta}$ strength should also be used for Class 3 sections as local buckling is expected to occur prior to reaching the 2% strain limit. In addition, it was proposed that the true variation of strength and stiffness should be employed in cross-section classification and in determination of the effective section properties, leading to the ε_θ definitions given by Eq. (4), where $k_{y,\theta}$ is taken as $k_{2,\theta}$ for Class 1 and 2 sections and $k_{0.2,\theta}$ for Class 3 and 4 sections.

$$\varepsilon_\theta = \left[\left(\frac{235}{f_y}\frac{E}{210000}\right)\left(\frac{k_{E,\theta}}{k_{y,\theta}}\right)\right]^{0.5} \quad (4)$$

The fire buckling curve in EN 1993-1-2 is of the same general form as the room temperature buckling curve with the exception of exhibiting no plateau (i.e. $= 0$), including a yield strength dependent imperfection factor ($\alpha = 0.65\ (235/f_y)^{0.5}$) and defining the elevated temperature member non-dimensional slenderness, . Ng and Gardner (2007) proposed a revised buckling curve with the plateau length $\bar{\lambda} = 0.2$ and the imperfection factor taken as $\alpha = 0.55$. Uppfeldt et al. (2008) adopted Ng and Gardner's (2007) recommendations for the cross-section classification and proposed to use the same buckling curve as room temperature, with $\bar{\lambda} = 0.4$ and $\alpha = 0.49$ (for hollow sections), for elevated temperature design, with the plateau length changing as a function of temperature, as given by Eq. (5).

$$\bar{\lambda}_{0,\theta} = \bar{\lambda}_0 \left[\frac{k_{0.2,\theta}}{k_{E,\theta}}\right]^{0.5} \quad (5)$$

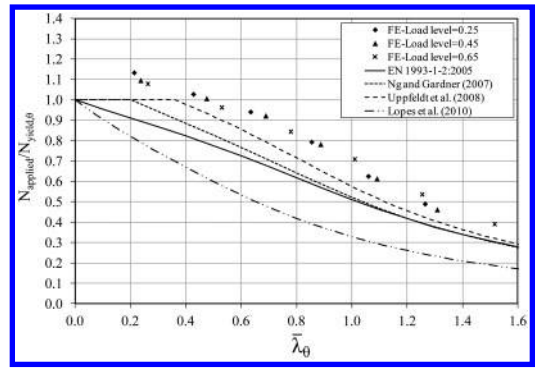

Figure 5. Comparison of SHS 80 × 80 × 6 FE results with the design models.

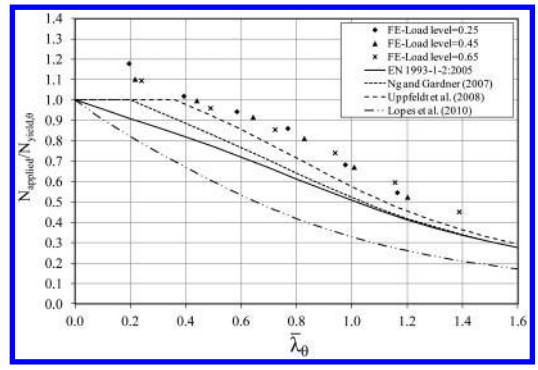

Figure 6. Comparison of RHS 120 × 80 × 6 FE results with the design models.

Based on their numerical study on welded I-section columns in fire, Lopes et al. (2010) modified the EN 1993-1-2 buckling curve such that it provides a good fit to the generated data. The imperfection factor α is defined as a function of temperature, resulting in different buckling curves for different temperatures. Figures 5 and 6 compare the above mentioned buckling curves with an average plateau length = 0.36 for the investigated specimens for the Uppfeldt et al. (2008) model, and an average failure temperature of 635°C for the Lopes et al. (2010) model with the parametric study results, where the applied load, normalized by the elevated temperature yield load based on $\sigma_{0.2,\theta}$ is plotted against the elevated temperature member slenderness.

A preliminary analysis of the results shows that the current EN 1993-1-2 (2005) buckling curve underpredicts the buckling load of ferritic stainless steel columns, while the proposals of Ng and Gardner (2007) and Uppfeldt et al. (2008) provide better predictions. The buckling curves proposed by Lopes et al. (2010) are considerably lower than other studies. This may be due to the section type analysed – welded I-sections which do not benefit from the corner strength enhancements found in cold formed sections and have higher residual stresses. The relative performance of different section types will be considered in future work.

5 CONCLUSIONS

A numerical study investigating the buckling response of ferritic stainless steel columns in fire was presented. A detailed description of the finite element models was provided, which were validated against test results. The results of the parametric study, investigating the effects of variation of load level and global slenderness were presented. Comparisons between the generated data and the existing buckling curves were made.

ABSTRACT: A numerical investigation of cold-formed high strength stainless steel square and rectangular hollow sections in compression has been presented in this paper. A non-linear finite element model that includes geometric and material non-linearities was developed and verified against experimental results. The model was then used for an extensive parametric study to investigate the interaction effects of constituent plate elements on Class 3 slenderness limit and section capacities of cold-formed high strength stainless steel square and rectangular hollow sections in compression. It is shown that the interaction effects of constituent plate elements on cross-section response are quite obvious particularly for slender sections. The design provisions on Class 3 slenderness limit in the EC3 Code and proposed by Gardner and Theofanous are suitable for square hollow sections, but not for rectangular hollow sections since they do not take into consideration of interaction effects of constituent plate element. Therefore, a new Class 3 slenderness limit is proposed in this study, which carefully considers the interaction effects of the constituent plate elements.

1 INTRODUCTION

The use of cold-formed stainless steel tubular members in construction is growing rapidly. Many researches have been carried out to study the structural behaviour of cold-formed stainless steel tubular members. Experimental and numerical investigations have been performed by Rasmussen & Hancock (1993), Young & Hartono (2002), Young & Liu (2003), Gardner & Nethercot (2004a), Young & Lui (2005), Ellobody & Young (2005), Gardner & Theofanous (2008), and Theofanous & Gardner (2009) on cold-formed stainless steel tubular columns. In most of these investigations, the applicability of the existing stainless steel design provisions on Class 3 slenderness limit and effective width formulae for internal elements in compression as well as the column buckling curve for hollow sections have been assessed.

Design rules for cold-formed stainless steel structural members are available including the ASCE Specification (2002) for the Design of Cold-Formed Stainless Steel Structural Members and the EC3 Code (2006) Design of Steel structures, Part 1.4: Supplementary Rules for Stainless Steels. The cross-section classification approach is used in the EC3 Code as a means of codified treatment for local buckling of cross-sections that are partly or fully in compression. However, the interaction of constituent plate elements is not taken into consideration. The EC3 Code treats the plate elements in the cross-section individually and classified according to their width-to-thickness ratios as compared to codified slenderness limits. The cross-section response is assumed to the behaviour of its most slender plate element in the cross-section. However, the interaction effects of constituent plate elements on cross-section response are obvious regarding the slenderness limits and the cross-section ultimate resistances for cold-formed stainless steel square and rectangular hollow sections subjected to compression (Theofanous & Gardner 2009) and also bending (Theofanous & Gardner 2010).

The purpose of this study is firstly to develop an accurate and efficient non-linear finite element model to simulate the cross-section response of cold-formed high strength stainless steel square and rectangular hollow sections in compression. The initial local imperfection and non-linear material properties of the flat and corner portions of the cross-section have been carefully incorporated into the finite element model (FEM). Secondly, a parametric study on a range of cross-section aspect ratios was performed based on the developed FEM. Thirdly, the interaction effects of constituent plate element on cross-section response of cold-formed high strength stainless steel square and rectangular hollow sections in compression are investigated. The design provisions on Class 3 slenderness limit specified in the current EC3 Code (2006), ASCE Specification (2002) and proposed by Gardner & Theofanous (2008) for internal elements in compression are assessed based on the results of the parametric

study. Lastly, a new Class 3 slenderness limit which carefully takes into account of the interaction effects of constituent plate elements is proposed in this study for cold-formed high strength stainless steel square and rectangular hollow sections in compression.

2 SUMMARY OF EXPERIMENTAL INVESTIGATION

The experimental investigation performed by Young & Lui (2005) reported the tests of cross-sections of cold-formed high strength stainless steel square and rectangular hollow sections in compression, which were used to verify the finite element model developed in this study. Table 1 summarizes the measured test specimen dimensions using the nomenclature defined in Figure 1. The material properties of the flat portions of the specimens for each section were determined by tensile coupon tests. Furthermore, the material properties of the corner portions of the specimen have also been determined by tensile coupon tests for section 160×80×3. The measured material properties of the flat and corner portions are detailed in Young & Lui (2005).

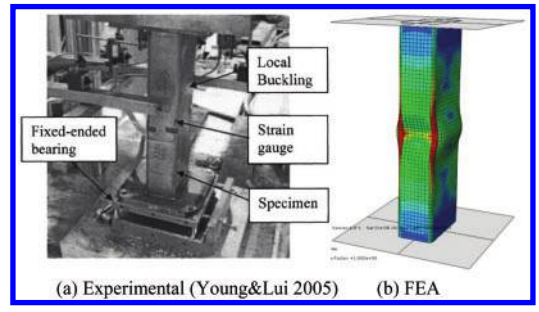

Figure 2. Comparison of experimental and finite element analysis failure mode for specimen RHS200 × 110 × 4.

The columns were compressed between fixed ends, as shown in Figure 2. A servo-controlled hydraulic testing machine was used to apply a concentrated compressive force to the test specimens. Displacement control was used to drive the hydraulic actuator at a constant speed of 0.5 mm/min for all test specimens. The experimental ultimate loads (P_{Exp}) of the specimens are also given in Table 1. The stub column tests are detailed in Young & Lui (2005).

3 NUMERICAL INVESTIGATION

3.1 *Finite element model*

The non-linear finite element program ABAQUS (2008) was used to simulate the cross-section response of cold-formed high strength stainless steel square and rectangular hollow sections in compression. Finite element analysis (FEA) for buckling requires two steps of analysis. The first step is linear perturbation analysis, which was performed on a "perfect" geometry to obtain probable elastic buckling modes of the cross-sections. The second step is non-linear analysis by incorporating both geometric and material non-linearities, which was performed to obtain the ultimate strengths and failure modes of the stub columns.

In the finite element model (FEM), the measured cross-section dimensions and material properties obtained from tensile coupon tests were used. The model was based on the centerline dimensions of the cross-sections. The corners of the cold-formed high strength stainless steel sections were carefully modeled. The S4R elements are used for all specimens. The finite element mesh used in the model was investigated by varying the size of the elements in the cross-section to provide both accurate results and less computational time. The finite element mesh sizes ranged from 2 × 2 mm (length by width) to 10 × 10 mm were used for the flat portions of the specimen depending on the cross-section size, whereas a finer mesh was used at the corners. The typical finite element mesh of a stub column is shown in Figure 2b.

The axial compressive force was applied by the load transfer plates. The load transfer plates were modeled using analytical rigid plates and the interfaces between

the load transfer plates and the specimen were modeled using the "tie constraint pair". The load transfer plates were the master elements, while the specimen was the salve element of the interface elements in the FEM model. The "tie constraint" ties two surfaces together, which ensure the translational and rotational degrees of freedom identical to the pair of surfaces.
