where the coefficient c_n for $n = 0, 1, 2, 3$ are combination of the coefficients for the same order in w_d of the Chebyshev polynomials.

4 REDUCED-ORDER MODEL

Substituting (32) into (36), we get:

$$\begin{aligned} &w_d^{iv} - \alpha_3 w_d^{vi} - \alpha_1 \int_0^1 \left({w'_s}^2 + 2w'_s w'_d + {w'_d}^2\right) dx\, w_d'' + \\ &- N w_d'' - \alpha_1 \int_0^1 \left(2w'_s w'_d + {w'_d}^2\right) dx\, w_s'' + c\dot{w}_d + \ddot{w}_d = \\ &= \alpha_2 \left(2V_{dc}V_{ac} + V_{ac}^2\right) \eta_0 + \alpha_2 \left(V_{dc}^2 + 2V_{dc}V_{ac} + V_{ac}^2\right) \times \\ &\times \left(w_d \eta_1 + w_d^2 \eta_2 + w_d^3 \eta_3\right) \end{aligned} \quad (37)$$

with $\eta_i = \frac{c_i}{(1-w_s)^{i+2}}$ for $i = 0, \ldots, 3$.

We discretize the continuous problem using the Galerkin decomposition method in order to rule out the spatial dependence in (37), we then assume:

$$w_d(x,t) = \sum_{i=1}^{\infty} \phi_i(x) u_i(t). \quad (38)$$

The spatial functions ϕ_i are picked up in the set of the linear undamped modal shapes. They are the solution of the eigenvalue problem given by (37) assuming an harmonic motion of the form $w_d(x,t) = \phi_n(x) e^{i\omega t}$ and neglecting the terms involving l_n ($i = 0, 1, 2$) and V_{ac}. In this problem the eigenfunction ϕ_n and the eigenvalue ω_n are respectively the nth vibrating mode and its natural (circular) frequency. For the i-th degree of freedom we have:

$$\begin{aligned} &\ddot{u}_i + c\dot{u}_i + K_i u_i + \sum_j C_{ij} u_i u_j + \sum_{j,k} E_{ijk} u_i u_j u_k = \\ &= F_{0i} + F_{1i} u_i + \sum_j F_{2ij} u_i u_j + \sum_{j,k} F_{3ijk} u_i u_j u_k + \\ &+ \sum_{j,k,m} F_{4ijkm} u_i u_j u_k u_m. \end{aligned} \quad (39)$$

To save space the expressions of the coefficients are not reported here, however, they can be easily obtained substituting (38) into (37), multiplying for the function ϕ_i and integrating from 0 to 1.

5 NUMERICAL EXAMPLES

Investigating on the variation of the maximum dimensionless deflection of the microbeam, we can see the nonlinear response of the device increasing the value of $\alpha_2 V_{dc}^2$. In figure 2 it is shown the influence of the parameter involved in the high order elastic theory, namely α_3. Inside this parameter we found the three material length l_n, that underlying the size dependence of material deformation behaviour at the microscale. An increasing value of α_3 moves the curves towards high values of $\alpha_2 V_{dc}^2$ and so staving off the risk of the instability in pull-in regime. The plot display also

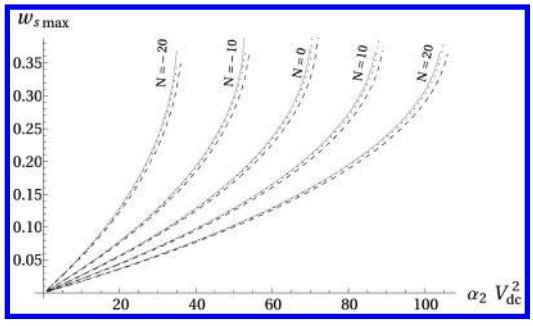

Figure 2. Variation of the maximum dimensionless deflection $w_{smax} = w_s(x = 1/2)$ for different values of axial load. The solid line curve has $\alpha_3 = 0$, while the dotted and the dashed refer respectively to $\alpha_3 = 10^{-6}$ and $\alpha_3 = 10^{-5}$.

Table 1. Hardening effect of α_1 parameter. Data refers on maximum nondimensional deflection with null axial load, $\beta = 0$, $\alpha_3 = 10^{-4}$.

$\alpha_2 V^2$	$\alpha_1 = 0$	$\alpha_1 = 3$	$\alpha_1 = 10$
50	0.168997	0.166576	0.161647
70	0.32668	0.295722	0.262641

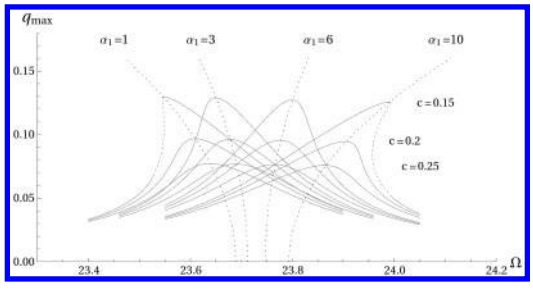

Figure 3. Variation of the nonlinear response for different α_1. The microbeam parameters are $\alpha_3 = 10^{-5}$, $\alpha_2 V_{dc}^2 = 25$, $N = 10$.

the influence of the axial load in both cases of compression and stretch loads. The parameter α_1 is, for a small values of l_n, proportionally to the square of the ratio between the initial gap g and the thickness h. Increasing this parameter there is an hardening effect that moves the pull-in limit towards higher values of $\alpha_2 V_{dc}^2$, as reported in table 1.

Regarding the dynamics, we report some results obtained from both the Runge Kutta numerical integration and the homotopy analysis method (Qian, Ren, Lai, & Chen 2012).

The considered system can present a flexible nonlinear behaviour, since both softening and hardening responses can be found by varying α_1, as shown in figure 3. The figure illustrates the frequency-response curves for different values of mechanical damping and a dynamic voltage of $V_{ac} = 0.1\cos(\Omega t)$. It is also shown, by means of the dotted back-bone curves, that the bending behaviour changes from soft to

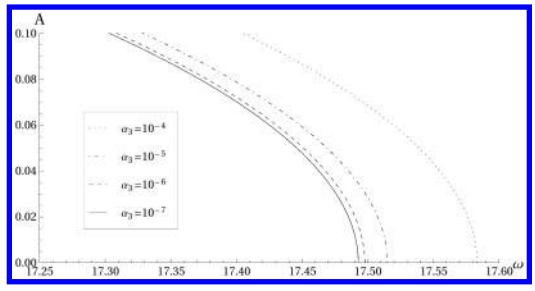

Figure 4. Variation of the nonlinear response for different α_3. Others parameters are: $\alpha_2 V_{dc}^2 = 25$, compressive axial load $N = -10$, $\alpha_1 = 0$.

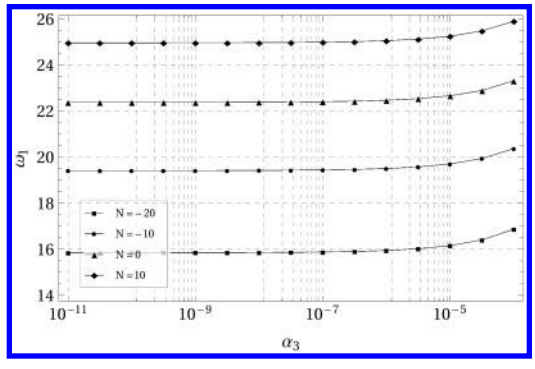

Figure 5. Variation of the first eigenfrequency ω_1 with respect to α_3 for different values of axial load. $\alpha_2 V_{dc}^2 = 0$.

hard increasing α_1. The comparison of the numerical and the analytical back-bone shows an excellent agreement. We investigate on the influence of α_3, the parameter generated by the use of the strain-gradient elasticity theory in the beam modeling. In figure 4, several back-bone curves obtained for different values of α_3, show the variation of the nonlinear frequency responses due to the high-order length scale parameters. It is shown how the influence decreases progressively for low values of α_3. The variation of the first eigenfrequency with respect to α_3 for different values of axial load is shown in figure 5. The plot shows how the influence on ω_1 is reduced decreasing the value of α_3.

6 CONCLUSIONS

We have obtained, by the use of the extended Hamilton's principle, the equation of motion and the corresponding boundary conditions for a clamped-clamped electrically-actuated microbeam, moving from the classical theory of the microbeams. With a modified strain-gradient elasticity theory, applied to a MEMS device, we have studied the influence of the high-order parameters. The static solution has been solved by the differential quadrature method, showing that the non-classical theory modifies the

response. Attention has been focused on the modeling of the nonlinear electric actuation term, involving a new procedure based on the Chebyshev method. The approximation obtained by this method reduces the error at the boundary of the prescribed domain.

Also the dynamic behaviour presents this dependence, as shown by means of both the numerical Runge Kutta results and the homotopic analytical approximated solution. The dynamic analysis has also highlighted, in the nonlinear regime, a multi-stable dynamic behaviour of the device.

Peak shear stress distribution in finite element models of concrete slabs

E.O.L. Lantsoght, C. van der Veen & J.C. Walraven
Concrete Structures, Delft University of Technology, Delft, The Netherlands

A. de Boer
Ministry of Infrastructure and the Environment, Utrecht, The Netherlands

ABSTRACT: For the evaluation of existing slab bridges in the Netherlands, the governing shear stress resulting from composite dead load and live loads is determined from a finite element model. It is necessary to determine over which length (expressed as a multiple of the effective depth) the peak shear stress can be distributed for comparison to the design shear capacity. To answer this question, a numerical model is compared to an experiment. A continuous reinforced concrete slab, representing a half-scale slab bridge, is tested under a concentrated load. The support consists of 7 bearings equipped with load cells, measuring the reaction force profile, that can be compared to the stress profile determined in the finite element model. The comparison of measured reaction force profiles over the support to finite element models results in a research-based distribution width that replaces the rules of thumb that were used until now.

1 INTRODUCTION

1.1 *Existing bridges in the Netherlands*

As a result of the expansion of the Dutch road network in the post-war years, a large number of bridges are reaching the end of their original service life. Within the current bridge stock, 60% of the structures were built before 1975. More specifically, a large number of the Dutch existing reinforced concrete bridges in the road network are short span solid slab bridges. Since the construction of these bridges, the traffic loads have increased significantly, resulting in heavier live load models in EN 1991-2:2003 (CEN, 2003) than in the previously used national code. Also, the prescribed shear capacity is more conservative in the recently implemented EN 1992-1-1:2005 (CEN, 2005) than in the former Dutch NEN 6720:1995 (Normcommissie 351001, 1995).

As a result, 600 slab bridges are found to be shear-critical when assessed with the Eurocodes. Upon inspection, these bridges did not show signs of distress (Walraven, 2010). This indicates that slab bridges possess of additional sources of bearing capacity that are not taken into account in the concrete design codes. In slabs, one of the major sources of additional capacity is the slab's ability for transverse load redistribution (Lantsoght et al., 2012c).

1.2 *Quick Scan approach and finite element models*

The large number of solid slab bridges that are identified as shear-critical requires a systematic approach. In a preliminary general assessment the database of slab bridges is screened in order to identify the bridges requiring a more detailed analysis. For this purpose, a fast, simple and conservative tool is required: the "Quick Scan" method (Lantsoght et al., 2012b, Lantsoght et al., 2012a). The first "Quick Scan" sheets are developed by Dutch engineering firms for the Ministry of Infrastructure and the Environment in the mid-2000s. The goal was to develop a spreadsheet-based approach that automatically evaluates the entire database and helps to identify the structures needing further assessment. The output of the Quick Scan sheet at a considered cross-section is a "unity check" value: the ratio between the design value of the applied shear stress resulting from the loads (composite dead loads and live loads) and the shear resistance as prescribed by the code.

1.3 *Interpretation of peak shear stresses*

For those bridges that are identified by the Quick Scan method as needing a more detailed assessment, the calculation is based on a finite element model. The spreadsheet-based method from the Quick Scan corresponds to a hand-calculation method, using conservative assumptions and only studying a selected set of cross-sections.

When using a linear finite element analysis, the loading consists of the composite dead load (self-weight of the structure and weight of the wearing surface) and the live loads as defined by Load Model 1 from EN 1991-2:2003. The results of the calculation at the face of the support is a shear stress distribution over the entire width of the support.

For assessment, the resulting shear stress at the support needs to be compared to the shear capacity as

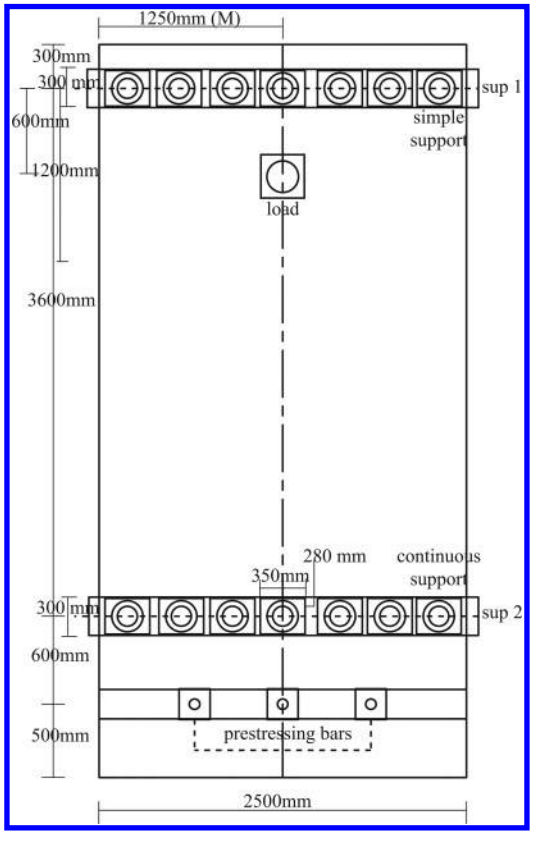

Figure 1. Top view of setup of S25T1.

prescribed by the code (eg. $v_{Rd,c}$ from EN 1992-1-1:2005). As this shear stress is now a distribution over the width, in practice a certain width is defined over which the peak shear stress can be distributed. The resulting average shear stress is then used for comparison to the shear capacity. The distribution width is typically determined based on rules of thumb and local practice. In The Netherlands, a multiple of the effective depth to the longitudinal flexural reinforcement, d_l, is used.

2 DESCRIPTION OF EXPERIMENT

2.1 *Test setup*

To study the shear capacity of slab bridges under wheel loads, a comprehensive series of experiments was carried out at Delft University of Technology. In a first series (Lantsoght et al., 2011), 18 slabs and 12 slab strips were tested under a concentrated load near to the support. In a second series, an additional 8 slabs were tested under a combination of a concentrated load near to the support and a line load. To study the distribution of the peak shear stress over the support, experiment S25T1 from the second series (Fig. 1), loaded with a concentrated load only, is analysed. The slab size was 5 m × 0.3 m × 2.5 m, representing a half-scale continuous solid slab bridge. Each support line consisted of 7 steel bearings equipped with load cells and hinges. On top of the steel bearings, a steel strip of 100 mm × 15 mm × 2500 mm was placed as well as 7 strips of N100 felt of 100 mm × 280 mm × 5 mm (Prochazkova and Lantsoght, 2011). The 300 mm × 300 mm concentrated load was placed in the middle of the width near to the simple support (Fig. 1).

2.2 *Specimen properties*

The main longitudinal reinforcement of S25 consisted of φ20 mm bars at 125 mm spacing, and the transverse flexural reinforcement consisted of φ10 mm bars at 125 mm spacing. The effective depth to the longitudinal reinforcement was $d_l = 265$ mm. Thus, S25 had a longitudinal reinforcement ratio $\rho_l = 0.996\%$ and a transverse flexural reinforcement ratio $\rho_t = 0.258\%$.

Normal strength concrete class C28/35 with a maximum aggregate size of 16 mm was used. The cube concrete compressive strength at the age of testing (170 days) was $f_{c,cube} = 58.57$ MPa and the tensile splitting strength was $f_{ct} = 4.47$ MPa.

2.3 *Description of experiment*

Failure occurred for a maximum concentrated load of $P_u = 1461$ kN. After the experiment, mostly longitudinal cracks were observed on the bottom of the slab (Lantsoght, 2012), as well as some punching damage. Remarkably, on the side faces no cracks were visible, not even flexural cracks.

2.4 *Reaction forces in experiment*

At the simple support line, 7 load cells were used to measure the reaction force continuously during the experiment. For the current study, 9 levels of the applied loading in increments of 10% of the ultimate load (up to 90% of the ultimate load on the slab) are used. The final interval from 90% of ultimate load to 100% of the ultimate load is not considered because the occurring failure cracking cannot be represented correctly by a linear finite element model. The measured reaction forces in the load cells are graphically represented in Figure 2.

3 DESCRIPTION OF FINITE ELEMENT MODEL

3.1 *Model assumptions*

The experiment is simulated in Diana, Release 9.4.4 (TNO DIANA, 2012). The slab was modeled as shell elements and the supports were modeled as 3D solid elements (Fig. 3). In between the solid elements and the shell elements, interface elements representing the layer of felt were used. For the model, 40% of orthotropy was assumed. The load was modeled as

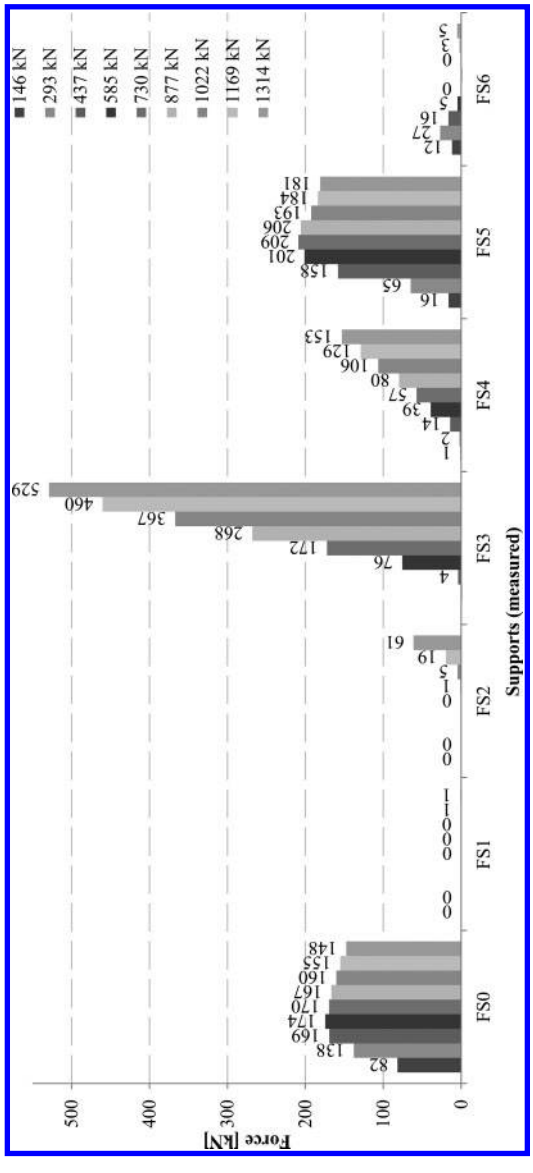

Figure 2. Measured reaction forces at 9 intervals of 10% of the ultimate concentrated load.

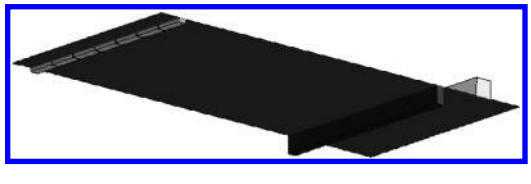

Figure 3. Overview of the finite element model.

300 mm × 300 mm, as in the experiment. The slab was not resting on all support bearings due to initial geometric imperfections. Based on the measurements of the reaction forces in the supports, a phased activation of the supports was implemented into the model.

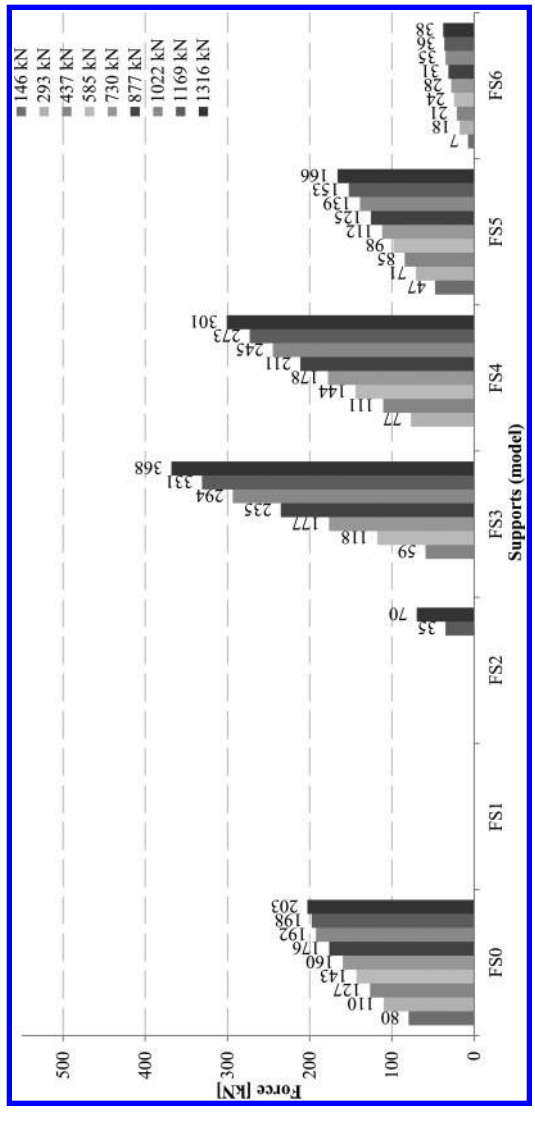

Figure 4. Reaction forces at 9 intervals of 10% of the ultimate concentrated load, using phased activation of the supports.

3.2 *Verification of model results*

Before the result of the finite element model can be used for comparison to the experiments, the measured reaction forces at the load cells are used to check if the model represents the experiment satisfactorily. The measured reaction forces as shown in Figure 2 can be compared to reaction forces in the model. The same 9 intervals of the applied load are considered. The resulting reaction forces from the model can be found in Figure 4. These results indicate that the performance of the finite element model is satisfactory and that the model can be used to study the distribution width of the peak shear stresses.

4 SHEAR STRESS ANALYSIS

4.1 *Shear stress distribution in experiment*

To determine the shear stress over a distribution width that equals a multiple of the effective depth d_l, the results of the measured reaction forces are translated into shear stresses. Two levels of the ultimate load are considered: 585 kN (40% of the ultimate load) and 1314 kN (90% of the ultimate load). The method is illustrated for a concentrated load of 1314 kN. The reaction forces are measured at discrete locations along the slab width. To distribute the reaction force over $2d_l$ and $4d_l$, it is assumed that the reaction force is distributed uniformly over the corresponding influence length of the support (Fig. 5, Fig. 6). The distance $2d_l$ or $4d_l$ is assumed around the center of the middle load cell (FS3), which is located at the middle of the slab width.

The total applied reaction force, $F_{tot,2d}$ over $2d_l$ is:

$$F_{tot,2d} = FS3 + \frac{86\text{ mm}}{358\text{ mm}}(FS2 + FS4) = 580\text{ kN} \quad (1)$$

The shear stress τ_{2d} over $2d_l$ can thus be defined as:

$$\tau_{2d} = \frac{F_{tot,2d}}{2d_l^2} = \frac{580\text{ kN}}{2(265\text{ mm})^2} = 4.13\text{ MPa} \quad (2)$$

A similar approach is used to determine the applied reaction force $F_{tot,4d}$ over $4d_l$:

$$F_{tot,4d} = FS3 + \frac{351\text{ mm}}{358\text{ mm}}(FS2 + FS4) = 739\text{ kN} \quad (3)$$

Similarly, the shear stress τ_{4d} over $4d_l$ can thus be defined as:

$$\tau_{4d} = \frac{F_{tot,4d}}{4d_l^2} = \frac{739\text{ kN}}{4(265\text{ mm})^2} = 2.63\text{ MPa} \quad (4)$$

At 40% of the ultimate load (585 kN) the largest reaction force occurs at load cell FS5 (Fig. 2). A similar procedure as described for a load of 1341 kN is followed, but now the distribution is considered around FS5. Assuming a distribution of $2d_l$, a total force $F_{tot,2d} = 212$ kN is found, resulting in a shear stress $\tau_{2d} = 1.51$ MPa. Assuming a distribution of $4d_l$, a total force $F_{tot,4d} = 244$ kN is found, resulting in a shear stress $\tau_{4d} = 0.87$ MPa.

4.2 *Shear stress distribution in finite element model*

When the results from the finite element model are analyzed, the shear stress over the distribution width can be determined from two methods:

1. By integrating the shear stresses over the considered distribution width to determine the shear force at the support, which is then divided by the distribution width and the effective depth, and

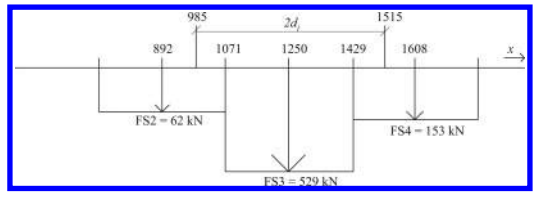

Figure 5. Method for determining the shear stress over $2d_l$ around the peak of the measurement. x-axis along width, distances in [mm].

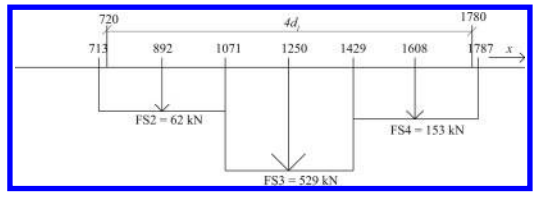

Figure 6. Method for determining the shear stress over $4d_l$ around the peak of the measurement. x-axis along width, distances in [mm].

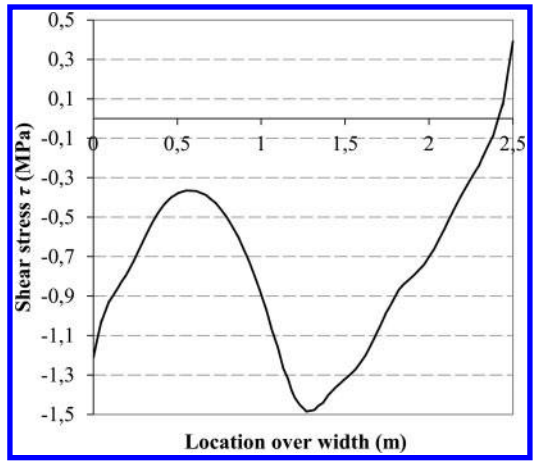

Figure 7. Shear stress distribution at the support in the finite element model.

2. Based on the reaction forces in the discrete supports, this approach is similar to the interpretation of the experimental results (Fig. 5, Fig. 6).

At a concentrated load of 585 kN, the stress distribution at the support in the finite element model is shown in Figure 7. Integrating the shear stress over $2d_l$ results in $\tau_{2d} = 1.30$ MPa and integrating over $4d_l$ results in $\tau_{4d} = 1.10$ MPa.

In Figure 4, the reaction forces in the load cells at the support at a concentrated load of 585 kN are given. The peak reaction force is found in FS4. If the method as described for the measured reaction forces is used around the peak for FS4, then $F_{tot,2d} = 196$ kN and the shear stress over $2d_l$ is found to be $\tau_{2d} = 1.39$ MPa. For a distribution over $4d_l$, the total load $F_{tot,4d} = 356$ kN and the shear stress $\tau_{4d} = 1.27$ MPa.

Table 1. Overview of results for comparison of experimental shear stress over $2d_l$ and $4d_l$ to the finite element model.

	585 kN		1314 kN	
Concentrated load Shear stress	τ_{2d} (MPa)	τ_{4d} (MPa)	τ_{2d} (MPa)	τ_{4d} (MPa)
Measurements	1.51	0.87	4.13	2.63
Model, integrating stresses	1.30	1.10	3.28	2.70
Model, reaction forces	1.39	1.27	3.25	2.60

4.3 *Comparison of distributions*

For the concentrated load at 90% of the ultimate load, a similar approach is followed for the results of the finite element model as discussed for 585 kN in §4.2. An overview comparing the results in the experiment to those from the finite element model is given in Table 1 for 40% of the ultimate experimental load (585 kN) and 90% of the ultimate load (1314 kN). The results in Table 1 show that distributing the peak shear stress over $4d_l$ gives a conservative estimate of the shear stress in the finite element model as compared to the shear stress based on the reaction forces in the experiment. The results in Table 1 also show similar results for both approaches to determine the shear stress based on the results in the finite elements program.

4.4 *Resulting unity check*

In the Quick Scan approach, the decision whether or not the considered bridge needs further investigation is based on the resulting unity check value. For the evaluation of the resulting shear stresses from the finite element model, a comparison to the shear capacity from EN 1992-1-1:2005 is provided:

$$v_{Rd,c} = 0.12k\left(100\rho_l f_{ck}\right)^{1/3} = 0.12\times1.87\left(0.996\times28\text{MPa}\right)^{1/3} = 0.68\text{MPa} \quad (5)$$

$$v_{min} = 0.035k^{3/2}f_{ck}^{1/2} = 0.035\times1.87^{3/2}\times28^{1/2} = 0.47\text{MPa} \quad (6)$$

The design shear stress is the maximum of v_{min} and $v_{Rd,c}$ and is thus $v_{Rd,c} = 0.68$ MPa. This value can be compared to the shear stress over $2d_l$ and $4d_l$, for example at 40% of the experimental ultimate load based on the results from integrating the stresses over the support in the finite element model. In that case, the unity check over $2d_l$ equals 1.91 and over $4d_l$ equals 1.62.

The resulting unity checks indicate the large inherent conservatism in the code as compared to the experimental result, as noted previously in the slab shear research (Lantsoght et al., 2013b). Also, the unity checks show that using a distribution width over $4d_l$ leads to a smaller underestimation of the capacity, and is thus to be preferred.

4.5 *Comparison to Quick Scan results*

To complete this study, a comparison between the Quick Scan results and the unity check based on a linear finite elements approach is briefly described (Lantsoght et al., 2013a) for an existing solid slab bridge.

The Quick Scan approach results in unity checks for 3 cross-sections, while the finite element results can be used to verify every cross-section in the studied spans.

For the considered case, the governing cross-section in the Quick Scan is at support 2-3 (Lantsoght et al., 2012a), resulting in a unity check of 1.02. If the results from the finite element model are used, the shear force at $2.5d_l$ from the support (Rijkswaterstaat, 2012) is found to be 278 kN/m. The shear capacity is determined by the lower bound of the shear stress v_{min} and results in $V_{min} = 451$ kN/m. The unity check is then 0.62.

This comparison shows that the goal of the finite element model – to be a more selective assessment tool than the Quick Scan method – is met. This observation is reflected by a smaller unity check value.

4.6 *Discussion*

In the experiments a flat slab is supported with steel bearings equipped with load cells and hinges. This support condition is different from the practical case of an existing solid slab bridge. In a real bridge, an edge beam is cast onto the slab, which results in an even better distribution of the load over the support. The choice of the distribution width to be $4d_l$ is thus a conservative approach.

5 CONCLUSIONS

For the assessment of existing reinforced concrete solid slab bridges in the Netherlands, the first approach is a spreadsheet-based calculation, the Quick Scan. If a bridge fails to meet the criteria of the Quick Scan, a more refined analysis needs to be carried out by means of a finite element analysis.

When interpreting the results from the finite element analysis for assessment, the key question is how to distribute the peak stress from the shear stress distribution over the support to obtain the design shear stress.

In this paper it is shown that the peak shear stress at the support can be distributed over a width of $4d_l$ and that conservative results are still obtained. The resulting shear stresses over $4d_l$ are smaller than the resulting shear stresses over $2d_l$ and thus, when the results are compared to the design shear stress from Eurocode 2, smaller unity checks result. This shows the improved selection capacity of the assessment method when using the distribution width of $4d_l$.

A case study of an existing bridge shows that the resulting unity check according to the Quick Scan is larger than the unity check resulting from a finite element analysis. This result shows that the Quick Scan

performs well as a coarse selection tool, and that using a finite element model leads to a more precise and less conservative result.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of Infrastructure and the Environment (Rijkswaterstaat) for financing this research work.

Elimination of slip-locking in composite beam analysis by using a meshfree method

R.E. Erkmen
Centre for Built-Infrastructure Research, School of Civil and Environmental Engineering, University of Technology, Sydney, Australia

ABSTRACT: Composite beams that consist of two different components juxtaposed with a shear connection find widespread applications, especially in the floor system and bridge design. The interlayer slip between the two components significantly affects the behaviour of the composite beams, and therefore mathematical models that consider the interlayer slip is adopted in their analysis. In the numerical analysis of composite beams inconsistencies in the shape functions of the transverse and longitudinal displacement fields may cause oscillations in the slip field and reduction in the accuracy of the results known as slip-locking. In order to eliminate slip-locking, matching field strategy is adopted herein by using a meshfree method in which shape functions of the longitudinal displacement fields are obtained from the derivatives of shape functions of the transverse displacement fields. Continuous blending method is modified in order to impose the boundary conditions.

1 INTRODUCTION

It is well know that interlayer slip between the components of composite beam-columns significantly affects the structural response. A mathematical model that considers the interlayer slip was initially developed by Newmark *et al.* (1951), in which two Euler-Bernoulli beams are connected by assuming that vertical separation does not occur between the two components. Subsequently, several displacement-based finite element formulations were developed e.g., Arizumi *et al* (1981). In order to prevent slip-locking in finite element analysis of composite beams consistent interpolation strategy was employed in Dall'Asta and Zona (2002), in which additional internal nodes are needed. An advantage of the meshfree methods e.g., Belytschko *et al* (1994) over the finite element method is that the polynomial order of the shape functions is not directly associated with the number of the nodes used, and at each integration point the shape functions of a displacement field can be produced to exactly match with the derivatives of the shape functions of another displacement field in order to eliminate locking in multi-field problems. This approach was first introduced in Donning and Liu (1998) within the context of Reproducing Kernel Particle Method (RKPM) to alleviate shear-locking.

On the other hand, the finite element method has several advantages over the mesh-free methods; computation and integration of approximation functions are less costly; imposition of the boundary conditions is simpler; and computation of the reaction forces is easier. In order to benefit from the advantages of both methods several coupling techniques have been proposed so that mesh-free and FE methods can be used jointly. Among these methods the continuous blending method introduced in Huerta and Mendez (2000) can produce shape functions that satisfy the Kronecker delta property at the nodes.

Erkmen and Bradford (2010) used the matching field approach to develop a locking free composite beam-column analysis method, in which the continuous blending method is also modified in order to be able to impose the boundary conditions directly at the specified nodes. In this study, results of Erkmen and Bradford (2010) are discussed and the numerical example shows that slip-locking in the composite beam-column behaviour can be totally eliminated using meshfree methods.

2 COMPOSITE BEAM-COLUMN ANALYSIS

2.1 *Kinematics*

Basic kinematic assumptions adopted in this paper were initially presented by Newmark et al. (1951) based on which the member is composed of two Euler-Bernoulli beam components, which are referred herein as beams 1 and 2. The composite cross-section is thus represented as $A = A_1 + A_2$, where A_1 and A_2 are the cross-sections of beams 1 and 2, respectively. The displacement field consists of the vertical displacement v of the reference axis and the longitudinal displacements w_1 and w_2 of the centroids of beams 1 and 2, respectively. The slip at the interface between the two components of the composite beam is denoted as Γ which is due to the difference in longitudinal

displacements w_1 and w_2, and the rotation of both Euler-Bernoulli beam cross-sections v', i.e.

$$\Gamma = w_2 - w_1 + hv', \tag{1}$$

where h is the distance between the centroids of beams 1 and 2, and $(\,)' = \mathrm{d}(\,)/\mathrm{d}x$. Strain expressions in each component can be determined by using the Euler-Bernoulli beam kinematics, hence in terms of the extensions w_1' and w_2' and the curvature v'' due to bending deformations as

$$\varepsilon_1 = w_1' - (y - h_1)v'', \tag{2}$$

$$\varepsilon_2 = w_2' - (y - h_2)v'', \tag{3}$$

2.2 *Variational formulation*

The total potential energy functional based on the deformations described in the Newmark's model can be written as

$$\Pi = \tfrac{1}{2}E_1A_1\int_L w_1'^2\mathrm{d}x + \tfrac{1}{2}E_2A_2\int_L w_2'^2\mathrm{d}x + \tfrac{1}{2}(E_1I_1 + E_2I_2)\int_L v''^2\mathrm{d}x + \tfrac{1}{2}\beta b\int_L (w_2 - w_1 + hv')^2\mathrm{d}x - \Pi_{ext} \tag{4}$$

where, L is the total span of the composite member, E_1 and E_2 are the modulus of elasticity for components 1 and 2 respectively, I_1 and I_2 are the second moments of area of the beams with respect to the principal axes of each cross-section passing through the centroids, β is the elastic stiffness of the shear connection (force/length^3) which is the uniformly distributed longitudinal shear stress across the width of the interface surface b per unit slip and Π_{ext} is the work done by the external forces. By using the first variation of the functional in Eq. (4), a Galerkin weak form can be obtained for the numerical analysis.

3 ELEMENT-FREE GALERKIN METHOD

Shape functions for the transverse displacement field v in Eq. (4) can be generated by using the moving least squares (MLS) approximation procedure, based on which the approximation of the transverse displacement field can be written as

$$v^a(x) = \sum_{i=1}^{n^\rho}\Phi_i(x)v_i, \tag{5}$$

where $i \in I^\rho$ denote the nodes within the meshfree analysis domain Ω^ρ, n^ρ is the number of nodes considered in the approximation of the displacement field, Φ_i are the shape functions and v_i are the nodal parameters which in general do not directly provide nodal displacements, i.e. $v_i \neq v^a(x_i)$. Details of the shape function calculations can be found in several resources.

3.1 *Elimination of slip locking by using the matching field approach*

The shape functions generated in Eq. (5) can also be used for the longitudinal displacement fields, i.e.

$$w_1^a(x) = \sum_{i=1}^{n^\rho}\Phi_i(x)w_{1i} \tag{6}$$

$$w_2^a(x) = \sum_{i=1}^{n^\rho}\Phi_i(x)w_{2i}, \tag{7}$$

in which w_{1i} and w_{2i} are the unknown nodal displacement parameters and in general, they do not directly provide nodal displacements, i.e. $w_{1i} \neq w_1(x_i)$ or $w_{2i} \neq w_2(x_i)$. Consequently, the approximate slip field $\Gamma^a(x)$ can be obtained by substituting Eqs. (5), (6) and (7) into Eq. (1). In order to show that oscillations may occur in the approximate slip field, the longitudinal displacement fields can be alternatively expressed as

$$w_1^a(x) = \sum_{i=1}^{n^\rho}\sum_{j=1}^{n^\rho}\Phi_{j,x}(x)b_{ij} + r_1(x) \tag{8}$$

$$w_2^a(x) = \sum_{i=1}^{n^\rho}\sum_{j=1}^{n^\rho}\Phi_{j,x}(x)c_{ij} + r_2(x), \tag{9}$$

in which $r_1(x)$ and $r_2(x)$ are residual functions to recover the approximations in Eqs. (6) and (7). The residual functions can be selected such that coefficients b_{ij} and c_{ij} in Eqs. (8) and (9) can be associated with the nodal parameters w_{1i} and w_{2i} by using n^ρ conditions as

$$\sum_{j=1}^{n^\rho}\Phi_{j,x}(x_k)b_{ij} = \Phi_i(x_k)w_{1i}, \tag{10}$$

$$\sum_{j=1}^{n^\rho}\Phi_{j,x}(x_k)c_{ij} = \Phi_i(x_k)w_{2i}, \tag{11}$$

where x_k are the coordinates of nodes within the support domain of weight functions whose peak point is at node $j \in I^\rho$. From Eqs. (1), (5), (8) and (9), the slip expression can be obtained as

$$\Gamma^a(x) = \sum_{j=1}^{n^\rho}\Phi_{j,x}(x)\Gamma_j + r(x), \tag{12}$$

in which $\Gamma_i = \sum_{j=1}^{n^\rho}(c_{ij} - b_{ij} + hv_j\delta_{ij})$ and $r(x) = r_2(x) - r_1(x)$ were used and δ_{ij} is the Kronecker delta operator. By using Eqs. (10) and (11), the nodal slip values can be written as

$$\Gamma^a(x_k) = \sum_{j=1}^{n^\rho}\Phi_{j,x}(x_k)\Gamma_j. \tag{13}$$

On the other hand, the residual function $r(x)$ does not necessarily vanish in between nodes which is the

source of oscillations in the slip field in Eq. (12). This can be shown by using Eq. (10) and (11), from which the coefficients b_{ij} and c_{ij} can be written as

$$b_{ij} = w_{1i} \sum_{p=1}^{n^\rho} \mathbf{D}_{ip} \mathbf{C}^{-1}_{pj} \tag{14}$$

$$c_{ij} = w_{2i} \sum_{p=1}^{n^\rho} \mathbf{D}_{ip} \mathbf{C}^{-1}_{pj}, \tag{15}$$

where

$$\mathbf{D} = \begin{bmatrix} \Phi_1(x_1) & \dots & \Phi_1(x_{n^\rho}) \\ . & \dots & . \\ \Phi_n(x_1) & \dots & \Phi_n(x_{n^\rho}) \end{bmatrix}, \tag{16}$$

$$\mathbf{C} = \begin{bmatrix} \Phi_{1,x}(x_1) & \dots & \Phi_{1,x}(x_{n^\rho}) \\ . & \dots & . \\ \Phi_{n,x}(x_1) & \dots & \Phi_{n,x}(x_{n^\rho}) \end{bmatrix}. \tag{17}$$

The residual function $r(x)$ can be obtained as (Erkmen and Bradford 2010)

$$r(x) = \sum_{i=1}^{n^\rho} \left[\sum_{j=1}^{n^\rho} \Phi_j(x)\delta_{ij} - \Phi_{j,x}(x) \sum_{p=1}^{n^\rho} \mathbf{D}_{ip} \mathbf{C}^{-1}_{pj} \right] \left(w_{2i} - w_{1i} \right) \tag{18}$$

Since shape functions $\Phi_j(x)$ are one order higher than their derivatives $\Phi_{j,x}(x)$, the residual function $r(x)$ shown in Eq. (18) does not vanish at any point x for any $\mathbf{D}$ or $\mathbf{C}$ unless $w_{2i} - w_{1i} = 0$ which is the cause of oscillations between nodes. On the other hand, for stiff connection limit, i.e. $\beta \to \infty$, Eq. (12) should vanish, i.e., $\Gamma^a(x) \to 0$ which in general requires the residual function to vanish i.e. $r(x) \to 0$. This enforces a spurious constraint on the approximate longitudinal displacement fields which can be stated as

$$w_2{}^a(x) - w_1{}^a(x) = \sum_{j=1}^{m-1} p_j(x) d_j, \tag{19}$$

where $p_j(x)$ are monomial basis functions (e.g. $p_1(x) = 1$, $p_2(x) = x, \dots, p_{m-1}(x) = x^{m-2}$) and d_j are coefficients. Thus, in order for the interface slip to vanish the highest order terms in the approximate longitudinal displacement fields $w_1^a(x)$ and $w_2^a(x)$ should cancel each other as stated by the condition in Eq. (19). This spurious constraint on the approximate longitudinal displacement fields causes poor or delayed convergence. The slip-locking behaviour can be alleviated by using the matching field approach, in which case the derivatives of the approximation functions $\Phi_i(x)$ are selected as the approximation functions of the longitudinal displacement fields, i.e.

$$w_1{}^a(x) = \sum_{i=1}^{n^\rho} \Phi_{i,x}(x) q_{1i} \tag{20}$$

$$w_2{}^a(x) = \sum_{i=1}^{n^\rho} \Phi_{i,x}(x) q_{2i}, \tag{21}$$

where q_{1i} and q_{2i} are the nodal parameters and in general, they do not directly provide nodal values, i.e. $q_{1i} \neq w_1(x_i)$ or $q_{2i} \neq w_2(x_i)$. It can be verified that using $b_{ij} = q_{1j}\delta_{ij}$ and $c_{ij} = q_{2j}\delta_{ij}$ in Eqs. (8) and (9) produce Eqs. (20) and (21), respectively in which case the residual functions in the approximate longitudinal displacement fields vanish, i.e. $r_1(x) = r_2(x) = r(x) = 0$.

4 TREATMENT OF BOUNDARY CONDITIONS

4.1 *Continuous blending method*

The shape functions produced by using the procedure described in section do not necessarily satisfy the Kronecker delta property at the nodes, i.e. $\Phi_i(x_j) \neq \delta_{ij}$, which complicates the imposition of the essential boundary conditions. In the continuous blending method, incomplete bases of primitive functions $N_j(x)$, which provide unity at the boundary nodes, i.e. $N_j(x_j) = 1$, are introduced at the prescribed region Ω^h. The nodes associated with these primitive functions are the boundary nodes (or the nodes that are connected to finite elements) i.e., $j \in I^h$ and are different from the meshfree nodes, i.e. $j \notin I^\rho$. Mesh-free functions $\tilde{\Phi}_i(x)$ complement these primitive functions and together they satisfy the polynomial reproducing conditions which can be written by using the shifted basis as

$$\sum_{i=1}^{n^\rho} \tilde{\Phi}_i(x) \mathbf{p}(x_i - x) + \sum_{j=1}^{n^h} N_j(x) \mathbf{p}(x_j - x) = \mathbf{p}(0), \tag{22}$$

where n^h is the number of the primitive functions. The nodes associated with these functions can be covered by or can be out of the support domain Ω^h of the primitive functions $N_j(x)$. By using Eq. (22), complementing meshfree functions $\tilde{\Phi}_i(x)$ can be calculated as

$$\tilde{\Phi}_i(x) = \left[\mathbf{p}^{\mathrm{T}}(0) - \sum_{j=1}^{n^h} N_j(x) \mathbf{p}^{\mathrm{T}}(x_j - x) \right] \mathbf{M}^{-1} \mathbf{B}_i, \tag{23}$$

The transverse displacement field in the interface region can be written as

$$v^a(x) = \sum_{i=1}^{n^\rho} \tilde{\Phi}_i(x) v_i + \sum_{j=1}^{n^h} N_j(x) \alpha_j. \tag{24}$$

where α_j denotes the displacement parameters of the boundary nodes. From Eq. (23), it can be verified that $\tilde{\Phi}_i(x_j) = 0$ at the boundary nodes $j \in I^h$ and by using Eq. (24) and $N_j(x_j) = 1$, the displacement parameters α_j can be shown to be equal to the transverse displacements at the nodes, i.e. $\alpha_j = v(x_j)$. Thus, the transverse displacements at the boundary nodes can be directly specified or the transverse displacements at the nodes

that are connected to finite element nodes can be identified as α_j. By using the matching field approach the longitudinal displacement fields can be approximated as

$$w_1^a(x) = \sum_{i=1}^{n^o} \tilde{\Phi}_{i,x}(x) q_{1i} + \sum_{j=1}^{n^h} N_{j,x}(x) \psi_{1j} \tag{25}$$

$$w_2^a(x) = \sum_{i=1}^{n^o} \tilde{\Phi}_{i,x}(x) q_{2i} + \sum_{j=1}^{n^h} N_{j,x}(x) \psi_{2j}, \tag{26}$$

in which ψ_{1j} and ψ_{2j} are the longitudinal displacement parameters associated with the boundary nodes $j \in I^h$. However, in general $\tilde{\Phi}_{i,x}(x_j) \neq 0$ and $N_{j,x}(x_j) \neq 1$ and thus the boundary conditions can not be directly applied to the longitudinal displacement fields at the boundary nodes. In order to be able to satisfy Kronecker delta property for both transverse displacement and the longitudinal displacement fields at the boundary nodes (or the nodes that are connected to finite elements) continuous blending method should be modified.

4.2 *Modification of the continuous blending method*

In addition to the primitive functions $N_j(x)$, a new set of primitive functions $R_j(x)$ is introduced in the support domain of the primitive functions Ω^h which satisfy $R_{j,x}(x_j) = 1$ and $R_j(x_j) = 0$. Also, the primitive function $N_j(x)$ is required to satisfy $N_{j,x}(x_j) = 0$ in addition to the previously required Kronecker delta property, i.e. $N_j(x_j) = 1$. By using the primitive functions the polynomial reproducing condition based on the shifted basis can be written as

$$\sum_{i=1}^{n^o} \tilde{\Phi}_i(x) \mathbf{p}(x_j - x) + \sum_{j=1}^{n^h} N_j(x) \mathbf{p}(x_j - x) + \sum_{j=1}^{n^h} R_j(x) \frac{\mathrm{d}\mathbf{p}(x_j - x)}{\mathrm{d}x} = \mathbf{p}(0), \tag{27}$$

It should be noted that the contribution of the primitive function $R_j(x)$ in the reproducing conditions is similar to a C^1 finite element formulation. From Eq. (27) complementing meshfree shape functions $\tilde{\Phi}_i(x)$ can be written as

$$\tilde{\Phi}_i(x) = \left[\mathbf{p}^{\mathrm{T}}(0) - \sum_{j=1}^{n^h} N_j(x) \mathbf{p}(x_j - x) - \sum_{j=1}^{n^h} R_j(x) \frac{\mathrm{d}\mathbf{p}(x_j - x)}{\mathrm{d}x} \right] \mathbf{M}^{-1} \mathbf{B}_i \tag{28}$$

in which matrices **M** and **B** can again be obtained from moving least-squares approximation (Erkmen and Bradford 2010). The approximation of the transverse displacement function in the support domain Ω^h of the primitive functions can be written as

$$v^a(x) = \sum_{i=1}^{n^o} \tilde{\Phi}_i(x) v_i + \sum_{j=1}^{n^h} N_j(x) \alpha_j + \sum_{j=1}^{n^h} R_j(x) \beta_j, \tag{29}$$

where α_j and β_j denote the displacement parameters of the boundary nodes, i.e., $j \in I^h$. By using Eq. (28), it can be verified that $\tilde{\Phi}_i(x_j) = \tilde{\Phi}_{i,x}(x_j) = 0$ at the boundary nodes $j \in I^h$. Thus, from Eq. (29) it can be shown that parameters α_j are equal to the transverse displacement at the nodes, i.e. $\alpha_j = v^a(x_j)$, since $N_j(x_j) = 1$ and $R_j(x_j) = 0$. On the other hand parameters β_j are equal to the rotations at the node, i.e. $\beta_j = v^a_{,x}(x_j)$ since $\tilde{\Phi}_{i,x}(x_j) = 0$, $N_{j,x}(x_j) = 0$ and $R_{j,x}(x_j) = 1$. Therefore, the transverse displacements or the rotations at the boundary nodes can be directly specified or the transverse displacements and the rotations at the nodes that connected to finite element nodes can be identified as α_j and β_j respectively. The longitudinal displacement fields can be interpolated by using the derivatives of the approximation functions used in Eq. (29) as

$$w_1^a(x) = \sum_{i=1}^{n^o} \tilde{\Phi}_{i,x}(x) q_{1i} + \sum_{j=1}^{n^h} N_{j,x}(x) \psi_{1j} + \sum_{j=1}^{n^h} R_{j,x}(x) \zeta_{1j} \tag{30}$$

$$w_2^a(x) = \sum_{i=1}^{n^o} \tilde{\Phi}_{i,x}(x) q_{2i} + \sum_{j=1}^{n^h} N_{j,x}(x) \psi_{2j} + \sum_{j=1}^{n^h} R_{j,x}(x) \zeta_{2j} \tag{31}$$

in which ψ_{1j}, ψ_{2j}, ζ_{1j} and ζ_{2j} are the longitudinal displacement parameters associated with the boundary nodes $j \in I^h$. Since $\tilde{\Phi}_{i,x}(x_j) = 0$, $N_{j,x}(x_j) = 0$ and $R_{j,x}(x_j) = 1$, the parameters ζ_{1j} and ζ_{2j} associated with the boundary nodes are equal to the respective longitudinal displacements at the boundary nodes, i.e. $\zeta_{1j} = w_1^a(x_j)$ and $\zeta_{2j} = w_2^a(x_j)$. Thus, the longitudinal displacements at the boundary node can also be directly specified or the longitudinal displacements at the node that are connected to finite element nodes can be identified as ζ_{1j} and ζ_{2j}.

5 APPLICATIONS

The evidence of slip-locking and the performance of the proposed method are illustrated for simply-supported boundary conditions, in which, total span of the composite beam-column is selected as $L = 10$ m and the cross-sectional and material properties for components 1 and 2 used in Eq. (5) are selected as $E_1 = 200 \times 10^3$ MPa, $A_1 = 6000\,\mathrm{mm}^2$, $I_1 = 1122 \times 10^2\,\mathrm{mm}^4$, $E_2 = 26 \times 10^3$ MPa, $A_2 = 7104\,\mathrm{mm}^2$ and $I_2 = 124 \times 10^6\,\mathrm{mm}^4$. Slip stiffness parameter β is varied between $2.16\,\mathrm{N/mm}^3$ and $216\,\mathrm{N/mm}^3$ for an effective surface width of $b = 200$ mm which correspond to $\alpha L = 25$ and $\alpha L = 250$, respectively where αL is a dimensionless slip stiffness parameter.

$$\alpha = \sqrt{\beta b \left[1/(E_1 A_1) + 1/(E_2 A_2) + h^2/(E_1 I_1 + E_2 I_2) \right]}. \tag{32}$$

For the simply supported beam shown in Figure 1 (i.e., $w_2(0) = v(0) = v(L) = 0$), 11 equally distributed nodes and 200 integration points are used. Polynomial basis used in the MLS procedure is quadratic, i.e. $m = 3$ and

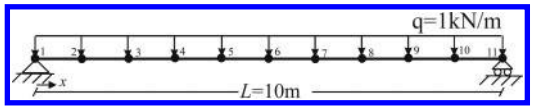

Figure 1. Simply supported beam under uniform load.

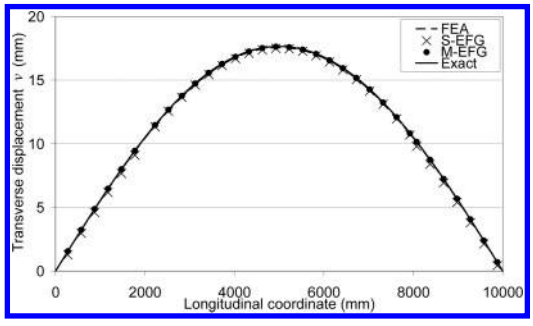

Figure 2. Displacement v for $\alpha L = 25$.

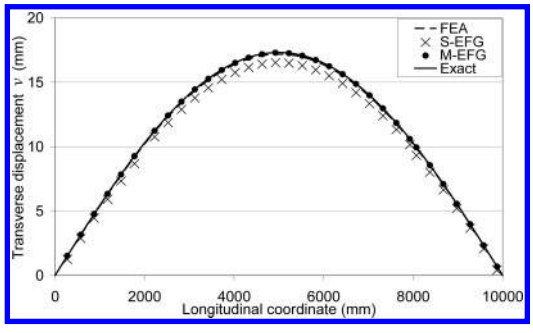

Figure 3. Displacement v for $\alpha L = 250$.

the support domain of the weight function is selected as $d_s = 4500$ mm.

The interface regions are selected between nodes 1 and 3 at the left end, and between nodes 9 and 11 at the right end. The primitive functions associated with nodes 1 and 11 are selected as

$$N_j(x) = \left[2\left(\frac{x-x_k}{x_j-x_k}\right) - \left(\frac{x-x_k}{x_j-x_k}\right)^2 \right] \left[1 - \left(\frac{x-x_j}{x_j-x_k}\right)^2 \right]^4 \quad (33)$$

where $j = 1$ and $k = 3$ at the left end and $j = 11$ and $k = 9$ at the right end.

Since the selected primitive functions satisfy $N_j(x_j) = 1$ at both ends, the boundary conditions can directly be applied for the transverse displacement field v, i.e. $\alpha_1 = v(0) = 0$ and $\alpha_{21} = v(L) = 0$.

When the same approximation functions are used for the longitudinal displacement fields w_1 and w_2, the results are referred as S-EFG to indicate the standard EFG analysis. When the derivatives are used as the shape functions of the longitudinal displacement fields, the results are referred as M-EFG to indicate matching field approach in which case an additional primitive function has to be introduced in the interface region.

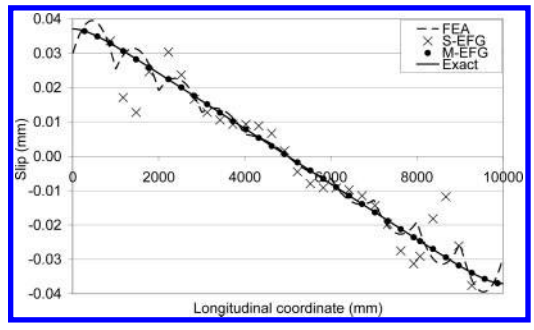

Figure 4. Slip for $\alpha L = 25$.

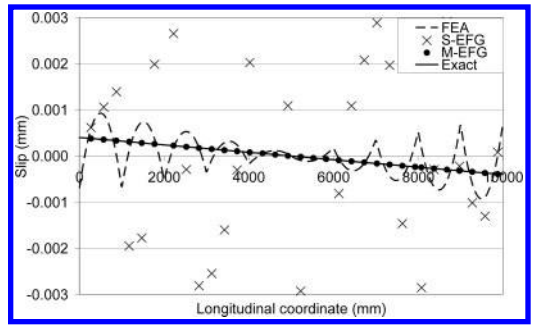

Figure 5. Slip for $\alpha L = 250$.

In order to be able to fix the longitudinal displacement w_2 at the left end the second primitive function is selected as

$$R_j(x) = \left[x_k - x + \frac{(x-x_k)^2}{x_j-x_k} \right] \left[1 - \left(\frac{x-x_j}{x_j-x_k}\right)^2 \right]^4, \quad (34)$$

where $j = 11$ and $k = 9$. The second primitive function $R_j(x)$ and its derivatives $R_{j,x}(x)$ are shown in Figs. 2d and e respectively.

It can be verified that $R_{j,x}(x_j) = N_j(x_j) = 1$ and $R_j(x_j) = N_{j,x}(x_j) = 0$. Since the shape functions for the longitudinal displacement fields are the derivatives of the shape functions of the transverse displacement field v, the boundary conditions can directly be imposed for the longitudinal displacement field w_2, i.e. $\zeta_{21} = w_2(0) = 0$. It should be noted that approximation functions together with the primitive function $N_j(x)$ form a partition of unity, where as similar to a C^1 FE formulation, primitive function $R_j(x)$ does not contribute to the partition of unity. Fig. 2 and 3 shows numerical analysis results for the transverse displacements and slip fields for slip stiffness parameters $\alpha L = 25$ and $\alpha L = 250$, respectively. For comparison purposes the results of the simplest Finite Element which is based on the cubic interpolation of the transverse displacement field v and the linear interpolation of the longitudinal displacement fields w_1 and w_2 is used and denoted herein as (FEA). Ten elements are used for the finite element analysis. The error in the strain energy is obtained by using an exact solution. In

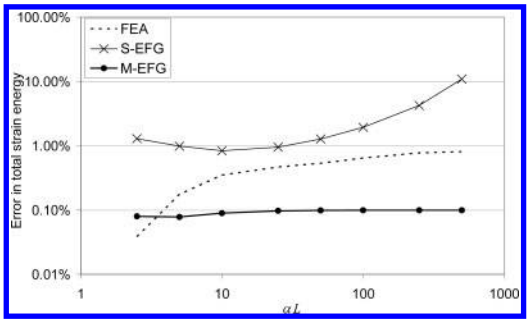

Figure 6. Error in strain energy versus αL.

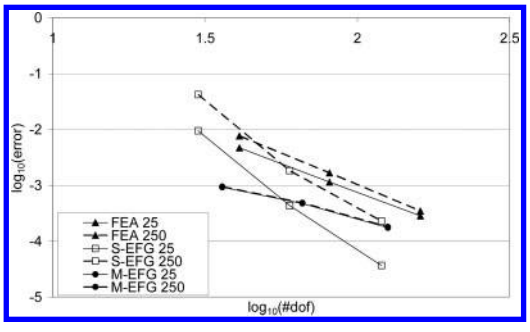

Figure 7. Convergence based on strain energy.

Figs. 2 and 3 it can be observed that when the dimensional connection stiffness parameter is changed from $\alpha L = 25$ to $\alpha L = 250$ S-EFG shows a stiffer behaviour comparison to other solutions. Locking behaviour can be observed in Fig. 4 and 5 in which slip results of the S-EFG solution show oscillations. On the other hand M-EFG results match with the exact results for both $\alpha L = 25$ and $\alpha L = 250$. Figure 6 shows the effect of slip stiffness on the strain energy error for S-EFG, M-EFG and FEA based on 11 node solutions. It can be verified that when the slip stiffness increases the error in the total strain energy increases for both S-EFG and FEA. On the other hand, error in M-EFG results is not affected by the slip stiffness.

Also, in Fig. 7 convergence rates based on the normalized errors in total strain energy are shown and compared for $\alpha L = 25$ and $\alpha L = 250$ by using 11, 21 and 41 node solutions in which all other parameters are kept constant including the span of the interface region. By comparing the slopes in Fig 7, it can be verified that S-EFG converges faster than the others however its convergence rate is slightly reduced for the stiffer connection. When the connection stiffness increases the accuracies of FEA and S-EFG results decrease, however the accuracy and the convergence rate of M-EFG results are not affected.

6 CONCLUSIONS

Displacement based numerical formulations suffer from slip-locking when used for the analysis of composite beams. The main problem is that for stiff connections slip results may be erroneous due to severe oscillations. In this study matching field approach was adopted which eliminates oscillatory behaviour due to slip-locking and the error estimates remain independent of the slip stiffness parameter. On the other hand, in order to be able to impose the boundary conditions, an efficient technique is developed by modifying the continuous blending method when the matching field approach is adopted.

Nonlinear analysis of semi-rigid steel frames subjected to blast or fire

A. Heidarpour
Department of Civil Engineering, Monash University, Australia

ABSTRACT: The behaviour of steel structures subjected to extreme actions such as fire or blast has become an important research area in structural engineering. This paper presents an innovative methodology to describe the nonlinear behaviour of steel structures subjected to extreme actions such as heating phase of a compartment fire or blast. The methodology is based on a non-discretisation semi-analytical formulation of a generic cross-section with elastic and plastic parts which allow for the spread of yielding to be modelled. The model incorporates large displacement and material nonlinearity effects whilst it considers the yielding and development of catenary action affects with an increase in the temperature. Each steel element is assumed to be restrained at its two ends with translational and rotational springs while the variations of the stiffness and yield strength at various load cases are simulated using empirical retention functions given elsewhere. The strain-rate effect is considered when the structure is subjected to explosion. The proposed methodology is shown to agree well with solutions given by ABAQUS finite element modelling.

1 INTRODUCTION

2 MECHANICAL PROPERTIES OF STEEL

Based on fire tests under transient or steady-state conditions of heating, a number of empirical models have been proposed for the material properties of steel and concrete at elevated temperature. Lie (1992) proposed a useful bilinear curve, with a small transition between the linear portions, to represent the stress-strain curve at elevated temperatures. The curve consists of two separate equations as

$$\sigma = \begin{cases} E_s.\varepsilon_e & \varepsilon \le \varepsilon_p \\ \left(c_1\varepsilon_e + c_2\right)\sigma'_y - c_3\,\sigma'^2_y \,/ E_s & \varepsilon > \varepsilon_p, \end{cases} \quad (1)$$

in which

$$\varepsilon_p = \frac{c_2\sigma'_y - \dfrac{c_3\sigma'^2_y}{E_s}}{E_s - c_1\sigma'_y} \quad (2)$$

The coefficients in Eq. (1) are taken as $c_1 = 12.5$, $c_2 = 0.975$ and $c_3 = 12.5$. In Eqs.(1) and (2), E_s is the elastic modulus of the steel and σ'_y is the yield stress. In the case of having blast loading, the strain-rate effect of steel material is considered such that (Perzyna, 1966)

$$\sigma'_y = \left[1 + \left(\frac{\dot{\varepsilon}^{pl}}{\gamma}\right)^m\right]\sigma_y \quad (3)$$

While at elevated temperatures, the mechanical properties of steel are obtained from

$$\frac{E_s}{E_0} = \begin{cases} 1 + \dfrac{T}{2000\ln(T/1100)} & 0 \le T \le 600^\circ\mathrm{C} \\ \dfrac{690\,(1 - T/1000)}{T - 53.5} & 600^\circ\mathrm{C} \le T \le 1000^\circ\mathrm{C} \end{cases} \quad (4)$$

and

$$\frac{\sigma'_y}{\sigma_0} = \begin{cases} 1 & 0 \le T \le 215^\circ\mathrm{C} \\ \dfrac{905 - T}{690} & 215^\circ\mathrm{C} \le T \le 905^\circ\mathrm{C} \end{cases} \quad (5)$$

in which E_0 and σ_0 are the modulus of elasticity and yield strength of steel material at ambient state.

3 THEORETICAL FORMULATION

The normal strain at a typical steel cross-section can be represented by (Fig. 1)

$$\varepsilon_t = \varepsilon_m + \left(y - \bar{y}\right)\kappa \quad (6)$$

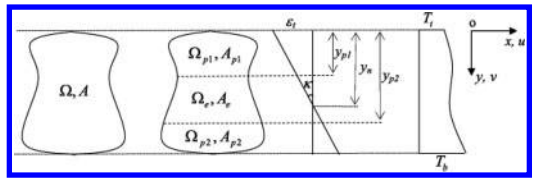

Figure 1. Cross-section and strains: (a) Steel cross-section before loading. (b) Steel cross-section after loading. (c) Total strain diagram. (d) Thermal profile over the cross-section.

The alternative forms of Eq. (6) are

$$\varepsilon_t = \varepsilon_e + \varepsilon_\theta \quad \text{and} \tag{7}$$

$$\varepsilon_t = (y - y_n)\kappa \tag{8}$$

In Eqs.(6) to (8) $\bar{y}$ is the location of the elastic centroid of the steel section below the local reference level,which is assumed to be coincident with the top fibre of the steel cross-section, y_n is the location of the neutral fibre, ε_m, ε_e and ε_θ are the appropriate membrane, mechanical and thermal strains which are obtained from

$$\varepsilon_m = \frac{\mathrm{d}u}{\mathrm{d}x} + \frac{1}{2}\left(\frac{\mathrm{d}v}{\mathrm{d}x}\right)^2, \quad \varepsilon_\theta = \Theta T(x,y), \quad \varepsilon_e = \varepsilon_t - \varepsilon_\theta \tag{9}$$

For a given cross-section Ω, the magnitude of the total axial force and internal bending moment can be obtained from

$$N_{\text{int}} = N_e + \sum_{i=1,2} N_{pi} \quad \text{and} \quad M_{\text{int}} = M_e + \sum_{i=1,2} M_{pi} \tag{10}$$

in which the subscripts "e" and "pi" indicate the internal actions which act on the elastic part (Ω_e) and on each of the two plastic parts (Ω_p) of the cross-section, respectively and are determined from

$$N_e = \int_{A_e} \sigma \mathrm{d}A_e \quad , \quad N_{pi} = \int_{A_{pi}} \sigma \mathrm{d}A_{pi} \quad \text{and} \quad (i = 1,2) \tag{11}$$

$$M_e = \int_{A_e} \sigma y \mathrm{d}A_e \quad , \quad M_{pi} = \int_{A_{pi}} \sigma y \mathrm{d}A_{pi} \quad (i = 1,2) \tag{12}$$

Substituting Eqs.(1) and (7) into Equation (11) leads to

$$N_e = \left(\overline{E_s B_e} - y_n \overline{E_S A_e}\right)\kappa - N_{eT} \tag{13}$$

$$N_{pi} = c_1\left[\left(\overline{SB}_{pi} - y_n \overline{SA}_{pi}\right)\kappa - N_{pTi}\right] \quad (i = 1,2) \tag{14}$$

where thermal section properties are defined as

$$\overline{E_s B_e} = \int_{A_e} E_s y \mathrm{d}A_e \quad , \quad \overline{E_s A_e} = \int_{A_e} E_s \mathrm{d}A_e \tag{15}$$

$$\overline{SB_{pi}} = \int_{A_e} y\sigma'_y \mathrm{d}A_{pi} \quad , \quad \overline{SA_{pi}} = \int_{A_{pi}} \sigma'_y \mathrm{d}A_{pi} \quad (i = 1,2) \tag{16}$$

and

$$N_{eT} = \Theta \int_{A_e} E_s T \mathrm{d}A_e \tag{17}$$

$$N_{pTi} = \int_{A_{pi}} \sigma'_y \left[\Theta T - \frac{c_2 - c_3 \sigma'_y / E_s}{c_1}\right] \mathrm{d}A_{pi} \quad (i = 1,2) \tag{18}$$

The location of the neutral axis y_n can be determined by substituting Eqs. (13) and (14) into Eq. (10) so that

$$y_n = \frac{\overline{E_s B_e} + c_1 \sum_{i=1,2} \overline{SB}_{pi} - \left[N_{\text{int}} + N_{eT} + c_1 \sum_{i=1,2} N_{pTi}\right] \Big/ \kappa}{\overline{E_s A_e} + c_1 \sum_{i=1,2} \overline{SA}_{pi}} \tag{19}$$

The magnitudes of the internal moment M_{int} in Eq. (10) can be obtained from Eqs. (1),(7) and (12) such that

$$M_{\text{int}} = \left(\frac{\omega_A \omega_I - \omega_B^2}{\omega_A}\right)\kappa + \left(\frac{\omega_B}{\omega_A}\right)\left[N_{\text{int}} + N_T\right] - M_T \tag{20}$$

where

$$N_T = N_{eT} + c_1 \sum_{i=1,2} N_{pTi} \, , \quad M_T = M_e + c_1 \sum_{i=1,2} M_{pTi} \tag{21}$$

and ω_A, ω_B and ω_I depend on the mechanical properties of the steel material which is given by

$$\omega_A = \overline{E_s A_e} + c_1 \sum_{i=1,2} \overline{SA}_{pi} \qquad \omega_B = \overline{E_s B_e} + c_1 \sum_{i=1,2} \overline{SB}_{pi}$$

$$\omega_I = \overline{E_s I_e} + c_1 \sum_{i=1,2} \overline{SI}_{pi} \tag{22}$$

where

$$\overline{E_s I_e} = \int_{A_e} E_s y^2 \mathrm{d}A_e \quad , \quad \overline{SI_{pi}} = \int_{A_e} \sigma'_y y^2 \mathrm{d}A_e \tag{23}$$

In Eq. (21) M_e and M_{pTi} are obtained from

$$M_{eT} = \Theta \int_{A_e} y E_s T \mathrm{d}A_e \tag{24}$$

$$M_{pTi} = \int_{A_{pi}} y\sigma'_y \left[\Theta T - \frac{c_2 - c_3 \sigma'_y / E_s}{c_1}\right] \mathrm{d}A_{pi} \quad (i = 1,2) \tag{25}$$

Equation (20) can then be rearranged so that the curvature κ at a cross-section is written as a function of the internal actions in the form

$$\kappa = \beta_1 (M + M_T) - \beta_2 (N + N_T) \tag{26}$$

in which the flexibility coefficients β_1 and β_2 are

$$\beta_1 = \frac{\omega_A}{\omega_A \omega_I - \omega_A^2} \quad \text{and} \quad \beta_2 = \frac{\omega_B}{\omega_A \omega_I - \omega_A^2}. \tag{27}$$

Using the equilibrium of the steel element in its deformed configuration, the magnitude of the internal bending moment M_{int} is written as a function of

bending moment, shear force and axial force at the left side of the element such that

$$M_{\text{int}}(x) = M_0 + R_0(x - u_0 - u) + N_0(\bar{y} - v_0 + v) - \int_{u0}^{x-u_0-u} (q_s - q_e + f_{id})(x - u - \zeta)\,d\zeta \quad (28)$$

in which u_0 and v_0 are the axial and vertical deformation at $x = 0$ respectively and u and v are the axial and transverse displacement fields along the steel element, respectively. In Eq. (28) f_{id} is the total inertia and damping forces which is given by

$$f_{id} = f_i + f_d = \left(\frac{m}{\Delta t} + \gamma\xi\right)\left(\frac{v_{t+\Delta t} - v_t}{\beta \Delta t} - \frac{\dot{v}_t}{\beta}\right) - \left[\frac{m}{2\beta} - \Delta t\left(1 - \frac{\gamma}{2\beta}\right)\xi\right]\ddot{v}_t \quad (29)$$

in which $\gamma = \frac{1}{2}$ and $\beta = \frac{1}{4}$ (or $\frac{1}{6}$ are the coefficients corresponding to the average acceleration method (or linear acceleration method), m is the mass per unit length of the steel element and $\ddot{v}$ and $\dot{v}$ are the local acceleration and velocity respectively, while ξ is a damping coefficient which represents the resistance to transverse velocity. In addition, the axial force equilibrium of the deformed configuration of the steel element leads to

$$N_{\text{int}} = N_0 \cos\theta - \left[\int_{u0}^{x-u_0-u} (q_s - q_e + f_{id})\,d\zeta - R_0\right]\sin\theta \quad (30)$$

The relationship between the slopes at the ends of the element can be numerically found by integration of the curvature in Eq. (26) so that

$$\theta_L - \theta_0 = \frac{L}{2}\sum_{j=1}^{n_G} \overline{w}_j \kappa(x_j) \quad (31)$$

Similarly, the difference in the deflections at two ends of element can be determined from Eq. (31) such that

$$v_L - v_0 = \frac{L}{2}\sum_{j=1}^{n_G} \overline{w}_j \theta(x_j) \quad (32)$$

in which

$$\theta(x_j) = \theta(x_{j-1}) + \frac{1}{2}(x_j - x_{j-1})\sum_{k=1}^{n_G} \overline{w}_k \kappa(x_k) \quad (j=1,..,n_G) \quad (33)$$

In Eqs. (31) to (33), n_G is the number of integration points in the Gauss-Legendre integration technique; $x_j \in [0, L]$ is the designation evaluation point and $\overline{w}_j$ is the associated weighting factor. Using Eqs.(6) to (9) the relationship between the axial deformations at the two ends of the steel element can be expressed as

$$u_L - u_0 = \frac{L}{2}\sum_{j=1}^{n_G} \overline{w}_j \left\{[\bar{y} - y_n(x_j)]\kappa(x_j) - \frac{1}{2}[\theta(x_j)]^2\right\} \quad (34)$$

in which $y_n(x_j)$ is the location of the neutral axis at $x = x_j$ given by Eq. (19).

At the end of the member,

$$N_0 = k_0 u_0 \quad , \quad N_L = -k_L u_L \quad (35)$$

$$M_0 = r_0 \theta_0 \quad , \quad M_L = -r_L \theta_L \quad (36)$$

and since the vertical deflection of the ends of the element is zero ($v_0 = v_L = 0$) and so $N_0 = N_L$ which produces,

$$M_L = M_0 + R_0(L - u_0 - u) - \int_{u0}^{L-u_0-u} (q_s - q_e + f_{id})(L - u - \zeta)\,d\zeta \quad (37)$$

For this boundary value problem, substituting Eqs. (35) to (37) into Eqs. (31) to (34) leads to a system of three equations which must be solved simultaneously for M_0, R_0 and N_0; this is done herein using the mathematical package MAPLE (2008). Since the deflection v in Eq. (28) is unknown a priori, the solution procedure is iterative. The following steps illustrate the solution methodology:

Step 1. The initial values of M_0, R_0 and N_0 are determined using an elastic analysis in which the yielded domain Ω_p at each Gauss_Legendre point $x = x_j$ is taken as zero, and the deflection is set initially as zero.

Step 2. Updated values of y_{p1} and y_{p2} (Fig. 1) at each cross-section $x = x_j$ are determined using von Mises' yield criterion at elevated temperature given by

$$\sigma^2 + 3\tau^2 = \sigma_y'^2 \quad (38)$$

in which σ is the normal stress produced by the axial force and bending moment, τ is the shear stress produced by the shear force and σ_y' is the yield stress (Eq. (5)). On a given cross-section, Eq. (38) defines the parts of it which have yielded.

Step 3. The magnitude of the slope, transverse and axial deformations at each cross-section $x = x_j$ are determined from Eq. (31) to (34).

Step 4. The mechanical properties of each cross-section at the locations $x = x_j$ are found from Eqs. (15), (16), (22),(23) and (27).

Step 5. Substituting the updated values of y_{p1} and y_{p2}, as well as the updated values of the displacement field and the mechanical properties at a cross-section determined in Steps 2 to 4 into Eqs. (31), (32) and (34) leads to a new system of three equations which are solved to find updated values of M_0, R_0 and N_0.

Step 6. Steps 2 to 5 are repeated until a convergence criterion is satisfied. Herein, convergence is deemed to have been achieved when

$$\frac{\|\mathbf{P}_n\| - \|\mathbf{P}_{n+1}\|}{\|\mathbf{P}_n\|} < \varepsilon_{tol} \tag{39}$$

in which $\|\mathbf{P_n}\|$ represents the Euclidean norm, n is the iteration number, ε_{tol} is a predetermined convergence tolerance and

$$\mathbf{P} = \langle M_0 \quad R_0 \quad N_0 \rangle \tag{40}$$

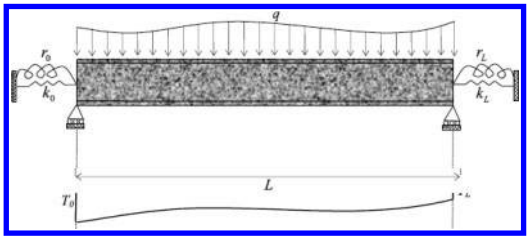

Figure 2. Steel beam subjected to a typical distributed and thermal loads.

4 ILLUSTRATION

4.1 *Example 1*

The numerical model developed in the previous section is used to investigate the behaviour of a generic steel beam at elevated temperatures as depicted in Fig. 2. The results have also been validated using ABAQUS (2008) modelling. For the analysis, the beam has a length $L = 8$ m, and it is subjected to a sustained uniformly distributed load of $q = 30$ kN/m which includes its self-weight. The steel section is chosen to be a UB $457 \times 152 \times 60$ with an elastic modulus $E_0 = 200$ GPa and yield strength $\sigma_0 = 300$ MPa at 20°C. The cross-sectional thermal regime is defined by a linear variation of temperature from the bottom fibre of T_b to the top fibre of βT_b, and this is taken as constant along the member. The end restraint stiffnesses are defined as

$$k_0 = k_L = \mu_c \left(\frac{E_s A_0}{L} \right), \quad r_0 = r_L = \mu_c \left(\frac{E_s I_0}{L} \right) \tag{41}$$

The efficiency of the proposed model has been evaluated by comparing its solutions with those of ABAQUS

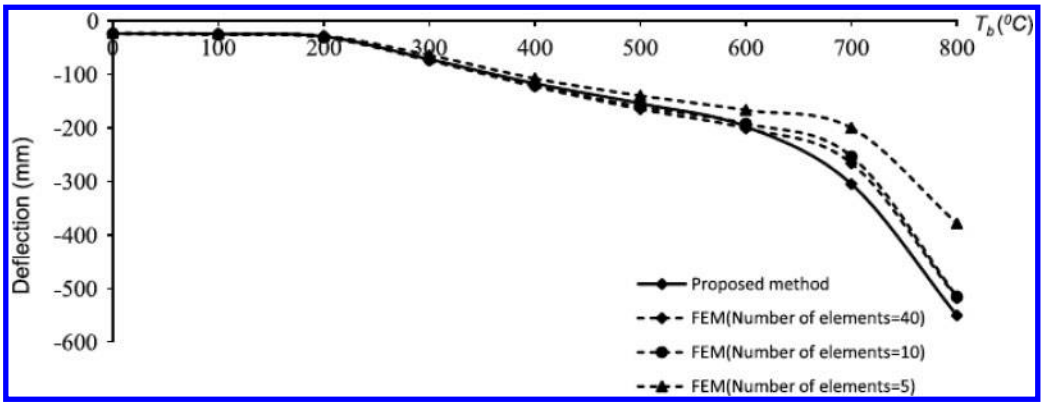

Figure 3. Deflection at mid-span given by proposed model compared to FEM ($\mu_c = 0.1$, $\beta = 1.0$).

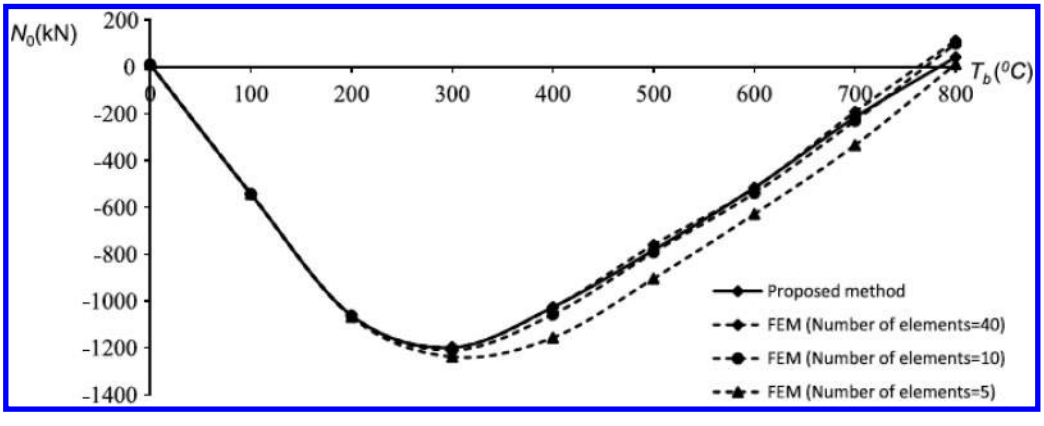

Figure 4. The magnitude of axial force N0 given by proposed model compared to FEM ($\mu_c = 0.1$, $\beta = 1.0$).

(2008) modelling of the beam in Figs. 3–5. These figures indicate that the proposed non-discretisation model which uses one 'element' with 8 Gauss-Legendre points ($n_g = 8$) agrees well with the finite element results as the number of elements increases; the agreement with the solution with 40 elements is good and this shows that the computational effort for obtaining accurate solutions from the proposed model is significantly less than that of the finite element method.

4.2 *Example 2*

The semi-analytical mechanical-based formulation developed in the previous section has been used to investigate the behaviour of a generic straight steel beam subjected to an explosion. The I-shaped steel cross-section is an Australian 610UB125, with the mechanical properties of the steel material being taken as $E_s = 200$ GPa and $\sigma_y = 300$ MPa in which the stress–strain relationship is represented by Eq. (1). The length of the steel member is $L = 6$ m and it is further assumed that the steel member is subjected to a uniformly distributed gravity load of $q_g = 30$ kN/m. (including self-weight), as well as to the blast load represented by a uniformly distributed overpressure $q_e(t) = q_0\overline{q}(t)$ in which q_0 is its intensity and $\overline{q}(t)$ is a typical normalised overpressure time–history for a gas–air mixture in a vented confined explosion initially proposed by Smith and Hetherington (1994) and later idealized by Izzuddin et al. (2000), as shown in Fig. 6. Figs. 7–9 show the variation of vertical reaction R_0, axial force N_0 and deflection at mid-span of the steel beam with respect to time ($\mu_c = 1.0$), given by the present model in comparison to the solution of ABAQUS (2008) while a good agreement is achieved. More details can be found in the papers published by author (Heidarpour and Bradford, 2009 & 2011).

5 CONCLUSION

The non-linear behaviour of an isolated beam–column steel element subjected to blast and fire loading was presented in this paper using a generic semi-analytical non-discretisation mechanical-based method, for which the steel member was restrained at its two ends by translational and rotational springs that represent semi-rigid joints in a frame. The formulation of the model allowed the geometric and material non-linearities, as well as the rate dependent effect of the steel material, to be considered accurately while it further allowed the statical and kinematic boundary conditions to be satisfied exactly. The non-linear solution was expedited by an iterative scheme in terms of three unknowns.

The model proposed in the paper was validated against the finite element model using ABAQUS, and good agreement was achieved. The scope of the formulation was illustrated by reporting a study of a steel member subjected to an explosion and fire, which demonstrated the variation of reactions as well as the displacements with different magnitudes of the blast loading or temperature. The solution was obtained using only one 'element', and is very efficient computationally. This model has the potential to be used in structural analysis and design.

Coupling different FE-models for the calculation of the thermo-mechanical behavior of ultra high performance concrete components under high temperature load

M. Siemon, D. Hosser & J. Zehfuß
Institute of Building Materials, Concrete Construction and Fire Protection (iBMB)
Technische Universität Braunschweig (Institute of Technology), Braunschweig, Germany

ABSTRACT: Although many commercial finite element programs are capable of coupling the thermal and mechanical calculation, the definition for an appropriate model for both calculations yields to several problems, especially in fire protection engineering. Due to high spatial and temporal temperature gradients, the resolution of the mesh has to be very high at edges and areas of a structure applied with fire load. This usually leads to problems in the mechanical calculation where a graded mesh results in deformed element geometries and convergence problems. An evenly spaced high resolution mesh on the other hand leads to excessive computational time consumption. By combining two different finite element models for the thermal and thermomechanical calculation with a transfer program, the contradictory mesh discretization requirements can be solved. As a second advantage, both models can be optimized for their purpose, the thermal or thermomechanical calculation. In this paper, this procedure is presented by an example of a simple geometry ultra high performance concrete column. Utilization of UHPC allows for the design of slight building components and small cross-sections when compared to traditional concrete components. When it comes to fire protection, these aspects yield to disadvantageous behavior under fire load. In this case, the assessment of the coupled thermomechanical approach using advanced finite element methodologies is capable of determining the behavior of such building components.

1 INTRODUCTION

This paper deals with the problems that occur in the field of fire protection engineering when utilizing state-of-the-art finite element software to calculate the thermomechanical behavior of building components. Although several powerful tools and solutions are existing for a huge amount of problems, there is a need of customization and freedom in defining constitutive material models as well as the general problem of contradictory meshing requirements for the thermal and thermomechanical calculations. In a lot of cases, this yields to the need of high computational resources, the occurrence of convergence problems or compromises in the formulation of the constitutive material model to meet the constraints of the utilized software. The approach presented in this paper is the transfer of the temperature values for defined spatial and temporal points from a microscale mesh (thermal calculation) to a macroscale mesh (thermomechanical calculation). As finite element methodologies are node-based, a main boundary condition is the coincidence of the nodes in spatial and temporal dimensions where the information needs to be transfered. This excludes nonconformal meshes when the usage of interpolation functions is not wanted. Here, the temperature as a scalar value is a simple variable as there are no directional informations like for displacements, flows or velocities. A comparable methodology is used in the field of computational fluid dynamics solvers, e.g. FDS (McGrattan, McDermott, Hostikka, & Floyd 2010) in cases where large volumes with comparable small details like ventilation openings leads to the demand of a coarse spatial resolution for the general volume and a high resolution at the openings.

2 PROBLEM AND MOTIVATION

2.1 *Special constitutive functions*

In the field of fire protection engineering, the fire scenario as the thermal loading of a building component is described via temperature-time curves as depicted in figure 1. These curves describe the environmental temperature due to a fire. The usual approach for the determination of the exposition of a building component is the definition of a heat flux W/m^2 derived from convective and radiative heat transfer conditions based on experimental results. These conditions, together with the temperature-time curves as environmental temperatures $\theta_{env,t}$ are then applied as Neumann boundary conditions to the assessed thermal problem. The

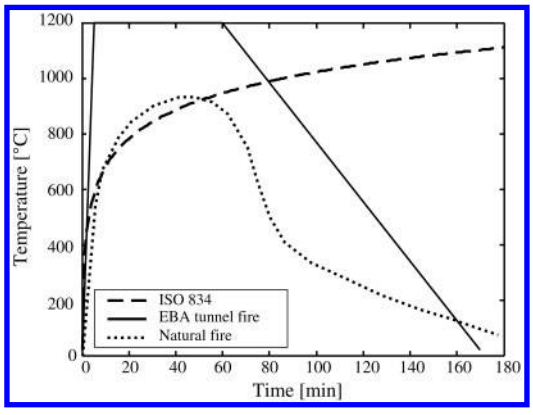

Figure 1. Temperature-time curves used in fire protection engineering.

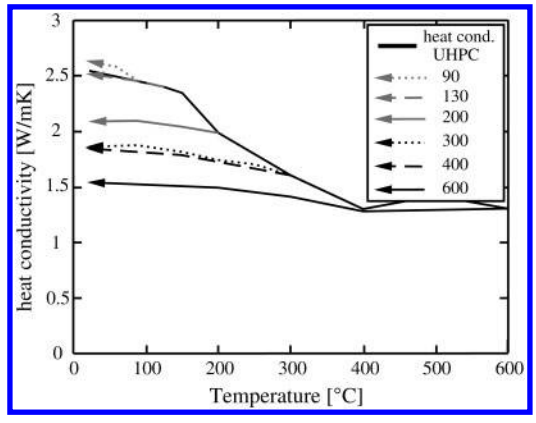

Figure 2. Heat conductivity of UHPC for heating and cooling Phase.

calculation is done after equation 1, equation 2 and equation 3.

$$\dot{h}_c = \alpha_c \cdot (\theta_{env} - \theta_\Gamma), \tag{1}$$

$$\dot{h}_r = \Phi \cdot \varepsilon_m \cdot \varepsilon_f \cdot \sigma \cdot [(\theta_{env} + 273)^4 - (\theta_\Gamma + 273)^4], \tag{2}$$

$$\dot{h_\Gamma} = \dot{h}_c + \dot{h}_r, \tag{3}$$

The depicted functions are then applied as boundary conditions to solve the Fourier equation shown in 4. The initial value for $\theta_{\Gamma,t=0}$ is usually defined as a starting condition (e.g. $\theta_{\Gamma,t} = 20°C$). The material parameters density $\rho(\theta)$, specific heat capacity $c_p(\theta)$ and heat conductivity $\lambda(\theta)$ are functions of the temperature. Like the stress-strain relationship for the mechanical analysis, these functions were derived from experiments and called constitutive material model. The resulting nonlinear partial differential equation is usually solved the finite element methodology, Newton-Raphson iteration for the linearization of the system of equations and explicit/implicit transient analysis in the temporal axis, e.g. described in Bathe (2002) or Zienkiewicz & Taylor (2000).

$$\rho c_p \frac{\partial \theta}{\partial t} - \lambda \cdot \frac{\partial^2 \theta}{\partial x^2} \cdot \frac{\partial^2 \theta}{\partial y^2} = -\dot{h_B}, \tag{4}$$

The calculation of temperature values is a basic function of many finite element solvers, as well as the consideration of the nonlinearity of the factors ρc_p and λ. As it can be seen in figure 1, the natural fire temperature curve contains a heating phase and a cooling phase. If you want to consider different thermal material behavior in those phases, a lot of FE solvers do not allow to define the material behavior in such a detailed manner. Recent research on ultra high performance croncrete showed a path dependency of the temperature dempendent heat conductivity. Figure 2 shows the temperature dependent heat conductivity of an assessed ultra high performance concrete for the heating phase (continous black line) and for the cooling phase for different reached maximum temperatures.

The consideration of this material behavior is important when the behavior of building components exposed to natural fires is the point of interest. In this case, the coupling of a self-developed heat solver with full access to all program internals with a consolidated and validated structural solver can be required.

2.2 *Contradictory meshing constraints*

A second problem is the different requirement for the mesh discretization for the thermal and the thermo-mechanical analysis. As a rule-of-thumb, the German guideline for fire protection engineers (Hosser 2009) recommends an element discretization according to the expected temperature gradient with maximum edge dimensions of 2 to 3 cm and edge to edge ratios larger than 1:2. As it can be seen in figure 1, the heating velocity of the design temperature curves can reach values up to 240 K/min for the EBA tunnel fire design curve (EBA 1997). This yields to the demand of strongly graded meshes and small element dimensions when modeling a concrete cross-section. Meshing the whole 3-dimensional model in appropriately small elements yields to non suitable computational times due to the large number of DOFs. The violation of the aforementioned meshing criteria on the other hand leads to convergence problems due to bad elementation or bifurcation phenomena resulting in unrealistic displacements for single nodes as shown in figure 3.

The standard behavior of a low-resolution mesh for thermal analysis in fire protection engineering is shown in figure 4 for a one-dimensional heat conduction problem. This example is taken from a calculation of the transient temperature development in 6 cm depth of a concrete tunnel shell exposed to the EBA fire curve (see figure 1). The low-resolution mesh was the maximum economic discretization for a following thermomechanical analysis of the whole tunnel shell utilizing solid elements whereas the high-resolution mesh shows the discretization needed to calculate the temperatures without numerical problems.

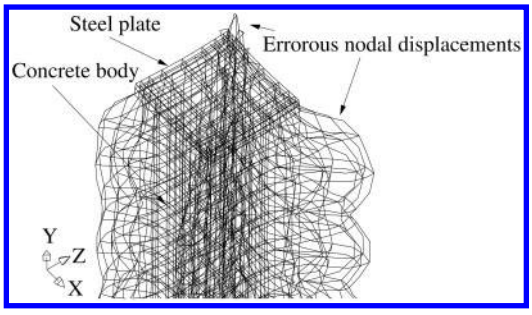

Figure 3. Bifurcation phenomena at the corners of a 4-side fire exposed column.

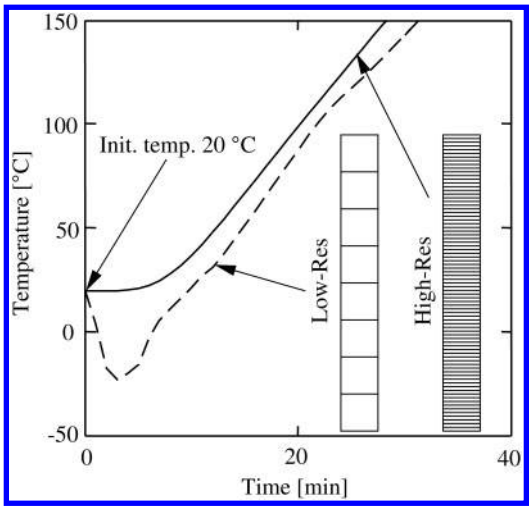

Figure 4. Transient temperature development for different mesh resolutions in the first 40 min.

3 MULTI-MESH APPROACH

In this paper, the advantages of the software DIANA (deWitte & Wijtze 2005) in modeling discrete reinforcement and passing user-supplied subroutines for the definition of the constitutional material behavior in the thermomechanical analysis should be used without the loss of flexibility for the thermal analysis. To avoid the problems explained in section 2, a multi-mesh approach with a microscale mesh for the thermal analysis and a macroscale mesh for the thermomechanical analysis was chosen. This approach is possible when meeting several requirements and basic estimates. Due to the uncertain nature lying in the description of fire scenarios, the design fire curves as depicted in figure 1 are applied over the complete height or length of a building component. This assumption leads to a simplification of the thermal analysis where only the cross-section of a building component needs to be analyzed depending on the edges exposed to fire, e.g. a column centered in the compartment exposed from four sides or a beam located at the ceiling which is usually assumed to be exposed from one or three sides. The resulting temperature field is then transferred to the FE-model defined for the thermomechanical calculation and adapted over the whole height or length (in case of a 3-dimensional mesh).

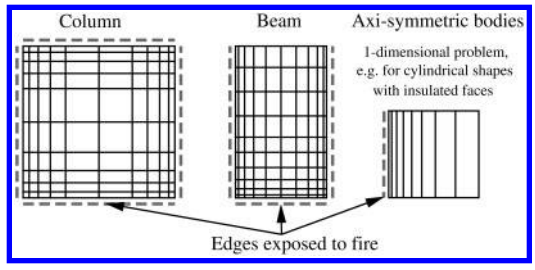

Figure 5. Different cross-sections discretized for thermal analysis.

3.1 *Microscale thermal analysis*

The temperature field needed for the analysis of the building component is calculated under consideration of the forementioned simplifications with a 2-dimensional model. For concrete members, most cross-sections are primitive shapes like squares and rectangles which are easily discretized with graded meshes concerning the exposed temperature boundary conditions. Examples for the most common cases are depicted in figure 5.

For the thermal analysis as the first step of the analysis process, there are two main conditions when setting up the FE-model. The discretization of the temporal domain (timesteps) has to fit the requirements of the following thermomechanical analysis, i.e. being the same or a multiple of the timesteps of the thermomechanical analysis. The other condition is the need of writing out the temperature values for every timestep at every point of interest (nodes of the cross-section of thermomechanical analysis) defined with global x-y-coordinates that need to comply with the coordinates of the nodes for one 'sliced' cross-section of the 3-dimensional thermomechanical model. A graphical overview of these basic conditions is shown in figure 7.

For usual problems in fire protection engineering, the compliance with this conditions is given because the thermal analysis usually needs a finer mesh as well as a finer temporal discretization. Additionally, the need for mesh and time step refinement due to large spatial and temporal temperature gradients is correlated with changes in displacements, which yields to an accordance of the requirements of numerical solving techniques for both analysis. In advance to figure 7, when utilizing an equidistant 3-dimensional mesh with 20-nodes elements, temperature values for every timesteps at the coordinates are written as corner node values for the 8-node main layer after the following rule $x \rightarrow [0 : x]$ with $\Delta x = \frac{x}{el_x}$ and $y \rightarrow [0 : y]$ with $\Delta y = \frac{y}{el_y}$. The edge nodes of the bottom layer are derived with the following rule $x \rightarrow [\frac{\Delta x}{2} : x - \frac{\Delta x}{2}]$ with $\Delta x = \frac{x}{el_x}$ and $y \rightarrow [\frac{\Delta y}{2} : y - \frac{\Delta y}{2}]$ with $\Delta y = \frac{y}{el_y}$.

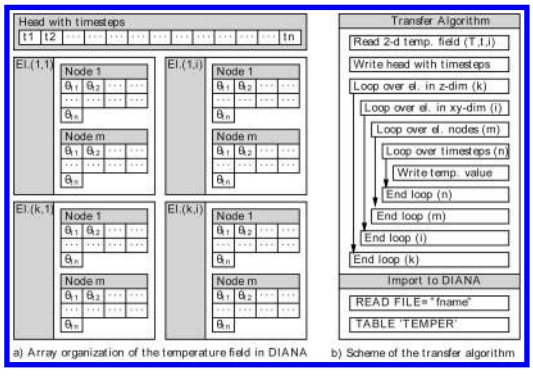

Figure 6. Required format for readable temperature field for DIANA.

The values for the middle layer nodes are then copied from the bottom corner nodes, with $z = \frac{z}{el_z} \cdot 0.5$.

3.2 *Combining Micro- and Macroscale*

The algorithm of a transfer program is based on the element formulation chosen for the thermomechanical model. This chapter shows the implementation of a transfer algorithm for a specific problem with the FE-software DIANA as thermomechanical solver and the assessement of a concrete column using 3-dimensional solid elements. In this case, the model for the thermomechanical calculation is based on a 20-node isoparametric element with quadratic interpolation functions (see deWitte & Wijtze (2005)). The discretization for the upstream 3-dimensional thermal analysis is derived from this mesh and based on linear isoparametric brick elements. Because the conditions mentioned in section 3.1 allow the free choose of a thermal solver, the setting of the ANSYS thermal analysis is not otherwise specified. For the following explanation, it is assumed that there exist valid temperature information for every timestep and every node following the conditions explained in section 3.1 grounding on a sufficiently fine mesh and an appropriate solver. The required input format for temperature fields in DIANA is shown in figure 6.

The first part of the temperature table as input file for DIANA is the head section containing the timesteps in seconds. The following blocks contain the temperature values for each element in ascending order. Each element block exists of temperature-time information for every node. In contrast to figure 6a, there is no seperation between the single nodes, i.e. the temperatures for node 1 are written for all timesteps in ascending temporal order, followed by the values for node m. The temperature table does not distinct between cross-section elements and height/length elements as shown in figure 6a, but this is easily done as the first $x \cdot y$ elements define the bottom layer with the mid-height of $z = \frac{z}{el_z} \cdot 0.5$ of the 3-dimensional model. When the temperature-time values for the xy-dimension are sortet by the transfer algorithm, the loop over the z-dimension simply copies the values of the cross-section (see figure 6b for the general explanation of the transfer algorithm). This methodology is only valid if the assumptions of section 3 are met. As shown in figure 7, $el_{x,y,z}$ is the number of elements in the x,y or z-direction, x and y are the cross-section dimensions and z is the height or length of the building component.

4 UTILIZATION FOR A SPECIFIC PROBLEM

4.1 *Ultra high performance concrete columns*

The thermal analysis was done utilizing a 2-dimensional graded ANSYS model with temperature-dependend material parameters for the heat conductivity $\lambda(\theta)$, the desity $\rho(\theta)$ and the specific heat capacity $c_p(\theta)$ which were derived from experiments (Hosser, Kampmeier, & Hollmann 2012). The thermal calculation in this context had two functions. The first function was a validation calculation of the derived contitutive functions from small-scale experiments with the experimental results of the large-scale column tests. As a second function, this calculation was the base for the following thermomechanical calculation of the column behavior under fire exposure and mechanical load.

The thermomechanical model contains of 3-dimensional solid elements already described in section 3. In addition to the concrete body, the load charging steel plate made of S235 was also modeled as a direct exposure of the column face with the mechanical load would lead to numerical problems due to the softening behavior under temperature influence. As a second advantage, the consideration of the steel plate leads to a more realisticaly modeling of the experiments. The reinforcement was modeled with discrete elements especially developed for modelling reinforced concrete components, assuming a perfect bond between reinforcement and concrete body. The capabilities of modelling discrete reinforcement is one of the main advantages of DIANA when it comes to FE-calculation of reinforced concrete components. Table 1 gives an overview of the experimental and numerical setup as well as further information on the used parameters.

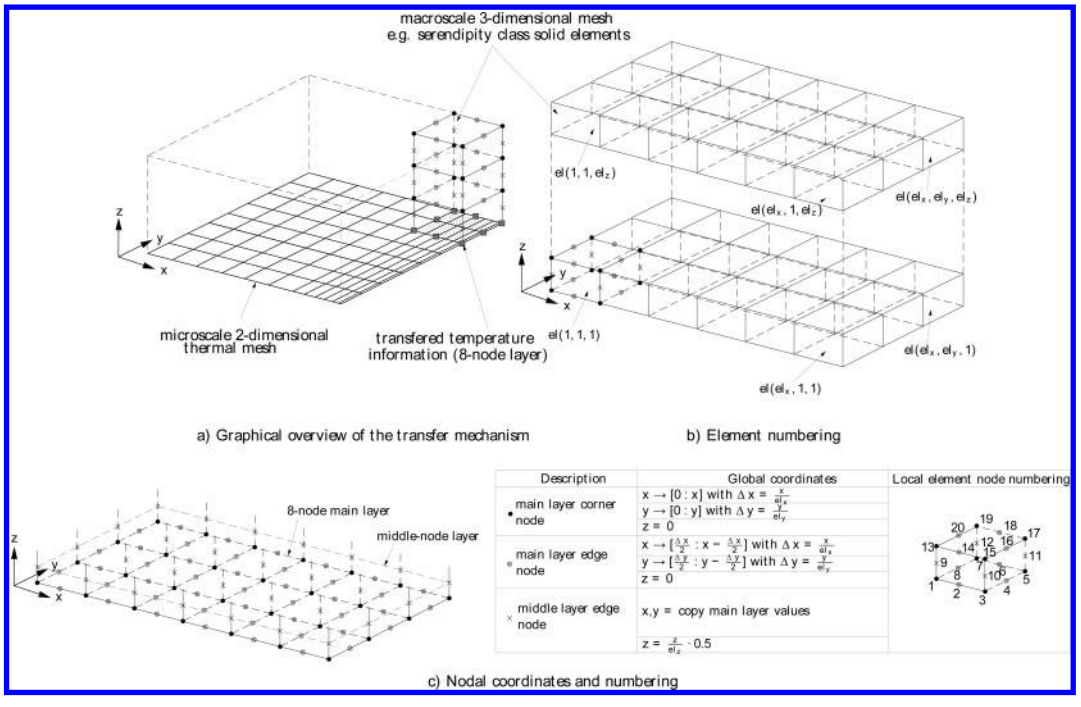

Figure 7. Graphical overview of the transfer mechanism.

In addition to table 1, all heat transfer conditions are derived from the Eurocode2 (2006). For a further look on the utilized material model and the contitutive stress-strain-temperature behavior of the concrete, take a look at the report of the research program 1182 which will be published this year.

4.2 *Results*

As shown in figure 8, the calculated temperatures show good compliance to the measured temperatures for different depths of the cross-section. The derived constitutive functions for the thermal material parameters can be viewed as a good approach to describe the temperature-dependend thermal behavior of UHPC. Furthermore, the gained temperature-time values are proven as a good basis for a following thermomechanical calculation.

The results of the coupled thermomechanical calculations with DIANA are shown in figure 9. As it can be seen, the general behavior can be reproduced by the calculation, although the experiments show smaller dispacements over the time. For fire engineering problems, the failure time of an assessed component is the main design value as it is important to ensure a minimum duration required by standards and codes.

As depicted in figure 9, the calculated failure times are slightly shorter than the ones derived from the experiments, underestimating the load-bearing capacity under fire exposure about 3 up to 10 min. The failure of the column in the calculation is usually at the

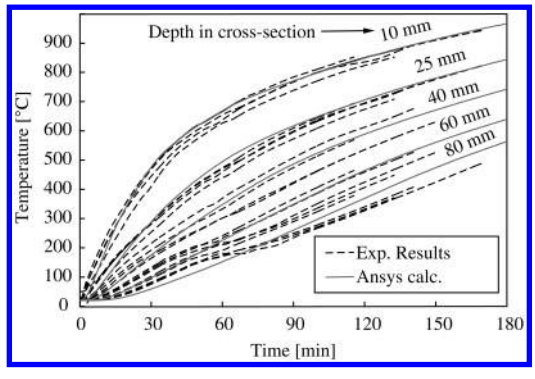

Figure 8. Calculated temperatures compared with experimental results.

point of convergence problems due to large displacements violating the agreeability constraints. As it is depicted in figure 9, the experimentally derived failure times of about 140 min for an eccentricity of 15 mm and 173 min for an eccentricity of 7.5 mm are slighlty underestimated by the calculation (10 min and 3 min). Due to the complex setup of the problem, resulting in physical and geometrical nonlinearities, the determined discrepancies in the failure time are comparable small. Hence, the method presented in this paper is generally capable of calculating the thermomechanical behavior of reinforced concrete building components exposed to fire.

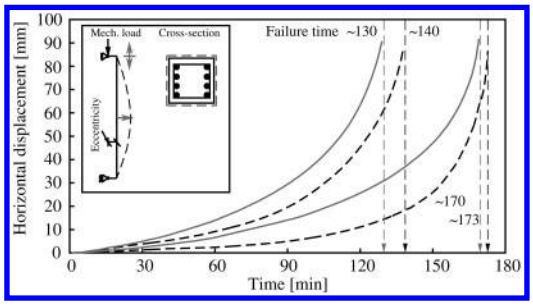

Figure 9. Calculated displacements and failure times.

5 CONCLUSION

Due to specific problems and shortcomings when utilizing standard FE-solvers in the field of fire protection engineering, the presented methodology offers a simple and effective solution combining different solvers and different meshes for the assessment of temperature-dependent behavior of reinforced concrete components avoiding usual shortcomings. Those shortcomings are contradictory meshing requirements for the thermal and thermomechanical calculation and the need for modeling complex contitutive functions describing the material behavior of modern concrete mixtures exposed to fire (see figure 2). The possibility of DIANA to read a temperature-time table offers the utilization of additional and specialized solvers for the thermal analysis and transfer of the derived values with a transfer algorithm. Another benefits is the possibility to use previously calculated temperature values without the need of a new thermal analysis. The standard approach of a combined usage of one mesh would yield to an increase of DOFs and as a result the additional need of computational time due to the 3-dimensional approach. This is avoided by relying on a fine discretization of the cross-section only when it is needed (thermal calculation). A main disadvantage is the confinement to primitive cross-section and building component geometries and the need of a static mesh which suspends the possibility of adaptive mesh refinement techniques of modern FE-software. Another point is the loss of the possibility for a mutual coupling of thermal and thermomechanical behavior, e.g. the simulation of cracking behavior which yields to a reduced heat conduction at this location. For standard fire protection engineering problems, this is theoretical problem as the uncertainties in modeling the fire scenario are high and a smeared (and isotropic) approach lowering the heat conductivity for fire-damaged concrete is generally capable of describing the temperature development quite well, as it can be seen in figure 8.

ACKNOWLEDGMENT

The authors would like to acknowledge the German Research Foundation (DFG) for the support of the research project 'Theoretische und experimentelle Untersuchungen zu Ermittlung und Optimierung des Brandverhaltens von ultra-hochfestem Beton' (Theoretical and experimental studies for determining and optimizing the fire behavior of ultra high performance concrete) in the priority program 1182.

FE modelling of semi-rigid flush end plate joints with concrete-filled steel tubular columns

A. Ataei & M.A. Bradford
Centre for Infrastructure Engineering and Safety, School of Civil and Environmental Engineering, The University of New South Wales, Sydney, Australia

ABSTRACT: A semi-rigid beam-to-column composite blind bolted connection is modelled using ABAQUS software. The composite beam is connected to the concrete-filled square column using blind bolts, and the model simulates a connection in hogging bending moment. Partial shear connection is considered, as well as the non-linear material properties of all constitutive components. All connection components were taken as roughly the same size as used in the experiments against which the method is calibrated, and the model does not need recourse to empirical push test data. The technique can be used to model connections easily, resulting in rapid and reliable solutions.

1 INTRODUCTION

Flush end plate joints in a connection between a composite beam and a concrete-filled square tubular column are an attractive design solution in low-rise composite framed buildings, because the semi-rigid nature of the joint allows for resistance against lateral forces without the need for diagonal bracing. However, facilitating a joint of this type can be problematic because the inside of the hollow tube is not readily accessible, and this has led to the use of "blind bolting" as a design solution.

Whilst necessary for validation purposes, experimental studies of composite connections are expensive and time-consuming and, as a result, considerable research momentum is gathering on using numerical simulations for connections. Early work on the numerical simulation of composite beams and joints including stud shear connectors was reported by Kalfas & Pavlidis (1997), Kim *et al.* (1999) and Bahaari & Sherbourne (2000). More recently, Mirza & Uy (2010, 2011) have reported the numerical modelling of composite joints that contain blind bolts. Despite bespoke numerical models such as those of Pi *et al.* (2006) and Liu *et al.* (2012) being computationally attractive, most research has focused on using commercial software packages such as ABAQUS and ANSYS, because of their flexibility in modelling all of the components in a composite joint. The advantages of this flexibility are often negated by their computational intensity, leading to slow convergence to the correct solution and, as a consequence, most models have focused on two-dimensional modelling rather than on three-dimensional studies.

In order to provide a robust and efficient means for modelling flush end plate joints in composite connections containing concrete-filled steel tubes with blind bolting, the present paper presents a three-dimensional modelling using ABAQUS software. It augments the studies presented by Mirza & Uy (2010, 2011) and, importantly, models the complex situation of cracked concrete in negative bending by a simple elastic-perfectly yielded representation. The modelling is benchmarked against the extensive testing of connections with blind bolting reported by Loh *et al.* (2006), and is shown to provide an efficacious technique for conducting parametric studies, so as to develop design guidance in this fast-evolving application in composite construction.

2 BENCHMARK EXPERIMENTAL RESULTS

Loh *et al.* (2006) presented a comprehensive set of experiments on composite connections. In this work, one non-composite and five semi-rigid composite beam to column connections were tested under symmetric loading, with the composite beams being connected to the tubular columns using blind bolts. Two rows of M20 Grade 8·8 blind bolts attached flush end plates to the columns, and to which the steel beams were connected (Fig. 1). Composite action was achieved between the steel beam and concrete slab by stud shear connectors welded through the profiled steel decking. The tests were designed to simulate an internal composite beam-to-column connection typical of a low-rise building system. In the tests, the variables were the degree of shear connection, the shear stud spacing and the area of reinforcement. Tables 1 and 2 summarise the dimensions and components in the experimental programme.

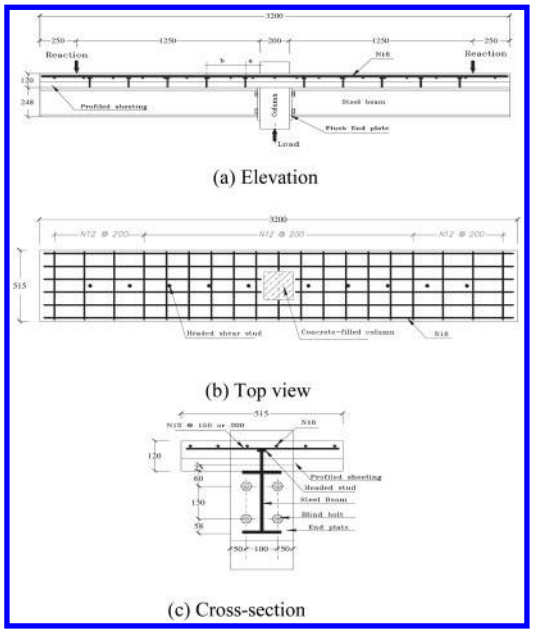

Figure 1. Composite joint tested by Loh *et al.* (2006).

Blind bolt	Hollow-Bolt M20
Stud shear connectors	19×100 mm

3 FINITE ELEMENT MODEL

3.1 *Material properties*

For the ABAQUS modelling, the actual stress-strain curves determined by Loh *et al.* (2006) were used for the shear connectors, steel beam, reinforcement, profiled sheeting and blind bolts. These are shown in Fig. 2, which also shows the piecewise linear representation of these curves for input into the ABAQUS model.

Concrete in compression and tension was represented using the damaged plasticity model in ABAQUS. For concrete in compression, the curve of Carreira & Chu (1985) is used, for which the stress-strain relationship is linear when the stress is less than $0.35f_c$, and

$$\sigma_c = \frac{f_c\gamma(\varepsilon/\varepsilon_c)}{\gamma - 1 + (\varepsilon/\varepsilon_c)^{\gamma}} \quad (1)$$

thereafter, in which

$$\gamma = (f_c/32{\cdot}4)^3 + 1{\cdot}55, \quad (2)$$

$\varepsilon_c = 0{\cdot}002$, f_c is the mean cylinder compressive strength and is in units of MPa.

For concrete in tension, the stress-strain relationship is linear until concrete cracking, after which the concrete is assumed to be perfectly plastic. This simplistic model circumvents several difficulties encountered in FE modelling and improves the rate of convergence, as vindicated with the close agreement between the numerical model and the tests of Loh *et al.* (2006).

3.2 *Element types*

Three-dimensional solid elements were used to model the bare and composite connections. 8-node solid elements with reduced integration (C3D8R) were used to mesh and simulate all components, except for the steel reinforcing bars. These elements lead to more precise and reasonable results and they avoid the shear locking difficulties encountered using other elements such as C3D8I. For the reinforcing bars, a two-node linear truss element (T3D2) was chosen. A typical FE model of a composite joint is shown in Fig. 3.

3.3 *Modelling of shear studs and bolts*

In the present study, the stud shear connector is included in the analysis discretely, in deference to other studies which model the shear connection using non-linear springs whose load-slip response must be defined from empirical push-test results. The shear connector meshing is shown in Fig. 4.

Most researchers have modelled blind bolts with axial and shear springs, with the axial and shear forces carried by these springs being defined based on the shear and tensile strengths of the bolts, with the pretension being neglected. ABAQUS provides an option for that allows for the pretension being included simply, in which the bolt is divided lengthwise into two, defining a surface on which the pretension is applied. The pretension is then applied in the bolts using the "bolt load" module, and this option was used in the present study. Fig. 4 illustrates the meshing of blind bolt. All components were modelled, except the threads on the shank and ledges. The head and nut of the bolts were assumed to connect completely to the shank.

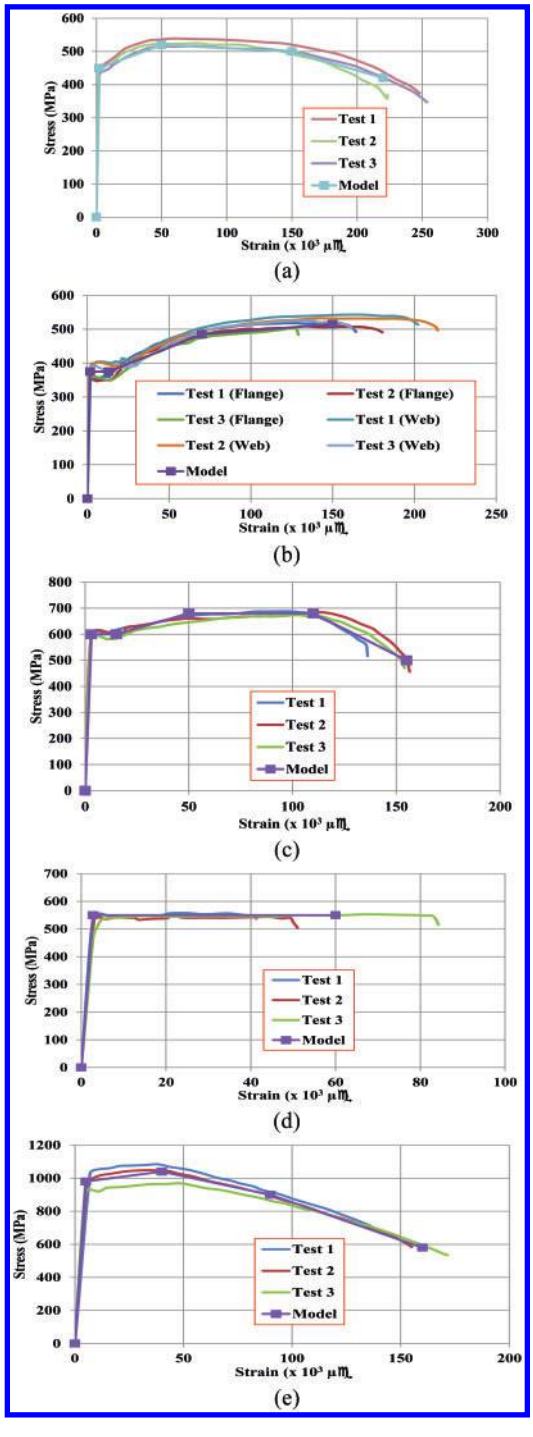

Figure 2. Test and adopted curves: (a) stud connector; (b) steel beam; (c) reinforcing bars; (d) profiled sheeting; (e) blind bolts.

3.4 *Load application*

Loading was applied in two steps. First, the pretension was applied to the blind bolts and the joints were then loaded, at which state the bolts were subjected to the pretension. Mirza and Uy (2011) have pointed out that Riks' technique is needed to capture any unloading in the non-linear analysis, and so the GENERAL method and modified RIKS method were used for the first step and second step respectively. A static concentrated load was applied at the centre of the CFST column, as was done in the tests.

In FE modelling, correct representations of the boundary conditions are essential since slightly different boundary conditions can produce significantly different results. For the simulation in this paper, the boundary conditions were taken as being exactly the same as in the tests, with the column being allowed to move in the vertical direction and with the flanking ends of the beams having roller supports.

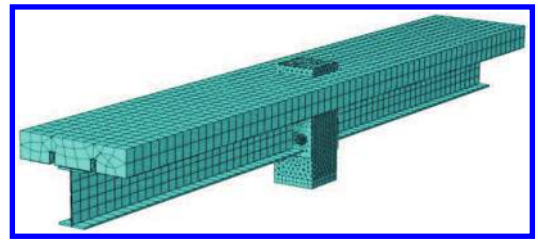

Figure 3. Finite element model of a composite joint.

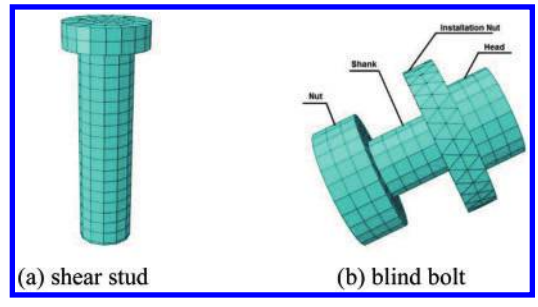

Figure 4. FE meshing of connector components

3.5 *Contact modelling*

One of the most important aspects of modelling is simulation of the contact interaction between components. There are various materials in composite connections which interact with each other, and the results of the FE analysis depend on the accurate modelling of the contact interaction between these materials. The interactions between these materials were treated in ABAQUS in the following way.

Experiments reported elsewhere show there is no separation between the head of the bolt and the flush end plate in a composite connection, and also between the nut of the bolt and the inner face of the steel column. Therefore, the TIE option was used for connecting these components which leads to their having the same displacements. The TIE option was also used for the steel beam and flush end plate because of the welding of these two components together.

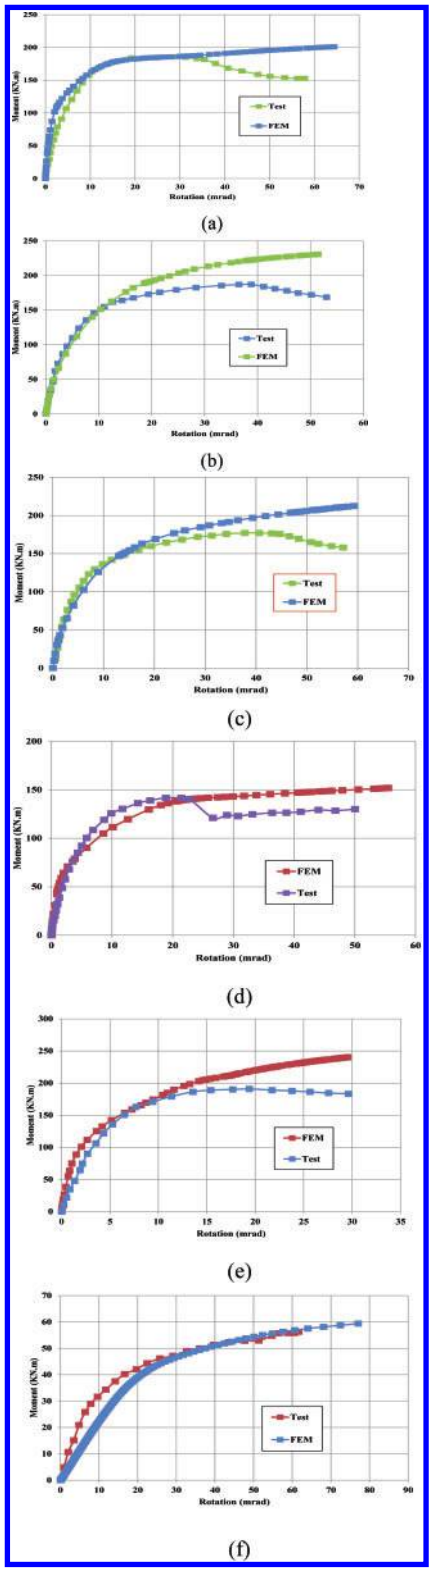

Figure 5. Comparison of FE model and tests for moment-rotation response. (a): test 1, (b): test 2, (c): test 3, (d):test 4, (e): test 5; (f): test 6.

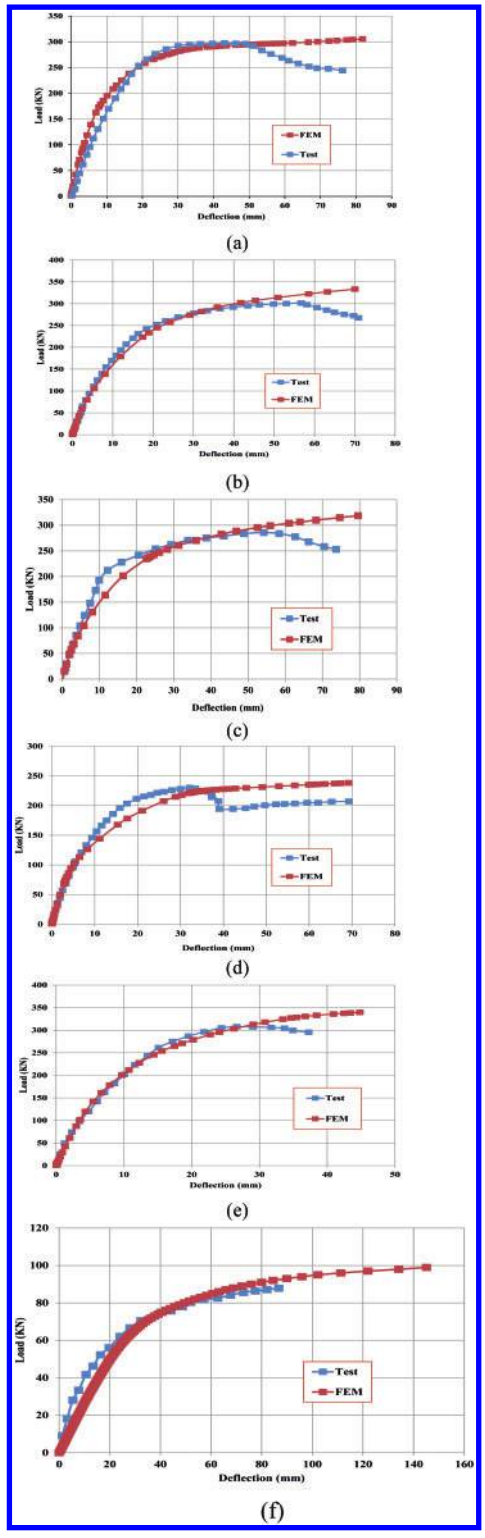

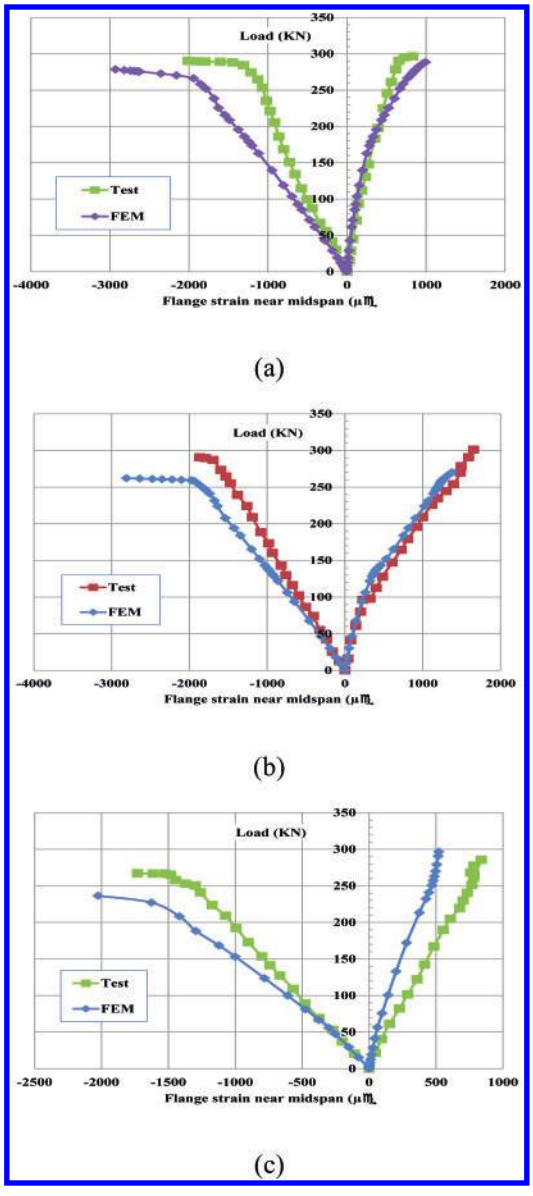

Figure 6. Comparison of FE model and tests for load-deflection response. (a): test 1, (b): test 2, (c): test 3, (d):test 4, (e): test 5; (f): test 6.

In order to simulate the interaction between the top flange of the steel beam and the lower part of the profiled steel sheeting, surface-to-surface contact interaction with a coefficient of friction of 0·1 was adopted, in which the top flange and the profiled sheeting were considered as master and slave surfaces respectively. The same interaction was used to model the interaction between the profiled sheeting and the lower part of the concrete slab. Because headed stud connectors are through-welded to the top flange, the TIE option was used.

As noted earlier, the shank and head of the stud shear connectors were simulated in the FE model. The studs and concrete slab were considered as being embedded and host regions respectively. Gil *et al.* (2013) have pointed out that if the headed studs in a composite joint are embedded in the slab, the model is able to capture the deformation of the concrete. Tahmasebinia *et al.* (2012, 2013) have also adopted this procedure. In this research, only the top part of the shank and head were embedded into the host region (concrete slab) to facilitate reliable convergence. Reinforcement was also embedded into the slab, with the slab being the host region and the bars being an embedded region. This technique connects these two different components and prevents slip between them. Interac-

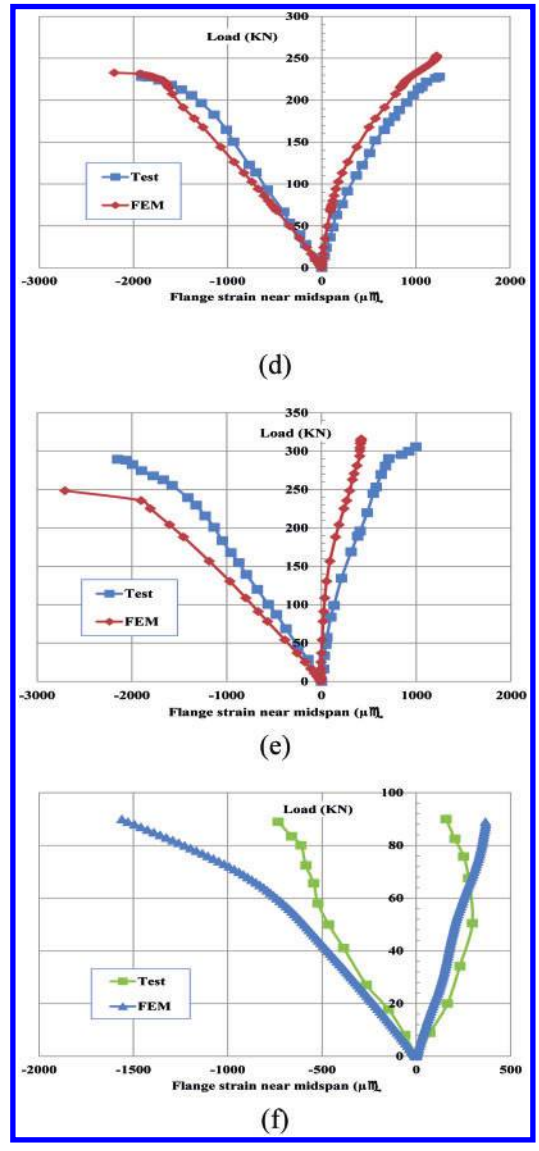

Figure 7. Comparison of FE moel and tests for top and bottom steel strain response. (a): test 1, (b): test 2, (c): test 3, (d):test 4, (e): test 5; (f): test 6.

tion of the concrete and inner faces of the steel tubular column was simulated as a surface-to-surface contact interaction with a coefficient of friction of 0·25.

4 COMPARISON OF TESTS AND FE MODEL

A most important consideration for a FE model is its validation with physical tests. In order to achieve this, the results of the ABAQUS-based FE modelling are compared herein with the experimental results of Loh *et al.* (2006). In this comparison, the moment versus rotation response was modelled, and the results are given in Figs. 5(a) to 5(e) for the five composite connections tested and in Fig. 5(f) for the connection with a bare steel beam. It can be seen that the agreement is very good for much of the range of response, with the discrepancies with large rotations (greater than 15 mrad) probably being attributable to the simplistic modelling of the cracked concrete. The evolution of the curves progressed rapidly using the ABAQUS model described in Section 3.

The load versus deflection response was also modelled, and the results are given in Figs. 6(a) to 6(e) for the five composite connections tested and in Fig. 6(f) for the connection with a bare steel beam. Again, the agreement can be seen to be satisfactory, except for deflections exceeding around 45 mm, for which concrete cracking in negative bending is dominant.

Finally, Loh *et al.* (2006) measured the strains in the top and bottom of the steel section 100 mm from the face of the columns. These were also determined using the ABAQUS model, with the results being given in Figs. 7(a) to 7(e) for the five composite connections tested and in Fig. 7(f) for the connection with a bare steel beam. The results can be seen to be in good agreement.

5 CONCLUSIONS

An efficient finite element modelling using ABAQUS has been developed to simulate the structural response of semi-rigid flush end plate joints with concrete-filled steel tubular columns. The modelling is simplified in its treatment of concrete in tension as quasi elastic-plastic, and it has the facility to handle the stud shear connectors in a discrete fashion rather than by the use of springs and empirical push test data. The technique was shown to be accurate when compared with comprehensive test data reported elsewhere, and it provides an efficacious means for structural modelling in order to develop much-needed design guidance for this application of composite structures technology.

ABSTRACT: This study presents a method for the numerical simulation of the rock cutting process, with the focus on the setup of the model and the description of the material. The aim is to obtain the loads on the pick for different pick geometries and modes of cutting. A quasi-isotropic and quasi-homogeneous rock type is chosen and described with a damage-plasticity constitutive law, which is implemented in the commercial finite element package Abaqus. The constitutive law is extended by a user-subroutine to account for the changing material behavior during the cutting process. The potentially fatal mesh distortion is avoided by the removal of critically damaged elements from the calculation with another user-subroutine. Fine discretization allows the adequate resolution of the contact area and therefore modeling of the effects of different pick geometries and modes of cutting. Additionally, infinite elements are applied as boundary conditions to reduce the model size and calculation time significantly and to prevent any undesirable shock wave reflections in the explicit analysis. It is shown that with the developed method different modes of cutting and pick geometries can be evaluated and compared.

1 INTRODUCTION

1.1 *Principles of excavation*

Roadheaders are widely used for excavation and mining purposes but high material strengths limit their usability (Tockner 1999). Nowadays a challenge is to extend their field of application to harder and more abrasive rock materials. The forces on the pick are of great importance and determine wear and especially the efficiency of the machine. Additionally the cutting capability is naturally limited by the weight of the machine, which makes the reduction of reaction forces by optimizing the process parameters rewarding. (Tockner 1999).

The cutting capability of a pick under certain cutting parameters is tested with the cutting test shown in fig.1. It consists of a rock specimen and one pick that is dragged through the specimen at a certain velocity, attack angle and cutting depth. The cutting test allows to determine the ability of a pick to cut out a certain amount of rock material and is performed to find the cutting parameters that maximize the excavated material and minimize the resulting forces (Tockner 1999).

Fig.2 shows the principle of cutting and the predominant forces. Variation of pick geometry, cutting depth or attack angle will result in an alteration of these forces and determine the efficiency of the process (Tockner 1999). In brittle materials cutting is a stepwise phenomenon of separation and removal of a large segment, the so called chip (Chiaia 2001). The mechanisms of rock cutting follow the principle of indentation (Kou et al. 1999). For spherical and conical indenters these mechanisms are summarized and

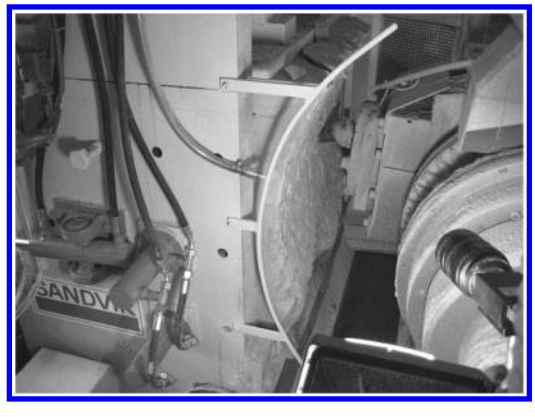

Figure 1. Picture of cutting test (Source: Sandvik Mining and Construction GmbH).

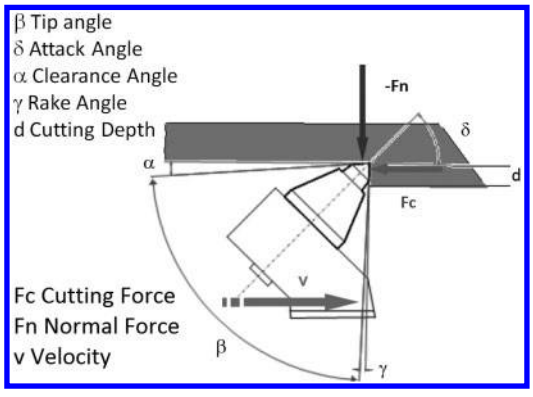

Figure 2. Scheme of the cutting test (Source: Sandvik Mining and Construction GmbH).

analyzed comprehensively by (Chiaia 2001). Directly under the indenter a hydrostatic stress state evolves causing the material to fail only due to crushing and fragmentation mechanisms. In the close surroundings large strains emerge and tensile cracks are formed but in a further distance the material behaves elastically. While blunt indenters form Hertzian cone cracks that propagate with increasing load, sharp indenters lead to the formation of penny shaped cracks and splitting. (Chiaia 2001) further states that with increasing load the fracture behaviour of a blunt object transitions into that of a sharp one. Depending on the rake angle the fracture propagation is either driven by tensile stresses or crushing, which makes the contact zone a determinant for the cutting (Chiaia 2001).

1.2 *Numerical approaches for excavation modeling*

Su & Akcin (2009) point out that rock cutting experiments are currently the most powerful method to characterize the tool-rock interaction. However, they are costly and time consuming.Numerical simulations represent one way to reduce these costs. Su & Akcin (2009) and Lunow & Konietzky (2009) regard particle methods adequate due to their ability of modeling heterogenity. Liu et al. (2002) consider FEM with coupled fracture models most promising and showed together with Kou et al. (1999) the possibility of modeling heterogenity with statisitcal material models. This approach allows the use and adaption of well elaborated constitutive equations available in FEM programs. Liu et al. (2004) point out the importance of an adequate material model and Saksala (2010) additionally mentions the importance of a special treatment of the boundary. Saksala (2010) uses dashpots to suppress energy refelction at the boundary but states that this approach works poor in multiaxial applications. Cho et al. (2010) introduce infinite transmitting boundary conditions to overcome the size limit of the model and maintain fine discretization to calculate rock fragmentation with disc cutters. The problem of potential large mesh distortions arising in the FEM simulation of an excavating cutterhead is solved by Shen et al. (2009) using an arbitrary langrangian eulerian method and by Cho et al. (2010) using element deletion. In a subsequent Cho et al. (2013) perform the numerical optimization of disc cutter spacing and relate the work to the mass of deleted elements as measurement for efficency.

2 THEORETICAL FRAMEWORK

2.1 *General aim*

A procedure is suggested to model rock cutting with the explicit FEM and evaluate the reaction forces on a pick for different cutting parameters and pick geometries. The focus is on the development of the method and its ability to simulate rock cutting. For this purpose the adequate constitutive equations and the adequate discretization are necessary. The zone of pick-rock interaction is crucial for cutting and must be discretized finely enough to resolve the pick geometry and the domain must be embedded such that boundary effects are eliminated.

2.2 *Constitutive equations*

The constitutive equations used, base on the plastic-damage model for concrete by Lubliner et al. (1989) extended by Lee & Fenves (1998). A yield function $F(\underline{\underline{\sigma}})$ in the three-dimensional principal stress space is required in order to identify the stress tensor $\underline{\underline{\sigma}}$ which is critical when inelastic deformation or failure initiates. When eq. (1) is fulfilled, the stress state causes inelastic deformation or failure. Additionally the consistency condition eq. (2) must be fulfilled to ensure that the stress state stays on the yield surface during plastic deformation.

$$F(\underline{\underline{\sigma}}) = 0 \tag{1}$$

$$\dot{F}(\underline{\underline{\sigma}}) = 0 \tag{2}$$

$$F = \frac{1}{1-\alpha(r_\sigma)}(\overline{q} - 3\alpha(r_\sigma)\overline{p} + \beta(\tilde{\epsilon}_c^{pl}, \tilde{\epsilon}_t^{pl}, r_\sigma)\langle\hat{\overline{\sigma}}_{max}\rangle - \gamma\langle-\hat{\overline{\sigma}}_{max}\rangle - \overline{\sigma}_c(\tilde{\epsilon}_c^{pl}) = 0 \tag{3}$$

$\overline{p}$ is the hydrostatic pressure, $\overline{q}$ is the Mises equivalent effective stress and α can be expressed in terms of r_σ, the ratio of initial equibiaxial compressive yield stress to initial uniaxial compressive yield stress. The function β denotes the ratio of the actual uniaxial compressive strength $\overline{\sigma}_c(\tilde{\epsilon}_c^{pl})$ to the actual uniaxial tensile strength $\overline{\sigma}_t(\tilde{\epsilon}_t^{pl})$. γ depends on the ratio of the slopes of the tensile and the compressive meridians in Haigh-Westergaard coordinates. $\hat{\overline{\sigma}}_{max}$ is the maximum principal effective stress, where $\langle . \rangle$ denotes the

Macaulay brackets. The compressive and tensile accumulated plastic strains are denoted by $\tilde{\epsilon}_c^{pl}$ and $\tilde{\epsilon}_t^{pl}$. They are zero at the initiation of failure or inelastic deformation. The constitutive equation can be used to model softening as well as hardening. This means that all parameters which are functions of the compressive and tensile accumulated plastic strains $\tilde{\epsilon}_c^{pl}$ or $\tilde{\epsilon}_t^{pl}$ can change during calculation. The elastic behavior is linear (Simulia 2012).

A different tensile and compressive behavior is modeled using the concept of damage-plasticity separated into tensile and compressive terms. This allows material subjected to tensile failure to stil bel able to bear compression.

$$d_t = d_t(\tilde{\epsilon}_t^{pl}) \tag{4}$$

$$d_c = d_c(\tilde{\epsilon}_c^{pl}) \tag{5}$$

$$d = d(d_t(\tilde{\epsilon}_t^{pl}), d_t(\tilde{\epsilon}_c^{pl})) \tag{6}$$

$$E^{el} = (1-d)E_0^{el} \tag{7}$$

The damage parameters d_t and d_c (eqs. 4,5) are tensile and compressive damage respectively and are combined in a total damage factor d (eq. 6) to degrade the elastic stiffness E^{el} during calculation according to eq. (7). The constitutive equations are therefore adequate to model tensile and compressive damaging and softening or stiffening separately as well as a combination of both. While eqs. (4–5) are user-specified linear functions, eq. (6) is defined in Simulia (2012).

2.3 *Modifications of the constitutive equations*

The constitutive equations are supplemented with a user subroutine. The status of an element (active or inactive in the calculation) as well as material behavior can be changed during the calculation accoring to additional equations. Within this work only the status and the dilation of the material are modified according to eqs. (8–9).

$$s(d_t) = \begin{cases} 1 & \text{if } d_t < d_t, crit \\ 0 & \text{else} \end{cases} \tag{8}$$

$$\phi(\tilde{\epsilon}_c^{pl}) = \begin{cases} \phi & \text{if } \tilde{\epsilon}_c^{pl} < \tilde{\epsilon}_{c,crit}^{pl} \\ 0.02 \cdot \phi & \text{else} \end{cases} \tag{9}$$

The status $s(d_t)$ determines the existence of an element. Changing the status from 1 to 0 indicates the removal of an element from the calculation. $\phi(\tilde{\epsilon}_c^{pl})$ characterizes the dilation of the material and determines the volumetric change due to plastic deformation. It is made adjustabled and set to a low value at $\tilde{\epsilon}_{c,crit}^{pl}$ to avoid unrealistic swelling due to plastic strain.

3 FINITE ELEMENT MODELING

3.1 *Strategy for the elimination of boundary effects*

When the region of interest is small compared to the surrounding medium, actions in the region of interest do not affect the surrounding, making it negligible. However a reasonable distance to the surrounding must be kept. A fine discretization and this reasonable distanceare mutually exclusive when the number of elements shall not increase excessively. To maintain fine discretization where it is needed, without an excessive number of elements on the one hand and without having to deal with numerical artefacts caused by the close boundary on the other hand, the discretized domain can be embedded into so-called infinite elements. This way the surrounding is regarded as unbounded or infinite medium and can be approximated by defining the infinite elements with decay functions over a semi-infinite domain. In dynamic analyses where classical boundary conditions (BCs) would reflect energy back into the domain, infinite elements suppress unrealistic reflection of shockwaves at the domain boundaries (Simulia 2012).

The benefit of infinite elements in explicit analyses is investigated by comparing their behavior against two other modeling approaches. Those are modeling with classical BCs by fixing degrees of freedom and modeling with classical BCs including a constrained discretization discontinuity. The latter allows reduction of elements in the model at positions where coarse discretization is acceptable. The three modeling approaches are compared in three corresponding models. Subjecting the cubic specimen to a time dependent pressure load induces a stress wave travelling through the material. Analyzing the time-dependency and behavior of the stress wave, especially at the boundary and the discretization discontinuity, allows a distinct comparison and choice of the modeling approach. The material is described using the constitutive equations eqn. (1–9).

3.2 *Evaluation of the boundary modeling*

In fig.3 the maximum principal stress with respect to the uniaxial tensile strength at every position along the three cubic test specimens is shown at different times. For simplicity this is further called the stress wave. Fig.3a shows the evolving stress wave in the specimen with classical BCs, while fig.3b shows it in the specimen with classical BCs including a constrained discretization discontinuity and fig.3c shows the stress wave in the domain embedded in infinite elements. The stress waves are plotted at given timesteps after the start of the calculation. The time discretization follows according to the stability requirements for explicit analyses and allows to completely observe the stress wave at any time of the simulation.

It can be clearly seen in fig.3 that the choice of boundary conditions and discretization strongly affects the results. The simulation with classical BC leads to a reflection of a stress wave at the boundary

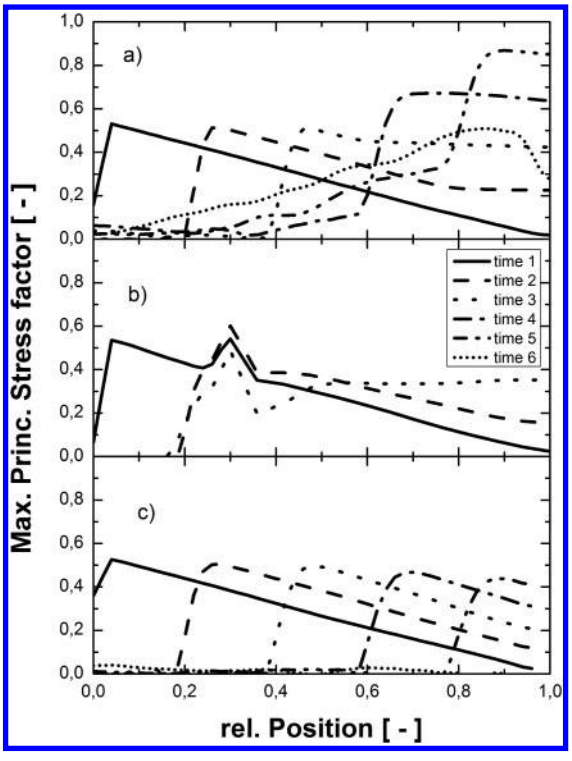

Figure 3. Wave experiment in a discretized domain with a) classical BCs b) classical BCs and discretization discontinuities and c) infinite elements.

(fig.3a). The interference of the reflected wave with the incoming one leads to stress peaks that could fulfill the failure criterion at the boundary and cause damage. In an unbounded domain this effect does not occur. In fig.3b it is evident that the stress wave is partly reflected at the constrained discretization discontinuity at position 0.3 which causes immediate interference and a pronounced stress peak at this position. Due to the resulting interferences a further analysis of the stress-wave after "time 3" is futile. In fig.3c the effect of infinite elements is shown. They replace BCs so that the incoming stress wave can continue without being reflected thus causing interferences. They so inhibit these numerical artefacts and are adequate to model a fine discretized domain within an infinite surrounding.

3.3 *Cutting simulations*

For the cutting simulations two different pick geometries, modeled as displacement-controlled rigid bodies, were used. The first is semi-spherical and the second conical with a height-to-radius ratio of 2. The attack angle was 45 degrees and the cutting depth was either 5 or 10 mm. The material is described according to the constitutive eqn. (1–9). Infinite elements were used to embed the domain and symmetry BCs were used to halve the problem size.

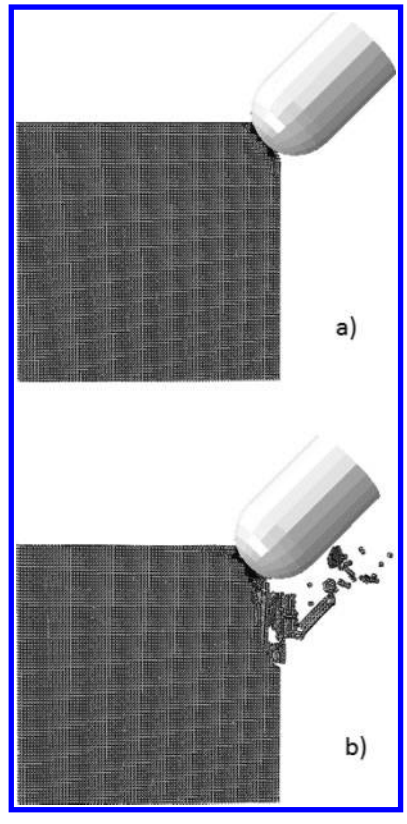

Figure 4. Three-dimensional cutting experiment with a semi-spherical pick at a) 5 mm cutting depth and b) 10 mm cutting depth.

4 RESULTS

4.1 *Results of the cutting simulations*

The cutting simulations yield the load displacement curves in fig.6 and fig.7. The corresponding picture of the cutting model is shown in fig.4 and fig.5 respectively. Each pick geometry and cutting position is evaluated separately for the cutting force and the normal force. The external work can be put in relation to the volume of the removed elements as Cho et al. (2013) did, but this is not adequate in the case of cutting with chipping. First of all it would neglect material that chips off, and second a smaller element size would lead to an increase of the work to removed volume ratio, making the efficiency dependent on the elment size. The direct comparison of the results is set aside because this determination of the efficiency is not satisfactory.

In fig.4a it is evident, that crushing can be modeled when the semspherical pick is pressed onto the surface at minor cutting depths. Fig.6a shows the corresponding force-displacement curve. In absence of sufficiently high shear or tensile stresses the force further increases and normal and cutting force are equivalent. High hydrostatic stresses increase the reaction force on the pick but will prefer crushing over

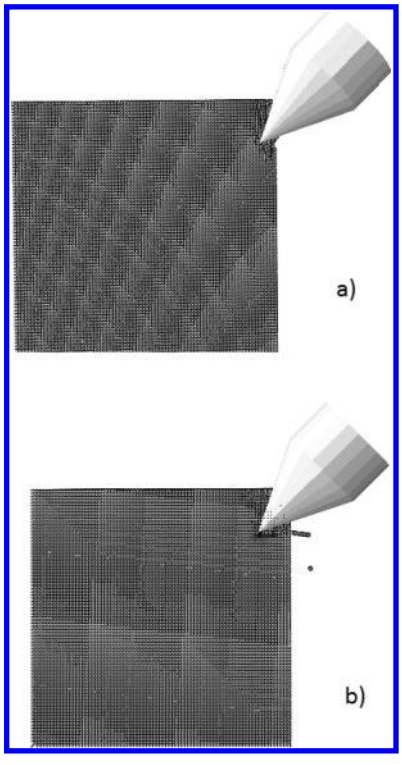

Figure 5. Three-dimensional cutting experiment with a conical pick at a) 5 mm cutting depth and b) 10 mm cutting depth.

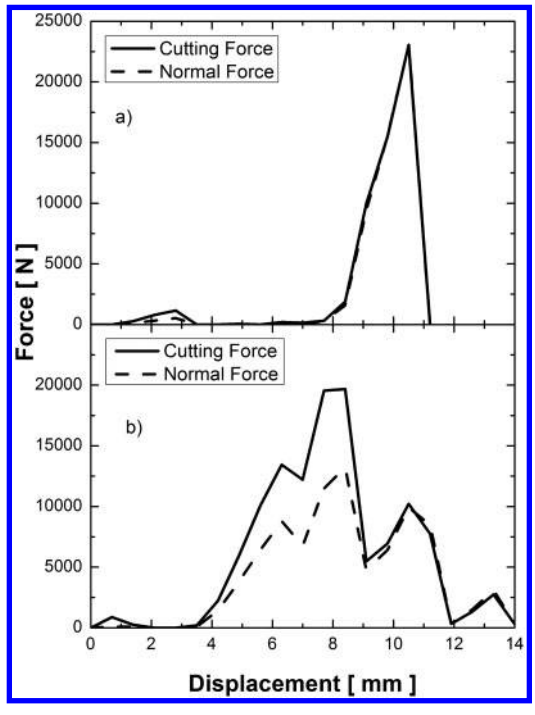

Figure 6. Force-displacement curve of the cutting experiment with a semi-spherical pick at a) 5 mm cutting depth and b) 10 mm cutting depth.

chipping and therefore indicate ineffective cutting. Additionally it can be seen that the forces are temporarily zero. This is caused by the removal of elements directly under the pick which causes the pick to lose contact.

Higher cutting depths favor chipping which can be seen in fig. 4b and in the corresponding force-displacement curve in fig. 6b where the cutting force is higher than the normal force. The chip forms due to tensile stresses in the specimen perpendicular to the cutting direction and surface. Fracture induced by only tensile stresses is favored over fracture accompanied by compressive stresses and chipping is prefered over crushing due to its higher efficiency (Tockner 1999). The high ratio of uniaxial compressive strength to uniaxial tensile strength makes tensile failure much more effective.

In fig.5a a very sharp pick pressed onto the specimen at low cutting depth is shown. The corresponding forces see in fig.7a obtained in the calculation are low due to the characteristics of sharp indenters (Chiaia 2001). The positive rake angles and the very sharp pick yields undercutting and tensile fracture as mentioned by (Chiaia 2001). The very low cutting force and the lower normal force suggest, that few elements are compressed hydrostatically and the major failure mode is due to tensile or shear stresses. The normal force is partly negative which indicates undercutting.

Cutting at higher cutting depth with the conical pick is shown in fig.5b with the corresponding forces in in fig.7b. The observed tendencies are the same as for lower cutting depths because the geometrical relations do not change for increasing the cutting depth. However they do not fully match, which shows the mesh dependency of the simulation when only few elements are in contact with the pick. For both calculations the forces temporarily become zero because the pick is losing contact when elements directly underneath it are deleted.

5 CONCLUSIONS

Within this work a method to simulate rock cutting with an explicit finite element analysis is developed and evaluated. An elaborate set of constitutive equations is extended with an element deletion subroutine to overcome large mesh distortions. It is shown that the treatment of the boundary is of great importance. The introduction of elements with decay functions over a semi-infinite domain (infinite elements) allow to suppress unrealistic reflection of energy back into the domain. The method is then tested by performing calculations where different picks are pressed onto specimens at different positions. It is shown that the process of fracture under high compression as well as chipping can be modeled with the developed modeling approach. Also the effect of different pick geometries

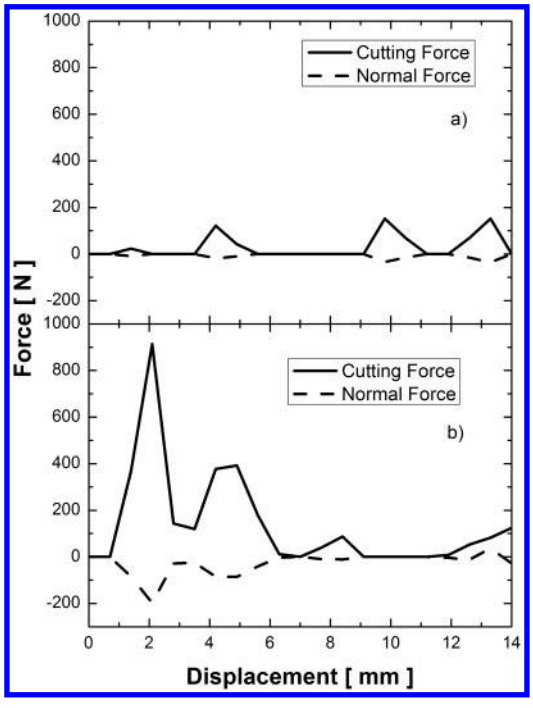

Figure 7. Force-displacement curve of the cutting experiment with a conical pick at a) 5 mm cutting depth and b) 10 mm cutting depth.

and cutting depths can be evaluated. However, direct comparison of the efficiency proves to be difficult due to the combination of chipping and element removal in the simulation. While the basic mechanisms of cutting are accessible with the proposed method, further work has to be put into the development of an adequate criterion to calculate and compare the efficiencies when cutting parameters are changed. Additionally the sensitivity of the model to the discretization must be investigated.

Material influence on the strength of aluminium column web in tension

G. Sarracco, G. Brando & G. De Matteis
Department of Engineering and Geology, University "G. d'Annunzio" of Chieti-Pescara, Italy

ABSTRACT: The current paper presents the first results of an ongoing research activity which aims at investigating the behaviour of aluminium beam-to-column joints. In particular, a wide parametric study, developed on the basis of reliable FEM numerical models and carried out in order to determine the influence of the used alloy on the strength of aluminium column web in tension, is described. In a first phase, the calibration process is implemented in order to validate, on the basis of experimental tests retrieved by literature, the proposed models. Then, alloys characterized by different hardening and ductility are analysed, in order to understand their influence on the resisting mechanisms of the studied component. Finally, the obtained outcomes are interpreted for providing suitable formulations to be adopted in Codes and Guidelines.

1 INTRODUCTION

In the design process of every metal structure particular care must be devoted to the joints. On the one hand, their performance is strongly affected by the intersection and overlap of stresses deriving from converging members. On the other hand, the limited ductility of certain components could give rise to undesired behaviours that must be properly controlled, in particular when the structure is located in strong earthquake prone zones.

With regard to beam-to-column connections, it would be important, for analysis purposes, to characterize the joints by proper moment-rotation relationships (M-Φ) able to reproduce their behaviour in both the linear and the non-linear field (see figure 1). To this aim, the well known component method is currently adopted in Eurocode 3 (EC3, 2003) for steel structures. This method basically allows to obtain the strength and the stiffness of the whole joint by determining, through the application of proper formulations, based on experimental and numerical studies, the mechanical features of the fundamental components.

This is also the general approach currently indicated by Eurocode 9 (EC9, 2007) and other Guidelines, such as the recent Italian CNR-DT 208 (2011), dealing with aluminium alloy structures. For some components, i.e. the ones that can be modelled by T-stubs, formulations traditionally given for steel have been properly adapted through the use of some corrective factors which have been calibrated on the basis of experimental and numerical analysis (De Matteis et al. 2000, 2009, 2012[b]). On the contrary, due to the lack of exhaustive studies in literature, other components have been considered by simply proposing the same expressions used for steel.

Considering the increasing interest on the aluminium employment for realizing new structures

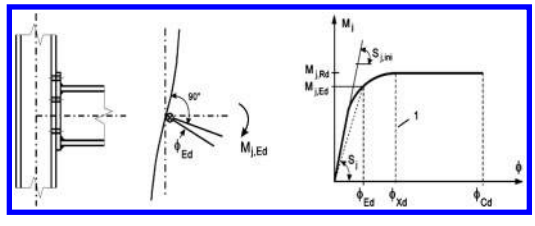

Figure 1. Beam-to-column joint modelling according to EC3.

(De Matteis et al., 2012[a]), as well as the peculiarity of the material itself with respect to steel, further studies are therefore necessary, as the above assumption seems to lead to a rough evaluation of the actual joint strength.

In front of this necessity, the current study, developed in the framing of an ongoing research activity focused on the interpretation of the behaviour of aluminium beam-to-column joints, aims at providing reliable formulations for a correct interpretation of the behaviour of the "column web in tension" component.

In particular, a wide parametric analysis, based on reliable FEM numerical models validated on the basis of experimental tests available in literature, is carried out, in order to highlight the influence of the of the used alloys features, on the strength of the considered component.

2 STATE OF THE ART

Apart from possible buckling phenomena, provided the iso-resistance of metal materials, both column web in tension and compression components behave in the same manner. This aspect allows to retrieve a large

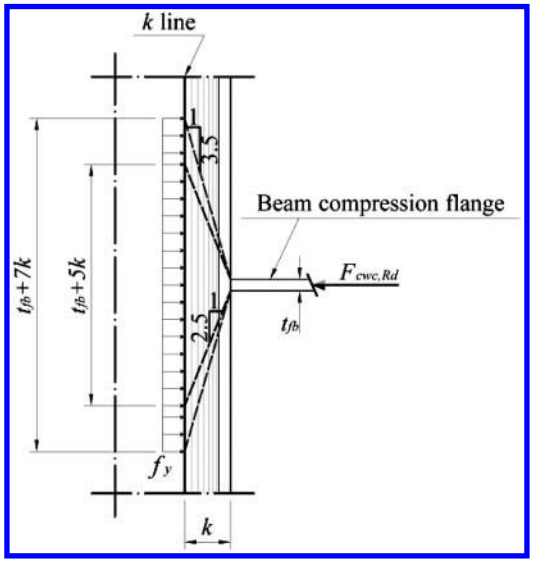

Figure 2. Linear stress distributions through the column web in compression according to Graham et al. (1959).

number of studies in literature which are the basis of the current Codes formulations.

The first researches were developed during the late fifties by Graham et al. (1959), who carried out tests on a simplified specimen of a flange-to-column joint, given by a plate in compression, acting as a beam flange, welded to the flange of a column profile (see figure 2).

The authors established that the maximum strength $F_{cwc,Rd}$ of a steel column web in compression component, when instability phenomena are avoided, is given by eq. (1)

$$F_{cwc,Rd} = f_y t_{wc}\left(t_{fb} + 7k\right) \tag{1}$$

where f_y is the yield stress of the column material, t_{wc} and t_{fb} are the column web and the beam flange thicknesses, respectively, k is the sum of the column flange thickness (t_{fc}) and the fillet root radius (r_c) and identifies the distance between the outer face of the flange and the longitudinal line, lying on the web, on which crashing may develop (henceforth called k line). The above equation results by the assumption of a linear distribution of the compressive stresses, trough the column web, characterized by a 3.5:1 slope.

In the same work, also on the basis of other experimental tests carried out on real complete beam-to-column joints specimens, the Authors recognized that the presence of the beam web, not explicitly considered in their first tests, could reduces the stress distribution inclination to 2.5:1. Hence, the final recommended design value for the strength of the column web in compression has been expressed according to eq. (2).

$$F_{cwc,Rd} = f_y t_{wc}\left(t_{fb} + 5k\right) \tag{2}$$

On the basis of another experimental activity, always focused on steel coupons similar to the ones shown in Figure 2, Aribert et al. (1981) developed a theoretical model able to give a more rigorous interpretation of the two previous equations. They empirically determined the stress distribution at different load steps, by measuring the strains by means of strain-gauges and video extensometers, so to identify three specific strength levels. The first corresponds to the elastic limit state, which is assumed to be attained when the early plasticity arises into the specimens. The corresponding force was given according to eq. (3).

$$F_{cwc,el} = f_y t_{wc}\left(t_{fb} + 2{,}3k\right) \tag{3}$$

The second force level $F_{cwc,pl}$, representing the plastic limit state, was given by eq. (4)

$$F_{cwc,pl} = f_y t_{wc}\left(t_{fb} + 5k\right) \tag{4}$$

The third strength level, corresponding to the section failure (ultimate limit state) was provided by eq. (5).

$$F_{cwc,u} = f_y t_{wc}\left(t_{fb} + 7k\right) \tag{5}$$

Therefore, the Authors obtained, by experimental observations, the same ultimate strength given in eq. (1), but they attributed it to the full exploitation of the strain hardening of the base material.

At the beginning of eighties, Witteveen et al.(1982) carried out some experimental tests in order to determine the moment capacity of both un-stiffened welded and bolted steel beam-to-column joints. For welded specimens they found that the column web in compression can be characterized by the following strength:

$$F_{cwc,Rd} = f_y t_{wc}\left[t_{fb} + 5\left(t_{fc} + r_c\right)\right] \tag{6}$$

On the other hand, for bolted end plate connections, the following expression was provided:

$$F_{cwc,Rd} = f_y t_{wc}\left[t_{fb} + 2\sqrt{2}\ a + 2t_p + 5\left(t_{fc} + r_c\right)\right] \tag{7}$$

where a represents the throat thickness of fillet weld connecting the beam flange to the end plate and t_p is the end plate thickness.

In both the above expressions, the stress distribution was assumed to be linear with an inclination of 45° through both the weld and the end-plate, whereas it was supposed to vary linearly with a slope of 2.5:1 (about 22°) in the column web. It is worth of being noticed that eqs. (6) and (7) are currently provided by EC3, where the expressions given in the square parentheses are defined as effective length (b_{eff}) and represent the portion of the "k line" in which the yielding stresses develop.

With regard to aluminium beam-to-column joints, experimental and numerical activities, aimed at predicting the yielding strength of column web in tension,

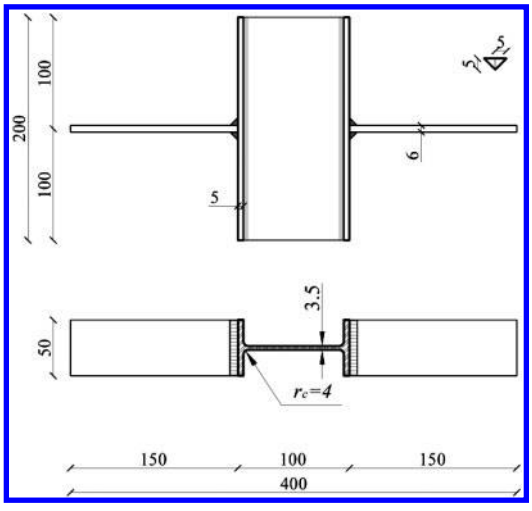

Figure 3. Geometrical dimensions of the specimens tested by Matusiak (1999).

Table 1. Parent material of tested specimens (Matusiak,1999): mean value of mechanical features.

Joint component	Dir.	$f_{0.2}$ (MPa)	f_u (MPa)	$f_{0.2}/f_u$ (MPa)	ε_u (MPa)
Plate	||	304.5	313.5	1.03	0.064
Profile I-100, web	⊥	262.7	281.6	1.07	0.068
Profile I-100, flange	||	268.9	283.4	1.05	0.061

have been described in Matusiak (1999). Specimens made of the EN AW 6082-T6 alloy, whose mechanical features are described in table 1 with regard to the parent material, were investigated.

Their geometry is depicted in figure 3.

The experimentally observed failure mode consisted in a column web fracture along the "*k* line", similar to that expected for steel. For this reason, the Authors proposed the following elastic strength (eq. 8)

$$F_{cwt,el} = t_w b_{eff,el} f_{0.2} \tag{8}$$

Therefore the same base formulation fixed for steel, given in eq. (7), was assumed, with the yielding strength of steel replaced by the conventional elastic strength of aluminium ($f_{0.2}$). The effective length $b_{eff,el}$ was assumed according to eq. (9).

$$b_{eff,el} = t_{pl} + 2\sqrt{2}a + 3.4(t_f + r) \tag{9}$$

In this case a linear distribution of 1.7:1 slope was considered for stresses, which is lower than the one considered for steel in (7), but is higher than the one considered in (3) for the elastic strength of steel.

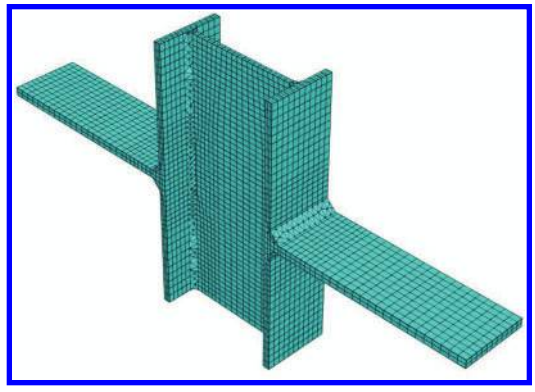

Figure 4. The proposed FE numerical model.

3 THE PROPOSED NUMERICAL MODEL

3.1 *Basis*

A numerical model of a simple aluminium flange-to-column joint has been set up on the basis of the tests carried out by Matusiak (1999) at the NTNU University of Trondheim (Norway). The reliability of the proposed model has been proved by ascertaining that the obtained numerical results fit well the experimental ones. Then, a parametric analyses, has been implemented.

The experimental tests are related to three equal samples, whose geometry has been already shown in Figure 3. The specimens were subjected to an increasing tensile force up to the failure, acting on two plates (equivalent to the beam flanges) welded to the flanges of a I-100 profile, acting as a column.

3.2 *Model Description*

The geometry of the above tested specimens has been modelled by using the ABAQUS FEM non linear software (Hibbitt et al. 1997). The three-dimensional 8-node hexahedral finite elements C3D8R, with reduced integration, have been adopted for meshing all the parts, except the ones representing the weld seams. For the latter, the 4-node linear tetrahedral elements (C3D4) have been used in order to prevent hourglass control problems (see figure 4).

Particular care has been spent in the model meshing algorithm: three elements have been set along the column flanges thickness, while two elements have been imposed transversally to the column web. A more refined mesh has been imposed in the proximity of the plate-to-column flange connection, to account for the higher stresses and strains expected in this zone. Totally, 8534 finite elements, with an average dimension of 4 mm, and 9647 nodes have been used.

As the numerical results could be mesh affected, in order to validate the adopted meshing algorithm, a sensitivity analysis has been performed. To this purpose, the previously described geometry has been also meshed with the same finite elements, but with a halved average size (2 mm instead of 4 mm).

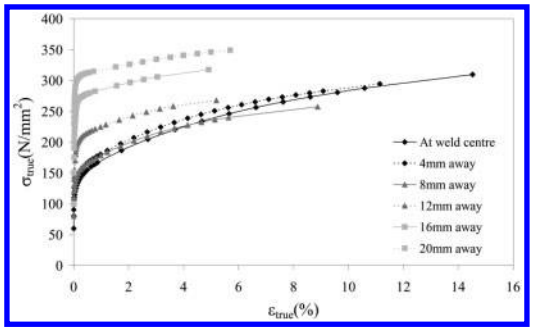

Figure 5. Experimental stress-strain curves of the heat affected material.

As far as the material modelling is concerned, the mechanical features previously described in Table 1 for the parent material have been imposed in terms of true stress-true strain. As far as the heath affected zone is concerned, the true stress-true strain relationships shown in figure 5 have been assumed depending on the distance by the weld seams, according to Matusiak (1999).

In order to simulate the same boundary condition imposed during the experimental tests, the nodes belonging to the free edges of one of the two external plates have been rigidly constrained to a reference point with all the degrees of freedom restrained. Nodes belonging to the free edges of the other plate have been tied to another reference point where all the displacements have been restrained except the one perpendicular to the column flange plane. Along this direction the reference point itself has been subjected to a controlled displacement linearly increasing up to the attainment of the ultimate strain in the specimen. A standard analysis procedure has been implemented and both the mechanical and the geometrical non linearity have been taken into account.

As it is possible to observe by the comparison of Figure 6.a and Figure 6.b, the deformed shapes corresponding to the collapse of both the experimental and the numerical specimens are very similar. Moreover, as revealed by Figure 6.c, the obtained numerical force-displacement relationships, for both the assumed meshes, are depicted and compared with the three curves obtained by tests.

The numerical and experimental results are in good agreement, thus proving the reliability of the implemented modelling process. Moreover the fact that the differences between the two numerical curves are almost negligible allows to state that the less refined meshed model is also reliable for carrying out parametric analyses without jeopardizing the trustworthiness of the obtained results.

4 THE PARAMETRIC ANALYSIS

The mechanical behaviour of aluminium joints is strongly dependent by the mechanical features of the

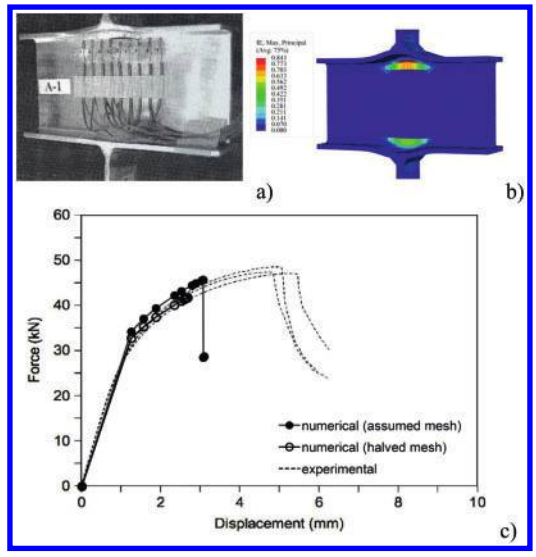

Figure 6. Numerical vs. experimental results: a) The specimen tested by Matusiak (1999), b) Inelastic strain of the numerical model before failure and c) force-displacements curves.

adopted alloys. In fact, as it is known, contrarily to steel, aluminium is characterized, in a different way according to the amount of alloyed elements, by a large strain hardening and a limited ductility. These peculiarities determine the modalities by which possible resisting mechanisms, such as stress distributions inside the components, can occur in the joint and therefore have to be investigated in order to understand their influence.

To this purpose, a parametric analysis has been carried out by imposing the 48 material different constitutive relationships shown in figure 7 to the model presented in previously, for which the presence of the heat affected zone has been neglected.

These have been obtained consistently to the Ramberg-Osgood relationship (Ramberg & Osgood 1943, Mazzolani 1995) given in eq. (10), by fixing the conventional yielding strength f_0 to a value of 250 MPa and by varying the material ultimate strain (ε_u) and the corresponding stress (f_u).

$$\varepsilon = \frac{\sigma}{E} + \left(\frac{\sigma}{B}\right)^{n_p} \tag{10}$$

In detail hardening parameter n_p equal to 5, 6, 8, 10, 15, 20, 30, ∞ have been imposed and, for each value, ductility levels (ε_u) of 4, 8, 12, 16, 20, 24 have been assumed. In this way, eight different families composed by six stress-strain relationships, each one characterized by a different ductility (for a totality of forty-eight constitutive low), have been obtained.

The numerical results obtained by the analysis have been interpreted by checking, for each loading level, both the stress and the strain distributions in the joint. For the sake of example, in Figures 8.a the Mises stress

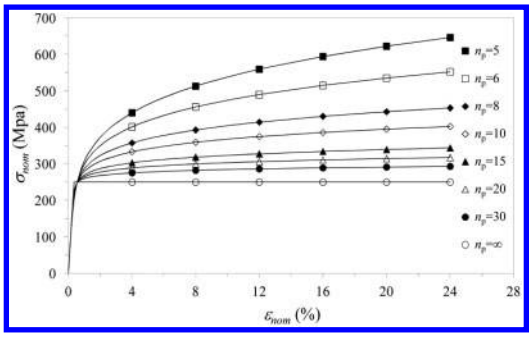

Figure 7. Nominal stress-strain curves for a ultimate strain ε_u=24 assumed in the parametric analysis.

distribution along the "k-line" at the failure attainment is shown for a material characterized by a hardening parameter n_p =30 and a variable ultimate strain (ε_u). It is possible to observe that as the material ductility increases, a larger distribution of plastic stresses is given. Analogously, when the ductility is kept constant, by increasing the strain hardening the slope of the stress distribution through the column web raises (see figure 8.b). Therefore both material characteristics, n_p and ε_u, affect significantly the component strength.

The integral of the above stress distributions represents the maximum strength of the column web in tension. Therefore, when divided by both the reference strength of the base material and the web thickness, it provides a conventional measure of the effective length to be used in equation (7). It is to be highlighted that as reference strength, contrarily to steel, for aluminium the ultimate strength of the base material appears to be more appropriate, allowing to account implicitly for the effect of hardening.

The new formulation for the effective length of the column web in tension has been therefore proposed (see eq. 11) by considering a correction factor β to be introduced in the formulation of the effective length given for steel according to eq. (7).

It has been calibrated so that the ultimate strength $F_{u,num}$ obtained by numerical analyses can be expressed by the following expression:

$$F_{u,num} = f_u \cdot t_w \cdot b_{eff,alu} = \\ = f_u \cdot t_w \cdot \left[t_{pl} + 2\sqrt{2}a_b + 2\beta\left(t_{fc} + r_c\right)\right] \quad (11)$$

The proposed effective length for aluminium joint $b_{eff,alu}$ by means of the β factor takes into account the actual slope (β:1) of the stress distribution in the web, due to the material parameters ε_u and n_p.

The results obtained for the forty-eight studied alloys are represented by the curves plotted in Figure 9., which are well fitted by the by the surface given in figure 10.

The latter has been expressed according to the following expression:

$$\beta(\varepsilon_u, n_p) = \xi(\varepsilon_u) \cdot \eta(n_p) \quad (12)$$

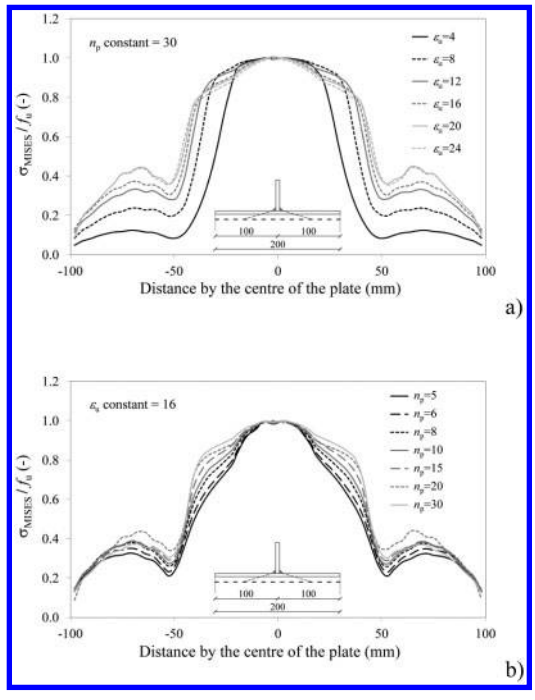

Figure 8. Mises stress distribution for a material with a) n_p =30 and variable ε_u and with b) ε_u =16% and variable n_p.

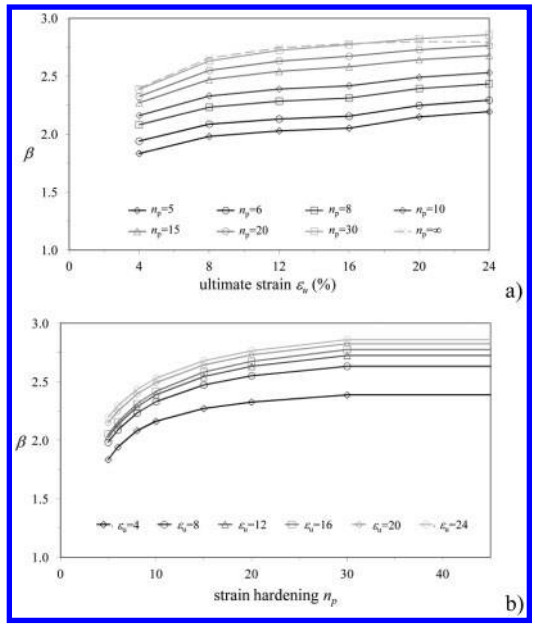

Figure 9. β correction factor as function of a) ultimate strain ε_u and b) strain hardening n_p.

in which

$$\xi(\varepsilon_u) = 0.21 \cdot \ln(\varepsilon_u - 1.6) + 2.2 \quad (13)$$

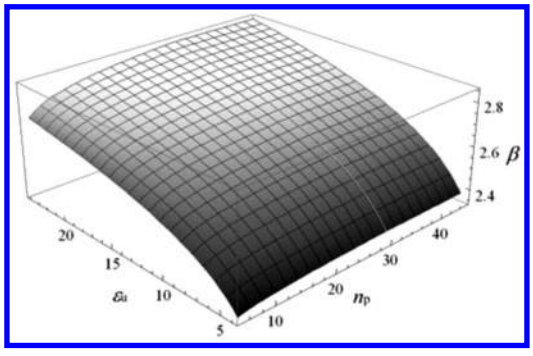

Figure 10. β correction factor: combined effect of ε_u n_p.

and

$$\eta(n_p) = \min\left[1.00\ ; \frac{0.31 \cdot \ln\left(n_p^{2/3} - 2\right) + 2.23}{2.86}\right] \qquad (14)$$

CONCLUSIONS

In the current paper, a parametric analysis aimed at investigating the influence of the base material features on the strength of aluminium column web in tension has been carried out.

In a first stage, a reliable FEM numerical model has been set up. This has been calibrated on the basis of useful experimental tests retrieved by literature.

Then 48 different constitutive models, obtained on the basis of the Ramberg-Osgood relationship, once the ductility and the strain hardening have been properly varied, have been imposed, in order to understand how the component strength is influenced by such parameters.

Static non linear analyses have been run, giving back results that put into evidence that the formulation provided by EC3 is not conservative if applied *sic et simpliciter* to the studied aluminium component.

As a consequence, a suitable β correction factor, to be adopted for properly modifying the effective length given by Eurocode 3 for the strength calculation, has been outlined.

These results are therefore to be intended as a proposal to be included in Codes and Guidelines focused on the use of aluminium structures.

Interaction forces between huge cargo vessels and quay walls

M. Bahr & V. Sigrist
Institute of Concrete Structures, TUHH – Hamburg University of Technology, Hamburg, Germany

ABSTRACT: The berthing maneuver of huge cargo vessels causes high reaction forces. To avoid damages to the ship and the quay walls, rubber fender systems are installed to absorb the kinetic energy of the berthing vessel. In order to analyse the entire berthing maneuver it is essential to understand the mechanics of a berthing vessel and to determine the force-deflection behavior of the rubber fenders in real conditions. Therefore, rather small rubber fenders are tested. The results of these tests can be applied to bigger identically built fenders.

1 INTRODUCTION

It is complex to determine the forces which are transferred from a container ship to a quay wall. There are several reasons for high reaction forces, such as wind pressure upstream, heavy sea or the kinetic energy of the berthing vessel. This paper aims at contributing to the theoretical treatment of the force transmission in case of berthing. During berthing the kinetic energy of the ship has to be absorbed by the quay wall, especially by the fender system. To absorb the kinetic energy of the vessel the fender has to have the right size and shape. There is a big range of different types of fenders to fulfill exactly the requirements for every dimension of vessel and quay wall. In the following the mechanical principles of a berthing ship will be explained and the kinetic impact energy will be determined. Afterwards, experimental and theoretical investigations are outlined that include the testing of fenders and the analysis of the results. In the tests the fender is compressed and unloaded with a constant loading velocity and the reaction forces and displacements are measured and the stored and dissipated energy is determined. Finally the similitude theory is used to transform the results to fenders of bigger size which leads to the conclusion that the reaction force of a huge cargo vessel at berthing can be extremely high.

2 BERTHING IMPACT ENERGY

To analyse the impact energy of a berthing vessel it is necessary to subdivide the berthing procedure at first. Usually the berthing maneuver does not proceed with the vessel lying in parallel to the quay wall (Fig. 1). Initially, the ship hits the first fender with its bow or stern so that the ship's kinetic energy is partially lost. Then the ship turns around its center of mass until it hits another fender with the other end. It can be

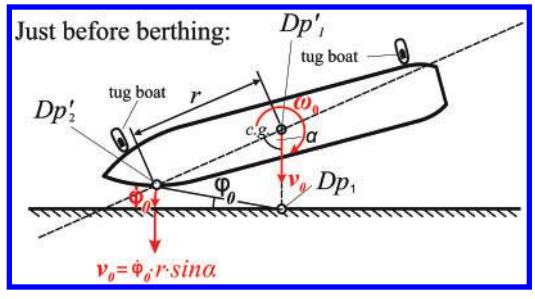

Figure 1. State (a) – geometry just before berthing.

assumed that the velocity vector does not have a component parallel to the waterfront structure because the berthing maneuver is assisted or totally controlled by tugs (Gaythwaite 1990). An angular motion ω_0 of the ship can be disregarded unless external forces such as wind, water current or tug thrust do appear (Gaythwaite 1990). The kinetic energy of the berthing vessel is mainly absorbed by the fender system but also by the ship's hull and the waterfront structure. (Gaythwaite 1990) and (PIANC 2002) refer to a method to determine the energy E_f which has to be absorbed by a fender at first contact. Based on the equation of translational energy E, the energy E_f can be determined to:

$$E_f = E\,C_e\,C_m\,C_s\,C_c = \frac{1}{2}\,m\,v_0^2\,C_e\,C_m\,C_s\,C_c \qquad (1)$$

Gaythwaite (1990) and PIANC (2002) specify the different factors of Eq. 1 as follows:

- Mass m [t]
  Ship mass.
- Vessel's velocity normal to the pier v_0 [m/s]
  The velocity v_0 depends on the shipload as well as on the berthing conditions. Under very difficult conditions a huge vessel berths with a maximum velocity of about 0.2 m/s. The berthing velocity v_0

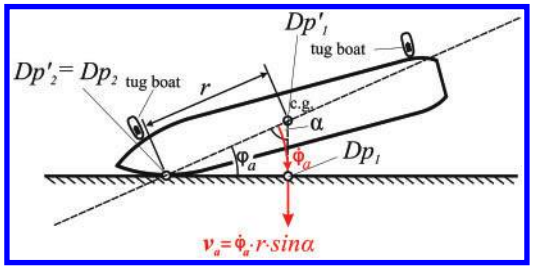

Figure 2. State (b) – geometry in the course of berthing.

Figure 3. Experimental assembly.

has a pronounced influence on the kinetic energy as the energy is proportional to the velocity squared.

- Eccentricity coefficient C_e
  Though formulas for the eccentricity coefficient can be found in the literature, no derivation is given. For this reason C_e is explained here:
  The first contact of the ship and the pier takes place at a point Dp_2 eccentrical to the center of mass $c.g.$ (Fig. 2). In order to determine the impact energy at Dp_2 the rotational energy of the vessel with the angular motion $\dot{\varphi}_a$ around Dp_2 has to be taken into consideration.
  Hence, the kinetic energy of the ship is multiplied by the eccentricity coefficient C_e:

$$C_e = \frac{k^2 + r^2 \cos^2\alpha}{k^2 + r^2} \qquad (2)$$

  where:
  k = radius of gyration of the vessel's mass about its $c.g.$ [m]
  r = distance between the $c.g.$ and the point of impact [m]
  α = angle between the vector of velocity v_0 and the line between the point of contact and the centre of mass [°]

  C_e usually ranges from 0.5 to 0.8. The eccentricity coefficient is calculated with help of the rigid body mechanics by considering eccentrical berthing in 2 states: (a) just before berthing; (b) in the course of berthing. Both states are shown in the Figures 1 and 2. The infinitesimal translatoric motion at the point of contact D_{p2} perpendicular to the shore line has to be considered as a rotational motion with the angular velocity $\dot{\varphi}_0$ and with the corresponding radius r (Fig. 1). This especially applies to long vessels.

  The eccentricity coefficient can be derived with the law of conservation of energy and the parallel axes theorem. Hence, the rotational energy of point Dp'_2 around point Dp_1 in state (a) has to be equated with the rotational energy of point Dp'_1 around point Dp_2 in state (b).

- Virtual mass coefficient C_m
  The virtual mass coefficient C_m accounts for the added mass due to entrained water. There are several suggestions to determine the mass of the water to be moved along with the ship. For C_m the default values are as follows:
  for small under-keel clearance: $C_m = 1.5$
  for large under-keel clearance: $C_m = 1.8$.

- Softness coefficient C_s
  A rather small part of the impact energy is absorbed by the ship's hull. For hard fendering and large ocean-going vessels C_s ranges from 0.9 to 1.0 while the value for soft fendering is 1.0.

- Configuration coefficient C_c
  The configuration coefficient accounts for the damping of the pier. C_c ranges from 0.9 to 1.0 depending on the type of structure to which the vessel is berthing.
  Especially in the case of closed piers (for example vertical sheet pile walls) part of the energy is dissipated because the water between the wall and the approaching vessel cannot drain off quickly enough from around and under the vessel.

3 FENDER MECHANICS

3.1 *Experimental investigation*

In the course of this research fender tests are carried out. For experimental and technical reasons rather small fenders are investigated.

In Fig. 3 the experimental assembly for testing a fender is shown. The tested version is a Cone Fender and is 0.4 m high and has a diameter of 0.5 m at the bottom. The fender is compressed and unloaded with a constant deformation velocity. First the fender is deformed to the maximum allowable value as stated in the product data sheet. Afterwards, the fender is unloaded again. Force and deformation are measured and displayed grafically. Figure 4 exemplarily shows the reaction force as a function of the deformation of the fender. The characteristics of the curve can be attributed to the material properties and the fender geometry.

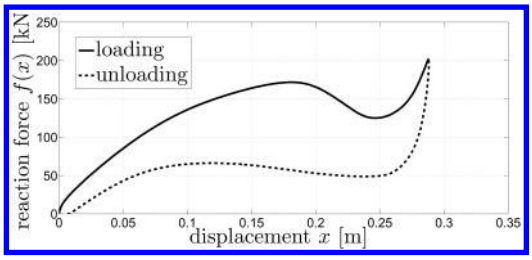

Figure 4. Loading behavior of a small Cone Fender.

During compression the reaction force is higher than during unloading which may be explained with the elastic after-effect. According to (Gerthsen & Vogel 1997) the elastic after-effect is defined as follows:

If an elastic material after loading needs some time to decrease, the material possesses an elastic after-effect. This is exactly what characterizes the fender's relaxation.

Immediately after the load piston is run up, it is measured that the fender has become smaller. At the very end of the phase of unloading ($x < 0.015$ m), the fender is out of touch with the piston and no reaction force is acting anymore (Fig. 4). The original size is not attained within the duration of the run but it rather takes several hours. Regardless of how many runs are executed, there is no accumulating plastic deformation of the fender.

3.2 *Theoretical analysis*

Each type of fender has a characteristic load and deflection behavior.

The integration of the load-deflection relationship yields the mechanical work or the absorbed energy $E(x)$ of the fender, respectively.

As shown in Fig. 4 the tested fender has a nonlinear characteristic and an elastic after-effect. This implies that the energy which is absorbed by the fender during compression is partially returned to the vessel and partially dissipated within the material (PIANC 2002). Both curves (loading and unloading) form a hysteresis. The area between those two curves is the dissipated energy, the part of energy which is not returned back to the vessel. The area under the unloading curve is the stored energy to push the vessel back.

The stored energy and the progression of the hysteresis depend on the deflection x as a result of the magnitude of the impact energy.

Hence, the potential energy $E(x)$ in the equation of motion attains in the phase of loading other values than in the phase of unloading. The potential energy $E(x)$ of the fender in the phase of loading is equal to the absorbed energy while the potential energy $E(x)$ in the phase of unloading is the stored energy, the difference of the absorbed and dissipated energy.

Eq. 3 is the equation of motion, whereas it is assumed, that the ship as well as the waterfront structure do not absorb energy, that means $C_s = 1$ and $C_c = 1$.

By integrating the equation of motion the law of conservation of energy is obtained (Eq. 4).

$$C\,m\,\ddot{x} + f(x) = 0 \tag{3}$$

where:

$f(x)$ = measured reaction-force [kN]
C = $C_e\,C_m\,C_s\,C_c$ [1]
m = ship mass [t]
$\ddot{x} = \frac{d^2x}{dt^2}$ = acceleration [m/s^2]

$$C\,\frac{m\,\dot{x}^2}{2} + E(x) = const = E \tag{4}$$

where:

$E(x)$ = potential energy [kNm]
$\dot{x} = \frac{dx}{dt}$ = velocity [m/s]

The sum of both terms in Eq. 4, here the addition of the kinetic and the potential energy, remains constant. The velocity of the berthing maneuver can be derived from Eq. 4:

$$\dot{x} = \sqrt{\frac{2}{C\,m}(E - E(x))} \tag{5}$$

This expression for the velocity is only be used for the process of berthing and for the duration of compression, respectively. The virtual mass factor C_m increases significantly when the ship is pushed back.

4 TRANSFER OF THE RESULTS

Experimental investigations of fenders for large ocean-going ships are not easy to realise, because of their large size and weight. The transportation is rather challenging and huge and powerfull testing devices are required. It is simpler to test small fenders and to transfer the results to identically built bigger size fenders.

The basis for the transfer of the results is the similitude theory. The evidence of physical similarity of two systems can be adduced by using the equation of motion. In the following the small fender is defined as system 1 and the bigger size fender is defined as system 2. Two systems are physically similar if the equation of motion of system 1 can be transferred to system 2 (Worthoff & Siemes 2012). In other words: If the equation of motion of system 1 is multiplied with a scalar λ and the result is the equation of motion of system 2, both systems are physically similar.

Therefore the system transformation is determined with the following skaling transformation to examine if the equation of motion remains invariant (Landau & Lifschiz 1962).

$$x_2 = \delta\,x_1 \tag{6}$$

$$t_2 = \beta\,t_1 \tag{7}$$

$$m_2 = \gamma\,m_1 \tag{8}$$

For a larger ship with the mass m_2, C has to be recalculated and is denoted as C' in the following.

Hence, Eq. 8 can be written by using the coefficients C and C' as follows:

$$C' m_2 = \gamma C m_1 \tag{9}$$

$$\Leftrightarrow \; M_2 = \gamma M_1 \tag{10}$$

Finally, the equation of motion of system 1 (Eq. 3) becomes the equation of motion of system 2 (Eqs. 11 or 12) with the derivatives:

$$\gamma M_1 \frac{d^2}{d(\beta^2 t_1^2)}(\delta x_1) + f_2(\delta x_1) = 0 \tag{11}$$

$$\Leftrightarrow \; \frac{\gamma\,\delta}{\beta^2} M_1 \frac{d^2}{dt_1^2} x_1 + f_2(\delta x_1) = 0 \tag{12}$$

The dynamic part of the bigger size system is determined by multiplying the dynamic part of the small system with the following factor:

$$\lambda = \frac{\gamma\,\delta}{\beta^2} \tag{13}$$

In the next step the reaction-force $f_2(\delta x_1)$ can be derived from $f_1(x_1)$.

Therefore the deformation of system 1 and of system 2, respectively, are calculated by using the principle of virtual displacements.

The deformation of system 1 is calculated as a function of the force $f_1(x_1)$, the deformation of system 2 as a function of the force $f_2(\delta x_1)$. If both equations are solved for the forces $f_1(x_1)$ and $f_2(\delta x_1)$ and afterwards the ratio of the forces is formed (Eq. 14) it is demonstrated that the ratio posesses the order 2 concerning the scaling of lenght.

$$\frac{f_2(\delta x_1)}{f_1(x_1)} = \left(\frac{x_2}{x_1}\right)^2 = \delta^2 \tag{14}$$

where:
$\delta =$ scaling of lenght

The equation of motion of system 1 can only be transformed to the equation of motion of system 2 if the ratio of the forces fullfilles Eq. 14.

To merge Eqs. 13 and 14, λ must additionally be defined as follows:

$$\lambda = \delta^2 \tag{15}$$

$$\Rightarrow \; \delta^2 = \frac{\delta\,\gamma}{\beta^2} \tag{16}$$

Eq. 16 points out that the scaling of mass γ and the scaling of length δ can be selected without restrictions. The scaling of time β follows as soon as γ and δ are set.

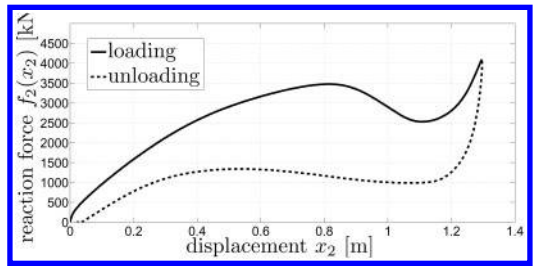

Figure 5. Behavior of fender 2 during loading and unloading.

Using Eqs. 13, 14 and 15, Eq. 12 results in:

$$\frac{\gamma\,\delta}{\beta^2} M_1 \frac{d^2}{dt_1^2} x_1 + \delta^2 f_1(x_1) = 0 \tag{17}$$

$$\Leftrightarrow \; \lambda M_1 \frac{d^2}{dt_1^2} x_1 + \lambda f_1(x_1) = 0 \tag{18}$$

If Eq. 18 is divided by λ, the equation of motion of system 1 is obtained, which means that the equation of motion remains invariant and the two systems are physically similar.

Eqs. 6 and 14 transform the load-deflection relationship of the tested small fender to a bigger size Cone Fender. The result is shown in Fig. 5.

The bigger fender (fender 2) is 1.8 m high and has a diameter of 2.25 m at the bottom.

Hence, this fender is 4.5-times bigger than the tested one and is able to withstand a very high kinetic energy.

The ratio of the reaction forces δ^2 of two systems (Eq. 14) and the principle of work and energy yields the ratio of energy:

$$\frac{f_2(x_2)}{f_1(x_1)} \frac{\Delta x_2}{\Delta x_1} = \left(\frac{x_2}{x_1}\right)^2 \frac{\Delta x_2}{\Delta x_1} = \frac{E_2(x_2)}{E_1(x_1)} = \delta^3 \tag{19}$$

With the ratio of the reaction forces δ^2 and the ratio of erergies δ^3 the following example can be treated:

The big fender is able to absorb a kinetic energy which is caused by a container vessel of the 6th generation with a length of about 395 m, a mass m_2 of about 250000 t and a berthing verlocity of $v_0 = 0.17$ m/s.

In this case the maximum reaction-force is obtained by Fig. 5 or from Eq. 20:

$$f_2 = f_1\,\delta^2 = 200 \cdot 4.5^2 = 4050 \text{ kN} \tag{20}$$

The ratio of energy and Eq. 5 imply that the velocity of a large ship progresses as follows:

$$\dot{x}_2 = \sqrt{\frac{2}{C_2\,m_2}(E_1 - E_1(x_1))\,\delta^3} \tag{21}$$

Figure 5 shows the velocity in the course of loading and unloading of a big fender. Although it is not quite correct to use the virtual mass factor C_m for the velocity of unloading, C_m remains fixed in the example to get a better understanding of the fender's potential energy.

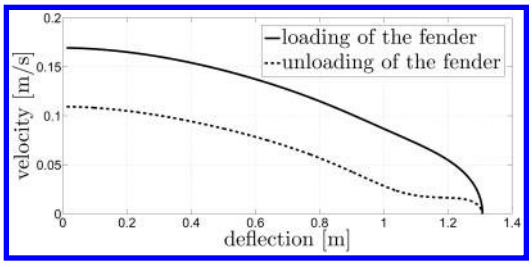

Figure 6. Velocity of the fender deflection.

5 SUMMARY AND CONCLUSION

In the previous sections it is shown how the results of the experimental investigations of small fenders can be transferred to identically built bigger size fenders.

An example for a berthing container vessel of the 6th generation illustrates that the maximum reaction force can be very high.

Response of a building envelope system to near field blast events

H.D. Hidallana-Gamage, D.P. Thambiratnam & N.J. Perera
Science and Engineering Faculty, Queensland University of Technology, Brisbane, Australia

ABSTRACT: This paper presents the methodology, numerical analysis and the initial findings of the research work conducted by the authors towards the safe and efficient design of building facades and their components to blast loads. Building facades using Laminated Glass (LG) windows are studied by considering their superior blast resistance compared to the other techniques used in building facades. The effects of support conditions on the blast response of LG windows are examined in the paper by varying the thickness of the structural sealant joints. The results from numerical analyses indicate that the LG panels with thick sealant joints undergo larger deformations absorbing higher blast energy compared to those with thinner sealant joints. The increase in the thickness of sealant joints causes significant reduction of the stresses close to the supports of LG panels improving their performance under blast loads.

1 INTRODUCTION

External facades forming a building envelope is the most vulnerable component in a building to blast loads. Glass facades are the most popular types among the building owners and architects for their architectural features and the aesthetical aspects. However, it is evident that more than 80–90% of injuries caused by blast loads are due to flying glass fragments and façade pieces (Muller & Wanger, 2006). If the building façade disintegrates, the blast pressure will enter the building causing injuries to the occupants and even structural collapse. Building facades should therefore be designed for a credible blast event to minimize, if not eliminate there consequences.

Research has investigated blast resistant window systems, as well as retrofit techniques to strengthen existing facades. Four different techniques commonly used in such building facades are window films, window catcher systems, laminated glass (LG) windows (or panels) and ballistic windows. Window films and catcher systems are especially used to retrofit existing windows. Window films are cheap, but usually the life span is less, as they degrade when exposed to the Ultraviolet (UV) light. On the other hand, window catcher systems affect the appearance of a building as they are attached inside the building façade. Ballistic windows are capable of resisting very high loads and are usually used in bullet resistant windows. However, they are very expensive and also transfer high loads to the window frames. LG windows are energy absorbing and the most popular because of their capability to withstand high blast loads. This paper therefore illustrates the blast response of building facades using LG windows.

LG is made of several glass panes that are interconnected using one or more interlayers. Different glass types such as annealed, heat-strengthened or tempered glass are used in LG windows where the polyvinyl butyral (PVB) is usually used as the interlayer material. LG windows are mounted to the window frames using structural sealant joints. LG provides superior blast resistance compared to normal glass as the interlayer holds the glass panes even after the glass cracks. It has been shown that the post-crack load carrying capacity of a LG panel is considerably higher than that at the pre-crack phase (Cormie et al., 2009).

Design standards such as American Society for Testing and Materials F 2248-09 (ASTM F 2248-09, 2010) and Unified Facilities Criteria 3-340-02 (UFC 3-340-02, 2008) are used for designing glazed facades to blast loads. However, both standards are conservative as they are based on simplified single degree of freedom analysis. The ASTM F 2248-09 neglects the effects of interlayer in the analysis, while the UFC 3-340-02 is limited to design of monolithic thermally tempered glass. The UK Glazing Hazard Guide (UK Glazing Hazard Guide, 1997) considers both pre and post-crack load carrying capacity of LG and hence provides a more realistic design approach compared to the previous standards. However, it was established for only few window sizes available in the UK and is restricted to military use. This emphasizes the requirement for a rigorous and reliable analytical procedure to investigate the behaviour of building facades with LG windows to blast loads.

2 METHODOLOGY AND NUMERICAL ANALYSIS

2.1 *Methodology*

This research was initiated to investigate the behaviour of building facades with LG windows, and study the

influence of controlling parameters such as material and geometric properties, support conditions and energy absorption to establish a framework for their design for a credible blast event. The developed framework will optimize the building envelope as well as the structural framework of the building while providing adequate blast resistance. Following tasks are conducted during this research in order to achieve the desired outcomes.

1. Develop a rigorous analytical procedure for reliable design of building facade systems and components for the effects of near field blast events
2. Investigate the effects of facade size, glass pane thickness, interlayer thickness, bed width and thickness of structural sealant joints and the type of secondary supports using parametric studies to enhance the blast resistance, system performance and safety
3. Parametric study on properties of glass, interlayer and structural sealant materials to enhance the performance under blast loading
4. Investigate the performance of different facade systems such as Double Skin Facades (DSFs), Cable Net Facades (CNFs) and alternative combined systems using the outcome of abovementioned studies

2.2 *Numerical analysis*

Numerical analysis with finite element (FE) codes is a feasible method to analyse the response of LG windows under extreme loads. FE codes with explicit capabilities such as LS DYNA, ABAQUS ANSYS and EUROPLEXUX FE have been used to analyse their behaviour under blast and impact loads. The authors have developed and validated a FE based procedure to analyse LG windows under blast loads with LS DYNA FE code. Both three and two dimensional (3D and 2D) LG models are presented incorporating different material models. In the 3D LG models glass panes and interlayer are modelled with 3D solid elements using material model 110 for glass while using material model 24 for the interlayer. In the 2D LG models the whole LG panel is modelled with 2D shell elements using material model 32. In both 3D and 2D LG models the structural sealant joints are modelled with 3D solid elements using material model 24.

It was observed that the 3D LG models provide more accurate results and can be used to investigate the effects of geometric and material properties of different façade components. On the other hand, the 2D LG models provide reasonably accurate results consuming less computational time compared to the 3D LG models, and hence can be used to investigate the global behaviour of large façade panels. The 3D LG models are used in this paper to investigate the effects of support conditions of LG panels by varying the thickness of the structural sealant joints.

3 EFFECTS OF STRUCTURAL SEALANT JOINTS

3.1 *Description of the case study*

(Kranzer et al., 2005) conducted experiments on LG panels with 1.1 m width, 0.9 m height and 7.5 mm thickness (3 mm annealed glass + 1.52 mm PVB + 3 mm annealed glass) under different blast loads. The numerical modelling techniques used in this paper had been validated using the results from one of them involving a free field blast test (FX005) and were presented in a previous research work. The experiment was conducted under a blast load with a maximum positive blast pressure of about 58kPa and positive load duration of about 3 ms. The blast pressure time-history curve of the experiment is shown in Figure 1.

The experiments were carried out according to (BS EN 13541, 2001) which states that the test panels should be clamped using rubber strips having about 50 mm width and 4 mm thickness. BS EN 13541: 2001 states that the thickness of rubber strips should be in the range of 3–5 mm. However, FE analyses were carried out by taking the thickness of the rubber strips as 3, 4, 5 and 6 mm to investigate the effects of thickness of these strips on the behaviour of the LG panel. The 3D LG model mentioned in section 2.2 was used in the FE analysis where one-quarter of the test panel was modelled by considering symmetry conditions. The blast load was applied uniformly on the top glass pane and the 3D view of the FE model is shown in Figure 2. Material properties required in the FE analysis for glass, PVB and the rubber sealant were obtained

Table 1. Material properties of glass, PVB and rubber sealant

Material property	Glass	PVB	Sealant
Density (kg/m^3)	2500	1100	1100
Young's modulus (MPa)	72000	530	2.3
Poisson's ratio	0.22	0.485	0.495

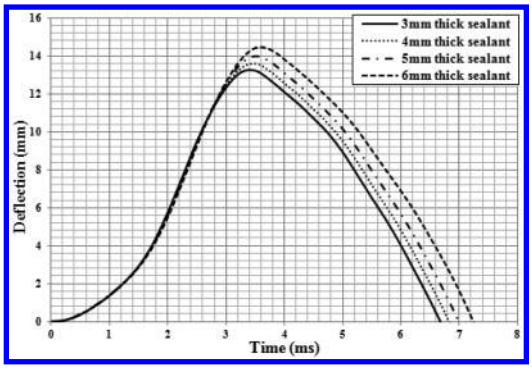

Figure 3. Deflection-time history curves at the centre for different thicknesses of sealant joints.

from the literature and are given in Table 1. (Hooper et al., 2012) mentioned that dynamic breaking strength of annealed glass can be about 80 MPa under blast loads, and was taken as the tensile strength (T) of the glass during the FE analyses.

3.2 *Results and discussion*

Results from FE analysis for deflections and principal stresses at critical locations as well as the total energy absorption of the FE models are presented. It could be noted that all the deflections presented in this paper are those normal to the plane of the LG panel at its initial stage. Figure 3 illustrates the variation of the deflection at the centre of the LG panel for different thicknesses of the structural sealant joints. Maximum deflection corresponding to LG panel with 3 mm thick sealant joints is 13.25 mm. It increased to 13.62, 13.98 and 14.45 mm when the thicknesses of the sealant joints are taken as 4, 5 and 6mm respectively. The increases in the maximum deflections are about 2.8, 5.5 and 9.1% respectively compared to that of LG panel with 3 mm thick sealant joints. It is clear that the increase in the thickness of the sealant joints increases the flexibility of the LG panels allowing them to undergo large deformations.

Figure 4 illustrates the variation of the deflection at the middle of the long edge of the top glass pane (refer location 2 in Fig. 2) for different thicknesses of the sealant joints. Maximum deflections occurred at about 4.5 ms in each case and there is a significant increase in those with the increase in the thickness of the sealant joints. The lowest maximum deflection, which is about 0.26 mm, occurs for the LG panel with

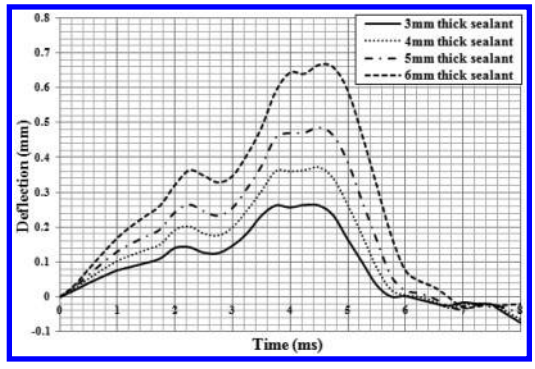

Figure 4. Deflection-time history curves at the middle of the long edge of the top glass pane (at location 2) for different thicknesses of sealant joints.

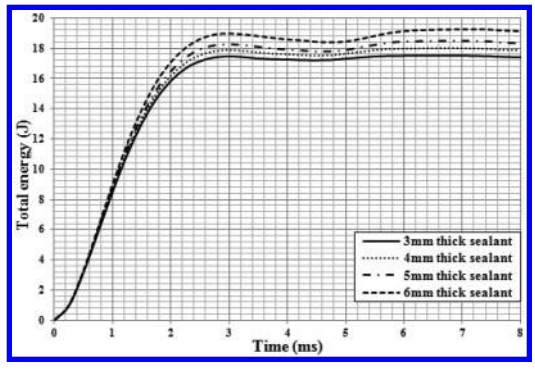

Figure 5. Total energy-time history curves for different thicknesses of sealant joints.

3 mm thick sealant joints. It increased to about 0.37, 0.49 and 0.67 mm when the thicknesses of the sealant joints are taken as 4, 5 and 6 mm respectively. The increases in the maximum deflections are about 42, 88 and 158% respectively compared to the value obtained for the LG panel with 3 mm thick sealant joints.

Figure 5 illustrates the total energy-time history curves for different thicknesses of sealant joints. The total energy increases rapidly until about 3 ms which is equal to the positive load duration of the blast load, and then becomes a constant value thereafter for each case. It is clear that the total energy absorbed by the FE models increases with the increase in the thickness of the sealant joints. The total energy absorbed by the LG panel with 3 mm thick sealant joints is about 17.46J. It increased to about 17.98, 18.5 and 19.25J when the thicknesses of the sealant joints are taken as 4, 5 and 6 mm respectively. The increases in the total energy are about 3, 6 and 10.3% respectively compared to the value obtained for the LG panel with 3 mm thick sealant joints.

Figure 6 compares the maximum principal stress variations at the centre of the bottom glass pane (refer location 1 in Fig. 2) for the LG panels with 3 and 6 mm thick sealant joints. The peak maximum principal stresses obtained from the FE models of those

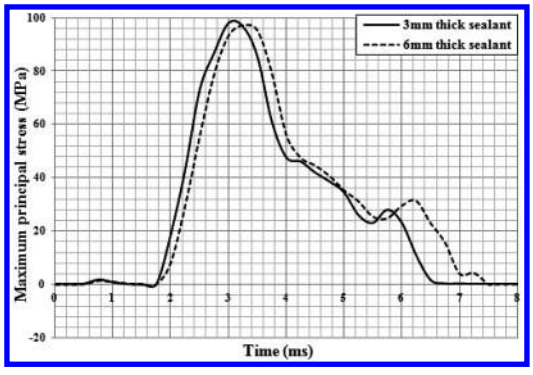

Figure 6. Maximum principal stress variations at the centre of the bottom glass pane (location 1).

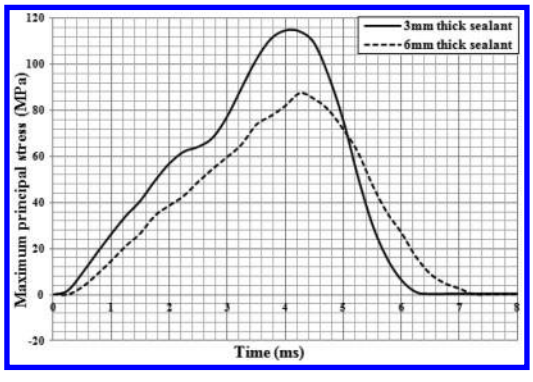

Figure 7. Maximum principal stress variations at the middle of the long edge of the top glass pane (location 2).

LG panels are 98.5 and 97.5 MPa respectively. Both occurred at about 3.1–3.4 ms and there is about 1% reduction in the peak maximum principal stress for the LG panel with 6 mm thick sealant joints compared to that with 3 mm thick sealant joints.

Figure 7 compares the maximum principal stress variations at the middle of the long edge of the top glass pane (refer location 2 in Fig. 2) for the LG panels with 3 and 6 mm thick sealant joints. The peak maximum principal stresses occurred at about 4.1–4.3 ms and corresponding values for LG panels with 3 and 6 mm thick sealant joints are about 116 and 88 MPa respectively. There is a significant reduction (about 24%) in the peak maximum principal stress for the LG panel with 6 mm thick sealant joints compared to that with 3 mm thick sealant joints. LG panel with 6 mm thick sealant joints undergoes excessive movements at the supports (as observed in Fig. 4) and hence causes a reduction in the tensile stresses along the edges of the top glass pane.

Even though a quarter of the LG panel was used for the FE analysis, maximum principal stress contours were plotted for the whole LG panel as shown in Figures 8–11. Maximum principal stress variations on the bottom glass pane at 3.25 ms for the LG panels with 3 and 6 mm thick sealant joints are shown in Figures 8 and 9 respectively. Stress variations at the middle of

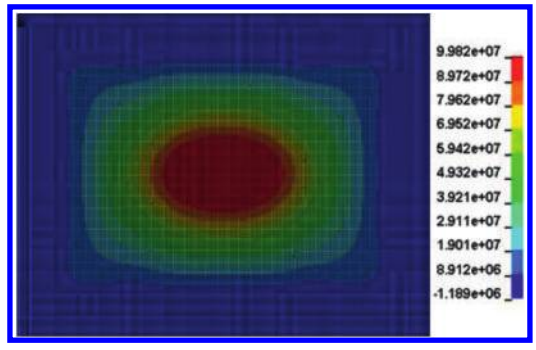

Figure 8. Maximum principal stress variation on the bottom glass pane at 3.25 ms for the LG panel with 3 mm sealant joints.

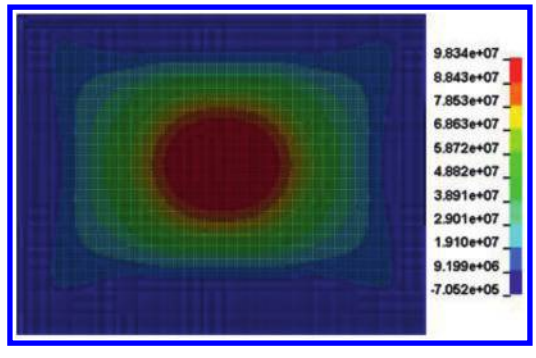

Figure 9. Maximum principal stress variation on the bottom glass pane at 3.25 ms for the LG panel with 6 mm sealant joints.

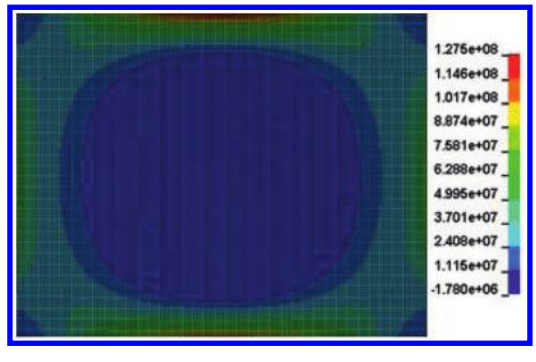

Figure 10. Maximum principal stress variation on the top glass pane at 4.25 ms for the LG panel with 3 mm sealant joints.

the bottom glass pane are similar in both figures, but the LG panel with 6 mm thick sealant joints shows an increase in stress distribution towards the supports.

Maximum principal stress variations on the top glass pane at 4.25 ms for the LG panels with 3 and 6 mm thick sealant joints are shown in Figures 10 and 11 respectively. It is clear that there is a significant reduction in the maximum principal stress along the edges of the LG panel with 6 mm thick sealant joints.

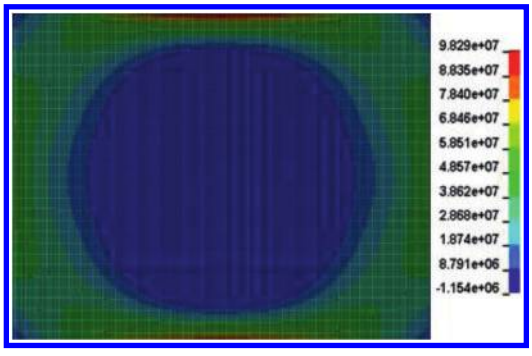

Figure 11. Maximum principal stress variation on the top glass pane at 4.25 ms for the LG panel with 6 mm sealant joints.

This might be due the increase in stress distribution throughout the perimeter of the LG panel with 6 mm thick sealant joints, than gathering the stresses into critical regions as observed in the LG panel with 3 mm thick sealant joints.

4 CONCLUSIONS

The results form FE analyses indicate that the increase in the thickness of the sealant joints causes an increase in the maximum deflection as well as the energy absorption of the LG panels. LG panels with thick sealant joints have freedom to undergo larger deformations at the joints reducing the stresses close to their supports and hence provide superior blast resistance compared to those with thinner sealant joints. It is evident that the increase in the thickness of sealant joints or the flexibility at the supports of LG panels increases their performance under blast loads. The authors therefore believe that the cable net facades with LG windows will further improve their performance as the cable net can itself undergo large deformations, and this will be investigated in the later part of the present research.

Impact velocity and initial length influence on the crushing behaviour of TWCF open section members under axial impact

M. Kotełko & R.J. Mania

ABSTRACT: The paper is devoted to the study of transition between progressive dynamic buckling and global bending failure of axially loaded open section steel columns subjected to the compressive impact force. Channel and top hat section are under investigation. An influence of the column initial length and impact velocity on the crushing behaviour (failure mode) is investigated. The analysis is performed on the basis of FE simulations and mainly experimental tests. The tests are realized on the drop hammer rig. Results of impact crushing tests carried out at different impact velocities on specimens of different length are presented. The impact tests are performed with the impact energy up to 5 kJ and impact velocity up to 10 m/s. Experimental results are compared with the results of the analytical calculations of critical (transition) buckling length based on the simplified theoretical model. The results are presented in load – time diagrams and failure patterns. Some conclusions concerning an influence of the impact velocity upon the final mode of failure related to the energy absorption capability of columns are derived.

1 INTRODUCTION

Dynamic buckling response of thin-walled structural members subjected to impact, axial compressive load has been investigated extensively by many researchers. In recent years some research have been carried out into the transition from progressive local buckling to global bending failure mode in thin-walled columns (bars) under axial impact. Such a transition is observed in the stage of collapse of relatively long bars and at impact velocities higher than a certain 'critical' one. Determination of 'limit' or 'critical' values of bar's length and impact velocity is still an open question. Since a transition from local progressive buckling to global bending leads to a significant decrease of energy absorption capability, the determination of a threshold criterion between those two failure modes is of crucial importance.

Experiments carried out on axially impacted circular tubes by Alves and Karagiosova (2004) and channel – section columns by Teramoto (2004) show, that the critical buckling length depends on initial impact velocity and material parameters. Research into analytical solutions of the problem was carried out by Alves and Karagiosova (2004), who proposed three theoretical models of dynamic buckling of circular tubes subjected to axial compressive force. There are three different theoretical "rod models" proposed, namely; the Euler buckling model (Fig. 1a), the three-link model (Fig.1b) and the "two-phase deformation model" taking into account inertia effects and allowing one to analyze an influence of initial velocity on the critical buckling length. The models have been derived for the circular tube. Two first models were adopted by Kotełko and Mania (2012) for the case of an arbitrary open section column, who presented results of preliminary impact tests of open section members.

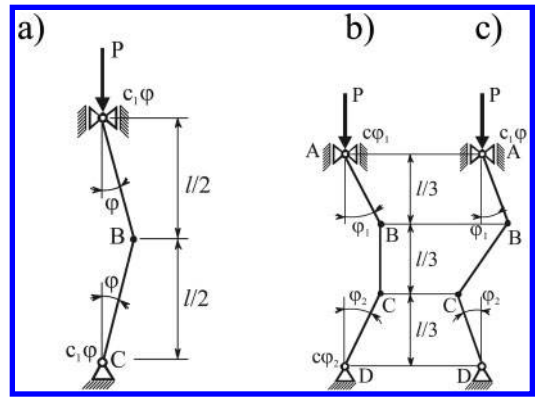

Figure 1. Collapse modes of "rod" models […]: a) – Euler buckling mode ($L^1_{cr(}$) , b) – three-link failure mode I. ($L^2_{cr(}$), c) – three-link failure mode II. ($L^3_{cr(}$).

These models are shown in Fig.1 with the notation of critical lengths corresponding to them. Table 1. shows relations describing those three cirical lengths.

Table 1. Critical buckling lengths

No	
1	Euler dynamic buckling mode: $L_{cr}^1 = \sqrt{\frac{6E_r I}{A\sigma_0}}$
2	Three-link first dynamic buckling mode: $L_{cr}^2 = 3\sqrt{\frac{E_r I}{A\sigma_0}}$
3	Three-link dynamic second buckling mode: $L_{cr}^3 = \sqrt{\frac{15E_r I}{A\sigma_0}}$

Where: A – sectional area, I - sectional moment of inertia, E – Young modulus, E_t - tangent modulus, σ_0 - yield stress.

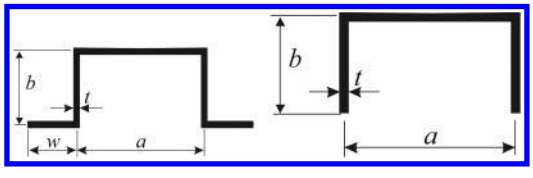

Figure 2. Open section members under investigation.

Detailed derivations are given by Kotełko and Mania (2012).

The aim of the present study was the experimental investigation into an influence of impact velocity and initial length of open section columns shown in Fig.2, subjected to axial impact, upon their crushing behaviour (failure mode and energy absorption capability). Additionally, experimental validation of FE simulations and mainly verification of analytical models mentioned above, are carried out.

2 EXPERIMENTAL TESTS

2.1 *Experimental stand*

Experiments were carried out on the drop hammer rig (Fig. 3), which consists of the impactor of changeable mass, hoisting mechanism and release mechanism of the hammer as well as additional springs, which allow one to increase the energy of impact. The springs are driven by the separate driving system. All mechanisms are controlled by a special computer program. The measuring system consists of piezoelectric force transducer, displacement transducer and accelerometer.

2.2 *Specimens*

Dimensions of specimens (columns), which have been tested are shown in Table 2. Impact tests were carried out on steel specimens of different a/b ratio and different length from 250 to 500 [mm], as well different impact velocities from 4 to 10 [m/s]. Wall thickness of

10	P2**	30	30	8	182	222	287

* channel sections ($w = 0$)

all columns was $t = 1$ mm, except P2, were wall thickness was 0.6 mm. Altogether about 50 impact tests were carried out. All specimens were clamped in two parallel plates (situated in grooves made by milling machine) and spot welded , as shown in Figure 4.

Material data: $\sigma_0 = 286$ MPa (eccept P2), $E = 194000$ MPa, $E_t = 3000$ MPa, $\sigma_0 = 165$ MPa (for P2).

2.3 *Results of impact tests*

The results of tests indicate, that in most cases the progressive buckling mechanism was observed, even for long columns, of lengths much greater , than critical values shown in Table 1. However, in some cases global bending was observed and collapse modes were similar to the "rod" models shown in Figure 1. In some

Figure 4. Lay-out of the specimen.

Figure 5. Specimen P1, $L = 275$ mm > L_{cr}, a) $-v = 4$ m/s, b) $-v = 6$ m/s.

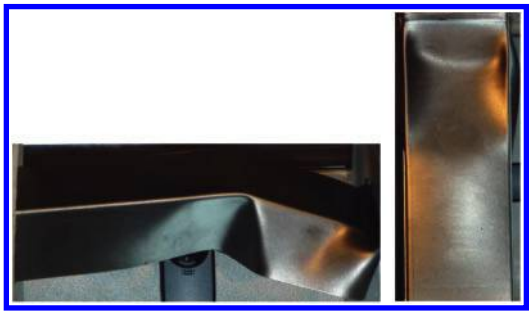

Figure 6. Specimen P1, $L = 375$ mm , quasi-dynamic test – $v = 600$mm/min.

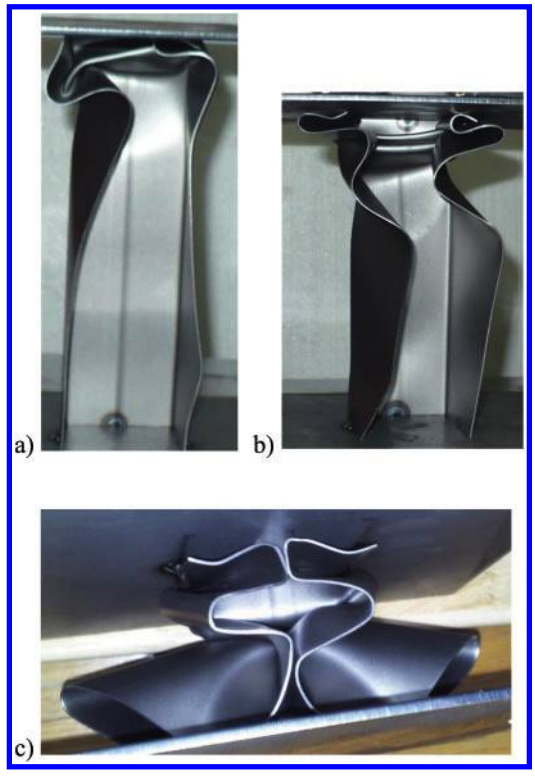

Figure 7. Specimens A1, $L = 250$ mmm: a) $-v = 4.5$ m/s, b) -v = 6 m/s, c) $-v = 9.5$ m/s.

Figure 8. Specimen B1, $v = 8$ m/s: a) $-L = 200$ mm, b) $-L = 300$ mm.

cases an anomalous failure mode was observed, similar to that reported by Teramoto (2004).

Figure 4 shows failure modes of specimens P1 (channel section, $a/b = 2$) for two different impact velocities. For lower velocity (Fig. 4a) the response is similar to the theoretical Euler buckling mode, but the column length is greater than L_{cr}^3. For the higher velocity the anomalous response is observed (Fig. 4b). The failure mode of the same specimen P1 at the impact velocity v = 4 m/s is compared with FE simulation result (Fig. 5). The agreement is satisfactory. The applied FE model and detailed simulation results for specimens P1 and P2 are reported by Kotełko & Mania (2012).

In order to illustrate the influence of loading velocity upon the failure mode, Figure 5 shows the failure mode of the specimen P1 under quasi-dynamic loading velocity. At this velocity the failure mechanism is nearly the same as under the static load. It was reported in details by Kotełko & Mania (2012). The influence of impact velocity upon the failure mode of specimens

Figure 9. Specimen D2, $L = 400$ mm, $v = 8$ m/s.

A1 is shown in Figure 7. All three failure modes can be classified as progressive buckling.

As was mentioned, only in some particular cases the global bending failure mode was observed, namely for channel sections B1 ($a/b = 2$). Figure 8 shows failure modes for two specimens: of length $L < L_{cr}$, were progressive buckling was observed and of length $L_{cr}^2 < L < L_{cr}^3$, were global bending mode II was observed.

In the case of top hat sections no global bending failure mode was recorded, even for the longest columns (Fig. 9). However, in that case for columns of $a/b \geq 1.5$, the failure mode, which may be classified as interaction of flexural-torsional and progressive buckling mode (Fig. 10) was observed.

The influence of a failure mode (progressive buckling or global bending) upon the load – versus time diagram and subsequently – upon the energy absorption capability , is show in Figure 11 and 12. As was mentioned, the global bending failure leads to the deterioration of the energy absorption capability (steep gradient of the first peak of load-time diagram).

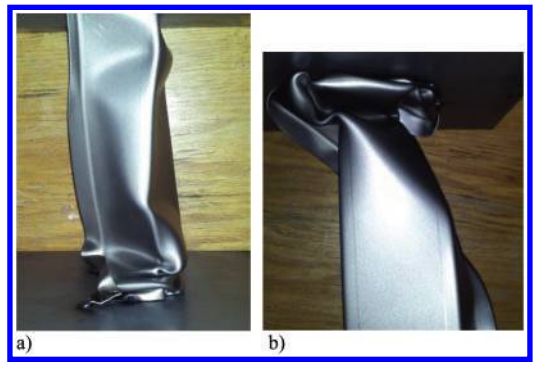

Figure 10. Specimen D2, $v = 8$ m/s, a) $-L = 250$ mm, b) $L = 400$ mm.

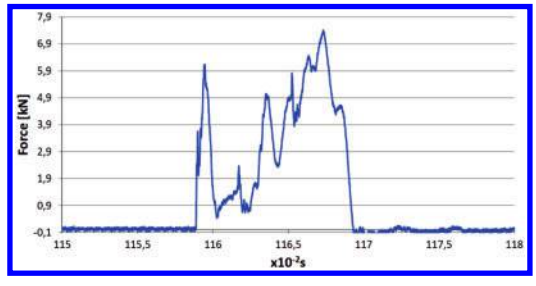

Figure 11. Load-time diagram of specimen B1, $L = 200$ mm $v = 8$ m/s (progressive buckling).

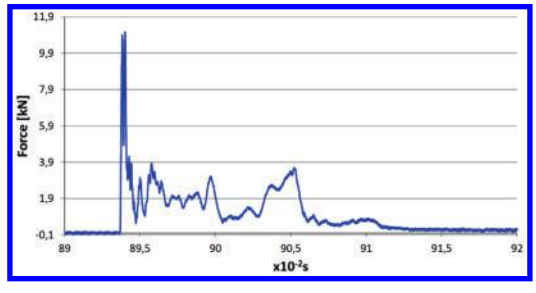

Figure 12. Load-time diagram of specimen B1, $L = 300$ mm, $v = 8$ m/s (failure mode II).

3 FINAL REMARKS

The "rod" model proposed by Alves & Karagiosova (2004) occurred to be not entirely adequate for open section members. The critical buckling length for dynamic buckling was not in a satisfactory agreement with the results of experiments.

In the case of channel section there are no clear indications into limit buckling length; in some cases an anomalous response against impact load is reported

In the case of top hat sections only the progressive buckling failure mode was observed. Additionally, in some cases, an interaction of progressive buckling and flexural-torsional buckling was recorded.

More clear indications of the threshold criterion (or criteria) of the transition between progressive buckling and global bending can be obtained from further research which would take into account larger diversity of impact velocities and dimensions. Also impact tests at different impact mass have to be performed in order to investigate inertia effects.

ACKNOWLEDGMENTS

This research has been conducted within the activity of the project N N501 215438 'Load-capacity and energy absorption in thin-walled structures under dynamic loading', funded by the Ministry of Science and Higher Education of Poland.

Computational modelling of reinforced concrete wall subjected to transformer tank rupture

ABSTRACT: Transformer is one of the vital equipment to provide reliable electricity. The worst of the transformer explosion may lead to the major blackout. Transformer explosion maybe due to, lack of maintenance or the problems inside itself. In the past, transformers were adjacent to each other and without a wall in between at substation. Nowadays, constructing reinforced concrete wall between transformers is in practice as protection precaution. Finite Element Method (FEM) software is used due to the capability of analyzing and simulating reinforced concrete structure subjected to high rate and short duration dynamic loading. The simulation results reveal the crack propagation behavior is identical for the different blast modes. The cracks start to occur at the bottom of the wall on the transformer side. Later follows with the crack propagations on the other side at about one third of the wall height in the curve shape.

1 INRODUCTION

Electric substation is the place where transformers are installed in order to transform the electric voltage from high to low level or otherwise before can be distributed to the respective customer. Typically, there are more than one transformers operating at one time to supply the electricity. These transformers are located adjacent to each other within the required distance. As a protection precaution, a wall is constructed in between the transformers. For comparison, in Brazil initially substations were operating for some years without a wall in between transformer (Duarte, 2004). Probably due to transformer fire at one of the substation, the firewall is constructed later. In the studies revealed, the wall can start to collapse after just one hour. In fact, the wall is designed for 4 hours fire resistance. This is because, the energy releases by the transformer explosion and the subsequent effect of fire did not take into consideration during the design stage.

This study presents the simulation result of the potential damage of the reinforced concrete wall due to transformer tank rupture. Three blast modes based on the point of transformer tank rupture are used for the modeling. Although, there is no direct experimental result available yet to validate the numerical result, the previous field test provided indirect result for the comparison.

2 TRANSFORMER TANK RUPTURE

In general, transformer explosions are originated from broken-down insulations, which may be caused by over load switching, lightning surges, deterioration of insulations, low level and moisture or acid contamination in the transformer oil. Inside the transformer, with the high temperature and energy released by the arc, the insulation oil will be decomposed to highly explosive gasses, mainly Hydrogen and Acetylene. This decomposition process will generate pressure inside the transformer tank until the tank cannot withstand and the tank rupture will be occurred (Surasit, 2008, Chille et al., 1998, GexCon, 2007).

According to the investigation report of Power Transformer Tank Rupture and Mitigation by the task force of IEEE Power Transformer Subcommittee, when the explosion happens, transformer is able to release arc energy between 1 MJ up to 147 MJ (IEEE, 2010). In the research works done by Sergi, it is discovered, for a 100 MJ electrical arc inside the oil, the first MJ creates 2.3 m^3, of explosive gas. The other 99 MJ add only 2 m^3. Obviously any electrical arc is very dangerous whatever its energy (SERGI, 2008).

The point of tank rupture will be varies for each transformer, normally occurred at the weakest point of the rectangular tank (IEEE, 2010), which is can be at; main cover to tank wall flange-welded joint; tank wall

corner-welded joint; tank wall to base plate-welded joint; high stress points at throats and large penetrations through the tank plate; and high stress at end of stiffeners where the end reaction force transmitted to the tank plate. Therefore, different blast modes are based on the point of rupture.

3 BLAST PRESSURE ANALYSIS

Detonation of high explosives usually produces an ideal blast wave, which is symmetrical. The pressure generated at distance R from the center of explosion originally at the ambient pressure, then instantaneously reach to peak pressure decay to ambient pressure. The resulting pressure can be described by the modified Friedlander equation, which is dependent on time. This equation allows some freedom to customize the pressure profile for any explosion at various distances from the source (Baker, 1973).

The Trinitrotoluene (TNT) mass equivalent used to model the effect of the explosion that the energy released is equated to the mass of TNT, where the impact will give the equivalent amount of damage. Once the equivalent is assumed, the variation of overpressure and impulse will be determined according to a graph or related equation (Philips et al., 1994). For the transformer tank rupture, the highest arc energy reported is used to calculate TNT equivalent masses (W_{TNT}) for further blast analysis.

$$W_{TNT} = \frac{explosion\ energy}{4.6MJ\ kg^{-1}} x\ efficiency\ factor \quad (1)$$

The blast scaling laws have been established since all blast parameters are primarily on the amount of energy released by a detonation in the form of a blast wave and distance from the explosion. The scaling law provides parametric correlations between a particular explosion and a standard charge of the same substance (Ngo et al., 2007).

Angle of incident is one of the factor affect the blast load on structural component. The angle of incident is the angle between outward normal to the direct vector from the explosive charge (Remennikov, 2007). This method is used to determine the blast load at the point of interest on the surface of the wall as stated in Equation 2.

$$Actual\ effective\ distance, R = \sqrt{{R_G}^2 + h^2} \quad (2)$$

3.1 *Blast calculation*

TM5-1300(UFC 3-340-02) – Structure to resist the effect of the accidental explosion by US Army Technical Manual (US Department of the Army, 1990) is used to predict the blast pressure on the structure. The scaled graph of the positive shock wave parameters for a hemispherical TNT explosion on the surface at sea level is used for the important parameters such as; peak reflected over pressure (P_r), peak over pressure (P_{so}), blast arrival time (t_a), positive phase duration (t_o) and blast velocity of wave front (U). With the data provided from the graph, the dynamic wind blast (P_q) as stated by Ngo is calculated by used Equation 3 (Ngo et al., 2007).

$$P_q = \frac{5{P_{so}}^2}{2(P_{so} + 7P_a)} \quad (3)$$

Kingery-Bulmash developed equations to predict air blast and it is widely accepted to predict free-field pressure and loads on structures (Kingery & Bulmash, 1984). The equation takes realistic approach and assuming an exponential decay of pressure in time as in the Equation 4.

$$P_t = P_{so}\left[1 - \frac{t - t_a}{t_o}\right] exp\left[-\frac{b(t - t_a)}{t_o}\right] \quad (4)$$

where P_t is the pressure at time t (kP_a); P_{so} is the peak incident pressure (kP_a); t_o is the positive phase duration (msec); b is the decay coefficient (dimensionless); and t_a is the arrival time (msec).To fully utilize the equation above, Equation 5 is used (Lam et al., 2004).

$$b = Z^2 - 3.7Z + 4.2 \quad (5)$$

3.2 *Pressure distribution*

The mapping method (Jaini & Feng, 2010) is used for the blast pressure distribution on the wall surface, where the arrival time (t_a) is used as the identification for the grouping purpose. In the computation sheet, the arrival time (t_a) for certain angles of incident will have a closer value. From these parameters, the different hemispherical radius can be mapped on the wall surface. The average value of blast pressure is taken for each groups based on the closest group of the arrival time (t_a). Figure 1 shows 18 different blast pressure time histories according to the blast energy of 147 MJ. The distance is 1 m from the center of explosion. Only the positive blast pressure phase is considered in this study. For each blast mode, on the blast pressure area, the blast pressure time history will be imposed accordingly.

There are three blast modes are assessed in the study, where the tank rupture is assumed to be occurred at; Blast mode A-at the bottom of the transformer tank; Blast mode B-at the height of 2.5 m from the bottom of the transformer tank; and Blast mode C-at the top of the transformer tank which is 4.4 m from the bottom of the transformer tank as shows respectively in Figures 2, 3 and 4.

4 COMPUTATIONAL MODEL

Elfen, a finite element package developed by Rockfield Software Limited in Swansea, UK (Rockfield) is used for the simulation in this research work. This

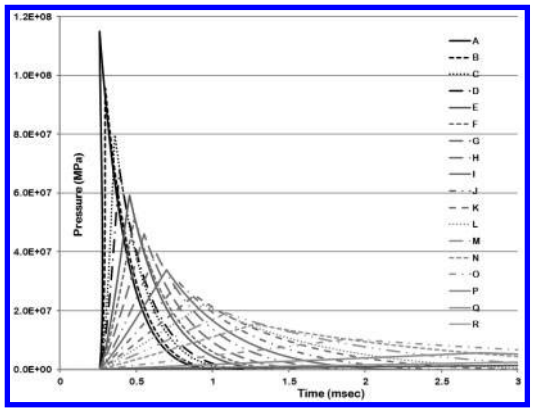

Figure 1. Blast pressure time history (P_t).

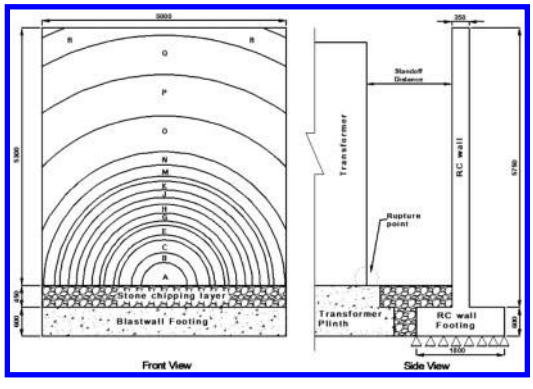

Figure 2. Blast pressure distribution for Blast mode A.

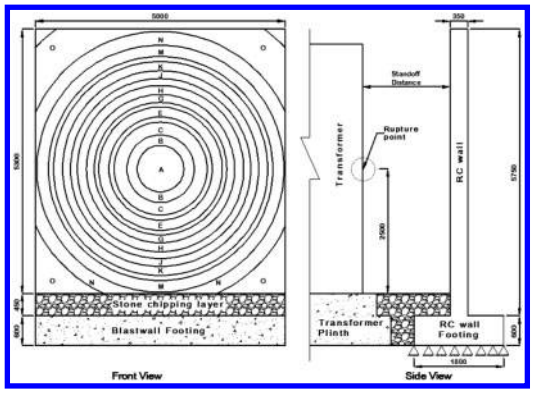

Figure 3. Blast pressure distribution for Blast mode B.

is because, Elfen has capability of analyzing and simulating the reinforced concrete structure subjected to high rate and short duration dynamic loading (Jaini & Feng, 2010, May et al., 2006).

The full scale of reinforced blast wall constructed by Tenaga Nasional Berhad (TNB) is modeled in Elfen. The wall constructed with Grade 30 (f_{cu} =30 N/mm^2) concrete and high yields steel (f_y =410 N/mm^2) bars. It is consists the reinforcement of 12 mm and 16 mm

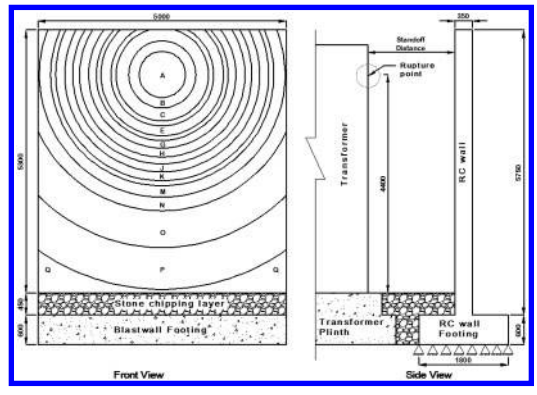

Figure 4. Blast pressure distribution for Blast mode C.

radius steel bars. The bars arrangement is 150 mm center to center with 25 mm reinforced cover. For the footing, both horizontal and vertical reinforcement arrangement used 16 mm bars. However for wall structure, only vertical arrangement used 16 mm bars.

Three-dimensional continuums with four-noded solid tetrahedral are used for both concrete and steel, where the size of 50 mm unstructured meshes is used. 3D beam elements with an elasto-plastic property are used to model reinforcement bars, and a perfect bond condition is assumed between the concrete and bars.

The Mohr-Coulomb criterion is used for the plastic strain of concrete, where it ranges between 0 to 100,000 s^{-1} and the tensile strength from 2.73×10^6 to 60.18×10^6 N/m^2. The implementation of this compression elacto-plastic material includes a cut-off tension in the form of complete Rankine tensile corner with fracture. According to the previous research work (Jaini & Feng, 2010), there is no explicit softening law included for tensile strength, while indirect softening does result from the degradation of cohesion. Fracture energy plays an important role to determine crack propagation. The fracture energy for concrete volume is taken between 75 and 100 N/m. For steel, the hardening properties are range from 0 to 0.0223 s^{-1} of plastic strains and the tensile strength in the range from 2.5×10^8 to 6.3×10^8 N/m^2. The Von-Mises criterion is applied for steel and utilized the backward Euler stress update algorithms. This rate independent model implemented in form of a nonlinear isotropic hardening form, where piecewise linear hardening is specifies using hardening material and hardening properties.

5 RESULT AND DISCUSSION

The computational result from this study revealed the propagation of the crack, fracture and displacement pattern at the specific time once blast load is applied on the structure. The crack propagation for all blast modes clearly shows, after the impact load is applied, the cracks start to occur at certain time instances at the bottom of the blast wall on the billet side (transformer side). This follows later with the cracks on the die

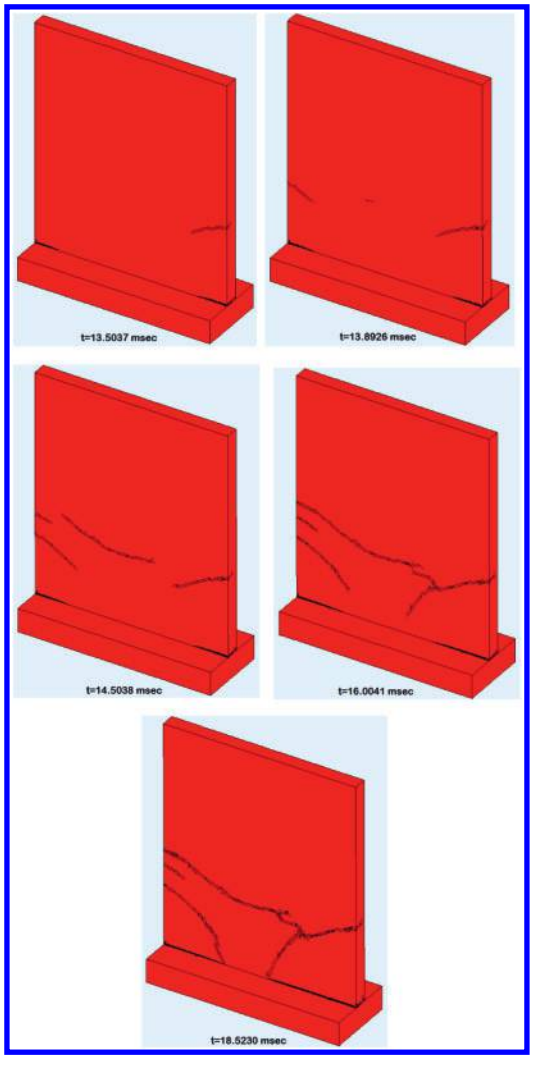

Figure 5. Crack propagations (Blast mode B).

side (other side) at about one third of the wall height. The propagations of the cracks then continue to move downwards to the center of the blast wall at the bottom part in the curvy shape. It is clearly discovered, the Blast mode B gives the worst scenario due to the transformer tank rupture at certain height. Figure 5 shows the crack propagation for Blast mode B, where clearly stated at the time instance when the crack start to appear. At the end of the simulation up to approximately 18 msec, the maximum displacements recorded are 22.51 mm, 24.05 mm and 17.29 mm for Blast mode A, B and C respectively.

Although there is no attempt yet done on the exact type on the wall as simulated, the earlier test shows a favor agreeable based on the blast loading map and the post impact on the reinforced concrete wall (Culberston, 1997). The crack patterns show a similarity.

6 CONCLUSION

Finite element analysis of reinforced concrete wall with strip footing subjected to transformer tank rupture is presented. The behavior and crack pattern of the reinforced concrete wall obtained from the present study is acceptable. This is because, the mapping method and the assumption for the Elfen package used for this simulation have already proved in the previous research work. Where the simulation result shows the same crack pattern and behavior in comparison to the experimental work. Besides, the blast test done on reinforced concrete wall shows similarity in the crack pattern after the blast impact.

Blast test and numerical simulation of point-supported laminated glass curtain wall

S. Chen, C.G. Zhu & G.Q. Li
State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China

Y. Lu
The University of Edinburgh, Kings Buildings, Edinburgh, UK

ABSTRACT: To investigate the blast resistance of point-supported laminated glass curtain wall, 9 site blast tests were carried out, considering 2 types of glass thickness and 6 different TNT charges from 0.4 kg to 30 kg. The overpressure and displacement were measured and the failure mode was observed. The tests demonstrated that the overpressure suddenly increased and quickly decayed within a few milliseconds; the displacement response of the glass curtain wall increased with the increase in TNT charge and decreases with the increase of the glass thickness; the final failure mode was featured by tearing off of PVB at the support of the laminated glass panel while the glass shards still adhered to the PVB. Nonlinear dynamic finite element simulation agrees well with the results from the blast tests. Severe stress concentration has been predicted at the rim of the support holes and leads to the failure at these supports, and this also agrees with the failure mode observed from the blast test.

1 INTRODUCTION

Blast loading has recently been considered in the design of glass curtain wall for concerns over the fact that high-speed flying shard from glass curtain wall is one of the main reasons to cause the casualties in the event of a blast (Norville 2006, Morison 1999). To ensure appropriate design consideration, it is necessary to thoroughly understand the blast performance of glass curtain wall. In the literature, a certain number of numerical simulations on glass curtain wall subjected to blast loading have been reported (Dharani & Wei 2002, Krauthammer & Altenberg 2004, Deng & Jin 2009]. Dharani & Wei (2002) used a 3-D nonlinear finite element model to predict the failure probability of laminated architectural glass subjected to blast loading. Martin et al. (2012) reviewed the applicability of smeared model, layered shell model and 3D solid model in simulating the failure of the glass as well as of the interlayer and found that layered shell model is efficient. Tao (2011) studied the dynamic responses of monolithic and laminated glass by the indoor blast simulator and found that there are almost no spatters after the failure of laminated glass while monolithic glass was broken and the glass fragments splashed. On the other hand, however, few experimental studies have been published, due apparently to the complexities involved in conducting a blast test of this kind.

A series of field blast tests has recently been conducted on four-point-supported laminated glass curtain walls. An associated finite element simulation study has also been carried out to check against the test observations. This paper presents the test programme and the main results. The numerical model and some of the comparisons are also described and discussed.

2 BLAST TEST

2.1 *Test specimen*

The specimens in this test were a type of laminated glass consisting of two layers of tempered glasses and a layer of polyvinyl butyral (PVB) with dimension of 1000 mm × 1000 mm. Each specimen was four-point-supported, as shown in Figure 1. In each test, four glazing panels were installed as shown in Figure 2, and the one in the left upper corner was instrumented for response measurements. Two different glass thicknesses of 8 mm and 10 mm, respectively, were used, while the thickness of the PVB remains the same of 1.14 mm. The tests consisted of 2 stages, as summarized in Table 1. In the first stage, eight sets of blast tests with small charges were performed and no obvious damage was observed. In the second stage, a larger charge of 30kg TNT was detonated to load the specimens to failure, and thus obtaining the failure patterns. Table 2 lists the parameters of each TNT charge. In all tests, the explosive charge was placed at a fixed standoff distance of 5 m (See Fig. 2).

2.2 *Instrumentation*

Thirteen pressure transducers CY-YD-205 were installed on a steel panel fixed in a reinforced concrete frame having the same standoff distance with the glazing specimens. Figure 3 shows the layout of the pressure transducers. Five displacement transducers BWG4-100 were installed one of the glazing specimens, located on the left upper corner as

–	B10-5	30	5	Failure stage

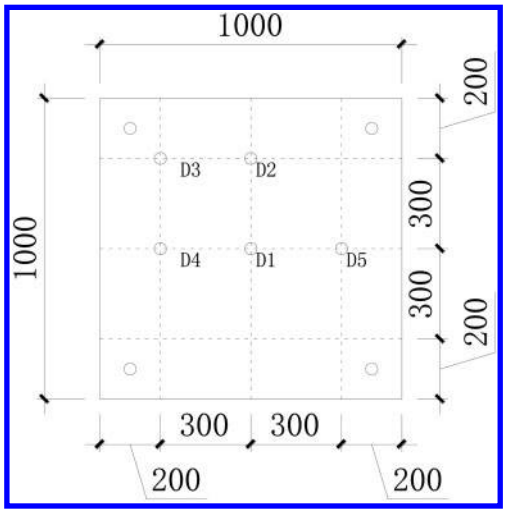

Figure 4. Arrangement of displacement transducers.

Figure 5. Failure at the support hole in case B10-5.

mentioned earlier, to measure the typical displacement responses of the specimens, as shown in Figure 4.

3 TEST RESULTS

3.1 *Failure modes*

The laminated glasses exhibited no visible damage after the stage 1 tests. Failure occurred when they were subjected to the stage 2 test. The failure mode of such four-point-supported glass curtain wall subjected to blast loading was featured by the tearing off of PVB at the supported areas while the glass shards still adhered onto the deformed PVB. This is clearly seen from Figure 5. Such a failure pattern illustrates clearly a significant advantage of the laminated glass for blast resistance.

3.2 *Overpressure measurement*

Overpressure-time curves at point P1, P8 and P12 of case B8-4 and case B10-5 are shown in Figure 6 and Figure 7, respectively. The Overpressure-time curves show a classical pattern in that there is a steep increase of the overpressure in the beginning and this is followed by a quick decay phase within a short duration of about several milliseconds.

The maximum, minimum and mean values of the 13 peak overpressures of each test set are listed in Table 3. It is obvious that the peak overpressure increases with the increase of the TNT charge.

The curves of point P1 in Figure 6 and Figure 7 have two peaks. The second peak appears to be the Mach stem that occurs when the reflected wave catches up with the incident wave and forms a third wave front.

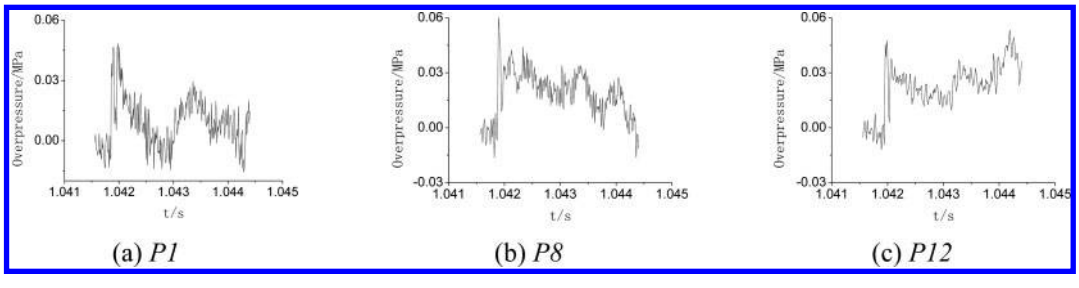

Figure 6. Overpressure-time curves for case B8-4 (TNT = 1.0 kg).

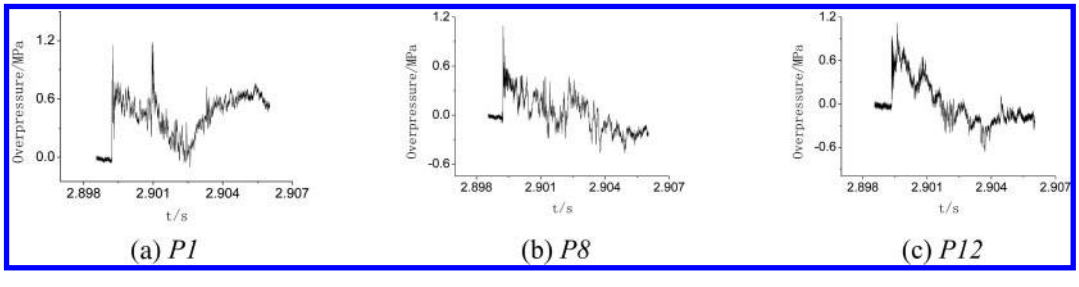

Figure 7. Overpressure time history curves for case B10-5 (TNT = 30 kg).

3.3 *Displacement response*

Typical displacement-time curves at point D1 for different cases are given in Figure 8. It can be observed that the laminated glass specimens mainly responded in the elastic range during the tests with small TNT charges (see Fig. 8a, b), whereas the specimens failed with a large residual displacement when subjected to the large TNT charge, as shown in Figure 8(c).

The maximum center displacement at point D1 of all the test cases are listed in Table 4 and the relationship between the maximum displacement and the TNT charge weights is shown in Figure 9. It can be observed that, for the same properties of the glazing panels the displacement response increases with the increase in the amount of TNT charge; an increase of the thickness of the glass improved the blast resistance behavior of the point-supported glass curtain wall.

4 NUMERICAL SIMULATIONS

4.1 *Finite element model*

Software ANSYS/LSDYNA is used for this simulation. Considering the symmetry, a quarter of a laminated glazing panel is modeled as shown in Figure 10 and symmetric constraints are imposed. SOLIDE164 elements are employed to model the glass and PVB. The glass is considered as elastic brittle material with an ultimate tensile strength of 84 MPa. The PVB is considered as visco-elastic material and a strain failure criterion is adopted with an ultimate strain of 1.0. The material properties are listed in Table 5 (after Wei (2010)). The blast load is idealized as a linear decaying curve.

Software A.T.BLAST is employed to calculate the peak overpressure and duration for the linear decayed curve. Table 6 shows a comparison between the peak overpressures from software prediction and the mean overpressures obtained from the blast tests (listed in Table 3). From the comparison, the overpressures from A.T. BLAST agree well with the test results. Thus, the peak overpressure and duration as obtained from the predictions were adopted for the numerical simulations and applied on the surface of the outer glass ply in the simulation.

Table 3. Peak overpressure for different test sets.

Case	TNT Charge/ kg	Peak Overpressure/kPa		
		Max	Min	Mean
B8-1	0.4	54.2	27.3	37.26
B8-2	0.6	59.4	30.3	45.57
B8-3	0.8	88.5	48.0	59.3
B8-4	1.0	62.2	44.5	55.34
B10-4	1.2	75.2	51.1	58.2
B10-5	30	1154.2	944.5	1064.4

*Case B10-2 did not collect any useful data of overpressure; the TNT charge weight of case B10-1 and case B10-3 are same to the case B8-2 and case B8-4 respectively, and the overpressures of the case B8-2 and case B8-4 are listed in the Table.

Table 4. Maximum displacement of the glass panel center D1.

Cases	TNT Charge/kg	Displacement/mm
B8-1	0.4	−5.612
B8-2	0.6	−8.936
B8-3	0.8	−12.238
B8-4	1.0	−14.771
B10-1	0.6	−6.683
B10-2	0.8	−9.670
B10-3	1.0	−11.762
B10-4	1.2	−13.174
B10-5	30	−82.4

Table 5. Material Properties.

Materials	Properties
Glass	Young's modulus, E = 72 GPa; mass density, $\rho = 2560\ kg/m^3$; Poisson's ratio, $\nu = 0.22$
PVB	Short term modulus,$G_0 = 1.1$ MPa; long time modulus, $G_\infty = 0.69$ MPa; bulk modulus, K = 10.63 MPa; mass density, $\rho = 1100\ kg/m^3$; decay factor, $\beta = 12.6\ s^{-1}$;

Table 6. Comparison of peak overpressure from tests and predictions.

TNT Charge/kg	Peak overpressure/kPa			Time/ ms
	Test	A.T. BLAST	Difference	
0.4	37.26	39.78	6.76%	2.06
0.6	45.57	49.16	7.88%	2.21
0.8	59.3	57.57	−2.92%	2.3
1.0	55.34	65.43	18.23%	2.36
1.2	58.2	72.88	25.22%	2.41
30	1064.4	1014.01	−4.73%	1.74

* Difference=(A.T. Blast results – Test results)/ Software results.

4.2 *Simulation results*

The center displacements from the simulation are compared with the test results in Table 7. The difference between the simulation results and the test results is less than 35%. The stress contour of case B10-5 is shown in Figure 11. Severe stress concentration is observed around the rim of the support hole.

The numerical simulation shows that damage initiates at the rim of the support and the final failure mode is the fracture of glass and tearing off of PVB extending from the support hole, as shown in Figure 12

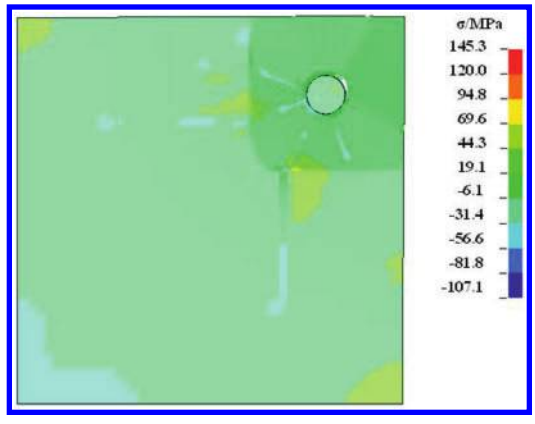

Figure 11. Stress contour (Case B10-5).

and Figure 13 respectively. This phenomenon agrees favourably with the test results.

5 SUMMARY

This paper investigates the blast resistance of pointed-supported laminated glass curtain wall. Main findings of this study are summarized as follows:

1) The overpressure curve has characteristics of an instantaneous rise, followed by a rapid decay and a relatively short positive phase.
2) Displacement response of the glass curtain wall increases with the increase of TNT charge; the increase of the glass thickness is useful to reduce the displacement response and increase the blast-resistance of the point-supported glass curtain wall.
3) The final failure mode may be characterized by the tearing off of PVB at the support hole while the glass shards still adhered on the PVB.
4) The difference between displacement response obtained by numerical simulation and blast test is less than 35%, which verified the effectiveness of the numerical model.

Thermodynamics-based constitutive modeling of coupled dissipative phenomena in engineering materials

H. Egner, W. Egner & M. Ryś
Institute of Applied Mechanics, Cracow University of Technology, Cracow, Poland

ABSTRACT: In the present paper a general phenomenological model, based on the irreversible thermodynamics, is formulated and used to describe the multi-dissipative material under the assumption of small strains. Two examples are presented: (1) modeling of thermo-plastic coupling in AISI L6 steel subjected to fatigue tests in non-isothermal conditions, and (2) thermodynamics-based modeling of coupling between plasticity, damage and phase transformation in 316L stainless steel at cryogenic temperatures.

1 INTRODUCTION

The increasing demands for high performance materials require the adequate constitutive modeling, as well as the appropriate predictions of the overall failure mechanisms under complex thermo-mechanical loading. When engineering materials classified as elastic-plastic are subjected to external loading, the material degradation connected with slip rearrangements of crystallographic planes through dislocation motion is observed at the macro-scale as plastic behavior. Another dissipative phenomenon is the development of micro-cracks and micro-voids. The nucleation, growth and interaction of these micro-defects under external loads result in a deterioration process on the macro-scale and, as a consequence, change of the constitutive properties of the material.

If the elastic-plastic-damage material is loaded so that not only inelastic strains develop, but also the temperature is changed, then thermo-elasticity, thermo-plasticity and thermo-damage are encountered, while not only the temperature itself but also the heating rate makes a significant impact on parameters that determine carrying capacity at elevated temperatures.

When FCC metals and alloys are loaded at very low temperatures another dissipative phenomenon is observed, which is plastic strain induced transformation from the parent phase (γ) to the secondary phase (α') . The phase transformation process leads to creation of two-phase continuum, where the parent phase coexists with the inclusions of secondary phase. Experimental results indicate the correlation between decreasing damage rate and increasing martensite content.

2 GENERAL MODEL OF DISSIPATIVE MATERIALS BASED ON IRREVERSIBLE THERMODYNAMICS

2.1 *Basic assumptions*

Continuum mechanics approach, applied in the present work, provides the state and evolution equations in the framework of thermodynamics of irreversible processes. The material heterogeneity (on the micro- and meso-scale) is smeared out over the representative volume element (RVE) of the piece-wise discontinuous material. The true distribution of micro-changes within the RVE, and the correlation between them are measured by the change of the effective constitutive properties.

In the case of infinitesimal deformation the total strain can be expressed as the sum of the elastic, ($\boldsymbol{\varepsilon}^E$), inelastic ($\boldsymbol{\varepsilon}^I$), and thermal strain ($\boldsymbol{\varepsilon}^\theta$).

The irreversible rearrangements of the internal structure can be represented by a group of state variables describing the current state of material microstructure: $\{\Lambda^k\}$, $k = p, d, ph, \ldots$ (p meaning plastic, d – damage, ph – phase change etc), where Λ^k may be scalars, vectors or even rank tensors. Another group of state variables consists of internal (hidden) variables corresponding to the modifications of loading surfaces: $\{h^k\} = \{r^k, \alpha^k_{ij}, l^k_{ijpq}, g^k_{ijpqmn}, \ldots\}$, where r^k is related to isotropic expansion of the loading surface, α^k_{ij} affects translatoric displacements of the loading surface, l^k_{ijpq} is a hardening tensor which includes varying lengths of axes and rotation of the loading surface, and g^k_{ijpqmn} describes changes of the curvature of the loading surface (distortion) related to k-th dissipative phenomenon (cf Egner, 2012). The complete

set of state variables $\{V_{st}\}$ reflecting the current state of the thermodynamic system consists of observable variables: elastic strain tensor $\boldsymbol{\varepsilon}^E$ and absolute temperature θ, and two groups of microstructural $\{\Lambda^k\}$ and hardening $\{h^k\}$ state variables:

$$\{V_{st}\} = \{\varepsilon_{ij}^E, \theta; \Lambda^k; h^k\},\ k=p, d, ph,\ldots \tag{1}$$

2.2 *Equations of the model*

By the use of state variables (1) the Helmholtz' free energy of the material can be written as a sum of elastic (*e*), plastic (*p*), damage (*d*), phase change (*ph*) etc. terms (cf Abu Al-Rub & Voyiadjis, 2003):

$$\rho\psi = \rho\psi(V_{st}) = \sum_{j=1}^{n} \rho\psi^j,\ \ j = e, p, d, ph,\ldots \tag{2}$$

The following state equations express the thermodynamic forces conjugated to state variables (1):

$$\sigma_{ij} = \frac{\partial(\rho\psi)}{\partial\varepsilon_{ij}^E}, s = -\frac{\partial\psi}{\partial\theta} \tag{3}$$

$$-Y^k = \frac{\partial(\rho\psi)}{\partial\Lambda^k}, H^k = \frac{\partial(\rho\psi)}{\partial h^k} \tag{4}$$

In the above equations s is specific entropy, Y^k stand for thermodynamic forces conjugated to microstructural state variables Λ^k, whereas H^k are hardening forces conjugated to hidden state variables h^k. To derive the kinetic equations the existence of several dissipation potentials F^k is assumed, corresponding to each k-th microstructural rearrangement (due to plastic flow F^p , damage growth F^d , phase change F^{ph} etc.) and defined independently but partly coupled.

The kinetic equations for state variables can be obtained by the use of the generalized normality rule (cf Chaboche, 1997; Egner, 2012):

$$\dot{\varepsilon}_{ij}^I = \sum_{k=1}^{n} \dot{\lambda}^k \frac{\partial F^k}{\partial\sigma_{ij}} = \dot{\lambda}^p \frac{\partial F^p}{\partial\sigma_{ij}} + \dot{\lambda}^d \frac{\partial F^d}{\partial\sigma_{ij}} + \dot{\lambda}^{ph} \frac{\partial F^{ph}}{\partial\sigma_{ij}} + \ldots \tag{5}$$

$$\dot{\Lambda}^k = \sum_{i=1}^{n} \dot{\lambda}^i \frac{\partial F^i}{\partial Y^k} = \dot{\lambda}^p \frac{\partial F^p}{\partial Y^k} + \dot{\lambda}^d \frac{\partial F^d}{\partial Y^k} + \dot{\lambda}^{ph} \frac{\partial F^{ph}}{\partial Y^k} + \ldots \tag{6}$$

$$-\dot{h}^k = \sum_{i=1}^{n} \dot{\lambda}^i \frac{\partial F^i}{\partial H^k} = -\left(\dot{\lambda}^p \frac{\partial F^p}{\partial H^k} + \dot{\lambda}^d \frac{\partial F^d}{\partial H^k} + \dot{\lambda}^{ph} \frac{\partial F^{ph}}{\partial H^k} + \ldots\right) \tag{7}$$

where $\dot{\lambda}^i$ are non-negative consistency multipliers and n is a number of dissipative phenomena, taking place in the material. For rate-independent problems the consistency multipliers may be calculated from the consistency conditions $\dot{f}^k = 0$, $k = 1,2,\ldots,n$.

The parameters $\dot{\lambda}^i$ are assumed to obey the classical Kuhn-Tucker loading/unloading conditions.

Table 1. State variables and thermodynamic forces for 2M1C model.

State variable	Conjugated force
ε_{ij}^E(elastic strain)	$\sigma_{ij} = E_{ijkl}(\theta)\varepsilon_{kl}^E$
θ(temperature)	s
$\alpha_{ij}^{(1)}$ (kinematic hardening)	$X_{ij}^{(1)} = \frac{2}{3}(C_{11}(\theta)\alpha_{ij}^{(1)} + C_{12}(\theta)\alpha_{ij}^{(2)})$
$\alpha_{ij}^{(2)}$ (kinematic hardening)	$X_{ij}^{(2)} = \frac{2}{3}(C_{22}(\theta)\alpha_{ij}^{(2)} + C_{12}(\theta)\alpha_{ij}^{(1)})$
$r^{(1)}$ (isotropic hardening)	$R^{(1)} = b_1(\theta)Q_1(\theta)r^{(1)}$
$r^{(2)}$ (isotropic hardening)	$R^{(2)} = b_2(\theta)Q_2(\theta)r^{(2)}$

3 MODELLING OF COUPLING BETWEEN DISSIPATIVE PHENOMENA IN ENGINEERING MATERIALS

3.1 *Thermo-viscoplastic coupling in AISI L6 hot work tool steel*

In this analysis the 2M1C model derived by Cailletaud & Sai (1995) and identified by Velay et al. (2006) to describe the elasto-viscoplastic behaviour of AISI L6 steel at different (but constant) temperatures, is extended to account for the effect of temperature change (nonisothermal conditions). The set of state variables and corresponding thermodynamic conjugated forces is given in Table 1.

Total strain is partitioned into an elastic, inelastic and thermal components: $\varepsilon_{ij} = \varepsilon_{ij}^E + \varepsilon_{ij}^I + \varepsilon_{ij}^\theta$, while inelastic strain can be partitioned itself in two different strain mechanisms: $\varepsilon_{ij}^I = A_1(\theta)\varepsilon_{ij}^{(1)} + A_2(\theta)\varepsilon_{ij}^{(2)}$.

The equations of the 2M1C model for isothermal case are in details presented in Velay et al. (2006). However, in nonisothermal conditions additional terms proportional to temperature rate appear in the evolution equations for thermodynamic conjugate forces, due to temperature-dependence of the material characteristics ($k = 1,2$; $l = 1,2$; $k \neq l$):

$$\dot{\sigma}_{ij} = (\dot{\sigma}_{ij})_{\dot{\theta}=0} - [-\frac{\partial E_{ijpq}}{\partial\theta}(\varepsilon_{pq} - \varepsilon_{pq}^I) + \frac{\partial\beta_{ij}}{\partial\theta}(\theta - \theta_0) + \beta_{ij}]\dot{\theta} \tag{8}$$

$$\dot{X}_{ij}^{(k)} = (\dot{X}_{ij}^{(k)})_{\dot{\theta}=0} + \frac{2}{3}(\frac{\partial C_{kk}}{\partial\theta}\alpha_{ij}^{(k)} + \frac{\partial C_{kl}}{\partial\theta}\alpha_{ij}^{(l)})\dot{\theta} \tag{9}$$

$$\dot{R}^{(1)} = (\dot{R}^{(1)})_{\dot{\theta}=0} + (\frac{\partial b_1}{\partial\theta}Q_{1\infty} + b_1\frac{\partial Q_{1\infty}}{\partial\theta})(1 - e^{-2\mu p^*})r^{(1)}\dot{\theta} \tag{10}$$

$$\dot{R}^{(2)} = (\dot{R}^{(2)})_{\dot{\theta}=0} + (\frac{\partial b_2}{\partial\theta}Q_2 + b_2\frac{\partial Q_2}{\partial\theta})r^{(2)}\dot{\theta} \tag{11}$$

3.1.1 *Discussion of results*

The numerical procedure based on the extended 2M1C model was built and verified for the isothermal case by comparing with the results presented in Velay et al. (2006). Good agreement was achieved.

Next the anisothermal fatigue test was subjected to numerical analysis, according to the strain and temperature controlling presented in Figure 1. A reversed strain cycles were considered with temperature changes taking place at the maximum total strain

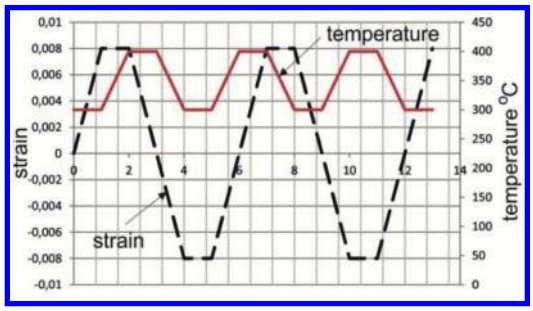

Figure 1. Anisothermal fatigue test: strain and temperature change.

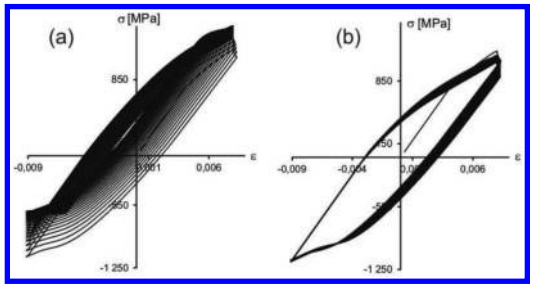

Figure 2. Hysteresis loops for (a) case 1; (b) case 2.

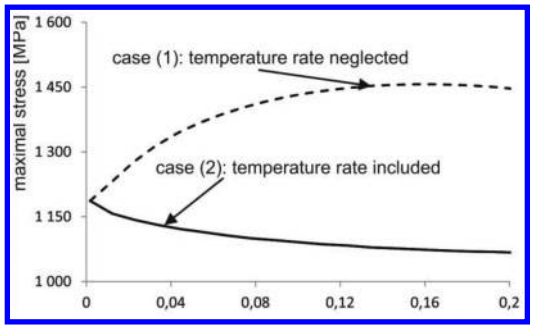

Figure 3. Evolution of maximal stress versus cumulated plastic strain for both cases.

(from low to high temperature) and at the minimum strain (from high to low temperature). During strain change the temperature is kept constant. Two cases were compared: (1) temperature rate terms in kinetic equations (8)-(11) neglected, and the influence of temperature changes accounted for only by changing material characteristics (case 1); (2) all temperature rate terms included (case 2). The stress-strain loops for both cases are presented in Figure 2a, b. Qualitatively different results were obtained: without temperature rate terms the response exhibits cyclic hardening due to unreasonable shift of hysteresis loops along the stress axis, while including additional temperature rate terms allows to preserve stable behavior (cyclic softening is observed). The results are confirmed in Fig. 3 showing the evolution of maximal stress versus cumulated plastic strain.

3.2 *Modeling of coupled dissipative phenomena in 316L stainless steel at cryogenic temperatures*

The RVE based constitutive model presented in the paper is based on the following assumptions:

- two-phase material is composed of the elastic-plastic-damage austenitic matrix and brittle martensitic platelets,
- current damage state, both in austenitic matrix and in martensitic inclusions, is described by the use of the second-order classical damage tensors,
- rate independent plasticity is applied,
- small strains are assumed,
- mixed isotropic/kinematic plastic hardening affected by the presence of martensite fraction is included,
- the material obeys the associated flow rule,
- isothermal conditions are considered.

The current state of the material in isothermal conditions is described by the following set of state variables: $\{V_{st}\} = \{\varepsilon_{ij}^E; D_{ij}^{\gamma}, D_{ij}^{\alpha'}, \xi; \alpha_{ij}^p, r^p\}$, where the elastic strain tensor ε_{ij}^E is the observable variable; D_{ij}^{γ} and $D_{ij}^{\alpha'}$ are second order tensors describing the current state of ductile damage in austenitic matrix and brittle damage in martensitic inclusions, respectively, ξ stands for the scalar variable reflecting the current state of phase transformation; α_{ij}^p and r^p denote internal variables related to kinematic and isotropic hardening of the material. The total material degradation in the RVE is described by the damage tensor $\mathbf{D}^{avg}$, being a superposition of the ductile part $\mathbf{D}^{\gamma}$ and brittle part $\mathbf{D}^{\alpha'}$. In general, one can introduce a function $m(\xi)$, such that $m(0) = 0$ and $m(1) = 1$, to define a general mixture rule: $D_{ij}^{avg} = [1 - m(\xi)]D_{ij}^{\gamma} + m(\xi)D_{ij}^{\alpha'}$.

The Helmholtz free energy of the material can be written as a sum of elastic (E), inelastic (I) and chemical (CH) terms:

$$\rho\psi = \rho\psi(V_{st}) = \rho\psi^E + \rho\psi^I + \rho\psi^{CH} \tag{12}$$

In the present model the following functions for $\rho\psi^I$ and $\rho\psi^E$ are assumed:

$$\rho\psi^I = 1/3C^p(\xi)\alpha_{ij}^p\alpha_{ij}^p + \\ + R_{\infty}^p(\xi)\{r^p + \frac{1}{b^p(\xi)}\exp[-b^p(\xi)r^p]\} \tag{13}$$

$$\rho\psi^E = 1/2\varepsilon_{ij}^E E_{ijkl}(\mathbf{D}^{avg})\varepsilon_{kl}^E \tag{14}$$

Term $\rho\psi^{CH}$ in Equation (12) represents the chemically stored energy:

$$\rho\psi^{CH} = [1 - n(\xi)]\rho\psi_{\gamma}^{CH} + n(\xi)\rho\psi_{\alpha'}^{CH} \tag{15}$$

The terms $\rho\psi_{\gamma}^{CH}$ and $\rho\psi_{\alpha}^{\prime CH}$ are the chemical energies of the respective phases, cf. Hallberg et al. (2010). This internally stored energy is different for the two phases and it will affect the generation of heat during phase transformation, as well as the transformation itself. Symbol $n(\xi)$ denotes a function similar to $m(\xi)$.

Since the $\gamma \to \alpha'$ phase transformation does not affect the elastic properties of the material, in the Equation (14) $E_{ijkl}(\mathbf{D}^{avg})$ stands for the current elastic stiffness tensor affected only by damage. Adopting the strain equivalence principle (cf. Lemaitre 1992), the current elastic stiffness is related to the initial stiffness of the undamaged material, E^0_{ijkl}, by the use of damage effect tensor $M_{ijkl}(\mathbf{D}^{avg})$ (cf Cordebois & Sidoroff 1983) in the following way: $E_{ijkl}(\mathbf{D}^{avg}) = M^{-1}_{minj} E^0_{mnkl}$. On the other hand, it is assumed here that damage does not affect plastic hardening properties, therefore, in Equation (13) the material parameters: $R^p_\infty(\xi)$, $C^p(\xi)$, and $b^p(\xi)$ depend on the current state of phase transformation only.

By eliminating all the reversible processes from the Clausius-Duhem inequality, the following state equation which expresses the thermodynamic force conjugated to the observable state variable is obtained:

$$\sigma_{ij} = \frac{\partial(\rho\psi)}{\partial \varepsilon^E_{ij}} \tag{16}$$

In addition, the forces conjugated to other state variables are postulated in a similar form to (16):

$$-Y^\gamma_{ij} = \frac{\partial(\rho\psi)}{\partial D^\gamma_{ij}}, -Y^{\alpha'}_{ij} = \frac{\partial(\rho\psi)}{\partial D^{\alpha'}_{ij}} \tag{17}$$

$$Z = \frac{\partial(\rho\psi)}{\partial \xi} = \frac{\partial(\rho\psi')}{\partial \xi} + \frac{dn}{d\xi}(\rho\psi^{CH}_{\alpha'} - \rho\psi^{CH}_{\gamma}) \tag{18}$$

$$X^p_{ij} = \frac{\partial(\rho\psi)}{\partial \alpha^p_{ij}} = \frac{2}{3} C^p(\xi)\alpha^p_{ij} \tag{19}$$

$$R^p = \frac{\partial(\rho\psi)}{\partial r^p} = R^p_\infty(\xi)\{1 - \exp[-b^p(\xi) r^p]\} \tag{20}$$

In the above equations Y^γ_{ij} and $Y^{\alpha'}_{ij}$ stand for the ductile and brittle part of the elastic strain energy release rate, respectively (cf. also Kintzel et al., 2010).

In Equations (18)–(20) Z is the chemical force for phase transformation, and X^p_{ij} and R^p are the plastic hardening forces.

The constitutive law (16) under isothermal conditions includes the plastic, irreversible damage and transformation strains:

$$\sigma_{ij} = E_{ijkl}(\mathbf{D}^{avg})\left(\varepsilon_{kl} - \varepsilon^p_{kl} - \varepsilon^{id}_{kl} - \xi\varepsilon^{bs}_{kl}\right) \tag{21}$$

where $\boldsymbol{\varepsilon}^p$ is the plastic strain tensor, $\boldsymbol{\varepsilon}^{id}$ is the irreversible damage strain tensor, and $\boldsymbol{\varepsilon}^{bs} = 1/3\Delta\upsilon\mathbf{I}$ denotes the free deformation called bain strain, expressed in terms of the relative volume change $\Delta\upsilon$. It is assumed that the mesoscopic strain tensor $\boldsymbol{\varepsilon}^{bs}$ is obtained by integrating the microscopic eigen-strain tensor $\boldsymbol{\varepsilon}^{bs}_\mu$ over the RVE (cf. Garion et al. 2006).

The Clausius-Planck inequality takes therefore the following form:

$$\begin{aligned}&\sigma_{ij}\dot{\varepsilon}^I_{ij} - \rho\dot{\psi} = \sigma_{ij}\dot{\varepsilon}^p_{ij} - X^p_{ij}\dot{\alpha}^p_{ij} - R^p\dot{r}^p \\ &+(\sigma_{ij}\varepsilon^{bs}_{ij} - Z)\dot{\xi} + \sigma_{ij}\dot{\varepsilon}^{id}_{ij} + Y^\gamma_{ij}\dot{D}^\gamma_{ij} + Y^{\alpha'}_{ij}\dot{D}^{\alpha'}_{ij} \geq 0\end{aligned} \tag{22}$$

As it can be seen from (22), the quantity $Q = \sigma_{ij}\varepsilon^{bs}_{ij} - Z$ is conjugated to the transformation rate $\dot{\xi}$ and can be treated as a thermodynamic force that drives the phase front through the material.

3.2.1 *Evolution of state variables*

It is assumed here, after Lemaitre (1992), that ductile damage and phase transformation mechanisms are governed by plasticity with a single dissipation potential F: $F(J_{cf}, V_{st}) = F^p + F^{d\gamma} + F^{tr}$ and normality rule involving only one plastic multiplier, $\dot{\lambda}^p$, determined from the consistency condition. The equations involving the dissipation potentials take the form:

$$\dot{\varepsilon}^p_{ij} = \dot{\lambda}^p \frac{\partial F^p}{\partial \sigma_{ij}}, \; \dot{D}^\gamma_{ij} = \dot{\lambda}^p \frac{\partial F^d}{\partial Y^\gamma_{ij}}, \; \dot{\xi} = \dot{\lambda}^p \frac{\partial F^{tr}}{\partial Q} \tag{23}$$

$$\dot{\alpha}^p_{ij} = -\dot{\lambda}^p \frac{\partial F^p}{\partial X^p_{ij}}, \; \dot{r}^p = -\dot{\lambda}^p \frac{\partial F^p}{\partial R^p} \tag{24}$$

The irreversible strain ε^{id}_{ij} related to damage evolution is here neglected.

In such approach the ductile damage and the phase transformation progress only when there is plastic flow. Similarly, beyond damage threshold there is no plasticity without a corresponding increase in damage, and beyond phase transformation threshold there is no plasticity without a corresponding increase in martensite content.

Plastic potential F^p is here equal to von Mises type yield surface:

$$F^p = f^p = J_2[\widetilde{\sigma}_{ij} - \widetilde{X}^p_{ij}(\xi)] - \sigma_y - \widetilde{R}^p(\xi) = 0 \tag{25}$$

where

$$\widetilde{\sigma}_{ij} = M_{ikjl}(\mathbf{D}^{avg})\sigma_{kl}, \; \widetilde{X}^p_{ij} = M_{ikjl}(\mathbf{D}^{avg})X^p_{kl} \tag{26}$$

$$\widetilde{R} = R/\left(1 - D^{avg}_{eq}\right), \; D^{avg}_{eq} = \sqrt{D^{avg}_{ij} D^{avg}_{ij}} \tag{27}$$

are the effective variables. The relevant potential of damage dissipation reads (cf. Egner & Skoczen, 2010):

$$\begin{aligned}&F^{d\gamma} = 1/2 C_{ik} Y^\gamma_{kl} C_{ij} Y^\gamma_{ij} \\ &\times\sqrt{\frac{(\widetilde{s}_{mn} - \widetilde{X}^p_{mn})L_{mnpq}(\mathbf{D}^{avg})(\widetilde{s}_{pq} - \widetilde{X}^p_{pq})}{(\widetilde{s}_{rs} - \widetilde{X}^p_{rs})(\widetilde{s}_{rs} - \widetilde{X}^p_{rs})}} - B^{d\gamma} = 0\end{aligned} \tag{28}$$

where
$L_{ijkl}(\mathbf{D}^{avg}) = M^{-1}_{ijmn}(\mathbf{D}^{avg}) M^{-1}_{mnkl}(\mathbf{D}^{avg})$, $\mathbf{C}$ is a tensor that defines the material properties related to texture, and $B^{d\gamma}$ denotes the barrier force for damage, and $\mathbf{s}$ is the deviatoric stress.

The phase transformation dissipation potential is assumed here in a simple form:

$$\begin{aligned}&F^{tr} = A(\theta, \boldsymbol{\sigma}, \dot{\boldsymbol{\varepsilon}}^p)Q \\ &\times\sqrt{\frac{(\widetilde{s}_{mn} - \widetilde{X}^p_{mn})L_{mnpq}(\mathbf{D}^{avg})(\widetilde{s}_{pq} - \widetilde{X}^p_{pq})}{(\widetilde{s}_{rs} - \widetilde{X}^p_{rs})(\widetilde{s}_{rs} - \widetilde{X}^p_{rs})}} - B^{tr} = 0\end{aligned} \tag{29}$$

where $A(\theta, \boldsymbol{\sigma}, \dot{\boldsymbol{\varepsilon}}^p)$, in general, is a function of temperature, stress state and strain rate, and B^{tr} is the barrier force for phase transformation. For rate independent plasticity, isothermal process and small stress variations function A may be treated as a constant value.

By taking into account relations (23) and (25), the following plastic flow rule is obtained:

$$\dot{\varepsilon}_{ij}^p = \frac{\partial f^p\left(\widetilde{\boldsymbol{\sigma}}, \widetilde{\mathbf{X}}, \widetilde{R}\right)}{\partial \widetilde{\sigma}_{kl}} \frac{\partial \widetilde{\sigma}_{kl}}{\partial \sigma_{ij}} \dot{\lambda}^p \tag{30}$$

Plastic hardening variables evolve according to (24) and (25):

$$\dot{\alpha}_{ij}^p = \dot{\varepsilon}_{ij}^p\,, \quad \dot{r}^p = \dot{\lambda}^p / (1 - D_{eq}^{avg}) \tag{31}$$

Ductile damage rate is governed by the relation resulting from (23) and (28):

$$\dot{D}_{ij}^{\gamma} = C_{ik}(\boldsymbol{\varepsilon}^p) Y_{kl}^{\gamma} C_{lj}(\boldsymbol{\varepsilon}^p) \dot{p} H(p - p_D) \tag{32}$$

where p_D denotes damage threshold, and $\mathbf{C}(\boldsymbol{\varepsilon}^p)$ represents texture induced anisotropy of damage (cf. Egner & Skoczen, 2010).

By taking into account (23) and (29) the evolution of phase transformation variable takes the form:

$$\dot{\xi} = A\, \dot{p} H[(p - p_{\xi})(\xi_L - \xi)] \tag{33}$$

In the above equation p_{ξ} stands for the phase transformation threshold (to trigger the formation of martensite), while ξ_L is a limit of martensite evolution, above which the martensitic transformation rate is considered equal to zero. The consistency multiplier $\dot{\lambda}^p$ is obtained from the consistency condition:

$$\frac{\partial f^p}{\partial \sigma_{ij}}(\dot{\sigma}_{ij} - \dot{X}_{ij}) + \frac{\partial f^p}{\partial R}\dot{R} + \frac{\partial f^p}{\partial D_{ij}^{avg}}\dot{D}_{ij}^{avg} + \frac{\partial f^p}{\partial \xi}\dot{\xi} = 0 \tag{34}$$

Martensite inclusions are subjected to brittle damage described by the second order damage tensor $\mathbf{D}^{\alpha\prime}$. According to Litewka & Debinski (2003) the deterioration of brittle material structure due to applied load can be described by damage evolution equation expressed in the form of tensorial function, $D_{ij}^{\alpha\prime} = f_1 \delta_{ij} + f_2 \sigma_{ij}$. Two multipliers, f_1 and f_2, are scalar-valued functions of the stress tensor invariants. The first term represents the isotropic damage and the second one accounts for the oriented damage due to different effects of the stress tensor.

Evolution of thermodynamic forces

The evolution equations for thermodynamic conjugated forces are obtained by taking time derivatives of equations (16)–(20):

$$\dot{\sigma}_{ij} = E_{ijkl}\dot{\varepsilon}_{kl}^E + \frac{\partial E_{ijkl}}{\partial D_{pq}^{avg}}\varepsilon_{kl}^E \dot{D}_{pq}^{avg} \tag{35}$$

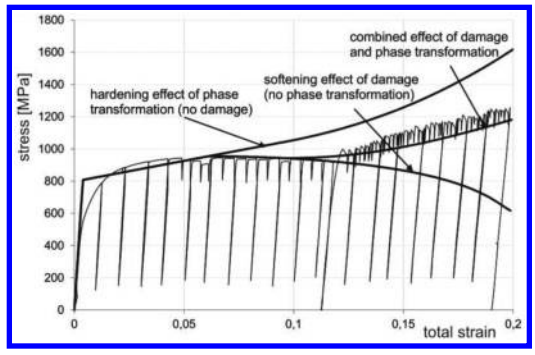

Figure 4. Numerical simulations of stress-strain curve.

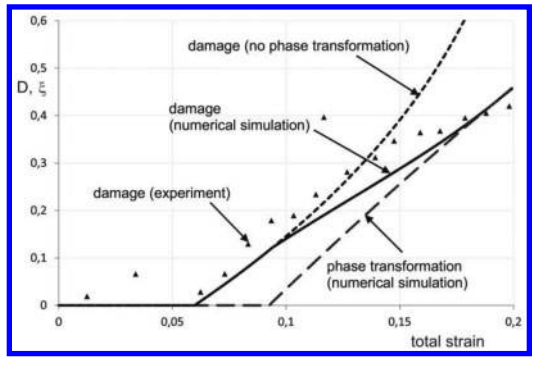

Figure 5. Numerical simulation of damage evolution.

$$\dot{X}_{ij}^p = \frac{2}{3}C^p(\xi)\dot{\varepsilon}_{ij}^p + \frac{1}{C^p(\xi)}\frac{\partial C^p}{\partial \xi}X_{ij}^p\dot{\xi} \tag{36}$$

$$\dot{R}^p = b^p(R_{\infty}^p - R^p)\dot{r}^p + \left[\frac{1}{R_{\infty}^p(\xi)}\frac{\partial R_{\infty}^p}{\partial \xi}R^p + (R_{\infty}^p - R^p)r^p\frac{\partial b^p}{\partial \xi}\right]\dot{\xi} \tag{37}$$

Functions $C^p(\xi)$ and $R_{\infty}^p(\xi)$ were derived via Mori-Tanaka homogenization in Garion et al. (2006).

3.2.2 *Discussion of results*

Accounting for three dissipative phenomena: plasticity, damage and phase transformation in the present constitutive model allows to obtain a satisfactory reproduction of the experimental stress-strain curve for 316L stainless steel subjected to uniaxial tension at cryogenic temperatures (see Fig. 4).

Another effect captured by the present model consists in the interaction between the increasing amount of the secondary (martensitic) phase and decreasing rate of damage (Fig. 5). Before the phase transformation threshold is reached, purely ductile damage develops. In agreement with the experimental observations, this stage exhibits accelerated character of damage rate. With the appearance of phase transformation a significant drop of damage rate is observed.

4 CONCLUSIONS

- The general constitutive model of dissipative material, based on thermodynamics of irreversible processes with internal state variables was presented.
- The model was used to investigate the influence of temperature rate on the response of the constitutive model when cyclic fatigue tests in nonisothermal conditions are simulated. The significant differences in results were obtained when the temperature rate terms, usually neglected in constitutive modeling, were included into the rate equations of thermodynamic hardening forces.
- The new, thermodynamically based constitutive model of stainless steel at cryogenic temperatures, accounting for coupling between ductile damage in austenite, brittle damage in martensite and phase transformation was also presented.

Heterogeneous structures studied by an interphase elasto-plastic damaging model

G. Giambanco, G. Fileccia Scimemi & A. Spada
Department of Civil, Environmental, Aerospace and Materials' Engineering,
University of Palermo – Palermo, Italy

ABSTRACT: Heterogeneous materials present a mechanical response strongly dependent on the static and kinematic phenomena occurring in the constituents and at their joints. At the mesoscopic level the interaction between the units is simulated by mean of apposite mechanical devices such as the zero thickness interface model where contact tractions and displacement discontinuities are the primary static and kinematic variables respectively. In heterogeneous materials the response also depends on joint internal stresses. The introduction of internal stresses brings to the interphase model or an enhancement of the classical zero-thickness interface. With the term 'interphase' we shall mean a layer separated by two physical interfaces from the bulk material or a multilayer structure with varying properties and several interfaces. Different failure conditions can be introduced for the physical interfaces and for the joint material. The interphase model has been implemented in an open-source research-oriented finite element analysis program for 2D applications.

1 INTRODUCTION

The mechanical response of all those structures that are constituted by heterogeneous materials is dependent by different static and kinematic phenomena occurring in each constituent and at their joints. Material degradation due to nucleation, growth and coalescence of microvoids and microcracks is usually accompanied by plastic deformations as decohesion and sliding that cause strain softening and induced anisotropy.

The mesoscopic approach is by now the most diffused technique to understand this kind of materials, because it overcomes the problems associated with the strong simplifications that have to be introduced when the macroscopic approach is applied. In particular, with the mesoscopic approach all the material constituents are modelled individually and their interactions are regulated by using appropriate devices able to reproduce the inelastic phenomena that usually occur at the physical interfaces. In the last decades zero-thickness interface elements (ZTI) have been applied in several engineering applications due to their simple formulation and to their easiness to be implemented in finite element codes.

The interface constitutive laws are expressed in terms of contact tractions and displacement discontinuities which are considered as generalized joints strains. In order to model the nonlinear behaviour caused by plastic deformations and damage evolution the constitutive laws of the interface elements are formulated making use of concepts borrowed by theory of Plasticity and Continuum Damage Mechanics.

In many cases the structural response depends also on internal stresses and strains within the joint. It is sufficient to think to the fracture that appears in the middle of masonry blocks caused by the horizontal tangential contact stresses between the mortar and the block when a masonry assembly is subjected to a pure compressive load. These tangential stresses cannot be captured by the classical ZTI model. Therefore, the usual assumption used in zero-thickness interface elements, where the response is governed by contact stress components, may require a correction by introducing the effect of the internal stresses into the analysis. This enhancement of the ZTI is known as interphase model, for the first time proposed by Giambanco and Mròz (2001).

The interphase element has been formulated by authors as a new contact element and introduced in a scientific oriented finite element code. Patch tests have been carried out in elasticity to investigate the numerical performance and convergence of the element. All the results are shown in the paper written by Giambanco el al. (2012). In particular, in that paper is shown how strategies such as the Reduced Selective Integration or the Enhanced Assumed Strain methods are necessary to avoid shear locking effects of the element.

In this work the interphase element is implemented for nonlinear applications by introducing separate limit conditions for the joint bulk material and for the physical interfaces. The overall model is thermodynamically consistent and the flow rules are derived by applying the Lagrangian method. With the aim to show

the effectiveness of the model the interphase constitutive laws have been implemented in an open-source research-oriented finite element analysis program for 2D applications and by using the Selective Reduced Integration.

2 GENERAL ASSUMPTIONS AND THERMODYNAMICS

Let us consider, in the Euclidean space $\Re^3$ referred to the orthonormal frame $(O, \mathbf{i_1}, \mathbf{i_2}, \mathbf{i_3})$, a structure formed by two adherents Ω^+, Ω^- connected by a third material Ω in contact with the two bodies by means of the two physical interfaces Σ^+ and Σ^- respectively, as in Figure 1.

It is assumed that the thickness h of the joint is small if compared with the characteristic dimensions of the bonded assembly.

The boundary of the two adherents is divided in the two parts $\Gamma_u^{\pm}$ and $\Gamma_t^{\pm}$, where kinematic and loading conditions are specified respectively.

The joint interacts with the two adherents through the following traction components:

$$\mathbf{t}^{\pm} = t_1^{\pm}\mathbf{e}_1 + t_2^{\pm}\mathbf{e}_2 + t_3^{\pm}\mathbf{e}_3 \tag{1}$$

which can be considered as the external surface loads for the joint.

In Equation 1 $\mathbf{e}_1$, $\mathbf{e}_2$ and $\mathbf{e}_3$ are the unit vectors of the local reference system, with $\mathbf{e}_3$ oriented along the normal to the middle surface Σ and directed towards the adherent Ω^+. The joint can be regarded as an interphase model. It is assumed that the fibers inside the interphase and directed along $\mathbf{e}_3$ are maintained rectilinear during the deformation process. In view of this hypothesis the interphase displacement field $\mathbf{u}$ can be easily obtained from the displacement $\mathbf{u}^+$ and $\mathbf{u}^-$ of the interfaces Σ^+ and Σ^-, thus

$$\mathbf{u}(x_1,x_2,x_3) = \left(\frac{1}{2}+\frac{x_3}{h}\right)\mathbf{u}^+(x_1,x_2) + \left(\frac{1}{2}-\frac{x_3}{h}\right)\mathbf{u}^-(x_1,x_2) \tag{2}$$

with x_1, x_2 and x_3 the Cartesian coordinates in the orthonormal frame $(O, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$.

Since the thickness of the joint is generally small if compared to the characteristic dimensions of the adherents, we can assume the strain state ε uniform along the $\mathbf{e}_3$ direction and given by:

$$\boldsymbol{\varepsilon}(x_1,x_2) = \frac{1}{h}\int_{-h/2}^{h/2} \nabla^s \mathbf{u}(x_1,x_2,x_3)\,dx_3 \tag{3}$$

Substituting the Equation 2 we have:

$$\boldsymbol{\varepsilon}(x_1,x_2) = \frac{1}{2h}\left([\mathbf{u}]\otimes\mathbf{n} + \mathbf{n}\otimes[\mathbf{u}]\right) + \frac{1}{2}\nabla^s\left(\mathbf{u}^+ + \mathbf{u}^-\right) \tag{4}$$

where $[\mathbf{u}] = \mathbf{u}^+ - \mathbf{u}^-$, $\mathbf{n}$ is the unit normal vector to the interphase plane and ∇^s is the symmetric gradient operator defined as $\nabla^s = \frac{1}{2}\left(\nabla + \nabla^T\right)$.

Let us note that in the interphase model the joint curvatures generated by displacement field (2) and the related flexural effect are neglected.

Equilibrium equations are derived by applying the principle of virtual displacements (PVD) that asserts that the external work produced by the contact tractions equals the internal work developed in the joint. According to the hypothesis of a constant strain state, by applying the divergence theorem and assuming that $\Sigma = \Sigma^+ = \Sigma^-$, the PVD leads to the following local equilibrium relations of the interphase model:

$$\begin{aligned} &\mathbf{t}^+ - \boldsymbol{\sigma}\cdot\mathbf{n} + \frac{h}{2}div\boldsymbol{\sigma} = \mathbf{0}; \\ &\mathbf{t}^- + \boldsymbol{\sigma}\cdot\mathbf{n} + \frac{h}{2}div\boldsymbol{\sigma} = \mathbf{0} \end{aligned} \qquad on\ \Sigma, \tag{5}$$

$$\mathbf{m}\cdot\boldsymbol{\sigma} = \mathbf{0} \qquad on\ \Gamma. \tag{6}$$

The basic kinematical hypotheses are the additive decomposition of total strain in the internal (i) and contact (c) parts and, for the contact strain only, a further decomposition in elastic (e) and inelastic (p) parts:

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^i + \boldsymbol{\varepsilon}^c \tag{7}$$

$$\boldsymbol{\varepsilon}^c = \boldsymbol{\varepsilon}^{ce} + \boldsymbol{\varepsilon}^{cp} \tag{8}$$

with

$$\boldsymbol{\varepsilon}^i = \mathbf{A}\boldsymbol{\varepsilon}\mathbf{A} \tag{9}$$

being $\mathbf{A} = \mathbf{I} - \mathbf{n}\otimes\mathbf{n}$ the unit second order tensor.

In order to comply with thermodynamic requirements, the interphase Helmholtz free energy is introduced in the following form:

$$\begin{aligned} \Psi\left(\boldsymbol{\varepsilon}^i,\boldsymbol{\varepsilon}^c,\boldsymbol{\varepsilon}^{cp},\boldsymbol{\omega},\xi_d,\xi_p\right) &= \Psi^i\left(\boldsymbol{\varepsilon}^i,\boldsymbol{\omega},\xi_d\right) + \\ &+\Psi^c\left(\boldsymbol{\varepsilon}^c,\boldsymbol{\varepsilon}^{cp},\xi_p\right) + \Psi^{i,c}\left(\boldsymbol{\varepsilon}^i,\boldsymbol{\varepsilon}^c,\boldsymbol{\varepsilon}^{cp},\boldsymbol{\omega}\right) \end{aligned}; \tag{10}$$

where Ψ^i and Ψ^c represent the free energies related to the internal and contact parts of the strain state respectively and Ψ^{ic} is the mixed term of the free energy

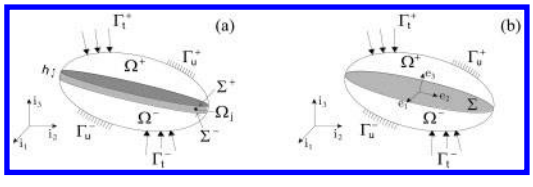

Figure 1. (a) Mechanical scheme of a third body interposed between two adherents; (b) Interphase mechanical scheme.

which takes into account the co-presence of the contact and internal strains. ξ_d and ξ_p are the damage and plastic internal variables, respectively.

The principle considered for developing the constitutive laws is that damage occurs in the bulk material, therefore the damage tensor ω appears in the two terms of the total free energy that are functions of the internal strains also. In this way the constitutive model takes into account the onset of microvoids and fractures along the thickness of the joint. On the other hand, debonding of the joint from the adherents, sliding and fractures developing on surfaces parallel to the middle plane of the interphase are modelled using elastoplasticity and the inelastic contact strains ε^{cp} are the related internal variables.

In this work a single scalar damage variable ω governs the loss of stiffness of the bulk material. It ranges from 0 to 1, with the inferior and superior limits having the meaning of a pristine and a fully damaged bulk material, respectively.

The explicit expression of the components of the free energy is given below:

$$\Psi^i = \frac{1}{2}(1-\omega)\left[\lambda\,\mathrm{tr}^2\left(\boldsymbol{\varepsilon}^i\right)+2\mu\boldsymbol{\varepsilon}^i:\boldsymbol{\varepsilon}^i\right]+ -h_d\left[\xi_d+\ln\left(1-\xi_d\right)\right] \tag{11}$$

$$\Psi^c = \frac{1}{2}\left[\lambda\,\mathrm{tr}^2\boldsymbol{\varepsilon}^{ce}+2\mu\boldsymbol{\varepsilon}^{ce}:\boldsymbol{\varepsilon}^{ce}\right]+\frac{1}{2}h_p\xi_p^2 \tag{12}$$

$$\Psi^{i,c} = (1-\omega)\lambda\,\mathrm{tr}\left(\boldsymbol{\varepsilon}^i\right)\mathrm{tr}\,\boldsymbol{\varepsilon}^{ce} \tag{13}$$

where λ and μ are the Lamè's constants, h_d is a material parameter which governs the softening response associated to the damage onset and growth, and h_p is a material parameter specifying isotropic hardening/softening interface response.

3 STATE EQUATIONS AND FLOW RULES

In order to derive the interphase constitutive equations, the second principle of thermodynamics, taking into account also the balance equation (first principle) can be applied in the form of the Clausius-Duhem inequality. This inequality for isothermal purely mechanical evolutive process reads as

$$D = \boldsymbol{\sigma}:\dot{\boldsymbol{\varepsilon}}-\dot{\Psi}\geq 0 \tag{14}$$

where D is the interphase dissipation (for unit surface) or net entropy production.

From the assumed form of the Helmholtz free energy its general rate has the following expression:

$$\dot{\Psi} = \left(\frac{\partial\Psi^i}{\partial\boldsymbol{\varepsilon}^i}+\frac{\partial\Psi^{i,c}}{\partial\boldsymbol{\varepsilon}^i}\right):\dot{\boldsymbol{\varepsilon}}^i+\left(\frac{\partial\Psi^c}{\partial\boldsymbol{\varepsilon}^c}+\frac{\partial\Psi^{i,c}}{\partial\boldsymbol{\varepsilon}^c}\right):\dot{\boldsymbol{\varepsilon}}^c+ +\left(\frac{\partial\Psi^c}{\partial\boldsymbol{\varepsilon}^{cp}}+\frac{\partial\Psi^{i,c}}{\partial\boldsymbol{\varepsilon}^{cp}}\right):\dot{\boldsymbol{\varepsilon}}^{cp}+\left(\frac{\partial\Psi^i}{\partial\omega}+\frac{\partial\Psi^{i,c}}{\partial\omega}\right):\dot{\omega}+ +\frac{\partial\Psi^i}{\partial\xi_d}\dot{\xi}_d+\frac{\partial\Psi^c}{\partial\xi_p}\dot{\xi}_p \tag{15}$$

Particularizing Equation 14 for a purely elastic incremental deformation process ($\mathbf{P}^{cp}=\mathbf{0}$, $\dot{\omega}=\dot{\xi}_d=\dot{\xi}_p=0$), assuming the decomposition of the stress state similar to that used for the strain state

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}^i+\boldsymbol{\sigma}^c, \qquad \text{being} \qquad \boldsymbol{\sigma}^i=\mathbf{A}\boldsymbol{\sigma}\mathbf{A} \tag{16}$$

and considering the adopted expressions of the free energy parts (Eqs. 11–13), the elastic stress-strain equations can be derived, thus

$$\sigma^i = (1-\omega)\left\{\lambda\left[\mathrm{tr}\left(\boldsymbol{\varepsilon}^i\right)+\mathrm{tr}\left(\boldsymbol{\varepsilon}^c-\boldsymbol{\varepsilon}^{cp}\right)\right]\mathbf{A}+2\mu\boldsymbol{\varepsilon}^i\right\} \tag{17}$$

$$\sigma^c = \lambda\left[(1-\omega)\,\mathrm{tr}\left(\boldsymbol{\varepsilon}^i\right)+\mathrm{tr}\left(\boldsymbol{\varepsilon}^c-\boldsymbol{\varepsilon}^{cp}\right)\right](\mathbf{I}-\mathbf{A})+ +2\mu\left(\boldsymbol{\varepsilon}^c-\boldsymbol{\varepsilon}^{cp}\right) \tag{18}$$

$$\chi_p = h_p\xi_p \tag{19}$$

$$\chi_d = h_d\frac{\xi_d}{1-\xi_d} \tag{20}$$

$$\zeta = \frac{1}{2}\left[\lambda\,\mathrm{tr}^2\left(\boldsymbol{\varepsilon}^i\right)+2\mu\boldsymbol{\varepsilon}^i:\boldsymbol{\varepsilon}^i\right]+\lambda\,\mathrm{tr}\left(\boldsymbol{\varepsilon}^i\right)\mathrm{tr}\left(\boldsymbol{\varepsilon}^c-\boldsymbol{\varepsilon}^{cp}\right) \tag{21}$$

where χ_p and χ_d are the static variables conjugate of the internal variables ξ_p and ξ_d respectively, and ζ the thermodynamic force conjugate of the damage variable ω.

Making use of the elastic strain-stress equation and of the previous positions, the final expression of the instantaneous dissipation is obtained:

$$D = \boldsymbol{\sigma}^c:\dot{\boldsymbol{\varepsilon}}^{cp}-\chi_p\dot{\xi}_p-\chi_d\dot{\xi}_d+\zeta\dot{\omega}\geq 0\,. \tag{22}$$

In order to regulate the activation of each dissipative mechanism, two different yield functions are defined in the space of the proper static variables, namely:

$$\Phi_p\left(\boldsymbol{\sigma}^c,\chi_p\right)\leq 0, \qquad \Phi_d\left(\zeta,\chi_d\right)\leq 0 \tag{23}$$

where Φ_p is the classical plastic yield function specifying the elastic contact domain assumed convex and Φ_d is the damage activation function also assumed convex.

The activation of each dissipation mechanism can be effectively described by a variational formulation which is represented by the generalized principle of maximum intrinsic dissipation:

$$\max_{\boldsymbol{\sigma}^c,\chi_p,\chi_d,\zeta}\left(\boldsymbol{\sigma}^c:\dot{\boldsymbol{\varepsilon}}^{cp}-\chi_p\dot{\xi}_p-\chi_d\dot{\xi}_d+\zeta\dot{\omega}\right) \tag{24}$$

subject to the constraints (Eq. 23). The Kuhn-Tucker conditions of the maximum constrained problem provide the plastic and damage evolution laws of the interphase:

$$\dot{\boldsymbol{\varepsilon}}^{cp}=\dot{\lambda}_p\frac{\partial\Phi_p}{\partial\boldsymbol{\sigma}^c}; \qquad \dot{\omega}=\dot{\lambda}_d\frac{\partial\Phi_d}{\partial\zeta} \tag{25}$$

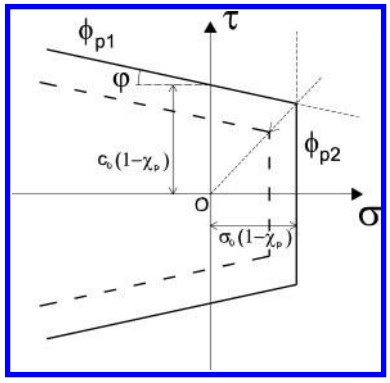

Figure 2. Plastic yield conditions represented in the stress space.

$$-\dot{\xi}_p = \dot{\lambda}_p \frac{\partial \Phi_p}{\partial \chi_p}; \quad -\dot{\xi}_d = \dot{\lambda}_d \frac{\partial \Phi_d}{\partial \chi_d} \tag{26}$$

$$\Phi_p\left(\boldsymbol{\sigma}^c, \chi_p\right) \le 0, \quad \dot{\lambda}_p \ge 0, \quad \dot{\lambda}_p \Phi_p\left(\boldsymbol{\sigma}^c, \chi_p\right) = 0 \tag{27}$$

$$\Phi_d\left(\zeta, \chi_d\right) \le 0, \quad \dot{\lambda}_d \ge 0, \quad \dot{\lambda}_d \Phi_d\left(\zeta, \chi_d\right) = 0 \tag{28}$$

being $\dot{\lambda}_p$ and $\dot{\lambda}_d$ the plastic and damage multiplier, respectively.

In the present study the elasto-plastic convex domain is defined by the intersection of the classical Mohr-Coulomb bilinear function with a tension cut-off:

$$\Phi_{p1}\left(\boldsymbol{\sigma}^c, \chi_p\right) = \left|\boldsymbol{\tau}^c\right| + \sigma^c \tan\varphi - c_0\left(1-\chi_p\right) \tag{29}$$

$$\Phi_{p2}\left(\boldsymbol{\sigma}^c, \chi_p\right) = \sigma^c - \sigma_0\left(1-\chi_p\right) \tag{30}$$

where τ^c and σ^c are the tangential stress vector and the normal stress component of the contact stresses, φ is the friction angle, c_0 and σ_0 the cohesion and tensile strength of the virgin interfaces.

The two yield functions are depicted in Figure 2. The following four zones can be distinguished:

I elastic zone: $\Phi_{p1} < 0,\ \Phi_{p2} < 0$
II plastic activation in shear: $\Phi_{p1} = 0,\ \Phi_{p2} < 0$
III plastic activation in tension: $\Phi_{p1} < 0,\ \Phi_{p2} = 0$
IV plastic activation in tension and shear (corner): $\Phi_{p1} < 0,\ \Phi_{p2} < 0$.

The damage activation function is linear and the first activation occurs when the thermodynamic force reaches the relative threshold value ζ_0:

$$\Phi_d\left(\zeta, \chi_d\right) = \zeta - \zeta_0\left(1-\chi_d\right) \tag{31}$$

4 NUMERICAL APPLICATIONS

The interphase model presented in Sections 2 and 3 has been implemented in an open-source research-oriented finite element analysis program for 2D applications. With the aim to run a step-by-step integration, flow rules have been rewritten as discrete laws. The implicit backward-Euler difference method was applied to obtain results within the time step $[t_n, t_{n+1}] \subset [0, \quad T]$. In particular the nonlinear solution at time t_{n+1} has been calculated by means of an elastic prediction – plastic and/or damaging correction procedure. The interphase element has four nodes and zero-thickness. The integration of the stiffness matrix has been solved by applying the Reduced Selective Integration method, that is two Gauss are used for the integration in the direction normal to the interphase plane while one Gauss point is used in the tangential one.

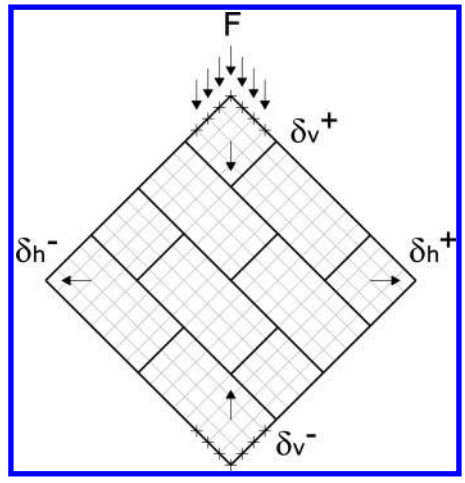

Figure 3. Diagonal compression test on a masonry panel: finite element model.

The numerical applications presented in this work regard diagonal compression test on a cylindrical masonry specimen and a masonry vault loaded by a monotonic increasing load. All numerical examples have been carried out under the hypothesis of plane stress state.

4.1 *Diagonal compression test on masonry*

A diagonal compression numerical test has been carried out on a masonry panel and compared with the experimental results obtained in laboratory. With reference to Figure 3, the specimen is made of four courses of sandstone blocks with calcium-cement mortar. It has a squared shape with a length of 67 cm for each side. A single block is 33 cm long and 16 cm high. The mortar layer has a thickness of 1 cm. A total number of 256 plane stress 2D solid elements and 72 interphase elements has been used to create the finite element model.

The mechanical variables for blocks and mortar and the parameters used for the finite element model are reported in Table 1.

The test has been run with 400 steps under displacement control. At each step the values of the total vertical load F and the displacement discontinuities $\delta h = \delta h^+ + \delta h^-$ and $\delta v = \delta v^+ + \delta v^-$, in horizontal and vertical direction respectively, have been evaluated and reported in the load-displacement curves of

Table 1. Parameters used for diagonal compression test.

Parameter	Brick	Mortar
E (MPa)	11141.67	37000
v	0.25	0.14
c_0 (MPa)	–	5.0
σ_0 (MPa)	–	1.0
ζ_0 (MPa)	–	10^{-5}
φ (°)	–	35
h_p	–	0.04
h_d	–	0.001

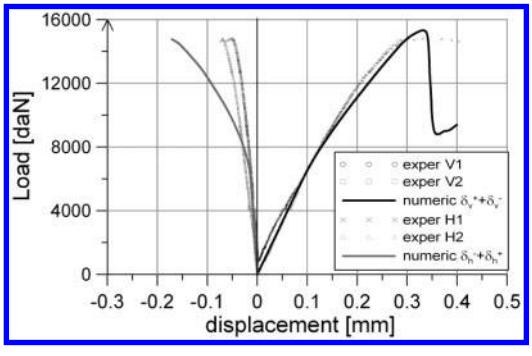

Figure 4. Load-displacement curves: comparison between numerical and experimental results.

Figure 4. A good agreement has been obtained with experimental results.

Figure 5 finally shows a comparison between the collapse experimental and numerical configurations. A very good agreement can be observed, even if the numerical model is not able to simulate the fracture inside the blocks because an elastic behavior was chosen for bricks.

4.2 *Cylindrical masonry vault*

The second example evaluates the structural response of a cylindrical masonry vault.

The results of the numerical analysis have been compared to the experimental work of Failla et al. (2004) who tested a vault made of 24 courses of calcarenite ashlars stones ($21 \times 36 \times 16\,cm^3$). Each course is separated by a mortar layer of average thickness h equal to 2.5 cm. The vault is 118 cm long, 16 cm thick and of internal radius equal to 260 cm. The imposts form an angle of 30° with the horizontal plane (Fig. 6). The vault has been subjected to a uniform load applied onto the seventh course of stones. The test has been performed under displacement control until the formation of four hinges has been reached.

The structure has been numerically implemented as a bi-dimensional arch, 118 cm wide. Each stone has been discretized with a 4×8 plane stress solid elastic elements (4-noded). The radial joints have been modeled using eight interface elements (4-noded).

To adhere to the experimental protocol, the numerical analysis has been carried out in displacement control.

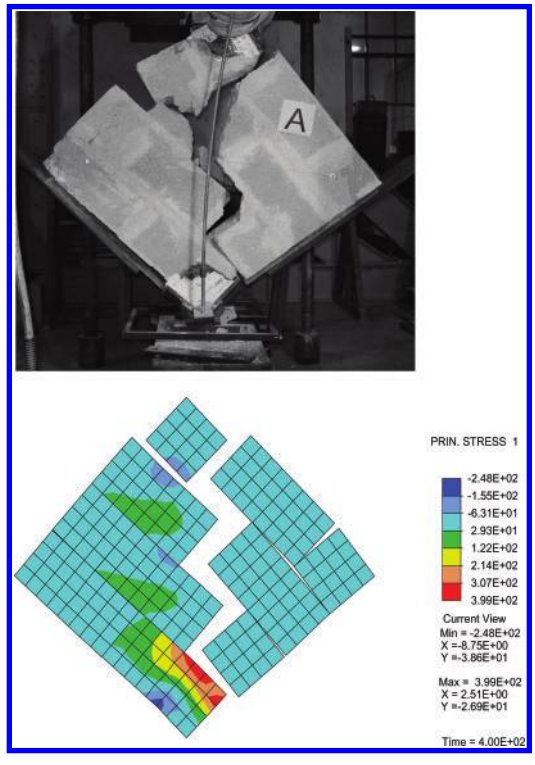

Figure 5. Comparison between numerical and experimental collapse configurations.

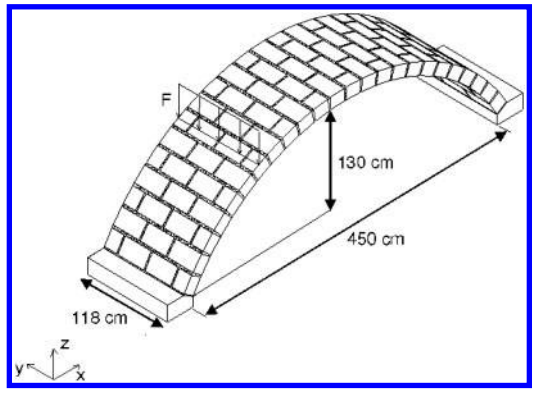

Figure 6. Tridimensional view of the vault.

The load-displacement curve, in comparison with experimental one, is reported in Figure 7. It is clear as the numerical model is able to catch the same stiffness, peak load and residual force of the experimental test. Figure 8 shows instead the final configuration of the vault after the formation of the hinges.

5 CONCLUSIONS

The present paper deals with the mesomodelling of heterogeneous structures by means of interphase elements, that can be considered as an enhancement of

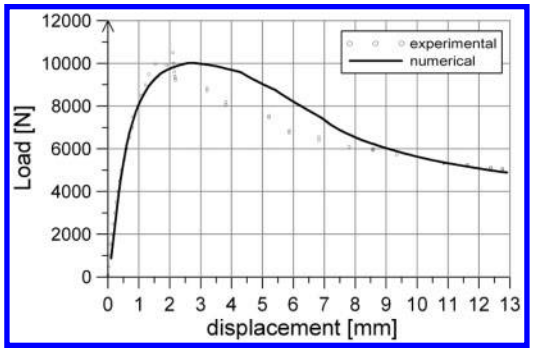

Figure 7. Load-displacement curve of the test on the vault.

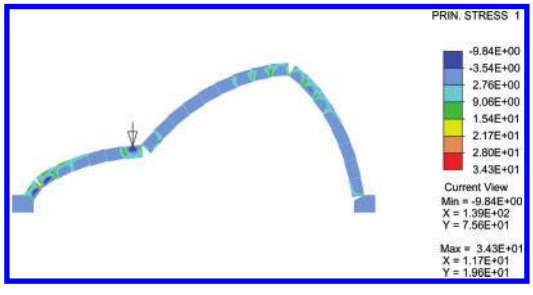

Figure 8. Collapse mechanism of the vault.

the common interface elements. Separate failure conditions have been considered for the bulk material and for contact tractions. An isotropic damage model has been used to model the nonlinear response of the bulk material, while an elastoplastic bilinear domain governs the evolution of plasticity for contact tractions. The interphase model has been written in the framework of a thermodynamically consistent theory. State equations and flow rules have been derived and rewritten in a discrete form to be suitable to be used for finite element implementation. Two numerical applications on masonry structural elements have been conducted.

Ongoing and future efforts are devoted to the introduction of plastic activation functions on the physical interfaces between mortar and block, and to the possibility to introduce a new damage model to catch horizontal fractures also.

A coupled local-nonlocal framework for modeling hydraulic fracturing in the Karoo

D.Z. Turner
Department of Civil Engineering, Stellenbosch University, Stellenbosch, South Africa

ABSTRACT: A great deal of debate over whether or not to allow hydraulic fracturing in the Karoo (in order to improve hydrocarbon production; making natural gas an economical local alternative energy source) has been waged with very little emphasis on scientific investigation. In particular, little is known about the transport of contaminants used in the process through the fractured formation. Many of the surfactants used to enable greater water penetration during fracturing can contain toxic chemicals, but the probability of underground water resource contamination by these chemicals has not been widely studied. This is partially due to a lack of modeling tools that can address such a complex engineering problem. This work presents a new computational framework for modeling hydraulic fracturing with the following features: a non-local representation of solid mechanics in which cracks are naturally part of the solution, a locally mass conserving, edge-based finite element model for flow and transport, and a general local-nonlocal coupling that includes loosely and strongly coupled algorithms. This framework is capable of modeling a number of stages during the fracturing process including the initial perforation of the reservoir, the fracture itself, leakoff in the vicinity of the fracture, poroelastic response, damage modified permeability, as well as transport of species through the damaged matrix. It is intended that this framework be used to assess the probability of contamination for a given fracturing scenario and to discover ways to improve the fracturing process to reduce the associated risk. An overview of the numerical formulation will be given as well as some numerical illustrations.

1 INTRODUCTION

Whether or not to allow hydraulic fracturing in South Africa's Karoo region has been widely debated. The amount of shale gas stored in the subsurface of this region is estimated to be able to provide over 400 years worth of the entire country's energy needs. Conversely, aggressive drilling techniques like hydraulic fracturing have the potential to pollute underground water resources. While many welcome the economic benefits of harvesting natural gas, they fear the loss of the Karoo's most vital water supply. Unfortunately, many of the policy decisions regarding fracturing in the Karoo are being made with little scientific investigation. This is primarily due to a lack of the tools necessary to carry out these types of investigations. This work presents a framework for modeling hydraulic fracturing that can be used to evaluate the efficacy of using this technique in the Karoo and estimate the probability of groundwater contamination.

Modeling hydraulic fracture (including flow, deformation, damage, and chemical species transport) involves a number of challenging aspects, for example discontinuities in the displacement field, strong gradients in concentration, fast acting reactions, and physically complex flow behavior, and evolving material properties (just to name a few). In order to build a framework capable of incorporating these aspects, the following components were selected according to the features they provide:

- Solid modeling based on the Peridynamic Theory, which naturally incorporates cracks as part of the solution
- Flow and transport modeling using control volume finite elements, since this discretization scheme is mass conserving
- Effective stress treatment of pore pressure to incorporate the influence of the fracturing fluid on the geologic media
- Damage modified permeability to model the effects of degredation of the porous material on the flow characteristics
- Loose physics coupling for algorithmic stability and for decomposing time scales (enabling sub-cycling of physics)
- Analytic fields for material properties to provide for user-specified material models
- And a control volume based stencil for the peridynamic horizon that facilitates transfer of information between the flow/transport and deformation discretizations.

2 FORMULATION

We present here the basic formulation for this coupled framework in terms of the peridynamic theory, control volume finite elements, and the alterations required to couple the various discretizations into one coherent model.

2.1 *Peridynamics*

Although the peridynamic theory can be generalized to more sophisticated solid modeling (including plasticity, complex material behavior, etc., for references see (Silling 2000, Silling 2007, Silling & Askari 2005, Silling & Lehoucq 2008)), to simplify the initial implementation, we shall employ a linear elastic, quasi-static, state-based peridynamic formulation. We assme that inertial terms may be neglected and that the geologic material performs as perfectly elastic until failure. In a more sophisticated presentation of this framework, these assumptions can be relaxed.

Consider a neighborhood $\mathcal{H}$ of a material point $\mathbf{x}$ of radius δ (called the *horizon*) that includes all other material points for which a non-zero force interaction exists. If we denote another material point in this horizon as $\mathbf{x}$' then the governing equation for state-based peridynamics can be written

$$\int_{\mathcal{H}_x} \{\underline{\mathbf{T}}[\mathbf{x},t]\langle \mathbf{x}'-\mathbf{x}\rangle - \underline{\mathbf{T}}[\mathbf{x}',t]\langle \mathbf{x}-\mathbf{x}'\rangle\}\, \mathrm{d}V_{\mathbf{x}'} + \mathbf{b}(\mathbf{x},t) = 0 \tag{1}$$

where $\mathbf{T}$ is the force vector state field that defines the force interaction between two points $\mathbf{x}$ and neighbor $\mathbf{x}'$ and $\mathbf{b}(\mathbf{x},t)$ is the usual volumetric force. If we assume that the force between these neighbors acts along the vector pointing from $\mathbf{x}$ to $\mathbf{x}'$, denoted $\mathbf{M}$, we can evaluate $\mathbf{T}$ as a scalar coefficient times this unit vector

$$\mathbf{T}[\mathbf{x},t] = \tilde{t}\mathbf{M} \tag{2}$$

This scalar coefficient, $\tilde{t}$, is computed as

$$\tilde{t} = \frac{-3p}{m}x + \beta e^d \tag{3}$$

where p is the peridynamic pressure, m is the weighted volume, x is the distance magnitude between the two points in the reference configuration, β is a material parameter and $e^d = e - \theta x/3$ is the deviatoric extension scalar state field ($e = y - x$, y is the distance magnitude between the points in the deformed configuration and θ is the dilatation of the material).

2.2 *Control volume finite elements*

Unlike traditional finite elements, that require special modification to ensure local conservation of mass, control volume finite element schemes are locally mass conserving by construction (Martinez 2006). This is due to the degrees of freedom for velocity being based on the flux over each surface of the control volume rather than a nodal velocity. A good introduction to control volume finite elements can be found in (Voller 2009). Not only are control volume finite elements advantageous from the perspective of mass conservation, but they also provide robustness in several realistic scenarios that traditional finite elements do poorly. For example, along boundaries where the material properties change drastically, often spurious oscillations occur in node based schemes like finite elements. This is not the case for control volume finite elements which can be used along these boundaries without loss of accuracy or advanced stabilization schemes.

2.3 *Effective stress principle*

This framework includes the influence of two factors on the crack propagation caused by hydraulic fracturing. The first is the force of the fluid in the crack (after the initial perforation stage) and the second is the pore fluid pressure caused by fracturing fluid penetrating the region of material in the vicinity of the crack. The relative magnitude of these effects with respect to each other will vary according to the injection parameters. A high flow rate injection into a low permeability material will have very little leakoff, as such the fluid force in the crack will completely characterize the driving mechanism. Conversely, a slow injection into a highly permeable material will result in extensive penetration of the fluid beyond the crack surfaces effecting the response of the material in these regions.

A modification of the peridynamic theory to account for pore fluid pressure was presented in (Turner 2012). To account for the influence of pore pressure in the leakoff region of the hydraulic fracture, the peridynamic pressure p is augmented with the pore fluid pressure p_f such that the peridynamic pressure includes both a dilatational term and pore fluid pressure term

$$p = -k\theta + \gamma p_f \tag{4}$$

where γ is the fluid pressure coefficient and k is the bulk modulus. Depending on the definition of γ one can recover various forms of effective stress. For example if $\gamma = 1$, the resulting formulation closely resembles the classical effective stress principle of Terzaghi or Biot (Terzaghi 1943, Biot 1941, Biot & Willis 1957).

2.4 *Bond aligned fluid forces*

Fluid forces on the surface of the crack as it propagates are represented by bond aligned fluid forces. Since the peridynamic model is discretized into cells having only a single node as the crack surface evolves (that represents the centroid of the cell), there is no means by which to evaluate a normal vector on the surface. As such, one cannot simply convert the fluid pressure into

a force on that surface. In this framework we assume that the fluid forces act in the direction **M** defined by the bonds between neighbors. This applies to bonds that are broken as well. The magnitude of the fluid force $\tilde{f}$ is computed as

$$\tilde{f} = \frac{3p_f}{m}x \tag{5}$$

In this way, the driving force of the fluid pressure is applied to the residual for each cell according to the accumulation of the force relationship with each neighbor and a fluid force with each neighbor that persists even when the bond is broken.

2.5 *Damage modified permeability*

Damage is incorporated in the flow model via the damage modified permeability approach (Turner 2011) whereby the permeability of the porous matrix degrades according to the damage field computed in the peridynamic analysis. If the pristine permeability of the porous matrix is $\tilde{k}$ the damage modified permeability $\hat{k}$ is written

$$\hat{k} = (1.0 - d)\tilde{k} + d\bar{k} \tag{6}$$

where $\bar{k}$ is the permeability of a fully damaged material (representative of flow through a crack). The damage field from the peridynamic analysis is computed as the percentage of broken bonds for a given cell. Damage is zero for a pristine cell and one for a cell with all of its bonds broken. Figure 1 gives a representation of this model from the undeformed and damaged perspectives.

2.6 *Coupling aspects*

As an initial implementation the various physics of this framework are coupled via loose coupling using either a Gauss-Seidel approach or Jacobi iterations. In both of these methods, the residuals are evaluated in lock-step manner such that the control volume fluid calculation is advanced, the fluid pressure is passed to the peridynamic calculation, the peridynamic calculation is advanced and the resulting damage is passed to the fluid model. More sophisticated coupling algorithms are currently under investigation.

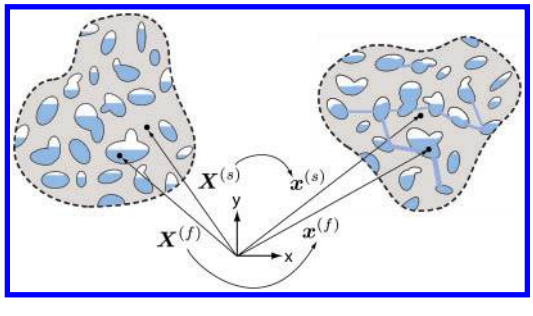

Figure 1. Pictorial description of the damage modified permeability model.

3 NUMERICAL EXAMPLES

3.1 *Breakdown pressure for constant flow rate injection*

To test the efficacy of this framework, initial simulations were performed to evaluate how well the proposed framework captures the breakdown pressure during a constant flow rate injection. In this scenario a subsection of the borehole is modeled as a plate in plane strain. The plate can be conceptualized as a slice of the material in the immediate vicinity of the borehole. The outer boundary of the plate is treated as the far-field and the inner boundary as the surface of the borehole which is pressurized by injection. The boundary condition consist of a constant mass flux into the borehole and lithostatic pressure conditions on the far-field boundary.

The complete process for this simulation can be broken down into several stages. In the first stage, the borehole pressurizes leading to dilation of the borehole. Eventually the material surrounding the borehole cracks leading to penetration of the fracturing fluid. Initially, the porous material is given a low permeability which degrades due to the presence of cracks. The fracturing fluid then flows into the regions of high permeability created by the cracks leading to crack propagation. Ultimately, due to increased volume in the cracks and less resistance to flow through the cracks the pressure profile drops substantially. The drop in pressure is indicative of the completion of fracturing. The ultimate pressure is known as the breakdown pressure.

The results of this simulation are shown in Figure 2 and Figure 3. Figure 2 shows the fluid pressure, fluid velocity and damage profile for a particular instance during the simulation just prior to breakdown. Figure 3 shows the breakdown pressure for two values of the bond critical stretch. The bond critical stretch

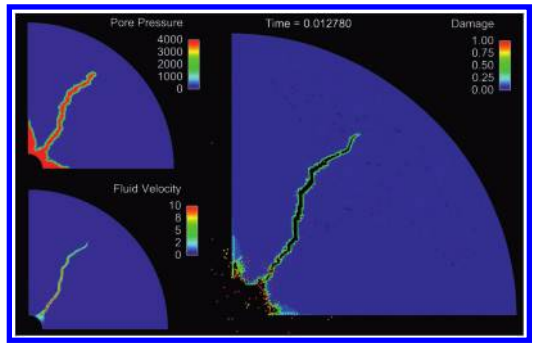

Figure 2. Snapshot of breakdown pressure prototype simulation. The top left image shows the fluid pressure, the bottom left image shows the fluid velocity and the right image shows the damage profile.

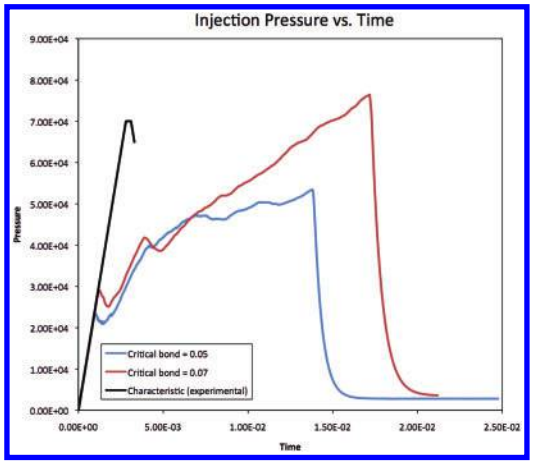

Figure 3. Breakdown pressure for various bond critical stretch values.

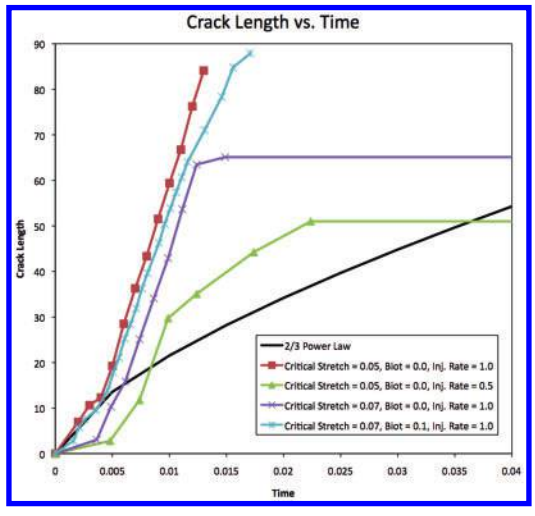

Figure 4. Crack length vs. time.

is representative of the ultimate strain the material. Note that the initial pressure profile increases linearly as expected, but the time of breakdown cannot easily be identified. Although the results capture the initial stages of the injection process, the ultimate ability of the material to resist damage propagation is overestimated as indicated by the lack of a distinct breakdown pressure. This is most likely due to the relationship between leakoff and crack penetration for a particular material. If the injection rate is high for a low permeability material, very little leakoff will occur. For a high permeability material with low injection rate, the fracturing fluid will permeate through a large portion of the material in the vicinity of the crack. This can have a large effect on the breakdown process causing aberrencies in the results such as those shown above.

3.2 *Crack propagation*

The proposed framework was also investigated with regards to the rate at which the cracks propagate in time. Depending on the injection parameters, the resulting cracks will either propagate enough to relieve the stress in the material resulting in a state of equilibrium or continue to race through the material with an infinite growth rate. Simulations were performed to evaluate the nature of crack propagation for the proposed framework.

Figure 4 shows the crack length vs. time for the injection simulations described above. Note that only in the initial stages does the crack propagate according to the 2/3 power law as predicted. Later stages in the simulation show cracks propagating in large increments or racing through the domain in one step. Further investigation is required to determine if modification of the time step or other simulation parameters will lead to closer correspondence with the 2/3 power law.

3.3 *Hydraulic fracturing in the Karoo*

This example illustrates the potential for this framework to evaluate the risk of underground water contamination from surfactants used in hydraulic fracturing. Given information such as the depth of the water table, the composition of the subsurface layers and associated material properties, as well as the nature of the groundwater currents, one can use the proposed framework to estimate the probability that contaminants introduced via the fracturing process will infiltrate underground water resources. The full capabilities of the proposed framework are employed for this problem: Propagation of the crack is modeled using the bond aligned fluid force method. The effects of leak-off are accounted for with the effective stress implementation. The injection behavior of the fluid is modeled using control volume finite elements as well as the transport of the contaminant. Finally, degradation of the permeability of the porous solid is captured via the damage modified permeability approach.

The domain of this problem is shown in Figure 5 by the dashed black line. A snapshot of the results from the simulation is shown in Figure 6. At the bottom of the domain, an initial perforation is placed to represent the damage that would have occurred in the initial stages of fracturing. This was done by preventing bonds from forming near a localized region of the injection. A constant pressure was applied to the surfaces of the perforation and lithostatic pressure was applied to the top of the domain. It was assumed that the concentration of the contaminant in the fracturing fluid was 1.0. This is of coarse not representative of the actual composition of a standard fracturing fluid, but can be treated as a worst case scenario. An advection velocity was used to represent underground currents such that the transport of the contaminant through the domain was characterized by diffusion and advection.

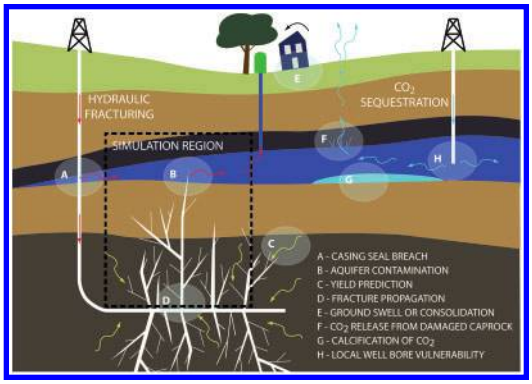

Figure 5. Cartoon showing domain of hydraulic fracturing simulation.

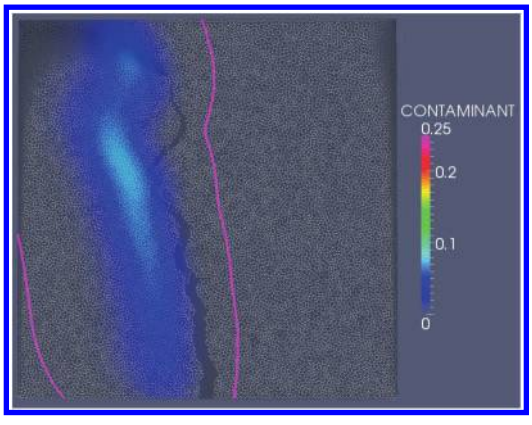

Figure 6. Snapshot of hydraulic fracturing simulation showing the concentration of contaminant as it is transported through the damaged domain.

4 DISCUSSION

Clearly, these initial simulations have not been experimentally validated, but rather illustrate the potential for this framework to model such a complex process under realistic conditions. In order for this framework to be applied effectively in decision making regarding hydraulic fracturing activities in South Africa's Karoo region an extensive study of the actual subsurface conditions must be performed. It is intended that in future works each component of the proposed framework will be verified through numerical investigation (mesh refinement studies, comparison with analytic or manufactured solutions) and validated with whatever experimental data is available. In addition, we intend to perform experiments to fill in the gaps where necessary.

Development of the numerical framework will continue as well, in particular with regards to assimilation of disparate time scales representing the various physics involved. Fracture propagation in porous media happens on a much faster timescale than the transport of the contaminants. These initial simulations were performed using a lockstep coupling by which each physics executes one step, variables are then passed, and the process is repeated for a certain time step until convergence is reached. This can be expensive computationally unless some type of subcycling is introduced. Also, the computational mesh used for each physics is identical (overlay) which aids in the transfer of data between peridynamics and the control volume finite elements, but in many cases requires much more refinement than is necessary.

5 SUMMARY

This work presents a coupled local-nonlocal framework for modeling hydraulic fracturing that can be used to predict the probability of subsurface water resource contamination. The framework consists of using peridynamics to model deformation and damage, control volume finite elements to model flow and transport, an effective stress principle to capture leak-off effects, damage modified permeability to represent the degradation of the porous material's resistance to flow, and bond aligned fluid forces to apply the driving mechanism of the fluid forces on the surfaces of the crack as it propagates. A number of simulations are presented that illustrate the potential of this framework. This work highlights the need for further experimental investigation of these processes to provide information with which to validate the model. It is intended that this work serve as a basis for further development of this framework to be used in numerical studies of hydraulic fracturing in the Karoo and other plays where groundwater contamination is a critical issue.

Tensile and compressive buckling of shear deformable damaged beams

S. Caddemi, I. Caliò & F. Cannizzaro
Dipartimento di Ingegneria Civile ed Ambientale, University of Catania, Italy

ABSTRACT: In this work the static stability analysis of the Timoshenko beam in presence of an arbitrary number of concentrated cracks is studied. The governing differential equations are formulated by modelling the cracks as a concentrated reduction of the flexural stiffness, accomplished by the use of Dirac's delta distributions. The adopted model allowed the formulation of exact closed form solutions of the buckling modes and the buckling load equation for an arbitrary number of cracks and under different boundary conditions able to account for the shear deformability. The presented closed from solutions, besides the classical compressive buckling, is also able to capture the tensile buckling phenomenon, i.e. damaged columns subjected to a tensile axial load. The influence of multiple cracks on the stability of shear deformable beams, particularly under the action of tensile loads, has never been assessed in the literature and is here addressed on the basis of an extensive parametric analysis.

1 INTRODUCTION

The problem concerning the analysis of damaged beams has received considerable attention in the specific literature and interesting developments have been recently proposed in the last few years with regard to the adopted models, the analysis methods and closed-form solutions for particular structural problems.

The interest of the scientific community towards the mentioned problem is strongly motivated by the influence that damage might play in several engineering problems. In particular, the case of concentrated cracks have been studied by providing expressions for a diffused stiffness reduction in the vicinity of the crack (Christides and Barr, 1984; Sinha et al., 2002; Chondros et al., 1998; Liebowitz and Claus, 1968). Concentrated cracks have been also modelled, according to a macroscopic approach, as an equivalent rotational spring that allows a rotation discontinuity interpreted as the crack effect on the response (Gounaris and Dimarogonas, 1988; Ostachowicz and Krawczuk, 1991; Paipetis and Dimarogonas, 1986). The effect of a single concentrated crack on the response of a straight beams has been mostly evaluated under the hypothesis that the crack remains open during the loading process, implying a linear behaviour. Particularly, when damage occurrence along the beam span is not restricted to a single crack appearance, the equivalent spring approach shows to be suitable for determining competitive procedures and closed form solutions.

Among the engineering problems involving straight beams, particularly important is the loss of stability of the equilibrium configuration due to buckling caused by axial loads in columns under different boundary conditions. It has been widely proved that the presence of concentrated cracks can cause a considerable decrement of the buckling loads as well as modification of the relevant buckling modes. The stability of single and multiple cracked columns has been studied both for the Euler-Bernoulli (Anifantis and Dimarogonas, 1983; Wang et al., 2004; Li, 2001; Gurel 2007) and the Timoshenko (Takahashi, 1999; Li, 2002; Fan and Zeng, 2003) models, with the particular purpose, in the latter case, of assessing the influence of the shear deformability of the column. To the authors' knowledge, all the studies, focussed on the buckling of cracked columns, consider the action of compressive loads, except that reported in (Zapata-Medina et al., 2010) where the buckling behaviour of a single cracked shear deformable column has been captured by means of a classical approach in presence also of a tensile load. In (Aristizabal-Ochoa, 2005) it has been stated that the tensile buckling occurs also in slender beams and, moreover, that the tensile buckling loads are not necessarily the mirror images of the compression counterparts. However, it seems that when rubber bearing isolators are subjected to tensile loads, they reach cavitation before the tensile buckling occurs (Kelly, 2003). In any case, the influence of shear deformation might play a fundamental role, since the tensile buckling load can decrease significantly and be comparable to the compressive buckling.

The contribution of the present work is intended towards the formulation of closed form solutions for buckling modes and buckling load equations of shear deformable columns, affected by an arbitrary number of cracks, able to capture also the buckling phenomenon under the action of tensile loads.

So far, the authors have studied extensively the Euler-Bernoulli beam within different contexts in presence of an arbitrary number of cracks, providing closed form solutions (Caddemi and Caliò, 2008, 2009, 2012). The latter studies provided encouraging results based on the adoption of generalized functions (distributions) to model both flexural and shear stiffness reductions due to different causes (Biondi and Caddemi, 2007; Caddemi et al. 2012).

Aim of this paper is applying the distributional model to shear deformable columns with multiple cracks for evaluating their influence on tensile and compressive buckling. The adopted integration procedure leads to explicit closed-form solutions for the buckling modes and the buckling load equations of the Timoshenko column under different boundary conditions.

2 THE GOVERNING EQUATIONS FOR THE STABILITY OF THE TIMOSHENKO BEAM WITH MULTIPLE CRACKS

In this section a model of Timoshenko beam showing multiple discontinuities in the rotation function is presented, and its capability of describing the influence of concentrated cracks is shown. In particular the governing equations of the latter model will be formulated in presence of an axial load N to study the stability of such a beam.

Multiple singularities in the rotation functions, due to the presence of internal rotational springs at x_{γ_i}, $i=1,\dots,n_\gamma$, with $0 \le x_{\gamma_i} \le L$, can be modelled as reductions of the reference flexural stiffness by means of the adoption of the well known Dirac's delta $\delta(x)$ distribution, as follows (Biondi and Caddemi, 2007):

$$\begin{aligned} E(x)I(x) &= E_0 I_0 \left[1-\sum_{i=1}^{n_\gamma} \overline{\gamma}_i \delta(x-x_{\gamma_i})\right] \\ G(x)A(x) &= G_0 A_0 \end{aligned} \tag{1}$$

where E_0I_0 and G_0A_0 are the flexural and shear stiffnesses and $\overline{\gamma}_i$ are parameters describing the flexural stiffness reduction associated to the concentrated rotational singularities.

The stiffness reduction introduced in the model adopted in Eq. (1) can be considered equivalent to the effect produced by concentrated cracks if a suitable correspondence with the crack depth is adopted (Caddemi and Caliò, 2008, 2009).

For simplicity, by considering the dimensionless coordinate $\xi = x/L$, and indicating with the apex the differentiation with respect to ξ, the governing differential equations of the Timoshenko beam, by accounting for the singularities introduced in Eqs.(1), take the following form:

$$\begin{aligned} &\left[\left[1-\sum_{i=1}^{n_\gamma} \gamma_i \delta(\xi-\xi_{\gamma_i})\right]\varphi'(\xi)\right]' = \\ &= br^2\left[u'(\xi)+\varphi(\xi)\right]+\sigma^2\left[u'(\xi)+\varphi(\xi)\right] \end{aligned} \tag{2}$$

$$br^2\left[u'(\xi)+\varphi(\xi)\right]'+\sigma^2\varphi'(\xi)=0 \tag{3}$$

In Eqs.(2),(3), the normalized displacement function $u(\xi)$, the rotation function $\varphi(\xi)$ and the normalised axial load $\sigma^2 = N L^2/E_0I_0$ have been introduced. Furthermore, in Eqs.(2),(3), the dimensionless singularity parameters $\gamma_i = \overline{\gamma}_i/L$, and the shear stiffness parameter br^2, with $b = G_0/E_0$ and $r^2 = L^2A_0/I_0$, have been introduced.

After some mathematical manipulation Eqs.(2),(3) are written as follows:

$$\varphi'(\xi) = \left[\sigma^2 u(\xi) + b_1\xi + b_2\right]\left[1+\sum_{i=1}^{n_\gamma} \lambda_{\gamma_i}\,\delta(\xi-\xi_{\gamma_i})\right] \tag{4}$$

$$u'(\xi) = \frac{1}{H(\xi)}\left[-\frac{\sigma^2}{br^2}\varphi(\xi)+\frac{b_1}{br^2}\right]-\varphi(\xi) \tag{5}$$

where the dimensionless parameters $\lambda_{\gamma_i} = \gamma_i/(1-A\gamma_i)$ have been introduced. The latter quantities λ_{γ_i} will be considered in this work as damage parameters since they can be easily related to the crack depth according to classical crack models as shown in (Caddemi and Caliò, 2009).

The governing equations of the Timoshenko beam in presence of multiple cracks provided by Eqs.(4),(5) can be, however, reduced to a single equation by means of differentiation of Eq.(5), substitution of Eq.(4), and after simple algebra, providing the following expression for $u^{II}(\xi)$:

$$\begin{aligned} u^{II}(\xi)+\overline{\sigma}^2 u(\xi) = &-\hat{\sigma}^2\left[b_1\xi+b_2\right]+ \\ &-\sum_{i=1}^{n_\gamma} B\left[u(\xi_{\gamma_i})\right]\delta(\xi-\xi_{\gamma_i}) \end{aligned} \tag{6}$$

with the following positions:

$$B\left[u(\xi_{\gamma_i})\right] = \hat{\sigma}^2\left[\sigma^2 u(\xi_{\gamma_i})+b_1\xi_{\gamma_i}+b_2\right]\lambda_{\gamma_i} \tag{7}$$

$$\hat{\sigma}^2 = 1+\frac{\sigma^2}{br^2} \quad , \quad \overline{\sigma}^2 = \hat{\sigma}^2\sigma^2 \tag{8}$$

Explicit expressions for the normalised deflection function $u(\xi)$ can be obtained by integration of Eq.(6) as outlined in the following section.

3 EXACT SOLUTION OF THE STABILITY GOVERNING EQUATIONS

The general solution of Eq.(6) is given by the solution of the corresponding homogeneous equation, $u_h(\xi)$ and a particular integral $u_p(\xi)$ as follows:

$$\begin{aligned} u(\xi) &= u_h(\xi)+u_p(\xi) = \\ &= \hat{C}_3\sin\overline{\sigma}\xi+\hat{C}_4\cos\overline{\sigma}\xi+u_p(\xi) \end{aligned} \tag{9}$$

where $\hat{C}_3$, $\hat{C}_4$ are integration constants. We seek a particular integral $u_p(\xi)$ to be determined such that Eq.(6) is verified. The particular integral is found as follows:

$$\begin{aligned} u_p(\xi) = &-\frac{1}{\overline{\sigma}}\sum_{i=1}^{n_\gamma} B\left[u(\xi_{\gamma_i})\right]\sin\overline{\sigma}(\xi-\xi_{\gamma_i})U(\xi-\xi_{\gamma_i})+ \\ &+c_1\sin\overline{\sigma}\xi+c_2\cos\overline{\sigma}\xi+C_1\xi+C_2 \end{aligned} \tag{10}$$

c_1, c_2, C_1, C_2 being integration constants. The general solution of Eq.(6) can be written, in view of Eqs.(9),(10) and (7), as follows:

$$u(\xi) = C_1\xi + C_2 + C_3 \sin\bar{\sigma}\xi + C_4 \cos\bar{\sigma}\xi + \\ -\sum_{i=1}^{n_\gamma}\left[\bar{\sigma}\, u(\xi_{\gamma_i}) - \bar{\sigma} C_1 \xi_{\gamma_i} - \bar{\sigma} C_2\right]\lambda_{\gamma_i} \sin\bar{\sigma}(\xi - \xi_{\gamma_i}) \tag{11}$$

where the positions $C_3 = c_1 + \hat{C}_3$ $C_4 = c_2 + \hat{C}_4$ have been introduced.

According to Eq. (11) the deflection function $u(\xi)$, at the generic abscissa ξ, depends on the response at the preceding sections, where concentrated cracks occur, in terms of deflection $u(\xi_{\gamma_i})$, $\xi_{\gamma_i} < \xi$. The latter circumstance requires the evaluation of $u(\xi_{\gamma_i})$, for $\xi_{\gamma_i} < \xi$, by making use of the same Eq. (11), which can be rewritten in explicit closed form expression as follows:

$$u(\xi) = C_1 f_1(\xi) + C_2 f_2(\xi) + C_3 f_3(\xi) + C_4 f_4(\xi) \tag{12}$$

The functions $f_j(\xi), j = 1, ..., 4$, introduced in Eq.(12), in view of Eq. (11), assume the following expressions:

$$f_1(\xi) = \xi \quad , \quad f_2(\xi) = 1 \\ f_3(\xi) = \sin\bar{\sigma}\xi + \\ \quad -\sum_{i=1}^{n_\gamma} \bar{\sigma}\, f_3(\xi_{\gamma_i})\lambda_{\gamma_i} \sin\bar{\sigma}(\xi - \xi_{\gamma_i}) U\left(\xi - \xi_{\gamma_i}\right) \tag{13} \\ f_4(\xi) = \cos\bar{\sigma}\xi + \\ \quad -\sum_{i=1}^{n_\gamma} \bar{\sigma}\, f_4(\xi_{\gamma_i})\lambda_{\gamma_i} \sin\bar{\sigma}(\xi - \xi_{\gamma_i}) U\left(\xi - \xi_{\gamma_i}\right)$$

The solution in terms of rotation function $\varphi(\xi)$ can be obtained by substituting $u^I(\xi)$ into Eq.(5), as follows:

$$\varphi(\xi) = C_1 g_1(\xi) + C_2 g_2(\xi) + C_3 g_3(\xi) + C_4 g_4(\xi) \tag{14}$$

where

$$g_1(\xi) = -(1/\hat{\sigma}^2) f_1^I(\xi) - (1/\hat{\sigma}^2)(\sigma^2/br^2) = -1 \\ g_2(\xi) = -(1/\hat{\sigma}^2) f_2^I(\xi) = 0 \\ g_3(\xi) = -(1/\hat{\sigma}^2) f_3^I(\xi) \\ g_4(\xi) = -(1/\hat{\sigma}^2) f_4^I(\xi) \tag{15}$$

Eqs.(12)–(15) represent the sought closed-form solution of the governing Eqs.(2),3) and will be exploited to evaluate the buckling load of the Timoshenko beam in presence of multiple cracks.

4 THE EXPLICIT EXPRESSION OF THE BUCKLING LOAD EQUATION OF MULTI-CRACKED SIMPLY SUPPORTED COLUMNS

The buckling load equation can be derived for Timoshenko columns with multiple cracks by simply imposing the standard boundary conditions, including the general case of rotational and translational spring supports. In this section, the closed form solution presented in Eqs.(12)–(15) are adopted to treat the case of simply supported Timoshenko columns. The buckling load equations are derived and numerically solved in order to obtain the critical loads of the considered multi-cracked columns and the corresponding modes. The presented buckling load equations are able to capture the behaviour in both cases of compression and tension axial loads. The two cases are recovered for positive and negative values of the solutions, respectively.

The boundary conditions of the simply supported Timoshenko column are:

$$u(0) = 0 \ , \ \varphi^I(0) = 0 \ , \ u(1) = 0 \ , \ \varphi^I(1) = 0 \tag{16}$$

The four integration constants can be obtained, by imposing the conditions in Eqs.(16), as follows:

$$C_2 = 0 \quad , \quad C_4 = 0 \\ C_1 + C_3[\sin\bar{\sigma} - \sum_{i=1}^{n_\gamma} \bar{\sigma}\lambda_{\gamma_i} f_3(\xi_{\gamma_i}) \sin\bar{\sigma}(1 - \xi_{\gamma_i})] = 0 \tag{17} \\ C_3[\bar{\sigma}^2 \sin\bar{\sigma} - \sum_{i=1}^{n_\gamma} \bar{\sigma}^3 f_3(\xi_{\gamma_i})\lambda_{\gamma_i} \sin\bar{\sigma}(1 - \xi_{\gamma_i})] = 0$$

The last of Eqs.(17) leads to the following buckling load equation for the simply supported Timoshenko beam in presence of multiple cracks:

$$\sin\bar{\sigma} - \bar{\sigma} \sum_{i=1}^{n_\gamma} f_3(\xi_{\gamma_i})\lambda_{\gamma_i} \sin\bar{\sigma}(1 - \xi_{\gamma_i}) = 0 \tag{18}$$

Once the smallest solution $\bar{\sigma}_{cr}$ of Eq.(18) is obtained, the value of the first critical load $\sigma_{cr}^2 = N_{cr} L^2/(E_0 I_0)$ can be inferred by the definition $\bar{\sigma}^2 = [1 + \sigma^2/(b\, r^2)]\sigma^2$, given by Eq.(8), as follows:

$$\frac{\sigma_{cr}^4}{br^2} + \sigma_{cr}^2 - \bar{\sigma}_{cr}^2 = 0 \tag{19}$$

Solution of Eq.(19) leads to the following values for the compression (positive value) ${}^{+}\sigma_{cr}^2$ and tension (negative value) ${}^{-}\sigma_{cr}^2$ critical load parameters:

$$\left.\begin{aligned} {}^{+}\sigma_{cr}^2 &= {}^{+}N_{cr} L/(E_0 I_0) \\ {}^{-}\sigma_{cr}^2 &= {}^{-}N_{cr} L/(E_0 I_0) \end{aligned}\right\} = \frac{br^2}{2}\left[-1 \pm \sqrt{1 + \frac{4}{br^2}\bar{\sigma}_{cr}^2}\right] \tag{20}$$

Furthermore, once the tensile ${}^{-}N_{cr}$ and the compressive ${}^{+}N_{cr}$ critical loads have been evaluated, the relevant buckling modes are determined by means of the evaluation of the integration constants by solving Eqs.(17) and substituting in Eq.(12).

5 NUMERICAL APPLICATIONS

The presented closed form expressions of the buckling modes and the buckling load equations allow an

Figure 1. A simply supported column with two cracks at symmetric cross-sections.

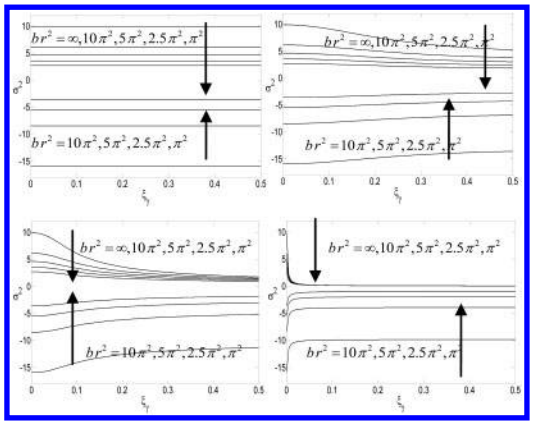

Figure 2. Critical load parameters ${}^{-}\sigma^2_{cr}$, ${}^{+}\sigma^2_{cr}$ versus crack position ξ_γ for different values of shear stiffness $br^2=\infty,\ 10\pi^2,\ 5\pi^2,\ 2.5\pi^2, \pi^2$ for the simply supported column with two cracks in Fig. 1: a) $\lambda_\gamma=0$; b) $\lambda_\gamma=0.2$; c) $\lambda_\gamma=1$; d) $\lambda_\gamma=100$.

extensive parametric analysis of columns with multiple cracks by accounting for the influence of the shear deformability. This section aims at new results regarding the influence of multiple cracks on the buckling under both tensile and compressive axial loads. The parametric analysis has been conducted by plotting graphs of the buckling load parameter σ^2 and the buckling shapes for different number, position and intensity of the cracks and analysing the sensitivity with regard to the shear deformability of the column.

It is shown how the tensile buckling load is very sensitive to the shear deformability in comparison to the compressive case.

The buckling behaviour of a simply supported column with two cracks occurring at symmetric cross-sections, as depicted in Fig. 1, is analysed. The critical load parameters versus the crack position ξ_γ along the column axis is plotted in Fig. 2 for different values of the shear stiffness and the crack intensity.

The results for the simply supported column with two cracks are reported in compact form in Fig. 3 where the surfaces representing the tensile ${}^{-}\sigma^2_{cr}$ and the compressive ${}^{+}\sigma^2_{cr}$ buckling load parameters versus the crack position and the crack intensity parameter are reported for different values of the shear stiffness. The buckling shapes for the case of double cracked simply supported column are reported in Fig. 4.

The novelty of the proposed procedure with respect to the others, available in the literature, lies in the capability of capturing the effect of the presence of an arbitrary number of multiple cracks by means of closed

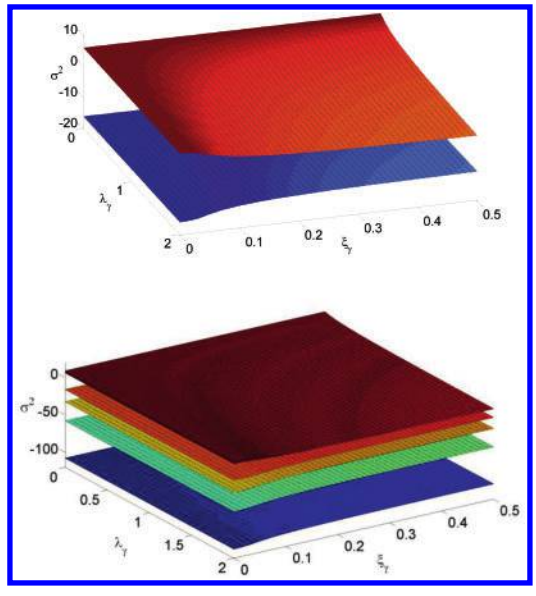

Figure 3. Critical load parameters ${}^{-}\sigma^2_{cr}$, versus crack position ξ_γ and intensity λ_γ for the simply supported column with two cracks in Fig. 1 for different values of shear stiffness: a) $br^2=\pi^2$; b) $br^2=10\,\pi^2,\ 5\,\pi^2, 2.5\,\pi^2, \pi^2$.

form solutions able to obtain also results concerning the tensile buckling phenomenon. No additional computational cost with respect to the classical undamaged case is required. Hence, finally, since to date extensive analyses for cases with multiple cracks are not available in the literature, in Figs.5-7 the case of simply supported column with an increasing number of cracks has been treated. In particular, in Figs.5,6 results in terms of buckling load and shapes, respectively, for $n_\gamma=5,\ 10$ cracks are reported. While in Fig. 7 the surfaces representing the tensile ${}^{-}\sigma^2_{cr}$ and the compressive ${}^{+}\sigma^2_{cr}$ buckling load parameters versus the crack intensity parameter λ_γ and the number n_γ of the cracks, uniformly spaced along the span, are reported.

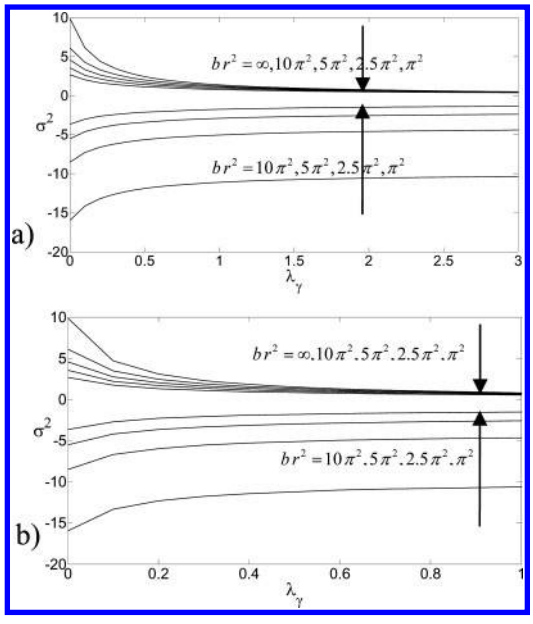

Figure 5. Critical load parameters ${}^{-}\sigma_{cr}^2$, ${}^{+}\sigma_{cr}^2$ versus the crack intensity parameter λ_γ for a simply supported column with multiple n_γ cracks, uniformly spaced along the span, for different values of shear stiffness $br^2=\infty,\ 10\pi^2,\ 5\pi^2, 2.5\pi^2, \pi^2$: a) $n_\gamma=5$; b) $n_\gamma=10$.

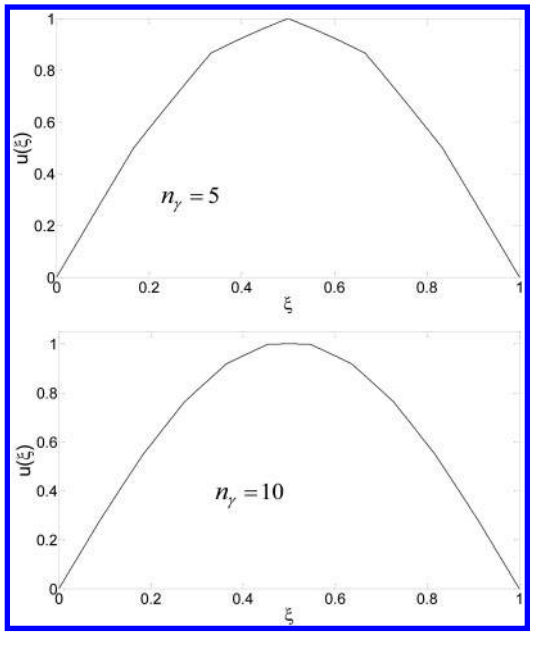

Figure 6. Compressive and tensile buckling shapes for a simply supported column with multiple $n_\gamma=5,\ 10$ cracks, uniformly spaced along the span, for crack intensity parameter $\lambda_\gamma=1$.

6 CONCLUSIONS

In this work a contribution towards the understanding of the buckling phenomenon of shear deformable damaged columns, in presence of compressive and tensile loads, has been provided. The damage has been considered in the form of multiple cracks modelled as a concentrated flexural stiffness reduction of the column that has been accounted for, in the governing equations, by means of Dirac's delta distributions. An integration procedure leading to closed form solutions of the buckling modes and the buckling load equations has been presented. The proposed explicit solutions concerning the buckling of shear deformable columns, accounting for the presence of an arbitrary number of cracks, represents a novel achievement in the specific literature. Moreover, study of the tensile buckling phenomenon of multi-cracked columns has been possible in this work, for the first time, by means of the proposed explicit solutions. Extensive parametric analyses for multi-cracked simply supported and clamped-clamped columns have been conducted and no additional difficulty with respect to undamaged columns is introduced. The model adopted in this work for the concentrated crack does not account for any influence on the local shear deformability. This latter aspect, however particularly significant in the tensile buckling phenomenon, is not trivial and is currently under investigation.

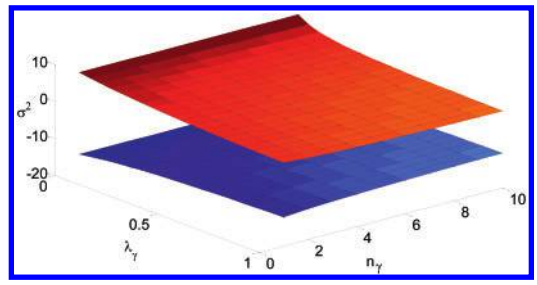

Figure 7. Critical load parameters ${}^{-}\sigma_{cr}^2$, ${}^{+}\sigma_{cr}^2$ versus the intensity λ_γ and the number n_γ of cracks, uniformly spaced along the span, for the simply supported column for the shear stiffness $br^2=\pi^2$.

The use of the theory of critical distances in fracture and structural integrity assessments

S. Cicero, V. Madrazo, I. Carrascal & T. García
Universidad de Cantabria, Santander, Spain

ABSTRACT: There are many situations where the structural integrity of a given component or structure is determined by the presence of defects acting as stress risers. Moreover, these defects are not necessarily cracks, which can be analysed using fracture mechanics concepts, but they may be notch-like defects (e.g., mechanical damage, fabrication defects, corrosion defects, holes…). In such cases, the application of ordinary fracture mechanics assessments may lead to overconservative results, so that it is important to define methodologies for the fracture and structural integrity assessment of components containing notches or any other kind of stress riser. This paper presents the capacities of the Theory of Critical Distances (TCDs) for the assessment of this kind of situations, gathering and summarising the results obtained by the authors in a wide range of materials. The results show how the TCDs provides reasonable results for the prediction of both the apparent fracture toughness and the load-bearing capacity. It also increases the accuracy of the structural integrity assessments performed using Failure Assessment Diagrams.

1 INTRODUCTION

1.1 *The theory of critical distances*

The Theory of Critical Distances (TCDs) is essentially a group of methodologies, all of which use a parameter (the critical distance, L) when performing fracture and fatigue assessments (Taylor (2007). The critical distance, in fracture assessments is defined by:

$$L = \frac{1}{\pi}\left(\frac{K_c}{\sigma_0}\right)^2 \tag{1}$$

K_c is the material fracture toughness and σ_0 is a characteristic material strength parameter named the inherent strength, usually larger than the material ultimate tensile strength (σ_u) that requires calibration.

As shown in Taylor (2009), the most important methodologies included within the TCDs are:

Figure 1. Stress-distance curve at the defect tip, and definition of the PM and LM methodologies.

a) The Point Method (PM): it establishes that fracture occurs when the stress reaches the inherent strength (σ_0) at a certain distance from the defect tip, L/2 (Equation 2):

$$\sigma\left(\frac{L}{2}\right) = \sigma_0 \tag{2}$$

b) The Line Method (LM): it assumes that fracture occurs when the average stress along a certain distance, 2L (starting from the defect tip), reaches the inherent strength, σ_0. Therefore, the LM expression is:

$$\frac{1}{2L}\int_0^{2L}\sigma(r)dr = \sigma_0 \tag{3}$$

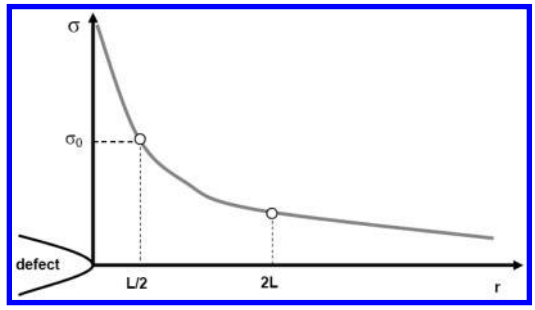

Figure 1. Stress-distance curve at the defect tip, and definition of the PM and LM methodologies.

Figure 1 shows an example of both methodologies:

c) The Imaginary Crack Method (ICM): it considers an imaginary crack at the defect tip, and failure occurs when a critical value of the stress intensity factor, K_c is reached. The length of the crack is, precisely, L.

d) Finite Fracture Mechanics (FFM): In this approach the failure is predicted using a balance of energies, analogously to Griffith (1920), but assuming finite

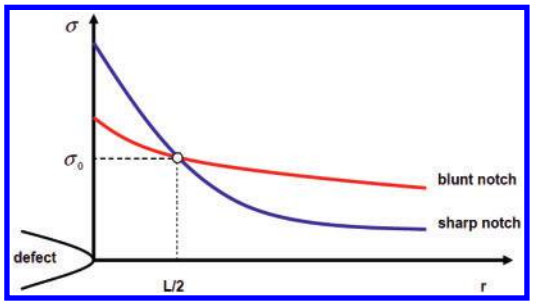

Figure 2. Obtaining of L and σ_0.

crack propagations (Δa, instead of da). The failure stress can be expressed as:

$$\sigma_f = \sqrt{\frac{G_c E}{\pi\left(a+\frac{\Delta a}{2}\right)}} = \frac{K_c}{\sqrt{\pi\left(a+\frac{\Delta a}{2}\right)}} \quad (4)$$

The most suitable value for Δa is 2L.

There is a relatively simple way to obtain L and σ_0 for a certain material, based on the PM. It consists in performing fracture tests on two specimens with different types of defects (e.g., sharp and blunt defect). The specimens can then be modeled at fracture with finite elements, obtaining the corresponding stress fields at the defect tip (Figure 2). The stress-distance curves cross each other at a point with coordinates L/2 and σ_0 (Taylor 2007, Cicero et al. 2012a, Madrazo et al. 2012, Cicero et al. in press).

Whichever the methodology used, one of the key aspects of the TCDs is that it can be applied to any kind of stress riser, not only to cracks, so it extends the fracture analysis of fracture processes far beyond the capacities of ordinary fracture mechanics, whose application to non-sharp defects (i.e., cracks) generally leads to overconservative results.

Once the TCDs and its different methodologies have been explained, the next sections are focused on the different applications of this theory when performing fracture and structural integrity analyses.

2 PREDICTIONS OF LOAD-BEARING CAPACITY

2.1 *Linking the TCDs to the load-bearing capacity*

The TCDs allows the load bearing capacity of a structural component containing any kind of stress risers to be estimated. For this purpose it is necessary only to apply the equations defining any of the different methodologies included within the TCDs. For example, Equation (1) must be applied in the case of the PM, or Equation (3) in the case of the LM.

2.2 *Experimental validation of load-bearing capacity predictions*

As an example, in Cicero et al. (2012b) there is a wide application of the PM on the fracture analysis of 38 different specimens made of Al7075-T651, combining different types of loads (tensile vs. bending) and defects (U-shaped notches, V-shaped notches, circular holes, etc). Figure 3 compares the predictions provided by the PM to the experimental results, revealing accurate results in most of the tested specimens.

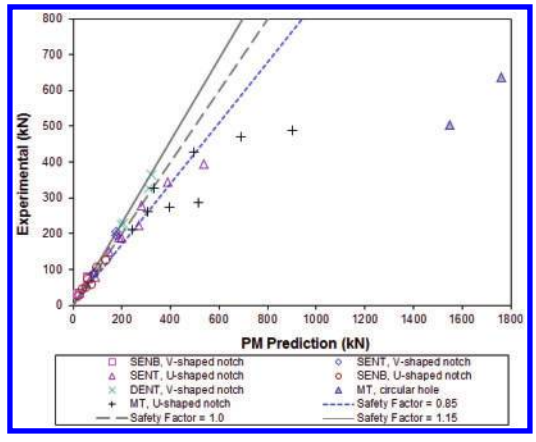

Figure 3. Comparison between the experimental results and the load-bearing capacity predictions provided by the PM.

Details concerning the limitations of this kind of predictions, as well as the justification of those inaccurate predictions shown in Figure 3, may be consulted in Cicero et al. (2012b). Here, it is sufficient to say that the strict application of the TCDs provides good results as long as the relation between the notch radius and the critical distance (ρ/L) is lower than 20. This ratio is known as the Neuber number (Taylor 2011).

The literature presents many other examples validating the application of the TCDs to perform load-bearing capacity predictions (e.g., Taylor 2007).

3 PREDICTIONS OF APPARENT FRACTURE TOUGHNESS

3.1 *Linking the TCDs to the apparent fracture toughness, K_{IN}*

The TCDs, in its different versions, allows the apparent fracture toughness (K_{IN}) of any material to be predicted in notched conditions, which is generally higher than the fracture toughness observed in cracked conditions. For this propose, it is necessary to consider the stress distribution on the notch tip. One commonly used expression is that provided by Creager & Paris (1967), Equation 5, for U-shaped notches, which is equal to that ahead of the crack tip but displaced a distance equal to ρ/2 along the x-axis:

$$\sigma(r) = \frac{K_I}{\sqrt{\pi}} \frac{2(r+\rho)}{(2r+\rho)^{3/2}} \quad (5)$$

where K_I is the applied stress intensity factor for a crack with the same dimensions as the notch being

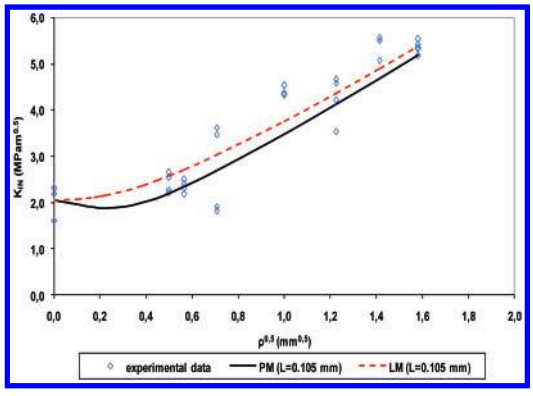

Figure 4. Comparison between experimental results and the TCDs (PM and LM) predictions of K_{IN}. PMMA.

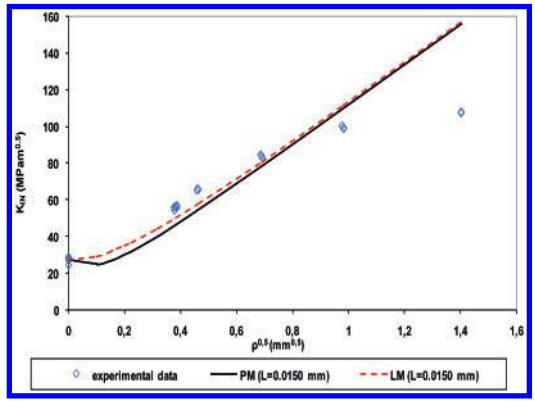

Figure 5. Comparison between experimental results and the TCDs (PM and LM) predictions of K_{IN}. Al7075-T651 (LT).

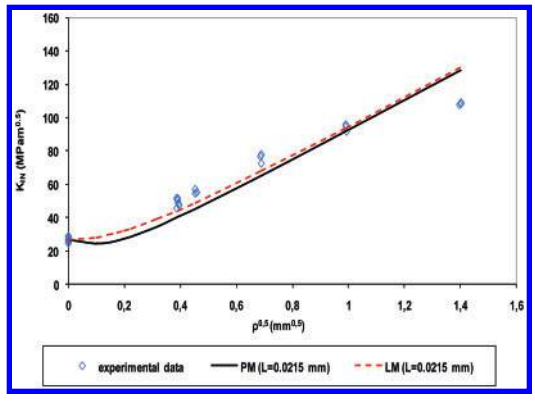

Figure 6. Comparison between experimental results and the TCDs (PM and LM) predictions of K_{IN}. Al7075-T651 (TL).

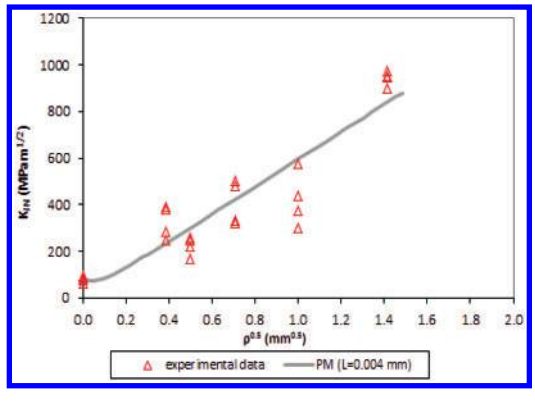

Figure 7. Comparison between experimental results and the TCDs (PM and LM) predictions of K_{IN}. Steel S275JR (−50°C).

analysed, and ρ is the notch radius. Then, combining Equation 5 and the different methodologies of the TCDs, the corresponding expressions of the apparent fracture toughness can be easily obtained. In the case of the PM, this gives:

$$K_{IN} = K_C \frac{\left(1+\frac{\rho}{L}\right)^{3/2}}{\left(1+\frac{2\rho}{L}\right)} \quad (6)$$

In the case of the LM, the expression is even simpler:

$$K_{IN} = K_C \sqrt{1+\frac{\rho}{4L}} \quad (7)$$

Once K_{IN} is determined, the fracture analysis of an existing notch in a material whose fracture toughness is K_c is transformed into an equivalent fracture analysis of an existing crack in a material whose fracture resistance is K_{IN}. Therefore, the analysis is reduced to Equation 8:

$$K_I = K_{IN} \quad (8)$$

Again, K_I is the applied stress intensity factor solution for a crack (with well-known existing solutions for a wide variety of geometries, e.g. BS7910 2005, FITNET FFS 2008), and K_{IN} is the so- called apparent fracture toughness.

3.2 *Experimental validation of K_{IN} predictions*

The K_{IN} predictions provided by the TCDs have been applied to a number of very distinct materials: polymer PMMA (Cicero et al. 2012a), aluminum alloy Al7075-T651 with two different orientations, TL and LT (Madrazo et al. 2012), and two structural steels, S275JR and S355J2 at −50°C and −150°C respectively (Cicero et al., in press).

The corresponding comparisons between the prediction of K_{IN} and the experimental results are shown in Figures 4–8. These figures represent the apparent fracture toughness as a function of the square root of the notch radius, which is a common representation in notch assessments (Taylor 2007), given that it clearly shows the notch effect on fracture resistance and also because the notch radius is included in a square root in K_{IN} predictions (Equation 7) or nearly (Equation 6).

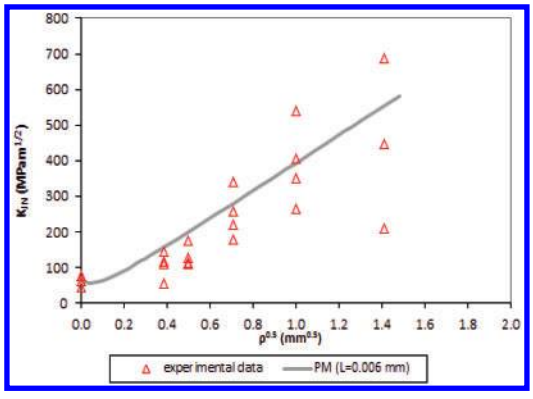

Figure 8. Comparison between experimental results and the TCDs (PM and LM) predictions of K_{IN}. PMMA.

From the results shown above, it is clear that the TCDs provides accurate predictions of the apparent fracture toughness. Again, details concerning the limitations of this kind of predictions may be consulted in Cicero et al. (2012a), Madrazo et al. (2012), Cicero et al. (in press).

4 COMBINING THE TCD WITH FAILURE ASSESSMENT DIAGRAMS

4.1 *Failure Assessment Diagrams*

Failure Assessment Diagrams (FADs) constitute one of the main engineering tools for the assessment of fracture-plastic collapse processes in cracked components (e.g., Anderson 1991, FITNET FFS 2008). These diagrams present a simultaneous assessment of both fracture and plastic collapse processes by using two normalised parameters, K_r y L_r, whose expressions are:

$$K_r = \frac{K_I}{K_C} \tag{9}$$

$$L_r = \frac{P}{P_L} \tag{10}$$

P being the applied load and P_L being the plastic collapse load. Therefore, L_r evaluates the structural component situation against plastic collapse, and K_r evaluates the component against fracture. Once the component assessment point is defined through the coordinates (K_r,L_r), it is necessary to define the component limiting conditions. With this purpose, the Failure Assessment Line (FAL) is defined, so that in case the assessment point is located between the FAL and the coordinate axes, the component is considered to be under safe conditions, whereas if the assessment point is located above the FAL, the component is considered to be under unsafe conditions. The critical situation (failure condition) is that in which the assessment point lies exactly on the FAL. Figure 9 shows an example with the different possible situations. In any

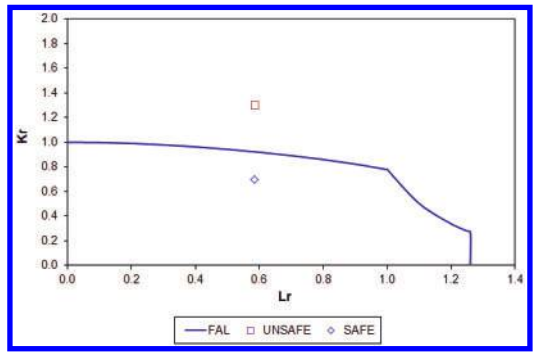

Figure 9. FAD analysis showing two possible situations: safe conditions; unsafe conditions.

case, a key point concerning FADs is that they allow fracture assessments to be performed for the whole range of plasticity levels, from linear-elastic fracture mechanics up to plastic collapse. This has particular importance when assessing notches, given that this kind of defects generate an increase in the non-linear phenomena occurring in the material (e.g., Cicero et al. 2012a), and fracture analyses based on Equation (8) would not take into account this fact (and thus would not be accurate).

4.2 *Combining the TCDs and FADs*

Now, if it is intended to perform structural integrity assessments on notched components using the FAD methodology, it is necessary to define both K_r and L_r for this particular case. Considering the fracture analysis of a notch presented above (Section 3.1), the K_r parameter would be:

$$K_r = \frac{K_I}{K_{IN}} \tag{11}$$

K_{IN} may follow the different solutions provided by the TCDs (e.g., Equation 6 or Equation 7).

In order to complete the FAD analysis, it is necessary to define the L_r parameter, which depends on the plastic collapse load (see Equation 10). Plastic collapse occurs through the yielding of the remnant section, so that in a perfectly plastic material it may be defined by the material yield stress and the defect dimensions, with no influence of the radius existing on the defect tip. In other words, at plastic collapse, the defect does not act as a stress riser, it reduces the resistant section, so that the plastic collapse does not depend on the notch tip and it is (ideally) the same for notches and cracks (which are actually notches whose notch radius tends to zero) (e.g., Miller 1988, Cicero et al. 2008). Therefore, the definition of L_r for notches is exactly the same as that defined for cracks, with P_L well known solutions provided by the literature.

If this methodology is compared to the assessment of notches as if they were cracks (a conservative practice), this correction would produce a reduction of

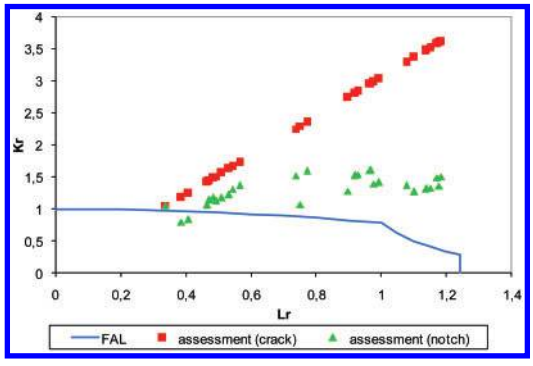

Figure 10. FAD assessment of PMMA notched specimens (K_{JC} value corresponding to a 95% confidence level).

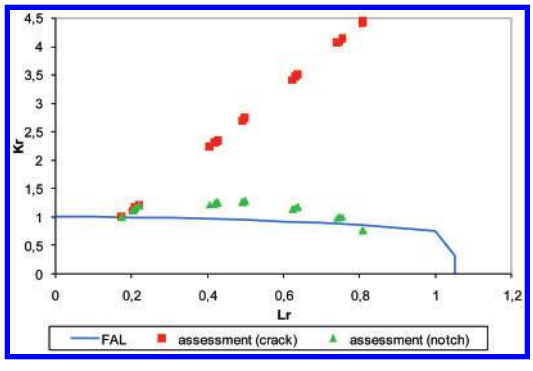

Figure 11. FAD assessment of Al7075-T651 specimens (K_{JC} corresponding to a 95% confidence level). LT orientation.

the K_r parameter and, then, a vertical displacement (downwards) of the assessment point.

In order to apply and validate the methodology here proposed, it is necessary to determine the corresponding K_c and L values for the materials being analysed. K_c can be directly obtained from the test results of the cracked specimens. A common engineering practice in FAD assessments is to consider a characteristic value associated to a given confidence level, when a probabilistic approach is pursued (e.g., 95% confidence level).

4.3 *Experimental validation*

Figures 10–14 gather, respectively, the results obtained for PMMA, Al7075-T651, and steels S275JR (−50°C) and S355J2 (−150°C), when performing a FAD assessment of fracture notched specimens made of these materials. The figures show a comparison between the analysis of notches without any consideration of the notch effect, and the analysis performed following the methodology proposed in this paper (thus, considering the notch effect). The expressions defining the FAD have been taken from the FITNET FFS (2008), Option 1, whereas the K_I and P_L solutions have been taken from Anderson (1991). The notch correction applied in the analyses was the one provided by the PM (Equation 7).

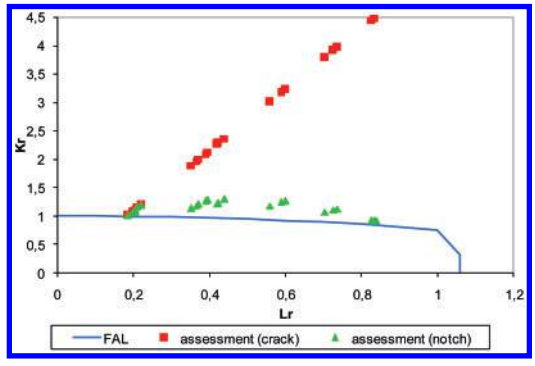

Figure 12. FAD assessment of Al7075-T651 specimens (K_{JC} corresponding to a 95% confidence level). TL orientation.

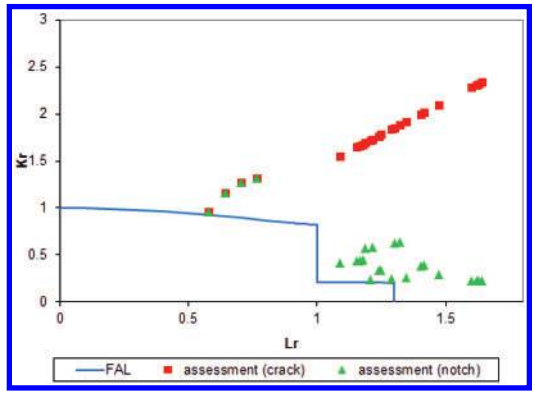

Figure 13. FAD assessment of S275JR specimens at −50°C (K_{JC} value corresponding to a 95% confidence level).

It can be observed how the assessment points (at failure) of the specimens when there are no notch corrections are located, in many cases, far from the critical condition defined by the FAL. This means that the failure load predictions derived from the FAD analysis would have been much lower than the actual ones (showing the conservatism of this type of analysis). However, once the notch corrections have been applied, the corresponding assessment points are located very close to the FAL, providing much closer predictions to the failure loads.

Here, it should be noted that in the case of the PMMA and the Al7075-T651 the fracture toughness was measured in terms of K_{IC}, providing K_{IN} values in notched conditions when using Equation 7, whereas for the two analysed steels the fracture resistance was measured in terms of K_{Jc} (ASTM E1820-11 2011), providing K_{JN} values through Equation 7. It can also be observed how the assessment points appears grouped together, each group corresponding to a given notch radius and, then, to a certain level of conservatism (the larger the notch radius, the further away the points from the FAL and, then, the higher the conservatism).

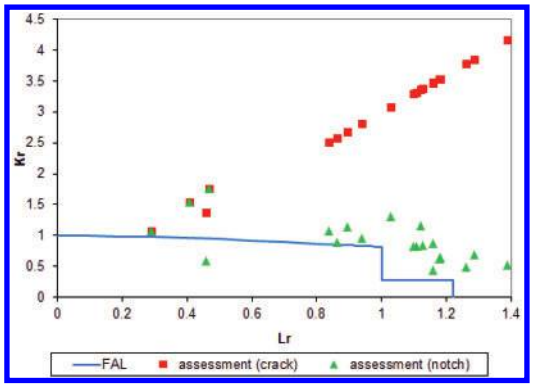

Figure 14. FAD assessment of S355J2 specimens at −150°C (K_{JC} value corresponding to a 95% confidence level).

5 CONCLUSIONS

This paper has presented the main applications of the TCDs, and its corresponding methodologies (e.g., PM and LM), to structural integrity assessments: a) the estimation of the load-bearing capacity by the direct application of the different methodologies included within the TCDs; b) the estimation of the apparent fracture toughness, which may be used in fracture assessments by direct comparison to the applied stress intensity factor; c) the combination of the TCDs with FADs, which allows notched components within the whole range of plasticity levels to be assessed, from linear-elastic conditions up to plastic collapse situations.

Experimental data covering different types of materials (PMMA, Al7075-T651, S275JR and S355J2) have also been presented, validating the above-mentioned applications, and demonstrating how the TCDs can be applied to the assessment of notched components, providing safe, accurate results.

Fracture mechanics as an improvement of fatigue life assessment in orthotropic bridge decks

W. Nagy, H. De Backer & Ph. Van Bogaert
Ghent University, Ghent, Belgium

ABSTRACT: Orthotropic bridge decks are widely used in long span steel bridges since they are extremely light weighted when compared with the load carrying capacity. In the past, fatigue life problems have sometimes been overlooked during design. Nowadays, approaches for fatigue design have reached their limits resulting in conservative design leading to overestimating the necessary dimensions. An improved fatigue life assessment method is thus necessary. One possibility is to start using fracture mechanics. These techniques have many advantages since they form a more in-depth analysis. This implies that an entire crack propagation can be evaluated. If the case study of the Temse bridge in Belgium is evaluated, a crack length of 461,703 mm is found while a crack length of 600 mm was detected in reality. Although the results show the effort of fracture mechanics, improvements are still necessary such as implementing residual stresses into the model.

1 INTRODUCTION

Although fatigue in steel constructions is the most important form of fracture, it is the least understood behaviour because of its complexity. In the past, fatigue life problems have sometimes been overlooked during design. Fatigue as a failure mode first came to light in the mid-nineteenth century with Wöhler's research work in Germany on the premature failure of railroad axles at stresses below the elastic limit (Polák, J. 2003). His work is still used in the form of SN-curves. The problem however is that these curves should be updated for every project where a different design approach or installation procedure is used. Of course, this is mostly not the case leading to a misunderstanding of the fatigue behaviour of the detail being studied. Additionally, the Palmgren-Miner method is used to calculate the lifetime of that detail. The most important advantage of this method is its simplicity while giving a good indication of the remaining lifetime. However, this method is not very accurate because the load history and the load sequences do not have any effect on the fatigue behaviour. These design imperfections lead to overestimating the dimensions when considering orthotropic bridge deck plates.

Orthotropic bridge decks are widely used in long span steel bridges since they are extremely light weighted when compared with the load carrying capacity and are therefore durable and very efficient. These types of bridge decks consist out of a complex network of closed trapezoidal longitudinal stiffeners and transverse web stiffeners welded to a deck plate (Fig. 1).

Because of the latter, various complex welding operations cause multiple fatigue problems across the bridge deck. To investigate the complex fatigue behaviour, other methods are needed besides the traditional way of fatigue calculation. Therefore, a more in-depth analysis is used: fracture mechanics. This method is well known in the aerospace, marine and automobile sector because it can evaluate the crack behaviour in detail. Also a much larger dataset will be available for estimating the total fatigue lifetime or even a more realistic evaluation for the remaining lifetime of existing bridges.

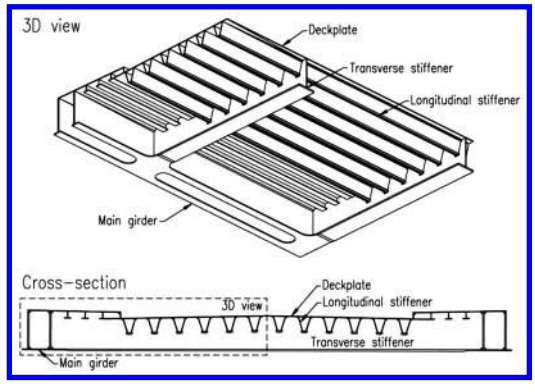

Figure 1. Cross-section and 3d view of an orthotropic bridge deck.

2 DESCRIPITION OF THE PROBLEM

In the past 10 years, several fatigue problems have been observed in several orthotropic bridge decks across Europe. Especially in the Netherlands, where many of

Figure 2. The Temse bridge across the river Scheldt (Belgium).

Figure 3. Movable part of the Temse bridge.

Figure 4. Orthotropic deck plate of the Temse bridge.

these bridge decks were constructed (Maljaars, J. et al. 2012). An example in Belgium described in this article, is the Temse bridge across the river Scheldt (Figs 2–4). Fatigue problems are mostly due to the lack of understanding of the fatigue behaviour. Additionally, the traffic intensity and also the traffic loads increased a lot since the construction of these bridge decks. But even recent constructed bridges could develop fatigue cracks (Maljaars, J. et al. 2012). This confirms that a more in-depth analysis is needed. In addition, fatigue cracks often initiate at the weld root. So, in the case of a stiffener-to-deck plate connection with closed stiffeners, the crack would propagate without any possible detection through visual inspection. Therefore, the fatigue crack would only be visible when there is already considerable damage.

3 CASE STUDY

An example of an orthotropic bridge deck with a poor fatigue behaviour is the Temse bridge across the river Scheldt in Belgium. This bridge is part of an important transport route for heavy lorries to the port of Antwerp.

Figure 5. Longitudinal crack through the deck plate at a stiffener-to-deck plate connection (left), multiple welds intersecting at the crack location (right).

The Temse bridge was built in 1955. Initially, the movable part had an aluminium deck plate. After many repairs, the movable part however was rebuilt in 1994 using a steel orthotropic plated deck (Fig. 4).

The deck plate of this movable part of the bridge is 12 mm thick and the stiffeners are 8 mm thick. The overall dimensions of the traffic lane are 53,90 m by 7,00 m. The trapezoidal stiffeners are 350 mm high and 300 mm wide on top and 90 mm width of the lower soffit. The distance between the longitudinal stiffeners equals 300 mm.

In 2004, a 600 mm long crack was detected in the stiffener-to-deck plate detail mid-span between two crossbeams (Fig. 5). The main reason for this crack is the occurrence of multiple welds intersecting one another (Van Bogaert, Ph. & De Backer, H. 2008, Nagy, W. et al. 2012). In addition, these welds were not chamfered and even the in the design demanded lack of penetration can be questioned here. In this particular case, the crack propagated through the deck plate starting from the weld root. Even when the crack had penetrated the deck surface, still no visible damage could be detected at the through because of the location of the crack initiation. With these cracks, there is already sufficient damage when the crack front occurs at the deck surface. A this stage, the crack is not stable anymore and propagates proportionally. Because the crack front occurs close to the high traffic loads, the crack has been repaired immediately (Van Bogaert, Ph. & De Backer, H. 2008).

4 ANALYTICAL STUDY

4.1 *General*

To verify the fatigue problem in detail, a more sophisticated method is needed instead of the traditional

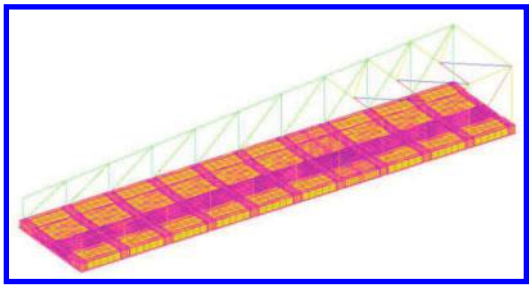

Figure 6. Large FEM-model of the Temse bridge.

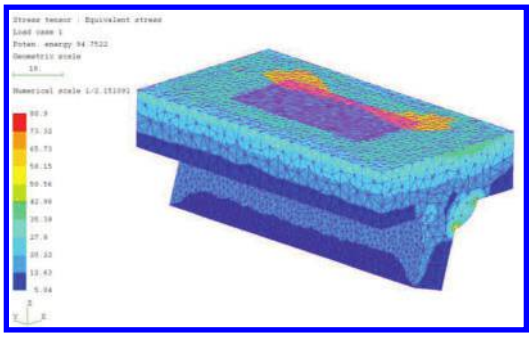

Figure 7. Von Misses stresses of the detailed small-scale model.

SN-curves and the Palmgren-Miner hypothesis as already explained. Therefore, the use of fracture mechanics could give a more detailed and improved look at the problem. To analyse the stiffener-to-deck plate connection detail, a FEM-model was developed in the finite element software Samcef. The advantage of using such software, is the ability to evaluate several fracture mechanics parameters and the crack propagation as well. This is done with an XFEM (eXtended Finite Element Method) method. With this method, the crack growth can be assessed without re-meshing the model in the vicinity of the crack. Although this is a very helpful tool, it needs a huge amount of computation time and power. Especially when the model is complex or when large cracks need to be evaluated.

4.2 *FEM-model*

In a first stage, a FEM-model is built of the whole movable part of the Temse bridge (Fig. 6). This is done with shell elements and beams. Although this model reflects the real behaviour of the structure well, a more detailed model is needed for studying the fracture mechanics parameters. Therefore, a more detailed small-scale model is constructed consisting of volume elements (Fig. 7).

To relate both models, the displacements and rotations are taken from the first model and introduced on the boundaries of the detailed model. This also implies that the big model is reduced to only the detail being studied, and that the computation time decreases.

4.3 *XFEM-model*

4.3.1 *Manual model*

Two possible ways to assess the fatigue life of welded connections with an XFEM-model exist. The first option is to insert a certain number of crack fronts in the weld corresponding to the crack front detected in a damaged detail of a construction. For this case study, an initial elliptical crack of 1 mm (both axes) was inserted at the weld root and perpendicular to the bridge deck (Fig. 9). The choice of this initial crack length could have a great influence on the total fatigue life of the structure. Depending on the welding detail, used construction technologies, lifetime of the structure, etc. an initial crack between 0,1 mm and 1 mm is often chosen (Polák, J. 2003, Nagy, W. et al. 2012). The reason why a 1 mm crack is assumed for this case study relies on a microscopic study of present weld details of a stiffener-to-deck plate connection (De Backer, H. 2006). The difference between several manufacturers is also taken into account.

After the fracture mechanics parameters are gathered from this initial crack, several other crack fronts could be evaluated with incrementing dimensions. An important parameter to evaluate is the stress intensity factor (SIF). This parameter can be used to evaluate the crack growth and its lifetime using one of the many crack propagation laws. In this case, the traditional Paris law is used:

$$\frac{da}{dN} = C \cdot \Delta K_I^{\,m} \tag{1}$$

where C and m are material properties and ΔK_I represents the stress intensity factor for mode I cracks. For structural steel C equals 3.10^{-13} [N, mm] and m equals 3 [−] (Maljaars, J. et al. 2012). For the assessment of existing (old) steel bridges, $C = 4.10^{-13}$ and $m = 3$ could be used (Kühn, B. et al. 2008).

Knowing the SIF-values for a certain number of crack fronts, it is possible to simulate the geometrical depended parameter $f(a)$ from equation 2:

$$\Delta K_I = f(a) \cdot \Delta\sigma \cdot \sqrt{\pi \cdot a} \tag{2}$$

In this equation $\Delta\sigma$ represents the applied stress range at the crack front and a the crack length. The geometrical parameter $f(a)$ not only depends on the crack length a, but also on the overall dimensions of the bridge deck. Therefore, once this parameter is evaluated for a particular bridge deck geometry and weld detail, this could be used for several other bridges with comparable dimensions.

Finally in order to get more realistic results, the Paris law could be expanded with the threshold value of the SIF-value:

$$\frac{da}{dN} = C \cdot (\Delta K_I^{\,m} - \Delta K_{th}^{\,m}) \tag{3}$$

This threshold value lies between 61 and 80 N/mm$^{3/2}$ for structural steel (Maljaars, J. et al. 2012, Kühn, B. et al. 2008).

From equation 3 it is now possible to evaluate the total fatigue life of the detail being studied:

$$N_f = \int_{a_i}^{a_f} \frac{da}{C \cdot (\Delta K_I{}^m - \Delta K_{th}{}^m)} \tag{4}$$

or:

$$N_f = \int_{a_i}^{a_f} \frac{da}{C \cdot ((f(a) \cdot \Delta\sigma \cdot \sqrt{\pi \cdot a})^m - \Delta K_{th}{}^m)} \tag{5}$$

4.3.2 *Automatic model*

A second and more accurate option to evaluate the crack front is with an automatic crack propagation method using the full advantage of the XFEM possibilities. Generally, the principle is the same as with the manual method. At first, an initial crack is placed in the model. After that, the XFEM-model uses the Paris law in order to propagate the crack automatically according to the path which uses the least energy to crack:

$$\frac{da}{dN} = C \cdot \left(\Delta K_I{}^{eff}\right)^m \tag{6}$$

The SIF-value in this equation is a function of $\Delta K_I, \Delta K_{II}, \Delta K_{III}, \theta_p$ (bifurcation angle) and the used material.

Besides the SIF-values and the fatigue lifetime, this method also gives the crack propagation path in a complex three-dimensional way. This is a great advantage in evaluating the weld geometry and their resulting cracks. The only disadvantage of this method is the computational effort. This method only gives accurate results if the mesh is sufficient fine enough around the crack front. Therefore, only relative small cracks could be evaluated with this method.

5 RESULTS

Before the XFEM analysis, a FEM analysis is done of the orthotropic bridge deck of the Temse bridge. Figure 7 illustrates the Von Misses stresses in the geometrical detail of the weld, while Figure 8 represents the third principal stresses of a cross section of the detail midspan two crossbeams.

Figure 8 also indicates a zone of compression at the weld root, which is the location of the initial crack for the XFEM calculation. Therefore, the crack propagation is due to compression and not tension.

According to a traditional fatigue analysis of this bridge deck (De Backer, H. et al. 2006), a total fatigue life of 23,8 years is observed. This incredibly small result indicates that it is obvious that a crack length of 600 mm was detected after 10 years of service life. One of the reasons of this poor result relies on the fact that only a very thin surface layer of 8 mm is used. And as Figure 5 indicates, the deck is already damaged at the crack location in a way that no load dispersion could be possible.

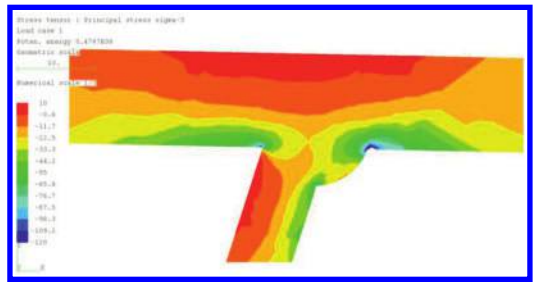

Figure 8. Third principal stresses of a cross-section of the detailed small-scale model.

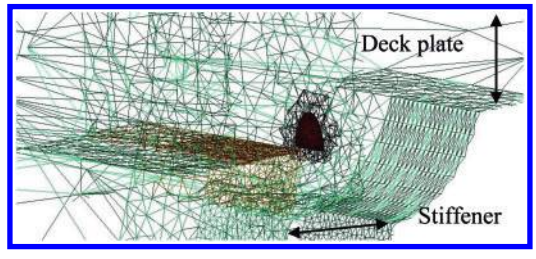

Figure 9. Initial semi-elliptical crack length of 1 mm on both axes.

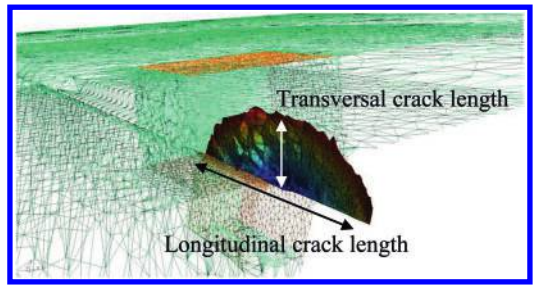

Figure 10. Large crack length developed through the deck plate.

5.1 *Manual XFEM-model*

The calculations with the manual XFEM method are done with an initial semi-elliptical crack length of 1 mm as already explained (Fig. 9). In addition, several other cracks with incremented dimensions are evaluated like the larger crack front in Figure 10.

Concerning the applied stresses, model 4 is used conform the Eurocodes (Structural Eurocodes 2010). This implies that a traffic distribution is used with five characteristic lorries. Figure 11 illustrates the location of the corresponding axle loads in relation with the crack location. As a result, Figure 12 and Figure 13 illustrate the SIF-values for all the crack geometries being studied. A best-fit curve could be found representing the formulation for the geometrical parameter $f(a)$. Therefore, all the SIF-values are known for every crack length and different axle loads. It is also visible

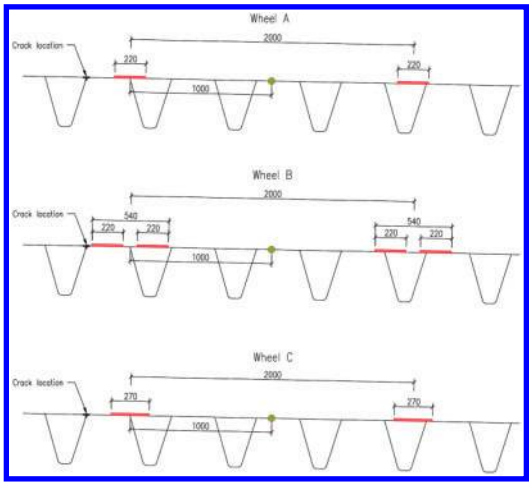

Figure 11. Position of the axle loads in relation with the crack location.

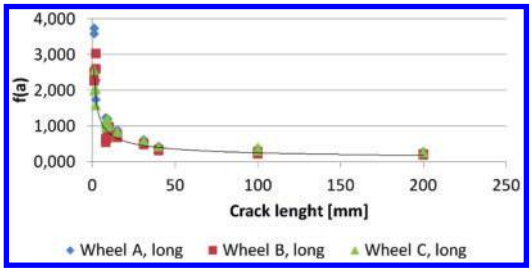

Figure 12. Geometrical parameter $f(a)$ for the longitudinal crack propagation.

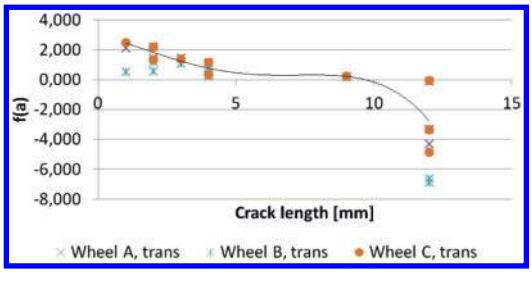

Figure 13. Geometrical parameter $f(a)$ for the transversal crack propagation.

that the crack would propagate much faster in the longitudinal direction and not so fast in the transversal. The crack only propagates much faster transversally, when the crack front counters the tensile zone of Figure 8. This indicates that the crack first propagates longitudinal through the weld before propagating through the deck plate, which confirms the problem of visual inspection of fatigue cracks.

It is known that during the past service live of 10 years, where the crack propagated until the crack length of 600 mm, an approximate load cycle history is equal to:

$$N = 10 years \cdot 250 days \cdot 2800 \frac{lorries}{day} = 7 \cdot 10^6 \qquad (7)$$

The corresponding fatigue crack with these load cycles could be derived from equation 2 and 3:

$$a = \sum_i C \cdot ((f(a_i) \cdot \Delta\sigma_i \cdot \sqrt{\pi \cdot a_i})^m - \Delta K_{th}{}^m) \cdot dN \qquad (8)$$

With this equation, a longitudinal fatigue crack length of 461,703 mm could be found for the 7.10^6 lorries and 10 years of service life. This is smaller than the 600 mm detected in real life, but it must be said that a FEM-model is still an ideal environment with no inhomogeneities. In addition, this model does not take into account any residual stresses, which are most likely present in the weld. Especially because multiple welds intersect at the crack location (Fig. 5) and the welds are not chamfered or treated at the surface to reduce any residual stresses.

5.2 *Automatic XFEM-model*

As with the manual method, an initial crack length of 1 mm was chosen. Although only a small crack propagation of several mm could be simulated due to the heavy computation time, a clear indication of the crack propagation patch becomes visible. The crack seems to propagate through the weld itself and not through the deck plate. This is not so peculiar because the largest stresses are within the weld throat itself and not in the deck plate (Fig. 8). Why the crack path is different for the crack in real life could be for the same reasons of the manual calculations. Residual stresses have a great influence on the crack initiation stage and also on the crack propagation.

6 CONCLUSIONS

It becomes clear that fracture mechanics as an improvement of the fatigue life assessment in orthotropic bridge decks has many advantages. In the traditional fatigue calculations, there are too many assumptions and simplifications to get accurate results. Especially when different geometries or construction technologies are used. Fracture mechanics on the other hand makes it possible to evaluate every detail separately, this being less conservative. In addition, once a particular detail is properly studied, a geometrical parameter $f(a)$ imposes itself. Therefore, other similar details could be evaluated without doing an intensive FEM and XFEM calculation.

Application of this method to the case of the Temse bridge in Belgium, resulted in a crack length of 461,703 mm after a service life of 10 years. Compared to the 600 mm of crack length found in reality, this is a good result although a bit optimistic. A possible

explanation is that the model does not take any residual stresses into account. The implementation of such stresses in the model could be an improvement for further research.

Analogies in the fracture mechanisms of concrete and ice

B. Chiaia, A.P. Fantilli & B. Frigo
Politecnico di Torino, Torino, Italy

ABSTRACT: The existence of a single model, capable of describing the fracture behaviour of both concrete and ice, is investigated in the present paper. More precisely, the fracture energy of concrete, and the fracture toughness of ice as well, are herein predicted through a new size effect law. As in the evaluation of crack pattern of reinforced concrete ties and beams, the proposed approach reveals that a "golden ratio" (i.e., the number $\phi = 1.61803$) plays a fundamental role in the fracture mechanisms of brittle and quasi-brittle materials. In other words, it can be argued that the centrality of golden section in the field of concrete and ice structures has profound physical meanings. Indeed, it can bring together the aesthetic of nature and architecture, where golden section frequently recurs, and the equilibrium of stress flow in solid bodies. This aspect is finally confirmed by the results of different experimental campaigns performed on concrete beams, tested in three point bending, and on ice sheets.

1 INTRODUCTION

As is well known (Rilem TC QFS 2004), size effect is an important aspect of cracked members made of plain or lightly reinforced concrete. It affects some mechanical properties (i.e., tensile strength, shear strength, fracture energy, etc.) because of the non-homogeneous character of the material and the occurrence of fractures.

A wide literature on size effect has considered the decrease of material strength, and the increase of fracture energy, with structural size. Weibull (1939) defined size effect as the result of statistical distribution of defects inside the material, whereas Bazant (1984) adopted an engineering approach based on the energy release rate. More recently, Carpinteri et al. (1995) combined the statistical and energetical approaches within the framework of fractal geometry, which permitted to take into account the intimate nature of energy dissipation during fracture propagation. As a result, the following Multifractal Scaling Law (MFSL) can be assumed for the fracture energy (Carpinteri & Chiaia 1996):

$$\frac{G_F}{G_{F\infty}} = \left(1 + \frac{l_{ch}}{D}\right)^{-1/2} \tag{1}$$

where G_F = nominal fracture energy; D = external characteristic structural size; $G_{F\infty}$ = nominal asymptotic fracture energy ($D \to \infty$); l_{ch} = internal microstructural length.

According to Eq.(1), fracture energy, and consequently fracture toughness, increase with the dimension D of the specimen, up to the asymptotic value $G_{F\infty}$. Several experimental analyses, performed on concrete an ice, seem to confirm the reliability of such law. Although concrete is a man-made material while ice is natural material, they show granular size depending behaviour and present a structurally similar brittle response. Thus, the mechanical properties of concrete and ice show, at different scales, some typical peculiarities of a fractal, characterized by scale invariant fractal porosity (Carbone et al. 2010, Carpinteri & Chiaia 1996).

Nevertheless, to apply the MFSL in brittle and quasi-brittle materials, the parameters $G_{F\infty}$ and l_{ch}, which cannot be measured through direct specific tests, have to be computed by using a best-fitting algorithm. Obviously, the regression procedure is more statistically reliable if the experimental measures of G_F are performed on a wide size range. In other words, a high number of tests are required to use correctly the MFSL (Carpinteri et al. 1995), as well as the Bazant's (1984) size effect law.

A new size-effect model is therefore introduced in the present paper with the aim of predicting the fracture energy of concrete, and the fracture toughness of ice, starting from few tests performed on a single scale. In the opinion of the authors, such a model should be based on the golden ratio, which recurs in the size effect of crack pattern of concrete ties and beams.

2 THEORETICAL AND EXPERIMENTAL OBSERVATIONS ON CRACK SPACING

As stated by Fantilli & Chiaia (2013), if the crack spacing of reinforced concrete (RC) member increases with

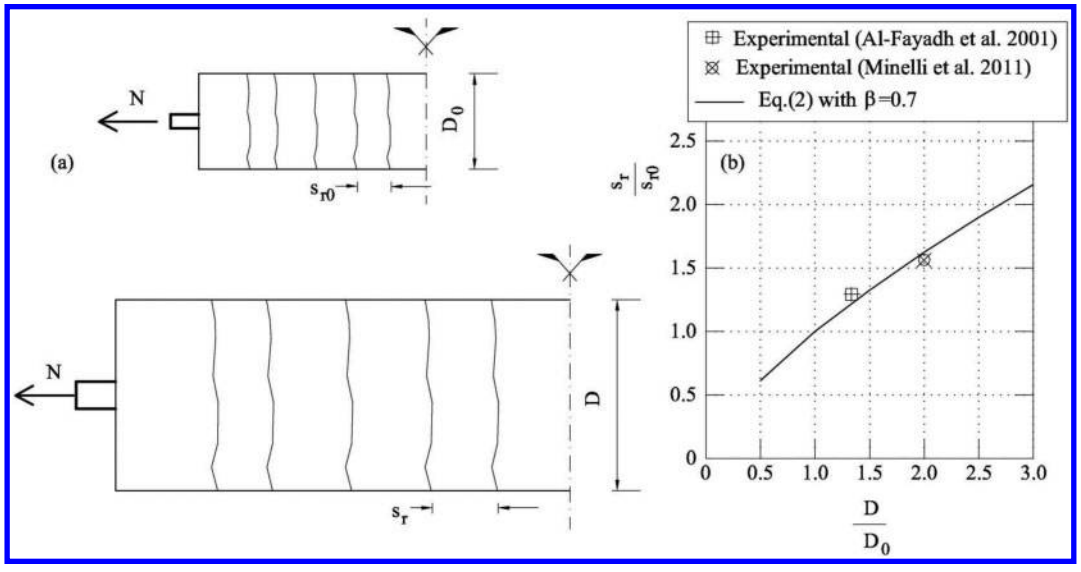

Figure 1. The tests performed by Minelli et al. (2011) and Al-Fayadh et al. (2001): (a) Geometry of the scaled specimens; (b) Comparison between the measured crack spacing and the proposed size effect law.

the size, a size effect law having the form of a power function (Rilem TC QFS 2004) can be introduced:

$$\frac{s_r}{s_{r0}} = \left(\frac{D}{D_0}\right)^{\beta} \tag{2}$$

where D_0 = reference dimension; D = dimension at a generic scale; s_{r0} = average distance between cracks in the reference member; s_r = average distance between cracks at a generic scale; and β = exponent that has to be defined by fitting experimental and/or numerical data. According to the model proposed by Fantilli & Chiaia (2013), when the geometrical dimensions of the RC member are doubled (i.e., $D/D_0 = 2$), transfer length and crack distances increase of a factor ϕ (i.e., $s_r/s_{r0} = \phi = 1.61803$), and therefore $\beta \cong 0.7$. In mathematics, ϕ is generally known as the golden ratio, or the divine proportion.

Results of different experimental campaigns validate the tension stiffening model by Fantilli & Chiaia (2013). This is the case of the ties tested by Minelli et al. (2011), and made with four different types of cement-based composites. As shown in Fig.1a, cracking has been investigated at two scales (i.e., $D_0 = 50$ mm, and $D = 100$ mm). In this case, the ratio between the average values of crack distance (i.e., $s_{r0} = 72.3$ mm when $D_0 = 50$ mm, and $s_r = 113$ mm when $D = 100$ mm) is very close to the golden ratio ϕ. As a matter of fact, the point of coordinates $D/D_0 = 2$ and $s_r/s_{r0} = 113$ mm/72.3 mm, as measured by Minelli et al. (2011), is adjacent to the curve given by Eq.(2) (with $\beta = 0.7$) and depicted in Fig.1b. In the same Figure, also the point of coordinates $D/D_0 = 80$ mm/60 mm = 1.33 and $s_r/s_{r0} = 132.5$ mm/102.5 mm [referred to the high strength concrete ties tested by Al-Fayadh et al. (2001)] is close to the proposed size effect law.

The previous observations can be extended to the RC beams depicted in Fig.2a (Swamy & Qureshi 1971). The first group of four beams have geometrical dimensions equal to half those of the largest beams. In all the beams, the average crack distances in the constant moment zone have been registered (i.e., $s_{r0} = 69.5$ mm at reference scale D_0, and $s_r = 113$ mm when $D/D_0 = 2$). Also in these beams, when the ratio $D/D_0 = 2$, the tests give $s_r/s_{r0} \cong \phi$, and therefore the above experimental bending results are correctly predicted by Eq.(2) with $\beta = 0.7$ (see Fig.2b).

3 EXPERIMENTAL OBSERVATIONS ON THE FRACTURE OF CONCRETE AND ICE

Similarly to the crack spacing of reinforced concrete ties and beams, the fracture energy of concrete, and the fracture toughness of ice, increase with the structural size. Some experimental campaigns, performed on both the materials and described in the following sections, evidenced such behaviour.

3.1 *Tests on concrete beams*

The procedure proposed by Rilem TC-50 FCM (1985) is generally used to evaluate the fracture energy of cement-based composites. Perdikaris & Romeo (1992) adopted such procedure in an experimental campaign performed on concrete beams. Specifically, the notched specimens depicted in Fig.3a, and tested in three point bending, were investigated at different scales. Table 1 shows the geometrical properties of these samples.

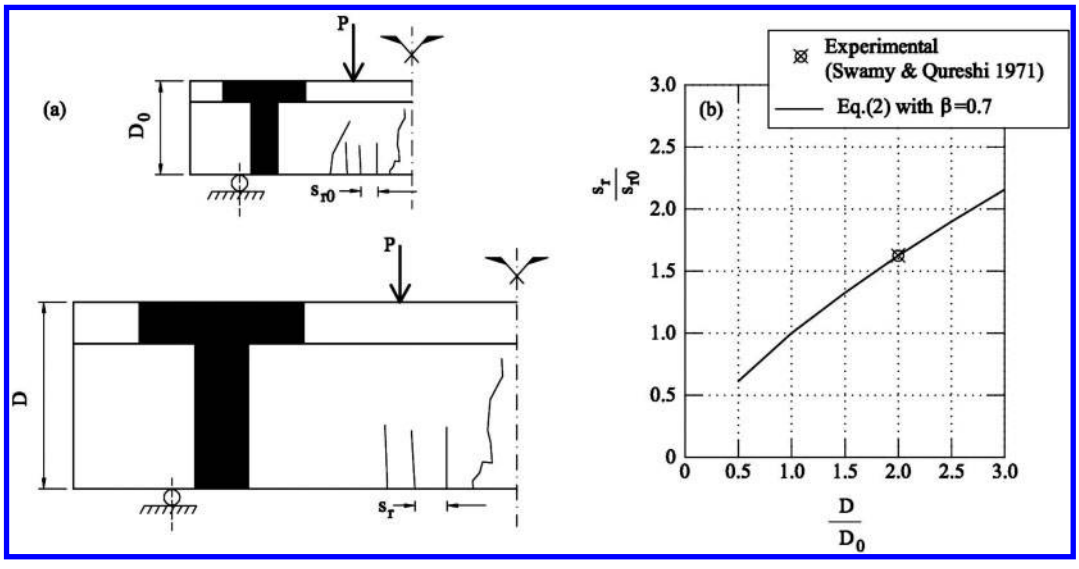

Figure 2. The tests performed by Swamy & Qureshi (1971): (a) Geometry of the scaled specimens; (b) Comparison between the measured crack spacing and the proposed size effect law.

Table 1. Three point bending tests on concrete beams (Perdikaris & Romeo 1992).

SF	concrete	H mm	L mm	a/H	B mm	G_F N/m
1	C1	63.5	254	0.3	127	76
2	C1	127	508	0.3	127	94
4	C1	254	1016	0.3	127	117
1	C2	63.5	254	0.3	127	69
2	C2	127	508	0.3	127	82
4	C2	254	1016	0.3	127	118

The beams were cast with two different concrete mixtures: C1 is a normal strength concrete (f_c = concrete strength = 35 MPa, E_c = elastic modulus = 33 GPa), whereas C2 is a high strength concrete (f_c = 75 MPa, E_c = 40 GPa). In both the concretes, the maximum aggregate size is 6.4 mm.

The external load P (Fig.3a) was applied by means of a servo-hydraulic testing machine, so that the peak was reached in approximately 10 minutes. Local LVDTs were also adopted to measure deflection η in the midspan of the specimen. Fig.3b shows a complete load midspan deflection curve measured in a single beam, and used to evaluate G_F. To be more precise, the value of fracture energy can be experimentally measured through the following formula (Hillerborg 1985):

$$G_F = \frac{W}{B(H-a)} \tag{3}$$

where, W = total amount of absorbed energy (i.e., the area below the measured load-deflection curve).

An increase of G_F with the size factor SF, which varies from 1 to 4, can be observed in Table 1. Nevertheless, such variation differs from that measured in the crack spacing of RC ties and beams. As reported in Fig.1 and Fig.2, crack distance becomes ϕ times higher when the geometrical dimensions of the specimen are doubled. Here, fracture energy shows the same increase only when $SF = 4$ (see Table 1). This difference can be ascribed to the geometry of the beams adopted in the three point bending tests (Fig.3b). In fact, only the height H, the notch a, and the span L of the beam were scaled. Conversely, the width B of the cross-section was kept constant, and equal to 100 mm, for all the specimens.

Finally, the size effect on G_F seems to be the same for both the types of concrete. Indeed, as observed by Perdikaris & Romeo (1992), at all the scales the fracture energy of higher strength concrete mix (C2) is either similar or slightly lower than that of the lower strength mix (C1).

3.2 *Tests on ice plates*

Ice is a porous medium consisting of air and a random assemblage of grains of solid water. It could be generated from metamorphosis of snow or direct freezing of water. In Nature, several types of ice, having different physical and mechanical properties, can be observed (e.g., sea and saline ice, equi-axed granular, macro-crystalline S1 and columnar S2 freshwater ice, glaciers, etc.). In all the cases, density can vary from 800 to 917 kg/m^3.

To investigate the fracture properties of ice, a set of samples are herein taken into consideration (Fig.4). The specimens, generally called base-edge-notched reverse-tapered plate (Mai et al. 1975, Defranco & Dempsey 1994, Dempsey et al. 1995), are those of the

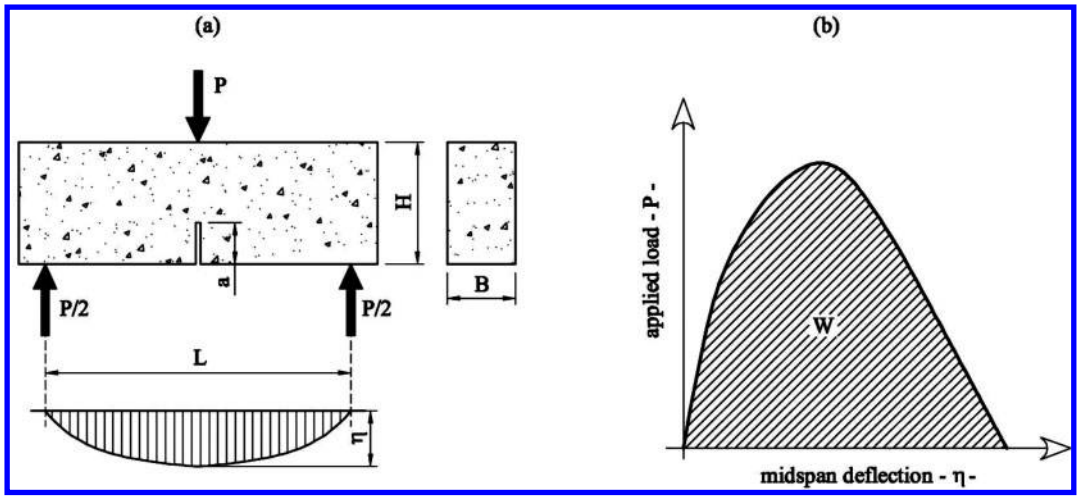

Figure 3. Three point bending tests on concrete beams (Rilem TC-50 FCM 1985): a) Geometrical dimensions of the specimens; b) Typical applied load vs. midspan deflection diagram.

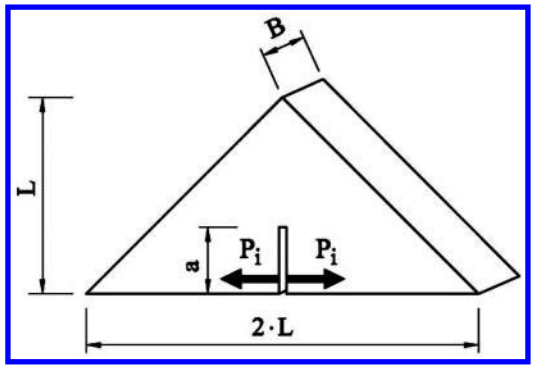

Figure 4. *In-situ* base-edge-notched reverse-tapered plate tests on S1 ice (Dempsey et al. 1999a).

SF	ice	L m	a m	a/L	B m	K_Q kPa m$^{0.5}$
1	RT1	1.41	0.43	0.3	0.5	97
2	RT7	3.18	0.99	0.3	0.5	193
1.5	RT8	3.20	0.99	0.3	0.5	144
7.3	RT6	10.36	20.8	0.3	0.5	186
20.3	RT9	28.64	8.98	0.3	0.5	297

in-situ experimental campaign performed by Dempsey et al. (1999a, 1999b) on S1 freshwater lake ice of Spray Lakes Reservoir (Alberta – Canada). The aim was to investigate the size effect on fracture toughness by testing several plates, whose geometry (see Table 2) varies from laboratory to structural-scale (1.41 m < L < 28.64 m).

S1 freshwater ice is a secondary congregation ice that usually grows under, or on, the primary ice (the first thin layer to form) or snow. It is typically composed by massive irregularly shaped crystals extended on vertical, or near vertical, c-axes (Michel & Ramseier 1971). The physical and mechanical properties of Spray Lakes Reservoir ice have been measured by Dempsey et al. (1999a) at Clarkson University.

The plates were cut from the parent ice sheet, having uniform and stable thickness ($B = 0.5$ m), by using chainsaws. The test temperatures were above −5°C, and the ambient weather did not affect the ice sheet thickness during the tests. In this campaign, Dempsey et al (1999a) consider the thickness B of the specimens not scaled. In fact, due to the crystalline microstructure of ice, it is necessary to have a 2D similarity to compare each specimen tested. Moreover, according to van Vliet & van Mier (1998), in quasi-brittle fracture tests, measurements do not depend on the length of the crack front.

The load P_i (see Fig. 4) was applied by means of flatjack loading device, controlled by a servo-hydraulic control system coupled with a displacement measuring gauge located on the crack (Shapiro et al. 1979). The specimen size and the loading rate are scaled to consider the homogeneity of the ice during the tests. In fact, as the specimen size increases, the material behaviour is expected to become more homogeneous, and eventually the length of the fully developed process zone will be lower in comparison with the specimen size (Dempsey et al. 1999a).

As no standard test exists, the theory of Linear Elastic Fracture Mechanics is generally applied to freshwater ice. Accordingly, the critical stress intensity factor K_{Ic} is generally substituted by K_Q (Dempsey 1991):

$$K_Q = K_{apparent}^{initiation} = K_I\left(a, \rho, P_Q\right) \tag{4}$$

where K_Q, which symbolically represents the assumptions involved and the lack of a standard test, also

depends on the crack tip radius ρ, and on the maximum load P_Q.

When the load P_i is applied on the crack surfaces by a flatjack, the fracture toughness K_Q can be easily evaluated through the following equation (Dempsey et al. 1999a):

$$K_Q = f\left(\frac{a}{L}\right)\frac{P_i}{w\,h}\sqrt{\pi\,a} \tag{5}$$

where w and h = width and thickness of the flatjack, respectively; and $f(a/L)$ = function defined by Dempsey et al. (1995).

For each plate, the related values of K_Q are reported in Table 2. As for the fracture energy of concrete specimens, the fracture toughness of ice increases with the size factor SF. To be more precise, K_Q becomes ϕ times higher when the geometrical dimensions of the specimen are scaled with a size factor $SF = 4$.

4 SIZE EFFECT AND GOLDEN RATIO

Similarly to crack spacing, if the fracture energy of concrete and the fracture toughness of ice specimens increase with the size, a size effect law having the form of a power function (Rilem TC QFS 2004) can be introduced:

$$\frac{G_F}{G_{F0}} = \frac{K_Q}{K_{Q0}} = \left(\frac{D}{D_0}\right)^{\beta} = SF^{\beta} \tag{6}$$

where, G_{F0} (or K_{Q0}) = average fracture energy (or fracture toughness) measured in the reference member ($SF = 1$); G_F (or K_Q) = average fracture energy at a generic scale ($SF \neq 1$); and β = exponent that has to be defined by fitting experimental data. According to the experimental results reported in the previous sections, when $SF = D/D_0 = 4$, fracture energy of concrete, and fracture toughness of ice, increase of a factor ϕ (i.e., $G_F/G_{F0} = K_Q/K_{Q0} = \phi$), and therefore $\beta \cong 0.35$.

The new model for fracture energy and toughness can be used to predict the experimental data previously described. In the case of concrete beams (Fig.5), the proposed size effect law of fracture energy [i.e., Eq.(6) with $\beta = 0.35$] seems to be in good agreement with the results obtained by Perdikaris & Romeo (1992). This is true for both normal strength concrete (C1 in Fig.5) and high strength concrete (C2 in Fig. 5).

Similarly, the fracture toughness of the reverse-tapered plates, tested by Dempsey at al. (1999a) and made with S1 freshwater ice, varies according to the proposed size effect law. As Fig.6 shows, Eq.(6) with $\beta = 0.35$ gives a reasonable approximation of K_Q also in the case of large specimens (i.e., $SF = 20$).

In the same figures, also the results of MFSL have been reported. The fracture energy of concrete predicted by Eq.(1) is in good agreement with both the experimental data and results of the proposed size effect law (Fig.5). Whereas, the fracture toughness of ice seems to be better evaluated by Eq.(6) with $\beta = 0.35$, especially at large scales.

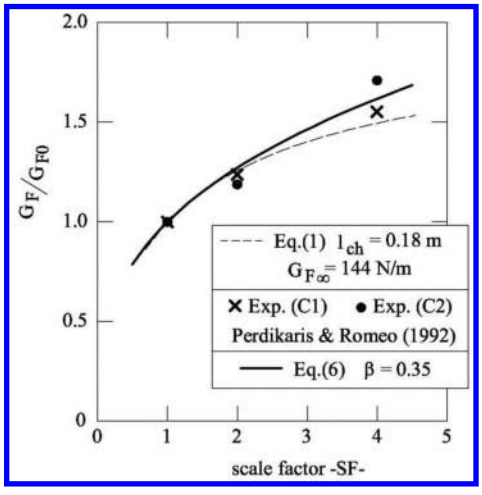

Figure 5. Comparison between the measured fracture energy of concrete and the proposed size effect law.

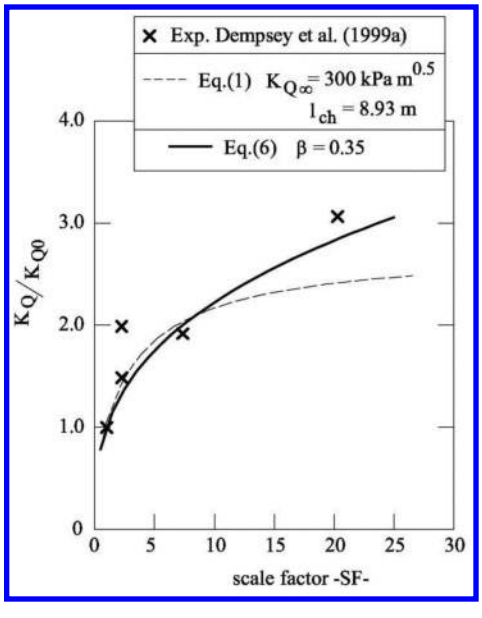

Figure 6. Comparison between the measured fracture toughness of ice and the proposed size effect law.

5 CONCLUSIONS

A new size effect law for the fracture energy and the fracture toughness of quasi-brittle materials has been presented. From the comparison between the results of the proposed model and some experimental data, the following conclusions can be drawn:

- Similarly to the crack pattern of reinforced concrete ties and beams, the golden ratio also recurs in the fracture mechanism of ice and concrete.
- A single size effect law can be used for the fracture energy of concrete and the fracture toughness of ice.

– With respect to the traditional size effect models, the proposed law can predict G_F, and K_Q with good accuracy, by using a reduced number of tests.

Nevertheless, only two quasi-brittle materials (i.e. concrete and ice) have been investigated in the present paper. Future works should therefore consider the behaviour of other materials, such as rocks, in order to generalize the effectiveness of the proposed size effect law.

An investigation of the double torsion geometry using peridynamics

T.H. Becker
Department of Mechanical and Mechatronic Engineering, University of Stellenbosch, South Africa

D.Z. Turner
Department of Civil Engineering, University of Stellenbosch, South Africa

ABSTRACT: The Double Torsion (DT) technique is a powerful experimental method for fracture parameter characterisation of brittle materials. One of the distinguishing features is that the geometry, in principle, provides a crack length independent test configuration. This attractive feature allows for the propagation of relatively long cracks in a highly controlled manner in exceptionally brittle materials (compared to compact tension and single edge notched beam geometries). Despite this salient feature, the DT technique is challenging to model computationally using traditional approaches (cohesive elements, extended finite elements, analytically enriched finite elements). Presented is an investigation of the DT geometry with the use of peridynamics to model the fracture of brittle materials. Peridynamics (a non-local theory of continuum mechanics based on an integro-differential equation without spatial derivatives) overcomes several of the challenging aspects of modelling the DT geometry. For example, discontinuities are naturally part of the solution, the crack path can be arbitrary, and the formulation is robust for a wide variety of material properties. This paper aims to investigate the DT technique using peridynamics by comparing numerical results with experimental data in terms of the obtained load, displacement and cracking behaviour in order to evaluate the efficacy of this approach for fracture test geometry analysis.

1 INTRODUCTION

The Double Torsion (DT) technique is a powerful testing configuration that facilitates fracture investigations of highly brittle materials, such as glass (Fuller 1979), and quasi-brittle materials such as rock (Ciccotti 2001), concrete (Tait 1987) and nuclear graphite (Becker 2011). The distinguishing feature of this technique is that the Stress Intensity Factor (SIF) is, as a first approximation, independent of crack length. This allows for the propagation of relatively long cracks in a highly controlled manner, compared to conventional compact tension (CT) and single edge notched beams (SENB).

The DT technique, however, is yet to be standardized and several question remain regarding the validity of a crack length independent geometry. Corrections to the technique have been proposed, which include Leevers' analytical large deflection correction (Leevers 1985), Chevaliers' experimentally based geometry correction (Chevaliers 1996) and Ciccotti's Finite element based correction factors (Ciccotti 2000a, 2000b). To date, none of the proposed corrections have been widely accepted in the literature and the utilization of the DT technique is predominantly based on experience. Contributing to the limited use of the DT technique is that the specimen geometry is challenging to model computationally using traditional approaches such as cohesive elements, XFEM or analytically enriched finite elements. The crack tip geometry is complex as both high tensile and compressive regions are present.

Presented in this paper is an alternative method to investigate the DT geometry using peridynamics. Peridynamics allows for the modelling of fracture and, as opposed to traditional formulations for solid mechanics (which are based on spatial partial derivatives), is integral based. As such, incorporation of cracks into the solution is much more natural. Peridynamics has been shown effective for a number of applications including membranes, reinforced concrete, carbon fibre reinforced composites, and hydraulic fracturing. The development of the peridynamic theory and some applications are presented in (Silling 2000, Silling 2007, Silling & Askari 2005, Silling & Lehoucq 2008, Turner 2013).

2 THE DOUBLE TORSION TECHNIQUE

The DT geometry essentially comprises a rectangular plate that is loaded in a four point bending configuration at one end across a notch (Figure 2). The specimen can be considered as two halves around the cracked portion, which deform independently. Subjected only to small torsional deformations, the stiffness of each

half is a function of its cross-section and length. As a result, the stiffness of each half is a function of the crack length. If assumed that the unbroken ligament remains completely rigid, a linear compliance relationship is obtained (Evans 1972)

$$C(a)=\frac{y}{P}=\frac{3W_m^{\ 2}}{Wd^3\mu}a \tag{1}$$

where, P and y are the applied load displacement at the load point respectively, μ is the shear modulus, W the specimen width and w_m the moment arm.

The actual crack profile in the DT geometry is curvilinear and therefore a crack front inclination is defined by $c=\Delta a/d$, where Δa is the crack extension difference between the upper and lower surface of the test specimen (Figure 2). Noteworthy is that the crack front shape and inclination is said not to change over the length of the specimen (Evans 1972).

Accordingly, the strain energy release rate, G, and hence the equivalent stress intensity factor (using $K=\sqrt{EG}$) can be calculated using (Williams and Evans 1973)

$$G_I=-\frac{dU}{dA}=\frac{P^2}{2d}\frac{dC}{da}=\frac{W_m^{\ 2}P^2}{2\mu Wd^4\psi} \tag{2}$$

where, U is the total strain energy, A the crack extension surface area and ψ a thickness correction given as a function of $W/d4$.

Noteworthy in Eq. (2) is the crack length independent strain energy release rate (or equivalent stress intensity factor), which allows for the aforementioned stable crack propagation in highly brittle materials.

3 PERIDYNAMIC THEORY

The peridynamics model presented in this work is the most basic implementation of the peridynamic theory. Considered is quasi-static deformation of the DT specimen as a linear-elastic solid (with bond breaking to represent the crack). Employed is a state-based rather than bond-based approach to the implementation of peridynamics.

Consider a neighbourhood H depicted in Figure 2 of a material point x of radius δ that includes all other material points for which a non-zero force interaction exists. If we denote another material point in this horizon as x' then the governing equation for state-based peridynamics can be written

$$\int_H \left\{T[x,t]\langle x'-x\rangle - T[x',t]\langle x-x'\rangle\right\}dV_{x'}+b(x,t)=0 \tag{3}$$

where, $T[x,t]$ is the force vector state field that defines the force interaction between two points x and neighbor x'. If we assume that the force between these neighbours acts along the vector pointing from x to x' denoted M, we can evaluate T[x,t] as a scalar coefficient times its unit vector

$$T[x,t]=\tilde{t}M \tag{4}$$

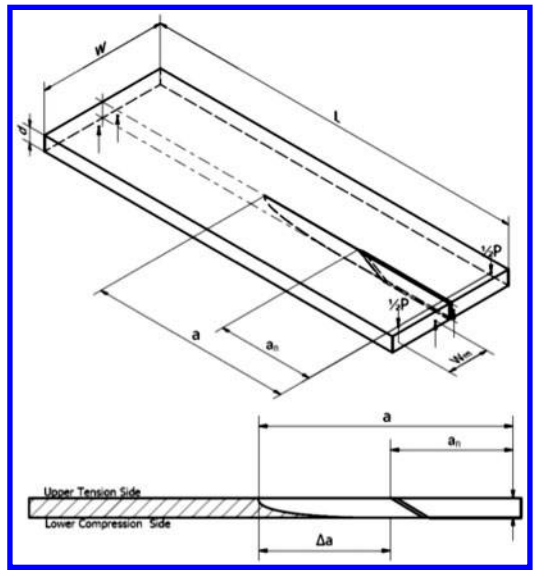

Figure 1. Schematic of the DT specimen geometry. L, W and d are the specimen length, width and thickness respectively, a the crack length and a_n the Notch Length.

This scalar coefficient, $\tilde{t}$, is computed as

$$\tilde{t}=\frac{-3p}{m}\bar{x}+\beta e^d \tag{5}$$

where p is the peridynamic pressure, m is the weighted volume, $\bar{x}$ is the distance magnitude between the two points in the reference configuration, β is a material parameter and $e^d=e-\theta\bar{x}/3$ is the deviatoric extension scalar state field ($e=\bar{y}-\bar{x}$, $\bar{y}$ is the distance magnitude between the points in the deformed configuration and θ is the dilatation of the material). In the discrete form, the governing equation above can be written as

$$\sum_{i=1}^{N}\left\{T[x,t]\langle x'-x\rangle - T[x',t]\langle x-x'\rangle\right\}\Delta V_{xi'}+b(x,t)=0 \tag{6}$$

where N is the number of neighbours and $\Delta V_{xi'}$ is the discretized cell volume of neighbour i. This way, equilibrium is evaluated for each cell on the basis of the force contribution from each neighbour. Damage is incorporated in this model via a critical stretch for each bond. Once the critical stretch is reached for a particular bond, that bond is treated as broken and contributes no force to the neighbouring cells. Once bonds are broken, it is assumed that they cannot be re-established.

4 METHODOLOGY

The DT geometry was modelled assuming Polymethylmethacrylate (PMMA) properties as $\mu=1.52$ GPa for the shear modulus and $k=2.13$ GPa for the bulk modulus (Kourtesis1997). The specimen size was set as $3W{:}W{:}0.04W$ for $L{:}W{:}d$ respectively,

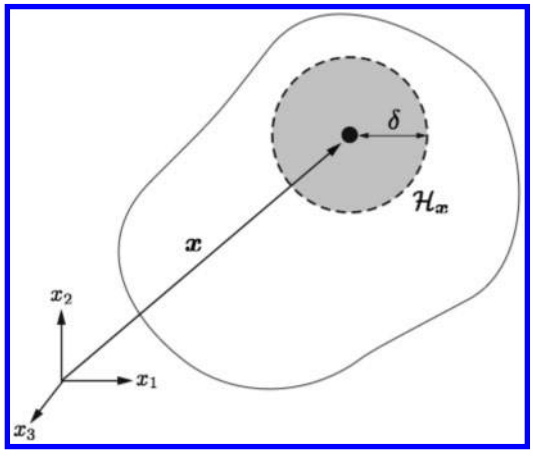

Figure 2. The peridynamic horizon of the material point at location x. The diameter of the spherical neighborhood is δ. All other material points within this horizon have a non-zero force interaction with point x.

where W was taken as 50 mm. The notch length $a_n = W/5$ and the notch inclination was set to $c = 0$.

The results were computed using a parallel software package developed in c++ by the authors that is built on the Trilinos framework (Trilinos 2013).

For each of the results presented, the damage was calculated as the ratio of the number of broken bonds to the number of original bonds for each element. Note that for a perfectly aligned crack that propagates along an element boundary, the damage for elements along this crack will be 0.5 as only the bonds along one side of the element will be broken. An arbitrary value of 1 millistrain was used for the critical stretch. When computing iterations for the equilibrium calculations, if a bond's stretch exceeds the critical stretch, the bond is removed from the neighbourhood (as if broken) and the iteration is restarted. Restarting the iterative solver after bond breaking is not always necessary, but it prevents the solver from diverging if the crack propagates over a large distance in a single step. Damage was also restricted to a zone of width 1 mm from the centreline of the domain, to ensure that the crack did not deviate from the centre due to asymmetry. It is worth noting, that future work will relax this constraint to investigate possible sensitivities to crack deviation from the centre.

4.1 *Boundary conditions*

The boundary conditions applied consist of a prescribed displacement of small sets of elements on the outer edge of the flanges (on each side of the notch) and on a set of elements near the vicinity of the notch as well to create an applied torque to each flange in opposing directions (as indicated in Figure 2) so that $W_m = 0.4W$. Displacement was restricted in the x and y direction (Figure 3) at one node to ensure that the boundary value problem is well posed.

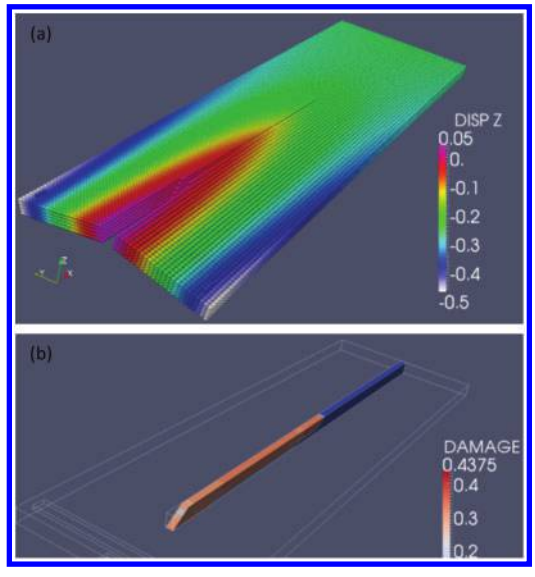

Figure 3. (a) Out of plane displacement map (in z) at time step 30 for the coarse mesh. (b) Crack propagation modelled as damage (only the central region of the domain is shown in the figure).

4.2 *Mesh sensitivity*

A simple mesh refinement study was performed to verify that no mesh sensitivity exist between computed results. A coarse mesh consisted of 5 elements through the thickness and an element diameter of 1.0mm. The medium mesh had 7 elements through the thickness and an element diameter of 0.6mm. The fine mesh had 8 elements through the thickness and an element diameter of 0.25mm. Number of elements for the course, medium and fine mesh are 59, 197 and 299 thousand respectively.

5 RESULTS

Snapshots of the computed results are shown in Figure 3. The top portion of the figure shows the out of plane displacement. The bottom portion of the figure shows the profile of the crack as it propagates down the centre of the domain (most of the domain has been removed to show the profile of the crack). The resulting curvilinear profile of the crack at the crack front shows excellent correspondence with the experimental results. Figure 4 shows the experimental profile superimposed on the computational results. Agreement between the two results was obtained for the entirety of the simulation, including the later stages in which the crack extends fully from the top to the bottom of the domain.

Figure 5 shows the crack length vs. time step, which shows a linear growth of the crack as expected. There is slight variation from the linear profile as in some steps the crack propagates further than predicted, however, this was typically followed by a slowing of the crack

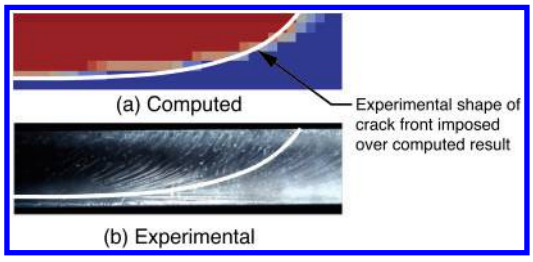

Figure 4. Comparisons of the (a) computed and (b) experimentally obtained crack front profiles.

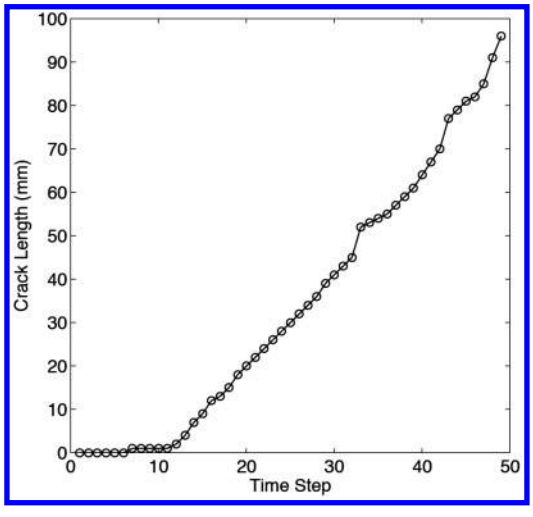

Figure 5. Crack length vs. time calculated as the distance of the furthest damaged cell from the origin of the notch.

growth in proceeding steps. A controlled growth of the crack, even for brittle materials is one of the advantages of the DT technique, which is clearly captured, in the simulated result.

Figure 6 illustrates a near constant applied force necessary to maintain a stable crack growth. These results illustrate the behaviour of the DT geometry. The predicted profile of the force vs. crack length curve is linear until the crack begins to propagate (suggesting the specimen behaves linear elastically). Once the crack begins to propagate, the predicted profile is a constant force, as the specimen can no longer withstand an increasing load due to the damage.

It is worth noting that the computed results in Figure 6 compare well with the experimental results in terms of a constant load state while the crack propagates, however, deviations during the initial stages exist. This deviation is largely due to the difference in the notch geometries being employed for the experimental and computed results (the experimental notch geometry is based on $c = 4$ inclination). As such, the constant force profile is delayed until the crack forms the characteristic curvilinear, full thickness crack font profile (whereas in the experiments the angled surface of the notch already closely matched the final profile of the crack).

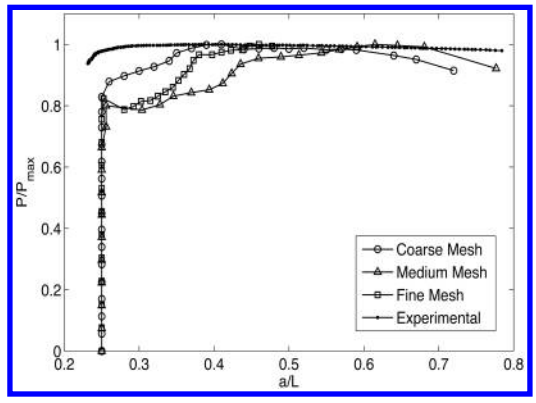

Figure 6. Force vs. crack length for meshes of various mesh sizes compared to experimental results.

Discrepancies, between the mesh sizes may also be attributed to the formation of the crack font where the mesh size effects the rate of achieving the constant crack front profile. Interesting to note though is that all geometries achieve the constant load curve over the middle of the specimen length.

6 CONCLSUIONS

It is clear that peridynamic modelling shows tremendous potential to simulate crack propagation for the DT technique, which in other contexts such as finite elements is quite difficult to accomplish. In particular, the shape of the crack front as it propagates is captured. A number of other features have also been simulated by the peridynamic theory including a (near) constant force profile as the crack advances in length.

This preliminary study into the use of peridynamics for modelling DT highlights the importance of further investigation on topics such as the convergence of the results with mesh refinement, alteration of the bond damage model, and using this method for alternative materials.

Propagation of non-planar pressurized cracks from a borehole

J.A.L. Napier

ABSTRACT: The in-situ stress field plays a crucial role in determining the orientation and shape of fractures that are initiated from a borehole. The paper outlines some investigations into the initial propagation of fractures from a pressurized borehole in both two-dimensional and three-dimensional cases. This has specific importance in understanding the stress field orientation and highlights some important contrasts between two and three-dimensional simulations of fracture propagation.

1 INTRODUCTION

Knowledge of the in-situ stress field is critical for mine planning and for designing underground excavations. One technique to measure the stress at depth is hydraulic fracturing; it consists of injecting water from a packed-off interval to create a fracture that propagates from the borehole. The fluid pressure-time record during propagation and eventually closure of the fracture after injection has stopped is then interpreted to extract information about the in-situ stress. However, only the least compressive in-situ stress σ_3^0can reliably be deduced from such a test; it is equated to the fluid pressure at which the fracture closes. Our current inability to deduce more information from the pressure-time record actually stems from the lack of a comprehensive model that can be used to simulate the 3D propagation of a crack, including fracture turning and warping if the borehole is inclined to the principal in-situ stress directions.

This paper presents the results of numerical simulations involving the propagation of the two wings of a fracture, which initially were longitudinal edge cracks aligned parallel to the borehole axis. The cracks are here assumed to be uniformly pressurized, i.e., the flow of water in the crack is not presently simulated. The numerical algorithm, RIFT (Napier, 2011), is based on the displacement discontinuity method (Crouch & Starfield, 1983) which only requires element mesh tessellation of the crack surface for problems involving homogeneous elastic infinite or semi-infinite domains. In RIFT, the three-dimensional crack surface is built up using flat, triangular or quadrilateral, displacement discontinuity elements with having constant, cubic or bi-quadratic strength. The displacement discontinuity formulation leads to a linear system of equations that relates the unknown displacement jumps in each element to the given tractions along the crack. The stress intensity factors are determined from the displacement discontinuities of the tip elements located next to the crack edge.

2 PLANE STRAIN FRACTURE PROPAGATION

A simplifying assumption that is often made in attempting to simulate propagation of fractures in a brittle material is to assume that the propagation path occurs in a representative plane section with respect to the local crack front edge as shown in Figure 1. In this case the x-axis is the outward tangent to the crack front edge, the y-axis is normal to the crack surface at the crack front and, by implication, the z-axis is parallel to the crack edge and points out of the plane in Figure 1. A suitable crack growth algorithm must be devised to determine the growth path direction and the stress state that matches the strength of the material. For brittle fracture in tension, the material strength is assumed to be determined by the Mode I fracture toughness, K_{Ic}. The simplest strategy that can be used to determine the growth path direction is to perform a direct search at a series of points located at a fixed distance, r, from the crack tip as shown in Figure 1. The hoop stress component $\sigma_{\theta\theta}$ is evaluated at each point (r,θ) and the maximum value $\sigma^*_{\theta\theta}$ is inferred using a suitable interpolation scheme to determine the optimum angle θ^* (see, for example, Napier & Hildyard, 1992). The crack path is then assumed to be a flat line segment joining the current tip and the point (r,θ^*). An analytic expression for the growth direction can be determined from the classic asymptotic crack tip expansions for a square

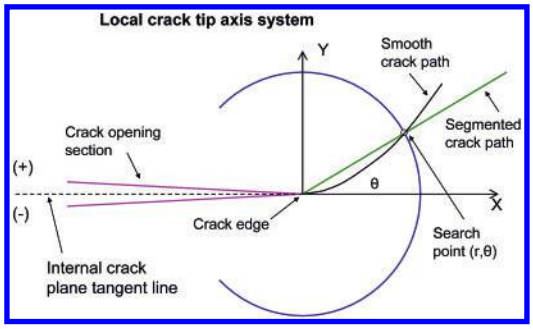

Figure 1. Crack tip axis system to define the crack front growth direction θ with respect to the current crack edge.

root crack tip opening and slip displacement discontinuity distribution (this scheme is adopted, for example, by Thomas & Pollard, 1993). In this case, the crack displacement discontinuity components Δu_x and Δu_y at a distance ε from the crack edge are defined by the difference in the displacement components $u_x(-\varepsilon, y)$ and $u_y(-\varepsilon, y)$ as $y \to \pm 0$ on the (+) and (−) sides of the crack as depicted in Figure 1. Specifically,

$$\Delta u_x = u_x(-\varepsilon, 0^+) - u_x(-\varepsilon, 0^-), \tag{1}$$

$$\Delta u_y = u_y(-\varepsilon, 0^+) - u_y(-\varepsilon, 0^-). \tag{2}$$

The relationships between the limiting shear and opening displacement discontinuity components are given in terms of the stress intensity factors K_I and K_{II} by

$$\Delta u_x = [8(1-\nu^2)/E]K_{II}\sqrt{\varepsilon/2\pi} \tag{3}$$

and

$$\Delta u_y = [8(1-\nu^2)/E]K_I\sqrt{\varepsilon/2\pi}, \tag{4}$$

respectively where E is Young's modulus and ν is Poisson's ratio. From the asymptotic crack tip stress fields (Lawn, 1993), the hoop stress component $\sigma_{\theta\theta}$ can be shown to be given by

$$\sigma_{\theta\theta}(r,\theta) = \cos^2(\theta/2)\{K_I\cos(\theta/2) - 3K_{II}\sin(\theta/2)\}/\sqrt{2\pi r}. \tag{5}$$

Differentiating Equation (5), provides the angle θ^* at which $\sigma_{\theta\theta}$ attains a maximum value as

$$\sin(\theta^*) = \rho(1-3\sqrt{1+8\rho^2})/(1+9\rho^2), \tag{6}$$

$$\text{where } \rho = K_{II}/K_I;\ K_I \neq 0. \tag{7}$$

If the fracture propagates in the direction θ^*, the incipient value of the mode I stress intensity factor K_I^* in the new direction is inferred to be

$$K_I^* = \cos(\theta^*/2)\{K_I(1+\cos\theta^*) - 3K_{II}\sin\theta^*\}/2. \tag{8}$$

Fracture propagation is assumed to proceed under the condition that $K_I^* = K_{Ic}$. In the construction of a crack growth algorithm, it is necessary to assume that the crack will advance by a specified distance, g, which, in the absence of a full crack tip velocity model, has to be viewed as a user parameter. Continued growth or halting of growth will be determined by the problem specific details of the boundary or crack surface loading. Tensile crack propagation at each active crack tip is considered to be locally stable if, under fixed loading stresses, a small advance, δs, at each crack tip position results in a decrease in the mode I stress intensity factor at each crack tip. Specifically, crack growth is assumed to be stable if

$$\partial K_I / \partial s < 0 \tag{9}$$

at each active crack tip.

In the limiting case where $K_I \to 0$in Equation 6 (mode II shear only),

$$\theta^* = \sin^{-1}\left[\frac{-\sqrt{8}K_{II}}{3|K_{II}|}\right] \sim 70.53° \text{ if } K_{II} < 0\ . \tag{9}$$

In this case, from Equations (5) and (8), the absolute value of the maximum hoop stress is given by

$$|\sigma_{\theta\theta}^*| = (2/\sqrt{3})|K_{II}|/\sqrt{2\pi r}. \tag{10}$$

It is important to note however that the corresponding maximum value of the asymptotic radial tensile stress component σ_{rr} within the crack surface (position $x = -\varepsilon; y = 0$ in Figure 1), is given by

$$\sigma_{rr} = 2|K_{II}|/\sqrt{2\pi\varepsilon}. \tag{11}$$

The singularity coefficient in Equation (11) is notably greater than in Equation (10) and, consequently, the asymptotic crack propagation would therefore be expected to initiate from within the crack surface and at right angles to the crack surface, rather than at the incipient angle given by Equation (9). This result appears not to have been noted in previous analyses of crack kinking (Cherepanov, 1968, Cotterell & Rice, 1980).

In general, the maximum tensile stress crack growth direction determination procedure outlined above will result in the construction of a kinked crack path trajectory comprising piecewise flat crack segments that are joined end to end. In extreme cases this can result in the initiated crack segment having a relatively large residual mode II shear component, Δu_x, at the crack tip which may, in turn, result in subsequent spurious oscillations of the simulated crack growth path. A more exact specification of the conditions required for smooth crack propagation (Cherepanov, 1979) is that at the crack tip,

$$K_{II} = 0 \text{ and } K_I = K_{Ic}. \tag{12}$$

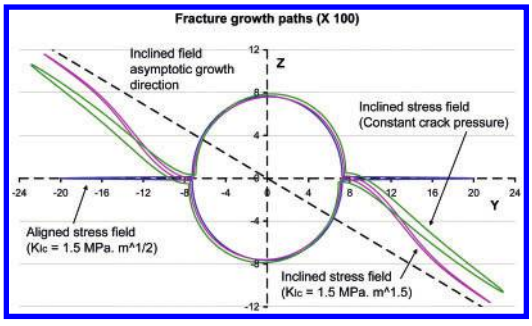

Figure 2. Superimposed fracture growth paths from the edge of a circular hole with starter cracks perpendicular to and tilted at 60 degrees with respect to the minimum principal field stress, σ_3^0. The volume-controlled growth paths are compared to the growth path that is found with constant pressure loading in the hole and within the cracks. (Axis scales in cm).

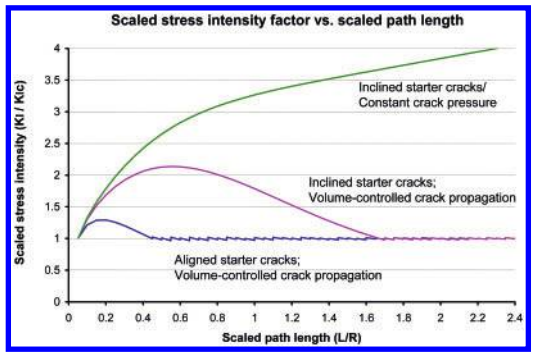

Figure 3. Comparison of Mode I stress intensity values at the crack tip (scaled to the assumed fracture toughness) plotted against the mean fracture path from each edge of the borehole, scaled to the borehole radius. (The three cases considered are respectively: (a) the starter cracks are perpendicular to the direction of the minimum principal field stress component, (b) the starter cracks are inclined at 60 degrees to the direction of the minimum principal field stress component, (c) as for case (b) but the pressure in the propagating cracks is constant).

If it is further demanded that the crack path be smooth (no kinks; see Figure 1) then it is possible to develop a theory that allows the crack radius of curvature to be determined at the successive crack tip positions (Cherepanov, 1979, Cotterell & Rice, 1980). However, this theory is still incomplete in the case of a three-dimensional crack front where double curvature of the front may generally occur and where Mode III loading may lead as well to the segmentation of the crack front (Napier, 2011). In the present paper the "first order" direction theory expressed essentially by Equations (6) and (8) above will be employed with the proviso that the crack increment advance step size g is sufficiently small to ensure that residual K_{II} values along the current crack front are "small" relative to the dominant values of K_I at the crack front.

3 PLANE STRAIN FRACTURE PROPAGATION FROM A CIRCULAR BOREHOLE

Consider next the case of a borehole section of nominal radius $R = 75$ mm centered on the origin in a y-z coordinate axis system as shown in Figure 2. The x-axis in this case is taken to be aligned to the borehole axis and the hole has an initial internal pressure, P_0. It is assumed that two initial edge cracks of length g = 0.375 mm exist at opposite points on the hole diameter where $z = 0$ in Figure 2. The subsidiary principal field stress components in the plane section of the hole are assumed to be $\sigma_3^0 = \sigma_{zz} = -10$ MPa and $\sigma_2^0 = \sigma_{yy} = -20$ MPa respectively. It is further assumed that the initial pressure P_0 is adjusted to a level where the stress intensity factor at the tips of the edge cracks reaches a postulated nominal fracture toughness, $K_{Ic} = 1.5\,\text{MPa.m}^{1/2}$, of the surrounding rock. In this analysis, the borehole circumference is simulated with 60 flat line segment displacement discontinuity elements. The surrounding rock is assumed to have a Young's modulus, $E = 72000$ MPa and a Poisson's ratio, $\nu = 0.2$.

Fracture growth is controlled by adjusting the total crack and borehole opening volume in a series of constant increments until it is found that $K_I \geq K_{Ic}$ at one or more of the active crack tips. Additional elements of length g are then connected to the active crack tips, in the appropriate advance directions calculated from Equation 6, and the element assembly is solved iteratively to satisfy the current opening volume constraint by adjusting the applied borehole and internal crack pressures. Alternatively, if it is found that the Mode I stress intensity factor increases at a particular crack tip when a new growth element is added to the tip, the total opening volume constraint value is "frozen" and successive crack elements are then introduced until the active crack tip stress intensity factors do not exceed the specified toughness parameter. (This allows the model to accommodate what is effectively an unstable growth phase).

The resulting fracture paths for three cases where fracture propagation initiates at the borehole edges in the plane $z = 0$ are shown in Figure 2. In the first case, the minimum principal stress is parallel to the z-axis and, in the remaining two cases, is tilted at an angle of 30 degrees to the z-axis. The Mode I stress intensity factors at each crack tip, scaled to the fracture toughness, are plotted in Figure 3 as a function of the crack path length, L, scaled by the borehole radius, R. It is observed that for the volume-controlled propagation cases there is an initial phase of "unstable" fracture growth where the stress intensity factor increases when the opening volume is held constant followed by "stable" crack propagation in the sense that the crack opening volume must be increased incrementally to maintain the advancing crack tip stress intensity at the magnitude of the assumed fracture toughness. In the case of constant pressure loading, the fracture propagation is "unstable" with the Mode I stress intensity

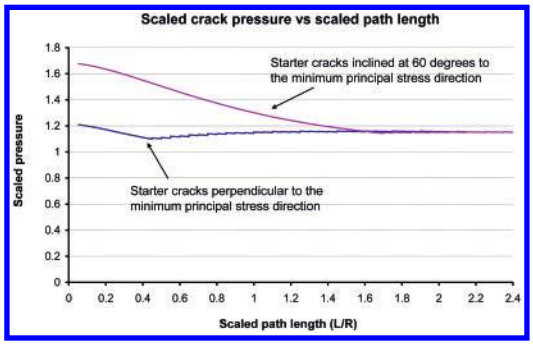

Figure 4. Comparison of the scaled crack pressure as a function of the scaled fracture path length for: case (a) the starter cracks are perpendicular to the direction of the minimum principal field stress component and case (b) the starter cracks are inclined at 60 degrees to the direction of the minimum principal field stress component.

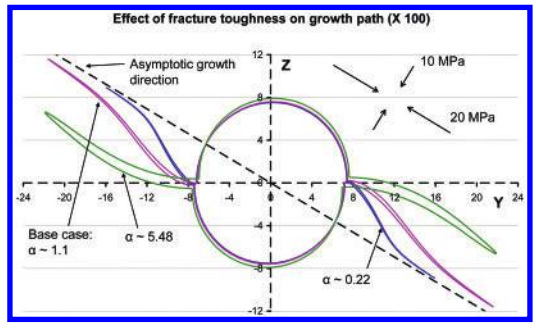

Figure 5. Comparison of crack growth paths for three values of the fracture toughness and the corresponding values of the dimensionless parameter α. (Axis scales in cm).

factor progressively increasing at each crack tip (see Figure 3). The constant pressure crack path in Figure 2 is observed to deviate significantly from the corresponding volume-controlled crack path in the inclined stress field.

The scaled crack and borehole surface pressure is shown in Figure 4 for the aligned and tilted stress fields respectively as a function of the evolving crack path length. The pressure is scaled by the minimum principal field stress value, σ_3^0. During the unstable crack growth phase, the pressure is observed to fall and then to increase steadily as the fracture length is increased. It is notable as well that the initial pressure for the tilted stress field case is significantly greater that for the case of the aligned stress field.

The alignment of the crack path trajectory to the asymptotic growth direction (corresponding to the direction perpendicular to the minimum principal field stress) is controlled by the dimensionless parameter α defined by (Mogilevskaya *et al*, 2000)

$$\alpha = K_{Ic} / S_0 \sqrt{R} \tag{13}$$

where S_0 represents the far-field deviatoric stress. For the field loading relevant to the present example in Figure 2,

$$S_0 = \left|\sigma_2^0 - \sigma_3^0\right| / 2 = 5 \text{ MPa.} \tag{14}$$

Fracture paths for the cases where $K_{Ic} = 0.3$ MPa.m$^{1/2}$ and $K_{Ic} = 7.5$ MPa.m$^{1/2}$ respectively are compared to the base case $K_{Ic} = 1.5$ MPa.m$^{1/2}$ in Figure 5. The corresponding values of the parameter α computed from equation 13 are 0.22, 5.48 and 1.10 respectively and indicate that for "small" values of α the growth path approaches the asymptotic growth direction more rapidly.

4 THREE-DIMENSIONAL FRACTURE PROPAGATION

4.1 Aligned stress field

The construction of a propagating crack front in three dimensions requires additional assumptions to be made to determine the growth advance distance at each point i on the crack front, located at an arc length position t_i measured from some appropriate initial point on the crack front. Whereas it is implicit that the stress intensity is uniform at each point along the crack front in the plane strain case (i.e. the out of plane direction in Figure 1), this assumption is no longer necessarily valid for a three-dimensional crack front advance (Napier, 2002). It is unclear, in fact, exactly how the crack front shape should be evolved to maintain the condition that $K_I = K_{Ic}$ at every point along the incrementally advanced crack front. The provisional assumption is made therefore that the advance distance at each point along the crack front will be scaled by a defined "growth potential metric", F_i, that is evaluated at selected points along the crack front. This metric may be chosen, for example, to be the estimated stress intensity factor of the incipient front advance, as in Equation 8. In the present study, F_i, is defined to be the maximum tensile hoop stress $\sigma^*_{\theta\theta}$ evaluated in a direct search at a fixed distance, ε, ahead of each position t_i along the current crack front. The value of F_i is determined in a local $x-y$ plane, as shown in Figure 1, where the x-axis is the outward crack tangent vector, the y-axis is the local normal vector to the crack surface at the crack front and the z-axis is the tangent direction parallel to the crack edge (see as well Napier, 2011).

The new crack front offset g_i from the existing crack front point i is determined according to the simple assumption that

$$g_i = \frac{F_i}{F_{\max}} g_{\max}, \tag{15}$$

where $g_{\max}$ is a user-specified maximum allowed advance distance and where $F_{\max} = \max[F_i]$ within

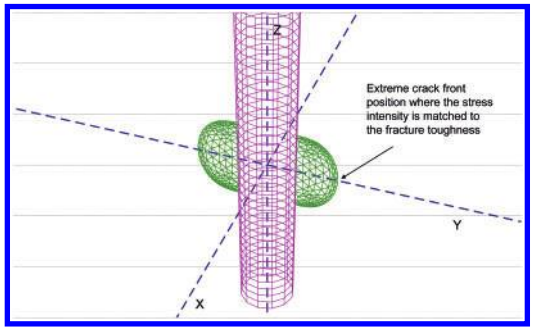

Figure 6. Fracture profile with a short fracture initiation length along the borehole wall. ($H_0/R = 0.267$).

a selected set of sampled positions along the current crack front. It is convenient as well to choose a threshold advance, g_c which can be expressed as

$$g_c = \gamma g_{\max}, \tag{16}$$

and where $0 < \gamma \leq 1$. In the subsequent simulations it is assumed that $\gamma = 0.5$.

The advanced crack front must then be constructed from a suitable element tessellation joining the old front and the new front offset positions. In the simulations presented in this paper, it is assumed that the bridging elements are triangular and that the displacement discontinuity values are constant within each element. (The element influence functions are described in Napier and Malan, 2007). The following simple procedure, based on the structure of Equation (4), is used to estimate the Mode I stress intensity factors at the mid points of the crack front element edges:

$$K_I = \frac{E\Delta u_y}{8(1-\nu^2)}\sqrt{\frac{2\pi}{\varepsilon + f_c\sqrt{A}}}. \tag{17}$$

In equation (17), f_c is an empirically chosen "correction factor" and A is the area of the local edge triangular element. It is found empirically that for constant strength, triangular displacement discontinuity elements $f_c = 0.5$ is an appropriate choice for the correction factor although there is some scatter in the estimated values with errors of ~5 percent.

It is assumed that the borehole radius, $R = 75$ mm as for the circular hole considered in Section 3. The borehole is represented as a truncated cylindrical crack of length H (where $H/R = 18.67$) and comprises rectangular displacement discontinuity elements as shown in Figure 6. The borehole axis is aligned to the z-axis coordinate direction as shown in Figure 6. The compressive principal field stress magnitudes in the x, y and z directions are set initially to 10 MPa, 20 MPa and 50 MPa respectively. The fracture is allowed to initiate from the surface of the borehole along a line of length H_0, parallel to the borehole axis in the y-z plane. Figure 6 illustrates the development of two planar fracture surfaces in the y-z plane on each side of the hole after 8

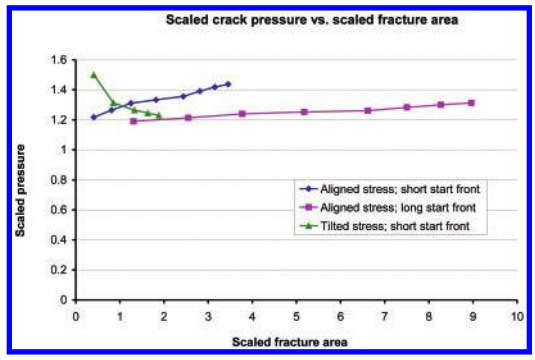

Figure 7. Evolution of scaled crack pressure as a function of the scaled fracture area to maintain an estimated match of the crack front stress intensity to the nominal fracture toughness.

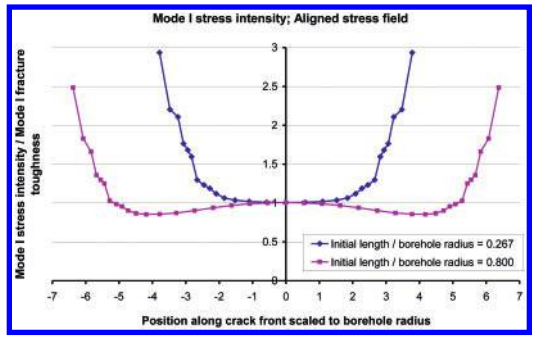

Figure 8. Mode I stress intensity variation along the crack front edge after 8 growth steps for (a) short fracture initiation length ($L_0/R = 0.267$) and (b) long fracture initiation length ($L_0/R = 0.800$).

growth steps for the case where $H_0/R = 20/75 \sim 0.267$. In each growth step, the borehole and crack pressure is adjusted to match the nominal fracture toughness $K_{Ic} = 1.5$ MPa.m$^{1/2}$ before determining the new crack front position. It is important to note that the fracture toughness is matched only at the extreme outer crack front positions in Figure 6 and, as noted before, is not necessarily uniform along the entire crack front. Figure 7 indicates the corresponding crack pressure values (designated by the label "aligned stress; short start front") scaled to the minimum principal stress magnitude σ_3^0 plotted against the total fracture area of both wing cracks scaled to the nominal cross sectional area of the borehole. A second case was analysed with a longer start crack length, $H_0/R = 60/75 = 0.8$. The corresponding evolution of the crack pressure as a function of the developed fracture area is shown in Figure 7. These results suggest that the initial fracture growth is stable in the sense that the pressure and the fluid volume have to be increased in order to propagate the cracks. This is in distinct contrast to the cases analysed in plane strain in section 3 and the pressure profiles shown in Figure 4.

The Mode I stress intensity values along the developed crack front of the wing cracks developed in the region y > 0 (Figure 6) are shown for the two cases

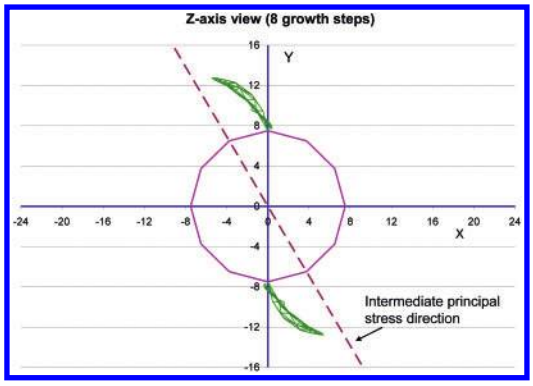

Figure 9. View along borehole axis of fracture surface evolution for tilted stress field.

of fracture growth from the short and long initiation lengths respectively in Figure 8. The distribution of the stress intensity values shows that although the nominal toughness is matched (as required) at the central position, it is in detail characteristically different for the short and long initiation length cases and exceeds the nominal toughness at the upper and lower extremities of the developed front with respect to the z-axis direction (see also, Figure 6). This suggests that the shape of the developed crack surface shown in Figure 6 (and the similar extended profile found for the case of the long initial crack length) must be treated with some caution.

4.2 Inclined stress field

The simulation of the fracture initiation from the short start length case was repeated for the case of an inclined stress field rotated about the z-axis as shown in Figure 9 where the z-axis view of the developed wing cracks after 8 growth steps are shown. The corresponding evolution of the crack pressure as a function of the scaled crack area is included in Figure 7 for the first 5 growth steps. It is of particular interest to note that the initial fracture growth now appears to be unstable in contrast to the two cases where the minimum principal stress field is perpendicular to the developing wing cracks.

It is significant to note that in this case, the stress intensity factor at the outer crack front mid-point was found to fall below the nominal toughness value after growth step 3 and ad hoc estimates of the average stress intensity values had to be made in order to estimate the appropriate crack opening pressure. This complex behaviour of the evolving crack front stress intensity profile is a critical feature of three-dimensional fracture growth simulation.

5 CONCLUSIONS

The stress field orientation plays a crucial role in determining the trajectories of fractures that are initiated from a borehole. It is of particular interest that the stability of three-dimensional fracture propagation may not match that of the plane strain case, depending on the initial fracture length along the edge of the borehole. It is noted further that there are a significant number of unresolved issues relating to the determination of the evolutionary shape of a three-dimensional crack front.

Hydraulic fracture simulation: Comparison with exact solutions

C. Detournay, P.A. Cundall & B. Damjanac
Itasca Consulting Group, Inc., Minneapolis, USA

ABSTRACT: Hydraulic fracturing is a technique to stimulate gas and oil-bearing rock layers through the creation of large cracks in the reservoir by injection of fluid from a borehole. The Particle Flow Code (*PFC*) and the new lattice based *HF simulator* are two coupled fluid-mechanical codes capable of modeling fracture initiation and propagation, including slip and opening along joints in a pre-existing Discrete Fracture Network (DFN). A new efficient coupled fluid-mechanical scheme (MIF) has been devised as part of the *HF simulator* design and development.

In the paper, we use a simple framework, and *PFC* as a test bed, to demonstrate the ability of the MIF scheme to capture important fluid-mechanical mechanisms associated with fluid injection in a fracture. Two example problems are considered: fluid injection at a fixed rate into a pre-existing crack, and linear fracture propagation along a pre-existing joint. The numerical solution for pressure and aperture evolution with time is compared to analytical solutions for the two examples. Different mesh resolutions are considered and it is shown that the trends of the analytical solution can be captured satisfactorily with a relatively coarse mesh and small model size.

1 INTRODUCTION

Hydraulic fracturing is a technique to stimulate gas and oil-bearing rock layers through the creation of large cracks in the reservoir by injection of fluid from a borehole. Recently, this technique has become critical to unlock the enormous reserve of gas contained in large deposits of shales throughout the world. However, numerical models that were developed to design hydraulic fracturing treatments for conventional reservoirs are not applicable for the stimulation of gas shales. Indeed, these models generally assume propagation of a single planar fracture in a homogenous elastic medium, and are not capable of accounting for the many discontinuities present in the shales that interact with the hydraulic fracture. The work presented in this paper documents a first step to developing a new generation of numerical models, which are freed of the restrictions of most previous models.

The particle flow code *PFC* (Itasca, 2008) and the more specialized, computationally efficient lattice based *HF simulator* (Damjanac et al., 2013) are two coupled fluid-mechanical codes capable of modeling fracture initiation and propagation, including slip and opening along joints in a pre-existing discrete fracture network (DFN).

An important aspect of any numerical development is the ability to compare model predictions with exact solutions. In the paper, we use a simple framework and *PFC* as a test bed to demonstrate the ability of the numerical scheme to capture important fluid-mechanical mechanisms associated with fluid injection in a fracture. Two example problems are considered: fluid injection at a fixed rate into a non-propagating crack, and linear fracture propagation along a pre-existing joint. The numerical solution for pressure and aperture evolution with time is compared to analytical solutions for the two examples. Different mesh resolutions are considered and it is shown that the trends of the analytical solution can be captured satisfactorily with a relatively coarse mesh and small model size.

2 NOTATION CONVENTION

By convention in the text below, R represents the discretization length used in the numerical model (i.e., distance between contacts in a *PFC* model or nodes in a lattice model) and a is the joint aperture. Also, K_R is rock bulk modulus, and K_F is (apparent) fluid bulk modulus. The quantities k_R and k_J are one-dimensional stiffness in the model (in units of force/displacement) associated with the rock and the joint, respectively. In addition, κ_F is the joint permeability factor (parallel plate model), expressed as $\kappa_f = 1/12\mu$, where μ is the dynamic viscosity of the fluid. Δt is the (explicit) time step increment.

Finally, a unit model thickness is considered in the discussion, and A is the apparent area of the joint element (in the order of R in a 2D model of unit thickness).

3 MIF SCHEME

The MIF scheme (Mechanical Incompressible Fluid) (Cundall, 2011) is a new coupled fluid-mechanical

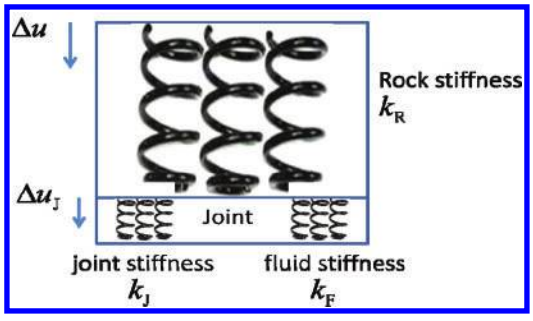

Figure 1. Schematic of a rock element the size of the resolution with embedded fluid-filled joint – normal direction.

algorithm to model the mechanisms associated with hydraulic fracturing and/or fluid injection in pre-existing joints. The scheme is applicable to situations in which the rock compressibility is much larger than that of the fluid. One of the main advantages of the scheme, compared to the algorithms currently implemented in Itasca codes, is the larger explicit time steps required for numerical stability.

We note that fluid pressure is defined at contacts in a *PFC* model (springs in a lattice), and flow occurs in pipes, which are linear entities connecting the contacts. Fluid compressibility is assumed to be very small compared to the rock.

The MIF scheme is described by considering an element of rock of a dimension equal to the discretization length, R, that includes a single joint. Figure 1 illustrates the mechanical arrangement in the normal direction. Fluid and rock stiffness in the plot are related to fluid and rock bulk modulus: $k_F = K_F A/a$, and $k_R = K_R A/R$. Also, typically $k_F >> k_R$.

The combined joint normal stiffness, k_C is $(k_J + k_F)$, and the total element stiffness, k_T is

$$k_T = \frac{k_R k_C}{k_R + k_C} \tag{1}$$

In one time step, Δt, an increment of relative displacement for the element, Δu gives rise to a force increment of

$$\Delta F = k_T \Delta u \tag{2}$$

And a joint displacement of

$$\Delta u_J = \frac{\Delta F}{k_C} \tag{3}$$

The increment in fluid pressure is $\Delta P = \Delta u_J k_F / A$; after some substitution, it is expressed as

$$\Delta P = \frac{\Delta u\, k_R}{A} \frac{k_F}{k_F + k_R + k_J} \tag{4}$$

If $k_F >> k_R$, the fluid pressure increment approaches

$$\Delta P \rightarrow \Delta u\, k_R / A \tag{5}$$

Thus, the fluid pressure increments depend only on rock spring stiffness, and the mechanical time-step is not affected by the presence of the fluid.

The apparent fluid modulus (used in the flow part of the model) is also modified as follows. Consider a fluid "displacement" increment Δu_F (derived from a flow imbalance, ΣQ in the joint), which is imagined to be injected in a series with the fluid spring, k_F at each fluid time-step. The increment in fluid force is then

$$\Delta F_F = \frac{(k_J + k_R)k_F}{k_J + k_R + k_F} \Delta u_F \tag{6}$$

The pressure increment $\Delta P = \Delta F_F / A$ approaches

$$\Delta P \rightarrow \frac{\Delta u_F (k_R + k_J)}{A} \tag{7}$$

when $k_F >> k_R$. Thus, in the limit of $k_F >> k_R$, the fluid "sees" an apparent bulk modulus of

$$K_F = \frac{a}{A}(k_R + k_J) \tag{8}$$

This apparent fluid bulk modulus is much smaller than a true fluid bulk modulus, allowing much longer fluid time-steps.

Finally, the lattice spring force is incremented as a result of fluid displacement arising from the flow calculation, as follows:

$$\Delta F = \frac{\Delta u_F\, k_R\, k_F}{k_R + k_J + k_F} \tag{9}$$

In the limit $k_F >> k_R$,

$$\Delta F \rightarrow \Delta u_F k_R \tag{10}$$

The stable fluid time-step in the MIF scheme (*PFC* test bed) is taken as:

$$\Delta t = 0.25 \frac{\lambda^3}{\kappa_f K_R} \tag{11}$$

where $\lambda = R/a$. For comparison, the fluid time-step in the existing (compressible fluid) scheme is (Itasca, 2008):

$$\Delta t = \frac{\lambda^2}{\kappa_f K_f} \tag{12}$$

For most practical applications: K_R and K_f are of the same order of magnitude, and thus, the denominators in (7) and in (8) are also of the same order. Compared to previous schemes, the "gain" in fluid time-step magnitude is directly proportional to λ, a number typically much larger than 1.

In the existing scheme, the stable mechanical-step is typically smaller than the stable fluid-step. In the new scheme, uniform density scaling is applied by giving the mechanical time-step a value equal to that of the fluid. (In this technique, inertial masses are multiplied by a factor, such that the computed mechanical time-step is equal to the fluid time-step. Gravitational masses are unaffected.)

4 INJECTION IN A PRE-EXISTING CRACK

We consider the two-dimensional problem of fluid injection at a constant rate into a pre-existing crack of constant length, embedded in an elastic medium of negligible permeability and large extent. The problem has been analyzed by Garagash and Detournay (1998), who also derived a semi-analytical solution. The numerical solution obtained using the new scheme is compared to the semi-analytical results, which were provided by the authors in the form of a spreadsheet.

4.1 *Semi-analytic solution*

The crack half length is$L$, and the constant injection rate is Q_0. The effective net pressure inside the crack is given by the difference between fluid pressure inside the crack, p and compressive far-field stress component normal to the crack σ:

$$p_e = p - \sigma \tag{13}$$

The initial crack loading (effective net pressure p_e) is assumed to be zero, and the crack has an initial opening a_0. The origin of reference axis is at the crack center (fluid inlet), and the x-axis points to the right along the crack. The following dimensionless variables are used: $\hat{x} = x/L$, $\hat{t} = t/t^*$, $\hat{p} = (p-\sigma)/p^*$, $\hat{a} = a/a_0$ where characteristic time t^* and pressure p^* are given for the plane stress case, as:

$$t^* = \frac{12\mu}{E'}\left(\frac{L}{a_0}\right)^3 \quad p^* = E'\frac{a_0}{L} \tag{14}$$

with $E' = E/(1-\nu^2)$, E is Young modulus, and ν is Poisson ratio. Also, the dimensionless fluid flux at the inlet (plane stress case) is:

$$\hat{Q} = \frac{12\mu}{E'}\frac{L^2}{a_0^4}Q_0 \tag{15}$$

The semi-analytical solution assumes that there is no lag at the crack tip; it gives the evolution of $\hat{p}$ and $\hat{a}$ as a function of $\hat{t}$ at equidistant points along the crack.

4.2 *Simulation data*

The elastic macro-properties for the crack are 6 GPa for Young modulus, and 0.3 for Poisson ratio. The crack length (2 L) is 11 m. Fluid viscosity is 10^{-3}Pa-s, and fluid flux at the inlet is 0.266 m^2/s (dimensionless fluid flux for the full crack is 200π). Initial fracture aperture is 0.4 mm. The joint stiffness is zero. Also initial stress σ is zero, and so is initial pressure p_0 inside the crack.

4.3 *PFC models*

The *PFC* models for the simulations are 43 m wide and 36.5 m high. The models use a hexagonal packing of balls, and two rows or rectangular packed balls along the line of the crack. Two different resolutions are considered for the models: the coarse model, shown in Figure 2, uses a ball radius of 0.5 m, and a ball radius three times smaller is used in the fine model.

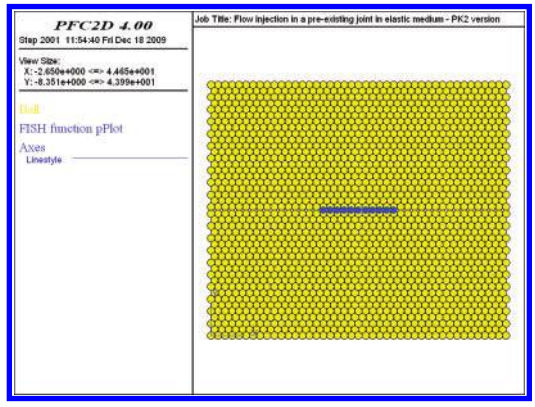

Figure 2. Ball assembly for coarse model.

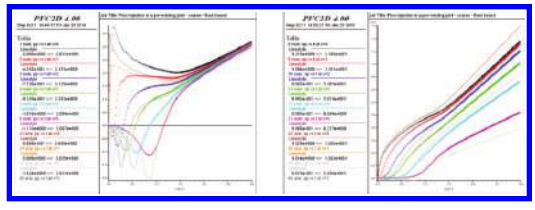

Figure 3. $\hat{p}$ versus $\hat{t}$ (left) and $\hat{a}$ versus $\hat{t}$ (right): comparison between analytical (gray) and numerical (color) predictions at selected monitoring points – coarse model.

Fixed (roller) boundary conditions are used in the simulations. The local x-axis is along the crack line, and the origin is at the inlet. Monitoring points are selected at six locations along the crack: x = 0, 1, 2, 3, 4 and 5 m.

4.3.1 *Elastic micro properties for the simulations*

The contact shear and normal stiffness for the ball assembly are derived from relationship between elastic macro-properties and micro-properties for a hexagonal packing (Alassi, H.T., 2008), i.e., $k_n = E/(\sqrt{3}(1-\nu))$, and $k_s = k_n(1-3\nu)/(1+\nu)$.

The calibration was verified successfully by conducting a dry compression test using the ball assembly shown in Figure 1, and checking the overall elastic model response.

4.3.2 *Coarse model results*

Comparison between numerical and analytical predictions for dimensionless pressure and aperture at selected points along the crack are shown in Figure 3. The numerical results for pressure and aperture evolution with time show trends similar to those predicted by the analytic solution for no lag. In particular, the effective net pressure shows a characteristic non-monotonic behavior, which occurs because the crack re-opens ahead of the (zero net pressure) fluid front. Note that problem results interpreted in their dimensionless

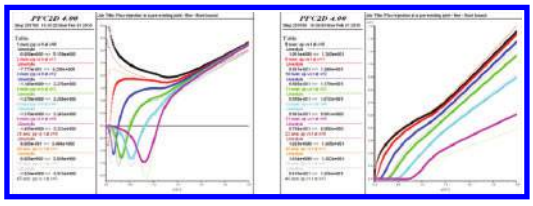

Figure 4. $\hat{p}$ versus $\hat{t}$ (left) and $\hat{a}$ versus $\hat{t}$ (right): comparison between analytical and numerical predictions at selected points – fine model.

form are not necessarily restricted to the particular set of data used to derive them; in particular, the occurrence of a negative dimensionless net pressure $\hat{p}$ does not always imply that fluid pressure is negative; it all depends on the actual level of confining stress σ.

As shown, there is an initial increase in net pressure at the inlet, followed by a decrease as the crack reopens progressively and the fluid progresses to the tip, and by a further increase as the full crack opens and an asymptotic solution is reached. Indeed, for sufficiently large values of $\hat{t}$ (when a non-zero net pressure acts along the full crack length), the rate of increase of net pressure becomes constant. The (constant) asymptotic rate can be evaluated by reasoning that Griffith's aperture solution applies at those large times.

The numerical values of pressure and aperture are within the expected analytical bounds. In addition, there is a reasonable match between analytical and numerical time prediction at negative peak net pressure; this shows that the new scheme is able to adequately estimate the problem time-scale.

4.3.3 *Fine model results*

The fine model has the same overall size and crack length as the coarse model, but with three times the number of balls in both the x- and y-directions. The numerical and analytical predictions for dimensionless pressure and aperture at selected points along the crack are shown in Figure 4.

The results in Figure 3 show a better fit with the analytical solution than those reported in Figure 2 for the coarse model, indicating convergence of the numerical predictions to the analytical solution for finer model discretization. A close-up view of displacement vectors near the crack is shown at the end of the simulation in Figure 5.

5 FRACTURE PROPAGATION ALONG A PRE-EXISTING JOINT

The two-dimensional problem of injection of a viscous fluid at a constant rate in a planar fracture with zero toughness is considered for this example. The medium is elastic and of large extent. The problem is similar to the one considered for early times in Example 1; however, particular focus is given here to the study of fracture propagation. The numerical results are compared with the zero toughness solution of Adachi and Detournay, 2002.

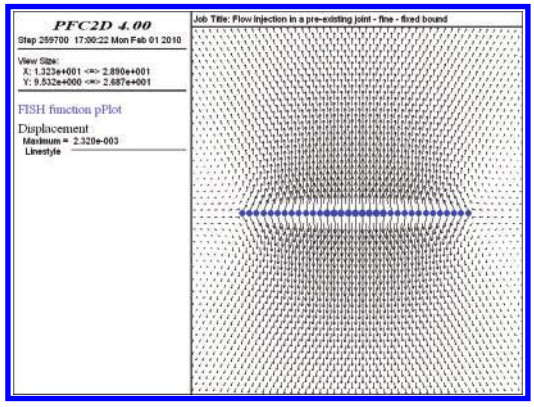

Figure 5. Displacement vectors in the vicinity of the crack at the end of the simulation – fine model.

5.1 *Analytic solution*

We use the same notation convention as in Example 1. The dimensionless variable $\hat{x}$ is introduced as $\hat{x} = \frac{x}{L}$ where L is the instantaneous half-length of the fracture (see (12), below).

The first order approximation of the zero toughness plane stress solution is (see Adachi, 2001; Adachi and Detournay, 2002, Detournay, 2004):

$$\begin{aligned} p - \sigma &= \varepsilon(t) E' \Pi_{mo}(\hat{x}) \\ a &= \varepsilon(t) L'(t) \Omega_{mo}(\hat{x}) \\ L &= \gamma_{mo} L'(t) \end{aligned} \tag{16}$$

where, by definition:

$$L' = \left(\frac{E' Q_0^3 t^4}{12\mu} \right)^{\frac{1}{6}} \quad \varepsilon = \left(\frac{12\mu}{E' t} \right)^{\frac{1}{3}} \quad \gamma_{mo} = 0.616 \tag{17}$$

The functions Π_{mo} and Ω_{mo} have a closed form expression; values tabulated at 80 regular $\hat{x}$ intervals were provided in the form of spreadsheet by the authors, and are used for the comparisons documented in this paper.

5.2 *Simulation data*

The elastic macro-properties for the crack are 6 GPa for Young modulus, and 0.3 for Poisson ratio. Fluid viscosity is 10^{-3} Pa-s, and fluid flux at the inlet is 4 10^{-4} m^2/s. Initial fracture aperture is 1 micron. Also initial stress $\sigma$is zero, and so is initial pressure inside the crack.

5.3 *PFC model*

The *PFC* models for the simulations are similar to those considered in the previous example. Fixed (roller) boundary conditions are considered. Fluid is injected at the center of the crack line for a total of

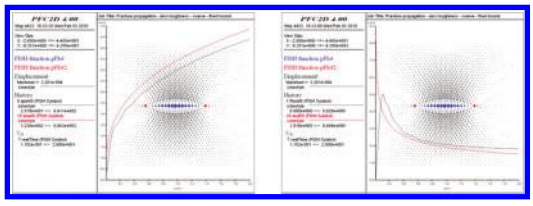

Figure 6. a/a_0 (left) and net pressure (right) versus time at injection point – comparison with analytical solution – coarse model.

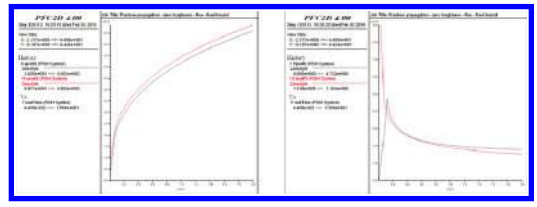

Figure 9. a/a_0 (left) and net pressure (right) versus time at injection point – comparison with analytical solution fine model.

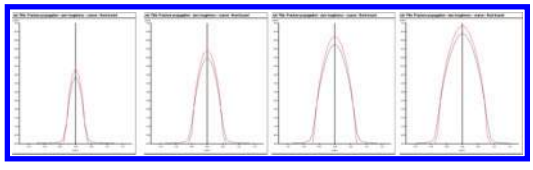

Figure 7. a/a_0 versus x at t = 5 s, 10 s, 15 s and 20 s – comparison with analytical solution (red) – coarse model.

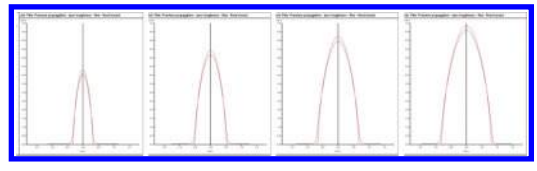

Figure 10. a/a_0 versus x at t = 5 s, 10 s, 15 s and 20 s – comparison with analytical solution (red) – fine model.

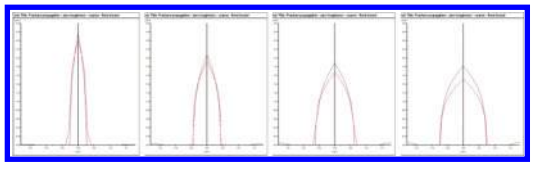

Figure 8. p_e versus x at t = 5 s, 10 s, 15 s and 20 s – comparison with analytical solution (red) – coarse model.

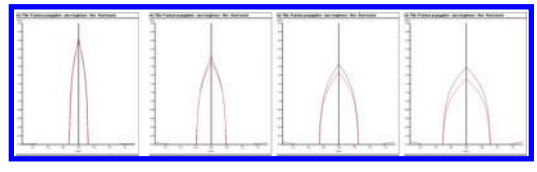

Figure 11. p_e versus x at t = 5 s, 10 s, 15 s and 20 s – comparison with analytical solution (red) – fine model.

20 sec. Pressure and aperture at the inlet are monitored during the simulation. Also, fracture aperture and pressure are recorded at four intervals in time (t = 5, 10, 15 and 20 sec), and the numerical predictions are compared to the zero toughness analytical solutions.

5.3.1 *Coarse model results*

Numerical values of relative aperture a/a_0 and net fluid pressure p_e at the inlet are plotted versus simulation time in Figure 6.

The net pressure in the fracture is represented by blue (positive) and red (negative) dots, and displacement vectors at the end of the simulation are also shown in the figure. The difference between numerical and analytical aperture values does not appear to grow significantly with time on Figure 5 (left plot).

The numerical estimate for relative aperture a/a_0 is plotted versus distance along the crack line and compared to the analytical solution at four different times in Figure 7.

The maximum relative error on aperture at the end of the simulation is about −6.6%. Net pressure from the simulation is plotted versus distance along the crack line and compared to the analytical solution at four different times in Figure 8; negative net pressure values, that develop necessarily to satisfy equilibrium, are not represented in the figure (only positive values are represented).

The numerical estimate for maximum aperture is *smaller* than the analytical value in Figure 6, and the estimate for maximum net pressure is *larger* than the theoretical value in Figure 7; this behavior is consistent with the approximation of finite size and fixed boundary conditions for the model used for the simulations.

5.3.2 *Fine model results*

The simulations are repeated with the fine model. The model has the same overall size as the coarse model, but with three times the number of balls in both the x- and y-directions. Numerical values of relative aperture a/a_0 and effective net pressure p_e at the inlet are plotted versus simulation time in Figure 9.

The maximum relative error on aperture at the end of the simulation is about −3.8% (compared to −6.6% for the coarse model case). The numerical estimate for relative aperture a/a_0 is plotted versus distance along the crack line, and compared to the analytical solution at four different times in Figure 10.

Net pressure predicted from the simulation is plotted versus distance along the crack line and compared to the analytical solution at four different times in Figure 11 (positive values shown).

5.3.3 *Fluid volume conservation*

Numerical and analytical value of injected fluid volumes are calculated from the area under the aperture curves, and compared to the product of fluid injection rate times and elapsed fluid time at the end of the 20-sec simulations. The relative error is about 3% for the coarse model and less than 1% for the fine

one. The numbers show that the fluid volume is conserved with good accuracy under the assumption of fluid incompressibility (in the MIF scheme, the fluid is only approximately incompressible, see (8)).

5.3.4 *Timing test*

To estimate computational efficiency, we ran the Example 1 simulations with the coarse grid using the MIF and the scheme currently used in *PFC2D* for simulations of hydro-mechanical coupling. A small modification was made to let the current *PFC2D* scheme use the same (linear) contact law as the MIF scheme.

The fluid-mechanical simulation was run for a total injection time of 0.1 s. The computational time on an Intel Dual Core 2.53 GHz machine is 143.8 sec. for the current *PFC2D* scheme, and 2.8 sec. for the new scheme. The MIF scheme is about 52 times faster than the current *PFC2D* scheme for this particular problem and specific computer.

6 CONCLUSIONS

Numerical simulations were performed, using *PFC* as a testbed to evaluate the accuracy and calculation speed of the new fluid-mechanical scheme (MIF) for application to hydraulic fracturing. Two examples were considered: fluid injection in a pre-existing fracture, and fracture propagation in a medium with zero toughness. The numerical results were compared to existing analytical and semi-analytical solutions. The results documented in the paper show that the numerical solutions have the same behavior as the analytical ones, and that the results converge to the infinite domain solutions when the discretization length is decreased (the impact of the size of the computational domain has not been investigated in this paper).

Timing tests were run on one of the coupled fluid-mechanical examples and it was shown that for that particular case, the new proposed scheme was 50 times more computationally efficient that former scheme.

ABSTRACT: The Double Torsion (DT) geometry is a test specimen configuration that facilitates for fracture investigations in highly brittle materials and is well-known to produce a stress intensity factor that is independent of crack length. This feature allows for the propagation of relatively long cracks in a highly controlled manner in exceptionally brittle materials. However, the DT geometry is yet to be standardised and to date many questions remain regarding optimal specimen dimension, load point deflections, and out of plane deformations. This paper aims to investigate the DT geometry using the Finite Element methodology in order to obtain an optimum specimen geometry that can be utilised in fatigue threshold and other fracture mechanics related investigations.

1 INTRODUCTION

The Double Torsion (DT) geometry is a test specimen configuration that facilitates for fracture investigations in highly brittle materials. The novelty of the DT technique lies in the property of a constant stress intensity factor (SIF) regime during crack propagation (Attia 2010), which is considered to produce a crack length independent geometry by achieving a constant stress intensity factor (SIF) regime (Attia 2010). As such, the DT geometry is commonly used when testing highly brittle materials such as rocks (Yoshitaka 2012), glass and ceramics (Lewis 1981) and nuclear graphite (Becker 2011a) for example. Furthermore, the technique is practical for situations where crack length measurements are not always possible (such as in high temperature test conditions) due to the fact that the SIF is crack length independent and no crack length measurements are required during testing (Attia 2010).

To date, however, several questions remain regarding the technique. The crack length independent SIF is not completely undisputed within the fracture mechanics community, as deviations from the crack length independent SIF have been observed (Fuller 1979, Baskaran 1985, Ebrahimi 1999, Ciccotti 2000a & Chevalier 2001, Becker 2011b).

The development of the DT technique is credited to the work undertaken by Outwater and Gerry (1969), Kies and Clark (1969) and William and Evans (1973). The load is applied in a four-point bend configuration at the one end (as shown in Figure 1), where the crack propagates through the centre of the specimen.

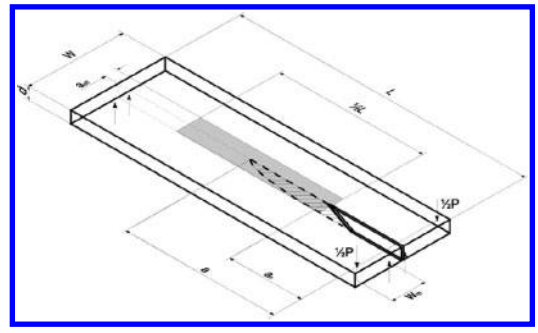

Figure 1. The DT layout and load configuration, (Becker 2011b).

The loading configuration is such that each specimen half, separated by the crack, is loaded in torsion. It is assumed that the compliance of the specimen is linearly dependent on the length of each torsion bar (i.e. the crack length) and that the unbroken ligament remains rigid during loading (Becker 2011b). This assumption, however, has been found to have implications on the crack length independent SIF; the deformation of the un-cracked ligament has been shown not to remain rigid (Becker 2011b) and large deflections at the load point result in a non-linear torsional compliance (Leevers et al.). Further reading on the DT geometry can be found by (e.g. Becker 2011a, Tait 1987, Evans 1972).

Several attempts have been formulated to model the geometry using the Finite Element (FE) method. Examples include Trantina (2006) who investigated

the DT geometry using a three-dimensional finite element model. An agreement was found between numerical and analytical obtained SIF over the middle of the specimen $0.18 < a/L < 0.78$ (for a specimen geometry $W = 3$). The work of Ciccotti et al. (Ciccotti 2000b & Ciccotti 2001) formulated a series of correction factors for a range of specimen geometry configurations to correct the deviations to the analytical solution.

Furthermore, Attia (2010) performed a three-dimensional FE analysis, evaluating for the optimum thickness of the DT geometry, and observed deviations between FE model and experimental data. The deviations have been attributed to the curvilinear crack front, which is typically modelled as a straight crack front in the FE environment.

These studies have however not investigated an overall optimum specimen geometry ratio that allows for a crack length independent geometry. Presented in this paper is the optimisation of the DT geometry which provides a crack length independent geometry. It is the aim to contribute to the understanding of the DT geometry and the use of this novel test configuration.

2 THE DOUBLE TORSION GEOMETRY

Figure 1 shows the DT geometry layout and the aforementioned loading configuration.

A linear compliance is obtained by assuming that the unbroken ligament remains rigid and only the cracked ligaments deform under torsion (Fuller 1979)

$$C(a) = \frac{y}{P} = \left(\frac{3w_m^2}{Wd^3\mu}\right)a \tag{1}$$

where y is the deflection caused by load P, w_m is the moment arm, d is the specimen thickness, W is the specimen width and μ is the shear modulus.

The strain energy release rate G is related to the derivative of compliance (mode I) assuming the crack extension area remains constant during crack propagation i.e., $dA = d \cdot da$. This leads to

$$G = -\left(\frac{dU}{dA}\right) = \frac{P^2}{2d}\frac{dC}{da} \tag{2}$$

where, U denotes the total strain energy release rate. According to Williams and Evans (1973), the relationship between the SIF (mode I) and the energy release rate is given by

$$K_I = \sqrt{EG} = PW_m\sqrt{\frac{3(1+\nu)}{Wd^4\Psi(d,W)}} \tag{3}$$

where Ψ is a thickness correction factor given by

$$\Psi(\tau) = 1 - 0.6302\tau + 1.20\tau e^{-\frac{\pi}{\tau}} \tag{4}$$

and $\tau(d, W) = 2d/W$ (Attia 2010).

As aforementioned, the crack front profile in the DT geometry is curvilinear. A crack front inclination

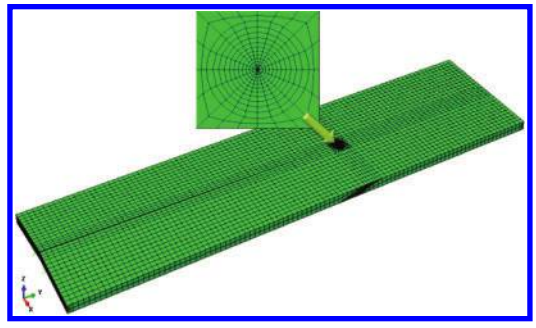

Figure 2. DT specimen meshed with quadrilateral hexahedral elements. A zoomed area around the crack tip showing a ring of element is also shown. Include is also specimen axis, x-axis the width, y-axis the length and z-axis the thickness of the specimen.

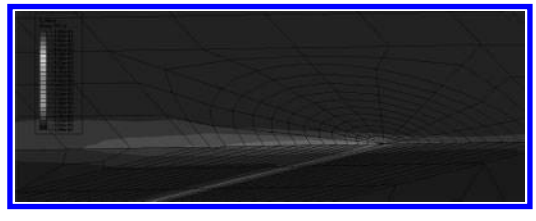

Figure 3. Inclined crack tip showing deformation stress, which signifies the crack opening.

is approximated by $c = \Delta a/d$, where Δa is the crack extension difference between the upper and lower surface of the test specimen (Becker 2011b). Furthermore, note that the SIF (in Eq. 3) is independent of crack length. It is this feature that allows for stable crack propagation in brittle materials.

3 FINITE ELEMENT MODEL

The DT geometry is analysed using ABAQUS version 6.10. In order to obtain optimum specimen geometry nine geometry configurations are considered. These include three different length to width ratios ($L/W = 2$, 3 and 4) and three different thicknesses to width ratios ($d/W = 0.06$, 0.08 and 0.1) where $W = 50$ mm. Each test geometry was analysed at five different crack length ratios ($a/L = 0.25$, 0.38, 0.5, 0.62, 0.75) generating 45 models in total.

3.1 *Mesh*

Each model simulated the entire DT geometry obtaining an average number of 6047 quadratic hexahedral elements (Figure 2). The mesh is refined mesh near the crack tip using a concentrated mesh with collapsed elements as illustrated along a vertical long-axis cross-section in Figure 3. This allows a better description of the strain field near the crack tip and has been validated against analytical solutions (Trantina 2006). Numerical solution values of the associated SIF are calculated using the contour integral method. The computed J-integral is converted to an equivalent SIF using

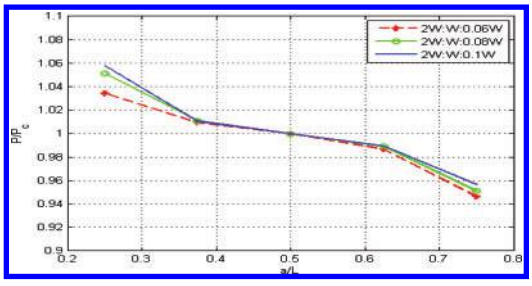

Figure 4. Normalised force vs crack length comparison of thickness of Length $L = 2W$.

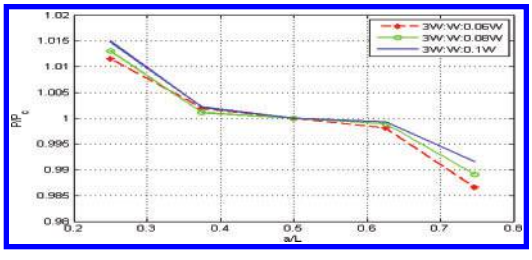

Figure 5. Normalised force vs crack length comparison of thickness of Length L = 3W.

Eq. (3) where J-integral is equivalent to G. A mesh refinement study was undertaken to ensure convergence of the numerical solutions.

3.2 *Boundary conditions*

The boundary conditions of the model assumed that the nodes near the loading points are constrained in the y direction and at the far side in the x, y direction (Figure 2).

To simulate the experimental setup of a four-point loading configuration a force couple is applied at one far end of the specimen. The resulting torsional moment is scaled to obtain a SIF equivalent to the $K_{IC} = 46.8\,\text{MPa}\sqrt{mm}$ (the fracture toughness of the PMMA).

In order to simulate a more realistic crack tip configuration, an inclined crack front of $c = 4$ was used (Figure 3). Contact was defined between the crack surfaces as tangential behaviour with 0.5 friction coefficient for rough surfaces.

3.3 *Evaluation of the crack length independent SIF*

The output parameters obtained for each model are the load point displacement y and the applied moment to obtain a SIF equal to that of the aforementioned PMMA fracture toughness. The applied moment can be seen as a concentrated load P with moment arm length w_m in Eq. (3). Since the SIF, i.e. K_I, is only a function of P in Eq. (3), it is possible to evaluate a crack length independent SIF only using P, normalised to P_c (the load at $a = 0.5L$).

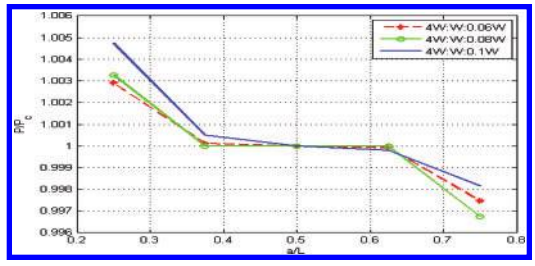

Figure 6. Normalised force vs crack length comparison of thickness of Length L = 4W.

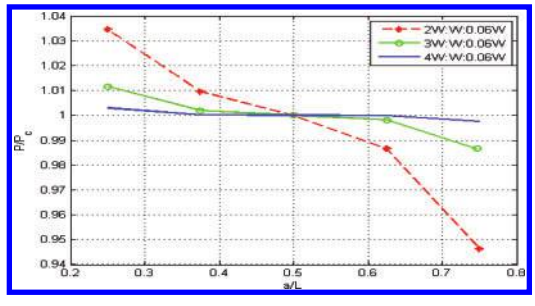

Figure 7. Normalised force vs crack length comparison of thickness of Length $L = 2W$.

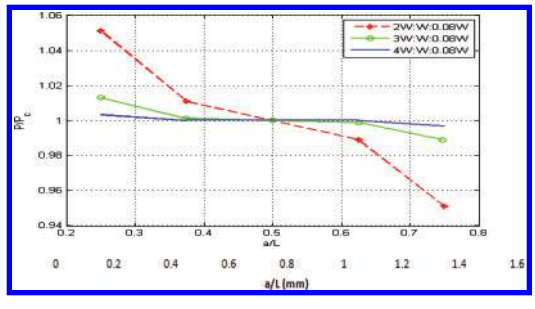

Figure 8. Normalised force vs crack length comparison of thickness of Length $L = 2W$.

4 RESULTS

Figures 4, 5 and 6 show the normalised force vs. crack length results for three different specimens length ratios of $2W$, $3W$ and $4W$ respectively.

Similarly, Figure 7, 8 and 9 show the normalised force vs. crack length results for three different specimen thickness ratios of $0.06W$, $0.08W$ and $0.01W$ respectively.

From Figures 4, 5 and 6 it can be seen that a thinner specimen configuration yields a more crack length independent geometry. Figure 5 for example, $L = 3W$, shows a relatively constant SIF between the range $0.37W$ to $0.75W$. Comparing Figures 7, 8 and 9, the thinner specimen configuration $d = 0.06W$ shows the constant SIF over middle of the specimen.

From Figures 7, 8 and 9 it can be seen that the specimen that is closest to producing constant SIF lies between $L = 3W$ and $L = 4W$ thickness.

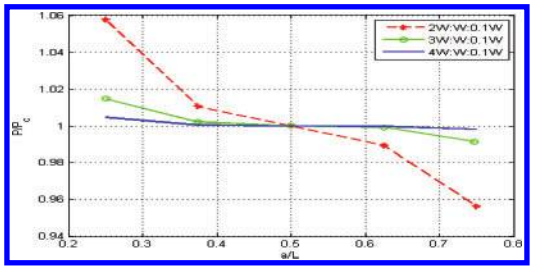

Figure 9. Normalised force vs crack length comparison of thickness of Length $L = 2W$.

Based on these two comparisons, involving length and thickness of the specimen geometries, respectively, we propose that the optimum specimen geometry should be of order $3.5W{:}W{:}0.06W$.

5 CONCLUSION

This paper investigated an optimum specimen geometry using nine different specimen geometry configurations. The analysis is undertaken in the FE environment to obtain a relationship between the SIF and crack length. An ideal specimen would yield a crack length independent SIF.

It is found that a thinner specimen results in producing constant SIF. It is found that a thinner specimen results in producing constant SIF. It is found that a thinner specimen produces a more constant SIF regime. Similarly, It was also observed that the longer specimen results in a more constant SIF regime. This is in agreement with Trantina (2006) and Tait (1987) who suggested that the SIF remains constant over $0.18 < a/L < 0.78$ range.

A comparison of the results suggests that an optimum specimen geometry exists around 3.5W:W:0.06W.

An experimental validation of residual stresses in weld clad pipelines

G. Schnier, J. Wood & A. Galloway
JW Analysis, UK

ABSTRACT: The nature and distribution of residual stresses are invariably critical for fatigue life with dissimilar material joints often inducing high tensile residual stresses. A fatigue-resistant concept of weld cladding process pipelines, producing compressive residual stresses, is under investigation to examine how these stresses may be influenced. Simplified weld cladding simulations have successfully illustrated the development and distribution of residual stresses through the joint. The study has highlighted the importance of accurate material data for clad and substrate materials with current analysis assumptions in a simple thick-walled pipe discussed. Experimental validation, using ICHD, measured residual stresses with depth on weld clad specimens, resulting in good correlation between simulation and experiment for a nickel-chromium-based superalloy clad on low alloy carbon steel as discussed. Future work, including a full 3D representation of the cladding process and a comparison of residual stress measurement methods, are also discussed.

1 INTRODUCTION

Residual stresses are typically described as the stresses in a body post-manufacture with no external loading or constraints present. Depending on the nature of these residual stresses, they can be beneficial or detrimental to the fatigue life of a component. It has been found that many machining processes induce tensile residual stresses which in turn shorten fatigue life. Tensile residual stresses also arise in dissimilar joints and can be as high as yield for the materials in question. From a fatigue perspective, it is desirable to maintain compressive residual stresses to increase fatigue strength, particularly at the surface of a component where operational stresses are often at their highest.

Residual stresses are elastic and self-equilibrating in nature and arise from various mechanisms in the case of dissimilar weld cladding: a surface "heat-treatment effect" due to materials varying with temperature affecting cooling rates and constraint levels, a "pre-heat shrink-fit effect" accounting for effective shrinking of the cladding relative to the substrate affected by material and temperature dissimilarity and "spatial and temporal variation" of the clad deposition process and subsequent cooling causing changes in microstructure through phase transformation and chemical reactions.

This paper presents results from initial simplified 2D models validated with experimental residual stress measurements and discusses the progression to a full 3D model. As will be shown, pipeline weld cladding and dissimilar material joints in general will also display significant discontinuity stresses at the interface between the dissimilar materials. Fatigue cracking may therefore occur sub-surface.

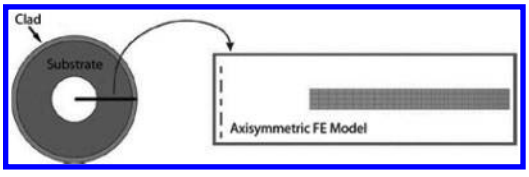

Figure 1. Axisymmetric FE Model.

2 DISSIMILAR JOINT SIMULATION

The weld clad pipeline model currently takes the form of a thermal transient stress analysis of a two-dimensional axisymmetric finite element model (Fig. 1). A simplified process of an entire clad layer being deposited onto the outer diameter of a pre-heated thick-walled pipe at melt temperature at time $t = 0$ seconds has been employed as an initial study. This modelling technique assumes that there is no variation in temperature or stress field in the axial and hoop directions as a function of time. The entire component was then subjected to slow cooling on the inner and outer surfaces using a convective heat transfer coefficient $h = 10\,\mathrm{W/m^2K}$ and a bulk temperature of 25°C, with latent heat effects being neglected. The *CAX4T* Abaqus element type was utilised with bi-linear displacement and temperature shape functions.

The radial edges of the model were insulated to simulate no axial heat transfer and plane strain conditions applied on the radial lines (Fig. 2).

Although this model is a simplification of a process with spatially and temporally varying deposition, it is representative of methods such as evaporative deposition or spray coating followed by sintering. In the following sections it will be shown however that it also

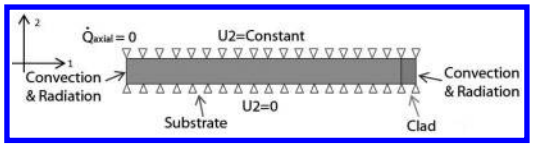

Figure 2. Axisymmetric Model Boundary Conditions.

provides good correlation to experimental measurements for the spatially and temporally varying weld deposition process used.

An elastic-perfectly plastic material model was assumed with temperature dependent thermal and mechanical material properties. Focus was placed on coefficient of thermal expansion, specific heat, thermal conductivity, Young's modulus and yield stress. These properties primarily govern the modelling of the thermal event, degree of constraint and therefore the development of residual stresses (Ahmed et al. 2007), with further contributing factors discussed in the reference given. Poisson's ratio and emissivity were assumed to remain constant. The nature of residual stresses differs depending on the state of a component, as discussed by Withers and Bhadeshia, with misfit resulting from different parts, phases and regions highlighted as the key characteristic influencing residual stresses (Withers & Bhadeshia 2001). Phase transformations in steels have been shown to influence residual stress development in X70 pipeline steel (Onsoien et al. 2010) for example.

Figure 3 shows a large discontinuity in the stress distribution in the vicinity of the low alloy carbon steel substrate and clad interface for both pre-heat and material combinations, with a change from compressive to tensile stresses. At the idealised interface between the substrate and clad there is a step change in the stresses with the nickel-chromium-based superalloy clad showing a reduction in residual stress, which remains significantly tensile throughout the clad. The form of residual stress graph for the nickel-chromium-based superalloy clad is indicative of yielding and reflects the elastic-perfectly plastic model used.

The stainless steel clad simulation results on the other hand show a further increase in residual stress in the clad, which is unexpected and is contrary to the experimental results obtained, which show a similar value of residual stress throughout the clad but compressive in nature.

3 EXPERIMENTAL VALIDATION

3.1 *Background*

Incremental centre hole drilling (ICHD) is a relaxation technique used for residual stress measurement through the measurement of local displacement in the vicinity of a drilled hole (ASTM International 2008). Material removal through the drilling of a hole into a component allows the consequent movement of remaining material to be measured and residual stresses to be deduced. This occurs most commonly

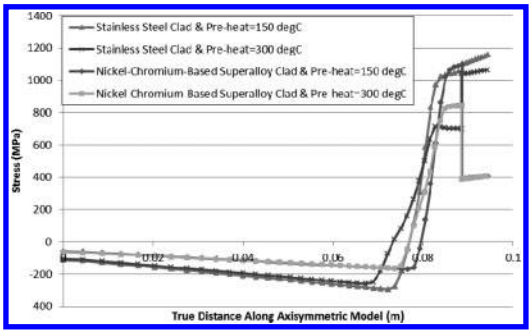

Figure 3. Cladding Simulation: Hoop Stress Comparison.

through the application of a strain gauge to obtain strain values throughout the material removal process, which can be converted into stress values. Through the drilling of the hole, additional stresses can be induced, however the application of high-speed air-driven turbines operating at speeds up to 400,000 rpm (Grant et al. 2006) minimises this effect.

3.2 *Hole-drilling method*

Specialised three element strain gauge rosettes are applied to the surface after appropriate surface preparation techniques. The method of surface preparation is dependent on the initial roughness of the surface and could require machining prior to finishing with fine grain sandpaper. Wiring and balancing of the gauges follows the laying of the gauge after which the fixture can be applied to the component by means of cementing the detachable legs prior to assembling the drilling kit.

Strain readings are then recorded at incremental depths, with accuracy of the readings decreasing with increasing depth due to the travelling further from the applied strain gauge on the surface. The maximum depth to which strain readings can be used for the purpose of residual stress measurements is to one half of the diameter of the drilled hole (Grant et al. 2006).

Residual stress measurements were obtained for both cylindrical and rectangular specimens. On the cylindrical specimens, gauges were installed at the centre of the outer diameter of the component at two diametrically opposed circumferential locations to demonstrate variability in cladding and measurement process. For the rectangular specimens, gauges were applied along the centre-line to allow effects of global bending to be deduced.

3.3 *Strain measurement conversion*

Three main conversion methods exist for the conversion of strain measurements, namely the Equivalent Uniform Stress (EUS), Power Series and Integral methods (Schajer 1988). Schajer notes that the EUS and Power Series are approximations of the Integral method, which provides the most acceptable interpretation of uniformly varying residual stresses through

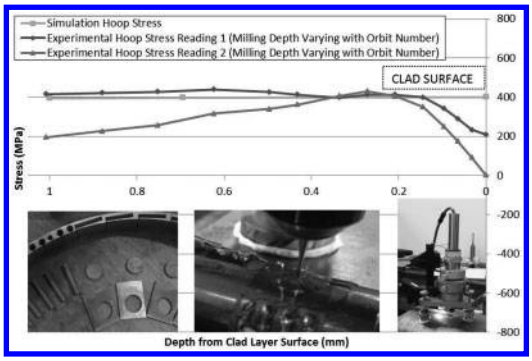

Figure 4. Simulation & Experimental Results Comparison: Nickel-Chromium-Based Superalloy Clad & Pre-heat Temperature = 150°C (EDM extraction of thermal property testing specimens & residual stress measurement equipment also shown).

applying the least smoothing of results and is therefore applied as the standard calculation procedure for residual stresses using ICHD.

4 RESULTS

Figure 4 shows good agreement between the nickel-chromium-based superalloy cladding simulation results and experimental measurements using ICHD. The two sets of experimental results are for two different diametrically opposed positions on the centre of the cylindrical specimen. The difference in the experimental results is indicative of the effect of process variability. The reduction in both sets of experimental results over the first 200 microns will largely be due to the machining of the weld profile to provide a flat surface for strain gauging.

4.1 *Comparison of surface preparation techniques*

Three surface preparation techniques were used in preparation for applying the strain gauge. The first was the use of a hand-held compressor driven stone grinder followed by fine finishing using P400 fine sand paper. The second technique was CNC milling at 500 rpm using 10 μm increments to a depth of 0.5 mm for the nickel-chromium-based superalloy clad and 0.7 mm for the stainless steel due to varying clad profiles. Lastly surface preparation using a PC-controlled machine tool beginning at 16 μm per orbit, decreasing to 8 μm and finally 2 μm for the final two orbits was applied to minimise machining effects.

From the results shown for a nickel-chromium-based superalloy clad pipe, it can be seen that in comparing hoop stress values for the three surface preparation techniques the hand grinding technique gives a highly inaccurate representation (Fig. 5). Results for the milling and PC-controlled surface preparation techniques produce a greater degree of correlation as would be expected, with discrepancies arising especially close to the surface however.

Focus is placed on hoop stress values in the following discussion as this stress component presents the greatest contribution to the final stress state.

The results shown for the stainless steel clad pipe (Fig. 6) show a greater variation in the CNC surface preparation method with alarming gradients shown in one milling measurement. This is most probably due to user technique, however the requirement for careful surface preparation is clear.

Overall, the residual stress values for the stainless steel clad material provide a tighter band of results with greater uniformity of stresses over the 1 mm depth shown. From these results, it can be concluded that there are greater effects due to process variability in the case of nickel-chromium-based superalloy clad.

4.2 *Errors associated with ICHD*

As mentioned in the previous sections, errors arising through the ICHD method can heavily influence strain readings and hence residual stress values. Strain measurement errors can also arise due to user technique, instrumentation errors and additional strains induced through material removal, while hole measurement errors in both the depth and diameter, tapering of the hole and any roundness in the bottom of the hole can influence calculated stress values. Differences can also

arise from using different strain gauge types which was the case in the last surface preparation technique of milling depth varying with orbit depth.

Furthermore, errors can arise from deviations in hole roundness and eccentricity errors in the location of the hole with respect to the strain gauge along with material constant errors arising from Young's modulus and Poisson's ratio values applied in the strain-to-stress conversion process (Schajer & Altus 1996).

4.3 *Additional considerations*

An area that requires careful consideration with regards to residual stresses is that of machining. Any machining of the component after cladding will modify the self-equilibrating residual stress distribution in a thin surface layer and for this reason care must be taken to ensure that any beneficial compressive residual stresses effects are not removed by such an operation. Machining can induce tensile residual stresses, which may also increase stress-corrosion cracking susceptibility in some materials, while also decreasing fatigue life. This was emphasised in a study in 1969 (Paxton & Procter 1969), highlighting the need for careful consideration of machining processes, through experimental procedures, to ensure an acceptable residual stress state while maintaining adequate corrosion resistance. Investigation into electro-polishing is underway to determine whether this technique, minimising stress state adjustment, can provide further increased accuracy.

Another aspect which could alter surface residual stresses is that of the thermal environment present at the surface during cooling.

Optimal depth increments have been discussed for differing strain gauge rosette radii and hole radii (Stefanescu et al. 2006). Arbitrary values were applied in this study due to the lack of measuring such precise increments, however in future it would be recommended that a method of determining and measuring such incremental values is employed with reference to the work noted above.

5 DISCUSSION ON INFLUENCING RESIDUAL STRESSES

5.1 *Pre-heat temperature*

The effect of pre-heating the substrate to a specified uniform temperature before commencing with the joining process was investigated using two temperature values. The purpose of pre-heating the substrate serves as a method of reducing the heat sink effect and a higher pre-heat would be expected to reduce residual stress levels. A higher preheat however will also increase the pre-heat shrink-fit effect referred to in the introductory section of this paper.

Results show that a lower pre-heat temperature for stainless steel clad specimens results in a higher residual stress level, desirable both economically and for fatigue purposes, however in the case of the nickel-chromium-based superalloy a lower residual stress occurred with a lower pre-heat temperature.

5.2 *Substrate geometry*

The investigation of substrate geometry effects suggests that there are no great variations in residual stresses in the clad pipe and rectangular specimen. Results for low alloy carbon steel clad with stainless steel on the cylindrical and rectangular specimens at a pre-heat temperature of 300°C in particular demonstrated that equal residual stress levels are attainable in both geometries providing the thermal transient event is maintained for the differing substrate geometry.

5.3 *Post-weld stress relief*

Post-weld stress relief was unsuccessful for the nickel-chromium-based superalloy clad case, thought to be due to the large mismatch in material properties between these materials. Results for stainless steel clad demonstrate a significant decrease in residual stress values post-stress relief, as well as an almost equi-biaxial stress field further beneficial to fatigue life. The stainless steel and low alloy carbon steel are both high-strength materials with similar metallurgical structure and material property values for CTE and yield stress. However, clearly in the case of stainless steel clad stress relief is not desirable as it would lower the high level of beneficial compressive residual stresses.

6 CONCLUSIONS

A simplified 2D simulation model of cylindrical dissimilar weld clad process pipeline specimens has shown good agreement with experimental residual stress measurements for nickel-chromium-based superalloy clad on low alloy carbon steel. The lack of agreement for a stainless steel clad has prompted an experimental programme to determine more accurate temperature dependent mechanical property data to increase residual stress representation in the FE model. Published data availability, even for wrought material, in this case was very limited neglecting the phase change present in stainless steel clad and substrate materials assuming instead a linear extrapolation beyond 400°C.

Simulation models using a step change in material properties at an idealised interface employ a significant approximation to reality. Studies (not reported herein) reveal a variation in elemental composition and grain structure across such junctions, reflected in micro- and nano-hardness measurements. It is likely therefore that other properties used in such simulations will also show a transition (albeit over a relatively short distance). This will have the effect of reducing discontinuity stresses and eliminating any theoretical singularities that may be picked up with very fine finite element meshes.

Experimental residual stress measurements concluded that surface preparation techniques are critical to ensure that the residual stress state in a component is not further altered prior to measurement, therefore rendering harsh hand grinding unacceptable. Additional sources of error were discussed and the sensitivity of readings with user technique highlighted.

Lastly a discussion on influencing residual stresses revealed that a lower pre-heat temperature was more beneficial in the stainless steel and low alloy carbon steel combination, however this was not found to be the case for nickel-chromium-based superalloy and low alloy carbon steel. Substrate geometry effects were found to be negligible and so residual stresses should be attainable in both the cylindrical and rectangular specimens at similar values, while stress relief was unsuccessful in the case of nickel-chromium-based superalloy cladding, although achievable with stainless steel clad material. Experimental variability in the cladding process revealed a much greater effect in the case of nickel-chromium-based superalloy cladding in diametrical measurements and along the centre line of the clad plate.

7 FURTHER WORK

Although acceptable representations of the residual stress states in the dissimilar joint were obtained for the nickel-chromium-based superalloy clad, it is important that the model is developed to include a more accurate representation of all relevant temperature dependent material properties. This will provide a better representation of the measured results for a stainless steel clad. In addition, although a simple axisymmetric idealisation has shown good agreement with experiment for the nickel-chromium-based superalloy clad, a 3D model taking into account both spatial and temporal process variation is underway. Sequential deposition of the clad material is currently being investigated in the 2D model and this feature of the process will also be included in the 3D simulation.

It is recognised that it is important in such simulations to capture the thermal behaviour of the joining process (Smith et al. 2011) and so calibration of the 3D simulation will be carried out using extensive temperature information obtained during the cladding process, which also reflects the weld inter-pass temperature used.

Further work is also underway to examine the use of functionally graded material properties in dissimilar joints in an effort to reduce the level of sub-surface discontinuity stresses whilst retaining the benefit of any compressive residual stresses that may result in the clad layer. The metallurgy of the joint will also be further examined with emphasis placed on the influence of weld parameters on joint metallurgy.

Due to limitations of ICHD it would be desirable to develop finite element models calibrating the residual stress state further into the component. Alternatively the deep-hole drilling method could be investigated providing residual stress measurements to depths of up to 750 mm (VEQTER 2013). Further investigation of surface preparation techniques will allow the curvature of cylindrical specimens to be accounted for such that gauges will be laid on a rounded surface as opposed to the milled surface being completely flat.

Assessment of fracture toughness in strain hardening cement-based composite (SHCC) made from fine and coarse sand

S.C. Paul & G.P.A.G. van Zijl
Stellenbosch University, South Africa

ABSTRACT: This paper investigates the effect on fracture toughness of matrices intended for strain hardening cement based composite (SHCC), using very fine sand (size up to 0.3 mm, subsequently referred to as FS) and local coarse sand (size up to 2.36 mm and 1.7 mm, CS). ASTM E-399 was followed for measuring fracture toughness of the matrices. A series of characterising tests are also reported, including 100 mm cube compressive strengths, 100 × 200 mm cylinder responses for the E-moduli and flexural strength from 100 × 100 × 500 mm notched beams tested in three point bending. The matrix fracture toughness K_{IC} was determined from the flexural response of the FS and CS beams together with the observed crack propagation in both matrices. The maximum value for K_{IC} was found to be 1.12 MPa.m$^{1/2}$ and 0.95 MPa.m$^{1/2}$ respectively for the CS and FS mortar matrices, compressive strengths of 32 MPa (CS) and 36 MPa (FS), and E-moduli of 17 GPa for both FS and CS. Finally, by performing direct tensile tests on both FS and CS matrices containing maximum 2.2% and 2% by volume of polyvinyl alcohol (PVA) fibres, the formation of multiple cracks were verified for both sand types. The purpose of the study was to determine the influence of the particle size on the fracture toughness as well as the relevant parameter of the SHCC matrix. The potential of using more realistic sands as aggregate in these high performance cement-based materials is shown by the results of the research presented in this paper.

1 INTRODUCTION

In the last twenty years much research has been conducted on high performance cementation materials such as strain hardening cement-based composites (SHCC) and of most importance was the improvement of structural durability. Structural durability depends on the performance of materials under various circumstances and until now such knowledge is limited. Much research is needed to fill these gaps, especially due to lack of understanding of the micromechanical behaviour of SHCC. Pseudo strain hardening (PSH) is one of the most important characteristics of SHCC, associated with multiple, fine cracks. Due to this crack control, higher strain and stress can also be found in SHCC (Li et al. 2002, Sahmaran et al. 2008, and Paul & van Zijl, 2012b). In SHCC, PSH can be achieved by inclusion of relatively low volumes of micro fibres (polyethylene (PE), polyvinyl alcohol (PVA), etc.). Good dispersion of micro fibres in SHCC is essential and depends on the particle size, as large particles push and displace the fibres in a random way (Liu et al. 2011).

An important requirement for multiple crack formation is steady-state cracks rather than Griffith type of cracks. The latter lead to fibre breakage or premature pull-out from the matrix and as a result, brittle failure of structures occurs (Li, 2003). A sufficient amount and homogeneous distribution of fibres provides enough reinforcement to bridge cracks and transfer the load to the next weakest point in the matrix. This usually requires a relatively low fracture toughness of the matrix to ensure that the energy required for fibre pull-out exceeds the crack tip toughness by a sufficient margin.

The common practise is to use very fine sand (FS) (particle size less than 0.3 mm) in SHCC as the main aggregate (Li, 1993, Wittmann et al. 2009, and Adendorff et al. 2009) together with a large volume of cement and fly ash. Special attention is needed in processing this kind of FS and therefore introducing coarse sand (CS) in SHCC could be a cost-effective alternative. However, the increased particle size leads to higher fracture toughness of the matrix (Paul & van Zijl 2013a), posing a challenge to retaining the multiple crack formation.

In SHCC the fine cracks offer significant potential of structural durability by retarding ingress of deleterious substances under service conditions, for instance by protection of embedded reinforcing steel in concrete. This paper is limited to the fracture toughness of SHCC matrix made from both FS and CS together with PSH behaviour in direct tensile testing as well as in flexural testing. Part of this work has already been published in Paul & van Zijl (2013a, 2013b) and is part of the durability assessment of SHCC in a large scale

research project carried out at Stellenbosch University and further inputs will be reported on in subsequent proceedings.

2 POTENTIAL OF SHCC

SHCC originated in 1990 for its extraordinary performance of high ductility as well as strength (Li and Wang 1990, Li 1992, 1993) relative to conventional concrete. Higher ductility of concrete is an important protection mechanism of structures against tensile action in hazardous environments, seismic action, wind load, tidal load, etc. Typically ultimate strain values of normal concrete (NC) range between 0.015–0.02%, while more than 4% strain can be obtained for SHCC (Sahmaran et al. 2008, Paul and van Zijl 2013,b). Until now SHCC has been used in several countries as a repair material for bridge decks, tunnels, retaining walls and offshore structures. Full scale SHCC structures are not yet generally constructed and the reasons behind it may be the high material cost and limited information available on SHCC performance as a relatively new material.

3 FRACTURE TOUGHNESS TEST

In most materials the failure mechanism of crack development can be examined by fracture mechanics. However the fracture mechanics of quasi brittle materials like concrete is not yet clearly understood due to the complexity of concrete, and its properties depending on many factors. The fracture toughness of concrete provides a quick assessment of the safety of a concrete structure at the post cracking stage.

Cracks in concrete structures are major sources of reduced durability of the structures. They allow quick entry of liquids and gases which may for instance lead to corrosion of the embedded steel. A damage zone starts to form in the structure when the tensile strain in the structure exceedes the concrete capacity. Using a numerical technique like the finite element method, and experimental tests such as to characterise the stress-crack mouth opening displacement (CMOD) curve (see Figures 1 and 2), it is possible to analize the damage zone and structural behaviour theoretically (Hillerborg 2004).

The CMOD of a flectural specimen (Figure 1) is used to calculate the fracture toughness of concrete. According to the recommendations by ASTM E399-09, each specimen is verified under certain conditions. To establish valid matrix toughness, conditional results of K_{IC} need to be calculated from the Load-CMOD curve. In the Load-CMOD curve a best-fit straight line first needs to be drawn to obtain the slope of the curve ($\tan\theta$) after which a second best-fit line with compliance 5% greater than that of the initial line needs to be drawn. If the maximum flexural load (P_{max}) falls in between these two lines, the matrix toughness can be calculated using the P_{max} value. If the P_{max} value falls outside these two lines, the load must be calculated using the second straight line connecting

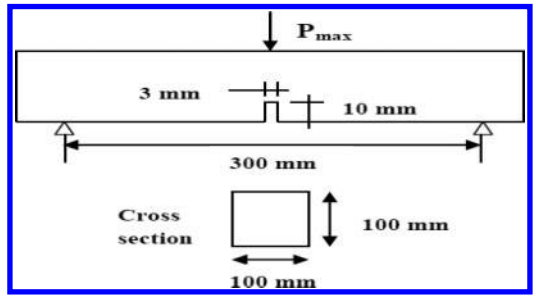

Figure 1. Flexural test for fracture energy.

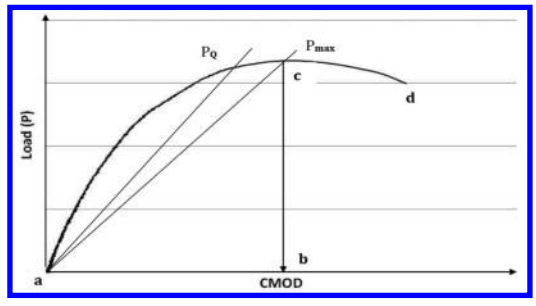

Figure 2. Calculation of fracture energy from the flexural specimen response.

point on the curve (P_Q). For the details see Figure 2. Furthermore, if the ratio of $P_{max}/P_Q < 1.1$, P_Q will be used to calculate K_Q otherwise the test is invalid. To recheck the validity of K_{IC}, it is also necessary to check that $2.5(K_Q/\sigma_y)^2 < b$ as well as the specimen ligament (d-a), where σ_y is the yield strength, b is the specimen width, d is the specimen depth and a is stable crack growth. If the above condition is satisfied the K_Q is valid and is equivalent to K_{IC} (ASTM E399-09). The reason of aforementioned test validity may be because this test method and equations are empirical, i.e. correlated from many experimental results to give reasonable results of K_{IC} despite the simple nature of the test method. Eqs (1) to (3) are used to calculate K_{IC} for both the mortar and SHCC specimens.

$$K_{IC} = \frac{3P_{max}S}{2bd}\sqrt{\pi a_1}F(x) \quad (1)$$

where P_{max} is the valid peak load
S is the specimen loading span
b is the width of beam
d is the depth of beam
a_1 is the effective critical crack length $= a_0 +$ stable crack growth at peak load

$$F(x) = \frac{1}{\sqrt{\pi}}\frac{1.99 \quad x(1 \quad x)(2.15 \quad 3.93x + 2.7x^2)}{(1+2x)(1 \quad x)^{3/2}} \quad (2)$$

$$x = \frac{a_1}{d} \quad (3)$$

Table 1. Materials used in this study.

Materials	FS, CS 1 (kg/m^3)		FS, CS 2 (kg/m^3)	
	SHCC	Mortar	SHCC	Mortar
Cement	450		390	
Fly-ash	670		670	
Sand	550		550	
Water	395		390	
Fibre	28.6, 26	–	26	–
SP	2.7, 3.6	–	3.6	–
VA	1.13	1.35	1.35	1.35
AEA	0.45	0.45	0.45	0.45

Table 2. The flow value and mechanical properties of the matrixes at 28 days (CoV (%) in brackets).

Type		Flow (mm)	f_{cu} (MPa)	E-mod (GPa)
FS-SHCC	1	170–200	39 (4%)	20 (12%)
	2	200–230	29 (5%)	13 (22%)
CS-SHCC	1	170–200	35 (2%)	18 (4.4%)
	2	195–225	25 (2%)	14 (7%)
FS-Mortar	1	200	36 (4%)	17 (0.1%)
	2	205	32 (7%)	17 (11%)
CS-Mortar	1	220	32 (6%)	17 (9%)
	2	225	29 (3%)	15 (11%)

Finally the matrix crack tip toughness J_{tip} can be calculated from K_{IC} and matrix modulus of elasticity (E_m) value as follows

$$J_{tip} = \frac{K_{IC}^2}{E_m} \quad (4)$$

4 EXPERIMENTAL METHODOLOGY

4.1 *Materials compositions*

The compositions of materials used in this study are shown in Table 1. CEM I 52.5 cement together with class F Fly ash were used as binder of the matrix. ASTM F95 graded fine Phillippi sand with maximum size of 0.3 mm was used as FS and local sand with maximum particle size up to 2.36 mm (in mix 1) and 1.7 mm (in mix 2) were used as CS. Dynamo Sp1 super plasticizer (SP), viscous agent (VA), air-entraining agent (AEA) and PVA fibre ($L_f = 12$ mm and $d_f = 0.04$ mm) were also used in this study.

4.2 *Specimen specifications*

In determining the matrix fracture toughness 22 beam specimens with dimention of $100 \times 100 \times 500$ mm^3 were prepared from both FS and CS. Another set of 16 specimens were prepared from FS-SHCC and CS-SHCC to compare the matrix toughness with and without fibre. Both mortar and SHCC cubes (100 mm) and cylinders (100 mm diameter, 200 mm long) were also made to determine the compressive strength and E-moduli of the matrices. From both SHCC mixes small dumbbell shaped specimens with a cross section of $30 \pm 2 \times 16 \pm 2$ mm^2 in the 80 mm gauge length were made for the direct tensile test.

4.3 *Specimen preparation and testing*

After mixing both mortar and SHCC, small slump flow was measured as given in Table 2. All specimens were demoulded after 48 hours, after which specimens were kept in a water curing tank at 21 ± 3°C until the testing day (28 days). In case of dumbbell specimens, the total curing period was 7 days, after which specimens were air dried until the 14 days of testing. All flexural beams were notched (3 mm width and 10 mm length) at the bottom surface before testing as is shown in Figure 1.

A Z250 Zwick materials testing machine was used to perform flexural and direct tensile tests. For determining the compressive strength and E-modulus, a contest materials testing machine was used. In case of the flexural test, a constant position control rate of 0.005 mm/s was maintained for all specimens while for the direct tensile test, a constant deformation rate was 0.0075 mm/s. In the dumbbell specimen the gauge length was 80 mm for measuring the tensile strain of the SHCC matrix.

The fracture energy obtained from the area under the stress vs CMOD curve has been shown to be a simple and accurate method (Byung-Hwan et al 1999). The fracture energy was calculated as the area under the ac curve in Figure 2 (where on the y axis stress calculated using equation provided for the three point bending test was used instead of load) where c is the ultimate stress point. The stress vs CMOD curve represents the total amount of energy absorbed by the specimen before failure in flexure. The area under the curve depicts energy per unit volume, absorbed by the whole specimen. It is worth mentioning that failure of the mortar specimen in the flexural test was sudden after reaching the ultimate stress. So the point d was not considered to calculate the fracture energy as the matrix behaviour is completely different after reaching the point c. Simpson's rule was used to calculate the area under the ac curve.

5 EXPERIMENTAL FINDINGS

5.1 *Compressive strength and E-modulus properties of the matrixes*

The 28 days mechanical properties of compressive strength (f_{cu}), E-modulus (E-mod) of the mortar and SHCC matrixes with their coefficient of variations (CoV) are shown in Table 2. In both cases, mix 2 of mortar and SHCC show higher slump flow than the mix 1. Mix 2 has lower f_{cu} and E-mod values than

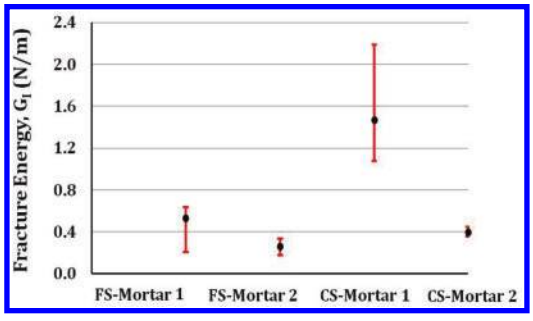

Figure 3. Variation of fracture energy (G_I) obtained from FS-Mortar and CS-Mortar matrix.

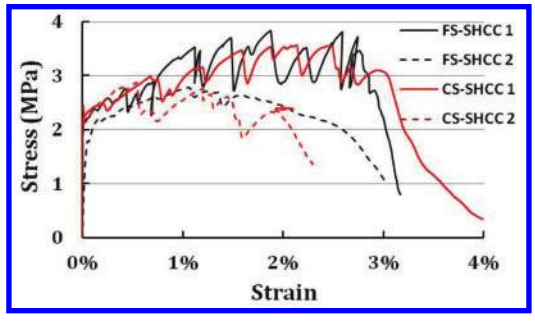

Figure 4. Stress-strain response of SHCC specimens in direct tensile test.

Table 3. Matrix fracture toughness (K_{IC}), crack tip toughness (J_{tip}) and fracture energy (G_I).

Type		K_{IC} (MPa.m$^{1/2}$)	J_{tip} (J.m^2)	G_I (N/m)
FS-Mortar	1	0.824	0.04	0.53
	2	0.95	0.053	0.26
CS-Mortar	1	1.12	0.080	1.47
	2	1.02	0.074	0.40
FS-SHCC	1	1.87	0.18	–
	2	2.48	0.48	–
CS-SHCC	1	1.61	0.15	–
	2	2.15	0.33	–

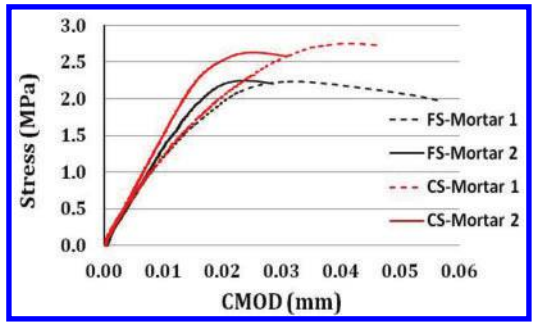

Figure 5. 28 days flexural testing response of mortar specimens.

mix 1, ascribed to the higher water-binder ratio of mix 2.

5.2 *Fracture energy of the matrix*

Figure 3 illustrates the variations of fracture energy for two different matrix types for both FS and CS-Mortar. In both matrices, mix 2 has lower fracture energy than mix 1. Higher variation of fracture energy was observed in both mix 1 matrices. Also, CS causes a higher fracture energy of the matrix.

5.3 *Fracture and crack tip toughness of the matrix*

Whether strain hardening is achieved depends strongly on the matrix toughness, as expressed by the crack tip toughness J_{tip}, and on the bond τ between the matrix and fibres. No direct measurement of J_{tip} has been attempted in this study. Eqs. 1 to 4 together with E-mod obtained for different matrices were used to calculate fracture and crack tip toughness. Matrix fracture toughness together with the crack tip toughness and fracture energy of the matrices are shown in Table 3.

From Table 3 it is clear that the fibres in the matrix lead to higher K_{IC} and J_{tip} values. Since the K_{IC} value is related to the P_{max} (in eq 1), lower P_{max} values of FS-Mortar have corresponding lower K_{IC} values than the CS-Motar. However in SHCC higher P_{max} values of FS-SHCC cause higher values of K_{IC} and J_{tip}than the CS-SHCC. Note that, in the test validity check (section 3), 10 out of 11 specimens from FS-Mortar and 7 out of 11 specimens of CS-Mortar satisfied the conditions mentioned in section 3. The CoV was also higher in case of CS-Mortar. In SHCC, almost all the FS-SHCC and CS-SHCC specimens satisfied the conditions.

5.4 *Direct tensile test response of SHCC specimens*

Figure 4 shows the typical stress-strain curve obtained from the direct tensile test of SHCC dumbbell specimens at 14 days. Note that these are typical individual responses and not average or best responses. The average ultimate tensile strengths of 3.61 MPa and 2.67 MPa were found for FS-SHCC 1 and 2. In case of CS-SHCC 1 and 2 maximum 3.64 MPa and 2.76 MPa ultimate tensile strengths were found. Maximum 3.4% tensile strain was observed for FS-SHCC 1 at 14 days and minimum 1.52% was observed for CS-SHCC 2. A lower number of cracks and larger crack widths were found in CS-SHCC compared to FS-SHCC. More detailed results of tensile strength and strain can be found in Paul & van Zijl (2013b).

5.5 *Flexural test response of mortar and SHCC specimens*

As it has already mentioned, the beam specimens were used to determine the G_I and K_{IC} values. Flexural testing of the notched beam specimens were performed. Figures 5 and 6 show the stress vs CMOD responses of the mortar and SHCC specimens. Note that these are

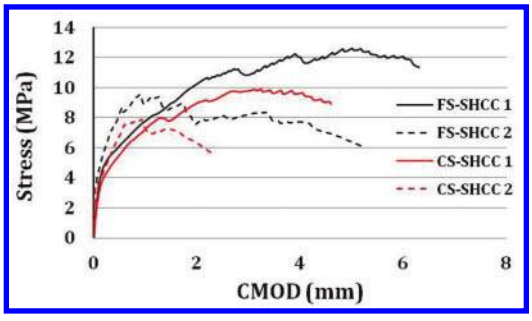

Figure 6. SHCC specimens under flexural stress vs CMOD.

Table 4. 28 days ultimate flexural strength (f_{fl}) of mortar and SHCC matrix.

Type		FS f_{fl} (MPa)	FS CoV (%)	CS f_{fl} (MPa)	CS CoV (%)
Mortar	1	2.34	10	3.41	9.4
	2	2.43	5.36	2.62	1.8
SHCC	1	11.5	8.5	9.24	6.65
	2	10.36	6.81	7.47	10.04

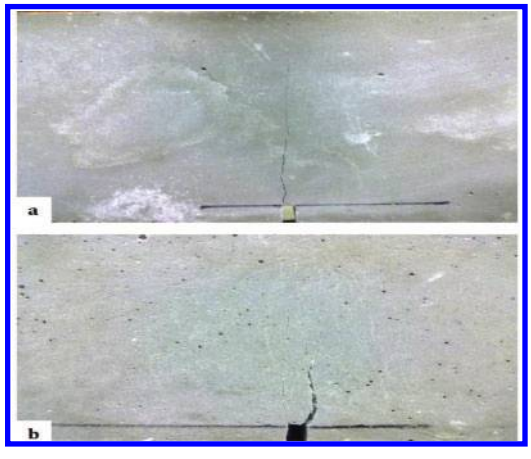

Figure 7. Crack growth in Mortar (a) and SHCC (b) specimens during flexural test.

typical individual responses and not average or best responses. In case of the mortar, specimens with CS show higher flexural strength (see Figure 5) than the FS specimen and for SHCC matrix it is vice versa. It can be explained by the presence of different particle sizes in CS than the FS which improve the matrix interlocking behaviour. Typically aggregate locking actions provide the crack bridging capacity in plain concrete, but additional crack bridging actions are introduced by adding fibres to concrete (Li et al. 1993). Table 4 shows the ultimate flexural strength (average and CoV (%)) of both mortar and SHCC matrices.

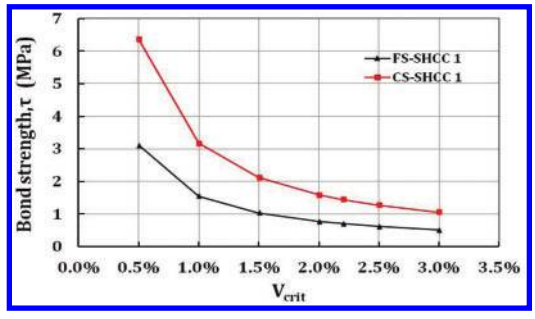

Figure 8. Bond strength vs critical fibre volume.

5.6 *Crack growth in mortar and SHCC specimens*

In most of the mortar specimens, only one crack (see Figure 7a) in the notched vicinity appeared close to the ultimate state and after that specimen failed abruptly. On the other hand, in SHCC specimens multiple cracks were observed in the vicinity of the notches and beyond (see Figure 7b).

5.7 *Bond strength of SHCC matrix*

For a particular mix of SHCC the bond strength (τ) was calculated for FS and CS-SHCC 1 by using the 28 days tensile strength, as well as E-mod and J_{tip} values from FS and CS-Mortar 1. Details of the calculation procedures can be found in Paul & van Zijl 2013a. The results obtained for τ with respect to V_{crit} are shown in Figure 8. No direct test was performed to calculate the τ values. The shown τ values are lower for an increase in fibre volume. Also CS shows higher bond than FS. This higher bond strength of CS leads to fibre breakage in the CS SHCC specimens and results in lower strain and number of cracks. To achieve higher strain and multiple cracking behaviour of SHCC, lower bond strength of the matrix is required so that fibres do not break, but rather pull out from the matrix.

6 CONCLUSIONS AND RECOMMENDATIONS

To achieve multiple cracking and PSH behaviour of SHCC, a matrix with low fracture toughness of the matrix relative to fibre pull-out resistance is required. The fracture properties of the SHCC matrix produced from two different types of sand and two different mixes have been reported in this paper. The outcome of this study may contribute to the knowledge of typical fracture toughness of SHCC matrices and may also help to predict the PSH behaviour for different particle sizes in the matrix. Based on the results of this study, the following conclusions can be made:

PSH behavior can be achieved with local CS. However, the larger particle size of CS leads to higher fracture toughness of the matrix. For both CS-Mortar and CS-SHCC higher fracture toughness and lower E-moduli were found. Higher crack tip toughness was found for the CS matrices than for the FS matrices.

Using fibre in both types of mortar matrices increased the fracture and crack tip toughness significantly since the crack growth rate in SHCC specimen is much lower than the mortar specimen.

Lower ultimate strain was found in direct tensile and flexural tests for CS-SHCC than for FS-SHCC.

CS-Mortar shows higher flexural strength than FS-Mortar.

The higher bond strength in CS matrices also leads to reduced ultimate strain and number of cracks, but wider crack widths in CS-SHCC.

In future studies single fibre pull out tests will be performed to determine the fibre bond strength on these FS and CS matrices to validate the results obtained from the indirect test. Several other issues are currently under scrutiny to understand the SHCC behaviour correctly in different applications, like critical fibre volume, fibre orientation, influence of local sand and cement replacement materials. These research results will be reported in subsequent publications.

Polymeric facades: fatigue performance of pultruded panel connections

P. T. Gates, Prof. T. J. Ibell, Dr. A. P. Darby & Dr. M. Evernden
University of Bath, Bath, England

ABSTRACT: The long-term performance of pultruded structural angle sections has been investigated through a campaign of fatigue testing. Equal angle sections have served to represent the connected element of Glass Fibre Reinforced Polymer (GFRP) façade panels. Suitable design limits on maximum recommended transverse strain at connections in the pultrusion have been established. Characteristic behaviour pertinent to application of GFRP pultrusions in facades is reported. The existence of a strain threshold in pultruded connections, below which fatigue does not occur over 100,000 cycles, has been revealed.

1 INTRODUCTION

1.1 *Polymeric facades*

Replacing a building's façade offers the prospect of improving the whole life performance of the building. This presents the opportunity to exploit the properties of advanced composite materials for maximum benefit. 'Upwards and outwards' retrofit, where extending floor slabs yields extra floor area, is permitted by a lightweight replacement façade, without the need for significant structural retrofit or to underpin foundations.

It is paramount to resolve how the connections in a façade system of glass fibre reinforced polymer (GFRP) can enable it to meet the many requirements of an integrated building envelope. The permanent action acting on light, self-supporting GFRP panels is small, however wind and occupancy loading impart significant imposed actions. Therefore, whilst creep deflection is often a significant consideration for structural GFRP design, quantifying fatigue performance is a higher priority for validating the ideology of polymeric facades.

Much existing research focuses on fatigue when stresses are in the principal fibre direction. (Salvia et al. (1997), Salvia & Vincent (1996), and Tong (2002).) However, this is not necessarily the critical stress direction in cladding connection situations. The unidirectional nature of pultruded glass fibre reinforcement yields a scenario of critical stresses at the panel interfaces, occurring in the weaker, secondary fibre direction. The fatigue-testing programme presented examines the performance of pultruded angles compatible with 'long-edge' panel connections.

1.2 *Testing of pultruded angle sections*

Six structural angle sections have served as the subject of experimental investigation. Two different pultruded profiles of equal angle sections have stood to represent the edge returns found to occur in abundance on prototype designs (Fig. 1) developed to form the connection assembly on a polymeric façade. Component testing of representative elements has avoided the need for whole panel fabrication. Testing methodology and loading parameters have been selected to profile how damage propagates in such an element, and how the performance of the represented connection type would endure the lifetime service of a polymeric façade.

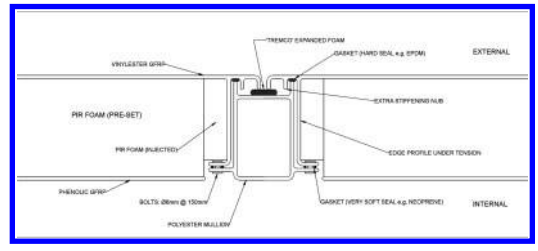

Figure 1. Façade scheme developed as a design platform for research. Suitable designs revealed an abundance of return angles in the pultrusions.

The aim of the testing campaign presented is to establish the general behaviour and response of a suitable connection scheme. A large volume of data is generated when monitoring fatigue testing of the type undertaken. The data capture and analysis options considered to best describe the structural behavior exhibited are discussed, and the chosen numerical procedures employed are justified.

2 METHODOLOGY

2.1 *Test rig set-up*

The angle section is situated in the test rig housing as shown in Figure 2. The prepared specimen is secured

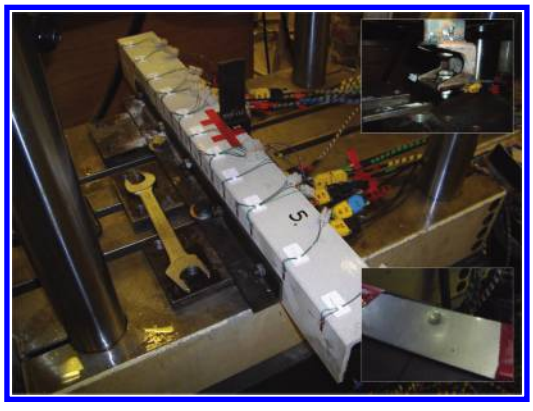

Figure 2. Prepared specimen situated in fatigue test rig set-up.

in place by the horizontal clamps and bolts, which pass through the specimen and grip the rails. The bolt-holes in the rails were drilled as low clearance and the bolt-holes in each specimen were filed out in-situ to yield as low clearance as possible and mitigate slipping and slack developing in the system. The rails are bolted securely to the fixed rig base.

In the arrangement shown in Figure 2 the clamped flange represents the façade panel face, and the free horizontal flange, gripped at a single discrete location, represents the edge return of a pultruded panel with a discrete mechanical connection. The flange is not drilled at this location, as testing is not intended to generate data concerned with stresses around bolts in pultruded GFRP. There is existing comprehensive literature available addressing such behavior (Turvey (2011), Turvey & Cooper (2004), Turvey & Wang (2008).)

The protective steel tabs at the load application point prevent localised damage in the composite. Taping to secure these using electrical tape proved the most efficient means that did not result in tabs breaking free; other tapes that could not stretch, tore away, and epoxy bonding of tabs fractured immediately upon commencement of cyclic loading. The gripper was clamped securely onto the horizontal flange and the crosshead brought down and clamped to the fin plate of the custom welded gripper. All cyclic loading commenced from a neutral displacement position at zero load. Cycling was conducted under displacement control at 1 H_z. The limits of displacement selected corresponded to maximum critical transverse strain measured on the material. (As shown in Table 1.)

2.2 *Preparation of angle sections*

Two different sized sections were tested at lengths of 500 mm. A total of six specimens were prepared and strain-gauged as shown in Figure 2.

There are two important parameters associated with strain gauge location and how the specimen is situated in the test rig. The gauge-offset distance from the inferred apex of the angle cross-section: this distance

Table 1. Specimen information.

Specimen	Flange (mm)		Max. strain ($\mu\varepsilon$)	% Stiffness retained
	l	*t*		
S1	75	6.4	3,000	37
S2	75	6.4	2,000	38
S3	100	9.5	3,000	42
S4	100	9.5	2,000	44
S5	75	6.4	1,100	100
S6	75	6.4	1,100	100

*l is flange length measured externally and t is flange thickness

Figure 3. Parameter for the gripped length of flange on angle section specimen.

was 30 mm for the larger section and 20 mm for the small section. This ratio is the same as that of the angle section leg thicknesses. The gripped length of flange element when clamped into the test rig rails was 60 mm for the larger section and 45 mm for the smaller section. This parameter is illustrated by figure 3 and is specified to be in the same ratio as the structural angle leg lengths.

The strain gauges applied captured the state of strain at increments along the specimen length, on the upstand element of the section; i.e. once the stress has passed around the root radius. The sampling rate for data logging chosen is 10 Hz. Throughout the duration of a test, the response of the specimen can be monitored, and the way the fatigue load is 'shared out' along the member length can be appreciated. The manner in which damage propagates along the element can also be assessed. The most important quantifiable connection property established is the connection stiffness, and the manner in which it diminishes.

2.3 *Data collection and processing*

Data from up to 17 channels, for strain, load and stroke (displacement) had to be recorded at a sufficient sampling rate to monitor behaviour of the specimen at all parts of the load cycle, and be able to represent some form of index relating to the performance of the specimen over the entire programme of loading.

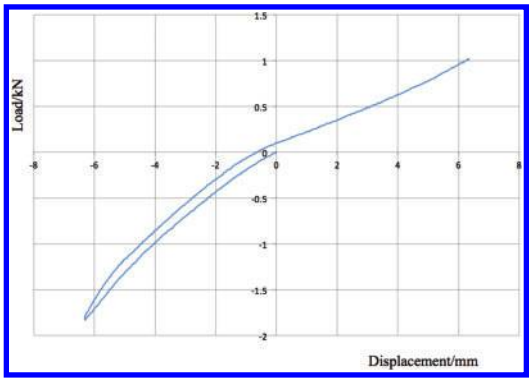

Figure 4. Typical response of connection to final linear ramp.

The average value of the stresses, strains, loads and displacements, recorded over a specific number of cycles in a fatigue programme, is zero. Another means to produce an index that can continuously depict the performance of the connection is therefore necessary. Under displacement control the resistive load is proportional to the specimen connection stiffness.

Applying a Route Mean Square (RMS) numerical procedure to the load data collected over a fatigue programme affords a continuous measure of the stiffness of the connection, and therefore, how the specimen response diminishes. A further benefit is that the procedure can reduce the amount of data by 100 times. If the RMS of loads and strains recorded over every 10 cycles (i.e. 100 data points) is assessed, the RMS load, or RMS strain at a certain strain gauge location can be presented as a continuous function of time with 100 times fewer data points. The time step, in this case, increased to 10 seconds. The RMS strain at each discrete gauge location along the specimen is a measure of how hard the material is working at that location.

3 RESULTS

3.1 *Specimen and loading parameters, and connection stiffness retained*

S1-S4 were cycled 10,000 times and S6 and S8 100,000 times. The % Stiffness retained, shown in the last column of Table 1, is inferred from the initial and final linear load ramps conducted. Figure 4 shows a typical load displacement graph for the final ramp. In contrast to the graph in Figure 5 for a typical initial linear ramp, it can be seen that post fatigue test, the connection specimen retains greater stiffness at the extents of its imposed displacement. This is more noticeable for the negative displacement in Figure 4, which corresponds to the external angle surfaces being in tension, and inner root in compression. The importance in the capacity of the RMS Load parameter to represent the stiffness of the connection over the whole range of imposed waveforms during the intervening fatigue cycling can be appreciated.

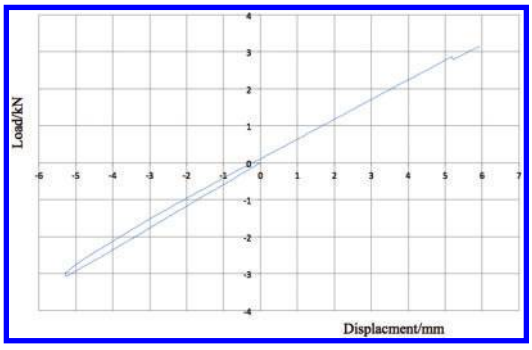

Figure 5. Typical response of connection to initial linear ramp.

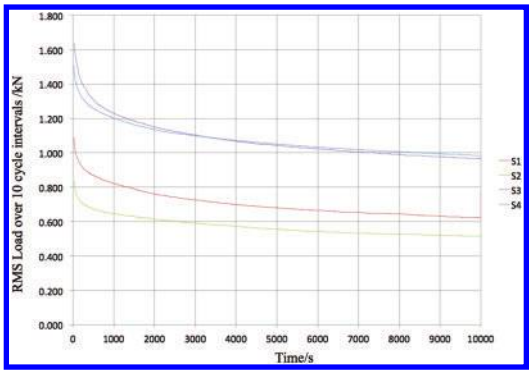

Figure 6. Plot of RMS load profiles for specimens S1-S4.

3.2 *Profiles for diminishing stiffness*

Testing at the levels of strain selected serves important function in understanding both the initiation, and propagation of damage in the connection component. The nature in which damage accumulates in the specimens can be seen in Figure 6.

The RMS Load is an arbitrary measure of stiffness, which has been established by others as proportional to, and a good measure of, damage in the composite material (Elmahi et al (1995) and Lemaitre & Desmorat (2005)).

It can be seen in Figure 6 that the two specimens of smaller section size, S1 and S2, appear to reduce in stiffness a similar amount, and follow a similar pattern of decay, despite the max state of stress and strain being initially much higher for S1. (3,000 $\mu\varepsilon$ for S1, as opposed to 2,000 $\mu\varepsilon$ for S2.)

The larger specimens, S3 and S4, behave quite differently. These specimens, which provide a greater resistive load to the imposed displacements, appear to be more sensitive to the imposed maximum cyclic strain. The specimen S3 which was subject to a higher cyclic displacement and critical strain (of 3,000 $\mu\varepsilon$), decays more rapidly than specimen S4, and in fact also ends up offering less resistance to the driving displacements than S4 does after 10,000 cycles. The case for the larger section specimens is perhaps more what was expected: the programme of larger displacements

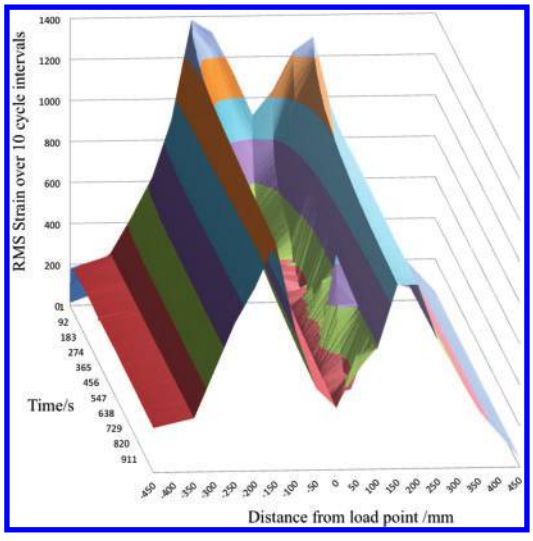

Figure 7. Plot of RMS Strain for the 1000 mm length specimen.

imposed is of greater detriment to the conservation of stiffness.

Specimens S3 and S4 appear to commence at a close state of RMS load. This could be evidence of initial damage having been caused by the monotonic loading (conducted at 1 mm/min, to the same maximum strain and displacement as that observed in cycling,) before the fatigue programme commenced.

Figure 6 portrays smooth curves indicative of a gradual decline in stiffness with progression of damage occurring at a steady rate. The continuous nature of this decay is exploited in Section 4 where the behaviour is modelled numerically.

3.3 *Profile for distribution of damage*

A plot for RMS strain in Figure 7 offers further insight into how damage propagates in a specimen. The specimen represented in this figure was tested in addition to S1-S6 under displacement control at a maximum transverse cyclic strain of 2,500 $\mu\varepsilon$. It can be appreciated that the specimen endured damage during the initial linear ramp, which has resulted in a reduced RMS Strain value at the central portion of the specimen from the very first cycle.

Figure 7 shows that this specimen exhibited initial damage followed by subsequent degradation behaviour in line with that previously observed for S1-S4. It can also be appreciated how the full length of the specimen is working to resist the load. This is an important finding from the 1,000 mm length specimen test, with implications on how cumulative action from adjacent connections on a façade panel could manifest itself. At a state of initial max strain imposed in the cyclic loading of 2,500 $\mu\varepsilon$, the influence of the imposed displacements was still just felt at the extents of a 1,000 mm span.

A further important finding indicated by the plot is that the cracked zone becomes weaker (or the crack gets deeper) where initiated, but does not spread any wider.

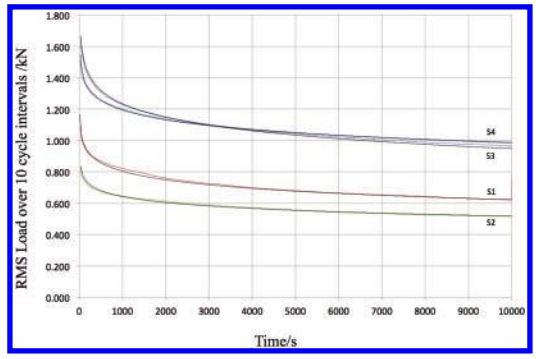

Figure 8. Plot of RMS Load for S1-S4 showing log law based curve-fitting relationships.

4 DISCUSSION

The three-dimensional response of the pultruded connections represented by the stiffness degradation curves is associated with onset of damage at levels of critical transverse strain as low as 2000 $\mu\varepsilon$.

These findings are in line with the findings of El-Assal & Khashaba (2007) who assessed the fatigue performance of pultruded rods under torsional loading as well as bending. It was found that torsional fatigue programmes resulted in a strength half that compared to specimens subjected to pure bending.

The torsion emanating in each longitudinal direction from a discrete connection point initiates damage at a lower transverse stress state than that initiated by plane flexure. Torsion, arising through stresses at connections, is verified to be of detriment to the interfacial bond of pultruded composites, under both quasi-static loading, and fatigue loading.

RMS load has served as a useful index of performance of the connection specimens, representing stiffness over the whole range of displacements from the imposed waveform. The continuous nature of the plot as a function against time permits further analysis techniques which employ 'curve fitting' to measure decay behaviour.

The form of the log law relationship adopted for the model is shown in Equation 1, and the values of the co-efficients, Φ and Ψ, for specimens S1-S6 are shown in Table 2.

$$RMS\ Load = \Phi - \Psi \ln(t) \quad (1)$$

It is of interest whether an RMS Load profile for a specimen displaying no fatigue could have been produced at a higher imposed max transverse strain than those at 1,100 $\mu\varepsilon$. In seeking to determine whether this is the case, the value Ψ, which signifies degradation in stiffness, or accumulation of damage, is examined in relation to the maximum imposed initial transverse strain. It can be seen that the green line plotted in Figure 9 suggests that Ψ is very sensitive to strain

Table 2. Ψ and Φ values for S1-S6.

Specimen	Ψ	Φ
S1	0.079	1.350
S2	0.054	1.018
S3	0.124	2.091
S4	0.090	1.814
S5	0.001	0.349
S6	0.001	0.349

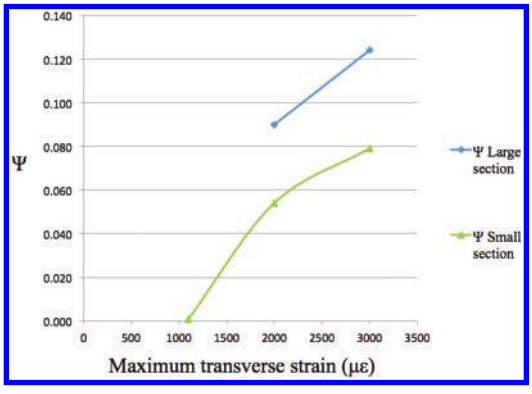

Figure 9. Ψ values, as a function of maximum imposed transverse strain.

near the threshold of onset of damage, even under displacement control testing such as that undertaken. (The gradient of this line is much steeper near $\Psi = 0$.) The implication of this finding is that though a damage threshold exists, if exceeded, the rate at which damage propagates is very sensitive to the loading parameters. Therefore, whilst a certain amount of damage over 10,000 cycle fatigue programme could be deemed acceptable, it is recommended that connection components are designed to retain full stiffness. There is no evidence to suggest a zero damage fatigue programme could have been achieved with any greater maximum transvers strain than that applied (of 1,100 με). The larger section size would appear to possess the same kind of limit on damage initiation if the same trend were observed. (Denoted by the blue line on the plot in Figure 9.)

5 CONCLUSIONS

At a maximum transverse strain of 1,100 με full connection specimen stiffness was retained after a 100,000 cycle fatigue programme. Specimens tested to fatigue loading parameters of high stress and strain (S1-S4) have demonstrated how the stiffness, or performance, of a connection component diminishes over 10,000 cycles.

The response of a pultuded GFRP angle element to a discrete mechanical connection load has been investigated through observation of the RMS strain at intervals along the section length throughout a fatigue-loading programme. This behavior is key to informing good design practice when considering cumulative action of adjacent connections on a façade panel.

The RMS strain profiles produced have revealed the nature of damage propagation. Specimens that suffered an initial amount of damage deteriorated further by cracks that perpendicularly bisected the direction of transverse strain. These cracks became progressively deeper, but not wider over the duration of the fatigue-loading programme.

The onset of damage accumulation at maximum cyclic transverse strains lower than that expected from testing reported concerning purely flexural fatigue, has evidenced a strong influence of torsion on the connection performance.

Testing has shown that though a threshold of damage accumulation does exist for transverse strain in fatigue loading of connections. The rate of damage accumulation once this limit is exceeded is very sensitive to the loading parameters, and the performance quickly diminishes with increasing maximum transverse strain.

The quantitative findings presented above relate to the specific design and fibre architecture of the pultrusions tested. The absolute values in the threshold of critical transverse strain determined will only be appropriate for these pultrusions. It is recommended however, that a factor of safety to be placed on the limit of max transverse strain in design, should be in line with that considered for ultimate failure though quasi-static loading on a façade, owing to the nature of the behaviour established through this testing campaign.

ATKINS Denmark A/S, Copenhagen, Denmark

C.T. Georgakis & G. Fischer
Department of Civil Engineering, Technical University of Denmark, Kongens Lyngby, Denmark

ABSTRACT: In this paper, the fretting fatigue behavior of pretensioned high-strength steel monostrands is investigated. A method based on the digital image correlation (DIC) technique was used to quantify the relative movement between individual wires along the length of the monostrand. The experimental data indicate that the interwire movement due to transverse deformations is highest at the neutral axis of the monostrand. The results show that the midspan and the anchorage of the monostrand are the two locations where the combination of tensile strains and the interwire friction is the most unfavorable. Moreover, the paper provides relevant information about the monostrand bending stiffness and the extent of relative displacement between core and outer wires of the monostrand undergoing flexural deformations. The results presented herein are of special interest for the fatigue analysis of modern stay cable assemblies where fretting constitutes the main mechanism of the fatigue life reduction.

1 INTRODUCTION

Parallel monostrand stay cable systems are frequently subjected to transverse vibrations due to wind and traffic (Gimsing & Georgakis 2012). The stay vibrations may lead to substantial relative movements between the monostrand wires (fretting) in the free span of the tendons and local bending stresses in the anchorage regions. The fretting mechanism leads to damage resulting from small amplitude displacements between the contacting surfaces of adjacent wires. These interwire movements significantly reduce the life expectancy of the cable and, consequently, the service life of the supported structure. Recent bending tests on high-strength steel monostrands axially pretensioned to 45% of the ultimate tensile strength (UTS) (Fig. 1) have shown that wire failures due to fretting and high localized bending stresses were concentrated in the cable anchorage and at the midspan (Wood & Frank 2010, Winkler et al. 2011). Modern cable anchorage systems often feature technologies that significantly reduce local bending effects and, therefore, fretting may often constitute the main mechanism of the fatigue life reduction. However, due to lack of data on the fretting fatigue performance of steel monostrands subjected to transverse deformations, the life expectancy of stay cables has not been evaluated in sufficient detail to date (Jensen et al. 2007).

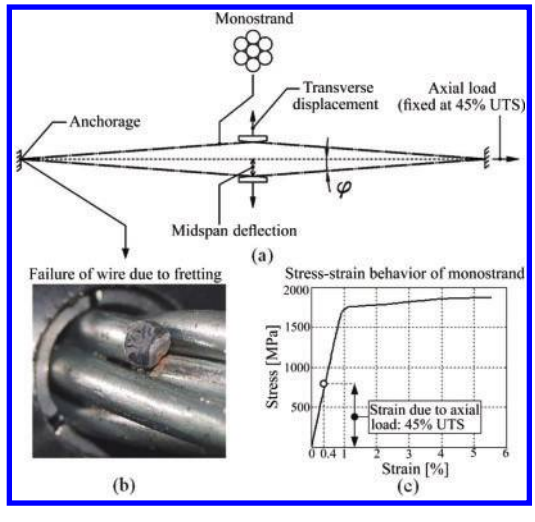

Figure 1. Schematic sketch of test setup (a), wire failure due to fretting (b) and stress-strain behavior of monostrand (c).

1.1 *Fretting fatigue of steel cables*

An important consideration in the fatigue analysis of steel cables is the fretting behavior of a monostrand. During bending tests on high-strength steel monostrands a hysteresis was observed in the

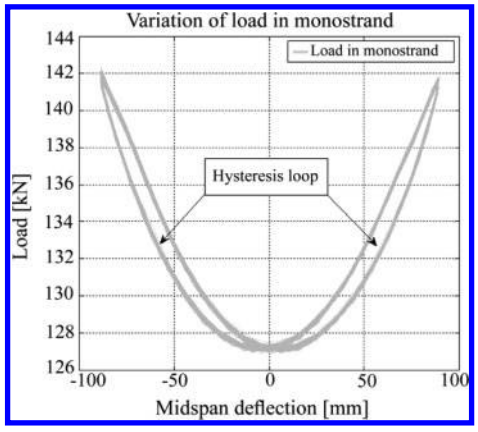

Figure 2. Variation of axial load and monostrand hysteresis.

load-displacement diagram (Fig. 2) (Rodríguez & Olabarrieta 2010, Winkler et al. 2011).

This was an indication that the monostrand experienced some form of internal energy dissipation which is likely a result of interwire movements. The interwire movement will accelerate the crack initiation, propagation and final failure of steel wires due to fretting. Fretting is an important degradation mechanism for steel cables and has been described previously (Hobbs & Raoof 1994). However, the relative movement between strand wires has been found difficult to deduce from strain gauge measurements. To date, there is no information about the distribution of the interwire movement along the length of the monostrand and the extent of the relative displacement between core and outer wires of the monostrand undergoing flexural deformations. The fretting problem is not yet fully clarified and, in the absence of relevant experimental data, it is difficult to draw reliable conclusions from purely analytical approaches.

In this paper, the fretting fatigue behavior of pretensioned high-strength steel monostrands is investigated. A method, based on the digital image correlation (DIC) technique was used to quantify the relative movement between individual wires along the length of the monostrand, leading to a more in-depth understanding of the underlying fretting fatigue mechanism.

2 METHODLOGY

2.1 *Materials and test setup*

An experimental investigation was carried out on high-strength steel monostrands with 5.1 m length and of 15.7 mm nominal diameter subjected to cyclic transverse deformations. The specimens consisted of two layers of galvanized round wires helically spun together. The monostrands were of low relaxation grade, waxed and PE coated. The ultimate tensile strength of the monostrand was 1860 MPa (279 kN) (Fig. 3).

To assess the fretting fatigue performance of a monostrand, a test rig that can simulate flexural effects

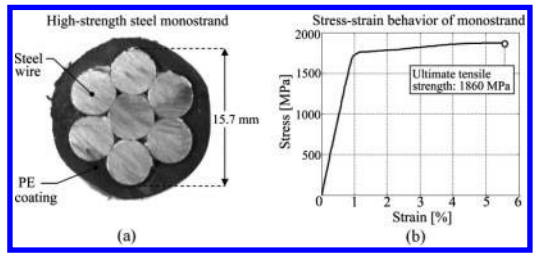

Figure 3. Cross section (a) and ultimate tensile strength of the monostrand (b).

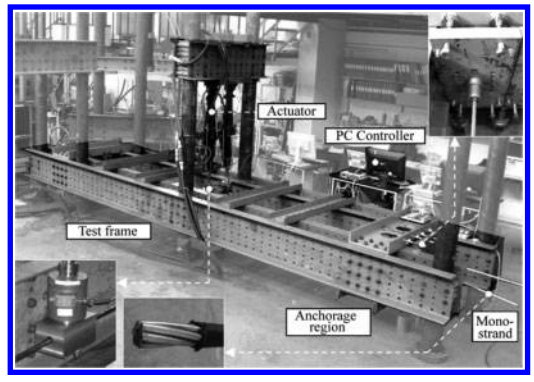

Figure 4. Test rig for monostrand bending tests.

was devised, so that the fatigue behavior of the monostrand with emphasis on relative wire movements could be investigated (Fig. 4). Full details of the cable specimens and testing arrangements have been described by Winkler et al. (2011) and therefore only a summary is presented herein. The high-strength steel monostrand was stressed to 45% of the UTS. The transverse deformation was applied by a hydraulic actuator attached to a deflection collar at the monostrand. With this setup, monostrand wires were subjected to varying degrees of bending, resulting in fretting-induced local stress and strain concentrations.

2.2 *Measurement technique*

Information on the extent of interwire movements corresponding to local curvatures is required to assess damage in the monotrands and estimate the remaining fatigue capacity of the cable. For this purpose, a digital image correlation (DIC) technique was employed as a tool for quantifying the interwire movement and measurement of individual wire strains along the length of the monostrand.

The applicability of the image analysis technique to measure local cable deformations was demonstrated previously by Winkler et al. (2012), with good agreement found between the wire strains measured using image analysis and those measured by conventional strain gauges (Fig. 5).

Details of the measurement technique were described earlier by Winkler et al. (2012), hence, the

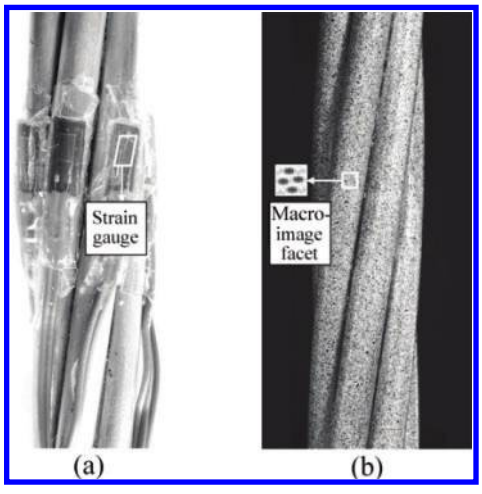

Figure 5. Conventional strain gauge measurement (a) and optical measurement based on DIC (b).

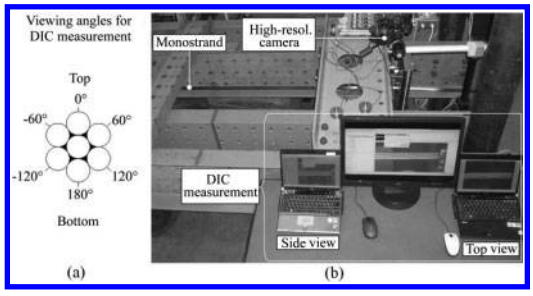

Figure 6. Viewing angles (a) and setup for the DIC analysis (b).

information provided here is intended only as a brief summary.

Image analysis involved capturing a reference image of the monostrand surface in its undeformed state. As the load was applied, additional images were collected. The deformation and the strain of the documented surface were computed using a post-processing algorithm. The post-processing algorithm of the photogrammetry software involved a stage-wise analysis, in which each stage consisted of one image resulting in a description of displacements occurring on the surface of the monostrand.

A high-resolution SLR camera with interchangeable lenses was used for image acquisition. The camera was controlled remotely from a computer where the collected images in JPG format were stored for processing with a commercially available photogrammetry software (Fig. 6b).

The orientation sketch of the monostrand with the different viewing angles used for capturing of the photogrammetric data is shown in the Figure 6a. The distance from the camera to the monostrand specimen was 35 cm.

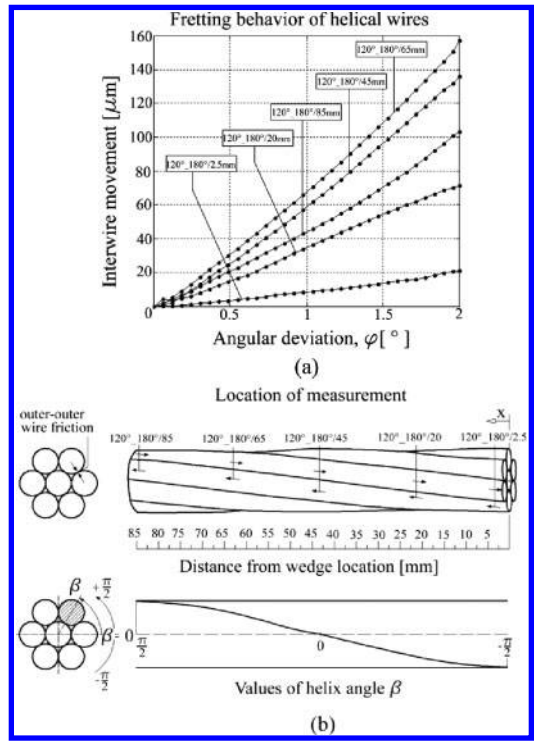

Figure 7. Fretting behavior of wires due to applied midspan deflection (a) and location of measurement (b).

3 RESULTS

3.1 *Interwire movement of outer wires of the monostrand*

The relative displacement of the outer wires was measured along the lay length of the monostrand (Fig. 7b). The DIC extensometers were placed on wires at 120° and 180° (120°–180°) and angular deviations φ between 0° to 2.0° were investigated. The interwire movement due to midspan deflection is plotted for each angular deviation φ and the measured response of the wires is shown in the diagram below (Fig. 7a).

The interwire movement (fretting) occurs as the radial forces in the monostrand are no longer high enough to prevent relative displacement between the individual wires due to the transverse deformation. The diagram in Fig. 7a shows that, depending on the value of helix angle b, the relative movement of wires will increase or decrease. The helix angle b varies along the lay length of wire from $-p/2$ to $+p/2$ and it can be seen that parts of the same wire slipped more while others slipped less. This is due to the fact that the Coulomb frictional forces acting on the wires are the smallest in the region of neutral axis ($b = 0$). Consequently, the slippage at $b = 0$ will be the highest. A similar fretting behavior has been observed in transmission line conductors (Papailiou 1997). It was also noticed that the failure due to fretting does not occur in the bending plane, where the bending stresses are highest, but

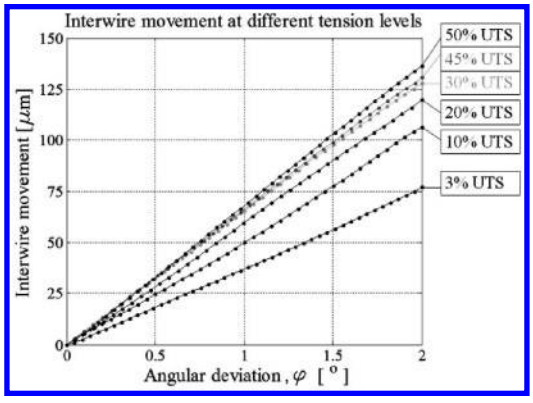

Figure 8. Interwire movement at different tension levels.

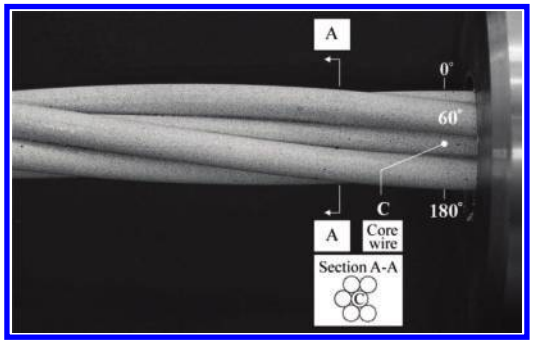

Figure 9. Strand specimen for the optical measurement of the core-outer wire relative displacement.

in the area where the combination of bending stresses and the tangential frictional forces is most unfavorable (Raoof 1991).

In addition, the interwire movement was measured at different tension levels ranging from 10% to 50% of the UTS (Fig. 8). The measurement was taken at the location of b = 0.

The diagram in the Fig. 8 indicates that the interwire movement increases with an increase of the tension load level in the monostrand. It can be also noticed that the difference of the interwire movement between 30% and 50% of UTS is negligible. Hence, the fatigue tests performed at a lower axial load levels (e.g. 30% of UTS) seem not to be more critical for the evaluation of fretting fatigue performance of the monostrand.

3.2 *Relative movement between core and outer wires of the monostrand*

The photogrammetry system enabled measurement of the relative movement between core and outer wires of the monostrand undergoing flexural deformation. For this test, the outer wire at 120° was removed allowing visual access to the core wire "C" and the 6-wire strand was pretensioned to an equivalent axial load level (45% of UTS) (Fig. 9).

The DIC extensometers were placed on the core wire "C" and the outer wires at 60° and 180° (Fig. 10b)

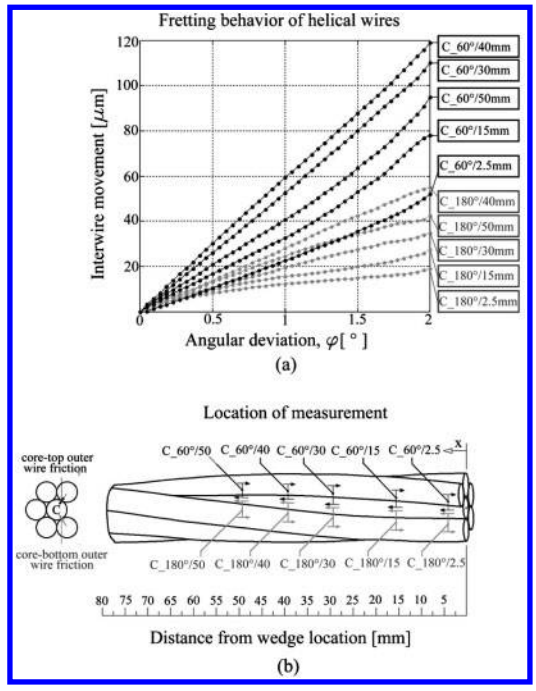

Figure 10. Fretting behavior of 6-wire strand specimen due to applied midspan deflection (a) and location of measurement (b).

and the ranges from 0° to 2.0° of angular deviations f were investigated. The interwire movement due to the midspan deflection obtained from the extensometers C_60° and C_180° are presented for each angular deviation (Fig. 10a).

Note the unequal interwire movement of bottom and top wires with respect to the core wire (Fig. 10a). It can be also seen that the bending-induced relative displacement between outer wires (Fig. 7a) is higher than the one between core and outer wires.

3.3 *Distribution of the interwire movement along the length of the monostrand*

It was possible to capture the interwire movement along the length of the monostrand by relocating the camera in the test rig (Fig. 11). The photogrammetry system enabled documentation of the side part of the monostrand from the anchorage to the midspan. The DIC extensometers measured the relative displacement between the core and outer wire at different angular deviations φ.

The experimental data show that the midspan and the anchorage of the monostrand are the two locations where the combination of the tensile strains and the interwire friction is the most unfavorable (Fig.12).

Aside from the anchorage region and the loading point most of the length of the monostrand showed a uniform tensile strain. Hence, the fatigue behavior of the strand in the free length (Fig. 12) is governed by the axial and frictional forces induced in the monostrand due to applied transverse deformation.

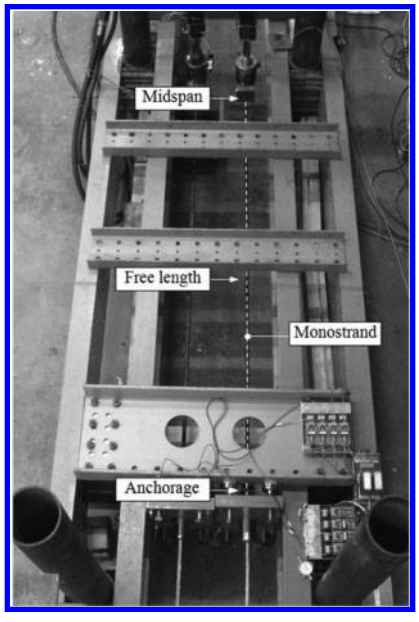

Figure 11. Test rig for the measurement of interwire movement.

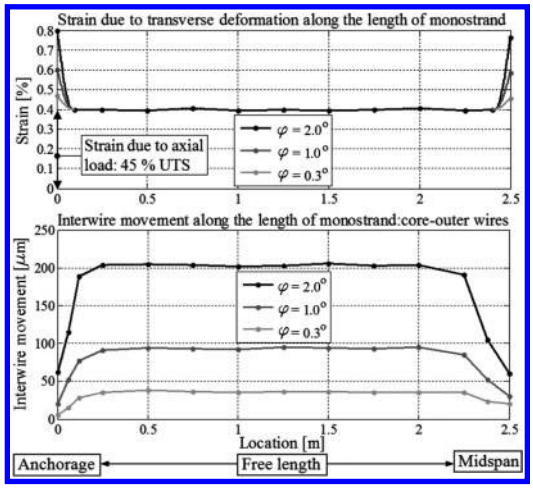

Figure 12. Distribution of the interwire movement and strain along the length of the monostrand.

3.4 *Transverse stiffness of the monostrand*

The transverse stiffness was measured at angular deviations of $\phi = 0°$, $1.0°$, $1.5°$ and $2.0°$. A linear least-square fit was used to plot the average measured stiffness for tension load levels ranging from 30 kN to 140 kN (10% to 50% UTS) (Fig. 13a).

The difference in stiffnesses (the vertical shift in the linear fit) is caused by an increase in tension load due to the applied midspan deflection (Fig. 13b) together with changes in the interwire movement.

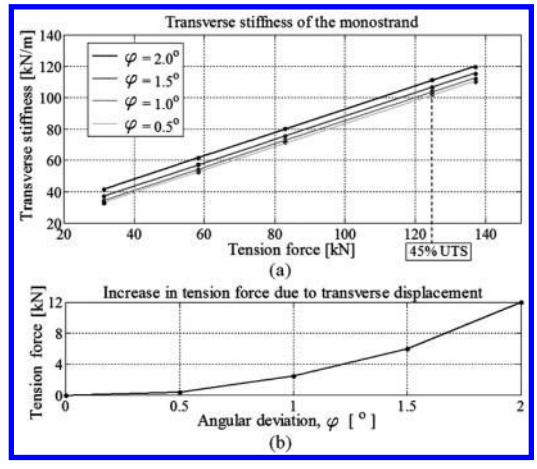

Figure 13. Measured transverse stiffness of the monostrand (a) and increase in tension force due to midspan deflection (b).

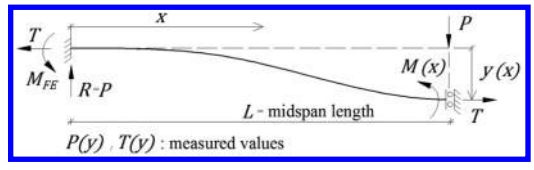

Figure 14. Free body diagram of the deformed monostrand.

3.5 *Bending stiffness of the monostrand*

The monostrand comprised of individual wires can be modeled as an elastic tension strut. The measurement of the bending moment in cables with a small diameter is not accurate enough for a direct validation of the theoretical models (Gourmelon 1992) and a similar problem was encountered in this study. However, it was possible to measure the midspan deflection and the corresponding vertical and tensile force in the monostrand. Consequently, the effective bending stiffness EI_{eff} of the monostrand was estimated from the numerical model described below.

3.5.1 *Description of the numerical model*

The monostrand was modeled as tension strut carrying an axial load and subjected to bending (Fig. 14).

Equation 1 defines the moment equilibrium equation for the deformed monostrand:

$$M(x) = R \cdot x - T \cdot y(x) - M_{FE} \tag{1}$$

where R = reaction at the left support; P = vertical force; T = tensile force; y(x) = transverse displacement at x; and M_{FE} = moment at the left support.

Substituting the relationship between moment and curvature, the vertical reaction for a symmetric loading condition, and defining the parameter $\lambda = \sqrt{T/EI}$, yields the governing equation:

$$\frac{\partial^2}{\partial x^2} y(x) - \lambda^2 \cdot y(x) = -\frac{R}{EI} \cdot x + \frac{M_{FE}}{EI} \tag{2}$$

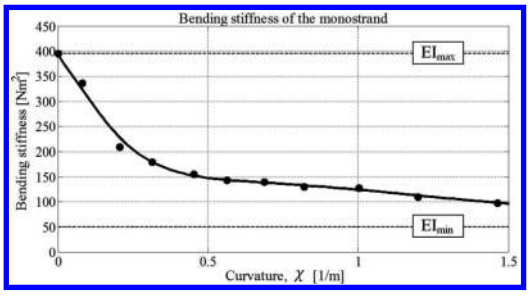

Figure 15. Effective bending stiffness of monostrand.

The general solution for the Equation 2 is of form:

$$y(x) = e^{\lambda \cdot x} \cdot A + e^{-\lambda \cdot x} \cdot B - \frac{M_{FE}}{T} + \frac{R \cdot x}{T} \quad (3)$$

The constants A, B and the unknown moment M_{FE} can be found by exploiting the boundary conditions:

$$A = \frac{M_{FE} \cdot \lambda - R}{2 \cdot EI \cdot \lambda^3}; B = \frac{R}{2 \cdot EI \cdot \lambda^3} + \frac{M_{FE}}{2 \cdot EI \cdot \lambda^2}; M_{FE} = \frac{(-1+e^{\lambda \cdot L}) \cdot R}{(1+e^{\lambda \cdot L}) \cdot \lambda}$$

Consequently, the constants and the moment are of the form:

$$A = \frac{M_{FE} \cdot \lambda - R}{2 \cdot EI \cdot \lambda^3}; B = \frac{R}{2 \cdot EI \cdot \lambda^3} + \frac{M_{FE}}{2 \cdot EI \cdot \lambda^2}; M_{FE} = \frac{(-1+e^{\lambda \cdot L}) \cdot R}{(1+e^{\lambda \cdot L}) \cdot \lambda}$$

3.6 *Estimation of the effective bending stiffness*

The effective bending stiffness EI_{eff}, indicated by the dots in the Figure 15, was determined by solving Equation 3 for the set of measured values: $y(L)$, $T(y(L))$, $R(y(L))$. The EI_{eff} was calculated for the displacements corresponding to the range of curvatures χ between 0 and 1.5 1/m (Fig. 15).

Figure 15 shows the variable bending stiffness of the high-strength steel monostrand over the monostrand curvature χ for the tension level of 40% UTS. EI_{max} (solid body assumption) and EI_{min} (full slippage of wires) constitute the upper and lower bound of the bending stiffness. One can see a significant reduction (55%) in the EI at the range of χ between 0 and 0.25 1/m. Note that the presented results are only applicable to single-strand bending. With an increased section size, the amount of the interwire movement might vary. It is recommended that further testing be performed on a multi-strand stay cable assembly to establish the correlation between the single and multi-strand bending response.

4 CONCLUSIONS

In this paper, the fretting fatigue behavior of pretensioned high-strength steel monostrands was investigated. A method, based on the DIC technique was used to quantify the relative movement between individual wires along the length of the monostrand.

The experimental data indicate that the interwire movement due to transverse deformations is the highest at the neutral axis of the monostrand. Moreover, the results show that the midspan and the anchorage of the monostrand are the two locations where the combination of tensile strains and the interwire movement is the most unfavorable.

The presented data show that the interwire movement increases with an increase of the tension load level in the monostrand. However, the difference of the interwire movement between 30% and 50% of UTS is relatively small.

Finally, the effective bending stiffness EI_{eff} of the monostrand was estimated from the numerical model showing the reduction in stiffness of 55% at the range of χ between 0 and 0.25 1/m.

Revised wind loading for linear and non-linear design of cooling towers

Hans-Jürgen Niemann
Ruhr-Universität Bochum, Department of Civil and Environmental Engineering, Bochum, Germany

Wolfgang Hubert
Niemann & Partner Consultants, Bochum, Germany

ABSTRACT: Natural draught cooling towers provide the most cost-effective technology for cooling the condenser circuit of thermal power plants. The tower is constructed as a reinforced concrete shell supported by a ring of columns. Wind effects dominate the structural safety regarding the reinforcement for tensile meridional and ring stresses, and for shell buckling. The wind pressures fluctuate randomly in time constituting a broadband stochastic excitation to the structure. Additionally, neighbouring buildings interfere with the flow, deforming the mean pressure distribution and providing additional turbulent energy to the excitation. For design calculations, various equivalent static loads have been adopted in the past. More recently, a method was developed to identify the momentary pressure distributions which generate the peak structural response for any leading structural response. The load identified in this manner is particularly useful for non-linear calculations of structural failure.

1 INTRODUCTION

Cooling towers provide the heat sink at the cold end of thermal power plants. Various cooling techniques are in use: The cooling airstream inside the tower is driven either artificially by a fan (forced draft), or by natural thermal updraft (Natural Draught Cooling Tower, NDCT) or by a combination of both (Hybrid Cooling Towers, HCT). NDCT cooling towers provide the most cost-effective technology because no additional power is required. The warm water coming from cooling the condenser is discharged into the water distribution of the cooling tower. The droplets falling down from the water distribution into the basin release the residual process heat via evaporation and convection to the ambient air. Warming up the air induces an updraft in the NDCT providing a continuous heat flow into the atmosphere. In this manner, cooling towers protect rivers or lakes, used otherwise for cooling, from overheating.

The NDCT is constructed as a reinforced concrete shell supported by a ring of columns. Ring beams at the lower and upper end of the shell stabilize its circular cross-section of the shell. Figure 1 shows the NDCT Tower Niederaussem in Germany designed in 1998. With this cooling tower, the enormous height of 200 m was reached for the first time. It is remarkable that the minimum wall thickness was not more than 22 cm. NDCTs even beyond 200 m are presently under construction in China.

The important actions are due to dead-weight, wind, temperature change, foundation settlements, and concrete shrinkage. Designing for the limit state of

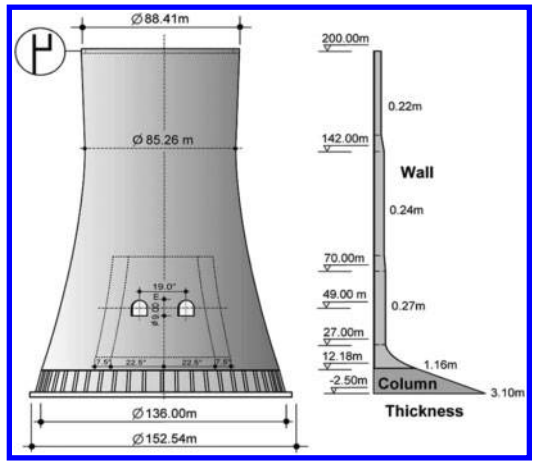

Figure 1. The 200 m Natural Draught Cooling Tower at the Power Plant Niederaussem, built from 1999 to 2001.

structural integrety, the combination of wind inducing tensile stresses plus dead-weight inducing compressive stresses is critical. In 1965, 3 NDCTs failed because of tensile failure of the vertical reinforcement in the lower part of the shells, during a "severe westerly wind". From the findings by the Committee of Inquiry (CEGB Report 1966), three main issues may be inferred:

(1) The maximum tensile membrane stress at the windward meridian, being the difference of two stresses nearly numerical equal, is very sensitive to wind uplift;

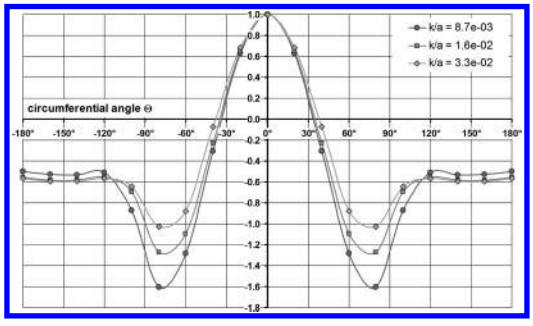

Figure 2. Pressure distribution around the circumference of a cooling tower model for different wind rib roughness.

(2) The wind pressures should be based on realistic pressure coefficients and an adequate gust wind speed;
(3) Sufficient structural safety cannot be achieved by a global safety factor but requires partial safety factors.

The collapse at Ferrybridge stimulated in the following years research efforts in areas such as shell theory and numerical calculation methods, material behaviour, structural safety, and – last not least – wind engineering.

2 THE NATURE OF THE WIND LOAD

Wind pressures act on the external and internal surfaces of the shell. They fluctuate randomly in space and time constituting a broadband stochastic excitation process. The mean of the process is defined as the average taken over 10 min. The fluctuations superimposed on the mean, are caused by the turbulence of the natural wind, and by vortices generated as the flow separates from the tower surface. Additionally, neighbouring buildings of comparable size interfere with the flow, deforming the distribution of the mean pressure on the tower surface and adding at the same time to the random excitation, eventually increasing the shell stresses.

Figure 2 shows a typical distribution of the variation of the mean external wind pressure at the circumference of a cooling tower model. The pressure, w_e is referred to the mean velocity pressure, q(z) at the same level.

At stagnation, the pressure is $w_e/q(z) = 1$. As the flow passes downstream along the contour, the flow velocity increases to a maximum and the pressure drops to a minimum. Behind it, the pressure rises again and, accordingly, the flow in the boundary layer is decelerated gradually until the velocity reaches zero. At this stage, the flow separates from the tower surface. The two separation points at each side mark the beginning of the wake behind the cylinder. The pressure rise which can be attained depends on surface roughness: when the surface is rough, the pressure rise is low as well as the magnitude of the pressure minimum.

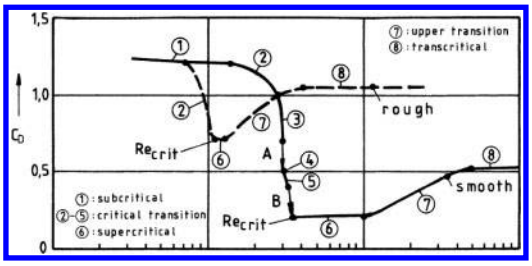

Figure 3. The flow regimes of circular cylinders with smooth and rough surface.

The total wind force resulting from this pressure distribution is however high. In both regards the opposite applies to a smooth surface. On the other hand, the wind uplift, i.e. the maximum of the tensile meridional force at stagnation, is more or less proportional to the modulus of the pressure minimum. Therefore, high surface roughness reduces the meridional stresses in the shell, although it goes along with a high total wind force. This is due to the specific load carrying behaviour of the shell structure (Niemann et al. 1972). For this reason, the majority of NDCTs in Germany is equipped with wind ribs.

Reynolds number Re, the surface roughness, the aspect ratio defined by (total height H)/(mean diameter d_m), and the profile of the wind flow are the dominating parameters for the pressure distribution. Turbulence scale and intensity are less important for the features of the mean flow.

Most of what we know about the flow around cooling towers is owed to research on the flow around circular cylinders performed in wind tunnel experiments (Fage, Warsap 1930; Roshko 1961, Schewe 1983, Wieselsberger 1921). The experiments have demonstrated the strong effect of Reynolds number on the flow regimes. Figure 3 depicts this effect on the dragforce coefficient, c_D of a circular cylinder. The drag varies considerably at Re-numbers up to 10ˆ6; it becomes independent of Re in the transcritical range. If the surface is rough, the critical pressure drop is less pronounced and the flow reaches the transcritical range at lower Re. One important result from Figure 3 is that at transcritical Reynolds numbers, the effect of Re on flow separation and subsequently on the pressure minimum has vanished. However, the effect of surface roughness – by wind ribs or distributed sand grain roughness – is still present.

At design wind speeds, the Reynolds number of high cooling towers, e.g. the NDCT Niederaussem is typically $Re_{full-scale} = 40 \cdot 98/15 \cdot 10\text{-}6 = 3 \cdot 10\text{ˆ}8$. For a smooth surface, it is beyond the range of wind tunnel experiments. This so-called Reynolds number disparity between the wind tunnel experiment and the full-scale flow was at that time a major source of ambiguity and posed one of the challenges encountered in determining the wind load for cooling towers. It was overcome by pressure measurements at full scale towers which were performed mainly in Germany, France, USA, and China. Figure 4 shows the effect of surface

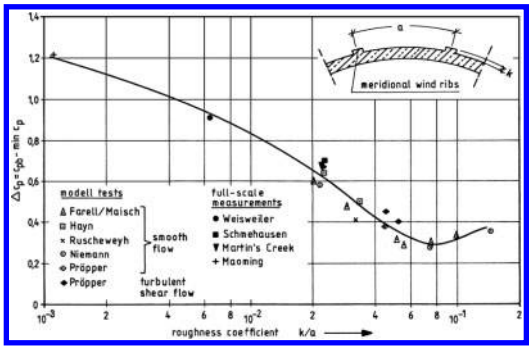

Figure 4. Influence of surface roughness on the pressure rise coefficient at transcritical Reynolds numbers.

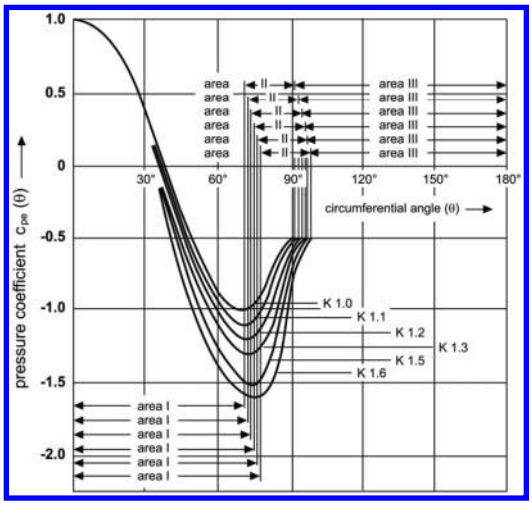

Figure 5. Pressure distributions for design of NDCTs in the VGB guideline BTR 2010 for Structural Engineering of Cooling Towers (VGB-R 610 2010).

roughness by wind ribs on the coefficient for the pressure rise from the minimum to the wake pressure at transcritical Re.

This result permitted to introduce realistic pressure distributions considering surfaces with and without wind ribs. They are applied as the basis of equivalent static wind loads for design. Figure 5 shows the regulation adopted in (VGB-R 610 2010).

A further result was that the transcritical full-scale pressure distribution can be simulated at much lower wind tunnel Reynolds numbers by increasing the surface roughness of the wind tunnel model.

3 WIND LOAD FOR DESIGN

3.1 *The gust response factor approach – equivalent static wind pressures for cooling towers*

In the detailed design calculations, the effect of the randomly fluctuating part of the wind pressures is in general taken into account by a static load. It is equivalent in the sense that its effect equals the real, most adverse gust load effect on the leading internal forces. It goes back to A.G. Davenport's gust response factor concept, in which the equivalent wind force F_w is based on the mean wind force, F_{wm}, amplified according to the effect of the fluctuating load component by the gust response factor G (Davenport 1967).

$$F_w = G \cdot c_f \cdot A \cdot q_{m_m} \tag{1}$$

in which c_f = aerodynamic force coefficient; A = loaded area; q_m = mean velocity pressure of the undisturbed flow. For NDCTs, the design calculations can only be based on wind pressures, not on resulting wind forces. The equivalent static wind load is given for external and internal pressures, w_e and w_i by (VGB-R 610 2010)

$$w_e(z,\theta) = c_{pe}(\theta) \cdot \varphi \cdot F_I \cdot q_p(z) \tag{2}$$

$$w_i = c_{pi} \cdot F_I \cdot q_p(H) \tag{3}$$

in which z – height above ground; Θ – peripheral angle; c_{pe}, c_{pi} – pressure coefficients at the external and internal shell surface; φ – dynamic response amplification due to resonance to turbulence; F_I – response amplification by flow interference with neighbouring buildings or structures; q_p – peak velocity pressure; H – tower height. In Equation 2, the external pressure at height z is proportional to the velocity pressure at the same height whereas the pressure coefficients c_{pe} are independent of z. The internal pressures, Equation 3, are constant over periphery and height; they are dominated by the velocity pressure at the tower top, q_p(H). Their contribution to resonant stress amplification is negligible.

In this formulation, the increase of the internal forces caused by the pressure fluctuations is included in the peak velocity pressure, q_p. The pressure coefficients are those of the mean pressures, s. Figure 5; they do not reflect peak pressures. The peak velocity pressure, q_p is derived from the gust response factor of a leading response. Since the resonant effect of the pressure fluctuations is small, it is allowed for separately by the dynamic factor, φ which is the ratio of total to the quasi-static gust response factors:

$$\varphi = {}^{G}/_{G_Q} \tag{4}$$

Then, merely the quasi-static gust response has to be calculated, and the co-variance method can be utilized (Niemann et al. 1996). The most important wind load effect is the meridional tension max n_{xx} at stagnation, where $\Theta = 0°$. It is rather constant in the lower third of the shell height. In this region maximum reinforcement is necessary. The peak velocity pressure is therefore derived from the gust response factor of n_{xx}. In this context, a simplified consideration may be applied for relating the meridional tensile force to the velocity pressure: (1) n_{xx} is proportional to the wind

Table 1. Gust wind profile parameters for NDCTs.

Tower Height	α	G_Q	α'	$q_p(10)/q_m(10)$
flat, open terrain with low vegetation, category II, roughness length 0.05 m				
120 m	0.16	1.831	0.110	2.25
200 m		1.766		
flat terrain without obstacles, category I, roughness length 0.01 m				
120 m	0.12	1.707	0.085	1.93
200 m		1.643		

force moment; (2) the diameter d and the aerodynamic force coefficient c_f are constant over the tower height. Then

$$G_Q = \frac{\int_0^H c_f \cdot d \cdot q_p(z) \cdot z \cdot dz}{\int_0^H c_f \cdot d \cdot q_m(z) \cdot z \cdot dz} \tag{5}$$

The profiles of the mean and peak velocity pressure are

$$q_m(z) = q_m(10) \cdot \left(\frac{z}{10}\right)^{2\alpha} \tag{6}$$

$$q_p(z) = q_p(10) \cdot \left(\frac{z}{10}\right)^{2\alpha'} \tag{7}$$

The exponent, α of the mean wind profile is well documented and defined in codes. The exponent, α' of the peak wind profile is smaller than α. It reflects a gust wind profile and depends on the gust averaging time. The values of α' are chosen for NDCTs as depicted in Table 1. The peak and mean values of the wind force moment are calculated from Equation 5, resulting for given G_Q in the ratio q_p/q_m. This factor is finally introduced in Equation 7.

The advantage of deriving the equivalent static load in this manner is that it is applicable to all customary tower dimensions. However, in addition to the design for tensile meridional stresses, more requirements have to be met such as sufficient hoop reinforcement, or sufficient wall thickness for the buckling safety of the shell. One equivalent static load may not cover all important stresses in all structural parts of the tower. In particular, the peaks of the tensile hoop force and of bending are sometimes underestimated. The internal pressure w_i produces circumferential compression, superimposed on the tension due to external pressure and reduces hoop tension. Therefore, two wind load cases have to be considered namely w_e and $(w_e + w_i)$ whichever is more harmful.

3.2 *Most adverse, momentary pressure distributions – the LRC-method*

A more precise wind load may become necessary, e.g. when the load-bearing capacity of an existing tower has to be investigated, or when strong interference has to be considered. For this task, an alternate approach consists of identifying, out of the randomly fluctuating wind pressures at the loaded surface, an extreme wind load distribution which produces the worst load effect (Kasperski 1988). Considering a wind load effect S, the peak can be written as a superposition of the mean, S_m, with the rms response, σ_S, amplified by the peak factor k_{Sp}:

$$S_p = S_m + k_{Sp} \cdot \sigma_S \tag{8}$$

The mean wind pressures for calculating the mean response are

$$w_m(z, \theta) = c_p(\theta) \cdot q_m(z) \tag{9}$$

The rms response is obtained by loading the structure with the rms-pressures. However, the effect of the pressure at a loading point depends on the correlation between pressure and response fluctuations. It can be shown that the weighting factor is exactly the correlation coefficient ρ_{pS} between the pressure and the response considered. The load has been termed LRC load since it is based on the **L**oad **R**esponse **C**orrelation. The gust load distribution for calculating the rms response σ_S is then (Niemann 1998, also the following Equations 10 to 12)

$$\Delta w(z, \theta) = \sigma_p(z, \theta) \cdot \rho_{pS}(z, \theta) \tag{10}$$

The LRC can be obtained by calculation when the vector of the mechanical influence coefficients, a, are known and the covariance matrix of the pressures, Cov(p) has been measured in a wind tunnel test. The response variance is then

$$\sigma_S^2 = \underline{a} \cdot \underline{Cov(p)} \cdot \underline{a}^T \tag{11}$$

where T indicates a transposed vector. The load response correlation required in Equation 10 is

$$\underline{\rho_{pS}} = \frac{1}{\sigma_S} \cdot \underline{a} \cdot \underline{diag(\sigma_p)} \cdot \underline{\rho_p^T} \tag{12}$$

An alternative is to measure the LR correlations in wind tunnel tests. For load-response-correlation tests, an elastic model is needed for measuring the response, e.g. in terms of strains. This method has been developed and frequently used for identifying interference factors. Figure 6 shows a cooling tower model for measuring strains and pressures simultaneously.

Pressure distributions for the isolated 200 m tower are depicted in Figure 7. The pressure coefficients at the 130 m level are normalized by the mean velocity pressure at that level. Three pressure distributions are considered: The mean pressures have a typical distribution with a maximum coefficient of 1 at stagnation, −1.4 at the minimum and −0.5 in the wake. The equivalent gust wind pressures are greater at this level by a constant factor of 1.9. The LRC-load has a higher value at stagnation and lesser values in the suction region. The meridional internal force n_{xx} at stagnation due to the LRC-load is 5% smaller than calculated with the equivalent static load according to the BTR.

Figure 6. Elastic wind tunnel model for Load Response Correlation tests.

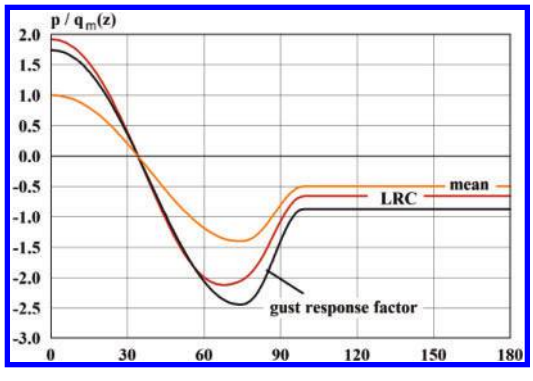

Figure 7. Comparison of external pressures p/q_m at a 200 m NDCT at the 130 m level.

4 APPLICATION TO INTERFERENCE EFFECTS

An example is presented of an NDCT in a strong interference situation where the extreme wind load effects are evaluated on the basis of most adverse, momentary pressures distributions. The LRC load is obtained by calculation. Measurements of time histories of wind pressures were conducted in the Boundary Layer Wind Tunnel at the Ruhr University Bochum. Mechanical influence coefficients relating a structural response to the surface pressures are derived from an FE model of the cooling tower.

The cooling tower is relatively slender having an aspect ratio of about 1.9. The roughness of the exterior shell surface, originating from formwork ribs and additional wind ribs, is classified by the pressure distribution curve K1.1 (Fig. 5).

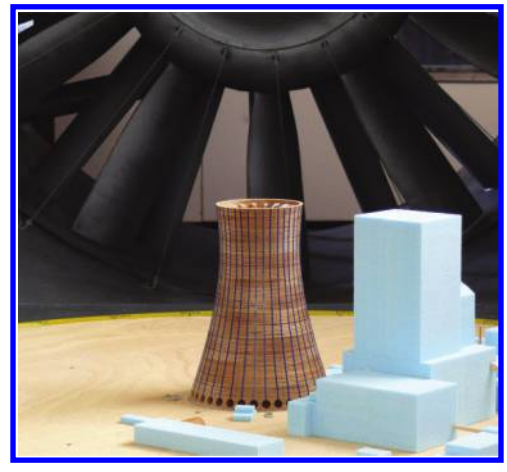

Figure 8. Wind tunnel model of a cooling tower in a strong interference situation.

A rigid pressure model was made at a scale of 1:400. It is equipped with 118 pressure tabs in total which are arranged in 5 sections with 18 pressure tabs for measuring the highly varying external pressures and several additional pressure tabs for measuring internal pressures simultaneously. Figure 8 shows the wind tunnel model of the NDCT with neighboring buildings. As it can be seen the boiler house and the cooling tower are of same height and in a very close configuration.

In order to evaluate the correlation coefficient ρ_{pS} between the pressure and the response considered the measured wind pressures have to be extended to the grid of the FE model. For this first step in the subsequent calculations a special interpolation and approximation scheme is used and the plausibility of the interpolation is controlled.

Based on such time histories of surface pressure distributions the evaluation of the load response correlations (Eqns. 11–12) and generation of most adverse pressure distributions from the mean and the gust wind load distribution is practicable. Measurements and subsequent calculations are done for the isolated cooling tower as well as for the interference configuration (Fig. 8). To identify decisive interference situations the wind rose is investigated in a step size of 10 degree.

Influence coefficients are provided for the shell forces. For each reaction force in each element an LRC wind load is generated for the upper and lower extreme value as well as for the two wind load cases w_e and $(w_e + w_i)$ and the corresponding force value is calculated. In case of a symmetric reinforcement the extreme values around the circumference in a particular height are of interest.

For the isolated tower the maximum meridional tensile force is identified at stagnation ($\Theta = 0°$) in a height $z/H = 0.38$ due to the net wind load. The corresponding LRC load is shown in Figure 9. The peak velocity

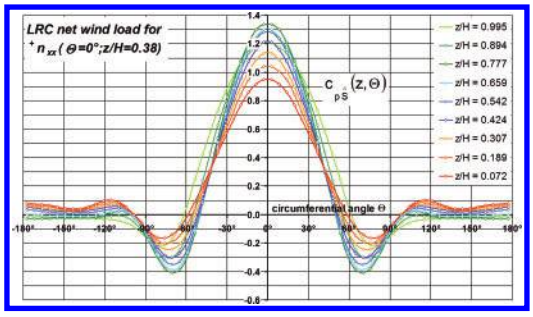

Figure 9. LRC wind load inducing the maximum meridional tensile force for the isolated tower: ${}^{+}n_{xx}(\Theta = 0°; z/H = 0.38)$.

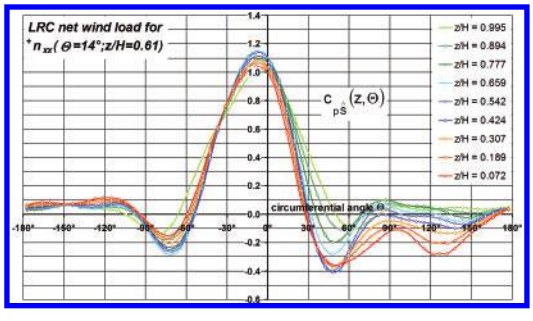

Figure 10. LRC wind load inducing the maximum meridional tensile force due to interference: ${}^{+}n_{xx}(\Theta = 14°; z/H = 0.61)$.

pressure at tower height H is used as reference leading to a varying pressure coefficient at stagnation in contrast to the formulation used in the VGB guideline (Eqn. 2, Fig. 2).

Analyzing interference effects the maximum meridional tensile force is found for a wind direction resembled in Figure 8. In contrast to the isolated case it occurs not at the circumferential angle equal to the wind direction ($\Theta = 0°$) but is shifted slightly to the left side. Beyond that it is also shifted to an upper part of the shell, $z/H = 0.61$. This is an important fact because the beneficial effect of the dead weight is decreased. The corresponding LRC load is shown in Figure 10.

With this example it could be shown that the LRC wind loads can be derived from measured pressure time histories. Time and effort for the wind tunnel tests, the determination of the mechanical influence coefficients and last but not least the calculations to generate the LRC wind loads are bearable for practical application. The wind load inducing extreme effects in the shell is determined more realistic and therefore also more suitable especially for nonlinear stress calculations.

ACKNOWLEDGEMENT

The wind tunnel tests were accomplished in the Boundary Layer Wind Tunnel Laboratory at the Ruhr University Bochum, Prof. Dr.-Ing. R. Hoeffer. The mechanical influence factors have been provided for this study by ZERNA Planen & Pruefen GmbH, Bochum. The collaboration with both partners is gratefully acknowledged.

Wind-tunnel investigations of pressure distribution over high-rise buildings

M. Cwik & M.A. Gizejowski
Warsaw University of Technology, Warsaw, Poland

A.M. Goliger
Council for Scientific and Industrial Research, Pretoria, South Africa

ABSTRACT: This paper deals with the wind-tunnel investigations of high-rise buildings. In the first part, an overview of the developments in model testing, as well as the future trends, have been discussed. Particular emphasis has been placed on methods of evaluating wind loads of high-rise structures. The second part provides a description of the research, conducted at the wind-tunnel of the Council for Scientific and Industrial Research, in Pretoria, South Africa. The aim of this research was to determine pressure distribution over the façade of 208 m high Warsaw Trade Tower building. Wind tunnel tests were a part of a wider research project which also includes full-scale measurements and numerical simulations (CFD, FEM), in order to examine the possibility of application of wind action simulations in structural health assessment of high-rise buildings. An overview of this research project and expected results are described in the third part.

1 INTRODUCTION

A realistic determination of environmental effects is essential to ensure an economic and safe design of structures. Within these effects, wind and seismic actions constitute the most critical aspect of the design of high-rise buildings.

Methods of evaluating wind loads of specific structures can be grouped into: 1) full-scale measurements; 2) model tests (BLWT – boundary-layer wind-tunnel tests) and 3) numerical simulations (CFD – computational fluid dynamics).

Generally full-scale measurements provide the most reliable results. Nevertheless, costs of research and difficulties in implementation, to infinite variety of situations, are high in comparison with other methods.

Despite of tremendous development and great potential of numerical simulations, there are still many issues which foreclose harnessing of this method without validating the results with one of the other methods.

It seems that for now the boundary-layer wind-tunnel tests are most suitable for the evaluation of wind actions on structures.

2 OVERVIEW OF BLWT TESTING

2.1 *Background*

Baker (2007) suggested a categorization of the history of wind engineering into five periods, namely: 1) traditional (up to 1750); 2) empirical (1750–1900); 3) establishment (1900–1960); 4) growth (1960–1980) and 5) modern (1980-present).

These periods, related originally to the entire discipline of wind engineering aptly fit to history of model testing. In the following section only the modern period will be described briefly, in terms of the developments in the boundary-layer wind-tunnel testing.

2.2 *Recent developments*

Most developments in the wind-tunnel testing of high-rise buildings took place in the last 30 years. The main reason for that was the significant progress in measuring technology. Efforts of scientists began in 1970s, led in 1980s to the development of high frequency base balance (H-FBB) (Tschanz & Davenport 1983). This method is used primarily for high-rise buildings tests. Next milestone was the development of synchronous multi-channel pressure sensors (SM-PSS) at the turn of the 1980s and 1990s (Cermak 2003). Both of these technologies are widely implemented till present. In the meantime researches on aeroelastic wind-tunnel testing of high-rise buildings were conducted. During this period a number of advanced and increasingly larger BLWTs have been designed and constructed.

Developments in the wind-tunnel testing during this period, enhanced significantly the height limits of buildings. BLWTs became fundamental tools for designing the high-rise buildings. The importance and impact of wind-tunnel investigations of high-rise buildings are best illustrated by a quote of the structural engineer of Burj Dubai, Bill Baker (Skidmore, Owings & Merrill): "In the old days, wind tunnels

were for confirmation of forces, not to tell you what the building would look like. We virtually designed [the tower] in a wind tunnel," (ENR 2006).

On the other hand there is an ongoing scientific debate regarding the inability of evaluating extreme pressures for very small areas by using wind-tunnel technology.

2.3 *Future*

Modern buildings become taller and wind effects, related to their shape, become critical design aspect. This brings designers closer to the wind-tunnels, where using the iteration process, building's shape can be optimized. It seems that this trend will prevail in the future.

Another noticeable tendency is the design and construction of increasingly larger BLWT. For instance in 2008 in Southwest Jiaotong University a BLWT with a test section of 22.5 m wide, 36 m long and 4.5 m high was put into use (Li et al. 2009).

Noticeable is also the supporting role of the wind-tunnel testing in development of the computational fluid dynamics (CFD) simulations. Recent developments in the CFD methods enable to combine them with wind-tunnel tests and validate results obtained using both methods.

Nevertheless, despite of the increasing role of CFD simulations and due to economic limitations of full-scale measurements, wind-tunnel testing remains the essential tool in predicting wind effects on high-rise buildings.

3 WIND-TUNNEL TESTS OF WARSAW TRADE TOWER

3.1 *Aim and scope of the research*

The aim of the research was to evaluate average pressure distribution over the façade of a Warsaw Trade Tower building under certain wind conditions. Warsaw Trade Tower (WTT), formerly Daewoo Center, building which is 208 m high (184 m excluding the spire) is currently the third tallest building in Poland (Fig. 1). It is used mainly for commercial offices purpose. The building was constructed during 1997–1999. The structure consists of a covered exterior steel framed tube lateral system and an interior reinforced-concrete core. It is 52 × 27 m in plan. The shape of the building reminds semi-cylinder with flat western façade and with cuboids intersecting the curved rest of the façade. The building is located in the northwest part of city centre. The nearest surroundings are 9% built-up, with buildings exceeding 15 m. The analyzed area can be characterized as a terrain between category III and IV, according to PN-EN 1991-1-4.

The scope of the study included determination of wind pressure values at 117 measuring points distributed over all façades of the model. Measurements covered the full range of wind azimuths. Research has been conducted at a Boundary-Layer Wind-Tunnel (BLWT) located at the Council for Scientific and

Figure 1. Warsaw Trade Tower (WTT) building.

Figure 2. CSIR boundary-layer wind-tunnel.

Industrial Research (CSIR), in Pretoria, South Africa (Fig. 2).

3.2 *BLWT at CSIR*

CSIR's boundary-layer wind-tunnel was established in the early 1980s. Since then several improvements were

introduced to the instrumentation and the data acquisition system. Modern instrumentation includes, among others, new pressure measuring system.

CSIR's BLWT is an open-circuit type with a boundary-layer development length of 18 m and a cross-section of 2 m by 1 m with a turntable of 1.8 m diameter. Wind-tunnel is equipped with a single centrifugal fan powered by a thyristor-controlled 75 kW variable-speed motor which allows obtaining variable air speeds of up to 22 m/s. The inlet area consists of 50 mm tripping wall and four 250 mm high × 100 mm wide triangular spires.

SM-PSS system, used for pressure measurements, is based on the RAD3200 system manufactured by Scanivalve Corp. It allows to measure, at the same instance of time, pressure at 32 points with a frequency of reading the same transducer of 625 Hz. 1-dimensional hot-wire anemometers are used to measure flow speed. Reference dynamic pressure is obtained from a pressure transducer connected to a pitot-tube which is attached at height of 740 mm above centre of the turntable. Reference static pressure is obtained from the pressure tapping in the roof above the model, slightly at the back. Analogue readings are converted into digital format and transferred to the computer measuring system. Software based on Scanivalve's RAD, and adopted for boundary-layer wind-tunnel tests, is responsible for archiving and post-processing of the data.

3.3 *Model*

The building model and its immediate surroundings were constructed at a geometric scale of 1:500. WTT model was about 40 cm height with a cross-section of 10 × 6 cm. It was divided into 11 horizontal measuring sections and one additional point located centrally at the horizontal surface of the roof. Each of 11 levels included from 7 up to 12 measuring points. In total pressure readings were carried out in 117 points located over the external surfaces of the model. After conducting measurements it was found that, due to the technical problems, data corresponding to point 2 at level 10 and points 5 and 6 at level 11 for all azimuths became corrupt and has been excluded from further analysis. Consequently from the initial 117, only 114 points were taken into account.

The surrounding model contained an area of the city within a radius of 450 m around the WTT building. Model included all the objects higher than 3 m. The overall number of structures in the analyzed area exceeded 250. In accordance to the terrain elevation measurements it was assumed that the area has a constant altitude.

3.4 *Testing*

Initially, measurements of the horizontal wind profile were conducted. Wind speed profile was measured in front of the wind-tunnel turn table. Readings have been taken for full-range of heights with a step of 25 mm,

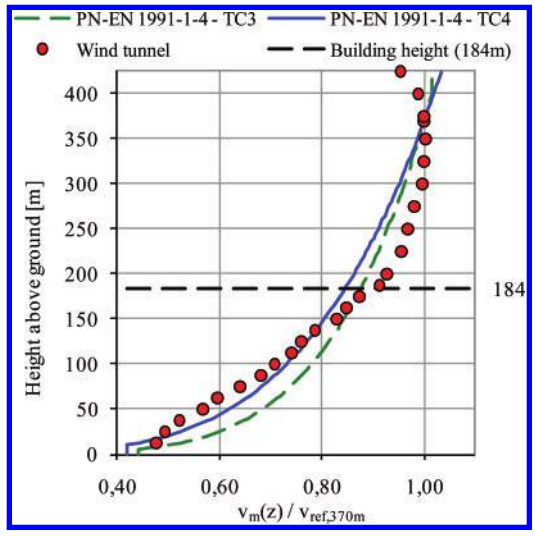

Figure 3. Comparison of wind speed profiles from tunnel tests and PN-EN 1991-1-4:2008 for TC III and IV.

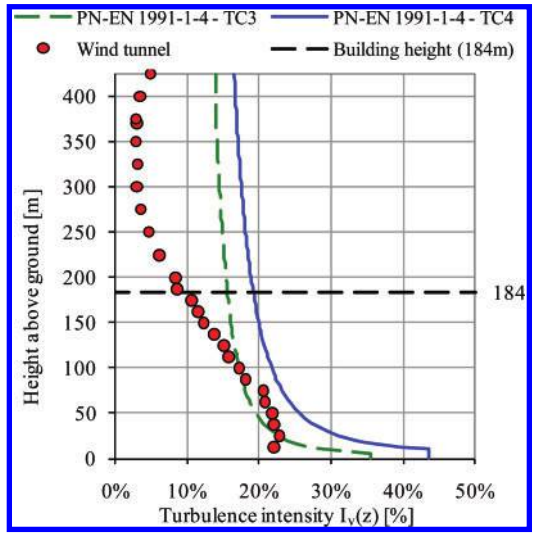

Figure 4. Comparison of turbulence intensity profiles from tunnel tests and PN-EN 1991-1-4:2008 for TC III and IV.

between 25 and 400 mm and a step of 50 mm from 450 up to 850 mm. Additional measurements were taken for the height of 740 mm which corresponds to the position of the pitot-tube. Each measurement cycle consisted of 24576 readings at a frequency of 625 Hz.

A comparison between the results and the power-law wind speed profiles as well as the logarithmic turbulence intensity profiles, corresponding to terrain categories III and IV from National Annex and code PN-EN 1991-1-4:2008, is shown in Figures 3, 4.

It can be noted that the wind speed profiles obtained in the wind-tunnel tests are fairly similar to those stipulated in the design codes. Below 100 m the wind-tunnel flow is slightly lower. Above that level, the speed is

increasing and is slightly higher than the code profile. Turbulence intensity profile in lower parts up to 125 m shows good fit. Differences between profiles increase with height.

Subsequently, pressure measurements for a full range of wind azimuths, with basic step of 20° have been carried out. Additionally, having considered the most frequent wind directions in Warsaw, for the azimuths between 250° and 290° a step of 5° has been applied. Consequently, measurements included 25 wind directions.

Each measuring cycle, for a specific level and wind azimuth, consisted of 24576 readings at a frequency of 625 Hz. The mean wind speed at a height of 740 mm was of 11.9 m/s. Assuming the full-scale wind speed derived from PN-EN 1991-1-4:2008, for terrain category III at height of 370 m, equal to 35 m/s, the wind speed scale was equal to 1:2.9. Taking into account the geometric scale of 1:500 and wind speed scale of about 1:2.9, the time scale was equal to about 1:170. Therefore the tunnel sampling frequency of 625 Hz corresponds to 3.68 Hz at full scale, so each of 39.3 seconds cycle corresponds to 111.4 minutes sampled at a time interval of 0.272 seconds. All statistical calculations have been performed using a program developed by the authors in Visual Basic for Applications in Excel. Before carrying out statistical calculations, filtering of electrical spikes and removing of influence of standing wave have been performed.

Finally, measurements of the wind speed at a location corresponding to the position of the weather station in the full-scale, were carried out. These were carried out for 35 wind directions. (The weather station in full-scale measurements was located in 1/3 distance between the lowest and the highest point of the upper edge of western façade 2 m, above interior edge of the parapet wall of the roof at height of 181.5 m above ground.) These measurements were done in order to the correlation of the results obtained in wind-tunnel tests, CFD simulations and full-scale measurements.

3.5 *Results*

The variations of wind speed and turbulence intensity, at a location corresponding to the weather station, are shown in Figure 5. Wind speed ratio was calculated as a ratio of wind speed at weather station to the undisturbed wind speed measured for the same height in the horizontal profile measurements. The wind speed ratio varies from 0.22 to 0.94. The results indicate a significant decrease of wind speed at weather station localization for wind azimuth from 220° up to 320° with minimum for 260° which correspond to wind direction perpendicular to western façade equal to 256°. Two peaks for azimuth 200° and 330° which corresponds to wind direction of 60° and 70° for western façade can be observed. Clear decrease of wind speed and increase of turbulence intensity related to deflection of wind direction from western façade are observed for wind azimuth from 0° up to 180°.

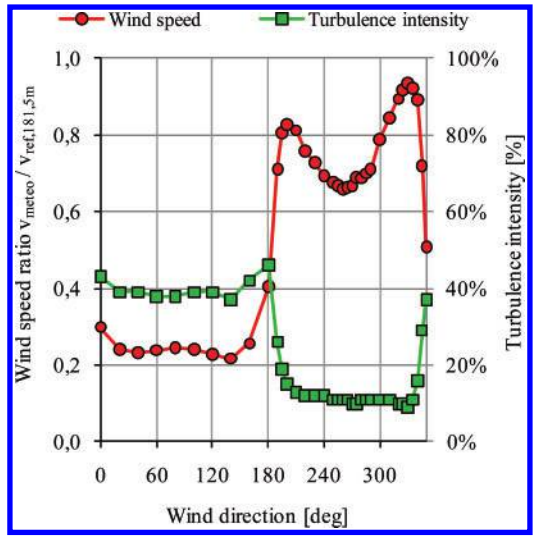

Figure 5. Variation of wind speed and turbulence intensity at weather station localization with wind azimuth.

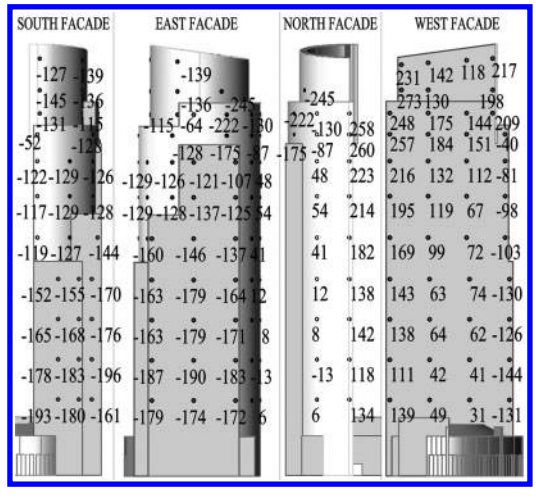

Figure 6. Average wind pressure over WTT facades.

Average values of the external pressure over building façade, shown in Figure 6, were calculated for wind speed of 24.2 m/s at height of 181.5 m (363 mm in model scale) and direction of 320°. All results are given in Pa. Wind speed and direction correspond to results obtained in full-scale measurements.

The average wind pressure varies between −245 and 273 Pa. Positive pressures occur for the most of the western and northern facades. For southern and eastern facades as well as for southern vertical edge of western façade and upper parts of the northern façade negative pressure values are observed. Lowest negative values were recorded in the upper parts of the northern façade. Highest positive values are observed at upper parts of the edge of western and northern facades. Average value of pressure at the roof is of 150 Pa.

The validation of the pressure values and wind speeds corresponding to the location of the weather station, using CFD simulations was carried out by Sitek et al. (2013). Both sets of the results indicate a fair degree of convergence.

4 STRUCTURAL HEALTH ASSESSMENT

Most of the high-rise buildings are designed to fulfill their function between 50 to 100 years or even more. At all time structures should remain safe, serviceable and durable. Obviously it is impossible to fulfill these requirements without appropriate maintenance. Apart of the standard maintenance activities it is necessary to undertake periodic inspections of structures. In Poland such compulsory inspections have to be carried out every 5 years and each time after the occurrence of an extreme action. Inspections should provide information on the condition of the building and answer the question whether the building is safe to further use or not.

Due to the possibility of fatigue, corrosion as well as the deterioration caused by other phenomena – comprehensive inspections require access to all components of a structure. These activities introduce interruptions in the utilization of various areas of the building. This will have financial implications, particularly in the case of high-rise buildings used for commercial purposes (e.g. removal of finishing elements and reconstruction, compensations for stoppages etc). Furthermore, among the others disadvantages, such inspections are time-consuming and sometimes introduce significant technical challenges.

These problems may result in limiting or adjusting the scope of inspections to suit the needs of specific buildings and their occupants. This situation can be considered as inappropriate and requiring the development of relevant solutions. The need for a quick, reliable, non-disruptive and inexpensive testing method is apparent.

One has to consider that it is almost impossible to access and evaluate every part of a structure. The principle of the proposed solution is not to examine the structure itself but rather to examine and analyze its response to a known loading. A comparison of the theoretical and measured responses would then constitute the indicator of structural condition. The above discussion suggests a solution in terms of a Structural Health Monitoring (SHM) system, which currently many of the high-rise buildings are being equipped with. General principles of SHM are based on three steps: continues measurements of the structure's behavior and environmental effects, analyses of the data which is obtained, and alerting when results extend beyond assumptions. The SHM appears to be a sufficient solution to evaluate the condition of a building. However, the cost of assembly and maintenance of such systems is relatively high and even more costly for existing buildings. In most cases, there are no reasons for conducting continues measurements for each and every high-rise building.

Proposed solution is not intended to replace the standard inspection process. The objective is to periodically evaluate general condition of a high-rise building and to evaluate the possible need of performing the comprehensive inspection. Structural health assessment can be described in 5 steps as follows.

Step 1. Full-scale measurements. Evaluation of the physical displacement of a structure using global navigation satellite system (GNSS) devices mounted on a building's roof. Simultaneously measurements of wind speed, direction and other meteorological quantities using weather station also mounted on building's roof. The results will represent the physical response of the structure subjected to specific wind loads.

Step 2. Wind-tunnel tests. Evaluation of pressure distribution over the building façade. Test conditions and calculations should correspond to those obtained in the full-scale measurements. The results would provide information on wind loading at specific points, which resulted in building's response, as measured in full-scale.

Step 3. CFD simulations. Evaluation of pressure distribution over the entire building's façade. Simulation conditions should correspond to those obtained in full-scale and wind-tunnel tests. Validation of the results to be carried out using the wind-tunnel data. The results will represent the estimation of a wind loading, over the entire building's façade, which resulted in the response, as measured in full-scale.

Step 4. FEM calculations. Evaluation of theoretical displacement of the structure caused by wind loads obtained in CFD simulations. The result would represent the theoretical response of the structure subjected to wind loads, which correspond to those observed in full-scale measurements.

Step 5. Analysis of the results. Comparison of theoretical (derived from FEM) and physical (measured in full-scale) displacements of the structure.

Similar approach was proposed by Chmielewski et al. (2009) who presented results of comparison of theoretical and measured response of the Stuttgart TV Tower. The assumption of the research was that the changes in the first natural frequency may indicate potential damage of the tower. The difference between methods is that Chmielewski et al. (2009) compared natural frequencies. Proposed method is based on comparison of displacements which is considered to be a more suitable approach in reference to high-rise buildings.

Authors expect to obtain a fair degree of similarity in theoretical and physical displacements of high-rise buildings which are in a good structural condition, and clear differences for buildings with structural deficiencies.

Clear advantages of the proposed structural health assessment system are: the non-destructive and non-disruptive testing, relatively low costs and ease of implementation. The biggest problem lies in the dependence on the weather, i.e. the required magnitude of wind loading which will introduce considerable displacement of the building. Nevertheless, reliable

system of measuring displacements of high-rise structures, subjected to low magnitude winds, using GNSS technology was presented by Breuer et al. (2002).

The wind-tunnel investigation of WTT building, presented in the current paper, forms a part of the research project to examine the possibility of application of the structural health assessment process.

5 CONCLUSIONS

The paper provides a brief historical outline of the developments as well as the future trends in wind-tunnel investigations of high-rise buildings.

The process of evaluating the mean wind pressures over the façade of a high-rise building (Warsaw Trade Tower), with the use of boundary-layer wind-tunnel technology, is presented. Wind-tunnel located at the CSIR in Pretoria, South Africa, which was used in the current research, is described. Comparisons of wind speed and turbulence intensity profiles measured in the wind-tunnel and those derived from Eurocodes are discussed. Results of the mean values of wind pressure over the building façade as well as the wind speed and turbulence intensity at the roof of the building are presented and discussed.

An overview of the research project, related to the use of wind engineering technology, as a tool to identify potential structural deterioration of high-rise buildings, is described. Assumptions of the proposed method are based on a comparison of theoretical and physical displacements of structures. The method involves the use of: wind-tunnel testing, CFD simulations, FEM calculations and full-scale measurements (including particular use of GNSS measurements). The expected results are also described.

ACKNOWLEDGEMENT

This paper is a review of the wind-tunnel tests, undertaken at the advanced stage of a PhD research study of the first co-author carried out at the WUT and CSIR. Part of the research, related to the wind-tunnel testing, has been carried out at CSIR.

The scientific interaction between the CSIR and WUT was undertaken within the framework of the SA/Poland Agreement on Cooperation in Science in Technology. The authors would like to express their appreciation to the South African National Research Foundation (NRF) and the Ministry of Science and Higher Education in Poland, for the financial support of this research partnership. Most of the wind-tunnel measurements were carried out by Mr Ters van Wyk of CSIR.

Probabilistic models for design of structures against wind loads

J.V. Retief & C. Barnardo-Viljoen
Stellenbosch University, Stellenbosch, South Africa

M. Holicky
Czech Technical University in Prague, Prague, Czech Republic

ABSTRACT: Much effort has been expended on the proper probabilistic representation of strong wind loading mechanisms; effective design procedures that are sufficiently operational, yet essentially capture variability and uncertainty; achievement of sufficient levels of reliability consistently over the range of design situations through calibration. There is nevertheless an acute need to improve probability models for strong winds in order to address specific needs. Capturing the complexity of the geographical distribution of the strong wind climate in deriving suitable probability models to serve as basis for stipulation of design values is one such a need. In this paper, the conditions in South Africa is used as a case to consider proper probabilistic representation of strong winds across a complex and diverse geography and climate. Based on a set of extreme value models and climatic strong wind characterization, a procedure is demonstrated for deriving characteristic values as distributed across a region, with dispersion properties on which design values are based per region. This provides the key components of the probabilistic modeling of strong winds are represented in a cohesive and systematic manner, for use in the calibration of reliability based operational design procedures.

1 INTRODUCTION

Wind loading represents an important class of action that needs to be provided for in structural design. The variable nature of the occurrence of strong wind conditions is a critical aspect of this type of structural loading that can only be treated probabilistically. Much effort has therefore been expended on the proper probabilistic representation of strong wind loading mechanisms. The probability models form the basis for effective design procedures that are sufficiently operational, yet essentially capture variability and uncertainty to achieve sufficient levels of reliability consistently over the range of design situations through calibration.

In spite of the attention received, there is still an acute need to improve probability models for strong winds in order to address specific needs. A specific need for instance is to improve the representation of the strong wind climate and probability models for a specific region, making use of the latest series of observations.

Certain classes of structure such as modern light steel structures are particularly sensitive to extreme environmental actions such as wind loading. For the design of important structures, very high levels of reliability is required; extreme wind loads at very low probabilities of occurrence need to be considered.

Design for wind loading can broadly be divided into the natural environmental processes and the conversion of the free field wind into wind pressure loading on the structure. Natural wind conditions are predominantly modeled by time variant probability models representing the stochastic nature of strong wind conditions. Probability modeling of the wind pressure loading process is predominantly a time invariant representation of uncertainties of predicting wind pressure conversion and distribution across the structure.

This paper is concerned with probability models for the natural conditions related to wind loading on structures. The loading process nevertheless needs to be taken into account in setting up appropriate probability models for the natural strong wind occurrence.

Two extreme cases can be identified for the probabilistic modeling of natural time variant strong wind occurrence: In the case of very important structures with high consequences of structural failure, extreme wind with very low probabilities of occurrence needs to be determined. For standardized design procedures, robust probability models for strong wind are required on which effective and optimal reliability based design wind load values can be based.

In both cases, the probability models can be constrained by limited data, as compared to the probabilities associated by the relevant levels of reliability.

Complementary information on strong wind processes such as the nature of the strong wind generating process can play an important role to improve the quality of the models by revealing unknown sources of

uncertainty. Climate change provides a serious challenge to proper probability modeling of strong wind (Retief et al 2013). The relationship between wind generating processes and strong wind occurrences is of critical importance to project future trends in terms of climate change modeling.

2 GENERAL WIND LOAD PROBABILITY REPRESENTATION

2.1 *Extreme value probability models*

The extreme values (maximal or minimal) in a population of a certain size are random variables and their distribution is extremely important for the theory of structural reliability. The General Extreme Value (GEV) distribution covers three types of distribution of extreme values that are usually denoted as types I, II and III. Each of the types has two versions – one for the distribution of minimal values, the second for the distribution of maximal values. All these types of distribution have a simple exponential shape and are convenient to work with.

The extreme value distribution of type I, which is commonly called the Gumbel distribution, is described in detail by Equations (1) and (2) (Holicky 2009). The distribution parameters are the shape coefficient α and the mode β which are related to the population paramters for the mean (μ) and standard deviation (σ) as given by Equation (3).

$$F(x) = EXP(-EXP(-y)) \tag{1}$$

$$y = (x - \beta)/\alpha \tag{2}$$

$$\alpha = \sigma\sqrt{6}/\pi \qquad \beta = \mu - 0.577\alpha \tag{3}$$

In a similar way as type I Gumbel distribution, type II distribution, the so-called Fréchet distribution, and type III distribution, the so-called Weibull distribution, are defined by exponential functions. All three types of distribution complement each other with regard to possible values of the skewness s. Each type covers a certain area of skewness, as shown in Figure 1.

Types I and II of the extreme values distribution are often applied in the description of quantities of which the maximal values are studied (wind actions), and type III distribution is applied for quantities of which the minimal values are studied (e.g. strength and other material properties).

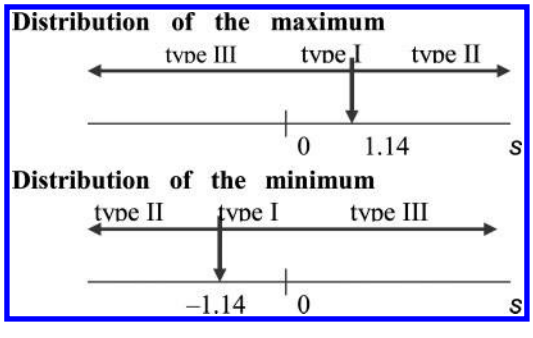

Figure 1. Types of distributions of extreme values with skewness s.

However, it should be mentioned that both these distributions have relatively high skewness ($\alpha \geq 1.14$) and should be applied with a caution. Long term experience shows (Holicky 2009) that when the available data indicate a low skewness ($s$close to zero) then the Gumbel distribution may lead to conservative estimates of extremes and the General Lognormal (three-parameter) distribution may provide a better approximation.

2.2 *Wind load probability model*

The wind pressure on a structure may generally be written as the combination of the time variant effect of the wind velocity v or Q_{Ref} and the time invariant processes given in Equation (4). The variables are defined in Table 1, together with listing of typical distribution values; ρ is the deterministic value of the air pressure.

$$Q = 0{,}5\rho v^2 c_r c_a c_g c_d = Q_{\mathrm{Ref}} c_r c_a c_g c_d \tag{4}$$

Where ρ is the air density and v the wind speed, with other basic variables defined in Table 1; representative distribution values are also tabulated:

2.3 *Design values for wind load*

Assuming a Gumbel distribution for the wind load, expressions can be formulated for the design value (Q_d) and characteristic value (Q_k) of the wind load in terms of the mean value (μ_Q), the target level of reliability (β_T), the coefficient of variation of the wind load (w_Q) and the annual pressure ($w_{Q,Ref}$), the ratio of reference period to design life N (typically 50) (Holicky 2009).

By stipulating the characteristic value of wind load at the 2% probability level, the ratio of characteristic to mean value is given by Equation (5).

$$Q_k/\mu_Q = 1 - w_Q\,(0.45 + 0{,}78\,\ln(-\ln(0.98))) \tag{5}$$

The ratio of design to mean wind load value is given by Equation (6). The partial load factor γ_Q can be

Table 1. Representative distribution parameters and time dependence for wind load.

Symbol	Variable	Time Dep.	Mean	CoV w_o
Q_{Ref}	Annual pressure extreme	Yes	0.8–1.0	0.25
c_r	Terrain roughness	No	0.8–1.0	0.15
c_a	Aerodynamic shape	No	1.0	0.20
c_g	Gust effects	No	1.0	0.15
c_d	Dynamic effects	No	1.0	0.15

obtained from the ratio of design to characteristic value as shown by Equation (7).

$$Q_d/\mu_Q = 1 - w_Q F_1 + w_{Q,\mathrm{Ref}} F_2 \quad (6a)$$

$$F_1 = 0.45 + 0{,}78\ln(-\ln(\Phi(-0.7\beta_T))) \quad (6b)$$

$$F_2 = 0.78\ln(N) \quad (6c)$$

$$\gamma_Q = Q_d / Q_k \quad (7)$$

Based on the parameter values listed in Table 1 to obtain w_Q whilst parametrically varying the values for $w_{Q,Ref}$, indicative values for the characteristic wind load from Equation (5) and the partial load factor (γ_Q) from Equation (7) are shown in Table 2 to for typical target reliability (β_T) values used in Eurocode and South African standards.

The inverse of the characteristic value ratio (~0.5) should be compared with the indicative relative mean of $0.8 \times 0.8 = 0.64$ from Table 1. The relative sensitivity of the partial factor (and the design value from Equation (7)) to the variability of the annual pressure extreme can be observed from these indicative results.

3 STRONG WIND MODELS FOR SOUTH AFRICA

Updating the probability models for strong winds for South Africa serves as an illustration of the process of the application of these models as input to reliability based design models.

3.1 *Observations and records*

The specific nature of strong wind for structural design needs to be taken into account when extracting observations form general climatic records (Kruger et al 2011). Since only annual maximum wind speed is extracted for further analysis, quality assessment of the records is of critical importance. The recording period is of critical importance, due to the low probabilities for which the models are to be applied.

Due to boundary layer effects on strong wind loading, the height of observation and exposure of the weather station are critical factors influencing the quality of the observation. General terrain roughness, topography and upwind obstructions over extensive distances may have directional influences on the observations.

The density of coverage of the network of weather station has an important bearing on the geographic resolution of the strong wind records. Sufficiency of coverage is related to climatic and topographic characteristics of the region.

Table 2. Indicative values for characteristic wind load and partial load factors.

$w_{Q,Ref}$		0.20	0.25	0.30
Q_k/μ_Q		1.99	2.06	2.14
γ_Q	$\beta_T = 3{,}8$	1.55	1.62	1.69
	$\beta_T = 3{,}0$	1.32	1.39	1.45

3.2 *Related climatic information*

The relationship between strong winds and the related climatic conditions provides useful information to complement the statistical treatment of observations (Kruger et al 2012). The weather conditions under which strong winds are generated are of critical importance for example to differentiate between synoptic scale events and meso scale thunderstorms in terms of turbulence of the wind.

Mixed climate conditions need to be taken into account in probabilistic modeling of strong winds (Kruger et al 2010). Significant under-estimation of strong winds can occur if differentiation of strong wind mechanisms is not taken into account (Kruger et al 2012).

3.3 *Strong wind datasets*

The strong wind record of the present wind design maps for South Africa are based on 14 weather stations with a record length ranging from 18 to 43 years, with an average period of 26 years. However, from a quality audit, these records were rejected for further analysis (Kruger et al 2011). Analysis is now based on a network of 172 new generation of automatic weather stations (AWS) deployed since 1990. From a quality audit, 74 AWS records are selected mainly on the basis of at least ten years of recording.

The main features of the dataset of strong wind records are:

- Recording periods limited to 10 – 18 years
- Improved geographical distribution
- Identification of strong wind mechanism associated with each occurrence

3.4 *Strong wind climate*

The main features of the strong wind climate as shown in Figure 2 can be summarized as (Kruger et al 2010):

- The strong wind climate shows a complex geographical distribution;
- Two dominant strong wind mechanisms (frontal and thunderstorm) with several secondary conditions that can be identified;
- Mixed climate conditions with both frontal and thunderstorm wind occurs is prevalent over large areas;
- There is limited agreement between gust and hourly mean strong wind distribution.

Strong wind generating mechanisms and its geographical distribution need to be taken into account in compiling probability models for wind speed.

3.5 *Representative strong wind models*

Since design is primarily based on static equivalent wind load, gust wind models are considered in

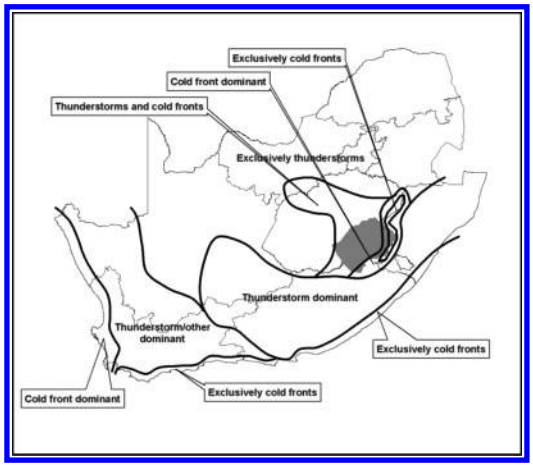

Figure 2(a). Strong wind mechanisms for gusts.

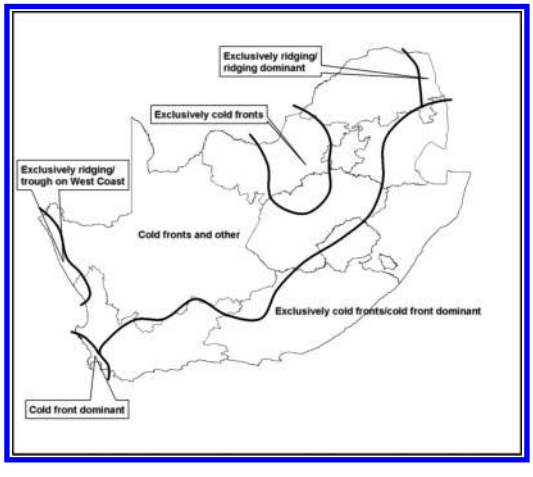

Figure 2(b). Strong wind mechanisms for hourly mean wind.

assessing probability models for South Africa. Various probability models are employed by Kruger et al (2013) to take account of short record lengths and mixed strong wind climate effects. Gumbel models are however sufficient to illustrate the main features of the South African strong wind climate.

Representative probability models for the three main metropolitan centers of the country are given in Figure 3, based on parameters summarized in Table 3.

In addition to indicating strong wind characteristics for significant regions of the country, Figure 3 is also representative of upper and lower ranges of strong wind probability distributions. It also represents the two main strong wind generating mechanisms of synoptic scale frontal wind and meso scale thunderstorms. Strictly speaking Cape Town should be classified as "mixed climate" although the second mechanism is also of synoptic scale; it is therefore not as significant as cases where the mixed climate derives from frontal and thunderstorm events.

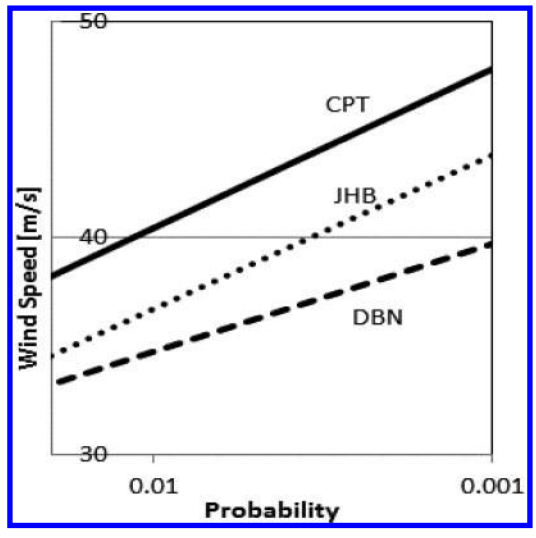

Figure 3. Representative strong wind probability models for Cape Town (CPT), Johannesburg (JHB) and Durban (DBN).

Table 3. Summary of distribution parameters.

DATA/PARAMETER	JHB	DBN	CPT
Record period (y)	14	16	16
Mean $\bar{x}$ (m/s)	24.4	26.1	27.7
Standard Deviation s	3.94	2.76	4.08
Dispersion α	3.07	2.16	3.18
Mode β	22.6	24.8	25.8
Skewness	0.77	1.01	0.75
Thunderstorm (TS) or Synoptic scale (SS)	TS	SS	SS

The range of strong wind values are characterized by its relative vertical position, as related to the mode (β) and slope of the graph, related to the shape parameter (α) or dispersion for the Gumbel distribution. Frontal winds cover the full range, with high values for both the mode and the dispersion for Cape Town and low values for Durban respectively; thunderstorms are generally characterized by larger dispersion such as for Johannesburg.

3.6 *Regional effects*

An indication of geographical effects can be obtained by comparing the probability models for the three main centers given Figure 3 to their respective regions.

Wind maps are conventionally expressed in terms of characteristic values at an exceedance probability of 0.02 per annum, or approximately the expected 50 year extreme value. It is therefore convenient to normalize the distribution to the characteristic wind speed for each location (V-0.02) as shown in Figure 4.

Differences in slope of the normalized graphs reflect differences in the dispersion parameter value

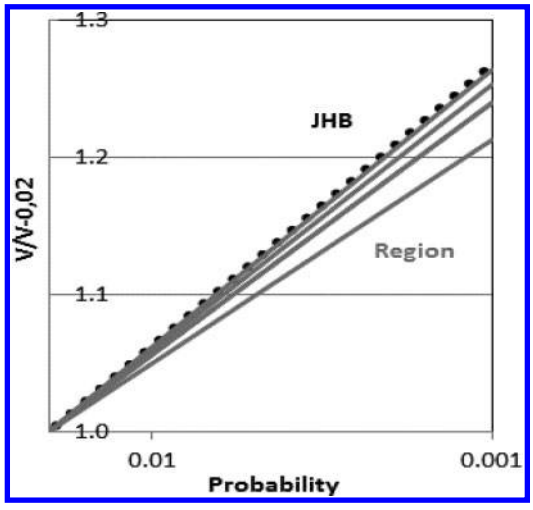

Figure 4(a). Comparison of normalized strong wind probability models for Johannesburg (JHB) and regional locations.

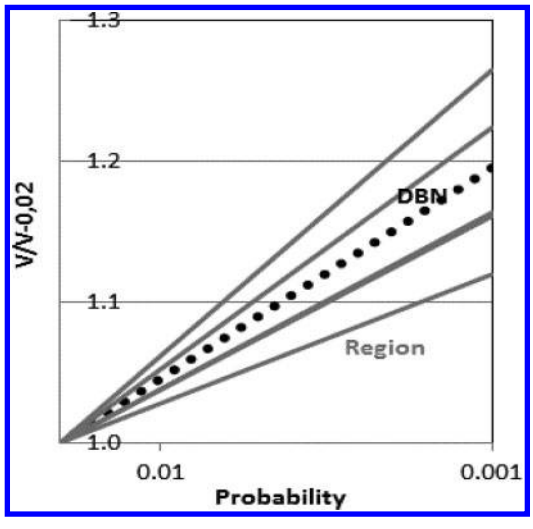

Figure 4(b). Comparison of normalized strong wind probability models for Durban (DBN) and regional locations.

(α) for the respective locations. Different regional features for the three regions can be related to the local strong wind climate and other geographical factors.

The graphs for regional locations lie relatively close below the Johannesburg graph, probably reflecting the homogeneity of thunderstorm wind.

The regional graphs are scattered widely around that for Durban; this is probably due to the effects of synoptic wind close to the coastline, with thunderstorms becoming the main source of strong wind from a small distance inland. The upper graph is however quite similar to the graph for Johannesburg.

In spite of the fact that strong wind is predominately generated by synoptic conditions, the scatter of the normalized graphs is the widest of the three regions. This can probably be ascribed to the topography of the

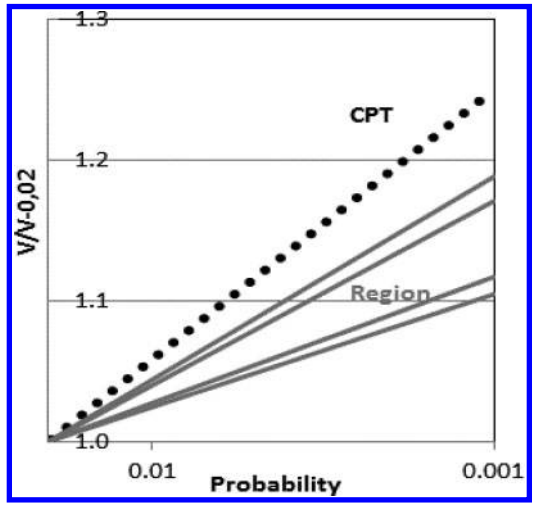

Figure 4(c). Comparison of normalized strong wind probability models for Cape Town (CPT) and regional locations.

region and the occurrence of frontal and other synoptic conditions causing strong winds.

3.7 *Applied probability model*

The strong wind climate of South Africa is complex due to the large geographical area covered and the diverse basic climate from which strong winds derive. Strong winds are generated from thunderstorms or various synoptic scale conditions, or mixed climate combinations of these mechanisms.

The agreement of the upper limits of the wind speed normalized to the characteristic wind speed for the three main metropolitan centers of the country however provides the basis for modeling dispersion conservatively.

An envelope of the dispersion of strong winds describing the quantile wind speed as a function of the annual exceedance probability can be described by a Gumbel function of the upper limit of the sets shown in Figure 4. The parameters for this Gumbel function V_{Disp} are $\alpha = 0.09$; $\beta = 0.65$; with a mean $\mu_{Disp} = 0.70$ and standard deviation $\sigma_{Disp} = 0.115$ as obtained from Equation (1).

The quantile wind speed V_P at exceedance probability P is then obtained as the product of V_{Disp} and the characteristic wind speed $V_{0.02}$ as given by Equation (8):

$$V_P = V_{0.02} V_{Disp} \tag{8}$$

The geographic distribution of V_P can be obtained by taking the value of $V_{0.02}$ for a given location from the map of characteristic wind speed from the map for South Africa presented by Kruger et al (2013).

Similar assessment needs to be done to confirm that this procedure is sufficient for other regions; alternatively to identify regions that need special treatment or exclusion from such simplified basis for design procedures.

4 CONCLUSIONS

Appropriate procedures for design wind loading to achieve the required levels of performance determined from the principles of structural reliability requires the representation of strong wind in terms of suitable probability models.

In an example it is demonstrated how the geographical distribution of strong winds can be represented in the form of a characteristic wind speed map, whilst the dispersion on which calibration of design procedures are based can be represented by conservative modeling of dispersion for a diverse range of strong wind climatic conditions.

Extension of this approach to include all the regions identified from previous investigations will provide for the compilation of a comprehensive map of characteristic wind speed. Furthermore, calibration of design procedures can be based on regional dispersion models for the whole region.

A.M. Goliger
Council for Scientific and Industrial Research, Pretoria, South Africa

ABSTRACT: Wind flow influence on a high-rise building is analyzed. The research covers full-scale tests, wind-tunnel experiments and numerical simulations. In the present paper computational model used in simulations is described and the results, which were obtained, are compared with wind tunnel data.

1 INTRODUCTION

Many high-rise buildings with complicated geometry are currently built in Poland. In the last few years several of them were constructed in the centre of Warsaw. This new situation requires a modern approach to design. Dynamic influence of wind on smaller buildings is typically negligible and, if relevant, can be incorporated into the loading in terms of a static load combined with a dynamic magnification factor. Dynamic influence becomes important when tall structures are taken into consideration. Greater precision of computations during the design process is necessary. Wind gusts frequency can be close or equal to natural frequency of a building and cause resonant effect. Recently introduced Polish code PN-EN 1991-1-4:2008 covers this subject to a wider extent than the previous one, but still the guidelines for designers are not sufficient for all structures.

The influence of wind loads on structures can be assessed by full-scale measurements, boundary-layer wind tunnel tests and numerical simulations. Full-scale tests give the most reliable results, but they are also expensive and time consuming. Currently wind tunnel tests are considered to be the primary method in the determination of loadings for tall buildings. However, computational fluid dynamics (CFD), which has been a focus of many researchers (e.g. Huang, Li & Xu 2006, Dagnew et al. 2009, Bitsuamlak & Simiu 2010, van Hooff et al. 2011) will become the future alternative. The advantages of CFD are numerous e.g.: computations are cheaper, faster and provide an opportunity to modify the model and to test more variants. The computations are made in the whole domain therefore give more useful information. Furthermore, the results can be presented in a form of advanced visualizations. Although the numerical models cannot generate exactly the same results as those obtained in wind tunnel tests, they are generally in good agreement.

The most common approach to solve equations of motion is to use spatial or time averaging of pressure and velocity fields. This results in a set of Reynolds Averaged Navier-Stokes equations (RANS). This concept requires turbulence modeling which sometimes introduces significant errors to the solution. The advantage is that the computational mesh doesn't have to be as dense as in direct solution methods and require smaller computational resources. RANS methods are widely used in CFD software, ANSYS/Fluent among others.

There is no turbulence model that is generally acknowledged and suitable for every problem. One of the most popular models is a two-equation k-ε model (Launder & Spalding 1972) along with its latter modifications: renormalization group theory, RNG (Yakhot & Orszag 1986) and realizable (Shih et al. 1995). Both are recommended, over the standard model, because of their successful performance in many problems.

2 THE SCOPE OF THE PAPER

Present study is a part of a research project (Cwik et al. 2009, Cwik et al. 2012) concerning wind action on a 208 m high Warsaw Trade Tower building, shown on Figure 1, which is located in a central but undeveloped part of Warsaw. The project covers: full-scale measurements, wind tunnel tests and numerical simulations.

The main goal is to examine the possibility of application of wind action simulations in structural health assessment of high-rise buildings. Another aim is to perform a comparative analysis of the results and to verify the recommendations of the Polish design code.

Figure 1. Warsaw Trade Tower (WTT) building.

Considering the scope of this project, it is the first such comprehensive attempt on this topic in Poland.

This paper presents preliminary results of CFD simulations and their validation through a comparison with experimental data from wind tunnel tests (Cwik et al. 2013). Initial conditions (mean velocity and turbulence intensity) for the computations are taken from the experiment and they correspond to wind direction 320°. A convergence analysis for various grids is performed to assess the best grid density in this particular problem. Mean pressure coefficient distribution over building's façade is obtained and compared with the wind tunnel measurements. In addition mean wind speed at the site corresponding to the location of the weather station is checked. Percentage error of mentioned quantities, with respect to the experimental data, is also given.

3 NUMERICAL MODEL

3.1 *Computational domain*

The geometry and mesh of the computational model are created in Abaqus. Then an input file is imported

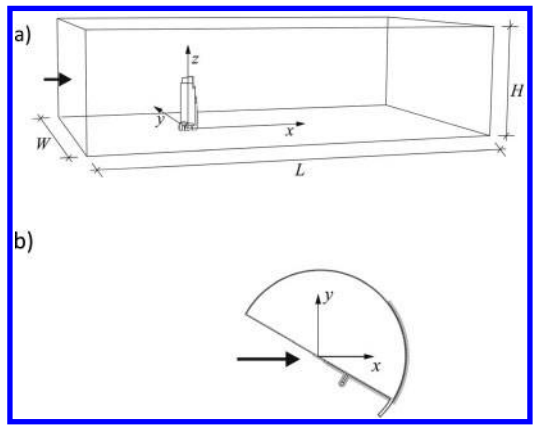

Figure 2. a) Geometry of the computational domain and b) top view of the building. Wind direction is indicated schematically with an arrow.

to ANSYS/Fluent 14.0, where RANS equations are solved.

The dimensions of the computational domain are adopted so that the cross-section of the domain is the same as the cross-section of the tunnel. The upstream length is chosen to equal $2h$, downstream length – $5h$, where h is building's height. Therefore the dimensions are $L \times H \times W = 2.7\,\text{m} \times 1\,\text{m} \times 2\,\text{m}$ (Fig. 2). A Cartesian coordinate system is chosen with coordinates: x – on ground plane, along wind direction, y – on ground plane, perpendicular to wind direction, z – perpendicular to ground plane. The geometry of the building model is simplified and the structures surrounding WTT are omitted. Building dimensions are the same as the dimensions of the model from experiment, which was made in a scale of 1:500.

The domain is discretized with an unstructured tetrahedral mesh. Cell sides are aligned with the contours of the building and domain boundary. The building has a fairly complex geometry and the grid used is fine enough to model the details. Three cases of grids are considered – coarse, medium and fine. Coarse mesh has 409706, medium – 694850, and fine – 1844736 cells.

3.2 *Solver configuration*

It is assumed that RANS equations are time independent. They are solved using RNG $k - \varepsilon$ turbulence model. Default ANSYS/Fluent model constants are adopted: $C_{mu} = 0.0845$, $C_{1\varepsilon} = 1.42$, $C_{2\varepsilon} = 1.68$.

Coupled pressure-based algorithm is chosen as a method for pressure-velocity coupling. Spatial discretisation gradient is based on the least squares cell. Pressure interpolation is standard. The convection and viscous terms are modeled with second-order discretisation schemes. Hybrid initialization is chosen as the solution initialization method. The solution convergence is monitored by checking the values of scaled residuals, following each iteration. The computations are completed when the difference for two consecutive

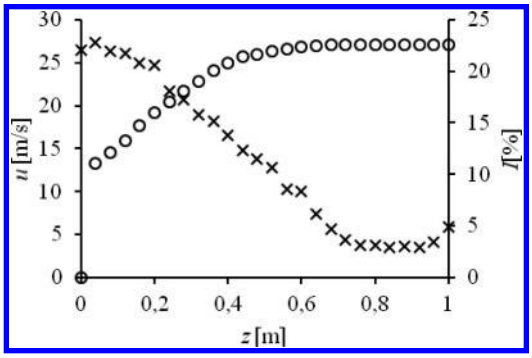

Figure 3. Mean velocity u (ooo) and turbulence intensity I ($\times\times\times$) inlet profiles.

iterations is smaller than 10^{-5} for continuity, 10^{-6} for x-velocity, 10^{-5} for turbulent kinetic energy and 10^{-5} for turbulence dissipation rate.

3.3 *Boundary conditions*

At the inlet of the domain, profiles of mean wind velocity, turbulent kinetic energy and turbulence dissipation rate are defined. Values of mean wind velocity u as well as turbulence intensity I are those derived from tunnel test measurements. Profiles of these two parameters are shown on Figure 3. Turbulent kinetic energy is calculated from $k = 1.5(uI)^2$ and the turbulence dissipation rate is established from $\varepsilon = C_\mu^{3/4} k^{3/2} / z\kappa$, where turbulence viscosity constant equals $C_\mu = 0.09$ and von Karman constant is $\kappa = 0.42$.

Wall boundary conditions are used to model ground and building surfaces, with standard wall functions (Blocken et al. 2007). No-slip boundary condition is enforced.

On the top and sides of the domain the same boundary condition is prescribed. Because tunnel test is being modeled in CFD, then according to recommendations found in literature (Tominaga et al. 2008), these boundaries should be represented as no-slip walls.

The flow exit is modeled by outflow boundary condition which corresponds to a fully developed flow, where the velocity is constant in the flow direction and the diffusion gradients in x-direction, for all flow variables are zero. There are no values to provide at this kind of boundary in ANSYS/Fluent.

4 NUMERICAL RESULTS

4.1 *Grid convergence*

Three aforementioned grids are checked for convergence. Figure 4 depicts static pressure along a vertical line on south-west façade passing through points nr 2 between levels 1 and 9.

It can be seen that with an increase in grid density the solution is converging. Therefore the finest mesh is chosen for further analyses. Although it requires more computational resources than medium mesh, it enables to obtain more accurate pressure distribution on the building façade and therefore better agreement of the results.

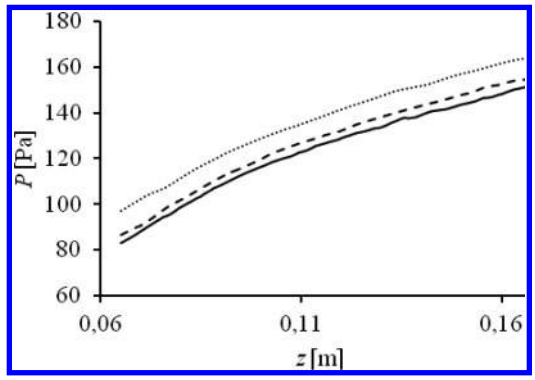

Figure 4. Comparison of static pressure for three meshes: coarse (…), medium (- - -) and fine (—) along a vertical line on south-west façade passing through points nr 2 between levels 1 and 9.

4.2 *Comparison of numerical and experimental results*

One specific wind direction of 320^0 (Fig. 2b) is selected from full-scale tests for validation of numerical modeling. Values of velocity at weather station location and pressure coefficient distribution are compared with wind tunnel data. Locations of the sensors on the building model are shown on Figures 5a)–b).

The weather station is located on the south-west side of the roof, 182 m above ground, as shown on Figure 5a. Mean wind speed measured in full-scale at this point is equal to 21.5 m/s. From numerical computations value of 22.2 m/s is obtained, which accounts for a good approximation.

Further evaluation of the results concentrates on establishing values of mean pressure coefficient on building façade. This parameter is fundamental in engineering design process. Pressure coefficient is calculated as $C_p = (P - P_{ref})/0.5\rho u_{ref}^2$, where: P – local static pressure, P_{ref} – reference static pressure, ρ – air density ($\rho = 1.25\,\mathrm{kg/m^3}$), u_{ref} – reference wind velocity at height 370 m ($u_{ref} = 27.34\mathrm{m/s}$). In order to compute the pressure coefficient with an adequate precision, the reference pressure must be established very carefully (Montazeri & Blocken 2013). The location of reference point corresponds to the pitot-tube position in the experiment. The sensor was located right above the building model at the height of 740 mm, which corresponds to the full-scale reference height of 370 m.

Figure 6 depicts change of static pressure along a vertical line passing through the origin of coordinate system xyz. The reference point is located in a flow field undisturbed by the building model and reference pressure equals to about 36.12 Pa.

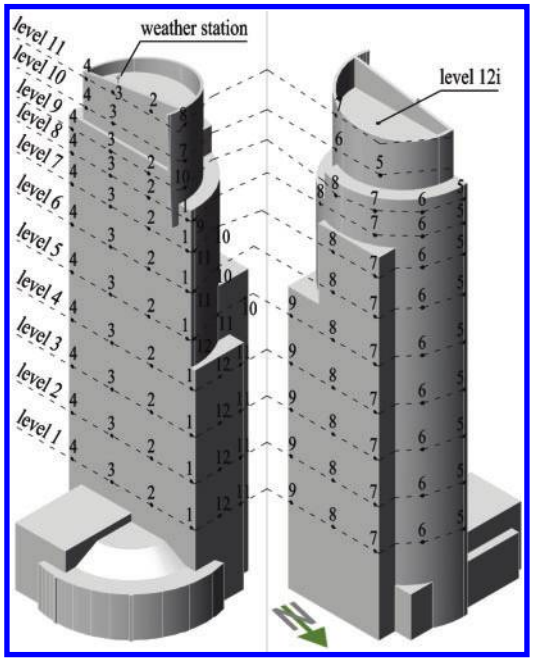

Figure 5a. Location of pressure measuring points on south-west (left) and north-east (right) facades. Weather station position.

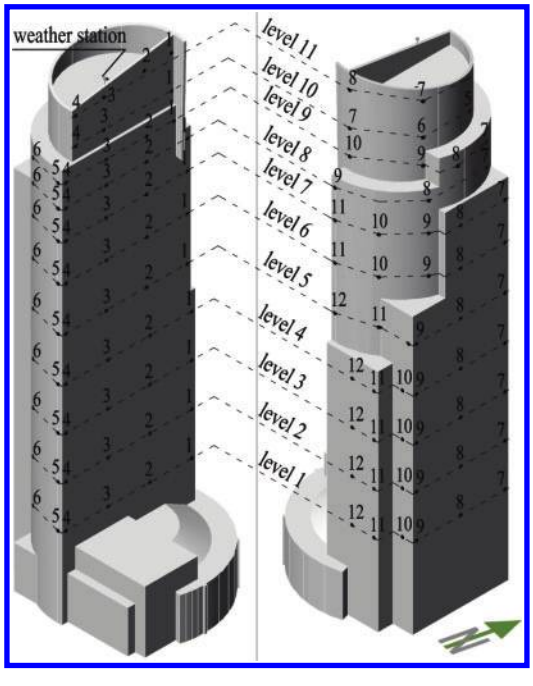

Figure 5b. Location of pressure measuring points on north-west (left) and south-east (right) facades.

Figures 7a)–d) show contour plots of mean pressure coefficient distribution on model façades obtained from calculations.

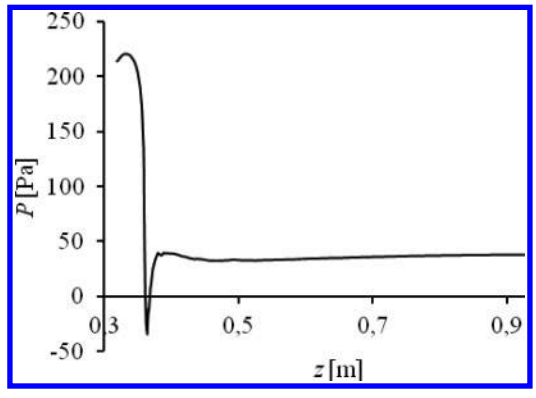

Figure 6. Static pressure along global coordinate z.

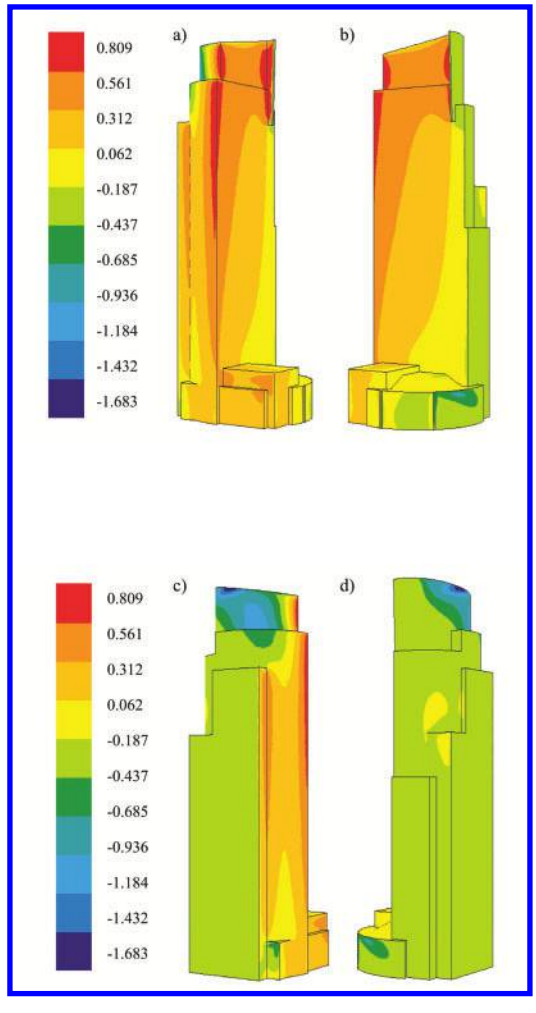

Figure 7. Contour plots of mean pressure coefficient distribution on building façades.

Comparison with wind tunnel results is shown on Figures 8–10. Three representative sets of measuring points are chosen. Sensors nr 2 and 3 are located on windward façade and points nr 8 on leeward façade.

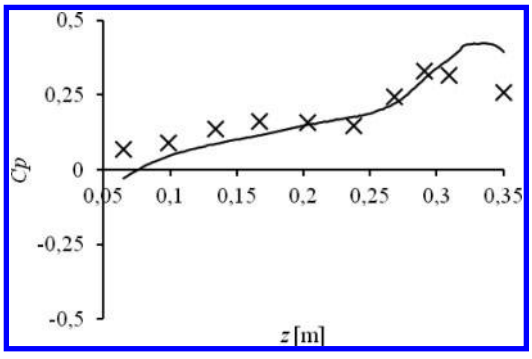

Figure 8. Mean pressure coefficient at points nr 2 between levels 1–11. Solid line – numerical results, ××× – experimental results.

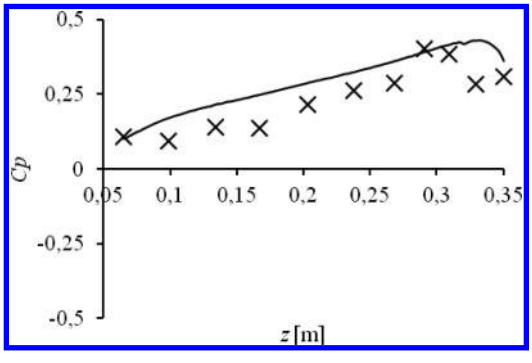

Figure 9. Mean pressure coefficient at points nr 3 between levels 1–11. Solid line – numerical results, ××× – experimental results.

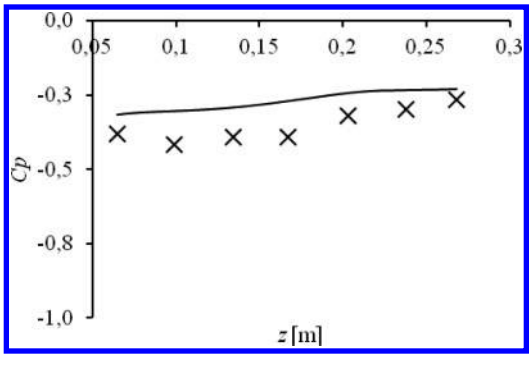

Figure 10. Mean pressure coefficient at points nr 8 between levels 1–7. Solid line – numerical results, ××× – experimental results.

5 DISCUSION AND FURTHER RESEARCH

Horizontal velocity at the weather station location is slightly higher than measured in the wind tunnel, but the difference is only 3%.

Numerical values of C_p make up for a better estimation in higher parts of the model. Moreover, error is smaller in central regions of the façades than near the edges. As an oblique wind direction is considered, divergence of results is similar on all facades. The average difference of the coefficient at windward façade between point levels 1 to11 equals 17% for points nr 2 and 34% for points nr 3. At leeward façade, for points nr 8 between levels 1–7, it is equal to 23%. Deviation in max value of C_p on windward façade is equal to 3%. Minimum value on leeward façade differs by 27%.

The differences in experimental and numerical results can be caused by a number of factors. Present investigation is of a preliminary nature and there are some simplifications made. Geometry of the model consists of an isolated building. Changes will be made in this respect to concentrate on the modeling of the surrounding structures. Moreover, in the current analysis steady state conditions were assumed. RANS simulations are known to have limitations, because they use only spatial averaging and are unable to imitate properly effects of flow fluctuations in time. Following analyses will consist of using Large Eddy Simulation (LES) which uses time averaging and is said to be more accurate, but also requires more computational resources.

In addition, further research will include: influence of various wind directions on the flow around the building, fluid-structure interaction analysis (building's roof displacements due to wind gusts) along with comparison with the data obtained from Global Navigation Satellite System (GNSS) measurements and also the influence of the high-rise building on other buildings in its vicinity.

6 CONCLUSIONS

Numerical results of CFD simulations of wind loading on a high-rise building are presented and compared to data from wind tunnel experiments. Computational setting, including: geometry, boundary conditions, discretisation of the domain as well as solver configuration, is chosen.

The paper concentrates on pressure coefficient distribution over building's façades and wind mean speed at the weather station location. The analysis shows that CFD prediction of the considered quantities agrees well with wind tunnel results.

A more detailed investigation will be carried out in the future.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to the Council for Scientific and Industrial Research, Pretoria, South Africa, where the wind tunnel tests were carried out.

This paper was made possible due to the financial support of the South African National Research Foundation and the Ministry of Science and Higher Education in Poland.

Equivalent static wind loads for structures with non-proportional damping

N. Blaise & V. Denoël
Department of Architecture, Geology, Environment and Constructions, Structural Engineering Division, University of Liège, Liège, Belgium

T. Canor
F.R.S.-FNRS, National Fund for Scientific Research, University of Liège, Liège, Belgium

ABSTRACT: Usually, wind structural design is often carried out by a recourse to the concept of equivalent static wind loads. The main advantage of such loadings is to reproduce, with static analyses, the same extreme structural responses as those resulting from a formal buffeting analysis. This paper proposes an asymptotic method for the computation of equivalent static wind loads for structures with non-proportional damping in a modal framework. This method is based on recent results obtained with asymptotic expansion of the modal transfer matrix of such structures. The method is illustrated on a wind-sensitive high building mitigated with a Tuned Mass Damper (TMD) or a Tuned Liquid Column Damper (TLCD). Each damping device produces a different level of coupling allowing to study the convergence of the proposed method. For a similar level of mitigation, the TMD introduces more coupling than the TLCD does. Relative errors on structural responses (displacements, internal forces) are critically analysed.

1 INTRODUCTION

Over the last years, methods have been derived to compute equivalent static wind loads for structures with quasi-static (Davenport 1967, Holmes 1988, Kasperski 1992) or resonant behaviour (Holmes 1996, Zhou, Gu, & Xiang 1999, Chen & Kareem 2001, Blaise & Denoël 2013), analysed in nodal or modal basis. Equivalent static wind loads are derived to produce, with static analyses, the same extreme structural responses as those obtained with formal dynamic analyses. In the modal basis, such static loadings are defined as weighted combinations of inertial loads. An inertial load statically applied to the structure produces a deflection affine to the corresponding mode shape. The control of dynamic response of wind-sensitive structure such as wide-span roofs or bridges and high-rise buildings may be achieved using damping devices, e.g. tuned mass damper as well as tuned liquid dampers. These damping devices are source of non-proportional damping and consequently, the modal damping matrix and the modal transfer matrix are no longer diagonal. In this case, the dynamic analysis in the modal basis enables to reduce the size of the system, M-modes $\ll N$-degrees of freedom, but not to decoupled the modal equations. Rayleigh (1945) has proposed a decoupling approximation that neglects these off-diagonal elements of the modal damping matrix due to their relative smallness compared with the diagonal ones. Recently, an asymptotic expansion of the modal transfer matrix has been proposed by Denoël & Degée (2009) in a deterministic framework and then extend to a stochastic context (Canor, Blaise, & Denoël 2012), that enables to avoid full transfer matrix inversions for all frequencies.

For structures with non-proportional damping, this paper further extends the formulation of the asymptotic expansion to the weighting coefficients necessary to derive equivalent static wind loads with the inertial loads. The proposed method is formulated with the by-products resulting from the application of the asymptotic expansion of the modal transfer matrix.

The method is illustrated with a realistic example and a detailed analysis of the asymptotic convergence of both modal amplitudes and weighting coefficients of the inertial loads is performed.

2 BUFFETING WIND ANALYSIS

We consider a stationary Gaussian random loading $\mathbf{p}_{tot}(t)$, representing wind actions, although the concepts could be generalized to other loadings. For convenience the loading is split into a mean part $\boldsymbol{\mu}_p$ and a fluctuating part $\mathbf{p}(t)$

$$\mathbf{p}_{tot} = \boldsymbol{\mu}_p + \mathbf{p}. \tag{1}$$

The dynamic motion $\mathbf{x}(t)$ of a linear structure loaded by this random excitation, in the nodal basis, is obtained by solving the equation of motion

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{p} \tag{2}$$

where $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are $N \times N$ mass, damping and stiffness matrices, respectively. Contributions to the damping matrix are the structural $\mathbf{C}_s$, concentrated $\mathbf{C}_c$ (due to damping devices) and aerodynamic damping $\mathbf{C}_a$ matrices. The structural responses $\mathbf{r}(t)$ (nodal displacements, internal forces or reactions) are considered here to be expressed as linear combinations of the nodal displacements

$$\mathbf{r} = \mathbf{O}\mathbf{x} \tag{3}$$

where $\mathbf{O}$ is a matrix of influence coefficients, typically known from the FE model. The structural response of a given linear dynamic system can be computed using a small number M of normal modes of vibrations ($M \ll N$) characterized by mode shapes $\mathbf{\Phi}$ (Clough & Penzien 1993). These modes are normalized to have unit generalized masses. Using the modal superposition principle, the equation of motion (2) is written as

$$\ddot{\mathbf{q}} + \mathbf{D}\dot{\mathbf{q}} + \mathbf{\Omega}\mathbf{q} = \mathbf{g} \tag{4}$$

where $\mathbf{q}(t)$ ($\mathbf{x} = \mathbf{\Phi}\mathbf{q}$) is the vector of modal coordinates, $\mathbf{g}(t) = \mathbf{\Phi}^{\mathrm{T}}\mathbf{p}(t)$ is the vector of generalized forces, $\mathbf{\Omega}$ is a diagonal matrix containing generalized stiffnesses (equal, in this case, to the squared circular frequencies) and $\mathbf{D} = \mathbf{\Phi}^{\mathrm{T}}\mathbf{C}\mathbf{\Phi}$ is the modal damping matrix. The frequency domain formulation of the equation of motion in the modal basis is obtained by a side-by-side Fourier Transform of (4)

$$\mathbf{Q} = \mathbf{H}\mathbf{G} \tag{5}$$

where $\mathbf{Q}(\omega)$ and $\mathbf{G}(\omega)$ are respectively the Fourier transforms of $\mathbf{q}$ and $\mathbf{g}$. The modal transfer matrix $\mathbf{H}(\omega)$ is defined by

$$\begin{aligned} \mathbf{H} &= \left(\mathbf{\Omega} - \omega^2\mathbf{I} + i\omega\left(\mathbf{D}_d + \mathbf{D}_o\right)\right)^{-1} \\ &= \left(\mathbf{I} + \mathbf{H}_d\mathbf{J}_o\right)^{-1}\mathbf{H}_d \end{aligned} \tag{6}$$

where $\mathbf{D}_d$ and $\mathbf{D}_o$ are built as $D_{d,ij} = D_{ij}\delta_{ij}$ (diagonal elements) and $D_{o,ij} = D_{ij}(1 - \delta_{ij})$ (off-diagonal elements) where δ_{ij} denotes the Kronecker-delta function and $\mathbf{H}_d(\omega) = (\mathbf{\Omega} - \omega^2\mathbf{I} + i\omega\mathbf{D}_d)^{-1}$, $\mathbf{J}_o(\omega) = i\omega\mathbf{D}_o$. The asymptotic expansion of the modal transfer matrix (6) for small off diagonal elements (Denoël & Degée 2009) gives

$$\mathbf{H}_k = \mathbf{H}_d + \sum_{i=1}^{k} (-1)^i \left(\mathbf{H}_d\mathbf{J}_o\right)^i \mathbf{H}_d \tag{7}$$

where k is the approximation order of the transfer function. The psd matrix of the modal coordinates $\mathbf{S}^{(q)}(\omega)$, is obtained by

$$\mathbf{S}^{(q)} = \mathbf{H}\mathbf{S}^{(g)}\mathbf{H}^* \tag{8}$$

where the superscript * denotes the conjugate transpose operator and where $\mathbf{S}^{(g)}(\omega)$ is the psd matrix of the generalized Gaussian forces. The kth approximation of the psd matrix of the modal displacements (8) is obtained by

$$\mathbf{S}^{(q_k)} = \mathbf{S}^{(q_d)} + \sum_{i=1}^{k} \mathbf{\Delta S}^{(q_i)};\ \mathbf{S}^{(q_d)} = \mathbf{H}_d\mathbf{S}^{(g)}\mathbf{H}_d^* \tag{9}$$

where $\mathbf{S}^{(q_d)}$ ($k = 0$) is the psd matrix in the uncoupled system and the successive correction terms $\mathbf{\Delta S}^{(q_i)}$ are expressed in a general recurrence relation

$$\begin{aligned} \mathbf{\Delta S}^{(q_i)} &\overset{i=1}{=} -\left(\mathbf{H}_d\mathbf{J}_o\mathbf{S}^{(q_d)} + \mathbf{S}^{(q_d)}\mathbf{J}_o^*\mathbf{H}_d^*\right) \\ &\overset{i>1}{=} -\left(\mathbf{H}_d\mathbf{J}_o\mathbf{\Delta S}^{(q_{i-1})} + \mathbf{\Delta S}^{(q_{i-1})}\mathbf{J}_o^*\mathbf{H}_d^*\right) \\ &\quad -\mathbf{H}_d\mathbf{J}_o\mathbf{\Delta S}^{(q_{i-2})}\mathbf{J}_o^*\mathbf{H}_d^* \end{aligned} \tag{10}$$

with $\mathbf{\Delta S}^{(q_0)} = \mathbf{S}^{(q_d)}$. In the following, the covariance matrix $\mathbf{C}^{(q_k)}$ of the modal coordinates, is calculated by integration (along the circular frequencies) of the corresponding psd matrix

$$\mathbf{C}^{(q_k)} = \int_{-\infty}^{+\infty} \mathbf{S}^{(q_k)}\, d\omega = \mathbf{C}^{(q_d)} + \sum_{i=1}^{k} \mathbf{\Delta C}^{(q_i)} \tag{11}$$

where k denotes one of the aforementioned methods, namely (i) the exact approach ($q_\infty \equiv q$), (ii) the decoupling approximation ($q_0 \equiv q_d$), (iii) the proposed approximation with k correction terms.

The structural design needs envelope values (minimum and maximum) of the structural responses which are computed here as expected values of extrema on 10-minute observation windows. The envelope ($\mathbf{r}^{min}$, $\mathbf{r}^{max}$) is defined as

$$\mathbf{r}^{k,min} = -\mathbf{g}^k \circ \boldsymbol{\sigma}^{r_k};\ \mathbf{r}^{k,max} = \mathbf{g}^k \circ \boldsymbol{\sigma}^{r_k} \tag{12}$$

where $\boldsymbol{\sigma}^{r_k}$ is the standard deviation of the structural response, $\mathbf{g}^k$ is the peak factor derived from Rice's formula (Rice 1945) and $\circ$ denotes the Hadamard product operator. The kth approximation of standard deviations of the structural responses are derived from the corresponding covariance matrix of the modal displacements using

$$\boldsymbol{\sigma}^{r_k} = \sqrt{diag\left(\mathbf{\Upsilon}\mathbf{C}^{(q_k)}\mathbf{\Upsilon}^{\mathrm{T}}\right)} \tag{13}$$

where $\mathbf{\Upsilon} = \mathbf{O}\mathbf{\Phi}$ is the matrix of modal structural responses with υ_{im} the value of the ith structural response in the mth mode and *diag* is a matrix operator that keeps only the diagonal of the matrix. For the

structural design, the maximum value of the jth structural response is given by the following formula with a CQC approach:

$$r_j^{k,max} = g_j^k \left(\sum_{m=1}^{M} \sum_{n=1}^{M} \upsilon_{jm} \upsilon_{jn} \sigma_{mn}^{q_k} \right)^{1/2} = g_j^k \frac{\sum_{m=1}^{M} \sum_{n=1}^{M} \upsilon_{jm} \upsilon_{jn} \sigma_{mn}^{q_k}}{\sigma_j^{r_k}} \quad (14)$$

where $\sigma_{mn}^{q_k} = \sigma_{mn}^{q_d} + \sum_{i=1}^{k} \Delta\sigma_{mn}^{q_i}$ is the covariance between the mth and nth modes, formally obtained with (11), or more efficiently with an approximate relation (Denoël 2009).

3 EQUIVALENT STATIC WIND LOAD

The static analysis under an equivalent static wind load (ESWL) $\mathbf{p}_j^{e,k}$ associated with the jth response reproduces the maximum dynamic response $r_j^{k,max}$ obtained with a classical buffeting analysis:

$$\mathbf{r}_j^{e,k} = \mathbf{A}\mathbf{p}_j^{e,k} \text{ with } r_{jj}^{e,k} = r_j^{k,max} \quad (15)$$

where $\mathbf{r}_j^{e,k}$ is a vector of structural responses under the jth ESWL and $\mathbf{A} = \mathbf{O}\mathbf{K}^{-1}$ is a matrix of influence coefficients.

Inertial forces are defined as inertial load excitation that produce the dynamic displacement from (2) under a static analysis, i.e.

$$\mathbf{x} = \mathbf{\Phi}\mathbf{q};\ \mathbf{K}\mathbf{x} = \mathbf{\Psi}\mathbf{q} \quad (16)$$

where $\mathbf{\Psi} = \mathbf{K}\mathbf{\Phi}$ is the matrix of inertial forces with $\boldsymbol{\psi}_m$ the inertial force associated with the mth modal shape. Chen & Kareem (2001) have proposed to derive ESWL from combinations of these inertial forces using adequate weighting coefficients.

What is discussed next is the formulation of these weighting coefficients with corrections terms if the system is coupled. The matrix of modal structural responses may be also computed with the inertial forces as

$$\mathbf{\Upsilon} = \mathbf{A}\mathbf{\Psi};\ \upsilon_{jm} = \mathbf{a}_j \boldsymbol{\psi}_m, \quad (17)$$

and the introduction of (17) into (14) gives

$$r_j^{k,max} = a_j g_j^k \sum_{m=1}^{M} \left(\frac{\sum_{n=1}^{M} \upsilon_{jn} \sigma_{mn}^{q_k}}{\sigma_j^{r_k}} \right) \boldsymbol{\psi}_m = a_j g_j^k \sum_{m=1}^{M} \left[\frac{\sigma_j^{r_d}}{\sigma_j^{r_k}} W_{jm}^d \boldsymbol{\psi}_m + \sum_{i=1}^{k} \Delta W_{jm}^i \boldsymbol{\psi}_m \right]$$

where the weighting factors W_{jm}^d and ΔW_{jm}^i are expressed by

$$W_{jm}^d = \frac{\sum_{n=1}^{M} \upsilon_{jn} \sigma_{mn}^{q_d}}{\sigma_j^{r_d}};\ \Delta W_{jm}^i = \frac{\sum_{n=1}^{M} \upsilon_{jn} \Delta\sigma_{mn}^{q_i}}{\sigma_j^{r_k}}.$$

The kth approximation of the static loading, $\mathbf{p}^{e,k}$, is described as a summation of two contributions: (a) a scaling of the equivalent loading that would be obtained if the system was uncoupled, $\mathbf{p}^{e,d}$ and (b) a corrective equivalent loading, $\Delta\mathbf{p}_j^k$, resulting from the non-proportionality of damping:

$$\mathbf{p}_j^{e,k} = \left[\alpha_j^k \mathbf{p}_j^{e,d} + \Delta\mathbf{p}_j^{e,k} \right] = g_j^k \sum_{m=1}^{M} W_{jm}^k \boldsymbol{\psi}_m \quad (18)$$

$$\mathbf{p}_j^{e,d} = g_j^d \sum_{m=1}^{M} W_{jm}^d \boldsymbol{\psi}_m \quad (19)$$

$$\Delta\mathbf{p}_j^{e,k} = g_j^k \sum_{m=1}^{M} \sum_{i=1}^{k} \Delta W_{jm}^i \boldsymbol{\psi}_m \quad (20)$$

where $\alpha_j^k = (g_j^k \sigma_j^{r_d})/(g_j^d \sigma_j^{r_k})$ is a scaling coefficient and the kth approximation of the weighting coefficients W_{jm}^k is derived from

$$W_{jm}^k = \alpha_j^k W_{jm}^d + \sum_{i=1}^{k} \Delta W_{jm}^i \quad (21)$$

which well extends the formulation $W_{jm}^k = W_{jm}^d$ corresponding to the case where modal coupling is neglected. Notice also that α_j degenerates in $\alpha_j = 1$ for $k = 0$.

4 ILLUSTRATION

A 76-story, 306 m tall building is analysed under wind actions. This structure is a numerical example used in (Xu, Samali, & Kwok 1992) to study the mitigation of the along-wind response of structures using a tuned liquid column damper (TLCD) instead of a tuned mass damper (TMD). The structural model is a 10 lumped-mass cantilever model with 11 nodes and the finite element (FE) model is an assembly of classical 2-D beam elements with two DOFs per node (rotation and horizontal displacement). The proposed method is illustrated on this structure, with each damping device, keeping the first four modes for the modal analysis. The TMD or the TLCD are connected to the top floor of the building and are tuned to match the fundamental frequency of the structure. Both structures (with TMD or TLCD) have similar natural frequencies equal to 0.16, 0.19, 0.57 and 1.33 Hz. Figure 1 depicts the horizontal components of the first two modes and the corresponding inertial forces. A one-dimensional Gaussian velocity turbulence field is considered. The longitudinal turbulent component v of the velocity field is modeled by the spectrum of longitudinal turbulence proposed by Davenport (1961). The spanwise coherence function of v between two points of the tower separated by a height l is modelled by a decreasing exponential. Structural, TMD, TLCD and wind load spectrum data are not reported here for sake

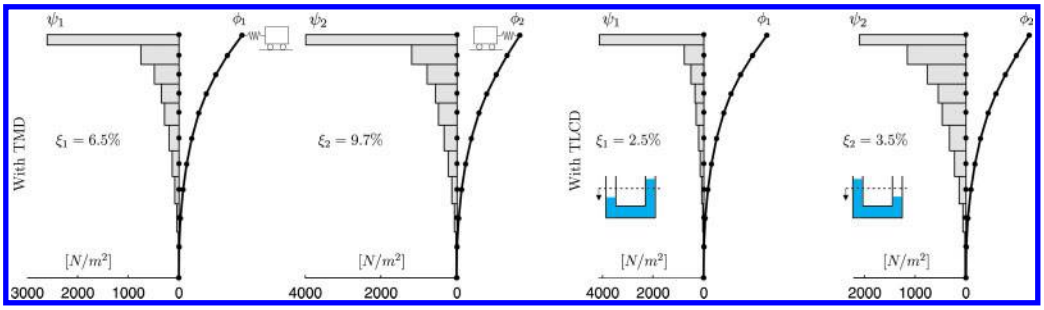

Figure 1. First two modal horizontal components (normalized to have a top displacement equal to 10 cm) and inertial horizontal forces per wind area. Each circle represents the nodes of the FE model. For each figure, the left and the right illustrate results for the structure with TMD and with TLCD, respectively.

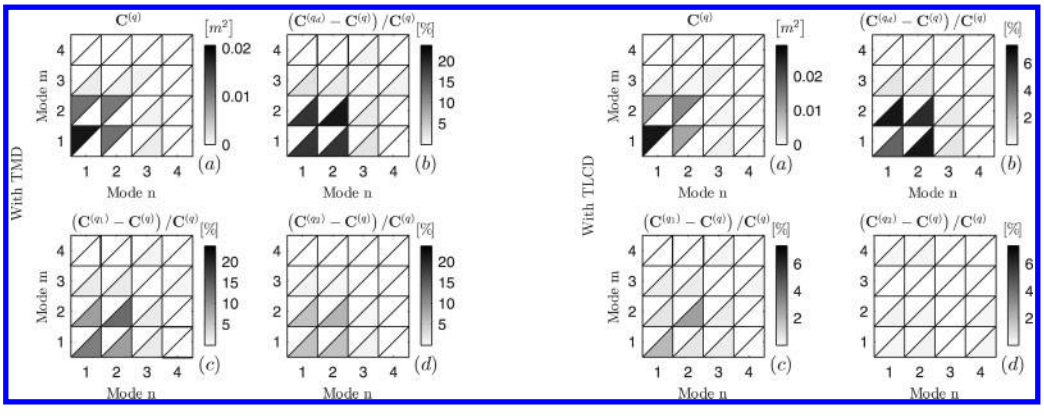

Figure 2. (a) Exact covariance matrix of the modal coordinates $\mathbf{C}^{(q)}$ (b) and relative error for different approximations $\mathbf{C}^{(q_d)}$, (c) $\mathbf{C}^{(q_1)}$ and (d) $\mathbf{C}^{(q_2)}$. Relative errors are expressed with respect to $\mathbf{C}^{(q)}$. For each square, the upper left corner correspond to positive value and the lower right corner to negative value.

of conciseness but may be found in (Xu, Samali, & Kwok 1992). In a unidimensional turbulence model, a linearized expression of the zero-mean fluctuating applied force at the ith level $p_i(t)$ is adopted as

$$p_i = C_{a,i} v_i \tag{22}$$

in which $C_{a,i}$ reads

$$C_{a,i} = \frac{\overline{W}_{10}}{\overline{V}_{10}} \sqrt{6K_0} C_d A_i \left(\frac{H_i}{10}\right)^{\alpha} \tag{23}$$

where $\overline{W}_{10}$, $\overline{V}_{10}$ K_0, C_d, A_i, H_i and α are the mean wind pressure at 10 meters, the mean wind velocity at 10 meters, the surface drag coefficient, the drag coefficient, the surface exposed to wind, the height of the ith level and the exponent coefficient, respectively. The aerodynamic damping is taken into account and therefore a diagonal aerodynamic damping matrix $\mathbf{C}_a$ is added to the structural $\mathbf{C}_s$ and concentrated damping $\mathbf{C}_c$ to constitute the total damping matrix $\mathbf{C} = \mathbf{C}_s + \mathbf{C}_c + \mathbf{C}_a$. The index of diagonality (see Horn & Johnson 1945) defined as $\rho(\mathbf{D}) = \sigma[\mathbf{D}_d^{-1}\mathbf{D}_o]$ where $\sigma[\,\cdot\,]$ is the spectral radius is an indicator of the diagonal dominance of $\mathbf{D}$. A low value indicates that the off-diagonal terms are small compared to the diagonal ones. The structure without damping device but considering the non proportional aerodynamic damping has an index equal to 0.02 and the classical decoupling approximation may be applied. Because of the TMD (resp. TLCD) the index of diagonality increases to 1.72 (resp. 1.03) and the classical decoupling approximation can not be formulated anymore. A larger diagonal index for the structure with TMD rather than with the TLCD, indicates that the solution with the decoupling approximation has a larger discrepancy with the reference solution ($k = \infty$). The reference covariance matrix ($k = \infty$) of modal coordinates and the relative error for the different approximations are represented in Figure 2. Concerning modes 1 and 2 the proximity of their natural frequencies and the similarities of mode shapes induce dynamic coupling (Denoël 2009) and high modal correlation coefficients equal to 0.78 and 0.5, respectively with TMD or TLCD. Figure 2-(b) on the left indicates that neglecting off-diagonal terms of the damping matrices, induces a maximum error of -23% on the variance of mode 2. The proposed method with first and second order correction terms offers a reduction of this error down to -14% and -6%, respectively. Figure 2-(b) on the right indicates that the decoupling approximation, induces a

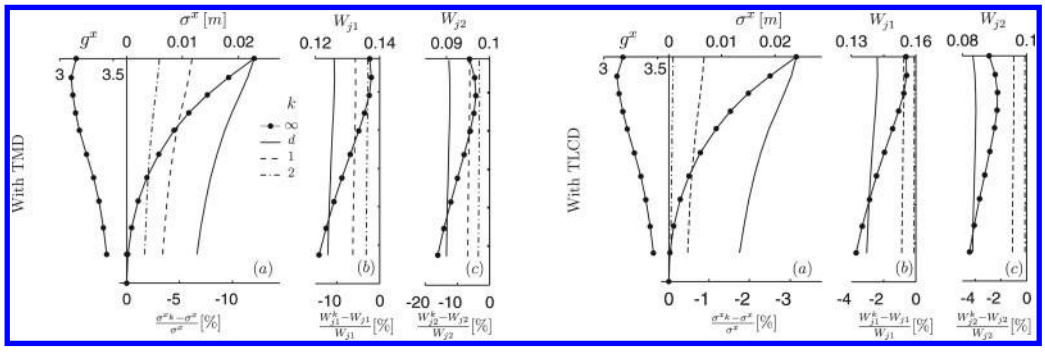

Figure 3. Results for the structural displacements. The upper axis, corresponding to reference values ($k = \infty$), is associated with lines with circles. The lower axis, corresponding to relative errors, is associated with solid ($k = d$), dashed ($k = 1$) and dashed-dot ($k = 2$) lines. (a) On the left, the peak factors and on the right standard deviations. (b) Weighting coefficients of the first and (c) the second inertial force for each structural displacement.

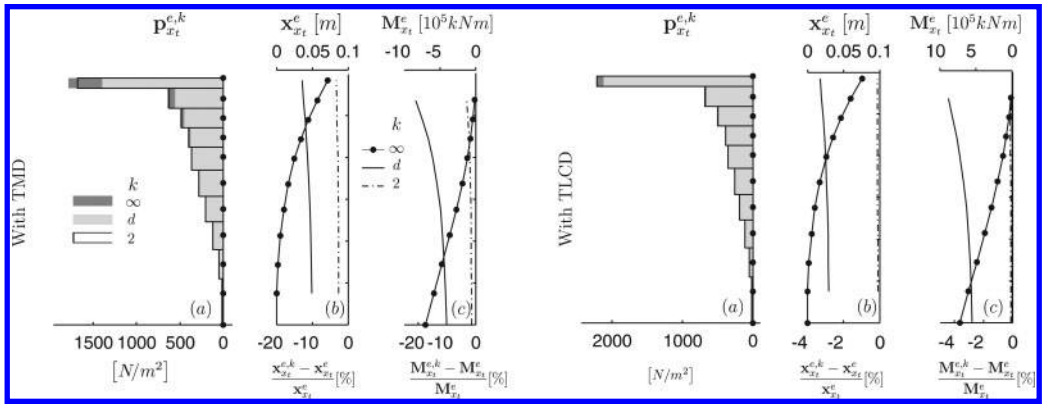

Figure 4. Equivalent static analysis associated with maximisation of the top displacement x_t. (a) Reference equivalent static wind load (grey patch) and those obtained with the decoupling approximation (lighter patch) and the proposed method with second order correction (line). (b) Reference equivalent static displacement and (c) reference equivalent static bending moments. Same conventions of Figure 3 applied for the lower and upper axis.

maximum error of -7.3% on the covariance between mode 1 and 2. Addition of the first and second correction terms reduces this error down to -1.9% and -0.25%, respectively. For the three approximations, the errors are the most significant for the group of correlated modes (1 and 2). Comparison of these relative errors on the covariance matrix for two levels of non proportionality (quantified by $\rho(\mathbf{D})$) shows that the proposed method with second order (or more) correction terms have to be considered for the structure with TMD while only the first correction term may be sufficient for the structure with TLCD. Figure 3-(a) depicts the peak factors and standard deviations of nodal horizontal displacements obtained with the reference approach. On the right is also represented the relative errors for each displacement, for the first three approximations. The decoupling approximation leads to underestimations of the displacements up to -12% (resp. -3%) for the structure with TMD and TLCD. With only the first correction term of the proposed method, these extreme underestimations are divided by two (resp. by three). The second order approximation provides underestimations less than -3% (resp. $\simeq 0\%$) and therefore this order of approximation is used for the computation of equivalent static wind loads. In both cases, for the decoupling approximation, relative errors on the peak factors are less than 2% and therefore are not represented. For each structural displacement, Figure 3-(b) and -(c) illustrate the weighting coefficients for the first and second inertial force, respectively. As expected, the relative errors and the convergence are similar to those associated with the evaluation of the standard deviations of the structural displacements. The structural displacement at the top is chosen for the illustration of the proposed method. Figure 4-(a) depicts the reference equivalent static wind loads ($k = \infty$) and those obtained with the decoupling approximation ($k = 0$) and with second order correction terms ($k = 2$). Underestimations of the reference loadings occur with the decoupling approximation and a second order approximation is necessary to correctly fit the reference static loadings. The largest underestimations of the loadings are located at the top of the structure. Figure 4-(b)

illustrates the static displacement under the reference ESWL. For the structure with the TMD, the decoupling approximation produces underestimations up to −12% while with the first two correction terms, relative errors are reduced down to −3%. Figure 4-(c) shows the static bending moments under the reference ESWL. The decoupling approximation produces underestimations up to −21% which are reduced to −1.5% with the first two corrections terms. For the TLCD, as expected, relative errors are smaller than those obtained for the structure with TMD. Levels of errors for the static displacements and static bending moments are similar to those reported for the weighting coefficients, see Figure 3.

5 CONCLUSIONS

High-rise buildings may be excited by the wind loading resulting in unacceptable level of displacements, internal forces or stresses. For such cases, among other solutions, damping devices are usually used to mitigate the wind response of such structures. These damping devices may be tuned mass or liquid column dampers and introduce non-proportional damping. A new method consisting in the asymptotic expansion of the modal transfer matrix enables to avoid full transfer matrix inversion. This work developed further the method for the establishment of equivalent static wind loads. The new method is illustrated with a 306 m tall building tower with (a) a tuned mass damper and (b) a tuned liquid column damper. Introduction of the TMD produces a larger index of diagonality, $\rho = 1.72$, in comparison with $\rho = 1.03$ for the structure with the TLCD. Major results are listed below:

1. the asymptotic method with two corrections terms offers an accurate estimation of the response, while the reference solutions are obtained with full inversion of the transfer matrix;
2. expressions of the asymptotic expansion of the weighting coefficients of inertial forces have been derived in order to compute equivalent static wind load;
3. the decoupling approximation can not be stated for the structure with TMD. Indeed, too large underestimations occur for the structural displacements −12% and for the evaluation of the equivalent static wind load. Static analysis produces large underestimations of the static displacements and static bending moments;
4. for the structure with the TLCD, the decoupling approximation may be stated if relative errors smaller than −5% are acceptable. Otherwise, the proposed method with two correction terms produces solutions that are nearly identical to the reference ones;
5. for this structure, peak factors dot not vary significantly between the coupled and uncoupled system;
6. if ESWLs are used for the envelope reconstruction problem (Blaise & Denoël 2013), the decoupling approximation produces large errors on the bending moments under the ESWL that maximizes the top displacement. This justifies the use of the proposed method to ensure reliability when using equivalent static wind loads in a structural design.

ABSTRACT: Vulnerability of structures to progressive collapse and mitigation of the effects of local damages are topics widely discussed inside the scientific community. The progressive collapses that recently occurred due to terrorist attacks and the consequent huge loss of human lives, pointed towards the need for a new design criteria. A criteria that aims to design robust structures, i.e. structures able to withstand exceptional loads without being damaged to the extent disproportionate to the original cause. Event control, specific local resistance, redundancy, design of key elements, compartmentalization and detailing rules are some of the preventive strategies proposed by the recent studies and design standards. In this paper, the main facets of this problem are briefly illustrated. The approaches recommended by the standards, and in particular by the EN 1991-1-7, are presented.

1 INTRODUCTION

Progressive collapse of a building or part of it, caused by localized damage as a consequence of accidental actions, is a relatively rare event. The increasing frequency of terrorist attacks aimed at civilian and military targets and the consequent significant losses viz. economic and human lives caused by them, have highlighted the need to consider, more appropriately and rationally, the vulnerability of the buildings to progressive collapse. It requires a certain criteria to mitigate the effects of a localized damage.

The current design approaches, although based on probabilistic criteria, are not generally able to ensure an adequate level of security against local damage which can even lead to progressive collapse of the structure (Fig. 1). The first reason being that design guidelines are usually applied on a local level only (check of cross-sectional forces or element stability). Structural safety, therefore, is accounted for the local level only. The global safety, i.e., the safety against the collapse of the entire system or a major part thereof, is not only a function of the safety of all the individual elements against local failure but also of the system response to local failure. Different systems will respond differently to local failure. Such methods when applied to non-robust structures will produce unsafe designs. The other reason may be low probability of occurrence and the unpredictability of events, the difficulty in the retrieval of data regarding the scope of action and identification of an acceptable probability of collapse. These lead to the neglect of accidental actions during the design considerations (Starossek, 2006). Thus point out the need to identify new design criteria for robust structures.

Figure 1. Ronan Point, London, U.K. (1968).

A localized damage may result in progressive collapse extended to the whole or part of the structure. In such a case, the structure is not able to reach new stable equilibrium configurations or lacks the structural requirements such as strength, ductility, stability, continuity and redundancy. Development of chain reactions characterized by the activation of large displacements and deformations, separation of structural elements, redistribution of internal stresses, dynamic effects resulting from collapse are possible consequences of localized damage. In these circumstances,

the response of a structural system should be determined by non-linear dynamic analysis in the time domain, considering the variety of possible scenarios. The operational difficulties and the inability to predict in advance all possible causes initiating a progressive collapse, imposes the identification of design criteria to mitigate the effects. The aim of design is therefore realization of "Robust" structures for which the effects of damage are not disproportionate to the initiating event. The other possible strategies for prevention against progressive collapse are: event control, elements and connections designed for specific local resistance, redundancy, design of key structural elements, alternate load paths, compartmentalization, detailing rules for ductility and recommendations on the construction details and practices.

A small kitchen gas explosion in mid storey at Ronan Point in Canning Town, London in 1968 (Fig. 1) (Griffiths et al., 1968) has led to a catastrophic partial collapse of the building. This incident had prompted numerous efforts to develop structural design criteria for progressive collapse resistance. As an outcome, results of numerous studies were published in the seventies. This was also reflected in regulations with the introduction of specific projects aimed at creation of robust structures. During the eighties and nineties, the interest on this particular issue took a backseat. The terrorist activities leading to tragedies of Alfred P. Murrah Federal Building in Oklahoma in 1995 (Fig. 2), U.S. embassies in Nairobi and Dar-Es-Salam in 1998 and more recently the collapse of World Trade Centre Towers New York in 2001 (Corley, 2004), have provided impetus for research on improved building practices and design procedures to control the likelihood of progressive collapse.

This paper, dealing with the structural strength, analyzes the possible strategies for prevention of progressive collapse. Initially, the paper analyzes at general level, and then discusses in detail and in particular the design philosophy proposed in EN 1991-1-7 (Eurocode-1, 2006).

2 PREVENTION OF PROGRESSIVE COLLPAPSE – THE STRATEGY

The term robustness is commonly used with different meanings in different sectors of technological sciences (control theory, statistical inference, decision making, and programming). In civil engineering, in the context of structural systems subjected to exceptional hazards, the uncertainty associated with the structure, and the consequences of the hazard plays a prominent role in measuring structural robustness (Maes et al., 2006). A consensus meaning of the term is variously used as a synonym for stability, ductility, redundancy and resistance to complete collapse.

According to EN 1991-1-7 (Eurocode-1, 2006), the robustness is defined as "The ability of the structure to withstand events like fire, explosions, impact or consequences of human error, without being damaged to an extent disproportionate to the original cause". According to this definition, robustness is intended as intrinsic property of the structure and is explicitly linked to the concept of disproportionate collapse while recognizing that total collapse is an acceptable outcome from a hazard. "Resistance to collapse" is a property that is influenced by numerous conditions including the structural features and possible actions (Starossek, 2005). Robustness of structures varies widely with varying degree of actions while resistance to collapse may not be required for every structure. The distinction between "robustness" and "resistance to collapse" is defined so that the analysis and design strategies are differentiated according to the probability of occurrence of the event, extent of damage, structural response and consequences of collapse or, in other words, the level of risk. In relation to the latter, the lines of prevention can be grouped into two categories:

1) Within the contained levels of risk, the objective to confer "robustness" to the structure can be achieved by simple design and minimum requirements for ductile performance of structural elements and connections. Additional safeguards may be obtained through horizontal and vertical ties (tying), providing alternate load paths (bridging the gap), and design of key structural elements;
2) For high levels of risk, verification of the "resistance to collapse" against possible scenarios characterized by intensity, location and extent of the damage event is necessary. From this point of view, robustness can be achieved through the redundant design of structures and elements. Structure should be able to undergo limited damage, preventing the activation of chain reaction (performance-based design). The techniques that may be employed consist of redundancy, alternate load paths (bridging), design of key structural elements (key elements), control of events and compartmentalization.

A better understanding of the lines of prevention can be obtained starting from the definition of general likelihood of collapse. Given the generic accidental event 'E' characterized by a probability '$P(E_i)$', the local damage 'D' is the consequence of accidental event 'E_i', characterized by a probability '$P(D/E_i)$', and the probability of progressive collapse 'C' resulting in damage 'D', '$P(C/D \cap E_i)$'. The probability of progressive collapse of the structure, '$P(C)$' can be expressed as (Ellingwood & Dusenberry, 2005):

$$P(C) = P(C / D \cap E_i) \bullet P(D / E_i) \bullet P(E_i) \quad (1)$$

The probability of progressive collapse must be limited to an acceptable value. This is suggested by limiting the second variable in (1). The three probabilities discussed in (1) can be limited at three levels:

1. Event control i.e. reducing the probability of the event E_i, $P(E_i)$;
2. Local damage (range of type of structures characterized by low sensitivity to the damage, assured

requirements of specific local resistance), limiting the probability of local damage D as a consequence of event E_i, $P(D/E_i)$;

3. Progressive collapse (statically indeterminate structures, alternative load paths), limit the probability of progressive collapse resulting in the localized damage D caused by the event E_i, $P(C/D \cap E_i)$;

The first operating line, which provides for the adoption of preventive measures aimed at limiting the accidental action, is classified as non-structural. Direct as well as indirect design methods can be used to work on the local damage and the progressive collapse. The direct design methods are based on specific local resistance of structural elements i.e. structural response against accidents and the capability of the structure transferring the loads in case of "removal" of structural elements. The indirect design methods ensure minimum level of strength, ductility and structural continuity or minimum levels of robustness.

For contained levels of risk, the use of (1) can lead to operational difficulties. The adoption of equation independent of the type of accidental event can simplify the problem. In this case (1) assumes the simplified expression (Ellingwood & Dusenberry, 2005):

$$P(C) = P(C/D) \bullet P(D) \quad (2)$$

Prevention techniques in this case ensure the transfer of loads through "alternate paths" to avoid the propagation of the event. This can be achieved through the design of continuous structures, statically indeterminate and ductile.

3 STRUCTURAL ROBUSTNESS AND GLOBAL NORMS

The first regulations regarding the progressive collapse were based on studies conducted following the collapse of the Ronan Point in 1968. The concept of structural design to be implemented in a way that damages are not disproportionate to the cause of initiating event was introduced by the UK in 1976 by building regulations. Later it was 'Approved document A' to realize the concepts indicating the design criteria based on tying the horizontal and vertical elements, identification of alternative load paths by bridging the gaps and design of key structural elements. Later prevention strategies were implemented, modified and supplemented by major design codes on metal structures, masonry, timber and concrete. The use of these prescription rules and study of response of structures affected by accidental actions designed in compliance with these requirements have provided with the upgraded version of the documents. The recent version of this document is available as 'Approved document A' published in 2004 with amendments.

In the United States the basic concept regarding the progressive collapse were published through legislation in 1972 in the document ANSI A.58.1. Later these concepts were developed and published in extensive first version of the ASCE-7 document on general design requirements in 1982 which have been upgraded over the years. The basic concepts were similar to that adopted in the UK which were refined by normative documents relating to different materials and the codes regarding the structural design. A significant contribution to this subject was made by US government agencies like Interagency Security Committee (ISC), General Services Administration (GSA), Department of Defense (DoD), Federal Emergency Management Agency (FEMA) which have published specific documents related to progressive collapse. Similarly, for other places like Canada, Australia and New Zealand, the methodology regarding the design criteria of robust structures is analogous to that of the UK and the US.

The studies with research papers and the subsequent normative laws provide the basic criteria for the design of robust structures. With these as reference point, most of the regulations and codes have adopted the same design philosophy and methodological approach. The same observation applies to the Eurocode in EN 1991-1-7 that specifically deals with the issues related to the structural design in the presence of accidental actions. However, the 'Approved document A' and EN 1991-1-7 follow the same approach, the latter proposes an extensive discussion of accidental actions and the corresponding methodologies for analysis.

4 ROBUSTNESS AND EN 1991-1-7

The prevention strategies identified by EN 1991-1-7 initiates with the general principles of design provided by EN 1990. It states that the structure must be designed so as to ensure adequate fire resistance, accidental actions, human error so that the effects are not disproportionate to the cause. Ensuring these, the chances of collapse are limited signifying an acceptable level of structural sustainability which is economically justifiable. With this consideration, it becomes necessary to consider the accidental actions in the planning stages. Including this aspect EN 1991-1-7 provides for the classification of buildings into three consequence classes (CC) characterized by low (CC1), medium (CC2) and high (CC3) consequences of failure. The division of the buildings in these classes depends on the type and use of the building, number of storey and extensions plans. In each of the consequences classes, the method of analysis and prevention strategies vary. The consequences classes are:

1) Consequence Class 1 (CC1): There are no specific considerations against accidental actions except that the required structural design is in accordance with the criteria set by EN 1990 – EN 1999;
2) Consequence Class 2 (CC2): The recommended design analysis based on simplified static equivalent actions that can reproduce the accidental actions and respect the prescriptive detailing requirements;

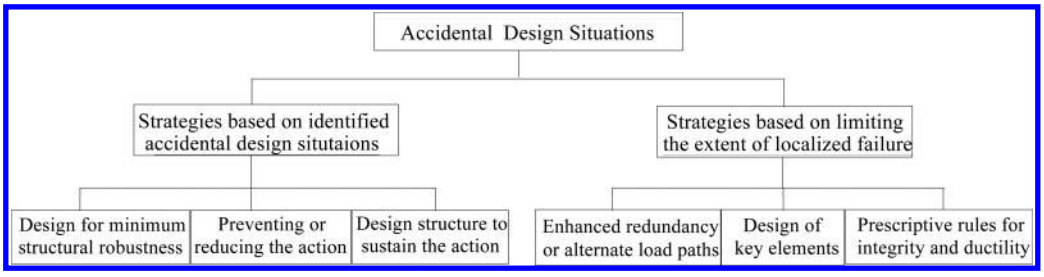

Figure 2. Strategies for accidental design situations as per EN 1991-1-7.

3) Consequence Class 3 (CC3): An examination and study of possible scenarios and if necessary, implementation of hazard analysis and non-linear analysis in dynamic range.

Along with the consequences classes, additional definitions are considered by EN1991-1-7 to define the strategic lines for prevention of accidental actions. Considering the randomness of the accidental events which cannot be established in advance for all possible scenarios, EN1991-1-7 has broadly classified the accidental actions into identifiable and unidentifiable actions as shown in Fig. 2. Factors such as the probability of occurrence of action, the consequences of its occurrence, the possibility of using preventive measures and the level of acceptable risk for deciding the set of accidental actions qualify as identifiable actions. Apart from the case of earthquake and fire, which are dedicated to specific parts of Eurocodes, EN1991-1-7 explicitly considers the identifiable actions of explosions and impact. In the case of impact, the actions considered due to vehicles, forklifts, trains, ships and helicopters as a result of abrupt maneuvers landing. For explosions and impact, it proposes representation of actions, operational criteria and risk analysis wherever necessary.

The preventive measures suggested in case of identified actions are:

1) Control of events such as:
   – reduction of the probability of occurrence of action at a level considered acceptable;
   – controlling of intensity of the action through structural identification;
2) Measures to protect the structure can limit the effects of accidental actions;
3) Structural Identification
   – identification and design of key structural elements;
   – use of materials and design of structural elements with adequate levels of ductility;
   – Redundant structures ensure the redistribution of load through alternate load paths.

The preventive measures depend on the peculiarity of the action like intensity or mode of action, characteristics of the structure and the consequence of the collapse.

In case of unidentified accidental actions, the choice of prevention strategies should mitigate the potential failure. The ultimate goal of the design and construction of structures shall be to survive in partial or whole for a time sufficient to evacuate the building and the area surrounding it. The strategies suggested are:

1) Design key elements, on which the stability of the structure depends to sustain the effects of model accidental action (suggested value for buildings is 34 kN/m^2);
2) Design the structure so that the localized damage will not endanger the stability of the whole or part of it;
3) Apply the prescriptive rules of detailing to provide acceptable level of robustness for the structure.

In this specific case for structures, EN 1991-1-7 divides and specializes prevention strategies in four consequences classes (CC1-CC3) as follows:

1) Consequence Class 1 (CC1): Design for normal use in accordance with the criteria of the Eurocodes 0-9;
2) Consequence Class 2a (CC2a): In addition to the requirements for consequence class 1, inclusion of horizontal ties in the case of framed structures (Fig. 3) and anchoring systems on the floors in the case of load-bearing masonry structures;
3) Consequence Class 2b (CC2b): For load-bearing masonry and framed structures, in addition to the requirements for consequence class 1, inclusion of horizontal ties (Fig. 4) corresponding to each vertical column or bearing wall. Alternatively, the building shall be so designed that the "removal" of any column does not affect the stability of the whole structure and that the damage does not exceed a limit deemed acceptable (acceptable limit suggested: damaged area of the floor adjacent to the element "removed" less than 15% of the total area);
4) Consequence Class 3 (CC3): In depth analyses are suggested that include risk analysis. The complexity and the degree of depth of analysis will depend on the particular problem analyzed. Intervention strategies may be structural (design structure and its elements for adequate levels of resistance, via the alternate load paths) or non-structural (reduction of the probability of occurrence of the action, its intensity and consequences of the collapse).

From the design viewpoint, it is important to note that the specific criteria for dimensions are provided

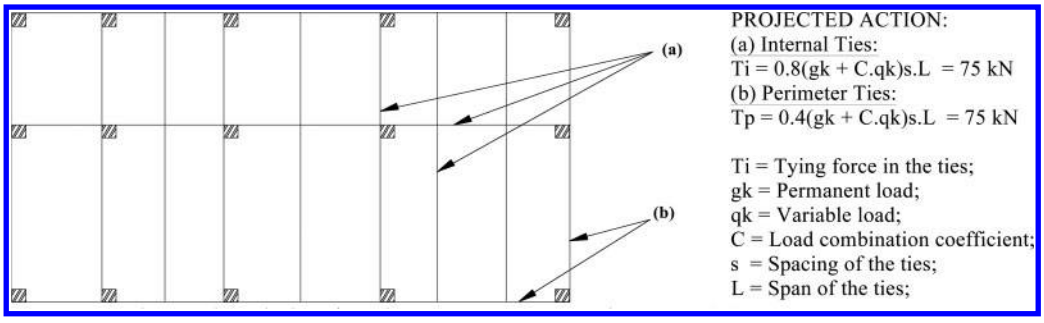

Figure 3. Horizontal tying of members as per Consequence Classes 2a and 2b as per EN 1991-1-7.

only to the classes 2a and 2b (Fig. 4). The objective of these design requirements is to give the structure a minimum level of robustness, which ensures the development of resistant mechanisms to enable the transfer of stresses, in the case where the redundancy is less. For consequence class 3, however, possible intervention strategies are indicated to the particular problem analyzed.

The risk analysis for consequence class 3 (CC3) may be conducted at qualitative, and where the importance of the problem makes it necessary, also at quantitative level. The need for possible action against the progressive collapse is dependent on the adoption of risk acceptance criteria. In this respect the EN 1991-1-7 provides only limited guidance, delegating the choice to the engineer. If necessary, the measures of mitigation of the risk may consist in:

- Attenuation of events implemented by aid either structural or non-structural;
- Event control;
- Design of structures characterized by reserves of strength, stiffness and redundancy;
- Reduction in the levels of damage by controlled collapse.

5 ROBUSTNESS AND DUCTILITY

A complete understanding and fulfillment of required ductility and available ductility is a key step which accompanies several advantages for the system. Economical advantages, avoiding a brittle damage which in turn gives more escaping time and dissipation of more energy with less damage are the major advantages that are achieved with careful design of ductile system. Thus ductility should be quantified at same level as strength and stiffness. For a structural system, ductility is quantified as its ability to undergo large deformations after initial yielding without any significant reduction in the ultimate strength. Ductility in a system can be achieved by enabling the joints to provide large rotations, so that membrane forces can be activated allowing a redistribution of internal forces. Thus an adaptive structure is created which keeps sufficient strength even under exceptional loading and large deformations.

Research till date has exploited ductility as an essential tool for systems when subjected to seismic forces. This has resulted in seismic design standards where, ductility requirements for joints are formulated in terms of deemed to satisfy rules i.e. provided that certain design requirements are met, the joint may be assumed to behave in a ductile manner sufficient enough to ensure a safe structural behaviour. However, here a big question arises whether the seismic design rules are adequate for protective design methods against progressive collapse? Studies have shown that with seismic detailing, the damage due to blast can be significantly reduced. A case study of terrorist bombing of the Alfred P. Murrah Federal Building in Oklahoma City in 1995 is such an interesting case to evaluate this point. The building at the time of design and construction phase was in accordance with the prevalent regulations. Later, the seismic standards were included and updated. Researchers had commented that if the building would have been designed according to the present seismic regulations, it would have performed better by minimum of 50% to a maximum of 80% depending upon the seismic structural measures adopted, leading to less damage and causalities (Corley 2004). But, conclusively, it can be stated that the seismic regulations are not equivalent to the blast effects or impact or fire loads and is one of the cases to be considered under extreme loading conditions. Some guidance is available in literature regarding the nature of occurrence and effects of blasts overpressures and fire loads and some recommendations are also available to include them into design. But consistent experimental verification, numerical assessment and codified literature are the requirements so that these can be implemented and such extreme events as progressive collapse can be prevented.

6 CONCLUSION

This paper focuses on the problem of structural design in the presence of accidental actions. In the absence of specific structural requirements, the damage due to the accidental actions can lead to the development of chain reactions with a consequent collapse of the whole or part the structure. Therefore, establishing the

importance of accurate, sustainable but economically feasible prevention strategies is crucial.

The probability of failure resulting from accidental actions is influenced by the type of event (intensity, mode of collapse), the local damage caused by these event and the structural response. From the structural point of view, the probability of failure can be limited by acting on the accidental events, by means of control of events, the local damage by design of structures with limited sensitivity to the damage and provided with appropriate performance requirements and, ultimately, on statically indeterminate structures by providing continuity and ductility to the structural system. Studies and research on the subject have been accompanied by the development of codes and regulatory requirements which, although different in different countries when compared at local level, have a common approach to the philosophy and methodology. To better analyze the design strategy, the last part of the work was devoted to an analysis of EN 1991-1-7 (Eurocode-1, 2006).The regulations are normative in nature and lack consistent experimental and numerical verification.

According to EN 1991-1-7 (Eurocode-1, 2006), the characteristics of the consequence classes classify the accidental actions and guides the choice of prevention techniques from progressive collapse. These can range from simple design specifications to real strength and ductility requirements, depending on the event type and structural response. From the computational point of view, simplified analyses by forces equivalent to the actions or more sophisticated analysis is non-linear dynamic range are recommended.

At the conclusion of the work, it is important to note that although the prevention strategies against the progressive collapse are well outlined, these are not yet adequately translated into design specifications/ guidelines. The peculiarity of each problem in terms of accidental action and structural response makes it difficult to identify structural design criteria of general validity. The problem is further complicated by the lack of experimental data; the complexity of the numerical analysis necessary for the study of the structural response and the multiplicity of possible scenarios. Instead the definition of rules aimed to acquire the minimum strength and robustness achieved through requirements such as continuity and structural ductility seems more feasible. In that regard, efforts are required in terms of both numerical and experimental study. Studies and research on this specific issue are currently underway. The same authors of this paper are involved in a research project that seeks to identify requirements for minimum ductility for beam-column joints of composite steel and concrete structures as a tool for the prevention of the progressive collapse.

ABSTRACT: Seismic design of tall building frames poses special problems because of factors such as, participation of higher modes, P-Delta effects, column design, etc. Current code practice does not yield very satisfactory designs. In recent years a design methodology, which accounts for structural inelastic behavior directly and practically eliminates the need for any assessment or iteration after initial design, has been developed. The method is called Performance-Based Plastic Design (PBPD). It is a complete design method that considers factors such as determination of appropriate design lateral forces, member strength hierarchy, selection of desirable yield mechanism, and target drift right from the beginning of the design process. This paper will briefly present the methodology. Design examples of tall steel and RC moment frames are included along with results of inelastic static and dynamic analyses under severe ground motions to demonstrate the merits of the PBPD method.

1 INTRODUCTION

Tall buildings have become a solution to the increasing population of cities on the urban landscape. However, the design of these tall buildings in seismically active regions may require more work beyond a traditional design based on elastic analysis and force reduction factors.

Design codes, such as the International Building Code (ICC 2006), were mainly developed for application to low and medium-rise buildings. In addition, they use elastic analysis with force reduction factors for strength design which may not be adequate for tall buildings where higher modes of vibration contribute significantly to seismic response. Moreover, no guidance is provided as to how to get the initial starting design or how to make changes during iteration to achieve the intended performance.

The objective of this paper is to present a performance-based practice developed by Goel and his associates at the University of Michigan for the seismic design of high-rise buildings. This method is called Performance-Based Plastic Design (PBPD). The design concept uses pre-selected target drift and yield mechanism as key performance objectives. This method has been successfully applied to steel MF, BRBF, EBF, STMF, and CBF (Goel & Chao 2008). Results of extensive inelastic static and dynamic analyses have proven the validity of the method. In all cases, the frames developed the desired strong column-weak beam yield mechanisms as targeted, and the story drifts/ductility demands were well within the selected design values, thus meeting the selected performance objectives. Comparisons of responses with corresponding baseline frames designed by current practice have consistently shown superiority of the proposed methodology in terms of achieving the desired behavior. An overview of the PBPD method and examples of a 20 story steel moment frame and a 20 story RC moment frame are briefly presented in the paper.

2 WEAKNESS OF CURRENT CODE PRACTICE FOR TALL BUILDINGS

Seismic design of tall building frames poses special problems because of factors such as, participation of higher modes, P-Delta effects, column design, etc. Current code practice, which is primarily based on elastic analysis, does not yield very satisfactory designs. In the current U.S. seismic design practice it is common to obtain design base shear from code-specified spectral acceleration assuming the structures to behave elastically, and reducing it by force reduction factor, R, depending upon available ductility of the structural system. This strength demand is increased according to the importance of specific structures by using an occupancy importance factor, I. After selecting the member sizes for required strengths as obtained from elastic analysis, the calculated drift at design forces is multiplied by a deflection amplification factor, C_d, and kept within specified limits (generally

in the order of 2%). Appropriate detailing provisions are followed in order to meet the expected ductility demands. When struck by severe ground motions, however, the structures designed by such procedures have been found to undergo inelastic deformations in a somewhat "uncontrolled" manner. The inelastic activity, which may include severe yielding and buckling of structural members and connections, can be unevenly and widely distributed in the structure. This may result in rather undesirable and unpredictable response, sometimes total collapse, or difficult and costly repair work at best.

While the above design practice has served the profession rather well in the past, societal demands are pushing the practice to achieving higher levels of performance, safety and economy including life cycle costs. Los Angeles Tall Building Structural Design Council and similar organization in San Francisco have recommended alternative design procedures for tall buildings based on inelastic behavior, albeit requiring extensive iterations to arrive at the desired design.

For the practice to move in that direction, design factors such as, determination of appropriate design lateral forces and member strength hierarchy, selection of desirable yield mechanism, and structure strength and drift etc., for specified hazard levels should become part of the design process right from the start.

3 PERFORMANCE-BASED PLASTIC DESIGN (PBPD) METHOD

3.1 *PBPD concept*

The PBPD method uses pre-selected target drift and yield mechanism as key performance objectives. These two design parameters are directly related to the degree and distribution of structural damage, respectively. The design base shear for a specified hazard, which is generally given as design spectrum in the codes, is calculated by equating the work needed to push the structure monotonically up to the target drift to the energy required by an equivalent EP-SDOF to achieve the same state (Fig. 1). Also, a new distribution of lateral design forces is used, which is based on relative distribution of maximum story shears consistent with inelastic dynamic response results (Chao et al. 2007). Plastic design is then performed to detail the frame members and connections in order to achieve the intended yield mechanism and behavior. Thus, determination of design base shear, lateral force distribution, and plastic design are three main components of the PBPD method.

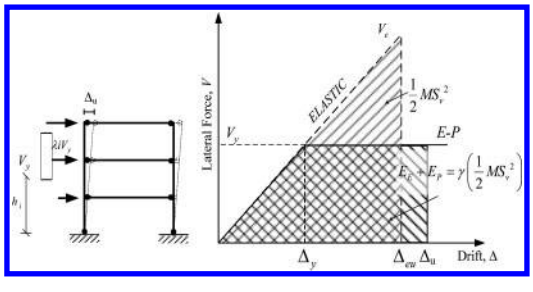

Figure 1. PBPD concept.

3.2 *Determination of design base shear*

Determination of the design base shear for given hazard level is a key element in the PBPD method. It is calculated by equating the work needed to push the structure monotonically up to the target drift to that required by an equivalent elastic-plastic single degree of freedom (EP-SDOF) system to achieve the same state. Assuming an idealized E-P force-deformation behavior of the system, the work-energy equation can be written as:

$$(E_e + E_p) = \gamma\left(\frac{1}{2}MS_v^{\,2}\right) = \frac{1}{2}\gamma M\left(\frac{T}{2\pi}S_a g\right)^2 \quad (1)$$

where E_e and E_p are, respectively, the elastic and plastic components of the energy (work) needed to push the structure up to the target drift. S_v is the design pseudo-spectral velocity; S_a is the pseudo spectral acceleration; T is the natural period; and M is the total mass of the system. The energy modification factor, γ, depends on the structural ductility factor (μ_s) and the ductility reduction factor (R_μ), and can be obtained by the following relationship:

$$\gamma = \frac{2\mu_s - 1}{R_\mu^{\,2}} \quad (2)$$

Because of their simplicity, spectra proposed by Newmark and Hall (1982) were used to relate the ductility reduction factor, R_μ, and the structural ductility factor, μ_s, for EP-SDOF. It should be mentioned that for this purpose any inelastic spectra for EP-SDOF systems can be used as preferred, such as by Miranda and Bertero (2004).

The work-energy equation can be re-written in the following form

$$\frac{1}{2}\left(\frac{W}{g}\right)\cdot\left(\frac{T}{2\pi}\frac{V_y}{W}g\right)^2 + V_y\left(\sum_{i=1}^{N}\lambda_i h_i\right)\theta_p = \frac{1}{2}\gamma\left(\frac{W}{g}\right)\cdot\left(\frac{T}{2\pi}S_a g\right)^2 \quad (3)$$

or

$$\left(\frac{V_y}{W}\right)^2 + \frac{V_y}{W}\left(h^*\cdot\frac{\theta_p 8\pi^2}{T^2 g}\right)\theta_p - \gamma S_a^{\,2} = 0 \quad (4)$$

The admissible solution of Equation (4) gives the required design base shear coefficient, V_y/W:

$$\frac{V_y}{W} = \frac{-\alpha + \sqrt{\alpha^2 + 4\gamma S_a^{\,2}}}{2} \quad (5)$$

where α is a dimensionless parameter given by,

$$\alpha = \left(h^*\cdot\frac{\theta_p 8\pi^2}{T^2 g}\right) \quad (6)$$

The term θ_p represents plastic component of the target drift ratio, and

$$h^* = \sum_{i=1}^{N} (\lambda_i h_i) \tag{7}$$

As mentioned earlier, Equation (5) for V_y was derived by assuming ideal elastic-plastic (E-P) force-deformation behavior and "full" hysteretic loops for the system. That is characteristic of a number of ductile steel framing systems, such as MF, EBF, STMF, and BRBF. For systems that do not posses such hysteretic property, such as steel braced frames with buckling type braces or RC frames, some modification is warranted.

Based on consideration of the effect of degrading hysteretic behavior on peak (target) displacement, Investigators have studied the effect of degrading hysteretic behavior of SDOF systems on resulting peak displacements. The results show that the peak displacements are larger than those of systems with non-degrading hysteretic behavior in short period range, but are about equal for longer periods. Approximate expressions have been proposed for modification factors to account for this effect, e.g., factor C_2 in FEMA 440 (2006). Thus, the target design drift for a given structural system with degrading hysteretic behavior can be divided by the C_2 factor which will give design target drift for an equivalent non-degrading system. The design base shear can then be calculated by using this modified target drift and Equation (5).

3.3 *Lateral force distribution*

Traditionally, vertical distribution of design lateral forces in modern building codes has been based on elastic fundamental mode response of MDOF systems. Modifications have been made in the basic equations to account for effects, such as contribution of higher modes. Chao et al. (2007) proposed a modified lateral force distribution mainly derived by empirical fit with results from a variety of common structural systems as shown in Equation (8).

$$F_i = (\beta_i - \beta_{i+1}) \cdot \left(\frac{w_n h_n}{\sum_{j=1}^{n} w_j h_j} \right)^{0.75T^{-0.2}} V_y \tag{8}$$

where F_i is the design lateral force at level i, the terms w and h represent seismic weight and height above the base, and V_y is the total base shear. β_i is the ratio V_i/V_n, termed as shear distribution factor.

4 ADVANTAGES OF DESIGN OF TALL BUILDINGS BY USING PBPD METHOD

The PBPD method not only accounts for structural inelastic behavior directly but also considers factors such as determination of appropriate design lateral forces, member strength hierarchy, selection of desirable yield mechanism, and target drift right from the beginning of the design process. Thus, advantages of design of tall buildings by using PBPD method can be summarized as below:

- Assure strong column/weak beam design reached because the yielding mechanism is preselected and all non designated yielding members (columns) are designed by capacity design approach considering an entire "column tree" instead of single joints.
- P-Delta effect is included in the determination of required moment capacity of beams, particularly for the 20-story RC SMF, in order to provide necessary strength to counter the overturning due to gravity loads.
- The higher mode effects are considered in a more representative distribution of lateral design forces used in PBPD design, which is based on relative distribution of maximum story shears consistent with inelastic dynamic response results.

5 DESIGN EXAMPLES

5.1 *20-story steel moment frame*

An example of a tall steel moment frame is presented in this section. This 20-story frame was the subject of extensive analytical study as part of the SAC Steel Research Program (Gupta & Krawinkler 1999). The frame was re-designed by the PBPD method as outlined in the preceding sections. The resulting design and its responses under static pushover and dynamic time-history analyses due to selected set of ground motions are compared with those of the original SAC frame.

The framing plan of the structure is shown in Figure 2. Since the original SAC frame was designed according to UBC (1994), same loading and other design parameters were used for redesign of the frame by PBPD method. The story heights are 5.5 m for the

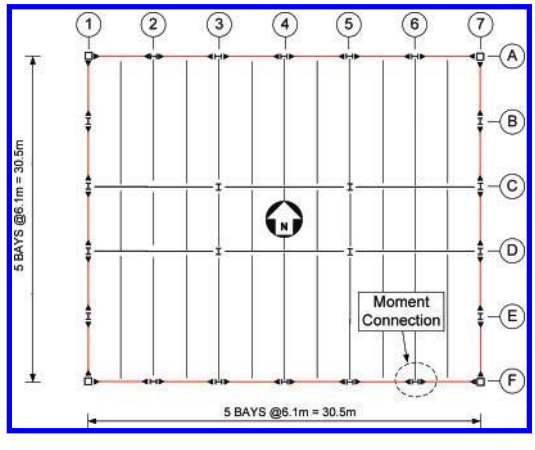

Figure 2. Floor plan of the LA 20-story SAC building.

Table 1. Design parameters for 20-story steel PBPD frame.

Design parameters	10% in 50 years Hazard (2/3MCE)	2% in 50 years Hazard (MCE)
S_a	0.36 g	0.54 g
T(sec.)	2.30	2.30
Yield Drift Ratio	1.0%	1.0%
Target Drift Ratio	2%	3%
Inelastic Drift Ratio	1%	2%
μ	2.0	3
R_μ	2.0	3
γ	0.75	0.438
α	0.942	1.884
V/W	0.094	0.037
Design Base Shear	5098 kN (governs)	2033kN

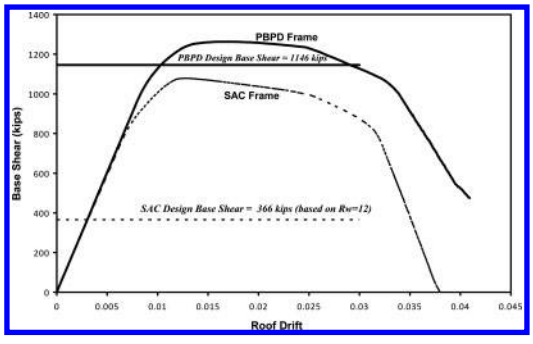

Figure 3. Comparison between pushover curves of PBPD frame and SAC frame.

first story and 4 m for all others. The PBPD procedure as described in the preceding sections was used to redesign the 20-story SAC frame. The important design parameters are given in Table 1. The target yield mechanism is sway mechanism similar to the one shown in Figure 1. Grade 50 steel was used. More details can be found elsewhere (Bayat 2010).

Nonlinear static (pushover) and dynamic (time-history) analyses were carried out for the SAC and PBPD frames by using Perform-3D program (CSI 2007). A lumped "gravity column" was added which enables the model to capture the P-Delta effect as well as the contribution of all gravity columns in the response of the structure. Strength degradation of moment-rotation behavior of plastic hinges and panel zone deformations were also modeled.

Figure 3 shows base shear versus roof drift plot of the two frames from the pushover analysis. The PBPD frame has somewhat greater ultimate strength than the SAC frame. The design base shear for SAC frame is significantly smaller than its ultimate strength because for steel moment frames, the design is generally governed by drift. As targeted in the design, absence of plastic hinges in columns of the PBPD frame (except at the bases) can be noticed. In contrast, significant plastic hinging in the columns of the SAC frame in lower stories is observed, which is also reflected in the

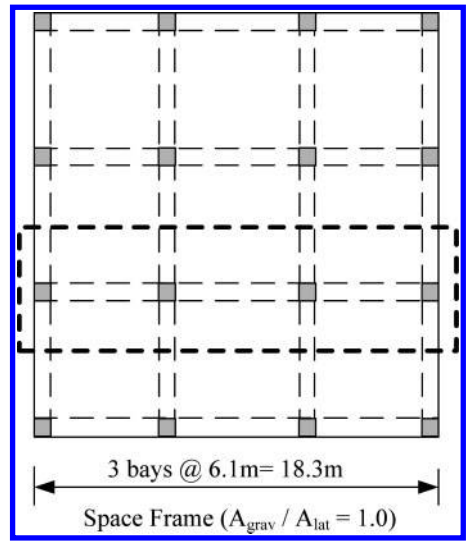

Figure 4. Floor plan of the 20-story RC space moment frame building.

differences in deformed shape of the two frames, i.e., concentration of drift in the lower stories of the SAC frame. Also, plastic rotations in the beams and column bases at 3.5% roof drift are significantly smaller in the PBPD frame as compared with those in the SAC frame.

Inelastic dynamic analyses of both frames were carried out by using 10/50 and 2/50 SAC ground motions for LA site (Somerville et al. 1997). The results showed superior behavior of the PBPD frame under 10/50 as well as 2/50 hazard levels. No unexpected plastic hinging was observed in the columns of the PBPD frame, whereas significant plastic hinging was observed in the SAC frame columns under both sets of ground motions (Bayat 2010). Moreover, collapse of the SAC frame was seen for three ground motions, namely LA30, LA35, and LA36. Even though those ground motions caused large story drifts in the PBPD frame, but the structure did not lose stability.

5.2 *20-story RC special moment frame*

RC structures present special challenge due to their complex and severely degrading ("pinched") hysteretic behavior. While development of the PBPD method for RC structures is currently in progress, results from the study so far have been most promising. An example of a 20-story RC moment frame structure is briefly presented in this section. This baseline space frame was designed to comply with the requirements of ASCE 7-05 and ACI 318-05 (Haselton & Deierlein 2007). It was redesigned by the modified PBPD method by using the FEMA 440 (2006) C_2 factor approach as mentioned in Section 3.2. More details can be found elsewhere (Liao & Goel 2010).

Typical floor plan is shown in Figure 4, and important design parameters are given in Table 2. For

Table 2. Design parameters for 20-story PBPD RC moment frame.

Design parameters	10% in 50 years Hazard (2/3MCE)	2% in 50 years Hazard (MCE)

R_μ	4	6
γ	0.4375	0.3056
α	0.662	1.103
V/W	0.055	0.054
Design Base Shear	1135 kN (governs)	1103kN

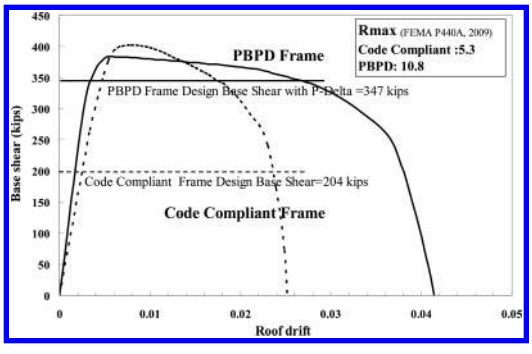

Figure 5. Pushover curves for PBPD and code compliant 20 story RC moment frames.

response evaluation purposes the baseline code compliant frame and the PBPD frame were subjected to inelastic pushover and time-history analyses by using Perform 3D as well.

It should be mentioned that P-Delta effect was not included in Equation (18). That is the way design of beams of the PBPD steel frame was performed. However, due to strength degradation at beam plastic hinges it was found necessary to include P-Delta effect in the determination of required moment capacity of beams for the 20-story RC frame. That was accomplished by adding "P-Delta lateral force" to the basic design force, F_i, in Equation (8). Force F_{i-PD} can be taken equal to $P_i\theta_u$, where P_i represents the tributary gravity load at floor level i and θ_u the target design drift ratio which is assumed constant for design purposes. Their influence on the total lateral design force can be clearly noticed as it has significant effect on the required frame strength.

The pushover curves for the two frames in Figure 5 show that even though the design base shear for the baseline is smaller than that of the PBPD frame, the ultimate strength of the two are almost equal. That is mainly due to the fact that the design of the baseline

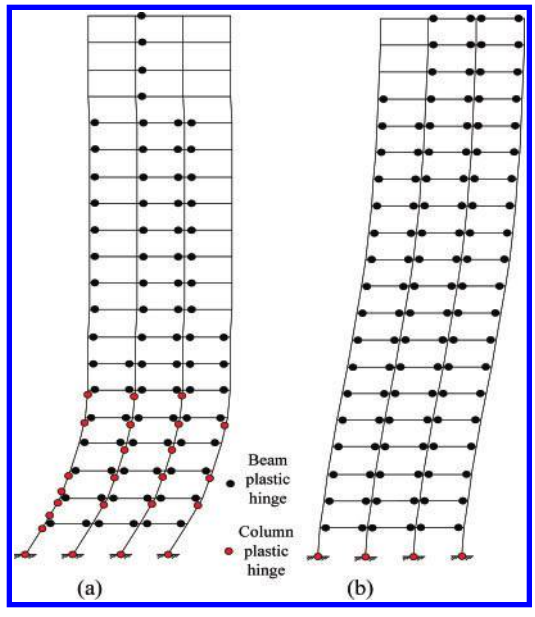

Figure 6. PH locations at 2.5% roof drift, (a) Code compliant frame, (b) PBPD frame; Pushover Analysis.

frame is governed by drift which requires major revision of the member sizes after they have been designed for strength. That iteration step is not needed in the PBPD method.

Figure 6 shows the deformed shape and location of plastic hinges of the two frames at 2.5% roof drift. Formation of plastic hinges in the columns and story mechanism in the lower part of the baseline frame can be clearly noticed. In contrast, there are no unintended plastic hinges in the columns of the PBPD frame, resulting in more favorable deformed shape and yield pattern as targeted in the design process.

The comparison of maximum interstory drifts of the baseline and PBPD frames obtained from time-history analyses using appropriately scaled ground motion records representative of 2/3 MCE and MCE hazard levels can be found in Figure 7. For clarity and brevity only the mean values of maximum interstory drifts are shown here. The results show that the mean maximum interstory drift ratios of the PBPD frames are well within the corresponding target values, i.e., 2% for 2/3 MCE and 3% for MCE. Moreover, the story drifts of the PBPD frames are more evenly distributed over the height as compared with those of the baseline frame where undesirable "softness" in the lower stories is evident, which is caused mainly by plastic hinges in the columns. Formation of plastic hinges in the columns and story mechanism in the lower part of the baseline frames can be clearly noticed. In contrast, there are no unintended plastic hinges in the columns of the PBPD frame, resulting in more favorable deformed shape and yield pattern as intended in the design process.

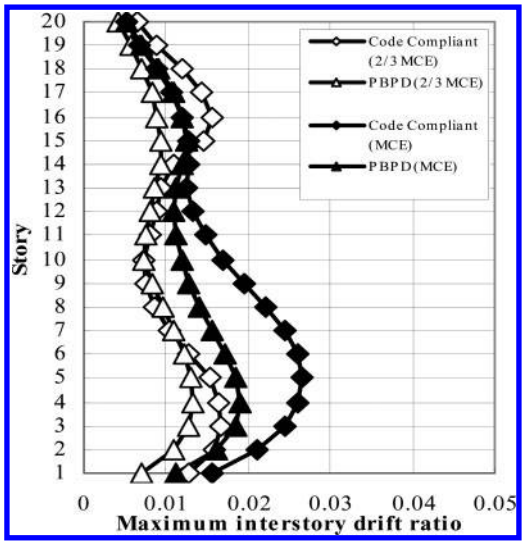

Figure 7. Comparison of maximum interstory drifts by time-history analyses of code complaint and PBPD frames for 2/3 MCE and MCE hazard levels.

6 SUMMARY AND CONCLUSION

The PBPD method is a direct design method which uses pre-selected target drift and yield mechanism as key performance objectives. The examples of 20-story steel and RC moment frames as presented in this paper showed that the method is especially advantageous for tall frames where the cumbersome and lengthy iterative process in current design practice can be completely eliminated, while leading to excellent performance as targeted.

Parametric study of pyramid-like tubular structure

Gin-Show Liou & Heng-Chih Kuo
Department of Civil Engineering, National Chiao Tung University, Hsin-Chu, Taiwan

ABSTRACT: Framed-tube structure is a generally used structural type for tall buildings. Its basic form is closely spaced columns connected with deep spandrel beams at the periphery of building structure. This structural type is very efficient for resisting horizontal (wind) load. However, Shear lag phenomenon is the main cause to reduce the effectiveness of tubular structure. Therefore, reducing shear lag effect become a challenge to design a framed-tube structure. The paper will study the behaviors of pyramid-like tubular structure, which could effectively soothe the shear lag problem.

1 INTRODUCTION

Due to urban development and economic necessity, tall building becomes an solution for the concentration of population. As the building is getting taller, the technique to withstand the horizontal loadings induced by earthquake and wind is more demanding. To resist the horizontal loading, many structural systems are available such as large-scale bracing, core, diagrid, outrigger, framed tube structures and others as explained by Ali and Moon (2007).

Among these structure forms, framed tube structure has the advantage of arranging all the resisting component at the perimeter of the building. This makes the components more efficient to resist the overturning moment caused by horizontal loading. The concept of tubular structure was first proposed by Khan and Amin (1973). However, the disadvantage of tubular structure is the shear-lag problem. The shear lag will reduce the efficiency of the components. Therefore, bundle tubular structure is introduced as explained by Ali and Moon (2007) in order to relieve the problem of shear lag. Wang (2012) has presented the typical shear lag phenomenon in Fig. 1 for a 3×3 bundle tubular structure with some modular tubes curtailed at the heights of 400 m and 800 m. In the figure, symbol I is relative moment of inertia of cross sections of spandrel beam. However, for the higher story, Singh and Nappal (1994) have shown that negative shear lag will occur. The typical negative shear lag phenomenon is shown in Fig. 2 for the 3×3 bundle tubular structure by Wang (2012). This means that the axial stress of the interior column in the flange frame is larger than that of the exterior column. By observing Figs. 1 and 2, one can conclude that as the moment of inertia of cross section of spandrel beam (I) becomes larger, the effect of shear lag will be reduced. As the effect of shear lag is diminishing, the tubular phenomenon becomes more apparent. This can be observed in Fig. 3. In the figure, the vanishing of shear lag effect, as seen in Figs. 1 and 2, will make the horizontal stiffness of the building larger. This means the lateral displacement of the building subjected to horizontal loading is reduced.

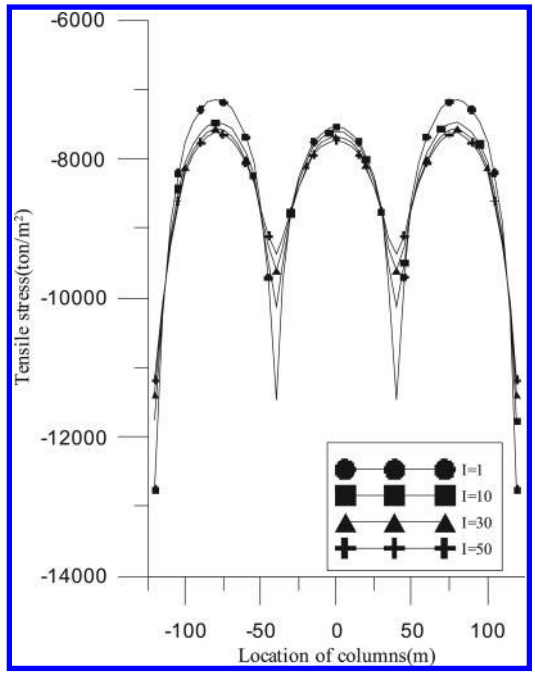

Figure 1. Typical shear lag phenomenon for compressional flange frame at height 0 m (Wang 2012).

In order to mitigate the shear lag problem, a pyramid-like tubular structural form is suggested for tall buildings. The pyramid-like tubular structure is defined as the tubular structure with gradually reduced floor area through the height of floor. Since the floor area is reduced through the height, the periphery columns have to be inclined accordingly. The inclined

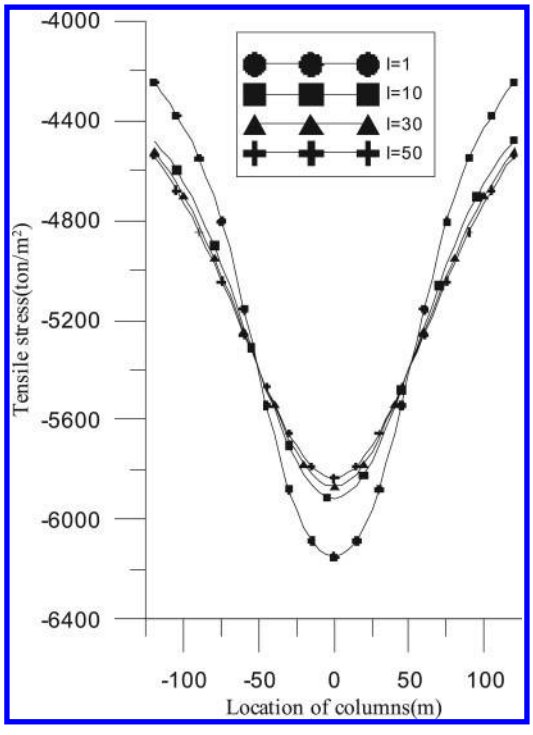

Figure 2. Typical negative shear lag phenomenon for compressional flange frame at height 200 m (Wang 2012).

columns can balance part of horizontal load directly. This could also mitigate the shear lag problem.

The paper will investigate the behavior of the pyramid-like tubular structure by changing the relative stiffness of spandrel beams to periphery column, and the effectiveness of the structure type for withstanding horizontal load. Also, the shear lag phenomenon for the structural type will be discussed. The analysis program SAP 2000 will be employed to model and analyze the structures. In the analysis model, only 3-D beam elements are used and rigid zone at beam-column joints is assumed.

2 NUMERICAL ANALYSIS

In order to study the behavior of pyramid-like tubular structure, the building structure shown in Fig. 4 is assumed. In the figure, the base of the structure is 240 m × 240 m and the height is 1200 m. This means the inclination of columns at periphery of the structure is 1/10 in the horizontal x and y directions. The story height is 5 m. This leads to 240 stories for the structure. The building code of Taiwan (2006) is adopted to calculate the horizontal wind load. The wind pressure on the building is shown in Fig. 5. In the figure, the wind pressure is calculated by assuming 5% damping ratio for the structure.

Computer program SAP2000 is employed to model the pyramid-like structure. In the model, only beam

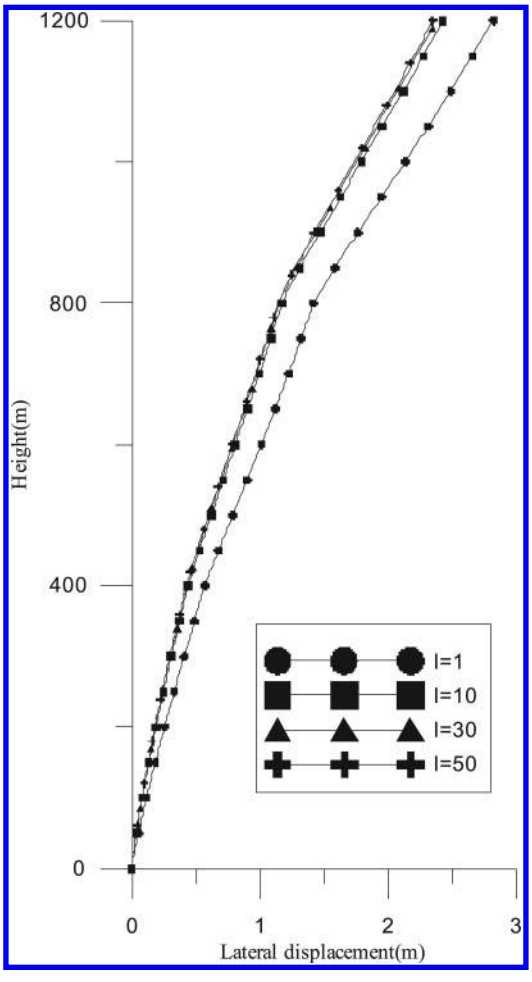

Figure 3. Typical lateral displacement (Wang 2012).

element is used to model columns and spandrel beams, rigid diaphragms for all the floors are assumed, and the option of rigid zones at beam-column connections is selected. The members for the four corner columns are circular tubes with 200 cm in diameter and 6 cm, 8 cm or 10 cm in thickness. The members for the other periphery columns are 100 cm × 50 cm rectangular tube with 6 cm, 8 cm or 10 cm in thickness. In order to keep total area of corss sections of columns constant at periphery of the structure, the spacing of the columns is 3 m for the thickness 6 cm, the spacing of the columns is 4 m for the thickness 8 cm, and the spacing of the columns is 5 m for the thickness 10 cm. Three types of member are selected for the spandrel beams. The cross sections of the three types of beams are shown in Fig. 6. Therefore, one totally has 9 cases (3 different cross sections of spandrel beams times 3 different spacing of periphery columns) to be studied. In the study, the vertical loading (gravity loading) is not taken into account. Therefore, only periphery columns and spandrel beams are modeled in Fig. 4 to resist the horizontal wind pressure shown in Fig. 5.

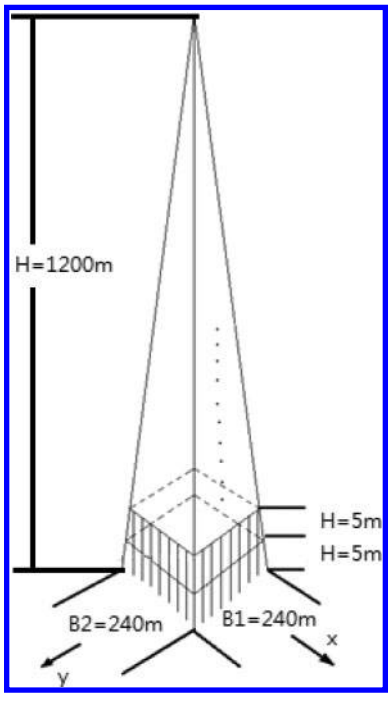

Figure 4. Pyramid-like tubular building structure.

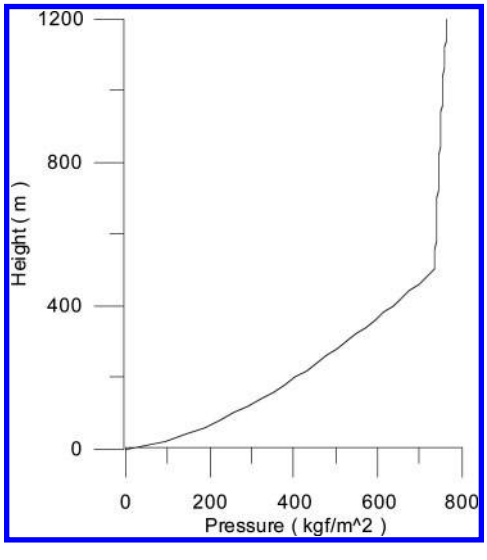

Figure 5. Design wind pressure by building code of Taiwan (2006).

The lateral displacement due to the wind load of Fig. 5 is shown in Fig. 7. In the figure, the symbol 3 m-1 represents the case with 3 m column spacing and spandrel beam type No. 1 of Fig. 6, and the other similar symbols (3 m-2…etc.) represent the corresponding cases. From Fig. 7, one can observe the phenomenons as follow:

(1) Stiffer spandrel beam will make the lateral displacement smaller. For examples, the sways for

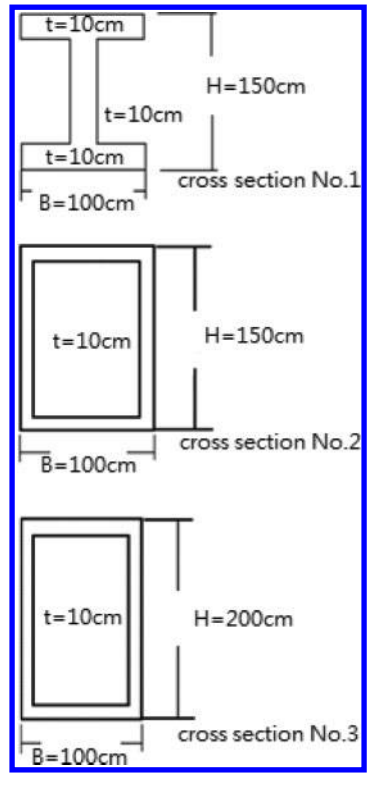

Figure 6. Cross sections of spandrel beams.

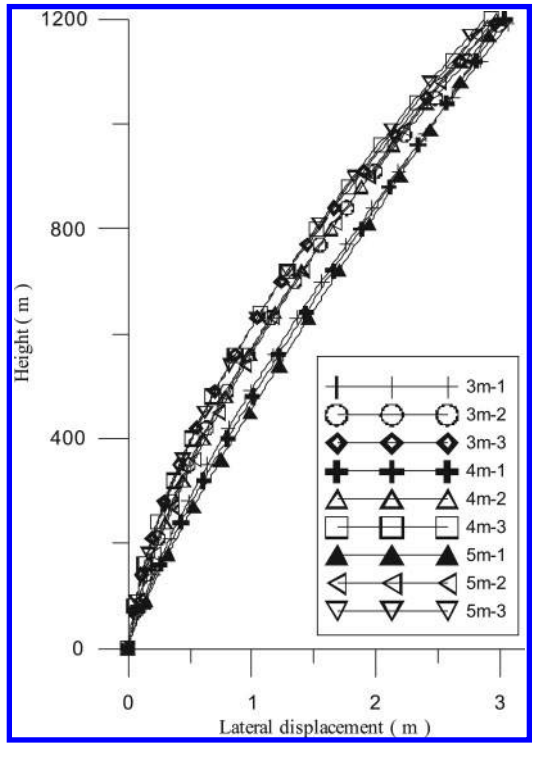

Figure 7. Lateral displacement due to wind load.

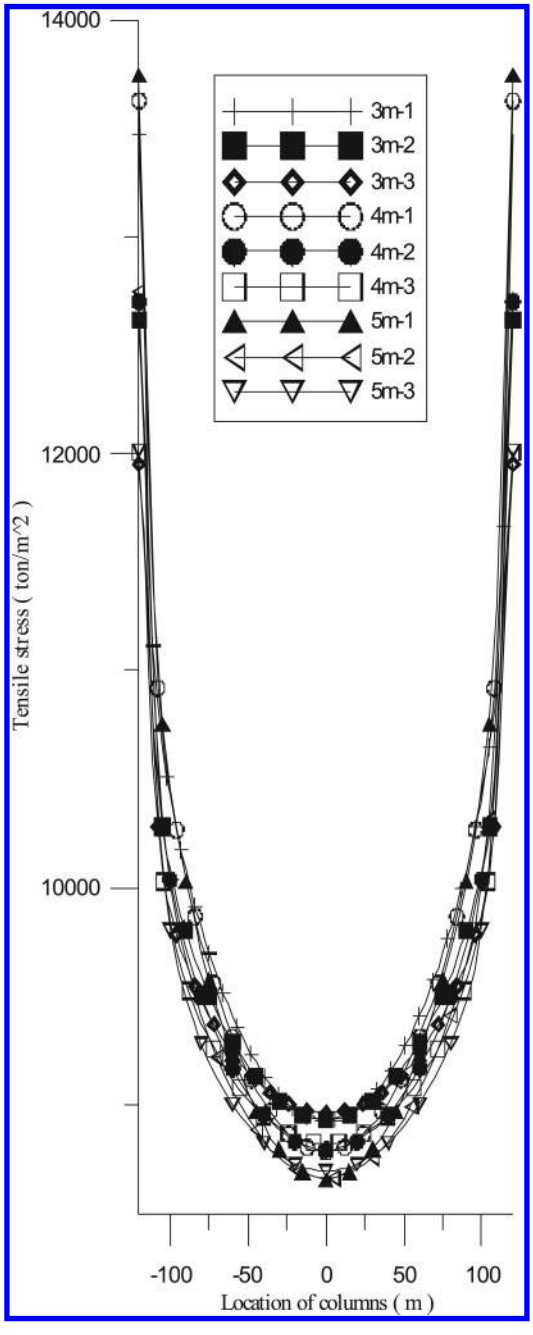

Figure 8. Tensile stress of columns of flange frame at height 0 m (1st story).

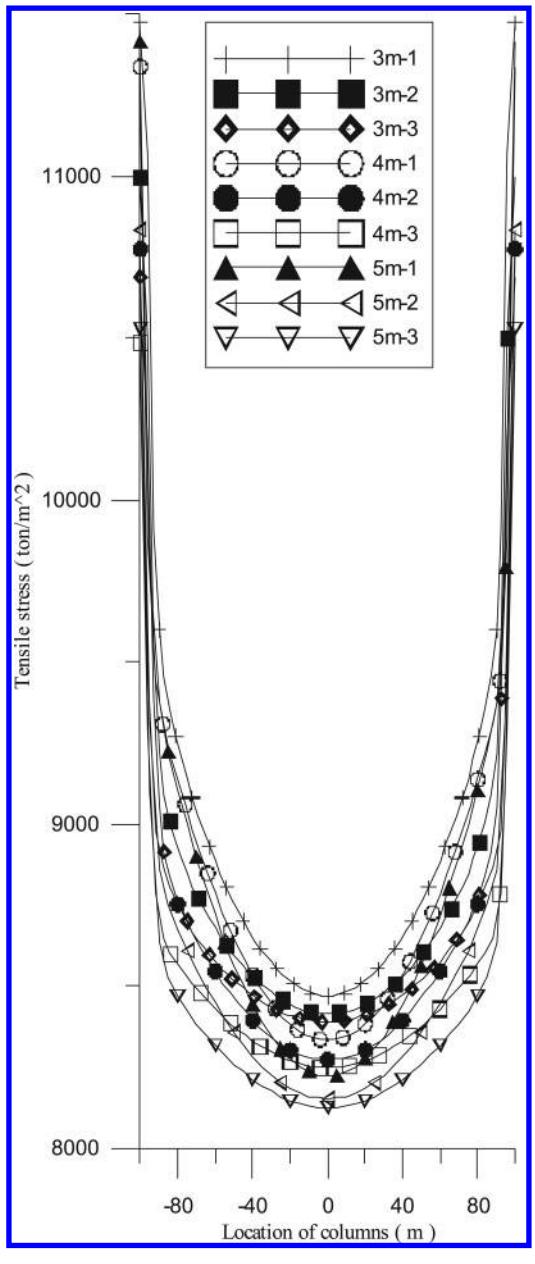

Figure 9. Tensile stress of columns of flange frame at height 200 m.

the cases 3 m-3, 4 m-3 and 5 m-3 are smaller, while compared to the corresponding cases 3 m-2, 4 m-2 and 5 m-2, and 3 m-1, 4 m-1 and 5 m-1, respectively.

(2) If the column area is more evenly distributed around the periphery, the sway is smaller. For examples, results for the case 3 m-1 is smaller than that for the cases 4 m-1 and 5 m-1.

(3) However, the maximum lateral displacement at top of the building structure seems entangled for the 9 cases.

Fig. 8 shows the tensile stress of the columns of flange frame at height 0 m. In the figure, one can see that the curves for shear lag phenomenon can be divided into 3 groups for the 3 types of spandrel beams shown in Fig. 6 respectively. For stronger spandrel beam, the shear lag effect is lesser. For example, the shear lag phenomenon is lightest for the strongest

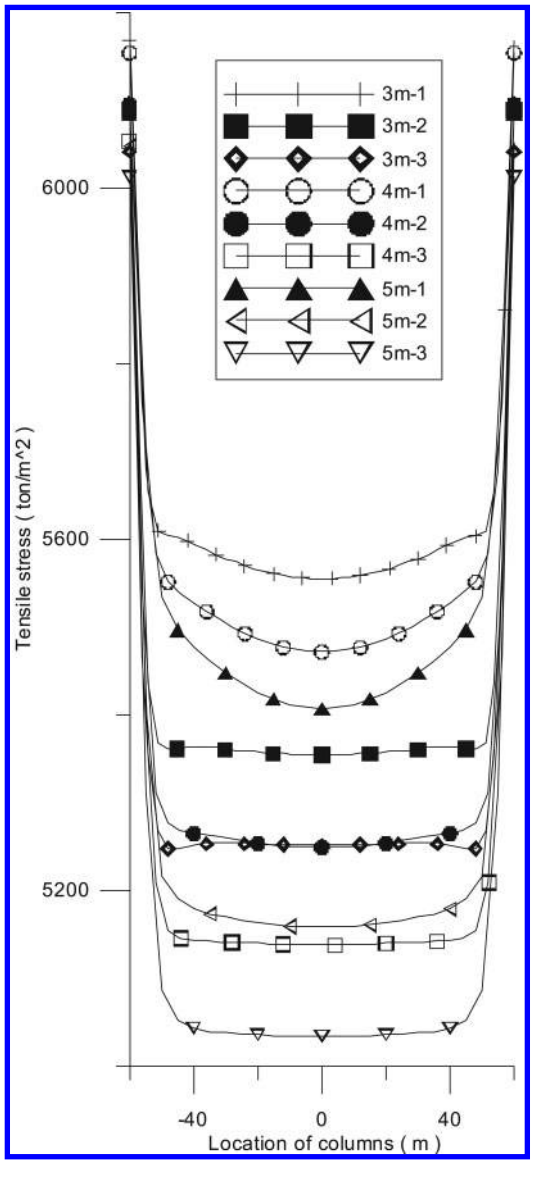

Figure 10. Tensile stress of columns of flange frame at height 600 m.

spandrel beam (Type No. 3 in Fig. 6). However, the effect of evenly distributed column area seems not so obvious to reduce shear lag phenomenon. This can be observed by comparing the results for cases of 3 m spacing to that for the corresponding cases of 4 m and 5 m spacings.

Figs. 9 and 10 show the tensile stress of columns at heights 200 m and 600 m respectively. From these two figures, one can observe that negative shear lag phenomenon does not occurs for all 9 cases. As a matter of fact, there is no negative shear lag observed along the height of the building, as one examines all the column stress. This could be the effect of inclination of columns.

3 CONCLUDING REMARKS

The pyramid-like structural type is suitable for super tall building. It has the advantages to effectively reduce shear lag phenomenon along periphery columns and lateral displacement along the height of building. Also, this structural type can be easily combined with other structural forms, e.g. large scale bracing and outrigger structures, to resist horizontal wind load.

More optimal seismic design of highrise structures using nonlinear analysis techniques

S.A. Ashrafi
Thornton Tomasetti, New York, NY, USA

ABSTRACT: It is a well-known feature of dynamic response of highrise structures that their seismic response, including the distribution of strength and deformation requirements, is very different from low-rise structures. Most design codes allow for or require the use of modal analysis techniques to allow the design to capture the effects of higher modes present in the response. However, buildings are typically designed to undergo significant nonlinearity during a design level strong earthquake. These nonlinearities change the value and distribution of the strength and displacement demands in ways that can be very different than what linear modal analysis implies. Nonlinear dynamic analysis allows for capturing the expected behavior of the building and designing accordingly. The result can be safer and more optimal design of the structure. This paper will discuss how the design of a tall building can change as a result of using nonlinear analysis in the context of performance based design.

1 INTRODUCTION

Most building design codes rely on a force-based seismic design approach. In this approach, some prescribed seismic forces are calculated for a building and the building elements are proportioned to have sufficient strength and stiffness to carry these forces. As the design for most structures relies on significant nonlinearity during strong seismic events, the prescribed forces are reduced compared to elastic demands.

For short buildings, a single mode in each direction can be considered to comprise most of the dynamic response. On the other hand, several modes can be present in the response of highrises, with different relative importance in deflections and internal forces at different levels of the building. Using a single reduction factor to modify all the responses makes the implicit assumption that the nonlinearity affects all the modes similarly, and that initiation of nonlinearity in the structure only changes the amplitude of the force and displacement demands, not their distribution.

Nonlinear dynamic analysis gives the tool to the designer to study the actual expected response of a structure to any given set of ground motions, not relying on simple assumptions to estimate the effects of nonlinearity. There have been several studies looking at such effect. For example, see Klementec et al. 2007, Moehle et al. 2011, Fry et al. 2010, and Zekioglu et al. 2007. However, one important fact about nonlinear analysis is that it needs an initial design with a given distribution of strength and stiffness. The nonlinear dynamic analysis then becomes largely a verification process for that initial design. Part of the reason for this common approach is the level of effort required in modeling and analyzing a proper nonlinear model of a structure, and the large computational and time costs associated with a nonlinear analysis.

There are several ways in which the nonlinear analysis approach can be used for the design. The first approach is to design the building using standard codes, and then perform nonlinear analysis to verify that the structure meets its performance criteria. This is most often the way nonlinear analysis is used.

The second approach is to design the building using the standard code approach, but for a service level seismic force. Then nonlinear analysis can be used to check the adequacy of the design for higher levels of ground shaking, and if necessary, the design can be updated. This approach has the advantage that it does not fully design the structure based on some fictitious loads, but rather, uses realistic loads at service level and then allows the designer to increase stiffness and strength at various locations as required to achieve satisfactory performance for extreme events. The downside is that there is no guidance provided in how best to modify the building properties to achieve a satisfactory and also optimal design. Similarly, it does not provide any direction for proportioning the structure at the service level. The desired design philosophy in terms of how various components have to be proportioned relative to each other is not clear, beyond proportioning members for strength based on linear analysis results.

The third approach id to use nonlinear analysis in the context of performing parametric studies within the range of the design parameters for a specific project to allow finding the near optimal solution that satisfies the performance criteria. There are many parameters to look at, such as moment and shear at various floors,

internal forces of members, drifts and deflections. Also, these parameters can be looked at in the terms of average demands, maximum demands, standard variation of the demands, and in general, fragility of various responses. Therefore, it might be hard to find what combination of these parameters should be part of the optimization processand what their relative weights are. However, the nonlinear parametric study will help clarify the effect of various design choices and let the designer achieve a near optimal design based and the cost and benefits for any design choice.

The last approach clearly provides room for maximum efficiency in design and flexibility for the designer. It is also the option with the maximum computational costs. However, given the potential gains in a design, an intelligent adoption of this approach early in the design process could allow for a much better overall design. In addition, a group of such studies can be used to draw broader lessons regarding proper design principles to guide the initial design and the parametric study for different structural systems.

2 CASE-STUDY OF THE EFFECTS OF NONLINEARITY

Effects of nonlinearity on structural response and variations in the response as a result of parametric changes in the strength of various components are studied for a sample 150 m tall concrete core structure. Strength of the walls and link beams are variedproportionally and the effects on the response are studied.

The structure is studied subject to seven pairs of ground motions representing high seismic demand. Expected properties are used for the concrete and steel reinforcement in lieu of the minimum specified properties since the goal is to capture the realistic structural response. The strength of steel and concrete in the analysis models are 484 MPa and 52 MPa, respectively. This study is performed using a concrete core as the sole lateral system of the structure.

Perform 3D program is used for nonlinear analysis (CSI, 2011). Walls are modeled using fiber elements. The fiber elements allow for cracking of concrete under tension and incorporate confinement effects in compression, in addition to accounting for yielding of the rebars. Moment hinges are used to capture nonlinearity in link beams. Since structural elements are allowed to yield and crack explicitly, no additional modifications are used to adjust wall stiffness, as would be the case for linear models. Energy dissipation is modeled through a combination of modal damping to model the ever-present low-amplitude damping, and explicit modeling of nonlinearity within elements. Based on the data on ambient damping of structures of similar height and construction, a modal damping ratio of 2% is selected for the nonlinear models (CTBUH 2009).

The core models have walls that are 1.1 m wide at the base and narrow down to 0.6m at the top. However, the nonlinear capacities of the wall elements and link beams are varied between the models. The strongest nonlinear model (Model 1) has 2% reinforcement at the base with 2.5% reinforcement at the corners. The reinforcement is reduced through the height, ending with 1% reinforcement at the top. The link beams have diagonal reinforcement and are considered to have strength similar to the maximum capacity allowed for link beams per ACI code (ACI, 2008). Table 1 shows the variations in the amount of reinforcement in the models. As the nonlinear strength of the structure is limited by the capacity of link beams and tension capacity of the walls, the reduction in reinforcement is also a good estimate for reduction in strength as long as the limiting force types do not change.

Table 1. Description of models.

Model	Description
Model 1	Baseline nonlinear model
Model 2	25% reduction in wall and link beam reinforcement compared to Model 1
Model 3	50% reduction in wall and link beam reinforcement compared to Model 1
Model 4	67% reduction in wall and link beam reinforcement compared to Model 1

All the four case study models have roughly the same initial period of 3.3s in both principal directions because the initial period is mostly a factor of the core wall and link beam geometry, not the amount of reinforcement and hence strength provided in the model. Here lies one weakness of relying fully on linear models for design. Whereas the four models will have very different behaviors under the same dynamic loading, linear models are incapable of capturing such differences or providing guidance as to which model provides the best seismic behavior.

3 PARAMETRIC STUDY RESULTS

Models are analyzed using seven sets of ground motions. Because of the variation of the response depending on the individual ground motion being considered, a statistical measure of each response, such as mean, or mean plus one standard deviation, is typically used for evaluation of the performance of the structure. Here, average values are used for comparison.

For tall buildings, large modal mass and response spectrum values for higher modes result in significant contribution of higher modes to the seismic response. This phenomenon is well understood for linear models (Smith & Coull 1991, Taranath, 2005). For the first mode in each principal direction, the equivalent forces all act in the same direction. As a result, story shear forces and overturning moments increase monotonically from top to the base of the structure. The effective moment arm defined as the base overturning moment divided by base shear would be about 2/3 of the height for a linear first mode.

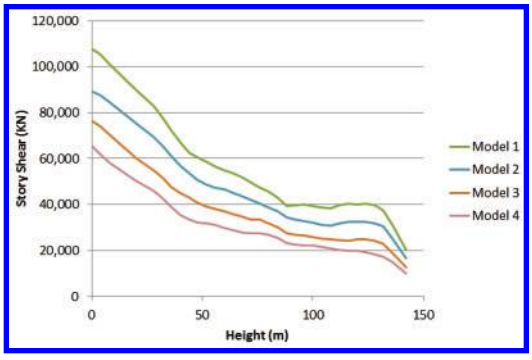

Figure 1. Mean story shear forces throughout the building height.

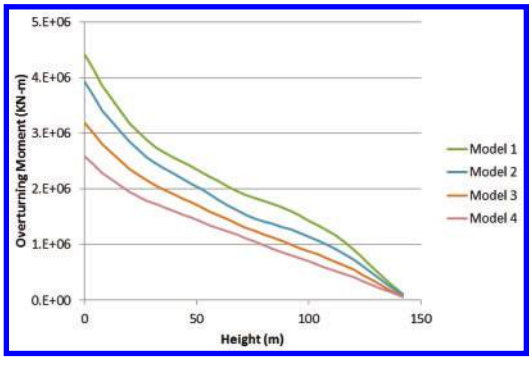

Figure 2. Mean story overturning moment throughout the building height.

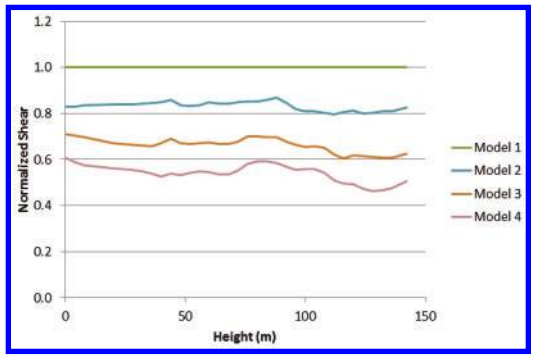

Figure 3. Normalized story shear throughout the building height.

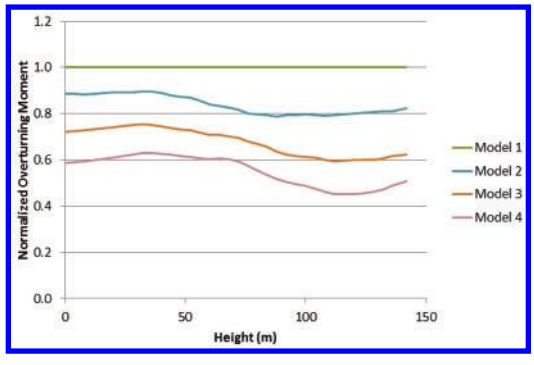

Figure 4. Normalized story overturning moment throughout the building height.

For the second mode in a direction, the structure tends to move one way at the top and another way lower in the structure. Because the effective forces on the structure act in opposite directions through the height, the story shears and overturning moments do not increase monotonically and the effective moment arms is lower for higher modes. Also, the ratio of the shear forces in some upper floors to the base shear is higher than what it would be for the first mode. In addition, the high curvature mode shape result in high interstory drift contributions. The same observations can be made regarding the third and higher modes in any direction. Therefore, the first mode is expected to dominate the base overturning moments and roof displacements. The higher modes are expected to make a meaningful difference to the base shear, as well as story shear forces, overturning moments, and story drifts in upper stories.

Figures 1 and 2 show the story shears in X direction and the corresponding overturning moments about the Y axis in the models. Figures 3 and 4 show the same results, as normalized to the results of Model 1. As expected, reduction in strength of the structural elements generally results in reduction of structural forces. When comparing to results from linear models, the reduction in overturning moment is expected to be more than that in shear (See Ashrafi 2013). That is because the strength of the core is mostly governed by a plastic hinge close to the base .A reduction in first mode response due to such plasticity will not affect the shear forces from the higher modes as much and these higher mode shear forces could be a significant part of the total shear. However, when comparing the nonlinear models, the reduction in shear forces does not show a substantially different trend than the reduction in overturning moment. An interesting observation from Figures 3 and 4 is that the reduction in forces in the structure does not correspond to a simplistic definition of the reduction of strength. For example, Model 4 has 1/3 the reinforcement of Model 1. However, its shear and bending forces are 45–60% of Model 1. The reason is the yielding in such a structure with many elements does not occur all at once. Rather, different elements at different locations in plan and height yield at different times. As a result, any global force deflection curve (such as story overturning moment vs. lateral movement) will be a gradually softening curve, as opposed to an elastic perfectly plastic curve. Therefore, Model 4 can reach a force larger than 1/3 that of Model 1, albeit at a different deformation level.

Figures 5 and 6 represent the variation of average and maximum story drifts. In general, reduction of structural strength leads to higher peak drift, but this trend does not monotonically hold at all the elevations or for all strength levels. Figure 5 seems to indicate

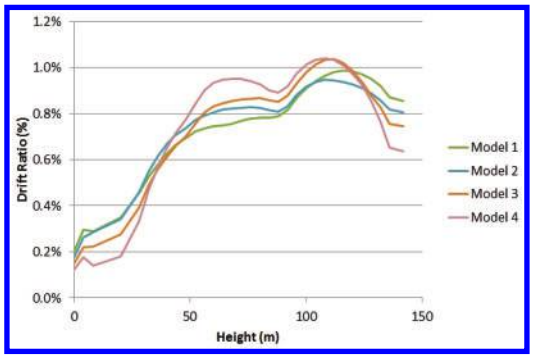

Figure 5. Mean drift ratios throughout the building height.

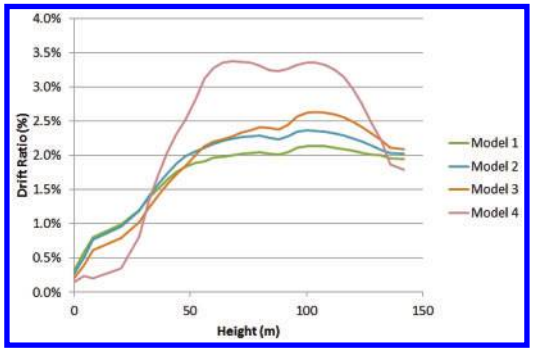

Figure 6. Maximum drift ratios throughout the building height.

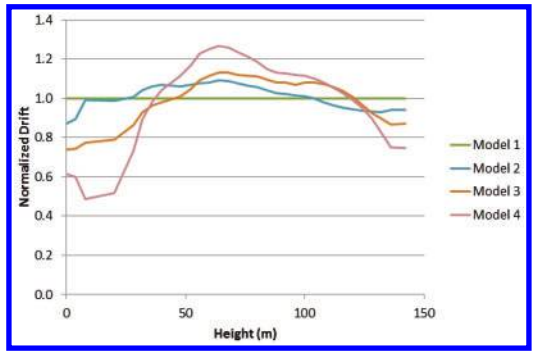

Figure 7. Normalized mean drift ratio throughout building height.

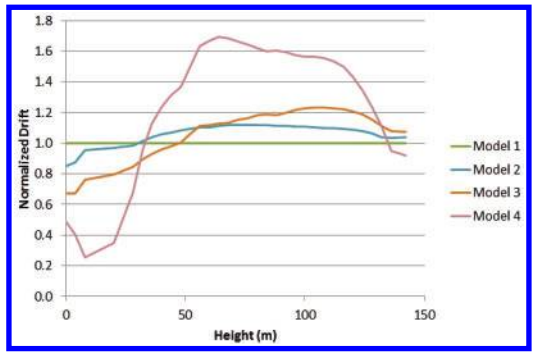

Figure 8. Normalized maximum drift ratio throughout building height.

relative insensitivity of mean drift responses for models with a wide range of strengths. However, Figure 6 shows that when looking at maximum drifts, Model 4 is clearly separated from the other models and exhibits much higher deformations. The maximum displacement here provides information on the sensitivity of the results to variations in ground motion. Given the inherent uncertainty in ground motions, it is important to be cognizant of the probability distribution of the response values, as opposed to just the mean values. Whereas the savings in design can lead to choosing Model 2 or Model 3 instead of Model 1 as the desired design, Model 4 is clearly a risky design where the building seems to have passed a threshold for stability of the results. The final design decision depends on the performance and design targets, but it is this parametric nonlinear analysis that allows for understanding of the full meaning of the design choices, and hence an optimal design to achieve the design goals. Figures 7 and 8 that show mean and maximum drift values, normalized to the values for Model 1, are important in their own right. A comparison with Figures 3 and 4 shows that varying the strength of the elements affect the distribution of drift values more than those of shear or overturning moment. The normalized shear and bending values are roughly uniform for each model, suggesting little change in distribution of these forces. On the other hand, Figures 7 and 8 show very non-uniform curves, indicating more drifts in mid-height floors, but less close to the top and base of the structure.

Overall, it can be seen that variations in strength affect distribution of forces and displacement, but not in a uniform manner. Parametric studies using nonlinear analysis allow for understanding of the design tradeoffs and informed selection of the right design for the project.

4 CONCLUSIONS

Linear analysis can only use the initial stiffness of the structure. Given a set of seismic ground motions and assumption of a reduction factor for the forces, it will provide unique required strength values for all the structural members. The designer's hands will be tied to change those design strength values. Under a strong earthquake, the actual demands on the structure could end up being quite different.

The study here illuminates how models with the same linear properties could have very different dynamic responses. Some of the conclusions from this study are:

1. Linear models cannot distinguish between models with similar initial stiffness but different strength levels. In nonlinear models, final deformations and

internal forces of the structure depend on elastic stiffness properties as well as force capacities. The designer can adjust both sets of parameters to achieve the design goals. Relying solely on linear analysis procedures limits the designer to adjusting the stiffness of the members and designing for the forces, as reduced by a reduction factors. Linear analysis method is simply incapable of providing any direction for a more optimal and efficient design. Using nonlinear analysis results gives the designer more flexibility for a proper seismic design.

2. Using nonlinear analysis to confirm the adequate seismic performance of building designed using linear procedures is beneficial. However, only a design based on the results of parametric nonlinear study of the structure has the potential to guide the designer towards the most rational and optimal design given the response parameters of interest. Nonlinear analysis expands the available design options and significantly improves reliability of the prediction of structural demands. Instead of changing stiffness and designing for the obtained forces, the designer can play with strength and stiffness values within the entire structure. The design can push forces away from elements that have undesirable response or expensive design and toward elements with more desirable response. The full interplay between different performance targets and the tradeoffs involved in terms of cost, reliability, and response of various components of the structure are not fully clear until nonlinear behavior of the structure is parametrically studied.
3. Nonlinear studies of various types of structures can provide a general understanding of the interplay between design parameters for each type of building. Such efforts are encouraged as they would provide guidance to the designer and allow for a more targeted parametric study for each individual project, incorporating the broad lessons from previous studies.

Progressive collapse prevention of drive-in steel storage racks

Siddharth Yadwad & Lip H. Teh
University of Wollongong, Wollongong, Australia

ABSTRACT: Unlike residential and commercial buildings, a more effective and rational approach to preventing progressive collapse in storage racks is to sacrifice the bay where a local failure initiates. The cost of a confined collapse of one bay is insignificant compared to the cost of a progressive collapse. This paper investigates the use of fuse connectors between the portal beams and the uprights of typical drive-in steel storage racks for preventing a local collapse in a bay from propagating to adjacent bays. Through nonlinear dynamic analysis, it identifies the topology and conditions where fuse connectors may be effective.

1 INTRODUCTION

Steel storage racks are widely used to store consumer and industrial goods. There are two primary types of steel storage racks: selective racks and drive-in racks (DIRs). DIRs are characterised by topologies that enable forklift trucks to drive into the rack structure to deposit or retrieve pallets on a 'first in, last out' basis. A layout of a typical DIR is provided in Figure 1.

DIRs are composed of upright members laced together by frame braces in the direction perpendicular to the aisle (cross-aisle direction), and by portal beams in the direction parallel to the aisle (down-aisle direction). Portal beams are installed only at the top of the uprights, and vertical down-aisle bracing (called spine bracing) is confined to either the rear of the rack in the case of a single entry DIR, or to the middle plane in the case of a double entry DIR. Sometimes the entire storage space of one bay is sacrificed for spine bracing, and the rest becomes a drive-through rack. Pallets are stored on rail beams, which are connected to the uprights in the cross-aisle direction via support brackets. The members composing DIRs are typically cold-formed, thin-walled open steel sections.

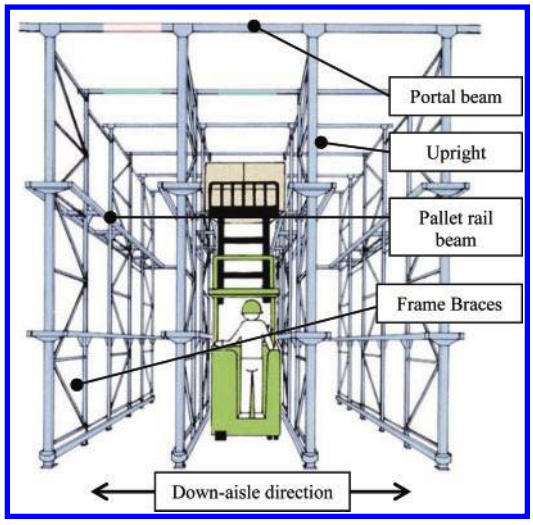

Figure 1. Diagrammatic representation of a typical steel DIR (HR Largertechnik 2010).

DIRs are particularly susceptible to collapse due to their loading process, tight design and topology. Collapses are often initiated by a localised upright failure resulting from accidental overloading or impact from forklift trucks (Gilbert & Rasmussen 2009). In some cases, the redistribution of load associated with the localised failure can produce a progressive failure mechanism, resulting in disproportionate collapse of the rack. Many such collapses have occurred worldwide, with the cost of damaged goods, repairs and lost production estimated to total more than ∈500 million in Europe alone in 2003 (Coutinho 2008).

McConnel and Kelly (1983) studied the progressive collapse of selective steel storage racks, concluding that the axial pull-out strength of the connection between the pallet beam and the upright (the "beam end" connection) largely determined whether a collapse would be progressive or confined. In cases where progressive collapse occurred, the beam end connections remained intact, and in cases where the collapse of the rack was confined, the beam end connections were found to have failed.

The tendency of a beam end connection to fail is dependent on the tensile force developed in the portal beam and the capacity of the connection in axial tension. The tension developed in the portal beam following the localised collapse of an upright was explained by McConnel & Kelly (1983) as an effect of the 'joint rotation' mechanism: a downward translation of the damaged upright that draws the adjacent uprights inwards, causing a rotation of the

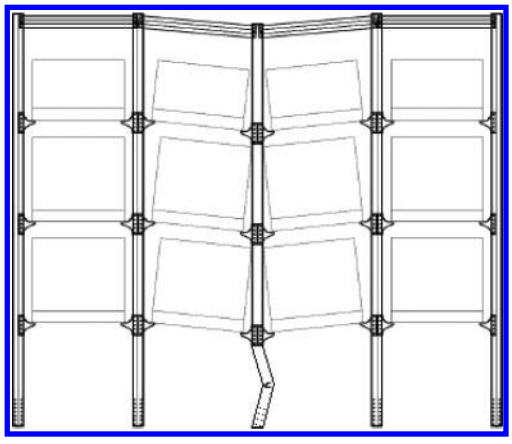

Figure 2. Joint rotation mechanism in a DIR following a localised upright failure, based on McConnel & Kelly (1983).

pallet beams. This mechanism was also noted to occur in DIRs (Gilbert 2010), an illustration of which is provided in Figure 2.

A proposed measure to prevent the occurrence of disproportionate collapse in DIR structures is the installation of fuse connectors; connections that are designed to fail under a certain tensile force or displacement. Fuse connectors would be installed between the portal beams and the uprights, acting as beam end connectors. In principle, if an upright is to fail, the tensile forces developed in the portal beams attached to it would cause failure of the fuse connectors, disengaging the portal beams from the uprights in the adjacent bays. This would inhibit progressive collapse, confining the collapse to one bay on either side of the initially damaged upright.

Of course, the failure of uprights is not the only reason tensile forces develop in the portal beams. Tension in portal beams will also develop under normal operating conditions including design loading, component misfit and ordinary accidental impacts. As such, it is important to ensure that fuse connectors do not fail under the tensile forces associated with these design actions.

This paper establishes whether fuse connectors may be feasibly applied for the prevention of progressive collapse in a DIR by comparing the smallest peak tensile forces experienced by the portal beams leading to progressive collapse against the largest tensile forces experienced by the same beams under normal operating conditions. Based on the premise of McConnel & Kelly (1983), in order for fuse connectors to be feasibly applied, the tensile forces found to occur in the DIR portal beams following the localised failure of an upright must be substantially larger than those found to occur under normal operating conditions.

2 DIR CONFIGURATIONS ANALYSED

A number of DIR configurations were analysed over the course of the present research, of which DIR3, DIR4 and DIR5 best represent the findings. These configurations vary only in their spine bracing arrangements. The upright spacing in the down-aisle direction is 1475 mm, and the vertical spacing between pallet rail beams is 1250 mm. Down-aisle views of these configurations are shown in Figure 3, Figure 4 and Figure 5.

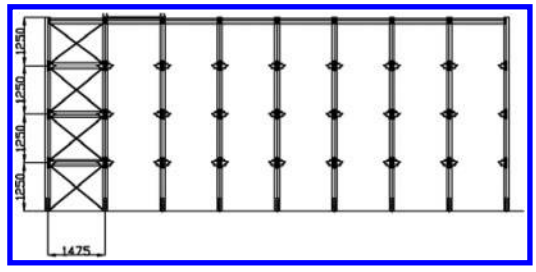

Figure 3. DIR3 – One spine bracing module *at the back* of one end bay.

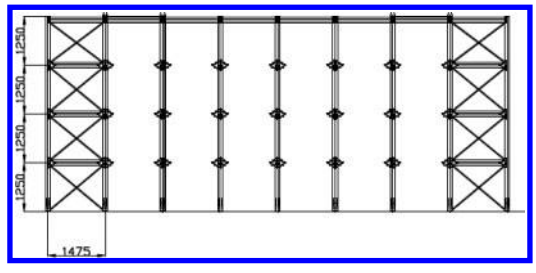

Figure 4. DIR4 – Two spine bracing modules, one *at the back* of each end bay.

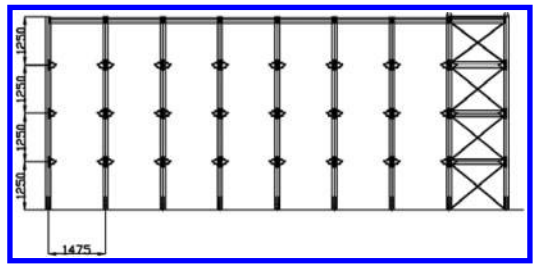

Figure 5. DIR5 – A 'Drive-Through Rack' where one entire end bay is sacrificed to accommodate bracing between every pair of uprights.

3 ANALYSIS OF DIR UNDER NORMAL OPERATING CONDITIONS

3.1 *Ordinary design loading and out-of-plumb*

Nonlinear static analysis was employed in studying the behaviour of DIRs under ordinary design loading and out-of-plumb. The provisions of the Australian Standard AS 4084-1993 (Standards Australia 1993) were used to define the magnitude of the out-of-plumb forces and the load factors for the ultimate limit state. A number of loading configurations were considered,

with the largest portal beam tensile forces found to occur in DIRs that are fully loaded.

3.2 *Ordinary accidental impact loading*

Minor accidental impacts between forklift trucks and DIR uprights are a common occurrence and are therefore considered to be a normal operating condition. Two separate methods were used to evaluate the response of DIRs following an accidental impact. The first considered a static equivalent force, with the magnitude consistent with the approach described in European Standard EN15512 (CEN 2009). The impact location used was in accordance with FEM 10.2.07 (FEM 2002), which specifies that the impact force must be applied at the location in the DIR that will produce the critical case of the action being determined; in this case the portal beam tensile force.

The second approach is a dynamic method employed by Ng et al. (2009) and refined by Gilbert (2010). Using this method, a transient impact load was applied to the DIR at various locations. For any given topology, the impact location that produced the largest portal beam tensile force was taken to be the critical case.

4 ANALYSIS OF DIRS FOLOWING A LOCALISED UPRIGHT FAILURE

4.1 *Modelling residual upright capacity*

Transient inelastic dynamic analysis was used to simulate the response of DIR structures following the localised failure of an upright. A procedure that is consistent with the progressive collapse simulation methodologies described by Marjanishvili (2004) and Marjanishvili & Agnew (2006) can be summarised as follow:

1. The axial force and bending moment at a particular location of the to-be-damaged upright are determined by performing a nonlinear static analysis under design loading conditions.
2. A portion of the damaged upright is removed from the model and replaced with the equivalent reaction forces as determined in Step 1.
3. A transient nonlinear inelastic dynamic analysis is performed in which the equivalent reaction forces are reduced over time as illustrated in Figure 6. The response of the remaining DIR structure is evaluated to determine whether any components fail as a result of this initial failure.
4. If a member is found to fail, it is deleted from the model and replaced with equivalent reaction forces that vary according to the response hysteresis recorded in Step 3 up to failure. After failure, the reaction forces are reduced to zero over a short time.
5. In the event that failure occurs in an upright outside the cross-aisle plane of the initial failure, a progressive collapse is taken to have occurred and the analysis is terminated. The peak portal beam tensile force during the analysis is recorded.

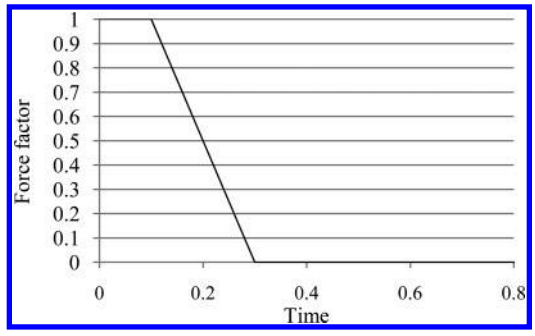

Figure 6. Reduction of initial reaction forces over time, used to model the initial local failure of an upright.

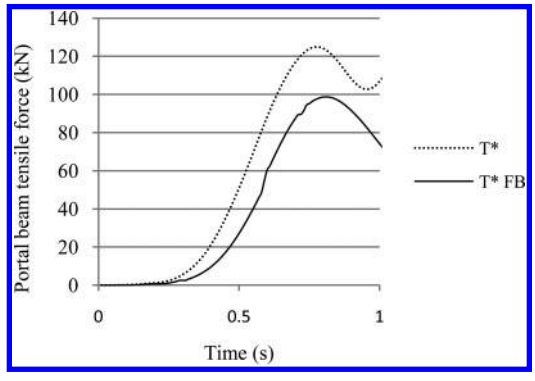

Figure 7. Response hysteresis illustrating the effect of incorporating the residual resistance of a failed upright on the portal beam tensile force.

The preceding procedure assumes that failed uprights disappear from the structure. However, in reality, they continue to provide some resistance in the upward and downward directions. The residual resistance of the failed upright is modelled in the present work using frictional contact elements that produce a force of constant magnitude in the opposite direction to the upright's displacement (either downwards or upwards). Where the residual resistance was more than 10% of the original member capacity, a significant reduction in the magnitude of the peak portal beam tensile force was noted, as shown in Figure 7.

In Figure 7, T* denotes the portal beam tensile force in a model that did not incorporate residual resistance. T^*_{FB} is the portal beam tensile force observed in a model incorporating the 'frictional damper' element with a residual resistance in both directions equal to 10% of the member capacity.

4.2 *Behaviour of DIRs following a localised upright failure*

The behaviour of a DIR following the localised failure of an upright is most conveniently explained by considering it in each of the primary directions of the structure, i.e. the cross-aisle plane and the down-aisle plane. Figure 8 shows a section of an analysed DIR

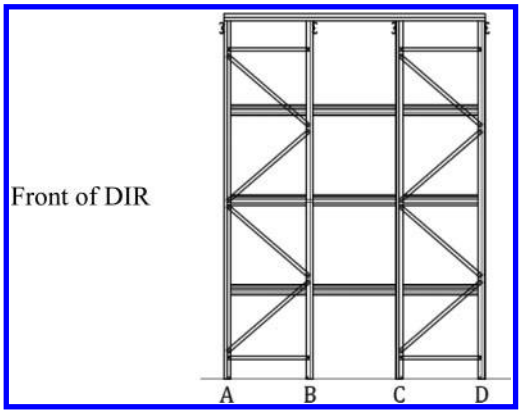

Figure 8. Elevation of a DIR in the cross-aisle plane.

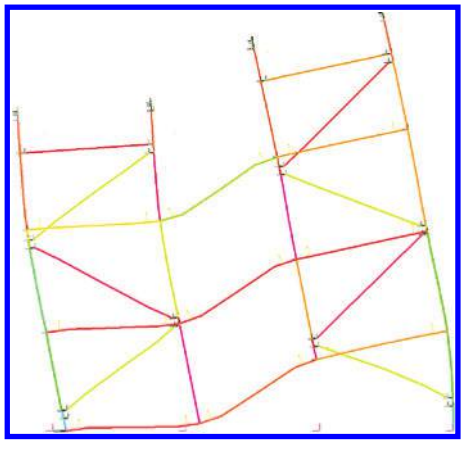

Figure 9. Load transfer to upright C, facilitated by the formation of shear and axial forces in the pallet rail beams.

in the cross-aisle plane where a localised upright failure would occur. The initially damaged upright in this case is marked 'A' with subsequent uprights labelled 'B' to 'D'.

Following the failure of upright 'A', the pallet load it previously supported in axial compression is transferred to upright 'B'. This load transfer is facilitated by the cross-aisle braces and pallet rail beams. Upright 'B' then fails due to the increased axial compression. The frame consisting of upright 'A' and 'B' then translates downward, resulting in deflection of the pallet rail beam and the formation of tensile forces in the attached portal beams.

The pallet load originally supported by uprights 'A' and 'B' distribute to the corresponding uprights in the adjacent bays and to upright 'C'. Load transfer to upright 'C' is facilitated by shear and axial forces in the pallet rail beams, as can be visualised from Figure 9.

It should be noted that the failure of an upright in the same cross-aisle plane is not considered to be a progressive collapse in the present work.

The portal beam tensile forces, in addition to producing an increase in axial compression in the adjacent

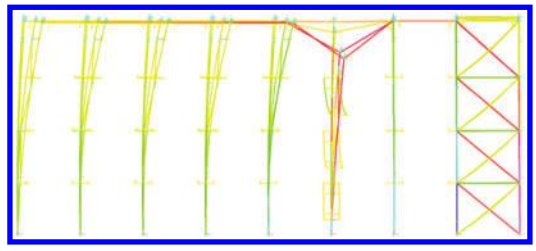

Figure 10. Load transfer to uprights in adjacent cross-aisle planes via portal beam tensile forces.

Table 1. Maximum portal beam tensile forces associated with ordinary impact and ordinary design loading/out-of-plumb.

DIR4	6.28	0.68
DIR5	4.33	0.54

uprights, also cause large bending moments. The combined actions may cause failure of the uprights, which is considered to be a progressive collapse. In some cases, upright 'C' may fail prior to the failure of the uprights in adjacent cross-aisle planes, however the load transfer mechanism remains the same.

Load transfer to the uprights in adjacent cross-aisle planes (bays) is facilitated by the formation of tensile forces in the portal beams between the uprights, as illustrated in Figure 10.

5 PORTAL BEAM TENSILE FORCES UNDER NORMAL CONDITIONS AND FOLLOWING A LOCALISED UPRIGHT FAILURE

The tensile force that develops in a portal beam is dependent on the pallet weights, the location of the portal beam and the applied loading condition. The primary concerns were to establish the portal beams in which the largest tensile forces occurred, and the variation of portal beam tensile forces within the structure under normal operating conditions and following an upright failure.

Accidental impact load cases analysed using the dynamic approach described in Section 3.2 were found to produce the largest tensile forces of all the normal operating conditions as shown in Table 1.

Therefore, the minimum strength required by a fuse connector for a given DIR may be established by analysing the structure for accidental impacts. In all cases analysed, the largest tensile forces were found to develop in the portal beams connected to the impacted upright. The largest tensile forces associated with

*No progressive collapse.

design loading and out-of-plumb, on the other hand, were found to occur in braced bays, however the magnitudes of these forces were significantly smaller than those associated with ordinary accidental impacts.

It was noted that larger peak portal beam tensile forces occurred following upright failure in DIRs with topological features that increase the down-aisle stiffness of the structure. These include spine braces in DIRs and braced bays in Drive-Through Racks (DTRs). The inclusion of these features was not found to result in larger portal beam tensile forces under normal operating conditions.

Peak portal beam tensile forces exceeding those in the ordinary impact load case were found to occur in some, but not all, of the DIR structures in which upright failure was simulated. Table 2 shows the peak portal beam tensile forces that develop following upright failures in DIR3, DIR4 and DIR5. A bracketed number means that the force is lower than the largest in the rack developed under normal operating conditions (with factored design loads).

From Table 2, it can be seen that the largest peak portal beam tensile forces are developed in DIR5, which is the drive-through rack. The peak portal beam tensile forces in DIR3 were significantly smaller and, in some cases, less than the maximum portal beam tensile forces found to occur under normal operating conditions.

The reason behind the significant difference in peak portal beam tensile forces can be explained by considering the DIR as two separate 'sub-structures' on either side of the failed upright in the down-aisle direction. In cases where the 'sub-structure' attached to the portal beam had a higher down-aisle stiffness, the peak portal beam tensile force was found to be larger. An example of this phenomenon can be observed in the case of DIR5. A failure of the upright in the centre cross-aisle plane produces a very high stiffness 'sub-structure' at the braced end, and a very low stiffness 'sub-structure' at the unbraced end. Progressive collapse analysis shows the peak tensile forces developed in the portal beams connected to the braced region to be about 25% larger than those in the portal beams connected to the unbraced region, as shown in Figure 11 for post progressive collapse responses.

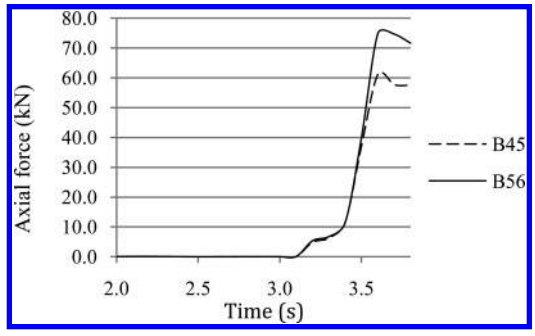

Figure 11. Comparison of tensile forces post progressive collapse – portal beams connected to high (B56) versus low (B45) stiffness 'sub-structures'.

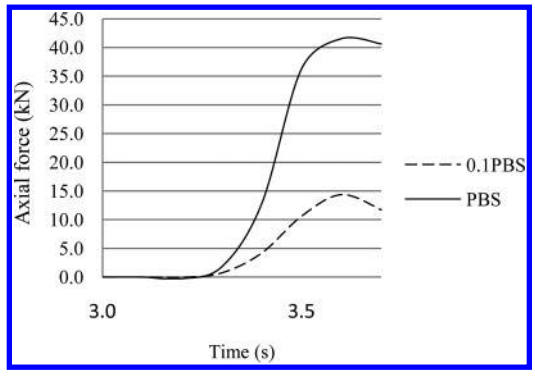

Figure 12. Effect of fuse connector stiffness on portal beam tensile force following upright failure.

6 ANALYSIS OF DIRS INCORPORATING FUSE CONNECTORS

To incorporate fuse connectors into models of DIR structures, 25-mm long 'fuse' elements were inserted at each portal beam end connection. The structural properties of the fuse elements were taken to be the same as the portal beams, however, if a specified tensile force was exceeded, the element would disappear from the model. For each DIR, the fuse strength was taken to be 110% of the largest portal beam tensile force developed under the normal operating conditions (factored loads).

The axial stiffness of the fuse connectors has an effect on the tensile forces developed in the portal beams following a localised upright failure. As the stiffness was decreased, the peak portal beam tensile force decreased. This phenomenon is illustrated in Figure 12, where the axial stiffness of the fuse connector is expressed as a ratio of the axial stiffness of the portal beam, PBS. For this purpose, fuse behaviour was disabled to allow post progressive collapse analysis.

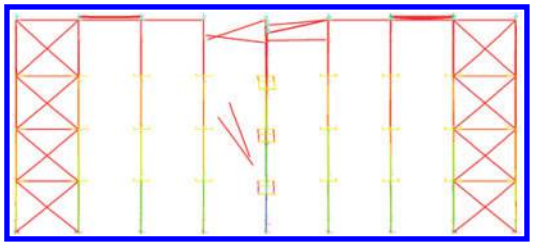

Figure 13. Confined collapse following failure of an upright in a model of DIR4 incorporating fuse connectors.

In the present analyses, where the fuse connector axial stiffness was equal to the axial stiffness of the portal beam, the portal beam tensile forces measured were the same as those in the DIR model that did not include fuse connectors.

In cases where the portal beam tensile force incurred by an upright failure exceeded the fuse connector strength, the fuse connector disengaged the portal beam from the upright, confining the collapse. An example of a confined collapse due to the incorporation of fuse connectors into DIR4 is provided in Figure 13.

7 CONCLUSIONS

The application of fuse connectors, based on the premise of McConnel & Kelly (1983), to prevent progressive collapse in DIRs is feasible under certain conditions only. DIR topologies can be designed so as to increase the magnitude of the peak portal beam tensile forces which develop following an upright failure, relative to those which develop under normal operating conditions.

The most effective arrangement would be to sacrifice both end bays entirely for the installation of spine braces between every pair of uprights.

Accidental fork-lift truck impact was found to be the normal operating condition in which the largest portal beam tensile forces tend to occur, and as such may be used for specifying the minimum strength that a fuse connector must have.

For a DIR with a low down-aisle sway stiffness, which may be unavoidable in practice, a different type of fuse connector is required as described during the conference's oral presentation.

V.V. Toropov
School of Civil Engineering, University of Leeds, UK

ABSTRACT: Sudden removal of column has been the basis for progressive collapse assessment in existing literatures, codes and design guidelines around the world. This provision is based on the fact that a structure should be capable of bridging over a loss column in case of any eventuality probably due to any unforeseen event like impact, blast, or explosions. The response of the structure for progressive collapse assessment depends on how 'sudden' a column is lost. The time lapse at which a column is removed significantly affects the stress redistribution within the structural system and the joint displacement response. This paper investigates the response of moment resisting frame structure to varying time of column loss. Selective time points ranging from 0.001 to 0.5 was used for this investigation and it was observed that the rate of column removal affects the structural response. It is observed that structural stability begins at 0.2 seconds, beyond this time up to 0.5 seconds, the dynamic effect diminishes to static response.

1 INTRODUCTION

Progressive collapse is characterised by chain transmission of localised failure initiated by damage of critical structural members. This could result to partial or total collapse of the structure depending on the magnitude of the abnormal load relative to the ultimate carrying capacity of the structure. Damage of single or multiple load bearing members (Columns, walls etc.) could trigger complex redistribution of stresses within the structural system which may exceed the magnitude initially assumed at the conceptual design stage. [1] Impact, blast, extreme fire or explosions on a structural system could trigger progressive collapse. In view of this, the structure seeks a new equilibrium state which involves a complex transmission of stresses via the joints to other connecting structural members. This process takes place within a fraction of a second and this may results to partial or total collapse of the structure.

Research interest in progressive collapse has been attributed to the disproportionate collapse of Ronan Point Building in the United Kingdom. [2,3] This event as reported by some researchers [4,5] was triggered by domestic gas explosion at the 18th floor of a 22 storey building apartment in 1968 in London. The collapse of this building is referred to disproportionate collapse when the magnitude of collapse is compared to the triggering event. [5] Other highly publicised collapses are: Alfred Murrah Building in 1995 and the world trade centre in 2001 due to terrorist activities. These landmark events stimulated research in progressive collapse assessment particularly in the United States which resulted in the development of current design guidelines used around the world. [6,7] Application of these guidelines, merits and demerits has been reviewed by some researchers in existing literature. [8, 9]

Different modelling techniques are adopted in existing literature for progressive collapse investigation. These affects the results and conclusion. [10]–[12] However, each modelling technique depends on the column removal time. The time lapse at which a column is removed for assessment defines how 'sudden' the structure responds to the dynamic effects of the triggering event. This paper is aimed at evaluating the effect of time lapse of column removal on structural responses using moment resisting frame structure. The Internal forces in the beams and columns, and the joint displacements were investigated to study the extent to which these design variables are affected by sudden column loss. SAP 2000 finite element code was used for these investigations. [13]

2 OBJECTIVES

The objectives of this investigation is outlined below; the time points used ranges from 0 to 0.5 seconds

- To determine the effect of column removal time on beam responses during progressive collapse
- To determine the effect of column removal time on the adjacent columns
- To determine the joint displacement response due to different rates of column removal time.

3 DESCRIPTION OF MODEL

Figure 1 and Figure 2 represents the elevation and plan view of the model used for this investigation. It is a 10 storey moment resisting frame structure having a span of 6m along the y-axis and a span of 4.5 m along the x-axis. An assume 3.5 m floor to floor height was used in building the model. Section size of 305 × 305 × 198UC was used from the ground floor to the fourth floor, 254 × 254 × 167UC from the fifth to seventh floor and 203 × 203 × 60UC from the eight floors to the roof. The foundation base is assumed to be fixed. The beam section along the y-axis was 406 × 140 × 39UB while along the x-axis was 305 × 127 × 37UB.

A slab thickness of 130 mm was assumed for this investigation while the unit weight of concrete is 23.6 kN/m^3. The perimeter wall loading of 15 kN/m was applied on the external frame excluding the roof structural elements. The slab span one-way in x-direction and the tie beams are assumed not been effective in resisting gravity load. The plan view of the model shown in figure two indicates the relative column positions before column removal.

The dynamic loading condition is based on the provision of GSA 2003 as shown in equation (1) and (2). A factor of 2.0 as shown in equation (1) accounts for the dynamic effects which is an amplification factor recommended in GSA 2003 design guideline and the acceptance criteria is based on the demand capacity ratio as defined in equation (3) for static analysis.

For static analysis procedure:

$$N = 2 \times (DL + 0.25LL) \quad (1)$$

For dynamic analysis procedures:

$$N = DL + 0.25LL \quad (2)$$

where N is the loading, DL is the dead load and LL is the live load.

$$DCR = AF/CE \quad (3)$$

AF is the acting or applied stress resultants on a member or connection which could either be moment, axial force or shear. CE is the ultimate un-factored capacity of the member or connection which could be moment, axial force and shear for assessment.

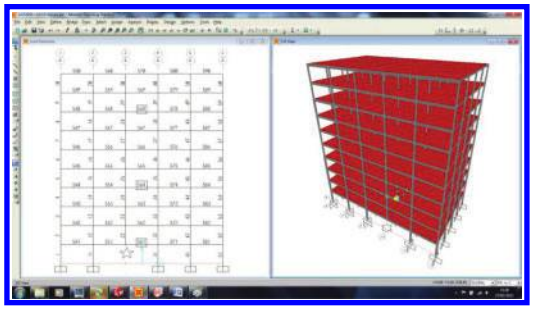

Figure 1. 3D model used for a case study.

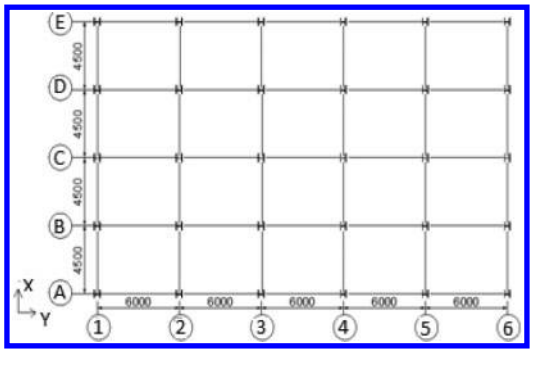

Figure 2. Plan view of the model.

4 ANALYSIS PROCEDURE

The column internal forces and the gravity loading are defined by the time history function path of PVM and N respectively as shown in figure 3. The stability period is represented with S_t, while the column removal time is represented by R_t. Column removal time points ranging from $0.001 \leq R_t \leq 0.5$ s was used for this investigation. The stability period (S_t) is assumed to be 3 seconds and this was used throughout the analysis while varying the column removal time (R_t). The GSA loading condition defined by equation (2) was used for this study. To model sudden column removal, the removed column is replaced by the internal forces; that is the axial force (P), shear force (V)

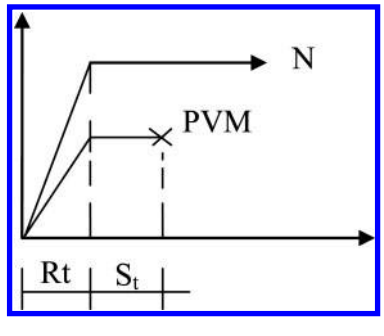

Figure 3. Loading history function.

and moment (M). The internal forces and the gravity loading are assumed to stabilise after three seconds when it gets to the maximum values.

5 ANALYSIS CASES

Three analysis cases were investigated and each case is described briefly below.

5.1 *Description of case one – Beam responses*

The perimeter column (Col 21) located on grid A-3 as shown on the elevation and plan view of Figure 1 and 2 was removed suddenly at varying time. The response of first floor beam (BM 561), the fourth floor beam (BM 564) and the eight floor (BM 568) as shown on the elevation of figure 1 were studied at each column removal time. Internal forces in the beams: Shear (V), moment (M) and axial forces (P) that determines the equilibrium state were studied when the column was removed suddenly at varying time. The results are presented in figure 4 to 6.

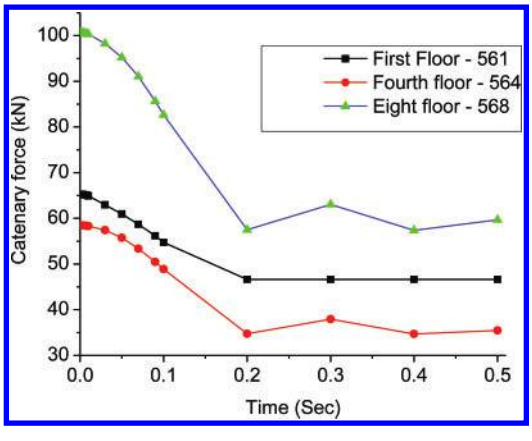

Figure 4. Maximum catenary force vs time.

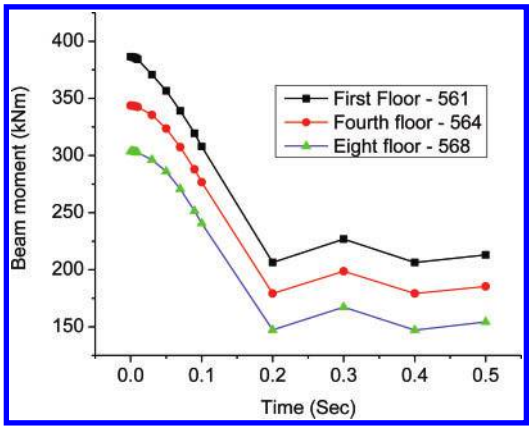

Figure 5. Maximum moment vs time.

5.2 *Description of case two – Column responses*

Four adjacent columns at different positions were investigated due to sudden column removal. The corner column located on grid A1 was removed to investigate the behavior of adjacent columns: Column on grid B1 (Col B1) and grid A2. (Col A2). The edge column located on grid A3 was removed suddenly and the behavior of the column on grid A4 (Col A4) was studied. Similarly, the interior column located on grid C4 was removed while the response of the column at grid 5C (Col 5C) was studied. The maximum internal forces (PVM) due to the varying time lapse for all the cases were compared as shown in Figure 7 to Figure 9.

5.3 *Description of case three – joint responses*

These investigations were carried to investigate how sudden column removal time affects joint behavior using displacement response. The corner column located on grid A-1 was removed based on time points between $0.001 \leq R_t \leq 0.5$ s and the maximum displacement was recorded. Similar procedure was

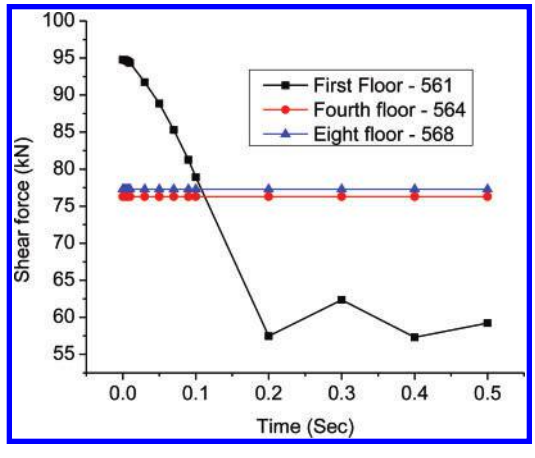

Figure 6. Maximum shear force vs time.

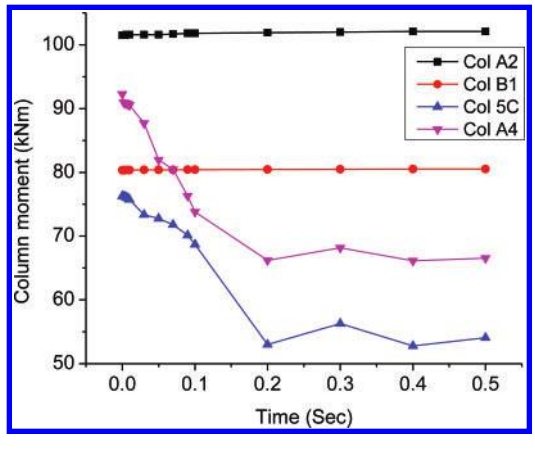

Figure 7. Maximum moment vs time.

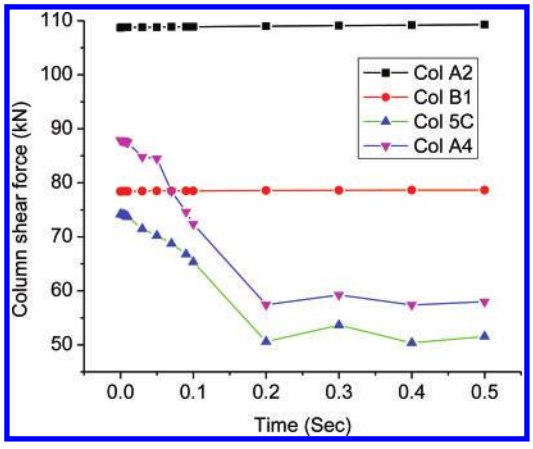

Figure 8. Maximum column shear force vs time.

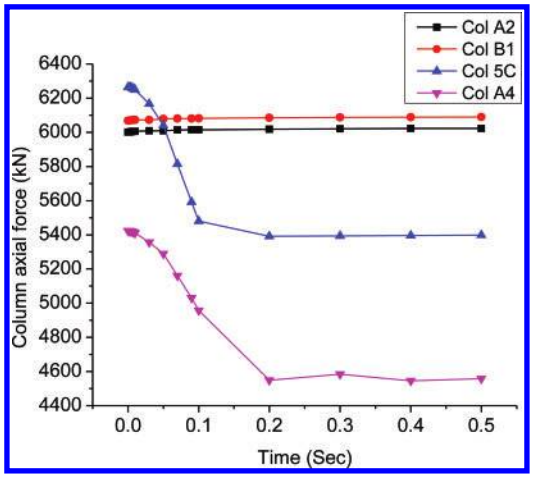

Figure 9. Maximum axial force vs time.

repeated by removing column located on grid A-3, and the interior column located at grid 4-C as shown on the layout of the building of figure 2. The maximum displacement at these joints at varying column removal time was recorded. The relative response of the joints due to varying column removal time is shown in figure 10.

6 DISCUSSION OF RESULTS

6.1 *Beam responses – Catenary action*

Axial responses of the beams at the first floor (Beam 561), fourth floor (Beam 564) and the eight floor (Beam 568) are shown in figure 4 to 6 below. Comparing the results, varying the time at which a column is removed significantly affect the beam behavior particularly at the first floor as shown through Figure 4 to 6. Most importantly, it is observed that significant changes in the axial forces occurred within the range $0.001 \leq R_t \leq 0.1$ seconds.

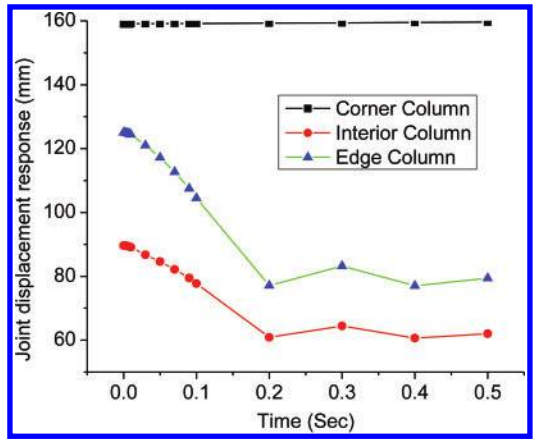

Figure 10. Maximum joint displacement vs time.

For the range $0.1 \leq R_t \leq 0.2$ s, sudden drop in response occurs in the axial force (P), Shear force (V) and the Moment (M). The structure begins to stabilize to static response beyond 0.2 seconds. Relative responses of the beams considered indicates that the catenary response at the eight floor is more critical with a maximum value of 101 kN followed by the first floor (65 kN) and the fourth floor having a value of 58 kN.

6.2 *Beam responses – Moment*

It is observed as in figure 5 that changes in column removal time significantly affect the moment responses of beam elements. Comparing the moment responses of Beam 561, Beam 564 and Beam 568, as shown in figure 5 below, it is observed that at 0.2 seconds, the moment in the beams begins to stabilize at the same pattern to a stable equilibrium state. A turning point from dynamic to static response begins at 0.2 seconds. The maximum beam moment at the first floor is 386 kNm, at the fourth floor is 342 kNm and at the eight floor is 303 kNm.

From 0.001 to a maximum of 0.1, the moment changes gradually at the time points considered, from 0.1 to 0.2, the changes are more significant. Maximum moment in beams increases in the order Beam 561, Beam 564 and Beam 568. Despite the fact that the load applied on the beams is the same, it is evident from Figure 5 that beam location significantly determines the response of the beam element to sudden column removal time and the critical beam for moment response occurs at the first floor.

6.3 *Beam responses – Shear force*

The shear force response in the beams at the first floor (Beam 561) fourth floor (Beam 564) and the eight floors (Beam 568) are shown in figure six. Comparing the beam response, the maximum shear force for the beams considered increases in the order Beam

568, Beam 564 and Beam 561 exhibiting the maximum response to sudden column loss time lapse. It is observed that Beam 561 and Beam 568 are not significantly affected by sudden column loss despite changes in column removal time from 0.001 to 0.5seconds. However, this is not the case for the first floor beam (Beam 561).

It is observed that structural stability begins at 0.2seconds, beyond this time, the dynamic response diminishes to static response. The maximum shear force at the first floor, fourth and eighth floor are: 94.9 kN, 76.3 kN and 77.3 respectively. The critical response for shear force occurs at the first floor.

6.4 *Column responses – Moment*

The maximum moment response at the adjacent columns (Col A2, Col B1) due to varying time of corner column removal, response of adjacent column (Col 5C) due to removal of interior column and the response of adjacent column (Col A4) due to perimeter column removal are shown in Figure 7. It is observed that the removal of the corner does not affect the response of the adjacent column significant. The adjacent column due to the removal of the perimeter column is more critical relative to that due to removal of corner and interior column. However, it is important to note that the response significantly depends on the mode of load distribution adopted for the model.

6.5 *Column responses – shear forces*

The time at which a column is removed suddenly does not affect the maximum shear force response of Col A2 and Col B1 significantly. However, sudden removal of column significantly affect the response of the interior and perimeter column as shown in figure 8.

From 0.001 to 0.1 seconds, gradual decrease in the maximum shear force occurs as column removal time was increased. From 0.1 to 0.2 intervals, shear force decrease linearly. From 0.2 seconds to 0.5 seconds, the dynamic effect of column removal time on the maximum shear force begins to diminishes to static response.

6.6 *Column response – Axial force*

Figure 9 shows the axial structural response of interior column (Col 5C), edge column (Col 4A) and adjacent columns (Col A1, Col B1) to varying time lapse. From 0.001 to 0.1 seconds, there is a gradual decrease in the axial force due to varying time lapse of adjacent column removal as shown in Figure 9.

The dynamic response is significant between $0.001 \leq R_t \leq 0.1$ s, and a sudden drop between $0.1 \leq R_t \leq 0.2$ s. The structure seeks stability to a static equilibrium state from $0.2 \leq R_t \leq 0.5$ s within the range considered. Beyond 0.2 seconds, a stability begins within the columns with minimal variation in response to axial force.

6.7 *Joint responses due to varying time of column loss*

Joint displacement responses due to the removal of corner column, perimeter column and interior column at varying time are shown in figure 10. The maximum joint displacement path is similar. From 0.1 to 0.2 seconds, an approximate linear response is observed in the displacement response for all the three joints. Although, below 0.1, the behavior is slightly parabolic with the maximum displacement of 160 mm. Joint sensitivity to varying column removal time occurs at the edge column removal point relative to the joint at the corner and interior column removal position. Beyond 0.2seconds, the structure seeks stability to a static response and varying column time does not have significant effect on the joint response.

7 ANALYSIS SUMMARY

Time lapse at which structural members are removed for progressive collapse assessment affect member response and the entire structural system. However, the response depends on the position of the structural member been considered and the direction of load distribution either one way or two way. Generally, considering the range $0.001 \leq R_t \leq 0.5$ s used for this investigation, it was observed that $0.2 < R_t \leq 0.5$ s does not accurately capture the dynamic response due to sudden column loss. it is observed that significant dynamic response occurs when the column removal time ranges from $0.001 \leq R_t < 0.1$

Furthermore it was observed that within the range of $0.2 < R_t \leq 0.5$ s the internal forces stabilize to a static equilibrium state such that the dynamic influence of sudden column removal does not affect the response of the structural system significantly. Beyond 0.2 seconds, the internal forces are unaffected by the time lapse at which a column is removed.

In conclusion, how sudden a column is removed affects the response of the structure and the internal forces that determine the equilibrium state under progressive collapse scenario. To account for the dynamic effect effectively, column removal time range of $0.001 \leq R_t < 0.1$ s is recommended. Further investigation is recommended to assess the exact time point that relates to the dynamic amplification factor of 2.0 recommended in GSA 2003 design guidelines. The behavior of structural elements under progressive collapse scenario depends on the location of the member within the structural system. Critical joint response occurs at the top of the removed corner column while the least response occurs at the interior joint.

Rotational capacity of concrete slabs and its influence on tensile membrane action in the framework of robustness analysis

D. Gouverneur, R. Caspeele & L. Taerwe
Ghent University, Department of Structural Engineering, Ghent, Belgium

ABSTRACT: Robustness of structures primary received significant attention 40 years ago following the famous collapse of the apartment building in Ronan Point (UK), and recent terrorist attacks at several locations were an unfortunate reminder of the potential fatal risks in case of initiation of progressive collapse. In order to investigate the strength reserve in concrete slabs subjected to large deformations, an experimental large-scale test series was established involving the testing of continuous, longitudinally restrained, reinforced concrete slab strips exposed to a simulated accidental failure of the central support and subsequent vertical loading until collapse. In case a support of such a statically indeterminate concrete specimen is removed, tensile membrane forces can be activated at large deflections. This effect was found to increase the load-carrying capacity considerably compared to predictions obtained from small deformation theories neglecting membrane forces. Further, the collapse of the specimens was ultimately induced by the tensile failure of the reinforcement bars in the cracked regions over the supports while being exposed to a plastic rotation. It is well established that such nonlinear effects are important to recognize as the development of plastic hinges influences the capacity of the structure to absorb energy and withstand extreme loads. The rotation of the sections over the supports created the necessary deformations to allow for the effect of catenary behaviour. As such, an appropriate modelling of the rotational capacity is of crucial importance when performing a failure analysis of concrete slabs subjected to tensile membrane action. The details of the test set-up are explained and some experimental data (among which those related to rotation angles) are discussed here. Finally, the results will be evaluated with numerical FEM analyses and the influence of the rotational capacity of the specimen on tensile membrane action will be assessed.

1 INTRODUCTION

Interest in the robustness of concrete structures emerged simultaneously to the partial collapse of the apartment building at Ronan Point (UK) in 1968 (Yi et al. (2008)). Due to this dramatic accident, extensive research associated with the progressive collapse of structures has been established. In addition, the bombing attacks on American buildings at several locations and the terrorist attacks on the World Trade Center in New York and the Pentagon in Washington in 2001 triggered a renewed interest in this research topic.

It has long been recognized that the development of membrane action can considerably increase the load-displacement response of concrete structures (Westergaard & Slater (1921) and Ockleston (1955)). Figure 1 illustrates a typical load – deflection curve taken from Park (1964).

Considering a rectangular slab panel with perfect edge restraints against lateral displacement, it was observed that compressive membrane action is induced due to restraining the outward movement along the slab edges in the early part of the loading phase. This may offer a much higher flexural load than the maximum load predicted by Johansen's Yield Line Theory (1962). After the maximum flexural load has been reached in point B, the load-displacement graph shows a rapid decrease of the supported load with increasing deflection as a result of the reduction of compressive membrane forces. Further, near point C, membrane forces being in the central part of the slab reach the stage where they change from compression to tension. The slab boundary restraints start to resist inward movement of the edges. Accordingly, cracks extend over the full thickness of the slab and the yielding of steel reinforcement is established due

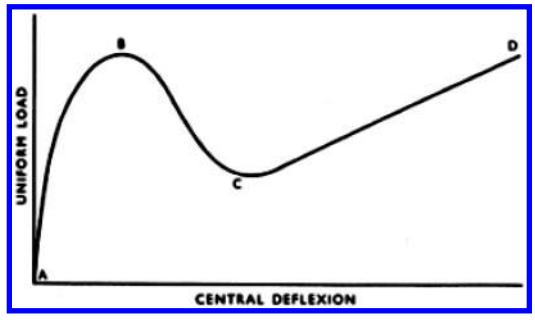

Figure 1. Load-deflection curve of a slab with full edge restraint according to Park (1964).

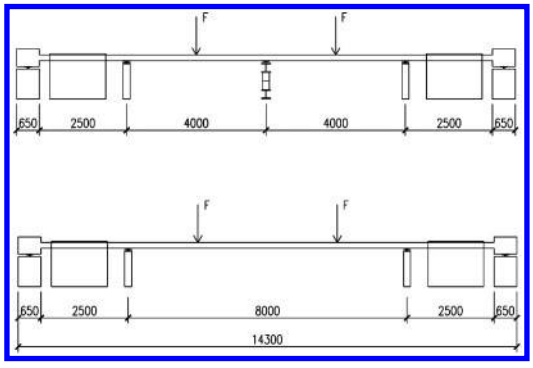

Figure 2. Loading scheme before (top) and after (bottom) removal of the central support.

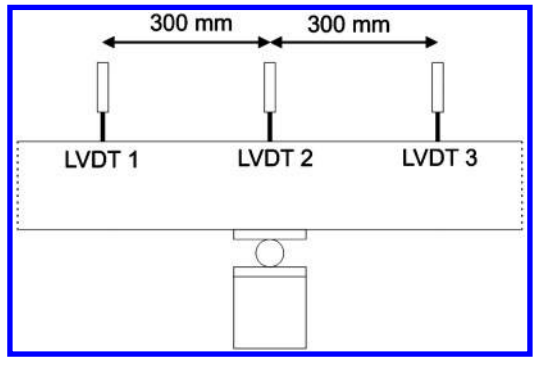

Figure 3. Detail for measurement of rotation angles.

to the elongation of the slab surface. It is observed that beyond point C the reinforcement acts as a tensile membrane that enables carrying the load under increasing deflections. The carried load increases for a second time until the reinforcement finally starts to fracture at point D. Already in 1964, Park stated that knowledge of the region CD in Figure 1 is of importance, since a snap through will occur in point B unless the tensile membrane strength of the reinforcement is high enough to absorb the load.

The main interest of research in the past decades has been in compressive membrane action. However, a few attempts towards tensile membrane action are reported in literature such as Brotchie & Holley (1971), Regan (1975) and Guice et al. (1989). Guice et al. (1989) state that the behaviour of reinforced concrete slabs is not entirely understood, in particular when large deflections occur. Researchers involved in case studies of failures in reinforced concrete slabs noted that an improved theoretical knowledge is necessary to characterise the behaviour of slabs under excessive loading.

2 EXPERIMENTAL INVESTIGATION

2.1 *Test set-up*

In order to investigate the tensile membrane action under accidental events in more detail, an experimental test set-up has been developed as illustrated in Figure 2. The configuration basically consisted of a 160 mm thick and 1800 mm wide reinforced concrete slab strip. The total length of the specimen was 14.30 m with the distance between the inner supports and the central support being 4 m, changing to one span of 8 m at the removal of the support (simulating an accidental situation).

A detailed description of the test set-up for a first experimental large-scale test is available in Gouverneur et al. (2013). This slab specimen was exposed to an artificial failure of the central support and subsequent vertical loading until collapse. However, the slab was reinforced with continuous longitudinal reinforcement bars. Further, a second reinforced concrete slab strip differing only in the reinforcement arrangement based on a more realistic situation of reinforcement curtailment according to the Eurocode EN 1992-1-1 (2004) was tested.

Besides, the rotation angles for this second test were measured by use of displacement transducers (LVDTs) at both inner supports as illustrated schematically in Figure 3.

3 NUMERICAL MODELLING

3.1 *General*

Creating a finite element model to study the large deformation behaviour of reinforced concrete structures implicates a lot of care in the definition of material models, mesh definition and boundary conditions. In the present study, an advanced finite element software (TNO Diana) was used to perform the analysis.

3.2 *Geometry and meshing*

As a result of the symmetry of the specimen regarding its geometry and loading, only half of the specimen was modelled. The geometrical nonlinearity was taken into account by a total Lagrange approach. Eight-node quadrilateral isoparametric plane stress elements (CQ16M) based on quadratic interpolation and Gauss integration were used to model the concrete elements. For the reinforcement, one dimensional fully embedded bar reinforcement (truss elements) were applied with perfect bond between the reinforcement and the neighboring concrete elements. Strains for the reinforcement are calculated based on the surrounding concrete elements.

3.3 *Loading and boundary conditions*

The loading procedure was applied in accordance with the laboratory tests by making use of a phased analysis. Initially, self-weight as well as the service load were applied. The obtained stresses and strains were transmitted to the next phase within which the elements

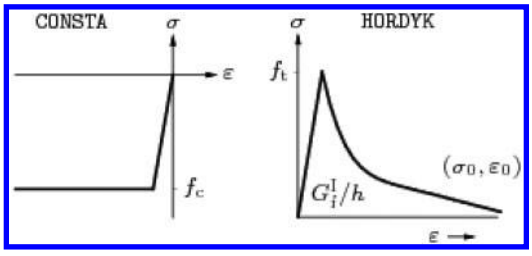

Figure 4. Material stress-strain behaviour: Concrete in compression (left), Concrete in tension (right).

of the central support were deactivated in order to simulate the removal of the central support. Further, self-weight as well as a displacement controlled load until the rupture of the reinforcement bars over the supports were applied. Interface as well as spring elements (with values based on the obtained measurement data) provided the vertical boundary conditions at the slab's ends.

3.4 *Material models*

The concrete compressive behaviour was implemented as a bi-linear stress-strain relationship as illustrated in Figure 4 (left). A Hordijk tension softening model and a total strain fixed crack model was adopted for concrete in tension (see Fig. 4 (right)).

For reinforcing steel, a multi-linear stress-strain relationship in accordance with laboratory testing on reference specimens was applied with a mean value of the ultimate strain $\varepsilon_u = 8.5\%$. Further, the strain hardening hypothesis together with the Von Mises plastic criterion was used.

4 RESULTS

4.1 *Validation of the model*

Figure 5 illustrates the load-displacement curves of slab 1 (continuous reinforcement) and slab 2 (curtailed reinforcement) measured during the laboratory testing in comparison with the numerical simulations.

Both the laboratory tests and numerical simulations showed that the development of tensile membrane actions can indeed significantly increase the load-carrying capacity of a slab strip in accidental situations when very large displacements occur (branch 1-2 of curve in Fig. 5). FE modelling is able to predict this increase in the load-carrying capacity due to tensile membrane forces. The load-displacement curves until the rupture of the top reinforcement bars over the inner supports (Point 2, Fig. 5) were calculated within a reasonable tolerance and showed good agreement with the laboratory tests.

4.2 *Influence of steel ductility (slab 1)*

The plastic deformation capacity of reinforced concrete structures depends mainly on the ductility of the

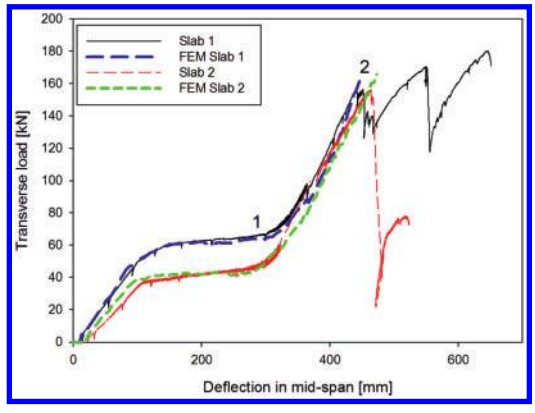

Figure 5. Load-displacement curves of slab 1 and slab 2 in comparison with numerical analyses.

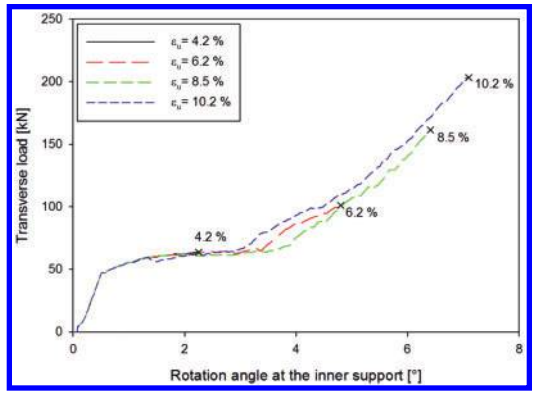

Figure 6. Load-rotation angle relationship for slab 1: influence of the ultimate strain of the reinforcing bars.

steel reinforcement. If linear elasticity is considered in the design of an element, there exists also a linear relationship between the curvature and bending moment in each section. However, in reality only the first part of the loading range can be considered to be linear. In case the yielding moment is exceeded, large cracks form and the moment-curvature relationship becomes non-linear. After yielding of the reinforcement bars, the deflections increase rapidly until either the concrete crushes or the steel ruptures. The influence of the ultimate strain of the reinforcement steel on the rotation capacity is investigated in this section. Figure 6 illustrates a parametric study of the rotation angles over the inner supports for slab 1. The stress-strain relationship of the reinforcement was modeled in accordance with tensile tests on the reinforcement bars differing only in the ultimate strain (4.2%, 6.2%, 8.5% and 10.2%) at an ultimate tensile strength of 605 MPa.

It was observed that the ultimate rotation capacity and the point of rupture of the reinforcement bars are highly influenced by the ultimate strain capacity of the reinforcement. The results of the parameter study are summarized in Table 1.

Table 1. Influence of the ultimate reinforcement strain on the rotation angle and ultimate load.

Ultimate reinforcement strain ε_u	Ultimate load F_u	Ultimate rotation angle θ_u
4.2%	63 kN	2.25°
6.2%	101 kN	4.80°
8.5%	162 kN	6.41°
10.2%	203 kN	7.10°

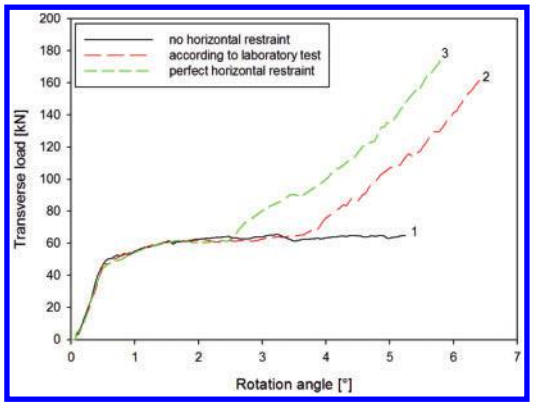

Figure 7. Influence of horizontal restraint conditions (slab 1).

4.3 *Influence of horizontal supports (slab 1)*

The influence of the horizontal restraint conditions for slab 1 is provided in Figure 7.

In total three cases of horizontal restraint were analyzed: (1) no horizontal restraint, (2) horizontal restraint according to laboratory testing taking the actual horizontal movement of the restraining concrete blocks into account as a load-dependent spring constant, (3) perfectly restrained edge beams against inward movement.

It was found that in case no horizontal restraint was present (Curve (1), Fig. 7) no increase in the load-rotation capacity could be obtained. As a consequence of the absent horizontal restraint, the reinforcement yields under the applied load without any increase in load until the reinforcement starts to rupture.

Further, Figure 7 illustrates that an increase in the horizontal stiffness caused the displacements associated with the perfect horizontal support (Curve 3) to be smaller compared to the case of the laboratory test at the same load level. Thus, the horizontal spring constant plays an important role when assessing the influence of tensile membrane action on the overall structural response.

4.4 *Influence of curtailment*

Figure 8 illustrates the load-rotation curve for slab 2 (curtailed reinforcement). Note that for this test also experimental results for the rotation capacity were

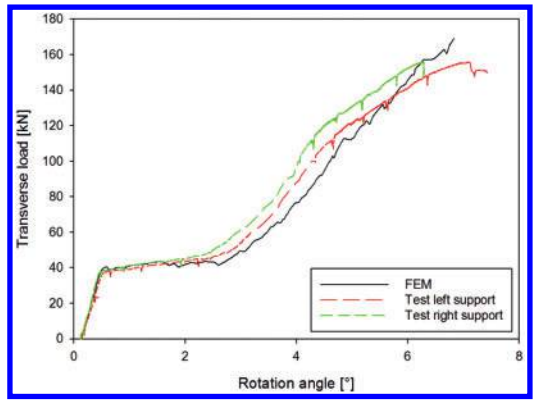

Figure 8. Numerical and experimental results for the load-rotation angle relationship for slab 2.

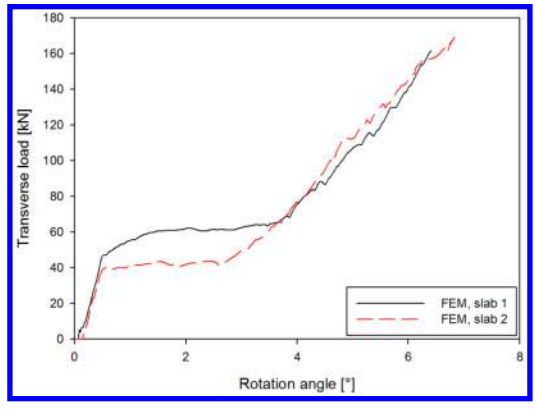

Figure 9. Numerical results for the load-rotation angle relationship of slabs 1 and 2.

available (see Fig. 3 for the measurement arrangement).

It was found that for this particular reinforcement arrangement the FE model shows still to be consistent and the results demonstrate a good agreement with the experiments. For the laboratory test an ultimate plastic rotation of 6.30° (right support) and 7.07° (left support) is obtained at a load of 155 kN (maximum load prior to the rupture of the top reinforcement bars). These values correspond to the numerically calculated ultimate plastic rotation of 6.83° at 169 kN.

In addition, a comparison of the numerical results of both slabs is provided in Figure 9.

It was observed that the predicted ultimate load as well as the ultimate plastic rotation for slabs 1 and 2 were approximately equal.

The results of the ultimate load and rotation angle obtained from the experimental investigation as well as the numerical results for slab 1 and 2 are provided in Table 2.

Hence, it can be concluded that the influence of curtailment on the ultimate rotation angle θ_u is rather limited.

Table 2. Influence of the reinforcement curtailment on the rotation angle.

Ultimate reinforcement strain ε_u	Ultimate load F_u	Ultimate rotation angle θ_u
Test left support, slab 2	155 kN	7.07°
Test right support, slab 2	155 kN	6.30°
FEM slab 2	169 kN	6.83°
FEM slab 1	162 kN	6.41°

5 CONCLUSION

The paper presents a novel real-scale test set-up. Some experimental results as well as a numerical verification are provided. It has been demonstrated that the development of tensile membrane actions can indeed significantly favour the load-carrying capacity in accidental situations of a slab strip when very large displacements occur. On the basis of the realized experimental investigations, it can be concluded that for this particular test arrangement, a loss of the central support did not cause the specimens to fail under gravity load. Note that slab 2 was not explicitly designed for this accidental event as the moment in mid-span changes sign as soon as the central support artificially fails. The central bottom region of the specimen, that was originally designed to be in compression, changes to tension which implies a severe alteration of the structural system as only 50% of the flexural reinforcement was provided due to the applied curtailment rules in case of slab 2.

Based on the realized numerical analysis it can be concluded that FE modelling is able to predict the increase in the load-carrying capacity due to tensile membrane forces as well as the development of the rotation angles over the inner supports. The load-rotation curve until the rupture of the reinforcement bars as well as the ultimate transverse load was simulated within a reasonable tolerance. Further, the influence of the ultimate reinforcement strain, the horizontal support conditions and the reinforcement curtailment was investigated. It was shown that the ductility of the reinforcement bars is of crucial importance with respect to rotational angles and ultimate load.

The development of the load-rotation relationship was similar for slabs 1 and 2 and the ultimate load capacity as well as the ultimate rotational angles were almost the same for both slabs and as such the effect of curtailment was found negligible with respect to the strength just prior to the rupture of the top reinforcement bars over the supports.

The impact of fire scenario to the collapse of a tall structure

S. Selamet
Bogazici University, Istanbul, Turkey

ABSTRACT: The aim of this study is to investigate the effect of the fire load to a tall structure and draw conclusions for a more robust structural design. If a building is not properly designed and constructed to withstand potentially catastrophic events due to risk factors posed by fires, such disasters can nullify the benefits gained from green construction. Leadership in Energy and Environmental Design (LEED) developed by the U.S. Green Building Council and other international certification organizations. One common aspect of most of these certification systems is a lack of consideration for the impact of risks such as fire hazard on sustainability. In order to design sustainable tall structures, their robustness against extreme fire scenarios must be adequately satisfied. In this study, a generic tall structure is modeled using the finite element software LS-Dyna. The two-dimensional model consists of line elements (beams and columns) as well as the shell elements (concrete deck). To simulate the building collapse, the explicit dynamic analysis is used with proper surface-based contact configurations.

1 INTRODUCTION

The progressive collapse behavior of tall buildings has been intensively studied after the collapse of World Trade Center Towers in 2001 (Hoffman, 2004, Gross, 2005). A sensitivity analysis of a moment resisting and a dual system steel frame due to a column loss is conducted by Kim et al. (2011) and they concluded that the beam yield strength is the most critical design parameter. A detailed three-dimensional composite floor structure with shear connections is modeled by Sadek et al. (2008) and Alashker et al. (2010). One-floor composite structure is suddenly subjected to a column loss and it is observed that the tensile forces in the composite floor are carried by the metal deck. Further, the effect of shear connection capacity is found to be limited. A similar observation is made by Yu et al. (2009). A comprehensive three-dimensional model of the eight-story Cardington steel frame building is created by Kwasniewski (2010). The nonlinear dynamic behavior is analyzed due to column loss at different locations and due to increased gravity loading. The dynamic behavior of a 20 story steel building is investigated due to column loss with several different column locations by Fu (2009). Izzuddin et al. (2008) and Vlassis et al. (2009) laid out a theoretical groundwork for steel frames due to a sudden column loss. A steel building might also collapse due to an extreme event such as fire. The underlying mechanisms of tall buildings when subjected to fire have been previously investigated by Lange et al. (2012). It was found that the main cause of collapse is the outward and inward deflection of the columns above and below the heated floor. These columns are called as 'pivot columns'. Sun et al. (2012) investigated the vulnerability of steel braced frames and the development of plastic hinges at elevated temperatures.

In light of the described previous research on this subject, the main objective of this study is the assessment of the structural response of a 49 story steel high-rise structure due to ISO834 fire. It is intended to provide a better understanding of the effect of fire loading leading to the collapse mechanism of a high-rise structure. For all case studies, 3 floors are heated simultaneously at different floor locations and regions (asymmetric vs. symmetric heating). The commercial finite element code LS-Dyna is used as the analysis tool for the uncoupled thermo-mechanical dynamic response of the structure. Simulations are carried out using the Central Difference explicit time integration scheme. Geometric nonlinearity in terms of large displacements and rotations are taken into account. Material nonlinear response is considered through the use of a bi-linear constitutive model. The steel yield stress and stiffness of the material vary at elevated temperatures according to Eurocode provisions. The high-rise steel frame consists of steel beams and columns modeled with 2-node 1D (line) finite elements and composite floors modeled with 4-node shell 2D finite elements. In order to cut down the computational expense, the beam and columns are not modeled with shell elements, which could have accurately captured the local buckling effects during fire as discussed by Selamet & Garlock (2012). The structural load carrying system of the high-rise structure is assumed to be a moment resisting frame. Perimeter (primary) beams are connected to each other and to columns with rigid (moment) connections, the secondary beams and the bracing members have pinned connections.

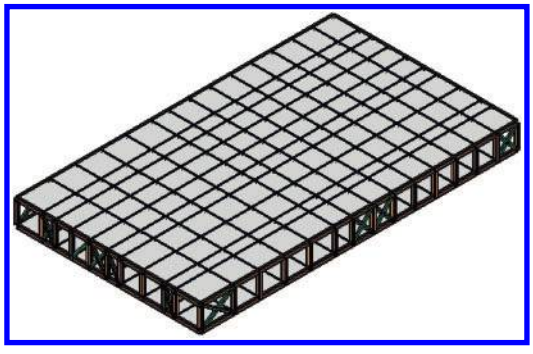

Figure 1. The floor structure of the tall building model.

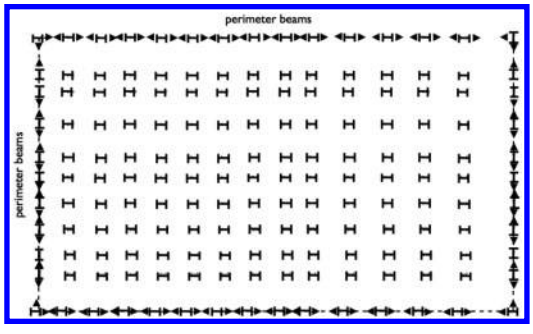

Figure 2. The column orientations for moment frame design.

2 TALL BUILDING STRUCTURE

2.1 *Design*

The tall steel structure is first modeled in ETABS, widely used structural engineering software. The steel frame sections (i.e. primary and secondary beams, bracings and columns) are designed with a combined earthquake and gravity load according to ASCE\SEI 7-10 seismic loading provisions (ASCE 2010). The prototype composite floor layout is based on Chase Tower (formerly known as BankOne) in Chicago, IL and it consists of secondary beams, primary beams, lateral bracings and 10 cm thick concrete slab with full composite action with the secondary beams. The building has 50 m by 29 m floors with a total height of 179 m. The model deflection calculations takes account the contribution of the concrete slab to the flexural stiffness; however this contribution is neglected for steel design calculations as a conservative approach. The height of each floor is 3.6 m and the member size of the columns is decreased at every 10th floor. Figure 1 and Figure 2 show the extruded view of a typical steel floor and the column orientations, respectively. The beam member sizes are shown in Table 1. The connections between the primary and secondary beams are idealized as pinned connections and the perimeter (primary) beams are connected with moment connections as part of the moment frame design. The bracings are modeled as truss elements. The prototype composite floor shown in Figure 1 is replicated for the upper floors.

Table 1. The structural steel member sizes.

Structural member	Steel section
Primary beam	W24 × 146
Secondary beam	W14 × 34
Lateral bracings	W14 × 120
Column (1–10th)	W24 × 335
Column (11–20th)	W24 × 306
Column (21–30th)	W24 × 207
Column (31–40th)	W24 × 146
Column (41–49th)	W24 × 103

2.2 *Gravity and earthquake loads for design*

The dead load is assumed to be the self-weight of the steel members and the superimposed dead load, which is estimated to be 3.6 kN/m^2. The superimposed dead load includes the weight of the light-weight concrete and the other structural elements such as partitions. The live load is assumed to be 2.4 kN/m^2, which is typical for an office building according to ASCE 7-10. The steel members are assumed to carry the gravity load depending on their tributary areas. The first natural period of the tall building is calculated as $T_d = 2.6174$ sec. Both the modal response spectrum analysis and the equivalent lateral force analysis methods are used for the earthquake design. Los Angeles CA region is taken as a basis for both methods. The response modification R and the occupancy importance I factors are taken as 8 and 3, respectively. The 0.2 sec (S_s) and the 1.0 sec (S_1) spectral accelerations are found as 2.1226 sec and 0.7837 sec, respectively. The base shear coefficient is calculated by ETABS as $C_w = 0.177$.

3 FINITE ELEMENT MODEL IN LS-DYNA

3.1 *Model description*

The geometry of the entire tall building model in ETABS is imported to LS-Dyna for uncoupled thermo-mechanical analysis with various fire scenarios, which requires an explicit dynamic scheme with highly nonlinear material behavior as well as large displacements. The Hughes-Liu beam elements and Belytschko-Tsay shell elements are employed in the model. The shell elements only provide additional stiffness to the building as a diaphragm. A rigid body is placed on the base to provide contact surface for the collapsed floors as seen in Figure 3. The gravity loading defined in the design is applied by using *LOAD BODY Z command for 6 seconds to ensure that no significant inertial (dynamic) forces are created before the fire starts. The reactions due to dead and live loads at the base are validated with the ETABS results. In order to simulate

progressive collapse, the contact interactions are introduced between the shells, beams and the rigid surface with *CONTACT GENERAL command. The steel material in the heated floors is defined as temperature dependent with *MAT ELASTIC PLASTIC THERMAL command. This material type does not have a failure limit state. Due to this limitation, the steel material for the other (not heated) floors is defined as temperature independent with *MAT PIECEWISE LINEAR PLASTICITY.

The temperature dependent material strength and stiffness of the steel sections and the material properties of the concrete slab are given in Table 2. A simple bilinear stress-strain relationship (constant E_t) is assumed, which is based on Eurocode 3 (CEN 2001). Since the concrete is not heated in the model, only ambient temperature material properties are used as seen in Table 2. For simplicity, no reinforcement bars are modeled for the concrete material. The temperature dependent thermal expansion coefficient α of steel is taken from Eurocode 3.

Table 4. Fire scenarios.

Label	Floor location	Fire spread
Case A1	5th–7th	Symmetrical
Case B1	25th–27th	Symmetrical
Case C1	40th–42nd	Symmetrical
Case A2	5th–7th	Asymmetrical
Case B2 25th–27th	Asymmetrical	
Case C2 40th–42nd	Asymmetrical	

3.2 *Gravity loading and fire scenarios*

A total of 6 fire scenarios are investigated, which are illustrated in Figure 4 and defined in Table 4. In conducting these scenarios, the aim is to understand the effect of the fire location (bottom, middle or top floors) and the fire spread (symmetric or asymmetric). For all cases, the steel building is gradually (quasi-statically) loaded with the dead load and the live load for 6 seconds. No oscillations are observed during the gravity loading, which validates that the loading remained static. The unprotected column members are heated with ISO834 fire curve as seen in Figure 4 (CEN 2001). The fire curve is applied at 6 seconds soon after the gravity load is applied. For computational efficiency, the fire curve is scaled to range only to 36 seconds as shown in Figure 4. Within the period, the kinetic energy of the system is carefully monitored in order to get a quasi-static behavior of the building during the thermal loading. The steel temperatures are calculated using lumped mass method with four-sided heating with convective heat transfer coefficient $h = 25$ W/m^2 °C and emissivity $\varepsilon = 0.5$. No fire protection is applied to the columns. ISO834 fire curve and the lumped column temperature are shown in Figure 4. The temperatures are directly applied to the nodes without a heat transfer analysis in LS-Dyna (uncoupled thermo-mechanical analysis). For Cases A through C, three columns at 5th–6th–7th floors, 25th–26th–27th floors and 40th–41st–42nd floors are heated uniformly considering a symmetrical collapse (A1, B1

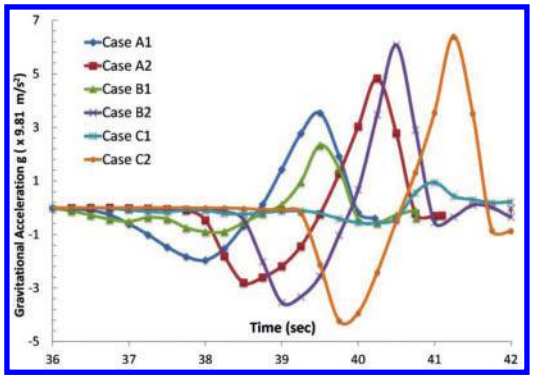

Figure 5. Rigid body acceleration of the entire building in the vertical direction.

and C1), respectively. For Cases 4 through 6, only half of the regions at 5th–6th–7th floors, 25th–26th–27th floors and 40th–41st–42nd floors are heated (A2, B2 and C2), respectively. Hence, the asymmetrical collapse is expected. After the plastic deformations of the structural members in the fire-applied floor, the gravity loading is scaled 5 times until 40 seconds to initiate collapse.

4 OBSERVATION AND RESULTS

4.1 *Collapse characteristics*

Figure 5 clearly shows the distinct collapse characteristics of the tall steel building. The collapse initiates soon after the fire application is over at around 36 seconds. At the onset of the collapse, the building has downward (negative) acceleration in g-units. But as the collapse progresses, the acceleration reserves the sign as the lower floors resist the impact and the downward motion slows down. The severity of the collapse is larger for the asymmetric fires. In general a fire in the lower floors causes the collapse initiation to occur slightly earlier. Further, the asymmetric collapse causes the building to lean over to one side and more debris is spread to a larger area on the rigid base as seen in Figure 6. This is a great concern in urban areas with high density of tall buildings in the neighboring regions. It is also observed that the asymmetric collapse in the lower floors causes an overturning moment, which tears apart the base columns and the shell elements in the cool (not heated) region.

4.2 *Column axial forces*

To analyze the behavior of the tall building at the collapse instant, the axial stress development of the three corner columns observed as shown in Figure 7. The heated column is compared to the (pivot) columns right below and above the heated region. Figures 8 through 10 show the axial stress development in these columns for Cases A, B and C, respectively.

In addition, the temperature dependent yield stress capacity of the columns is plotted. Note for some pivot

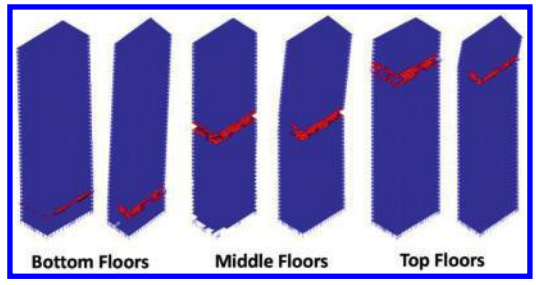

Figure 6. The collapse initiation for all cases. The heated floors are in red (lighter color).

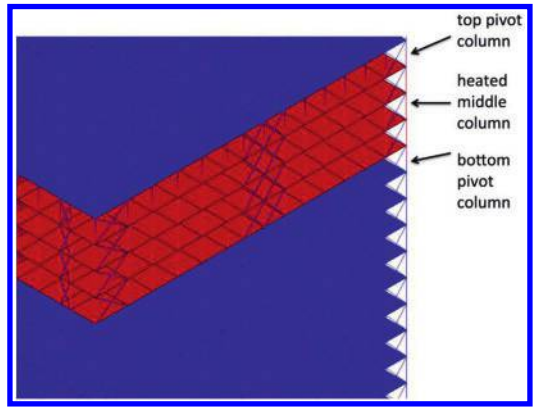

Figure 7. The location of the heated and pivot corner columns in the tall building for all cases.

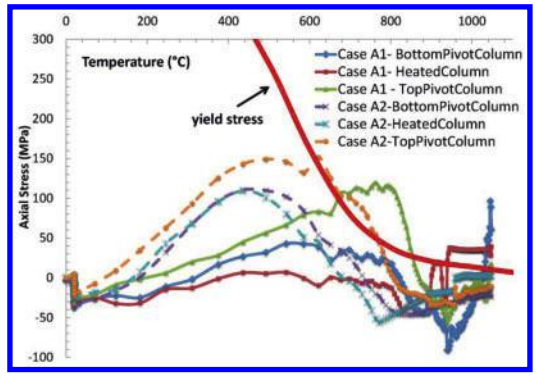

Figure 8. Column axial stress-temperature history for bottom floors fire (Cases A1 and A2).

columns, the axial stress surpasses the yield stress at some instances, which is expected since these pivot columns stay at ambient temperature. As seen in Figure 8, the initial compressive (negative) stress in the column due to gravity is considerably low. This is expected since the model is specially designed for lateral (earthquake) resistance of a large earthquake. It is observed that the heated column carries a minimum load whereas the pivot columns go into tensile action to the outward movement of the floors due to expansion.

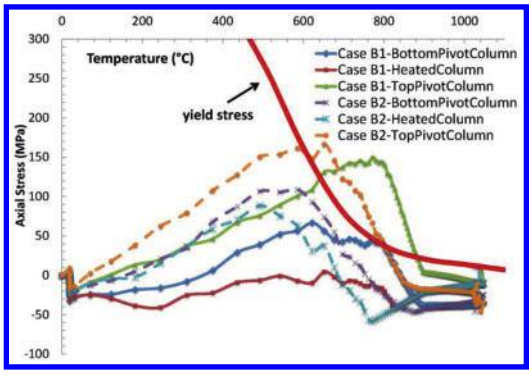

Figure 9. Column axial stress-temperature history for middle floors fire (Cases B1 and B2).

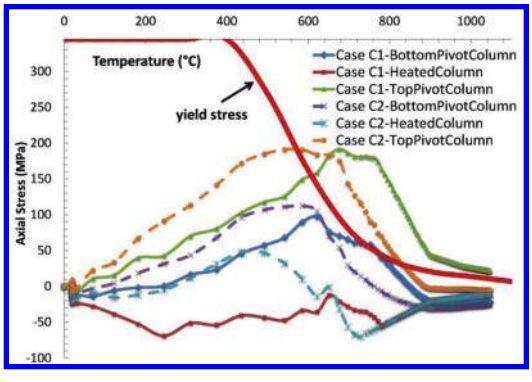

Figure 10. Column axial stress-temperature history for top floors fire (Cases C1 and C2).

The top pivot column carries the maximum load until it fails first at around 800°C. The difference between the symmetric and asymmetric collapse is seen in the magnitude of these stresses. Further, for the asymmetric case, the sudden drop in column stresses is seen at around 600°C.

Figures 9 and 10 show the same trend but the heated column has larger compression and the pivot columns have larger tension. This can be explained by the visual inspection in Figure 6. In Cases C1 and C2 with the heated top floors, the building leans over towards the corner region more than the other cases, which causes the stresses to differ significantly larger between the pivot and heated columns.

5 CONCLUSION

This study presents the ongoing research on the collapse mechanisms of tall steel buildings with symmetric and asymmetric fire conditions and various fire floor locations. The observations suggest that the asymmetric heating causes the steel building to collapse by leaning on the side that corresponds to the heated floor region. It also suggests that a building designed even for a large earthquake is not resistant to weakened floors due to the imposed ISO834 fire. In general, an asymmetric fire spread causes more damage to the building and the building collapse initiates earlier when compared to a symmetrical fire spread. The fire location seems to change the collapse behavior only slightly. In all cases, the pivot columns below and above the heated regions go into tension due to the lateral expansion of the floors. The author intends to expand the study by adding the *MAT EROSION command for the heated steel members. Furthermore, a finer meshing in the beam members will enable to capture a possible buckling behavior.

Behavior of tall buildings under blast loading with direct simulation method

Feng Fu
School of Engineering and Mathematical Sciences, City University, London, Northampton Square, London

ABSTRACT: In this paper, a 3-D numerical model with the direct simulation of blast load is proposed to study the real behavior of a 20-storey tall building under the blast loading. The modeling techniques are discussed in details. In the analysis, a typical package bomb charge was simulated to be detonated on the 12th floor. The corresponding dynamic response of structure was studied. The method to enhance the robustness of the buildings is also recommended.

1 INTRODUCTION

Recently, the special design requirement of buildings against blast load becomes more and more important for the safety of the occupants. The UK SCI publication 244[1] provides a guidance on the design of commercial and public buildings where there is a requirement to provide protection against the effects of explosions caused by the detonation of explosives. In United States, FEMA 426 [2] provides the design measurements to reduce physical damage to the structural and non-structural components of building and related infrastructures during conventional bomb attacks, as well as attacks using chemical, biological and CBR agents. Kambouchev *et al.* [3] discussed the nonlinear compressibility effects in fluid-structure interaction and their implications on the air-blast loading of structures Blanc et al. [4] discussed empirical method to estimate the blast loading.

However, due to the huge cost, it is almost impossible to investigate the response of the multi-story buildings against blast loads with full-scale experimental tests. Therefore, advanced numerical tools such as the finite element method become the main approach for the related research. The analysis and design of structures subjected to blast loads require a detailed understanding of blast phenomena and the dynamic response of various structural elements. Some numerical modeling has been done in the past decades. Børvik et al. [5] investigated if a pure Lagrangian formulation could be applied to determine the structural response in a specified blast load problem. Luccioni et al. [6] performed a detailed analysis of the structural failure of a reinforced concrete building caused by a blast load. However, most of the current numerical modeling research is involved with massive computational time and the model is difficult to build due to its complexity. Therefore, for designers, it is imperative to establish a simple modeling method to study the detailed behavior of the building after the blast denotation.

To solve this problem, in this paper, using ABAQUS [7], a 3-D finite element model representing a 20-storey building was built to perform the blast analysis. A simplified direct simulation method of blast load is applied here. The proposed method can apply the blast loads directly on the frames and the floors of the building. The nonlinear material behaviour and dynamic effects are also included in the simulation. The proposed method requires substantially less computational effort as compared to other direct numerical simulations. Based on this model, detailed response of the multi-storey buildings is also discussed. The measures to increase the robustness of the high-rise building in the future design are also recommended.

2 3D FINITE ELEMENT MODEL

As shown in Fig. 1, a three-dimensional finite element model was created by Fu [8] using the ABAQUS [7] package. It replicatesa20-Storey steel composite building with the grid spacing of 7.5 m in both directions. The main lateral stability of the building is provided by cross bracings in the exterior frame at the four facades. The floor height is 3 m for each floor. The slab thickness is 130 mm. All the structural steel members are using grade S355 steel. The columns are British universal column UC356X406X634 for ground floor to level 6, UC356X406X467 for level 7to level 13, UC356X406X287 for level 14 to level 19. All the beams are British universal beam UB533X210X92. The cross bracings are British circular Hollow section CHCF273X12.5. The section properties are shown in Table 1. The section sizes of the structural steel members were determined followed the capacity design principles of British standards [9],[10].

All the beams and columns were simulated using *BEAM elements. The Slabs were simulated using the four node *Shell elements. Reinforcements were represented as a smeared layer in each shell element using the *REBAR elements and were defined in both slab

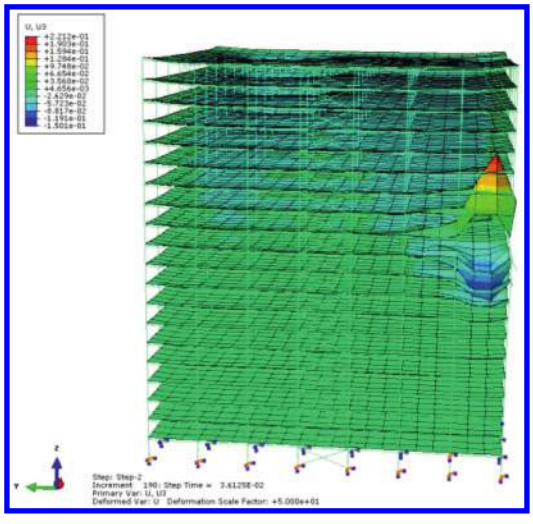

Figure 1. Isotropic view (blast detonated at level 12, deformation samplified).

directions. The beam and shell elements were then coupled together using rigid beam constraint equations to give the composite action between the beam elements and the concrete slabs. The detailed description of the modeling technique is shown in Fu[8]. The nonlinear behaviour and dynamic effects of the material due to blast or impact loading are also considered in the simulation which is determinated based on [1].

As it is discussed in [1][2], to precisely evaluate the shock propagation around the structure and the structure's response, using a fluid-structure interaction method is possible. However, it will generate big models. Another possibility is to use the empirical model to compute the load on the structure. This solution is computational effective and is used in this paper with the program ATBLAST [11]. A subroutine program with Visual BASIC language is designed by the author, which can transfer the blast load profile worked out by ATBLAST [11] to the 20-storey prototype model built in ABAQUS. In the simulation, the blast load was applied as an area load working directly on the slabs and line load directly on the beams and columns with all the related information as shown in Fig. 2. For the applied blast loading, the time of arrival and load duration are all different due to their distance to the blast charge locations. Therefore, the propagation of the blast wave was also simulated. Therefore, the response of the 20 storey prototype building can be evaluated.

There are many ways in which an explosive device may deliver an attack. As it is stated in [1], there are several conventional devices like Vehicle bombs, Package bombs, Mortar bombs, Culvert bombs and Incendiary devices. In this paper, the scenario of Package bombs is selected for the study, as this type of attack is more difficult to be prevented than other attack scenarios such as vehicle bombs.

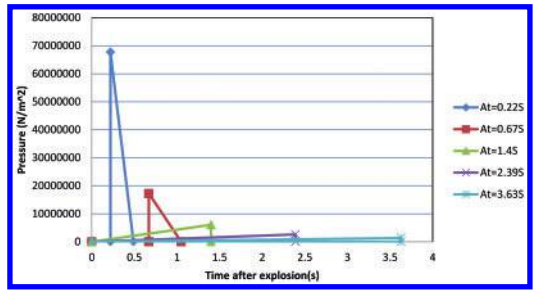

Figure 2. Blast overpressure profile at different Arrival time (At) of the proposed analysis model.

3 RESPONSE OF THE BUILDING UNDER BLAST LOAD

Using general purpose program ABAQUS, the response of the prototype building under the blast load is assessed here using a nonlinear dynamic analysis method with 3-D finite element technique. The loads are computed as dead loads (which is the self-weight of the floor) plus 25% of the live load in accordance with the acceptance criteria outlined in GSA guidelines [12].

The static analysis with the dead and live load loaded to the building was conducted in the first second as a static step. After this step, a blast load of 15 kg TNT is detonated at location of column A1 on level 12 as it is shown in Fig. 1. This is to simulate the typical charge weight for a package bombs indicted in SCI 244 [1] table 6.1 occurs inside an office building. Fig. 6 is the Pressure of distributed blast load on element surface at different selected time. It clearly shows the blast wave pressure propagating from the charging location to the adjacent structural members on level 12.

The simulations were conducted with 5% mass damping. In the analysis, the internal forces, such as axial force, shear force, bending moment, displacements and rotations for each of the members involved in the scenario are recorded. To facilitate the following discussion, the columns and beams are designated as follows according to the grid line shown in [8]. For instance, Column C1 stands for the column at the junction of grid C and grid 1. Beam E1-D1 stand for the beam on grid 1 starting from grid E to grid D.The response of the structure was extracted from the 3-D finite element model. And the results are shown in the following sections.

3.1 *Shear force comparisons of columns at different location*

The car bomb attack happened in Oklahoma City in 1995 shows that, except the failure of the column where the bomb was detonated, the adjacent columns were also sheared off. Fig. 3 is the shear force response of the column B1on level 12 which is adjacent to the blast charge location. It can be seen that at time 1.01S, the shear force of the column reach a peak value

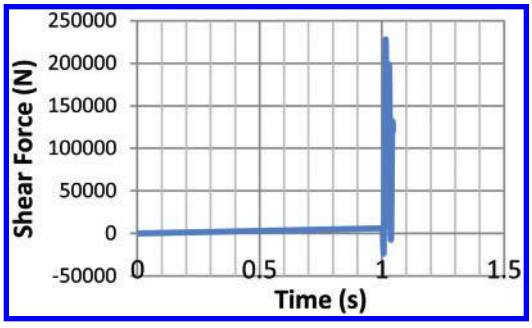

Figure 3. Shear force of column B1 at level 12.

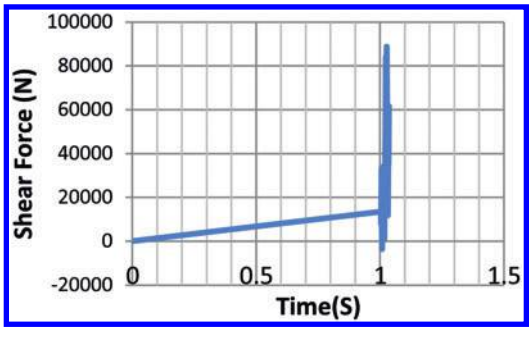

Figure 4. Shear force of column B2 at level 12.

220 kN. As this shear force is quite large, so it could not be ignored. Therefore, one way to mitigate the collapse of the building is to enhance the shear capacity of the column.

The shear forces of columns at other locations are chosen for the study as well, as it is shown in Fig. 4. It can be seen that, with the increasing of the distance, the response of the column decreased dramatically, the effect of the blast loading become quite small, can be ignored.

3.2 *Axial force comparisons of columns at different location*

In order to investigate the axial force of the columns, the columns at different location are chosen for the studies. Fig. 5 is the axial force response of the column B1on level 12. It can be seen that at time 1.006 s, the compressive force of the column reached a peak value −1200 kN, after that the force started to decrease until it become in tension.

The axial force of the columns at different location is shown in Fig. 6. It is the response of the column D4 at level 12. Following the principle of the scaling law. It can be seen that, compared with column A1 at level 12, the axial forces of D4 was almost kept unchanged after the blast charge.

3.3 *Collapse potential of the building*

It is well known that the columns play an important role in the prevention of the collapse of the building.

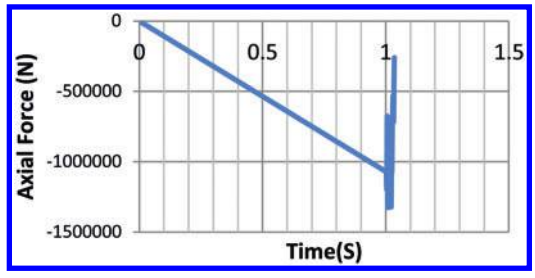

Figure 5. Axial force of column C1 at level 12.

Figure 6. Axial force of column D4 at level 12.

Following Progressive collapse analysis and design guidelines [12], the collapse potential of the building is checked here starting from the columns. From numerical analysis, it can be seen that, the three columns A1, B1 and A2 (due to symmetry, the force in B1 and A2 are identical)at level 12 near the blast charge location started to yield. However, a manual checking in accordance to BS5990 [9] is made, it shows that the maximum axial force, bending moment and shear force obtained from the analysis does not exceed the capacity of the columns, the three columns did not fail, nor did the adjacent columns. Therefore, no collapse of the whole building was triggered.

3.4 *Discussion of Analysis*

The above analysis shows that, the blast load decreases dramatically with the increasing of the distance, beyond certain distance, the effect of blast pressure can be ignored. It can also be seen that, one way to prevent the progressive collapse of the building under blast load is to enhanced shear capacity and increase the ductility of the column. For the buildings designed using the current design guidance, the small scale blast such as the package bomb will normally cause localized structural member damage, and it hardly triggers the collapse of the whole building, as long as the alternative path can be provided for the load to be redistributed.

4 CONCLUSIONS

In this paper, the numerical simulation of a tall building under a 15 Kg package bomb is conducted. The

dynamic behavior of the building is studied in details. The robustness of the tall building under the blast load is studied. The main conclusions are made as follows:

1. The Alternative Path Method ignores the huge shear force applied to the column due to the blast loading. Therefore, when using the APM method to evaluate the robustness of the building, the shear capacity of the column should also be checked.
2. To prevent the progressive collapse of the building under blast load, the shear capacity and of the column need to be enhanced.
3. For the buildings designed using the current design guidance, the small scale blast such as the package bomb will normally cause localized structural member damage, and it hardly triggers the collapse of the whole building, as long as the alternative path can be provided for the load to be redistributed.

A modal property analysis of linked tall buildings using a matrix model

K.T. Tse & J. Song
Department of Civil and Environment Engineering, The Hong Kong University of Science and Technology, Hong Kong, P.R. China

ABSTRACT: In order to study the effect of link on modal properties of linked tall buildings, a 3-D analytical matrix-form model of linked tall building that can consider varied locations and numbers of links is introduced. Then the effect of stiffness of link is investigated by parametric analysis. The results show that the link can decrease the natural periods of antisymmetric mode of linked twin buildings significantly, i.e. can stiffen the structure. In addition, the mode shapes of these antisymmetric modes could be changed from a linear form to a hyperbolic form, which is rather different from the ones of single building and should be received researchers' and designers' attentions.

1 INTRODUCTIONS

With the development of cities, there is a trend that increasing tall buildings are erected in a relatively close proximity owing to inadequate available land in urban area, especially in some metropolises, which gives a possibility to connect these adjacent buildings horizontally. Consequently, more and more tall buildings in close proximity are designed as linked buildings all over the world, such as the Petronas Twin Towers in Kuala Lumpur and Marina Bay Sands Hotel in Singapore.

Compare to regular isolated tall buildings, the dynamic properties of which have been analyzed comprehensively and thoroughly, there are only limited researches that have done for linked tall buildings. Xie & Irwin (1998, 2001) divided the mode shape of whole complex including several towers connected by sky-bridges into the mode shape of each substructure to calculate the wind-induced responses. For seismic response analysis, Zhang & Xu (1999) derived an analytical model for two adjacent buildings connected by viscoelastic dampers vibrating in one translational direction, i.e., one-dimensional (1D) motion. The coupling effect of dampers was introduced by modeling each damper as the Voigt model with axial stiffness and damping. Lim (2009) and Lim et al. (2011) reduced a complex with two towers connected by a skybridge to a six-degree-of-freedom model at the elevation of skybridge. This model provides a better understanding about the structural coupling of link by assuming that the first six mode shapes of linked buildings can be fitted by power functions. Lim also summarized that the effect of link on the structural coupling between towers can be sorted as two aspects: on one hand, the axial stiffness of link tends to synchronize the motion of two towers along the direction of link, which is similar to Zhang & Xu's the model; on the other hand, the bending stiffness may synchronize the motion of sway perpendicular to the link and torsion of two towers simultaneously.

However, it should be noted that due to recent trend of irregular or elongated building shapes, the mode shape of isolated buildings could be significantly three-dimensional (3D) coupled and nonlinear, let alone the one of linked buildings, which could be more complicated for the effect of link. So without a careful investigation the characteristics of mode shape of linked tall buildings, it should be cautious when using Lim's method to predict wind-induced vibration of linked tall buildings. In addition, this simplified model just addresses the case with one link at a given elevation. In real case, the links could cover a succession of floors or at several separate floors. Apparently, the whole system of two linked buildings by no means can be lumped at one location to form a six-degree-of-freedom model.

In view of the forgoing discussion, it is crucial to develop an analytical model of linked tall building that can take account the 3-D structural coupling caused by link and can deal with the case with links at a succession of floors or at several separate floors. Therefore, a 3-D analytical matrix-form model of linked tall building allowing for structural coupling of links at a succession of floors or at several separate floors was developed in this paper. To evaluate the accuracy of the proposed model, a case of linked buildings was modelled by finite element method (FEM) model and by the analytical matrix-form model, then the modal properties of the complex was calculated by the analytical model to compare to "exact" ones obtained by FEM model. Subsequently, a systematic parametric analysis was conducted to examine the effect of axial stiffness and bending stiffness of link on the modal properties.

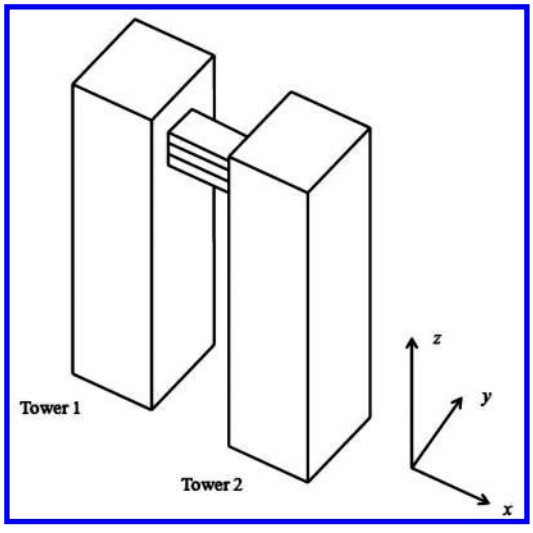

Figure 1. Isometric view of one case of linked buildings and definition of coordinate.

2 MODELLING OF STRUCTURAL COUPLING EFFECT OF LINK

A 3-D analytical model of linked buildings that can take into account the effect of structural coupling of link is outlined in this section briefly. Fig. 1 is a drawing of two twin tall buildings (tower 1 and 2) connected by *n*-floor links. Each tower with *m* floors can be modelled by lumped mass system having three dynamic degrees of freedom, i.e. sway motions along x and y and torsional motion along z, at the elevation of each floor. Each link can be modelled by a link beam with three degrees of freedom at each end.

In order to study structural coupling effect of link, the sub-matrix of structural property of each sub-part, i.e. two towers and link system, should be formed at first. The structural-property matrices of tower can be obtained by FEM model easily. If we do not consider the effect of link here, given the mass and stiffness matrices of each tower, we can easily assemble them as

$$\mathrm{M}_{tower} = \begin{bmatrix} M_1 & & & & & \\ & M_1 & & 0 & & \\ & & J_1 & & & \\ & & & M_2 & & \\ & 0 & & & M_2 & \\ & & & & & J_2 \end{bmatrix}_{6m\times 6m} \quad (1)$$

$$\mathrm{K}_{tower} = \begin{bmatrix} K_{1xx} & 0 & K_{1x\theta} & & & \\ 0 & K_{1yy} & K_{1y\theta} & & 0 & \\ K_{1x\theta}^T & K_{1y\theta}^T & K_{1z\theta} & & & \\ & & & K_{2xx} & 0 & K_{2x\theta} \\ & 0 & & 0 & K_{2yy} & K_{2y\theta} \\ & & & K_{2x\theta}^T & K_{2y\theta}^T & K_{2\theta\theta} \end{bmatrix}_{6m\times 6m} \quad (2)$$

where M_1, M_2, J_1, and J_2 are mass matrix and moment of inertial of tower 1 and 2, and mass matrix of links,

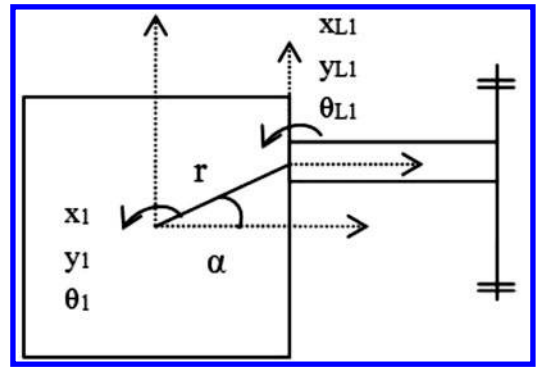

Figure 2. Relationship between link and tower in plan.

respectively; K_{trs} ($t = 1$ or 2, s, $r = x$, y or θ) is the stiffness matrix of tower t. For each tower, the centers of mass and stiffness of each floor are assumed to be coincident with the geometric center of each floor to eliminate the static and dynamic coupling within each building so that the structural coupling effect of link can be show more clearly and directly.

In order to take the structural coupling effect of link into account, the structural-property matrices of link should be formed and then the total matrices can be obtained by assembling them into the above tow matrices in Eq. 1 and 2. Assuming that link can be simulated by a fixed-fixed beam without the stiffness of out-plane, the stiffness matrix of link K_{link} for the deformation of two ends of link $\{\mathrm{x}_{L1}, \mathrm{x}_{L2}, \mathrm{y}_{L1}, \mathrm{y}_{L2}, \theta_{L1}, \theta_{L2}\}^T$ can be expressed as (Przemieniecki, 1985)

$$K_{link} = \begin{bmatrix} k_a & -k_a & 0 & 0 & 0 & 0 \\ -k_a & k_a & 0 & 0 & 0 & 0 \\ 0 & 0 & 12k_b & -12k_b & 6k_b l & 6k_b l \\ 0 & 0 & -12k_b & 12k_b & -6k_b l & -6k_b l \\ 0 & 0 & 6k_b l & -6k_b l & (4+\beta)k_b l^2 & (2-\beta)k_b l^2 \\ 0 & 0 & 6k_b l & -6k_b l & (2-\beta)k_b l^2 & (4+\beta)k_b l^2 \end{bmatrix} \quad (3)$$

where x_{Lt}, y_{Lt} and θ_{Lt} ($t = 1$ or 2) are deformations of end of links in the two translational directions and torsional directions along axis z; l is the length of link; axial stiffness $k_a = EA/l$; bending stiffness $k_b = EI'/l^3$, in which $\mathrm{I}' = I/(1+\beta)$, $\beta = 12\mu EI/(GAl^2)$; μ is a correction factor, for rectangular beam, $\mu = 1.2$.

It should be noted that the above stiffness matrix K_{link} is formed at the point connecting main towers and link. In order to assemble it to the total stiffness matrix, it should be transferred to the mass center of the related floor. According to the relationship shown in Fig. 2, the stiffness matrix of link for the deformation of mass center of tower can be derived as

$$K'_{link} = HK_{link}H^T \quad (4)$$

where H is the transformation matrix.

$$H=\left[\begin{array}{ccc|cc} 1 & -r_1\sin\alpha_1 & & & \\ & 1 & r_1\cos\alpha_1 & 0 & \\ & & 1 & & \\ \hline & & & 1 & r_2\sin\alpha_2 \\ 0 & & & 1 & -r_2\cos\alpha_2 \\ & & & & 1 \end{array}\right]_{6\times 6} \quad (5)$$

The above stiffness matrix K'_{link} is only for one link. Then the stiffness matrix for all links K_L can be formed by assembling all stiffness matrices of link as

$$K_L = K'_{link} \otimes U_n \quad (6)$$

where U_n is $n \times n$ unite matrix; $\otimes$ is Kronecker tensor product.

Now stiffness matrices of all subparts have been evaluated, then stiffness matrix K_{total} of this linked complex can be assembled as

$$K_{total} = K_{tower} + EK_L E^T \quad (7)$$

where E is a whole location matrix to show the relationship of connection between link and of towers,

$$E = diag\left(E_1, E_1, E_1, E_2, E_2, E_2\right)_{6m\times 6n} \quad (8)$$

here, E_t ($t = 1$ or 2) is a location matrix to show relative location relationship between links and each tower. Taking tower 1 for example, $E_1 = [e_1, e_2, \ldots, e_p, \ldots, e_n]_{m\times n}$, each e_p is a vector as

$$e_p = \{0 \quad \cdots \quad 1 \quad \cdots \quad 0\}^T \quad (9)$$

Since one link is only connected with one story of tower 1, elements of e_p are zero except the ith element equal to one, which mean that the ith floor of tower 1 is connected with the pth link. For example, if there are three links connected with tower 1 at the top three floors, E_1 can be formed as

$$E_1 = \begin{bmatrix} 0 & 0 & 0 \\ \vdots & \vdots & \vdots \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{m\times 3} \quad (10)$$

Lumping the mass of link to the connected floors of two towers equally, the total mass matrix M_{total} can be expressed as

$$M_{total} = M_{Tower} + M_L = M_{Tower} + \frac{1}{2}\times E\times\left[diag\left(1,1,r^2,1,1,r^2\right)\otimes M_L\right]\times E^T \quad (11)$$

In this way, the mass and stiffness matrices for the whole system are formed and hence then structural model properties such as frequencies and mode shapes can be calculated directly by eigenvalue analysis based on the equation of undamped free vibration

$$M_{total}\ddot{D} + K_{total}D = 0 \quad (12)$$

where D is displacement response vector, $D = \{D_{1x}, D_{1y}, D_{1\theta}, D_{2x}, D_{2y}, D_{2\theta}\}^T$, and $D_{ts} = \{d_{ts1}, d_{ts2}, \ldots, d_{tsm}\}^T$ ($t = 1$ or 2, s, $r = x$, y or θ).

Table 1. Natural periods calculated by the analytical model and FEM model.

	Natural period (s)					
Mode	1	2	3	4	5	6
Matrix model	4.182	4.182	3.368	1.779	1.656	1.553
FEM model	4.184	4.184	3.334	1.779	1.675	1.553
Difference (%)	−0.03	−0.03	1.02	−0.02	−1.15	−0.03

3 VERIFICATION OF THE ANALYTICAL MODEL

To evaluate the accuracy of the above analytical model of linked tall buildings, it is necessary to simulate the same complex with a detailed finite element model to capture comprehensive structural properties and then calculate "exact" modal properties of structure. In this section, therefore, an example of linked tall buildings with two identical towers is simulated by finite element method (FEM). Each tower is a 40-storey, 160 m tall reinforced concrete framed-tube structure with a uniform square floor plan of 30 m by 30 m throughout its height. At the top two floors, there is a two-story link with span of 15 m and width of 18 m.

Tab. 1 shows the comparison of natural periods of the two approaches, i.e. matrix-form method and FEM. Clearly, the natural periods hardly show noticeable differences between the two methods, which gives compelling evidence that the matrix-form model of linked buildings can provide satisfied accuracy as FEM. As we all know that one of drawbacks of FEM for dynamic analysis is its time-consuming calculation. As a result, for the subsequent analysis we can replace the time-consuming FEM model with the analytical matrix-form model, which can save a lot of time and improve efficiency of analysis remarkably.

4 PARAMETRIC ANALYSIS AND DISCUSSION

In order to examine the effect of stiffness of link on the modal properties of linked tall buildings, a parametric analysis is conducted in this section.

As in section two, we assume that the link has stiffness of out-plane and just has axial stiffness k_a and bending stiffness k_b in the horizontal plane.

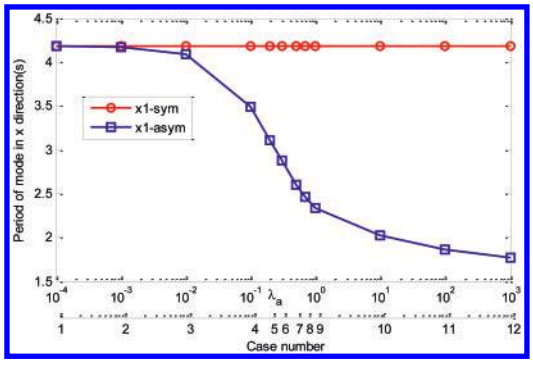

Figure 3. The effect of axial stiffness on periods of the first two modes in x direction.

According to Huang (2001), two relative values of stiffness are introduced

$$\lambda_a = \frac{k_a}{k_{e,b}} \qquad \lambda_b = \frac{k_b}{k_{e,t}} \tag{13}$$

where k_a is axial stiffness of link; $k_{e,b}$ is equivalent lateral stiffness of tower below the link, i.e., the required force applied at the level of link to make the tower sway one unite displacement at this level; similarly, k_b is bending stiffness of link; $k_{e,t}$ is equivalent torsional stiffness of tower below the link, i.e., the required torque applied at the level of link to make the tower rotate one unite degree at this level.

Even though the axial stiffness of links usually is correlated with bending stiffness of link somehow, we here study the effect of these two independently. And from the above derivation it is evident that dynamic motion in x direction is decoupled from those in the y and θ direction. We can, therefore, analyze them independently. Meanwhile, the axial stiffness of link k_a just affects the motion in x direction and the horizontally bending stiffness of link k_b just has an effluence on the motion in y and θ direction. So in the subsequent parametric analysis, the effect of k_a on the modal properties in x direction and the effect of k_b on the modal properties in y and θ direction are analyzed independently.

4.1 *The effect of axial stiffness of link k_a*

The axial stiffness of link, working as a spring to connect two objects, will tend to synchronize the motion of two towers in x direction. In order to study its effect on modal properties, 12 cases of axial stiffness of link, as shown in Fig. 3, are selected and then modal analysis is conducted for each case to obtain the structural frequencies and mode shapes in x direction.

It can be seen from Fig. 3 that the periods of symmetric mode, i.e. mode x1-sym, remains unchanged with the increase of axial stiffness, while the one of antisymmetric mode, i.e. mode x1-asym, decrease with the increase of axial stiffness. The reason for this can be explained by Fig. 4. The mode shapes of x1-sym

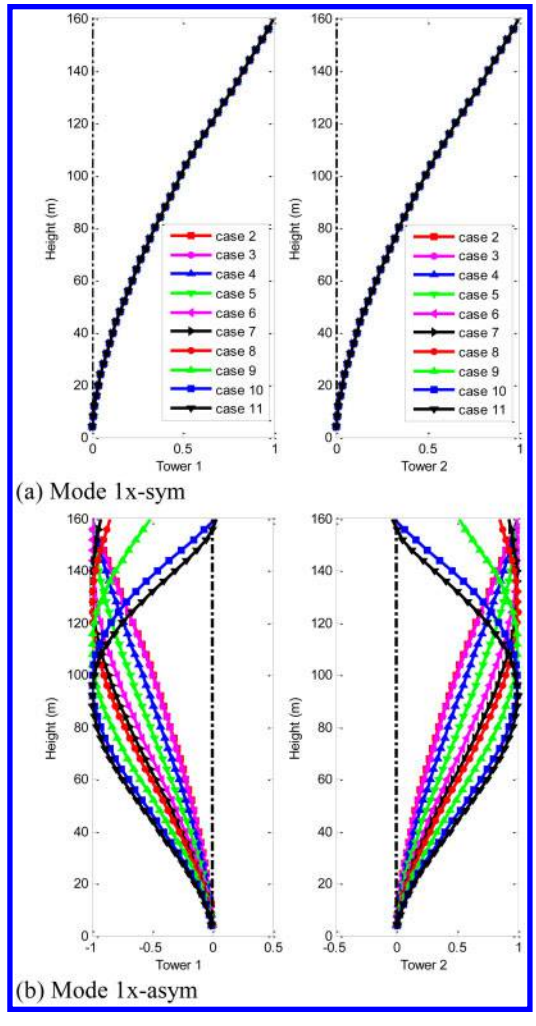

Figure 4. The effect of axial stiffness on mode shapes of the first two modes in x direction.

of two towers are symmetric so that there is no relative deformation between two towers. In other words, the link just sways with tower simultaneously and resultantly, has no effect on mode shape and frequency. For mode x1-asym, however, the mode shapes are antisymmetric so that there is relative deformation between two towers. This relative deformation will make link work as a spring to synchronize the deformation, which leads to the increase of stiffness of total structure and hence decrease the structural periods.

In addition, it should be noted that the axial stiffness has a significant effect on the nonlinearity of antisymmetric mode shape. As can be seen, when the stiffness is relatively small as in cases 2-5, the mode shape can be approximated by a straight line, while with the increase of stiffness, mode shapes of case 7 and 8 show noticeable curvature and for next cases such as 9 and 10, mode shapes already vary from an approximate linear function to a hyperbolic one.

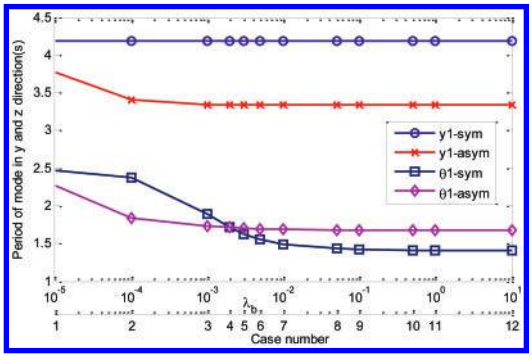

Figure 5. The effect of bending stiffness on periods of the first four modes in y and θ direction.

4.2 *The effect of bending stiffness of link k_b*

Similar to the axial stiffness, bending stiffness of link also can synchronize the motion of two towers in y direction. Moreover, as derived in section 2, this synchronization is coupled in y and θ direction. As the bending stiffness of link can limit the motion in y and θ direction, the modal analysis in these two directions is analyzed simultaneously.

The frequencies and mode shapes of the first 4 modes in y and θ direction are presented in Fig. 5 and 6. Compare to the ones in x direction, the mode shapes are more complicated so that we examine the first four modes one by one.

(1) *The first symmetrical sway mode in y (y1-sym)*
Obviously, the link has no effect on the mode shape and the frequency of this mode as the frequencies of this mode remain unchanged and the mode shapes are identical to a symmetric form in y direction, as shown in Fig. 6a. This is the corollary of symmetrical mode as the link just sways with the two towers and has no effect on structural motion. As a result, there is no coupling between y and θ direction for this mode.

(2) *The first antisymmetric sway mode in y (y1-asym)*
For all cases this mode shows a dominant antisymmetric mode shape in direction y, as shown in Fig. 6b. Apparently, even small bending stiffness of link such as $\lambda_b = 10^{-5}$ in case 1 can bring noticeable torsion motion, which means even small bending stiffness could cause moderate coupling of motion between y and θ for this mode. With the increase of bending stiffness, the natural period shows a trend of decrease from the beginning. However, it hardly goes on dropping once $\lambda_b \geq 10^{-3}$. For each component of mode shapes, Fig. 16b shows that the bending stiffness only has negligible effect on the y component of mode shape, whereas the portion of θ component rises with the bending stiffness from case 1 to case 3, i.e., the bending stiffness will enhance the coupling of motion between y and θ direction of this mode. After case 3, i.e. $\lambda_b \geq 10^{-3}$, however, the mode shape keeps almost identical,

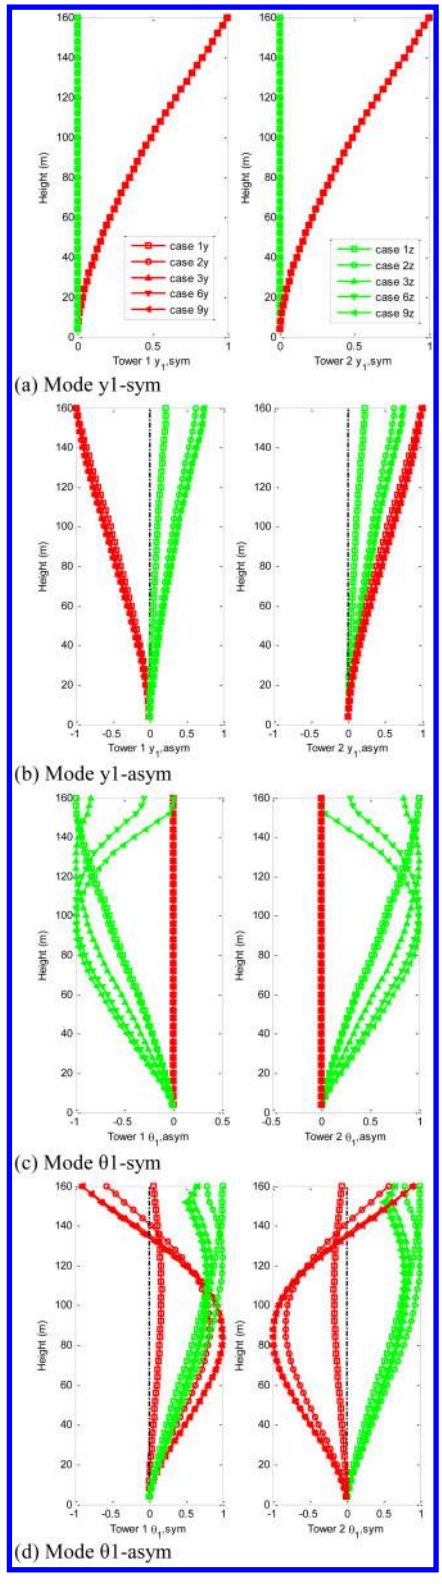

Figure 6. The effect of bending stiffness on mode shapes of the first four modes in y and θ direction.

which means that the additional increase of stiffness will not change the mode shape any more. In addition, even though its proportion will increase with the stiffness, the linearity of θ component hardly varies with the stiffness. We can conclude, therefore, that the bending stiffness will hardly change the linearity of this mode shape, for both y component and θ component

(3) *The first antisymmetric torsion mode in θ (θ1-sym)*

The period of this mode decrease remarkably with the bending stiffness, which means the stiffness can stiffen this mode significantly. For all cases, as can be seen in Fig. 6c, this mode just shows torsional motion in θ direction and the one in y direction is negligible. The reason for this is that antisymmetric torsional motion of two towers will lead to an equivalent symmetrical motion in y direction. Similar to the discussion on above section, link has no effect on symmetrical motion of two towers so that the y component of this mode shape maintain static as shown in Fig. 6c. On the other hand, the bending stiffness does affect the antisymmetric mode shape in θ direction, making it change from a linear form, such as in case 1 and 2, to a hyperbolic form, such as in the case after case 8, with the increase of bending stiffness.

(4) *The first antisymmetric sway mode in θ (θ1-asym)*

The period of this mode decreases dramatically from case 1 to case 3 and afterward, it almost keeps constant with the increase of stiffness. As can be seen in Fig. 6d, this mode shows a dominant symmetric motion in θ direction. With the increase of stiffness, the proportion of motion in y direction increase to a considerable part for the mode. As for the linearity of mode shape, the θ component of mode shape in the case with minor stiffness, such as $\lambda_b = 10^{-3}$ in case 3, is an approximate linear form. With the increase of bending stiffness, the linearity decrease dramatically. The y component of this mode varies more dramatically. It varies from a similar hyperbolic form, e.g. in case 1, to a typical second order mode shape, which shows a change the sign of mode in some elevation of height.

5 CONLUSIONS

A 3-D analytical matrix-form model of linked tall building that can consider varied locations and numbers of links is developed in this paper to investigate the effect of stiffness of link on model properties.

The results of parametric analysis show that although the link hardly shows noticeable effect on the modal properties of symmetrical modes, the periods of antisymmetric mode will decrease with the increase of stiffness of link. Moreover, the mode shape of antisymmetric mode will change remarkably from an approximately linear form to a hyperbolic form, which means that it could be inadvisable to blindly assume linear or power-function form of mode shape.

Composite steel-concrete cable-stayed bridges: Developments and future trends

J.J. Oliveira Pedro
Technical University of Lisbon, Civil Engineer – GRID, Consulting Engineers, Portugal

A.J. Reis
Technical University of Lisbon, Technical Director – GRID, Consulting Engineers, Portugal

ABSTRACT: Composite cable-stayed bridges are elegant and efficient solutions. Today, they are the most adopted solution for 400–600 m span range. Design developments of composite cable-stayed decks are resumed. Particular reference is made to medium-span road and railroad composite decks and to truss decks. Slenderness of the decks, material quantities of stays cables and decks are referred to. Future trends of composite cable-stayed bridges are at last discussed. Particular reference is made to the prospective developments in the field of structural materials, cables, and bridge concepts.

1 DESIGN DEVELOPMENTS

Cable-stayed structures are elegant and efficient solutions for bridges. In the last fifty years the range of these bridges has been steadily increasing and today they are the mostly adopted solution for medium and long-spans, reaching 1000–1200 m spans.

The increase on span required lighter and more resistant deck cross-sections. Steel decks adopting box-girder cross-sections made by orthotropic panels are suitable for very long spans. For cable-stayed bridges with spans up to 600 m, and possibly to 700 m, composite steel-concrete decks may be considered as the most efficient and competitive solution, as confirmed by the variety of composite steel-concrete decks built in the last years (Fig. 1).[1,2,3,4]

1.1 *Design of long-span roadway bridges*

Modern long-span composite decks adopted a simple deck (Fig. 2). Reducing the space between stay-cables, slender lateral main girders directly suspended by closely spaced cables, were feasible. Closely spaced floor-beams provided support for a slender and lighter slab. Deck slenderness, defined as the length/depth ratio of the main span, has been very much increased. Modern designs adopt thin and lighter decks, inducing savings in the deck, cables, piers and foundations. Field bolted splices provided fast and simple connections between almost identical modules, ensuring maximum repetition of pre-fabricated deck components and construction procedures.[3] These concepts have been applied to the majority of composite cable-stayed bridges with main-spans exceeding 200 m, built over the last twenty years by the balanced cantilever construction method.

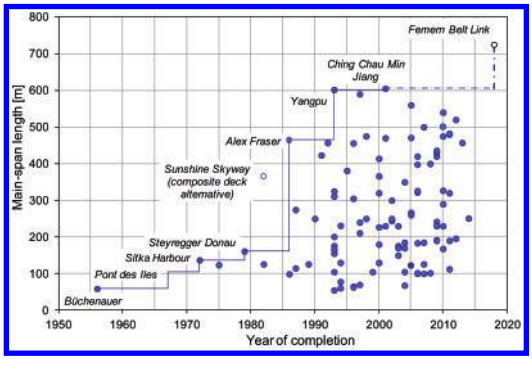

Figure 1. Composite cable-stayed span length evolution.[6]

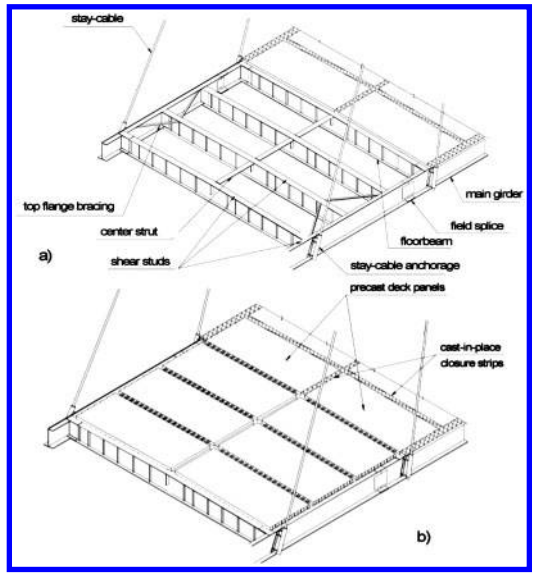

Figure 2. Typical composite cable-stayed decks: a) steel section detail and b) concrete slab executed with precast panels.[5]

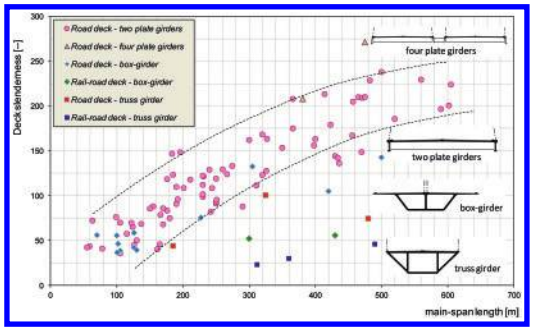

Figure 3. Deck slenderness (main-span length/deck depth) vs. main-span length, for composite cable-stayed bridges.[6]

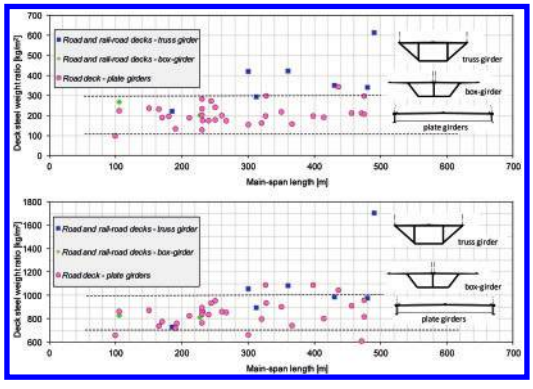

Figure 4. a) Deck steel weight ratio and b) deck self-weight ratio, per square meter of the deck, vs. main-span length.[6]

The study of the main features of road and railway composite cable-stayed bridges built all over the world led to some significant conclusions.[6] With respect to the deck slenderness (Fig. 3):

- For roadway girder decks, values grow up from 75 to 225 with the increasing on span length; slenderness tends to be approximately constant for spans over 500 m long;
- Out of this range, the four-girder deck of the Ting Kau Bridge has a very high slenderness of 271.
- Slenderness of railway decks is much lower, with typical values below 50, due to deformability restrictions imposed by functional requirements.

With respect to the deck self-weight:

- The structural steel weight ratio per square meter of the deck is between 125 kg/m^2 and 300 kg/m^2, with an average value of 213 kg/m^2 (Fig. 4a);
- The average deck self-weight ratio per square meter of the deck is 850 kg/m^2 (considering the weight of the structural steel and of the concrete slab), and typical values are between 700 kg/m^2 and 1000 kg/m^2 (Fig. 4b).

With respect to the stay-cables steel weight:

- steel weight ratio of the stays per square meter of the deck increases with the main-span length, according with the boundaries of stay-cables catalogues[7] for steel, composite and concrete cable-stayed decks (Fig. 5a);
- Plotting in the same graphic the steel weight of the stays per deck square meter, for the composite cable-stayed bridges, results are quite dispersed;
- Railroad decks present always stay's weight ratio much higher than the values recorded for road decks, due to greater deck dead and live loads;
- Assuming a equivalent main-span length for road bridges with an asymmetrical single tower equal to twice the real main-span length (Fig. 5b) stay's steel weight ratios per deck square meter are much better fit;
- A quadratic trend-line is almost over the average line proposed for composite decks with long spans in the stay-cables catalogues[7] (Fig 5b).

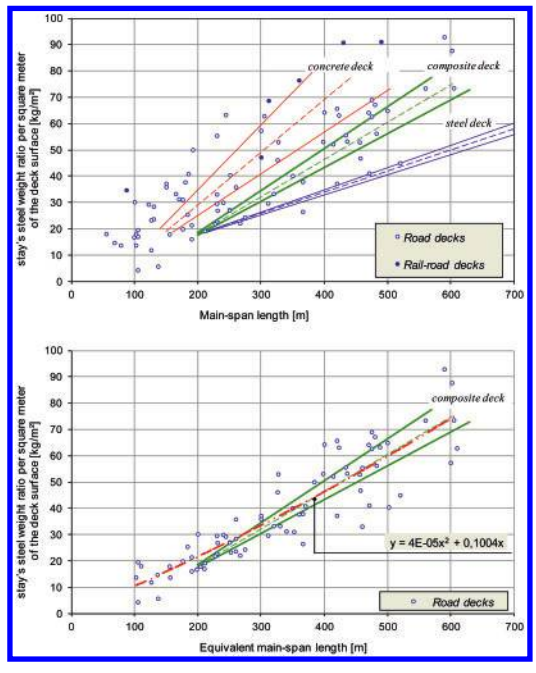

Figure 5. Cables steel weight ratio per square meter of the deck vs. a) main-span length; b) equivalent main-span length.[6]

1.2 *Design of medium-span roadway bridges*

For spans up to 250 m, cable-stayed bridges compete with box-girder bridges and arch bridges, and they are rarely economical for these spans lengths. However, a cable-stayed bridge with slender deck may be desirable in an urban environment for aesthetics or due to difficulties of positioning the deck supports. These aspects may favour the cable-stayed solution, not only in the transposition of rivers and canals, but also on very wide road and railways. Other factors supporting a cable-stayed solution are: 1) aesthetic due to transparency of the structure, resulting from the reduction on the number of piers and increased slenderness of the deck, and 2) reduction the traffic constraints during the execution.

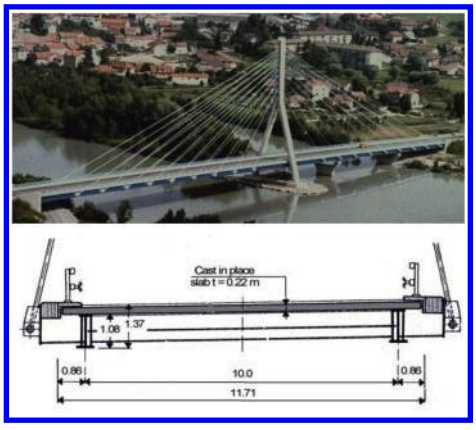

Figure 6. Seyssel Bridge, France.[10].

For medium-spans the usual symmetric cable-stayed layout with a three-span straight deck and two towers, is not very often the best solution. Asymmetric solutions with a single tower or with a curved deck may be more appropriate to overcome local and environment constraints.[8]

Design of medium-span composite cable-stayed bridges has allowed simple deck solutions erected by fast construction methods, like decks composed by two plate girders lateral suspended. The concrete slab on the top is still supported by closed spaced floor-beams, like the Saint-Maurice Bridge (Switzerland, 1986) and the Seyssel Bridge (France, 1987, Fig. 6). Built in the end of the eighties, these two bridges have a structural asymmetric layout. The first bridge consisting of two decks located at the exit of tunnels, with the towers built over the tunnels and suspending 99 m long spans, with two planes of three stays, 24 m apart at the deck level.[9] The second bridge has a more classical configuration, with a single tower suspending a 115 m long main-span and three side spans of 35.2 m, with two plans of nine stays at each side.[10]

Decks with lateral suspension have nevertheless a major drawback, due to the visual impact of two plans of stays. The axial suspension of the deck improves aesthetics but requires a deck with higher torsional rigidity, namely a box-girder cross-section. The Arena Viaduct[11] (Spain, 1993, Fig. 7), with five 105 m inner spans, and the Alzette River Bridge[12] (Luxembourg, 1994, Fig. 8), with two side spans 130 m long, are good examples of medium-span cable-stayed bridges in an in-plan curved road alignment, with an axial suspension.

The Arena cable-stayed deck was built using an unusual method. Each span was fully executed on the ground, including concreting the slab, and raised up to a height of 30 m by lifting deck segments of around 2600 tons. Each span was then welded to the previous one. Only after erecting all the deck, the steel masts were put in place and the six axial stays were installed on each side of the masts.[11]

Balanced cantilever construction method leads normally to longer construction time. For medium-span

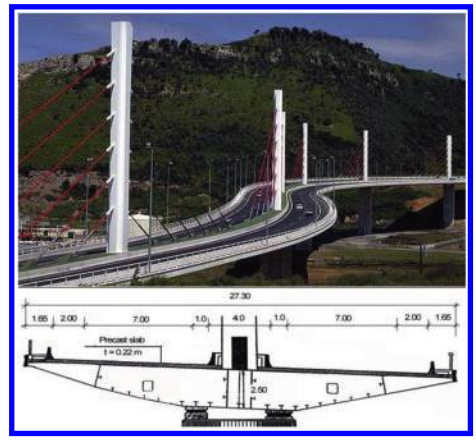

Figure 7. Arena Viaduct, Spain.[11].

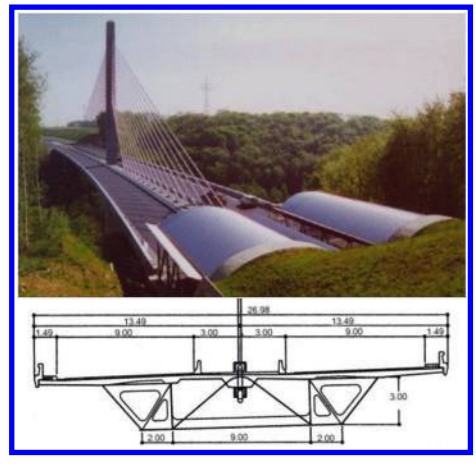

Figure 8. Alzette River Bridge, Luxemburg.[12].

bridges incremental launching or erection by cranes and temporary supports has been used, as in the Seyssel and Alzette River Bridges; the steel decks were launched using temporary supports, and the slabs were casted-in-place using mobile formworks supported on the steel structures.

A special reference should also be made to several medium-span cable-stayed bridges built by the incremental launching method in Finland, as the Tähtiniemi and Utsjoki Bridges, with main-spans of 165 m 155 m. The same method was used in the particular asymmetric Kemijoki Bridge (Fig. 9) with a composite box-girder deck with inclined struts supporting the cantilevers, and a 126 m main-span suspended by two axial plans of stays.[13]

1.3 *Design of composite cable-stayed truss decks*

The design of cable-stayed bridges with composite truss decks allows superstructures to be lighter than traditional prestressed concrete box-girders and less deformable than steel or composite plate girder decks. By anchoring the stays at the top slab level, the

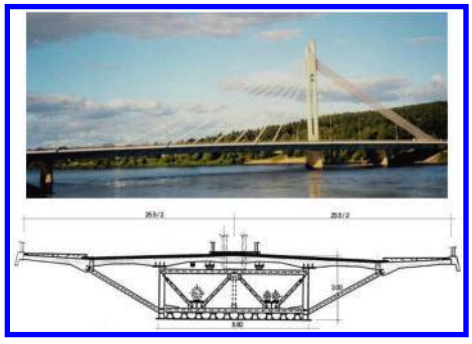

Figure 9. Kemijoki Bridge, Finland.[13].

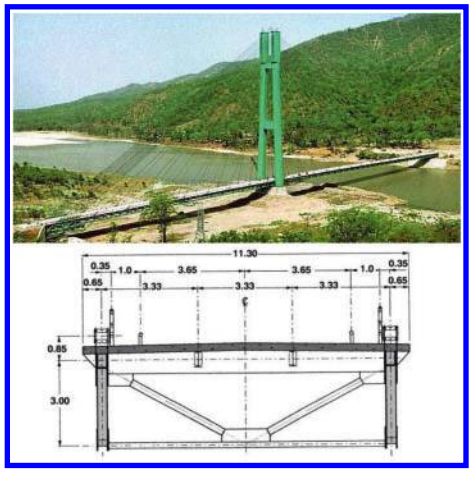

Figure 10. Karnali Bridge, Nepal.[14]

stays horizontal compression component is transmitted directly to the slab, since the truss girders are relatively flexible in the longitudinal direction compared to the axial rigidity of the slab. This feature of the deck is actually important for a composite deck, since it reduces the effects of shrinkage and creep of the concrete slab, as in the longitudinal direction each lattice girder acts as a "harmonium", allowing the deformations and reducing internal forces due to time dependent effects.

Karnali Bridge [14] (Nepal, 1993, Fig. 10) was the first cable-stayed road bridge with a composite truss deck. This outstanding structure has a 325 m lateral span, suspended by a single tower (deck slenderness approximately 100). To reduce deck deformability two lattices Warren girders 3 m deep were adopted.[14]

For rail and railroad bridges, a stiff deck is needed to ensure train's operation requirements. Truss girder decks are widely adopted in suspension bridges and in some cable-stayed bridges. In particular, composite steel-concrete truss decks combine high stiffness with relative low weight, using the concrete slabs to provide the proper circulation platforms. Composite truss decks were adopted in the Øresund Bridge (between Sweden and Denmark, 2000, Fig. 11), and more

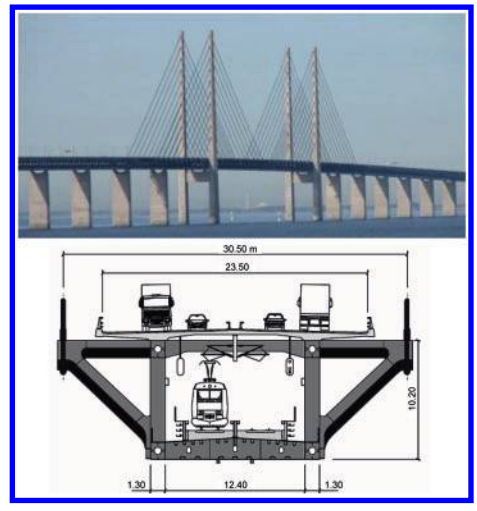

Figure 11. Øresund Bridge, Sweden/Denmark.[15]

recently in the Mercosur Bridge, over the Orinoco River (Venezuela, 2011).

The 490 m span Øresund Bridge,[15] adopted a deck with two vertical steel trusses, with a concrete slab on the top for the roadway. At the bottom level, a continuous orthotropic steel deck supports two ballast boxes for high-speed lines. The construction used deck steel segments pre-fabricated in Spain and transported by ship to Sweden, where the slab was pre-casted. Handling operations of these elements, 120 m to 140 m long, and weighting up to 6200 tons, were carried out with a crane mounted on a barge. Deck segments were placed on temporary supports and welded. Later, the stays were installed and temporary supports were removed to new positions.[16]

The 360 m long span Mercosur railroad Bridge[17] adopted also a composite steel-concrete Warren truss girder deck, with 10 m between truss joints, and upper and lower cross-beams 3.33 m apart. However, unlike the other examples, axial suspension was adopted, with two planes of stay-cables 0.80 m apart, and the deck steel framing of the side spans were erected by incremental launching. Afterwards, the concrete slab was casted in place and stays were installed and tensioned. The 120 m steel central part of the main-span, weighting 2400 tons, was then lifted from a barge by four strand jacks located on the existing cantilevers. The main-span slab was finally poured in several steps.[17] These two decks are relatively deep, with steel structures 10.2 m and 11.6 m height, which correspond to slenderness of only 48 and 28. Additionally, the self-weight and structural steel of these decks are higher than the values for double plate girder road composite decks (Fig. 4a).

But, all these bridges adopted longitudinal trusses with vertical diagonals. Three-dimensional tubular diagonals can also be used, as it was first done in the Europa Bridge[18] (Portugal, 2004, Fig. 12). This highway deck, with a 186 m long main-span, is axially suspended by two plans of stays fixed to a single mast

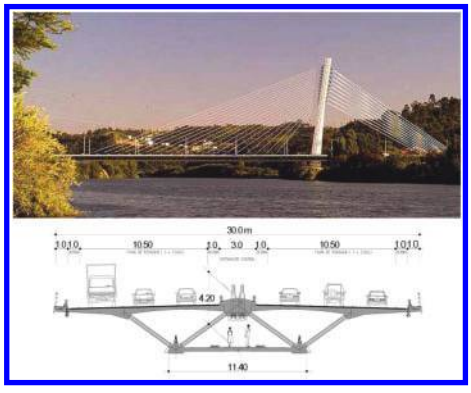

Figure 12. Europa Bridge, Portugal.[18].

located on the left bank of the river. The mast inclined 8° towards the side spans is retained by two layers of backstays externally anchored to the transition pier blocks. The specificity of this composite deck truss, with steel tube diagonals, comes not only from the steel elements joints to the concrete slabs, but also from shear deformability and effects of local concentrated bending moments introduced on the slab at the joints. The deck is a 3D composite truss 4.2 m deep and 30 m wide, made of high strength steel tubes with joints spaced at 3.75 m, and two concrete slabs prestressed in the transversal and longitudinal directions.

Steel plates enclosed by reinforced concrete were used at the upper truss nodes. These plates not only transfer the vertical forces from the slabs, but also balance the forces between the diagonal tubes that converge on the node, and transmit the horizontal forces to the concrete slabs. On the lower node between 3.75 m long segments, two "teeth" plates were used, perfectly matched to each other, to ensure the direct transmission of vertical and horizontal internal forces. The bridge deck was designed to be executed with precast segments with the pre-casting yard located on the left bank, and the precast segments (3.75 m length), weighing up to 150 tons, transported in the river by a barge, were lifted vertically to the deck. After deck assembling and longitudinal prestressing applied, the overhangs of the deck slab were cast in-place and a second phase of transversal pre-stressing was applied.

2 FUTURE TRENDS

2.1 *In the field of materials*

The use of precast slab panels with concrete strengths up to 70 to 100 MPa is gradually increasing for very long-span composite cable-stayed bridges. To reduce weight ribbed slab sections between floor-beams have been recently adopted.[1] Lightweight aggregate concrete (LWAC) was also used in at least one composite cable-stayed deck. The *Grenland* Bridge (Norway, 1996) adopted slabs of LWAC in the 305 m long main-span.[19]

The use of steel grades S420 and S460 has much increased in recent years. New steels allow the design of steel girders, floor-beams and stay anchors more compact and with thinner plates. However, the use of these steels has no significant advantage for fatigue resistance. The recent introduction of even higher steel grades in bridge construction, such as the S690 and S700, may be explored in the future.[20]

2.2 *In the field of cables*

Cables made of CFRP have been proposed to reduce weight and diameter, as they combine very high resistance with a self-weight lower than steel. However, their time dependant behaviour is still not well known, axial deformability is much higher, and CFRP stay-cables are costly compared to steel stays.

Cable forces in service are usually limited to 45% of its ultimate guaranteed resistant strength (FGUT). Few solid justifications have been given to continue using this limit, imposed to prevent the negative consequences of the fatigue stresses, and the local bending stresses in the anchorage of the first large-diameter stay-cables. For a characteristic combination of loads, the Eurocode 3, part 1-11 allows cable forces up to 50% of FGUT, if vibration damping devices are adopted at anchorages. In addition, during cables installation, the first strands may have installed forces up to 60% FGUT, provided after stressing the remaining strands of a cable work in the limit of 55% FGUT.

The assessment of stay-cable fatigue stresses needs also to be carried out for the service conditions (considering both the axial stresses and the bending stresses near the anchorages, due to angular deviations caused by catenary effects, wind forces and erection imperfections). The French recommendations[21] propose a simple method valid for road bridges, limiting the cables axial stress variation to 70 MPa for the passage of the fatigue vehicle LM3 of the Eurocode 1-Part 2.

2.3 *In the field of design*

In the field of design of composite steel-concrete cable-stayed bridges several new solutions have been recorded over the years, in some cases only with architectural aspects, but in other cases technically innovative. Both types of developments are important, since the public interest in cable-stayed bridges is, to a large extent, also a result of its high aesthetics quality. The recent *Boyne* and *Suir River* Bridges (Ireland, 2003 and 2009), *Sirhowy River* Bridge (Wales, 2005), *Berliner* Bridge (Germany, 2005), *Alcide de Gasperi* Bridge (Italy, 2005) and *Korabelny* Bridge (Russia, 2011), are good examples of medium-span composite cable-stayed bridges, following these principles. New bridges of the same type, such as the *Signature* Bridge (India, 2014), are under construction or being designed.

In the field of rail and railroad decks, composite solutions can also play an important role. In the future, this is certainly an area of composite cable-stayed bridge developments, as shown by the recent

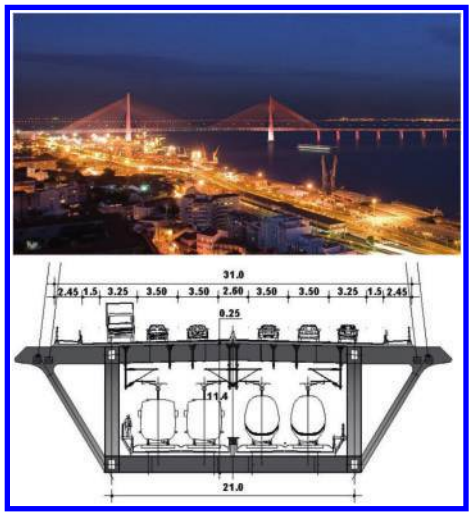

Figure 13. Preview of the Third Tagus River Crossing Bridge, in Lisbon.[22,23].

studies for the *Third Tagus River Crossing* Bridge in Lisbon[22,23] (Fig. 13), as well for the bridge connecting the *Fehmern Belt*[24] between Germany and Denmark (Fig. 14).

Analysis of steel and steel-concrete bridge girders through a higher order beam model

R.F. Vieira, F.B. Virtuoso & E.B.R. Pereira
Department of Civil Engineering, Architecture and Georesources, Instituto Superior Técnico, Universidade Técnica de Lisboa

ABSTRACT: The three-dimensional analysis of steel and composite steel-concrete bridges in practice engineering is usual performed using shell finite element models. Although these models allow to accurately consider a broad range of structural phenomena: geometric and material nonlinearities, non-linear dynamic and static analysis, the analysis of results becomes cumbersome, being also difficult to separate structural phenomena. A higher order beam model with the displacement field properly enriched to capture three-dimensional effects is presented in this paper as an alternative to shell finite elements. The higher order beam model considers the corresponding displacement field to be defined by a set of linear independent approximation functions defined over the cross-section. A consistent criterion for uncoupling the beam deformation modes based on a non-linear eigenvalue problem is adopted in order to render the model âŁœusableâŁž from an engineering perspective, allowing the definition of uncoupled higher order modes of the cross-section, e. g. cross-section warping and distortion. The presented higher order beam model is applied to the static and dynamic analysis of bridges, focusing on the cross-section warping behaviour and on the linear stability phenomena involving local and global buckling modes.

1 INTRODUCTION

The use of thin-walled beam models are successful alternatives for the analysis of bridges despite the widespread use of an increasingly finite element technology.

In fact, several beam models that include the classic cross-section deformation modes of warping, shear-lag and distorsion have been applied to bridge analysis, (Maisel 1982, Boswell & Zhang 1984, Kermani & Waldron 1993). Moreover, towards a more accurate representation of the cross-section three-dimensional structural behaviour, cross-section deformation modes of higher order were considered through a refinement of the beam displacement field approximation over the cross-section, (Paavola 1990, Razaqpur & Li 1991, Tesar 1996, Bogensperger 2000). However, the criteria for the definition of such deformation modes is dependent on *ab-initio* cross-section structural hypotheses, narrowing the applicability of the corresponding beam models.

The Generalised Beam Theory developed by (Schardt 1989) which has been further extended through additional formulations, (Möller 1982, Dinis, Camotim, & Silvestre 2006) to consider more general cross-sections and surpass some initial restrictions has been successfully applied to the analysis of stability phenomena and also to the analysis of bridges, (Schrade 2010).

A thin-walled higher order beam model to the analysis of steel and composite steel-concrete bridges is presented in this paper. This higher order beam model is properly enriched through a representative set of orthogonal displacement modes, which are obtained from a non-linear eigenvalue problem in order to represent the thin-walled structural behaviour.

The model has the advantage of providing a clear understanding and an adequate consideration of the structural phenomena involved, due to its uncoupling modal characteristic, benefitting from the simplicity of a one-dimensional model.

The higher order thin-walled beam model is applied to (i) the static analysis of a steel bridge girder by including appropriate higher order deformation modes; (ii) a linear stability analysis considering local and global buckling modes and (iii) the dynamic analysis of a bridge girder submitted to an eccentric moving load including the cross-section warping.

2 HIGHER ORDER THIN-WALLED BEAM FORMULATION

The thin-walled structural behaviour is obtained through the reduction of the corresponding three-dimensional elasticity formulation to a set of one-dimensional equilibrium equations written in terms of the displacement field **u** as follows:

$$\mathbb{D}\,\mathbf{C}\,\mathbb{D}^{*}\,\mathbf{u} + \mathbf{p} - \rho\ddot{\mathbf{u}} = 0 \qquad (1)$$

where $\mathbb{D}$ and $\mathbb{D}^{*}$ represent, respectively, the equilibrium and the compatibility differential operators, **p** represents the load vector and ρ the mass density.

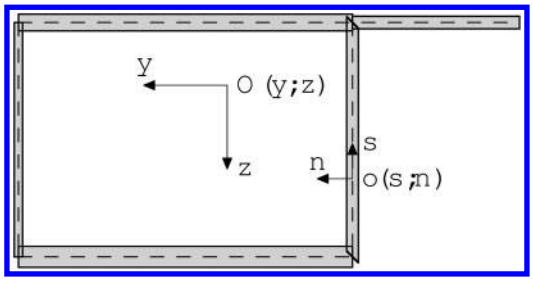

Figure 1. Approximation functions for a cross-section element.

The cross-section layout considered in this formulation corresponds to a set of rectilinear wall segments forming a generic shape, being considered to have both a flexural and a membrane structural behaviour. For the flexural behaviour, it is assumed that the elements are sufficiently "thin" in order to consider valid the *Kirchhoff* formulation and hence neglect the shear deformation on the planes perpendicular to the middle surface.

For an accurate representation of the cross-section structural mechanics the displacement field is approximated by a set of linearly independent functions defined over the thin-walled cross-section as follows:

$$\mathbf{u} = \mathbf{B}(s,n)\,\tilde{\mathbf{u}}(x) \tag{2}$$

where $\mathbf{u} = [u_x,\ u_s,\ u_n]^t$ and $\tilde{\mathbf{u}}(x) = [\tilde{\mathbf{u}}_x,\ \tilde{\mathbf{u}}_s,\ \tilde{\mathbf{u}}_n]^t$, being adopted the reference frame $O(x,s,n)$ represented in Fig. 2.

The approximation functions are defined in matrix $\mathbf{B}(s,n) = \mathbf{B}_0(s,n) + \mathbf{B}_1(s,n)\,\partial_x$ where $\mathbf{B}_0$ and $\mathbf{B}_1$ are given by:

$$\mathbf{B}_0(s,n) = \begin{bmatrix} \boldsymbol{\phi}^t & \cdot & \cdot \\ \cdot & \boldsymbol{\psi}^t & -n\boldsymbol{\chi}^t_{,s} \\ \cdot & \cdot & \boldsymbol{\chi}^t \end{bmatrix} \tag{3}$$

$$\mathbf{B}_1(s,n) = \begin{bmatrix} \cdot & \cdot & -n\boldsymbol{\chi}^t \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \end{bmatrix} \tag{4}$$

The vector subscript $(,s)$ stands for the component derivatives in the variable s and ∂_x represents the derivative of the corresponding components in the axial direction (d/dx).

The displacement field of the cross-section middle surface is thus approximated in the three spatial directions (x,s,n) through sets of approximation functions, $\boldsymbol{\phi}$, $\boldsymbol{\psi}$ and $\boldsymbol{\chi}$, respectively, which can globally (at a section level) be defined as follows:

$$\begin{aligned} \boldsymbol{\phi}^t &= [\phi_1(s),\cdots\phi_p(s)],\ \mathbf{u}_x = [u_{x1}(x),\cdots u_{xp}(x)]^t \\ \boldsymbol{\psi}^t &= [\psi_1(s),\cdots\psi_q(s)],\ \mathbf{u}_s = [u_{s1}(x),\cdots u_{sq}(x)]^t \\ \boldsymbol{\chi}^t &= [\chi_1(s),\cdots\chi_r(s)],\ \mathbf{u}_n = [u_{n1}(x),\cdots u_{nr}(x)]^t \end{aligned} \tag{5}$$

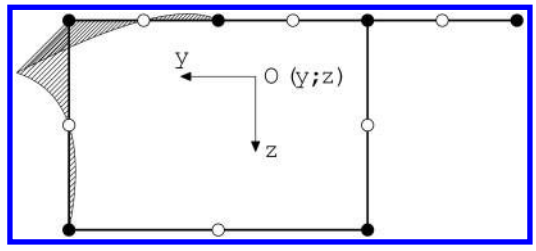

Figure 2. Approximation functions for a cross-section element.

with p, q, and r degrees of freedom for the x, s and n direction, respectively. The corresponding amplitudes are the unknowns $\mathbf{u}_x$, $\mathbf{u}_s$ and $\mathbf{u}_n$.

In order to properly capture the three-dimensional behaviour of thin-walled structures, the approximation can be refined either by increasing the degree of the approximation functions or by increasing the discretization at a cross-section level. A quadratic function for the axial displacement is represented in figure 2.

Substituting the displacement field approximation (2) into the equilibrium equations defined in equation (1) and weighting the result by the same approximation functions, the following one-dimensional equilibrium equation is obtained:

$$\int_A \mathbf{B}^t \left(\mathbb{D}\,\mathbf{C}\,\mathbb{D}^*\,\mathbf{B}\tilde{\mathbf{u}}(x) + \mathbf{p} - \rho\mathbf{B}\,\ddot{\tilde{\mathbf{u}}}(x)\,dA \right) = 0 \tag{6}$$

Considering the differential operator $\mathbb{D}$ decomposed into one part defining transverse derivatives and other defining a derivative along the beam axis and performing the integration of Eq. (6) over the cross-section, the following beam governing equations are obtained,

$$\mathbb{K}_4\,\partial_x^4\mathbf{u} + \mathbb{K}_2\,\partial_x^2\mathbf{u} + \mathbb{K}_1\,\partial_x\mathbf{u} + \mathbb{K}_0\,\mathbf{u} - \mathbb{M}\,\ddot{\mathbf{u}} = 0 \tag{7}$$

where the coefficient matrices $\mathbb{K}_4$, $\mathbb{K}_2$ $\mathbb{K}_1$ and $\mathbb{K}_0$ are defined in (Vieira 2010).

The analysis of the three-dimensional behaviour of thin-walled structures through the higher order beam model can be enhanced by refining the displacement field projection. However, if the resulting governing equations are not properly uncoupled, the result is a tangled set of equations that, despite representing the elasticity formulation of the problem, do not allow a clear physical interpretation of the structural phenomenon. The procedure of uncoupling is therefore essential to the usability of the higher order beam model.

A concept of uncoupling has been put forward in (Vieira 2010, Vieira, Virtuoso, & Pereira 2013) by considering the eigenvalue problem associated with the differential equations of the model, Eq. (7). A set of uncoupled deformation modes is obtained from the eigenvectors, retrieving the classic theories and defining deformation of higher order.

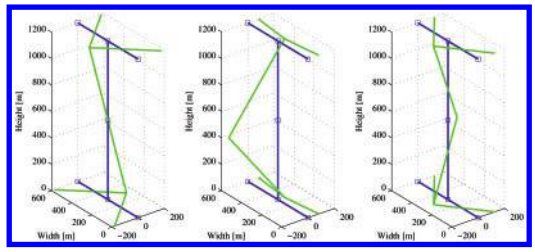

Figure 3. I section out-of-plane higher order modes.

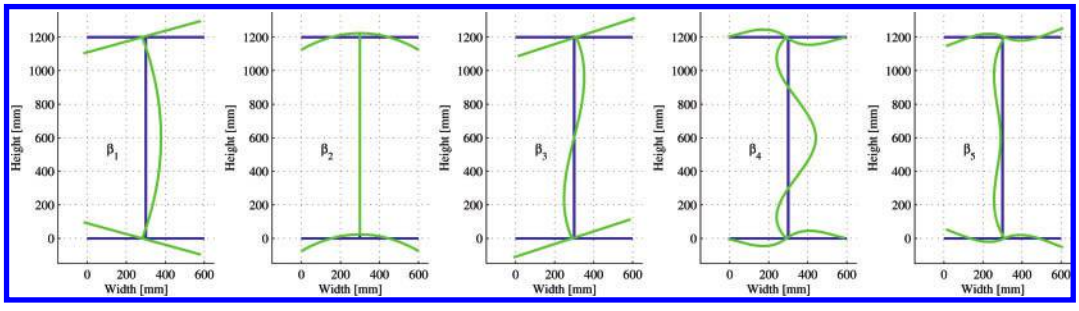

Figure 4. I section in-plane higher order modes.

3 APPLICATIONS TO BRIDGE ANALYSIS

The higher order thin-walled beam model is applied to the static and dynamic analyses of a bridge girder, highlighting its applicability in reproducing the three dimensional structural behaviour.

3.1 *Cross-section higher order modes*

The cross-section analysis towards the definition of uncoupled deformation modes is a key feature of the beam model. The cross-section analysis of a steel plated beam (I shaped) having a web with dimensions $1200 \times 20\,mm^2$ and equal flanges of dimensions $600 \times 50\,mm^2$ is performed. The cross-section is divided into 6 elements (two elements per flange and two elements for the web), being the displacement field for each element approximated by linear Lagrange functions for the thin-walled in-plane displacements and by Hermite functions for the displacements normal to the thin-wall middle surface. The displacement modes obtained from the eigenvalue uncoupling procedure are depicted in figures 3 and 4 for the out-of-plane and in-plane components (β_1 to β_4), respectively.

3.2 *Static analysis*

A cantilever beam with $5\,m$ long subjected to an eccentric tip load of $100\,kN$, which is represented in figure 5 is analysed. The displacement modes of the cross-section are represented by the orthogonal modes defined by the warping modes represented in figures 3, being the transverse deformation of the cross-section neglected. A numerical solution for the beam model

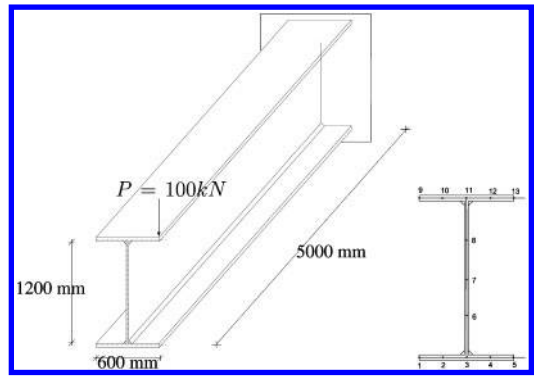

Figure 5. Steel cantilever beam.

was obtained within the framework of the finite element method by approximating the amplitudes of the displacement modes.

The beam stress field is computed taking in account the modal amplitudes distributions obtained and the corresponding deformation modes. The stress components are evaluated in a mesh of sampling points, being represented in figure 6 the membrane axial stresses at the beam upper flange; these stresses have maximums at the full fixed support, decaying along the beam axis towards its free end.

A comparison between the developed thin-walled beam model and a shell finite element model implemented in (Abaqus 2006) was performed, being verified a satisfactorily agreement of results both in terms of displacements and stresses.

The longitudinal distribution of the thin-walled middle surface stresses are plotted for the bottom

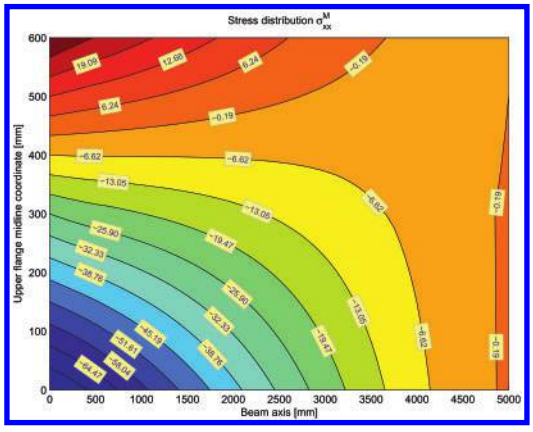

Figure 6. Steel plated I section, stresses in upper flange.

flange and for the axial component in figure 7 (alignments corresponding to nodes 1, 3 and 5 represented in figure 5.

The stresses obtained from classic theory were also compared with the stresses obtained through the higher order model (TW-model) and from Abaqus, being the corresponding results presented in table (1) and (2).

3.3 *Buckling analysis*

The linear governing equations for a configuration that is "disturbed" from the fundamental path are obtained

Table 2. Membrane stress comparison, $\sigma_{xx}^{M}, (N/mm^2)$.

	node 6		
(mm)	TW-model	Abaqus	Classic theory
0	3.12	2.87

2500	3.37	3.51	3.21
3750	3.69	3.73	
5000	0.29	−0.04	

by considering the contribution of the corresponding non-linear geometric terms in addition to the equilibrium defined by Eq. (7), being the resulting equation written as follows,

$$\mathbb{K}_4\,\tilde{\mathbf{u}}'''' + \left(\mathbb{K}_2 - \mathbb{K}_2^G\right)\tilde{\mathbf{u}}'' + \left(\mathbb{K}_1 + \mathbb{K}_1^G\right)\tilde{\mathbf{u}}' + \mathbb{K}_0\,\tilde{\mathbf{u}} = 0 \quad (8)$$

where $\mathbb{K}_2^G$ and $\mathbb{K}_1^G$ represent geometric matrices.

A linear buckling analysis is performed through the solution of Eq. (8) towards the evaluation of the corresponding bifurcation loads by making use of the beam model uncoupling criteria. To this purpose Eq. (8) is rewritten in the orthogonal displacement modes, allowing to identify the thin-walled structural behaviour, in particular the buckling modes "activated" by the applied loads through the corresponding fundamental path; in fact, the geometric matrices remain coupled in the orthogonal modes, which allows to identify for each buckling phenomenon the involved cross-section displacement modes.

The buckling modes are therefore defined through linear combinations of orthogonal displacement modes of the cross-section. The bifurcation loads corresponding to either global or local buckling modes are obtained from (8) by considering a suitable selection of displacement modes for the cross-section.

A linear stability analysis of an element with an I shaped cross-section submitted to a uniform compressive stress is presented. The displacement basis functions that correspond to the cross section rotations, translations and out-of-plane warping are considered for the global stability analysis, whereas the in-plane distortional displacement modes represented in figure 4 are considered for the local stability analysis.

The analysis of the linear stability equations allows to conclude that the transverse distortion, β_1, is coupled with the flexure along the cross-section weak axis through the corresponding transverse displacement, v, and to the web flexure mode, β_4 of an higher eigenvalue. Hence for a local buckling analysis, the in-plane distortional mode is defined as follows,

$$\mathbf{u}_{LB_1} = \begin{bmatrix} v & \beta_1 & \beta_4 \end{bmatrix}^t \quad (9)$$

Rewriting Eq. (8) for the displacement modes defined by Eq. (9) and considering a solution of

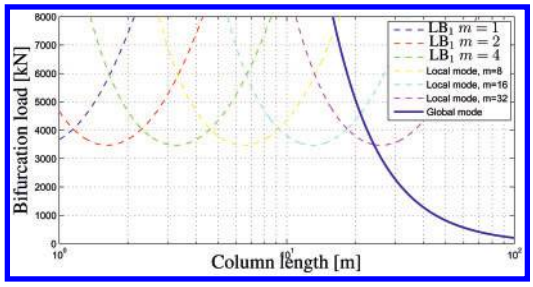

Figure 8. I section, distortional buckling mode, analytical model.

trigonometric functions with the same wavelength for all modes, which is a commonly adopted hypothesis for local buckling modes, (Allen & Bulson 1980), the buckling load is obtained through the solution of the following eigenvalue problem,

$$(\mathcal{K}_{LB_1} - P\mathcal{K}_G)\,\mathbf{u}_{0,LB_1} = \mathbf{0} \tag{10}$$

where the matrices $\mathcal{K}_{LB_1}$ and $\mathcal{K}_G$ are given as follows,

$$\mathcal{K}_{LB_1} = \mathbf{K}_{4,LB_1}(m\pi/L)^4 + \mathbf{K}_{2,LB_1}(m\pi/L)^2 + \mathbf{K}_{0,LB_1} \tag{11}$$

$$\mathcal{K}_{G_{LB_1}} = (\mathbf{K}_{G_1,LB_1} + \mathbf{K}_{G_2,LB_1})(m\pi/L)^2 \tag{12}$$

The bifurcation loads for the distortional buckling of the I section are plotted in figure 8 for several half-length waves. The minimum bifurcation load obtained for the local buckling is almost a constant value for different half lengths, $P_{cr} \cong 3470\,kN$.

The buckling analysis that considers the interaction between the local and the flexural mode that corresponds to the rotation around the y axis is performed by considering

$$\mathbf{u}_{FL+LB_1} = [\ \theta_y \quad v \quad \beta_1 \quad \beta_4\ ]^t \tag{13}$$

The linear stability equations are written for the degrees of freedom defined in 13, considering a solution of trignometric terms with the same wavelength for the global and the local buckling mode. The bifurcation loads for the interaction of flexural and local buckling modes are represented in figure 9.

A numerical stability analysis considering a finite element formulation for the higher order thin-walled beam model is performed in order to consider the possibility of different wavelengths for the local and global buckling mode. The finite element model considers all of the orthogonal modes defined by the eigenvalue analysis for the cross section displacement modes.

The bifurcation loads obtained numerically from the finite element model are represented in figure 10, being compared with: (i) the analytical results obtained from Eq. (10) and (ii) the results obtained from a linear

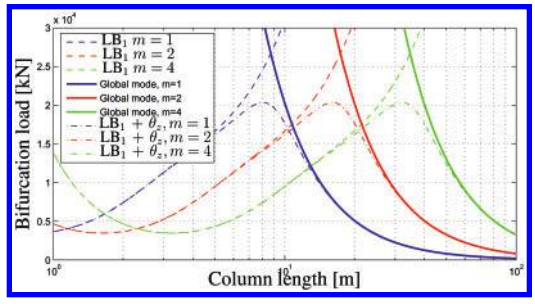

Figure 9. I section, distortional buckling mode, analytical model.

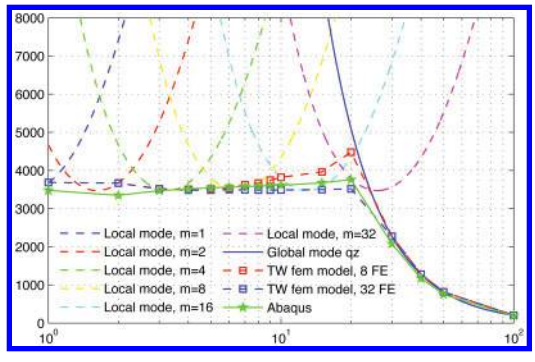

Figure 10. I section, global and distortional buckling modes; comparison between analytical and numerical model and .

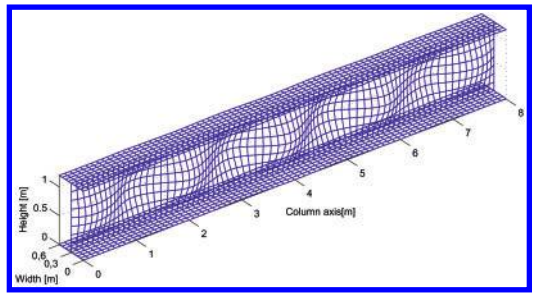

Figure 11. Buckling mode obtained from one-dimensional fem, $L = 8000\,mm$.

buckling analysis of a three-dimensional shell finite element performed in (Abaqus 2006). The results obtained either analytical or numerically through the proposed formulation are in a good agreement with the results obtained from (Abaqus 2006).

The buckling mode obtained from the one dimensional finite element model is represented in figure 11.

3.4 *Dynamic analysis*

The thin-walled beam model is applied to the dynamic analysis of a 3 span continuous bridge girder, with spans of 30m+40m+30m and a double T cross-section, submitted to an eccentric load $e = 2.5\,m$ as represented in figure 12.

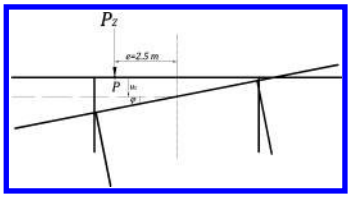

Figure 12. Sketch of the point P for the double-T section.

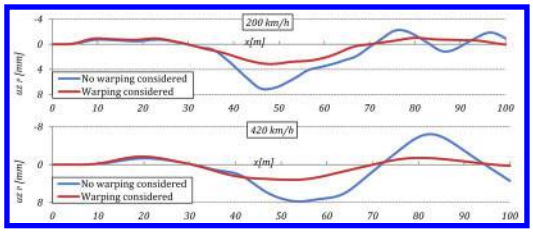

Figure 13. Dynamic influence line of the displacement u_z^P.

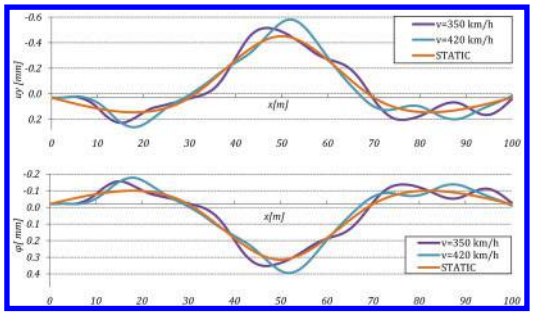

Figure 14. Comparison of static and dynamic influence lines of the displacement φ.

The dynamic influence line of the vertical displacement of point P is represented in figure 13 for the velocity of 200 km/h and 400 km/h, with $P_z = 1000\,kN$. The cross-section warping is considered in the analysis, being its influence evaluated through the vertical displacement of the cross-section; the relevance of the warping stiffness in evaluating the dynamic displacements for cross-sections with an open profile is highlighted by the results obtained.

The dynamic amplification of the displacement was evaluated by comparing the vertical displacement of the central mid-span obtained from a static and a dynamic analysis. The dynamic influence lines for the displacements u_y and φ of the cross-section are represented and compared with the static displacements in figure 14; the amplification factors obtained for the transverse displacement and torsion of the cross-section for a velocity of 350 km/h are respectively 1.13 and 1.11 and for a velocity of 420 km/h 1.24 and 1.27

Notice that a maximum train speed of 350 km/h corresponds to a design speed of 420 km/h, being the dynamic increment related to this speed quantified as 24% and 27%, for u_y and φ, respectively.

4 CONCLUSIONS

A higher order thin-walled beam model applied to the analysis of a bridge girder was presented. The model relies on the approximation of the displacement field over the cross-section by a set of linearly independent basis functions to accurately represents the three-dimensional behaviour of thin-walled structures.

The model has successfully represented the structural behaviour of a bridge girder both in static and in a dynamic analysis; the comparison with the results obtained from a shell finite model was sufficiently accurate.

The beam model is therefore considered a possible method of analysis for bridge girders, having the advantage of enhancing the interpretation of the structural phenomena involved due to its modal characteristic.

Full-scale testing of concrete deck slabs under fatigue-causing axle loads

G. Borkowski, K. Thoma & P. Roos
Lucerne University of Applied Sciences and Arts – Competence Centre Structural Engineering, Horw, Switzerland

ABSTRACT: The conservation of existing structures including maintenance, assessment and, if necessary, strengthening is a current challenge for engineers. For the evaluation of the load carrying capacity and the remaining service life, detailed knowledge of the load bearing behavior especially due to proceeding fatigue damage is required. In this paper, concrete deck slabs of hollow box girder bridges subjected to vehicle axle loads are examined.

The paper presents first test results from a large-scale experiment on a concrete deck slab specimen under cyclic loading. The test specimen has a span of 12m and a width of almost 6m. The axle loads (Swiss Code loads) are simulated using three hydraulic cylinders, which act one after another. First, the experimental procedure is presented. Second, the experimentally determined bending moments, strains and curvatures in the deck slab are shown. These results are calculated with an in-house software tool and they are compared with results from a 3D FE-Model based on nonlinear material behavior.

Finally, it is discussed how the load bearing behavior of the deck slab changes due to proceeding fatigue damage in the structure. This research project aims at contributing towards a better judgment of whether the service life of a bridge can be reached or strengthening is necessary.

1 INTRODUCTION

1.1 *Initial Situation*

The construction of prestressed concrete bridges started in the 1940s and reached its peak in the 1960s. By that time, the need for new bridges was increasing and the prestressing technology was extensively being taken advantage of. Today, increasing traffic loads and serious durability problems require regular inspections of the bridges. Since the planned service life of most of these bridges has not been reached, it is often more economical to maintain and strengthen, rather than replace them.

In 2009 a study on segmental bridges built between 1958 and 1976 was published (Buschmayer, W. et al. 2009). The study shows that almost 90% of the reviewed bridges exhibited cracks or damaged coupling joints and strengthening would be necessary. The question arises whether global or local strengthening of such bridges is really necessary or whether corrosion protection might be sufficient.

If strengthening is necessary, first it needs to be determined what stresses are acting on the bridge and what type of failure is decisive: Failure by reaching the bearing load or fatigue.

1.2 *Research Objectives*

In general, existing bridges are assessed using presently valid design loads. Due to constantly increasing traffic loads, the design loads in the present design standards are considerably higher than the design loads, which were used at the time of construction of the bridges. This means that often the requirements for the ultimate limit state and the service limit state cannot be met. Even when using detailed numerical calculations with sophisticated models, the resistances of the structures are frequently found to be much smaller than the design actions (Borkowski, G., Sigrist, V., 2012).

For the assessment of existing bridges, fatigue requirements often govern. In many cases these requirements cannot be met because the methods in the design standards are based on strongly conservative assumptions. The research project presented in this paper seeks to address these issues.

Large-scale bending tests on slabs are used to analyze their load-bearing behaviour. In these tests, segments of bridge slabs are cyclically loaded until their bending reinforcement fails due to fatigue.

Three hydraulic jacks are used to simulate recurring vehicle crossings. The applied vehicle loads meet the size and geometrical specifications given in the relevant Swiss standard (SIA 261, 2003).

The aim of the research project is to provide monitoring methods for determining and assessing the damage process cause by fatigue. Further, it is planned to incorporate the gained knowledge in the relevant design standards.

2 EXPERIMENTAL INVESTIGATIONS

2.1 *Specimen*

The investigations focus on determining the load transfer within deck slabs. The test setup is based on the

cross-sectional geometry and reinforcement detailing of older bridges. Further, the bending reinforcement is designed so that fatigue damage occurs after three to four million test load cycles (s. Tab. 1). The specimen dimensions can be seen in Figure 1.

The specimen represents the top slab of a box girder. As the bottom slab is missing in the test setup, the transverse stiffness of a box girder is reproduced with six prestressed (50 kN each) threaded rods (Figure 1–4). The test specimen is mounted on four 0.5 MN hydraulic jacks, so that its position can be adjusted during the test if necessary.

2.2 *Experiment set-up*

The load is applied with three hydraulic jacks, which successively load the specimen. Therefore, during one load cycle the three jacks are applied one after another. Following the provisions given in the relevant Swiss standard (SIA 261, 2003), a transverse beam distributes each jack load to two load distribution plates. The transverse spacing between the plates is 2 m (Figure 1) and corresponds to the distance between the two point loads of an axle load as stipulated by the code. The 270 kN load applied by each jack corresponds to the characteristic value of this axle load. In the longitudinal direction the distance between the jacks is 2.4 m (Figure 3). The load history of one cycle is shown in Figure 5. As can be seen, the loads are applied successively, but a minimal load of 30 kN is always maintained at each jack so as to ensure that the testing equipment is never completely unloaded during the test.

Besides the continuous load and deformation measurements at the locations of the jacks, the vertical deformations of the test specimen at 16 locations and the force in the prestressed transverse rods are measured every five hours for 20 seconds. This means that the specimen deformations due to at least five full load cycles (fictitious vehicle crossings) can be measured (Figure 5).

Table 1. Reinforcement in the specimen slab.

	Reinforcement	
Layer	Ø [mm]	Spacing [cm]
Top transversal	14	20
Bottom transversal	10	20
Top longitudinal	10	20
Bottom longitudinal	14	20

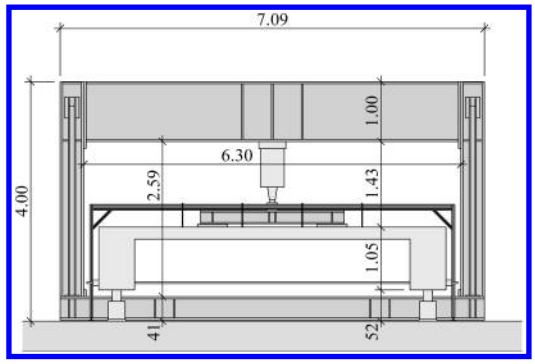

Figure 2. Cross section of the experiment set-up.

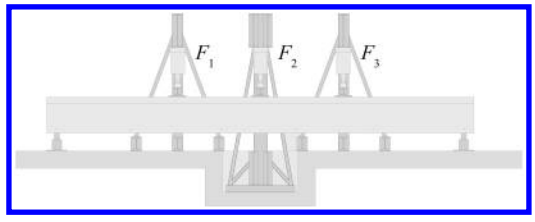

Figure 3. Longitudinal section of the experiment set-up.

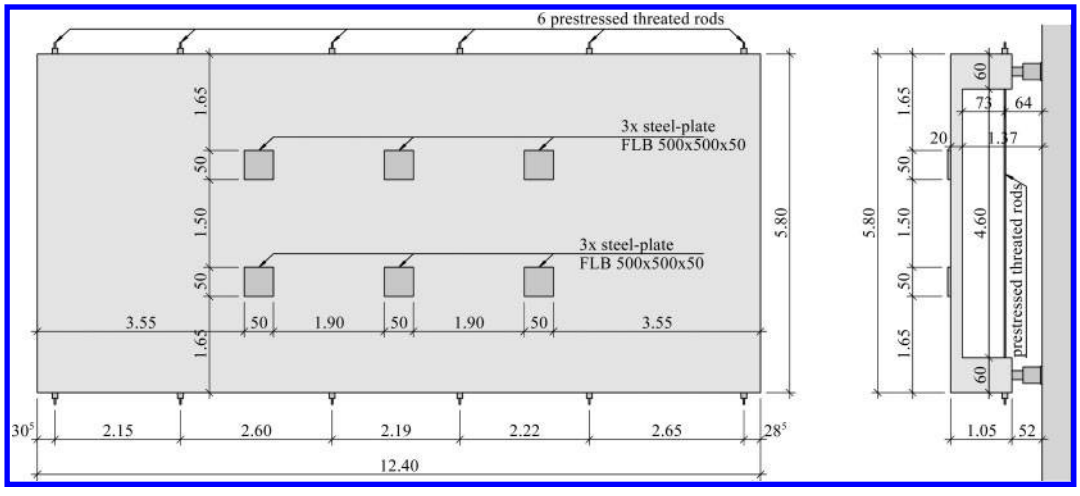

Figure 1. Specimen, left: top view, right: cross section.

Figure 4. Photo of the experiment set-up.

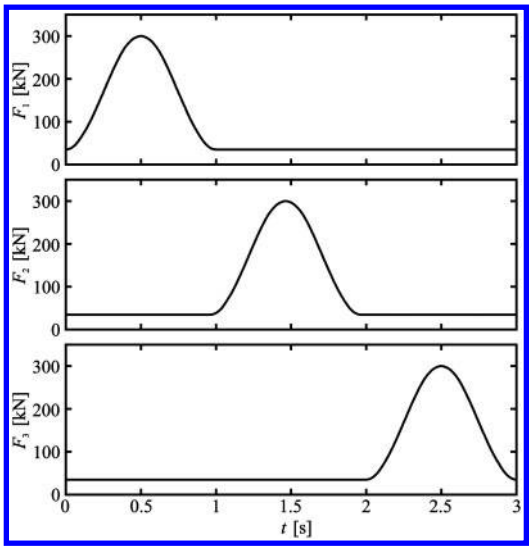

Figure 5. Load history for one cycle.

After every 500 thousand (500 k) cycles the loading process is interrupted. During these breaks the surface deformations on the upper and lower slab face are measured with a hand-held mechanical strain gauge (measurement accuracy 1/1000 mm). The measurements are carried out three times on one half of the slab. Thereto each jack is loaded separately up to 300 kN and put into deformation control mode, while the other two jacks are maintained at 30 kN. The crack pattern is recorded at each load application so that the cracking progress is documented after every 500k cycles (Figure 6).

With a program especially designed for this purpose, which is based on the layer model for slabs according to (Kollegger, J., 1991, CEB, 2008, Seelhofer, H. 2009, Urweider, T., 2012,), the cross-sectional strains, curvatures, steel stresses and bending moments in the slab can be determined from the deformation measurements taken with the hand-held mechanical strain gauge.

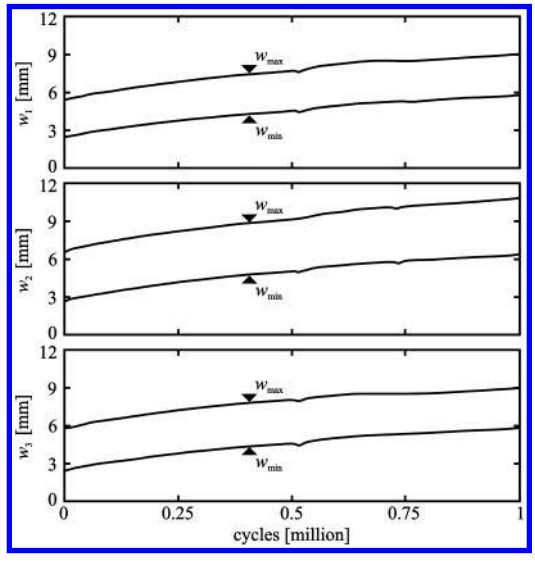

Figure 6. Vertical slab displacement vs. load cycles up to 1 million cycles.

Thereto, each layer is assumed to have a plane stress state, which is determined with the Cracked Membrane Model according to (Kaufmann, W., 1998).

3 RESULTS

3.1 *Measurements*

At the time of submission of this paper, a total of one million load cycles have been applied to the specimen. At present, only results from the load level of 500 k cycles can be presented as the mechanical strain gauge measurements are taken and evaluated every 500 k cycles.

Figure 6 shows the recorded vertical slab deformations below each of the three jacks. The envelopes of the maximal and minimal deformation values are shown. The figure shows to which extent the test specimen exhibits residual deformations due to cyclic loading. It can also be seen that the specimen stiffness relative to the load is almost constant.

Figure 7 shows the initial cracks and the crack pattern established after 500 k cycles. The top and bottom face of one half of the slab is shown. It is clearly visible that the cyclic loading caused a progression of the cracks. The cracks progressed in both the longitudinal and transverse direction of the slab, which indicates an enhancement of the global load-bearing action in the slab.

3.2 *Nonlinear FE-Calculations*

The deck slab was designed and verified with a nonlinear three-dimensional Finite Element (FE) Model. The results of the model allowed the determination of the right amount of reinforcement necessary to achieve

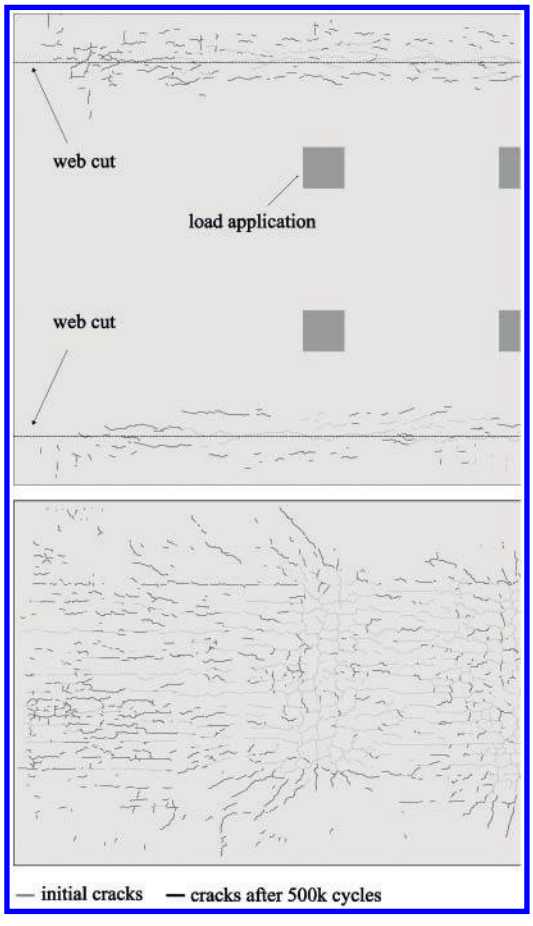

Figure 7. Cracks in one half of the deck slab; top: top view of the slab, bottom: bottom view of the slab between the webs.

the desired stress level in the reinforcement of the specimen. Through computational reassessment of the specimen during testing it is possible to check the model assumptions regarding the stress levels in the reinforcement to ensure that fatigue relevant stresses are developing.

Further, during the course of the test it is possible to determine to which extent the FE model needs to be adapted so that it can account for the progressive damage of the test specimen. Hence, from this model the necessary stiffness adjustments due to fatigue damage can be deduced for general recalculations of existing bridges.

The FE Model uses shell elements (Figure 8, Sofistik 2010). Bilinear material behaviour is assumed for the reinforcing steel. For the concrete in the compression zone non-linear material behaviour is adopted, while the tensile concrete is modelled according to Hillerborg et al. (Hillerborg et al. 1976). The material constants are determined during the course of the test and can be directly entered into the FE Model. The following figures show the calculated bending moments about the transverse and longitudinal axes

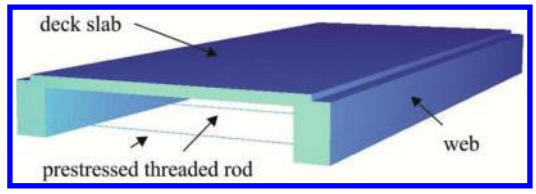

Figure 8. FE-Model.

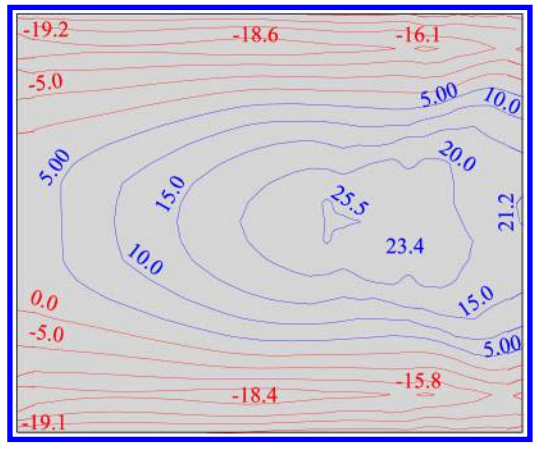

Figure 9. Calculated bending moments about the longitudinal axis.

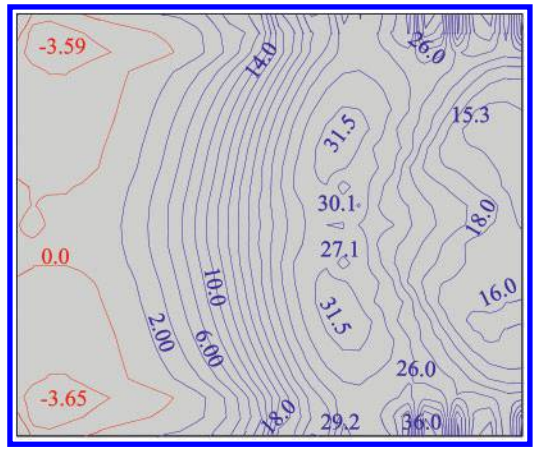

Figure 10. Calculated bending moments about the transversal axis.

(Figure 9 and 10). On both figures only one half of the slab is shown.

It can be seen that the calculated stress resultants correspond well with the stress resultants determined from the measurements (Figure 11 and 12). This means that the values obtained from the initial design describe the effective behaviour well and that the desired stress levels are being reached in the bending reinforcement of the test specimen. Further, the FE calculations can provide information for locations of the test specimen,

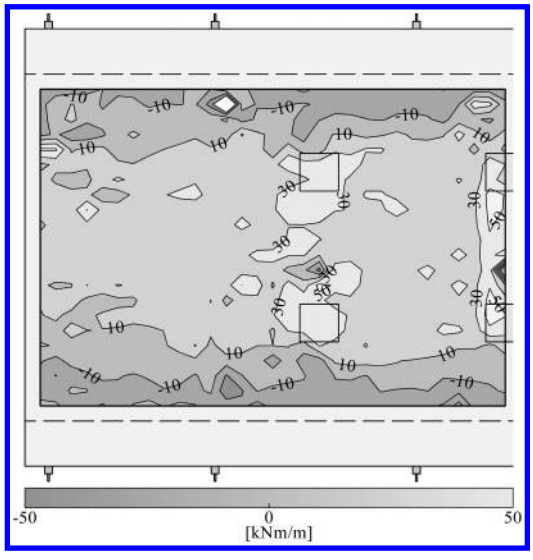

Figure 11. Bending moments about the longitudinal axis.

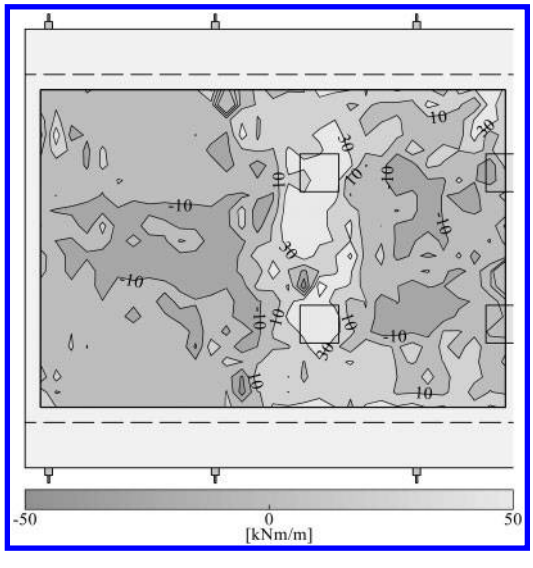

Figure 12. Bending moments about the transversal axis.

where no measurements are being carried out, e.g. the stress levels in the bending reinforcement in the web.

3.3 *Stress state of the Reinforcement*

Based on the measurements carried out on the test specimen and on the in-house software tool, the bending steel stresses can be determined for each reinforcement layer of the specimen. The following three figures show the stresses after 500 k load cycles in the top transverse reinforcement (Figure 13), the bottom transverse reinforcement (Figure 14) and the bottom longitudinal reinforcement (Figure 15).

These stresses can only be determined experimentally in regions with target studs on the top and bottom

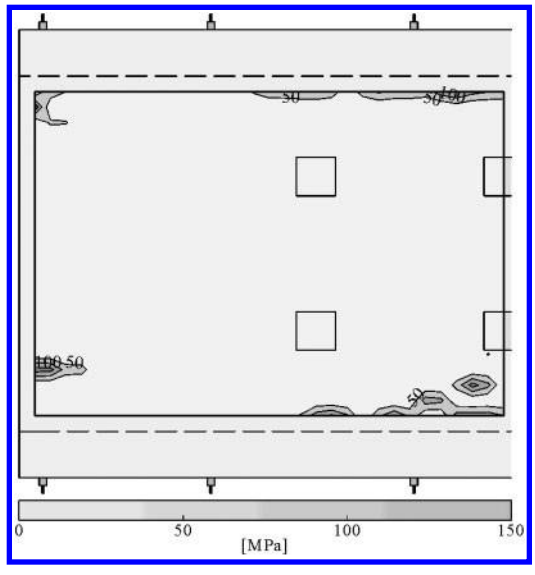

Figure 13. Stresses in the top reinforcement in transversal direction after 500 k cycles.

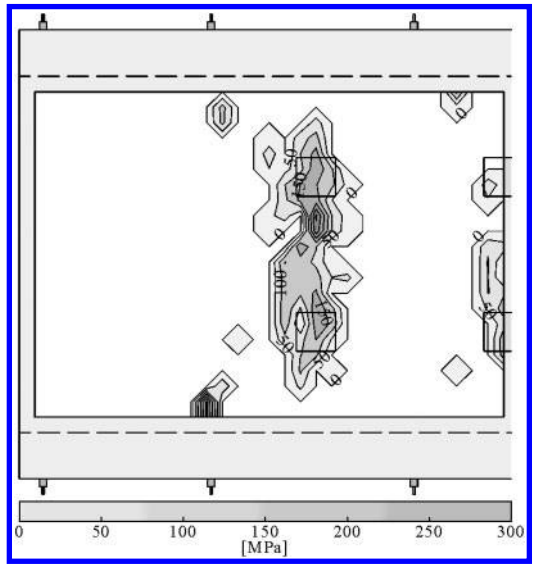

Figure 14. Stresses in the bottom reinforcement in transversal direction after 500 k cycles

face of the slab. This means that the steel stresses due to negative bending moments at the flange-web intersection cannot be determined. These values have to be provided by the FE model.

As can be seen in the figures, the bottom reinforcement in the transverse and longitudinal direction is subjected to stresses equal to 200 MPa. As the transverse negative moment at the flange-web intersection dies down rapidly, relatively low stress levels are measured experimentally. However, if the FE Model is used to determine the steel stresses, steel stresses of

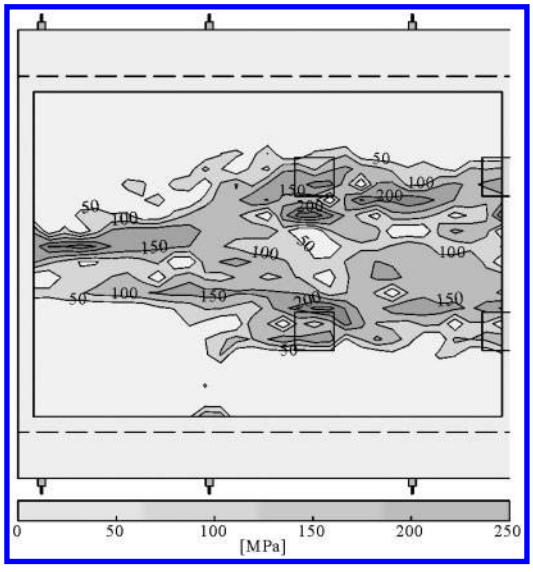

Figure 15. Stresses in the bottom reinforcement in longitudinal direction after 500 k cycles

170 MPa are found in the transverse reinforcement above the web.

As there is hardly any stress present in the reinforcement in the unloaded state, fatigue relevant stress amplitudes equal to 200 MPa and 170 MPa can be assumed.

4 CONCLUSIONS AND FURTHER RESEARCH

The present research work comprises the execution and evaluation of large-scale tests on bridge deck slab members, which are subjected to fatigue relevant stress levels caused by vehicle axle loads. First, the general testing program is presented. The test specimen is described and the loading sequence is explained.

Further, the components of the measuring program are presented and it is shown which data can be gained from the measurements. Then the experimentally determined stress resultants are compared with the results from non-linear FE calculations and a good agreement is found. Finally, the stress levels in the slab bending reinforcement are illustrated.

By means of the experiment and the evaluation program it is possible to illustrate the load bearing behaviour in the slab due to fatigue damage. It is planned to carry out at least three further tests on identical test specimens. These test specimens will be preloaded with tensile and compressive forces in the longitudinal and transverse direction, in order to be able to represent effects such as longitudinal and transverse bending in the span and support regions of the bridge.

FE calculations will be carried out to simulate the load bearing behaviour in the case of fatigue damage.

The knowledge gained from this research project is intended to be incorporated in the Swiss Standard for the assessment of existing structures. On this basis, the load bearing reserves of existing bridges can be more accurately determined and evaluated, in order to prevent unnecessary strengthening measures.

ACKNOWLEGEMENTS

The authors thank the Swiss Federal Roads Office (ASTRA) for financing the project. This project is also being assisted by the University of Applied Science in Rapperswil under the supervision of Prof. Dr. techn. sc. A. Kenel.

Cable stressing sequence of an asymmetrical cable stayed bridge

John R.B. Anderson
SMEC South Africa (Pty) Ltd, Cape Town, South Africa

ABSTRACT: This paper describes the cable stressing sequence for an asymmetrically rock anchored cable stayed pedestrian bridge at Tshelimnyama. The bridge crosses the N3 highway near Durban and was built for the South African National Roads Agency SOC Ltd (SANRAL). During the construction period various stressing sequences were analyzed with the aim of limiting the erection engineering effort and the construction risks. The final solution was found after a number of iterations and used the structures' self-weight to partially stress the most critical cables. Importantly this limited the forces on the temporary support cables and reduced the jacking forces needed to stress the permanent cables.

1 INTRODUCTION

1.1 *Introduction*

This paper describes the cable stressing sequence for an asymmetrically rock anchored cable stayed pedestrian bridge at Tshelimnyama on the N3 near Durban built for the South African National Roads Agency SOC Ltd (SANRAL). During construction various stressing sequences were analyzed with the aim of limiting the erection engineering effort and risks. After a number of iterations the final solution used the structure's self-weight to partially stress the most critical cables. Importantly this limited the forces on the temporary support cables and reduced the required jacking forces needed to stress the permanent cables resulting in an overall cost saving to the client.

1.2 *The bridge*

The bridge is a two span structure with a total length of 89.75 m, a main span length of 55.75 m and a back span length of 34.0 m. The 3.2 m wide deck is constructed from reinforced and prestressed concrete and is supported by 10 sets of stay cables. A 32 m long inclined, twin legged structural steel tower that is pinned at its base supports the cables by means of spade and fork connections.

Because the tower leans, the structural systems needs lateral restraint. The end of the bridge deck is therefore integral with the southern abutment which is anchored into the rock with twelve rock anchors. The first pair of cables (C1) on the bridge connects the tower to the rock anchored abutment. This connection to a rigid point provides much of the stiffness in the structural system and limits the deflection of the deck due to asymmetrical dead and live loads. As a result the C1 cable carries far higher loads than any of the other cables.

1.3 *The problem*

The method of erecting the tower and the associated temporary works design was a fundamental part of the project. In its final state the tower is held in position by the balanced forces in the back span and main span

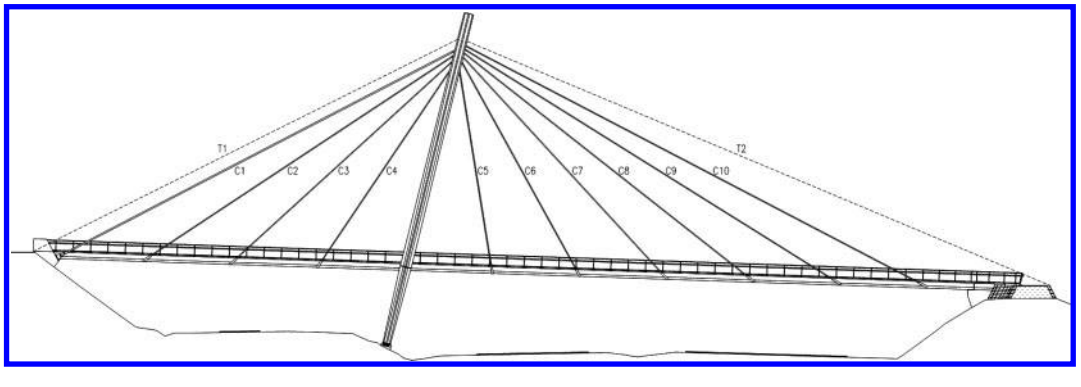

Figure 1. Bridge elevation and cable annotation.

stay cables. However, because the tower is pinned at its base, it was necessary to temporarily support it during the installation of the permanent stay cables.

The challenge became the design of temporary works because it required the detailed modeling of the installation and stressing of the permanent stay cables. In such instances it is considered impractical for a contractor to take full responsibility for the temporary works design. This is because he would have to employ an experienced bridge engineer to model the complete structural system. In the context of the South African construction market, and the low capital value of the project, this is not considered a practical expectation.

This paper highlights that the most appropriate temporary works solutions are not always found when the engineer and contractor are separated by their contractual roles. To this end the benefits of collaboration between the designer and the contractor are documented.

2 ORIGINAL STRESSING SEQUENCE

Early on in the design process it was decided to construct the deck section of the bridge on staging. Cantilever construction was considered to be impractical for the proposed structural system. In terms of the cable stressing sequence the design team's proposed method was led by the fact that the C1 cable provided the necessary stiffness to the structural system and carried the highest load.

The construction drawings required the C1 cable be installed first and nominally stressed by the self-weight of the tower structure and by whatever temporary supports the contractor proposed. As a fixed length cable the intent was that the C1 cable would control the top of tower position whilst the remaining cables were installed and stressed.

It was required that the cables adjacent to the tower be then installed and stressed to 25% of the design stress. Working outwards from the tower this process was repeated for each pair of back span and main span cables. Finally the C1 cable was to be stressed to 25%.

The intent of this process was to start by removing the slack from the cables and to get some stiffness into the structural system before the cables were sequentially stressed to their design forces. By starting with the cables adjacent to tower more vertical force was initially added to the tower than lateral force. This helped reduce the movements at the top of the tower during the stressing sequence.

The next iteration followed the same sequence now stressing the cables to 90% of their design forces. A final stressing pass to get the forces up to the target values was allowed to achieve the desired vertical alignment of the deck section.

Although the stressing sequence was considered logical in the end it was flawed on two accounts. The first was that stressing sub-contractors prefer to put as much force as they can into a cable to reduce the number of stressing operations. This said, generally cables have to be stressed in at least two operations to ensure that the correct deck alignment is achieved.

The contractor's cable choice of cable and anchorage system is also an important variable that can affect the stressing sequence. In some cases the cables anchorage assemblies need to be activated by a minimum force for safety reasons. This force can be as much as 30% of the cable's ultimate force.

The second more important flaw was that the stressing sequence did not account for the temporary works. During the conceptualization of the structure it was judged that the bidding contractors would each have a preferred means of providing temporary support to the tower. Fully detailing a temporary works solution was therefore ruled out. However, the interaction between the temporary works and the cable stressing sequence was fundamental. This was identified at the onset of the contractor's temporary works design when a set of temporary cables attached to the top of the tower were proposed.

3 TEMPORARY WORKS DESIGN

3.1 *General arrangement*

The temporary works proposal used two sets of temporary cables to stabilize the tower, by connecting the top of the tower to fixed points onto either side of the bridge. The T1 cables consisted of two cables connecting the top of the tower to the fixed abutment by means of a temporary steel anchorage assembly. The T2 cable followed a similar arrangement and connected the top of the tower to a temporary micropiled concrete structure at the other end of the bridge.

It was important that the force in the temporary cables could be varied if required. The contractor, Freyssinet and the design team therefore came up with a system of connecting the strands to steel connection boxes that then connected to a stress bar which was fixed into the anchorage assemblies. By stressing the stress bar the forces in the support system were then easily controlled.

A temporary steel support frame was detailed for the steel anchorage boxes to ensure that the stress bar was not subject to bending or shear stresses. Refer to figure 2.

3.2 *Permanent Cable system*

In any stressing sequence the cable supplier's requirements for stressing the cables are an important factor. In this case Freyssinet's H1000 cable system was used. The cables are made up of 15.7 mm galvanised and coated mono-strand housed within an uPVC sheath.

The C1 cables utilised spade and fork connections. A fixed anchorage was detailed at the top of the tower and an adjustable fork at the fixed abutment. An important constraint was that a minimum force was required to safety activate the anchorages in the assembly.

Figure 2. Steel anchorage assembly and support frame.

Figure 3. Jacking assembly on adjustable fork.

Figure 4. RAB type Anchorage assembly.

The C2 to C10 cables had fixed spade and fork assemblies that top of the tower and adjustable anchorages at the deck anchorages. It was impractical for the strands to be jacked individually and a jack that grabbed the whole anchorage assembly was needed to stress all strands equally. Freyssinet's RAB anchorage with a threaded collar was therefore used.

4 ANALYSIS MODELS

Using temporary cables attached to the top of the tower meant that as the permanent cables were installed the forces in the temporary cable changed. Similarly when the temporary cables were released the forces in the permanent cables changed. The temporary works cables where therefore included in the analysis model to review the stressing sequence.

It was also important to check that the temporary works were designed with sufficient redundancy to allow for the event of a temporary support cable breaking. This was checked with an impact analysis to calculate the magnified forces in the system due to a sudden failure of a cable.

When the original stressing sequence was analyzed with the temporary stays, the maximum force in T1 reached 578 kN. The main concern became designing the temporary anchorages to restrain this force and the construction risks associated with a cable out scenario.

As mentioned the cable C1 provides much of the stiffness to the structural system and in the bridge's final state its design force is significantly larger than the other cables. The challenge was that C1 could not be stressed unless the other cables were already in place. Without the internal cables there was essentially nothing to restrain the tower and therefore nothing to jack against.

A further issue was that the contractor initially wanted to stress the cables to close to 100% of the design load. However, the implication was that after the installation of cables C2 to C10 the temporary T1 cable was highly stressed. This sequence also required that T1 cable had to be re-stressed continuously to keep the top of the tower in the correct position. The consequence of the tower moving was that the tolerances in the permanent cable lengths could be exceeded.

5 FINAL SEQUENCE

Although various alternative stressing methods were tested for the purposes of this paper the final solution is explained.

The crux of the final sequence was to stress the C1 cable to its full force as soon as possible whilst the T1 cable remained in place. To get the full force into C1 all of the back-span and main span cables had to be in place. However if they were stressed to the design force the result was the increase in force in T1. The answer to the problem came from using the structure's dead weight to fully stress C1.

In summary the final construction sequence first involved installing the permanent stay cables (C2 to C10) and the stressing them to a nominal force. This required minimal effort and control from the contractor and was carried out relatively quickly. The main C1 cable was then installed and stressed to a force of 800 kN and the temporary T1 cables were removed. With the C2 to C10 cables installed the necessary restrain to jack against was present. The deck staging

Figure 5. Completed structure.

was then removed. The deck deflected downwards by up to 80 mm before the C2 to C10 cables were stressed to the design forces bringing the deck back up to the required alignment.

The initial C1 target force of 800 kN was found by an iterative process that limited the final force in the C1 cable after the release of the deck formwork and the C2 to C10 cable stressing to 1100 kN.

The above sequence greatly reduced the forces in the temporary cables, thus minimizing the construction risks. The maximum T1 force was limited to 217 kN increasing the redundancy in the temporary works design.

The cable forces and deck displacements where monitored closely on site during the stressing operation to check the structure's behaviour. The stressing sequence analysis proved to be accurate, with additional stressing required on only four of the cables to ensure correct the deck displacement.

In review the stressing sequence process required a significant amount of additional analysis and design work. The design actions on the tower and deck elements had to be checked at each stage of construction. This led to the formwork between C1 and C2 remaining in place till the completion of the stressing operations to limit the bending moments in the deck section.

6 CONCLUSIONS

This project highlights that, on certain structures, the temporary works design cannot be divorced from the detailed erection engineering. In the case of cable stayed structures the load effects on the temporary works change through the erection sequence. As a result collaboration with the design engineer is essential to accurately model the behaviour of the permanent structure and the load effects on the temporary works components. These type of projects could be considered by clients to be let rather as design and construct type projects using the EPC suite of the FIDIC documentation as an example due to the substantial amount of interaction between the designer and contractor.

The construction process also highlighted that the constraints of contractor's proprietary cable system and jacking methods have to be carefully understood when considering the erection methods.

The final stressing sequence used worked well in that it reduced the construction risks, simplified the erection engineering and saved significant time. It is considered that using the structure's dead weight to stress the cable stays is an effective method, especially for pedestrian bridges.

Design curves for stiffened flanges used in steel box girder bridges

P.S. Ferreira
Polytechnic Institute of Setubal, Escola Superior de Tecnologia do Barreiro and ICIST, Setubal, Portugal

F. Virtuoso
Technical University of Lisbon, Instituto Superior Técnico, DECivil-ICIST, Lisbon, Portugal

ABSTRACT: This paper presents a design method for stiffened flanges used in steel box girder bridges based on a set of design curves that take into account all relevant parameters regarding the ultimate strength of stiffened flanges, including the real boundary conditions for the in-plane displacements at the edges. These design curves were developed and calibrated based on the results obtained with nonlinear analysis using the semi-analytical and finite element methods and they were validated by comparison with the results of experimental tests in accordance with the target failure probability of the European standard EN-1990. Finally, it is presented a comparison between the ultimate strength obtained using the proposal design curves with that obtained using the nonlinear analysis and the current bridge design rules.

1 INTRODUCTION

National standards with design rules for stiffened flanges used in steel box girder bridges were almost non-existent until the early nineteen seventies. These design rules were based on the elastic critical stress (σ_{cr}) obtained by the linear buckling theory of plates with some correction factors to take into account the favorable effect of the postcritical strength reserve (ECCS Committee8 1976).

Research work to establish new design rules for plated structures was strongly increased in the early nineteen seventies as a result of well known accidents during construction involving box girder bridges (Galambos 1998). Although the behavior and strength of stiffened plates have been extensively studied over the last forty years, there are still some inconsistencies and gaps between the results of some studies and the results obtained through the design rules established in the European and American standards (EN-1993-1-5 2006, AASHTO-LRFD-BDS 2007), which are usually adopted by the bridge designers to solve the problem of predicting the ultimate strength of stiffened plates.

As the current design rules laid down in the European and American standards do not recognize the effect of boundary conditions for the in-plane displacements at the edges to obtain the ultimate strength of stiffened plates, the use of these design rules can give inaccurate results and in some cases against safety.

This paper presents a design method for stiffened flanges used in steel box girder bridges based on a set of design curves that take into account all relevant parameters regarding the ultimate strength of stiffened flanges, including the real boundary conditions for the in-plane displacements at the edges. These design curves were developed and calibrated based on the results obtained with nonlinear analysis using the semi-analytical and finite element methods and they were validated by comparison with the results of experimental tests in accordance with the target failure probability of the European standard EN-1990 (2002). Finally, it is presented a comparison between the ultimate strength obtained using the proposal design curves with that obtained using the nonlinear analysis and the current bridge design rules.

2 PROBLEM DESCRIPTION

The most widely used bridge structural elements that resort to the use of steel plates are the plate and box girders. Steel plates used in these structural elements are outstand flanges, internal flanges and webs.

Outstand flanges have a free longitudinal edge and they are used as upper and lower flanges of the plate girders and narrow top flanges in open top box girders of composite sections. Internal flanges are used as bottom flanges of box girders and wide top flange in closed box girders of steel sections. In wide flanges and webs of considerable height it is common to use longitudinal stiffeners to reduce the problems associated with the effects of buckling.

The study of the behavior and strength of steel plates with longitudinal stiffeners is very complex because they depend on a large number of variables, such as the shape and amplitude of the initial geometric imperfections, the residual stresses, the boundary

conditions for the in-plane and out-of-plane displacements, the load conditions and the geometric and material data. Recent numerical studies (Ferreira 2012, Braun 2010) showed that the behavior and strength of steel plates are very sensitive to in-plane displacements boundary conditions and the European and American standards (EN-1993-1-5 2006, AASHTO-LRFD-BDS 2007) do not provide a definition and clear guidance for the proper use of the simplified rules available to designers. These rules may give considerable errors, particularly when applied to the safety verification of stiffened plates where the transverse in-plane displacements at longitudinal edges cannot be considered as uniform (in-plane displacements perpendicular to the longitudinal edges constrained to remain straight).

In European standard (EN-1993-1-5 2006) the resistance assessment of webs and internal flanges with longitudinal stiffeners used in steel box girder bridges is performed through the same criterion and independent of the in-plane displacement boundary conditions of the plate. Just apparently both elements may have the same in-plane displacement boundary conditions. Indeed, the webs are usually connected to flanges that possess sufficient rigidity to consider uniform the in-plane displacements at longitudinal edges, while the flanges are connected to webs that usually do not provide this type of constraint and it is more conservative to consider free the in-plane displacements at longitudinal edges, as shown in the work of Ferreira & Virtuoso (2011) through a comparison between numerical and experimental results.

The design proposal presented in this paper for stiffened flanges aims to fill a gap in the current European bridge design rules, which should not be applied to stiffened plates with the fully free transverse in-plane displacements at longitudinal edges.

3 DESIGN PROPOSAL

3.1 *General*

The design proposal is a model based on design curves (arithmetic expressions) describing the influence of all relevant parameters on the ultimate strength of stiffened flanges used in steel box girder bridges. It was developed and calibrated based on the results obtained with the semi-analytical and finite element methods and it was validated by comparison with the results of experimental test in accordance with the target failure probability of EN-1990 (2002).

These design curves consider that the plate is subject to compressive longitudinal direct stress with a stress ratio higher than 0.5 (lower compressive longitudinal stress to the higher compressive longitudinal stress ratio, $\psi > 0.5$), the transverse stiffeners provide rigid support lines, the longitudinal stiffeners are fully effective and equally spaced and the plates have the longitudinal in-plane displacements constrained to remain straight at loaded edges (transverse edges) and the other in-plane displacements fully free. This design model does not consider the effects of local buckling of the stiffener elements and tripping of the stiffener. These effects can be avoided by adopting minimum values for the geometric properties of the longitudinal stiffeners as used in European and American standards (EN-1993-1-5 2006, AASHTO-LRFD-BDS 2007).

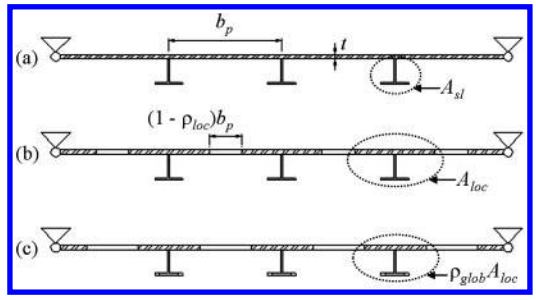

Figure 1. Reduction of the cross-sectional area of a stiffened plate in the design proposal: (a) the gross cross-sectional area, (b) the effective local cross-sectional area and (c) the effective cross-sectional area.

3.2 *Design procedure*

The design proposal is a design approach based on the reduced section concept, where the mean compressive stress at peak load (or ultimate strength σ_u) of a stiffened plate is estimated through the yield strength of the effective cross-sectional area according to

$$\frac{\sigma_u}{f_y} = \rho_{glob}\frac{A_{eff,loc}}{A} \tag{1}$$

where f_y = yield stress; ρ_{glob} = global reduction factor; $A_{eff,loc}$ = effective local cross-sectional area which takes into account the local buckling effects; and A = gross cross-sectional area of the stiffened plate.

From Equation 1 it can be noted that the effective cross-sectional area ($A_{eff} = \rho_{glob} \cdot A_{eff,loc}$) which takes into account the local and global buckling effects is obtained by reducing the cross-sectional area of the stiffened plate in two different steps, as illustrated in Figure 1.

In the first step the effect of local buckling in the panels between longitudinal stiffeners is taken into account and an effective width of these panels is adopted to obtain an effective local cross-sectional area ($A_{eff,loc}$) according to

$$A_{eff,loc} = \sum_{i}^{n_{st}+1}\left(\rho_{loc,i}b_{p,i}\right)t_i + n_{st}A_{sl} \tag{2}$$

where n_{st} = number of longitudinal stiffeners; ρ_{loc} = the local reduction factor; b_p = width of the panels between longitudinal stiffeners; t = plate thickness; and A_{sl} = gross cross-sectional area of a single longitudinal stiffener (without the contribution of the plate). The local reduction factor (ρ_{loc}) takes into account the favorable effects from postcritical strength reserve and the unfavorable effects of the initial imperfections

and it is defined for each panel between longitudinal stiffeners by

$$\rho_{loc} = \frac{\lambda_{p,norm} - 0.055(3+\psi)}{\lambda^2_{p,norm}} \leq 1 \quad (3)$$

where $\lambda_{p,norm}$ = relative slenderness of the panels. For a relative slenderness of the panels lower than 0.673 the local reduction factor should be considered equal to 1. Equation 3 is the same criterion used in European standard (EN-1993-1-5 2006).

In the second step, which takes into account the effect of global buckling in the stiffened plate, a global reduction factor (ρ_{glob}) is considered to reduce the effective local cross-sectional area ($A_{eff,loc}$). The global reduction factor is given by

$$\rho_{glob} = \max(\chi_c ; \rho_{p,\infty}) \quad (4)$$

where χ_c = reduction factor for the column buckling behavior; and $\rho_{p,h}$ = reduction factor for the plate buckling behavior estimated for a long stiffened plate (stiffened plate where the elastic critical stress σ_{cr} no longer depends of the plate length a).

Column buckling behavior is considered in stiffened plates with insignificant postcritical resistance. This behavior is modeled by removing the supports along the longitudinal edges of the plate and considering the cross-section of the column equivalent to the plate composed of a single stiffener with an effective width of the adjacent panels to the stiffener. The reduction factor for the column buckling behavior is obtained by

$$\chi_c = \min\left(0.66^{\lambda_{c,norm}}; \frac{1}{\phi_c + \sqrt{\phi_c^2 - \lambda^2_{c,norm}}}\right) \leq 1 \quad (5)$$

where $\lambda_{c,norm}$ = relative slenderness of the equivalent column; and ϕ_c = parameter that depends on the initial imperfections, the relative slenderness of the equivalent column ($\lambda_{c,norm}$), the relative flexural stiffness of the stiffened plate γ (second moment of area of the stiffened plate I_{st} to the second moment of area for bending of the plate corrected by the effect of the Poisson coefficient ($bt^3/[12(1-\nu^2)]$) ratio) and the number of longitudinal stiffeners (n_{st}).

The first term in Equation 5 ($0.66^{\lambda c,norm}$) is the critical criterion in stiffened flanges with low values of equivalent column relative slenderness ($\lambda_{c,norm}$) and it is equal to the reduction factor established in the American standard (AASHTO-LRFD-BDS 2007) for the column buckling behavior of stiffened plates. The other term in Equation 5 is the determinant criterion in stiffened plates with intermediate and high values of equivalent column relative slenderness ($\lambda_{c,norm}$) and it is equal to the reduction factor established in the European standard (EN-1993-1-5 2006) for the column buckling behavior of stiffened plates with an improvement that takes into account the relative flexural stiffness of the stiffened plate (γ) and the number of longitudinal stiffeners (n_{st}).

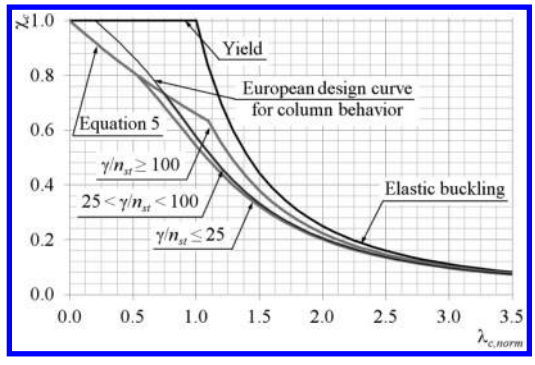

Figure 2. Reduction factor for the column buckling behavior obtained using the design proposal.

Figure 2 presents the reduction factor for the column buckling behavior (χ_c) obtained using the design proposal. It is also shown the yield, the elastic buckling and the European standard criteria. An equivalent geometric imperfection of 1/400 of the plate length (a) was used.

Plate buckling behavior is considered in stiffened plates with postcritical resistance. The design proposal uses this type of behavior to define the minimum ultimate strength of the stiffened plate, which is estimated considering a long plate. The reduction factor for the plate buckling behavior of a long stiffened plate is obtained by

$$\rho_{p,\infty} = \begin{cases} \dfrac{1}{4\xi} \leq 1 & for \quad \lambda_{p,norm} \leq 2\xi \\ \dfrac{1}{\lambda_{p,norm}} - \dfrac{\xi}{\lambda^2_{p,norm}} \leq 1 & for \quad \lambda_{p,norm} > 2\xi \end{cases} \quad (6)$$

where $\lambda_{p,norm}$ = relative slenderness of the stiffened plate; and ξ = parameter that depends on the compressive longitudinal stress ratio (ψ), the panel slenderness λ_p (width of the panels between stiffeners b_p to the plate thickness t ratio), the relative cross-sectional area δ (cross-sectional area of the stiffeners without any contribution of the plate $n_{st}A_{sl}$ to the cross-sectional area of the plate (bt) ratio), the relative flexural stiffness of the stiffened plate (γ) and the number of longitudinal stiffeners (n_{st}).

The reduction factor for the plate buckling behavior estimated for a long stiffened plate (ρ_p, ∞) is governed by the parameter ξ and Equation 6 becomes the well-known criterion proposed by Winter when this parameter is equal to 0.22. Based on the geometric parameters of the stiffened flanges identified in the survey of stiffened flanges used in real steel box girder brides presented in Ferreira (2012) the minimum and maximum values of the parameter ξ are 0.19 and 0.64 respectively.

Figure 3 presents the reduction factor for the plate buckling behavior of a long stiffened plate (ρ_p, ∞)

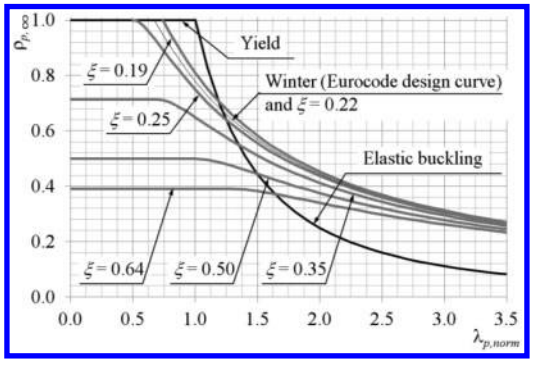

Figure 3. Reduction factor for the plate buckling behavior obtained using the design proposal with different values of the parameter ξ.

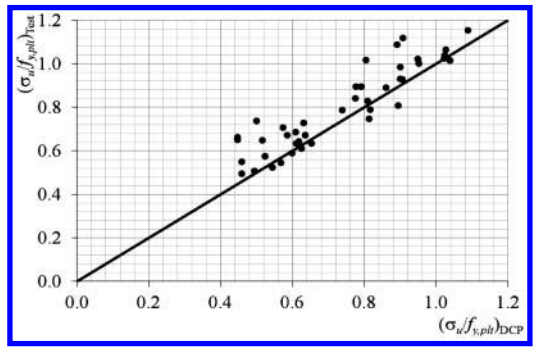

Figure 4. Ultimate strength results obtained by the design proposal (DCP) against the test results (Test).

obtained using the design proposal with different values of the parameter ξ. It is also shown the yield, elastic buckling and Winter criteria.

Figure 3 shows that the application of the design proposal results in a lower ultimate strength (σ_u) of the stiffened flange with fully free in-plane displacements at longitudinal edges than that obtained by the current European bridge design rules, which is consistent with the results obtained using nonlinear finite element simulations and with the results of experimental tests presented in the works of Ferreira & Virtuoso (2010, 2011).

The complete definition of the procedures and variables used in the design proposal can be found in the work of Ferreira (2012).

3.3 *Statistical evaluation*

In order to ensure that the design proposal for assessing the resistance of longitudinally stiffened compression flanges used in steel box girder bridges is safe and economical to use as a design rule, a statistical evaluation using experimental test results within the framework of a probabilistic reliability theory in accordance with EN-1990 (2002) should be carried out.

The target of this statistical evaluation is to establish the numerical value for the partial safety factor (γ_M) to be used in the design proposal. The use of this partial safety factor in the design proposal is achieved by replacing the yield stress f_y by f_y/γ_M in Equation 1. As the definition of the partial safety factors is a responsibility of each European country (Nationally Determined Parameter) the establishment of a minimum numerical value for this partial safety factor is extremely important for the national standards bodies.

In this work a reliability class RC2 and a consequence class CC2 (EN-1990 2002) were considered, which corresponds to a minimum value for the reliability index of 3.8 associated with a 50 year reference period, as defined in the background documents to support the implementation, harmonization and further development of design rules for plated structural elements (Johansson 2007).

The test results used to evaluate the partial safety factor were obtained from the experimental test programs conducted at the Research Institute of Industrial Science and Technology (RIST) in the Republic of Korea, carried out by Choi et al. (2009), the Pontifícia Universidade Católica of Rio de Janeiro (PUC-Rio) in Brazil, carried out by Ghavami (1994), the National Maritime Research Institute (NMRI) in Japan, carried out by Tanaka & Endo (1988), and the University of Manchester (UM) in the United Kingdom. The experimental test program at UM has been divided into two phases, the first was carried out by Horne & Narayanan (1976) and the second was carried out by Horne et al. (1977).

It was not possible to use all the available test results because fourteen tests were carried out on specimens with amplitude values for the initial geometric imperfections outside the range considered in the design rules. Thus, only 42 of the 56 available test results were used for the statistical evaluation. The specimens T5 and T6 from RIST, the specimens P1R, P2T and P2R1T from PUC-Rio and the specimens 1, 14, 12, D22, D21, E23, E21, PF2 and SW6 from UM were excluded from the statistical evaluation.

Figure 4 presents the comparison between the ultimate strength results obtained by the design proposal with the test results. From the analysis of Figure 4 it can be noted that the design proposal provides viable and conservative results. A coefficient of variation of 11.2% for the comparison between the ultimate strength obtained by the design proposal and the test results shows a slightly larger scatter, but in the safety side.

According to EN-1990 (2002) and with the purpose of obtaining economic design models it is possible to divide the total test population into appropriate subsets. These subsets should be associated with parameters that have the greatest influence on the scatter. A total of 5 subsets were considered taking into account the following geometric parameters: the plate aspect ratio (ratio between the length a and the width b of the plate), the panel slenderness (λ_p), the relative cross sectional area (δ) and the relative flexural stiffness (γ); and the different specimen buckling behaviors. To consider the variability of the geometric and material

Table 1. Minimum values of the partial safety factor for the subsets of tests.

Subsets	Test program	Number of specimens	γ_M
1	RIST	13	1.09
2	RIST	3	0.74
3	NMRI	10	1.11
4	UM	14	1.10
5	UM	2	1.21

properties in the probabilistic model of the resistance the following variation coefficients were taken into account (Johansson et al 2007): 0.07 for the yield stress; 0.03 for the plate thickness; 0.01 for the plate length; and 0.01 for the plate width.

In Table 1 are presented the minimum values of the partial safety factor (γ_M) for the subsets of tests obtained by statistical evaluation according to the probabilistic reliability theory established in EN-1990 (2002).

From the analysis of Table 1 it can be verified that a numerical value of 1.10 for the partial safety factor ($\gamma_M = 1.10$) is consistent with the experimental test results, which is the recommended numerical value for the partial factor for resistance of members to instability assessed by member checks (γ_{M1}) on bridges (EN-1993-2 2006). Just the subset 5 shows a significant difference for the partial safety factor of 1.10. This is however not a serious indication because this subset is not representative, since it has a small numbers of tests.

3.4 *Comparison with nonlinear analysis and current bridge design rules*

The comparison between the ultimate strength (σ_u) obtained using the design proposal with that obtained using nonlinear analyses and current bridge design rules established in the European and American standards (EN-1993-1-5 2006, AASHTO-LRFD-BDS 2007) was performed considering 20 stiffened flanges. The 20 stiffened flanges were obtained based on two types of cross-sections, SF1 and SF2, and considering for each cross-section the plate aspect ratio ϕ ($= a/b$) ranging from 0.5 to 5.0 at intervals of 0.5. Both cross-sections have five longitudinal equally spaced and single sided stiffeners, the stiffened flanges with the cross-section SF1 have a relative flexural stiffness γ ($= 12I_{st}(1-\nu^2)/(bt^3)$) of 65 and the stiffened flanges with the cross-section SF2 have a relative flexural stiffness γ of 130. All stiffened flanges have a relative cross-sectional area δ ($= A_{sl}/(bt)$) of 0.5, plate slenderness λ_{plt} ($= b/t$) of 150 and panel slenderness λ_p ($= b_p/t$) of 25.

The nonlinear analyses were performed using the semi-analytical model presented in the work of Ferreira (2012) and considering a yield stress (f_y) of 355 Nmm^{-2}, Young's modulus (E) of 2.1×10^5 Nmm^{-2} and Poisson's coefficient (ν) of 0.3.

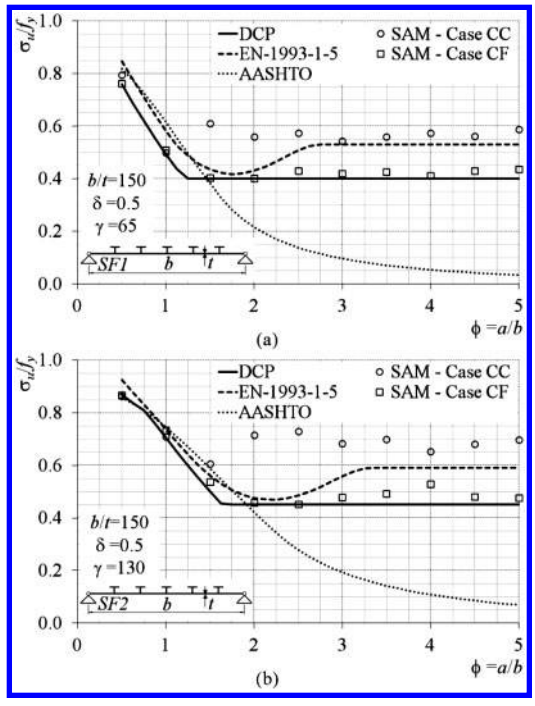

Figure 5. Comparison between the ultimate strength obtained by the design proposal (DCP), the semi-analytical model (SAM) and current bridge design rules for the stiffened flanges with the cross-section: (a) SF1 and (b) SF2.

The stiffened flanges were considered simply supported under longitudinal uniform compression (σ) with the following two cases for the in-plane displacement boundary conditions: in-plane displacements perpendicular to the edges constrained to remain straight in all edges (case CC) and in-plane displacements perpendicular to the edges constrained to remain straight at loaded edges and free at unloaded edges (case CF).

Figure 5 presents the comparison between the ultimate strength (σ_u) obtained by the design proposal, the semi-analytical model and current bridge design rules. Figure 5a shows the ultimate strength for the stiffened flanges with the cross-section SF1 and Figure 5b shows the ultimate strength for the stiffened flanges with the cross-section SF2. The results are presented in terms of normalized strength (mean compressive stress at peak load σ_u to the yield stress f_y ratio) for different values of the plate aspect ratio ϕ ($= a/b$).

From the analysis of Figure 5 it can be noted that the ultimate strength (σ_u) obtained by the design proposal presents a much better agreement with the nonlinear analysis results obtained by the semi-analytical model considering the case CF for the in-plane displacement boundary conditions than the ultimate strength obtained by the current bridge design rules. This observation is particularly clear in the case of long plates, where the design rules established by the European standard leads to nonconservative results and

the design rules established by the American standard leads to extremely conservative results.

4 CONCLUSIONS

From this study the main conclusions can be summarized as follows: (i) the ultimate strength (σ_u) obtained using the design proposal is in agreement with the test results and the main differences are in the safety side, (ii) the numerical value of the partial safety factor (γ_M) for the design proposal is 1.10, (iii) the ultimate strength obtained using the design proposal is in close agreement with the results obtained using the semi-analytical models considering fully free in-plane displacements at longitudinal edges and (iv) it presents a much better agreement with the results obtained using the semi-analytical model considering fully free in-plane displacements at longitudinal edges than the ultimate strength obtained with the current bridge design rules.

The design proposal predicts the ultimate strength (σ_u) in a quick and simple way and provides viable and conservative results, which thus proves its usefulness as a design tool.

Fatigue life assessment of existing motorway bridge

L. D'Angelo, A. Nussbaumer, M.-A. Fénart & A.-G. Dumont
Ecole Polytechnique Fédérale de Lausanne, ENAC-LAVOC, Switzerland

ABSTRACT: The aim of this paper is to provide a fatigue-life assessment of an existing composite steel-concrete bridge within Switzerland. The Venoge bridgeis a 219 meters length, four spans, four girder composite bridge, situated on the Geneva-Lausanne Swiss motorway. Stress response influence lines at fatigue critical details are characterized with a refined three-dimensional (3-D) Finite Element (FE) model that takes into account the effective transverse load repartition and the cracking of the concrete slab; the model is further validated using strain gauge measurements. Real traffic simulations are run to get the effective traffic histograms on the bridge. Weigh in Motion (WIM) data from the Denges station (1 km from the bridge) are used as input for the simulations. The effective slow lane position over the bridge section is taken in account and future traffic increase is considered. The fatigue failure probability of the bridge at a critical location under the long-term effect of highway traffic is calculated by defining a limit state function for fatigue reliability analysis. The results show that fatigue is not a concern for the Venoge bridge, even though particular attention has to be paid to future change in traffic lane configurations which could require re-consideration of the fatigue critical details.

1 INTRODUCTION

Reliable consideration of infrequent loads (rare extreme loads) is a technical challenge in the fatigue-life assessment of motorway bridges. In fatigue analysis, the proper evaluation of these extreme loads which lie near the fatigue constant amplitude limit (CAFL) is of fundamental importance. A small error in the load definition can result in a significant error in estimation of the bridge fatigue life. Weigh-in-motion (WIM) technology combined with traffic simulation tools is a solution to the problem.

WIM devices can capture static vehicle axle weights, which allow for characterization of traffic demands. Collected WIM data provide information on the frequency distribution of total gross weight, axle group weight, and axle distance. Prior to recent years, probabilistic approaches were used to find rare extreme load events and extrapolate them to longer time periods (i.e. one recorded week extrapolated to 120 years) (Bailey, 1996) (Crespo-Minguillón & Casas, 1997) (Meystre & Hirt, 2006); however, recent improvements in data storage, traffic simulators, and WIM technologies provide a deeper understanding of extreme load events (recorded traffic data of one or more years).

In this study, a traffic simulation software (AIMSUN (TSS Transportation Simulation System, 2011)) is coupled with Monte-Carlo Simulations (MCS) and finite element (FE) analysis to assess fatigue life of an existing motorway bridge within Switzerland. The chosen bridge is located on the A1 Swiss Motorway between the high population areas of Lausanne and Geneva and hereafter referred as the Venoge bridge.

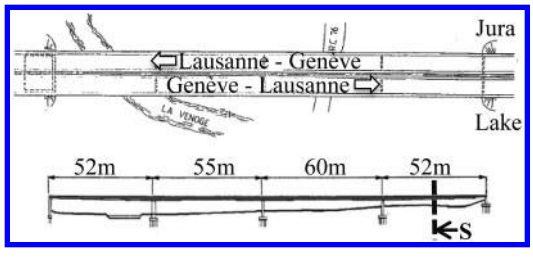

Figure 1. Venoge bridge: in plain view and elevation.

The Venoge bridge consists of two identical independent bridges (one for each direction) with a 219 meter length divided in four spans (see Figure 1). Each bridge was constructed in 1961 with two girders and then enlarged in 1995 to four girders (see Figure 2). Due to symmetry, only the bridge with traffic in the Lausanne-Geneva direction is considered in this study.

Two fatigue critical locations within the bridge are identified by inspection: 1) the stiffener weld attachment at the girder lower flange (location B in Figure 2) at the middle of the first span (FAT 56 according to EN 1993-1-9 table 8.4 (Eurocode EN 1993, 2005)); and 2) the cover plate weld attachment at the girder lower flange (location C in Figure 2) at the middle of the first span (FAT 40 according to EN 1993-1-9 table 8.5 (Eurocode EN 1993, 2005)). Due to the slow lane location over the enlarged bridge section (girders A and B in Figure 2), the majority of traffic is supported by girder B; therefore, detail 1 was chosen as the critical location for the fatigue failure analysis in this study.

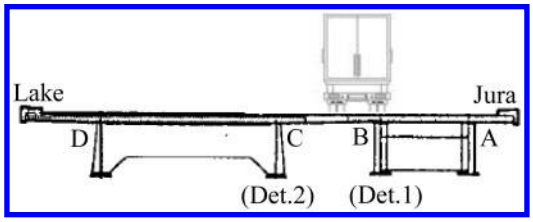

Figure 2. Bridge's section at the first mid-span: candidate fatigue critical locations.

2 FATIGUE RELIABILITY ANALYSIS

2.1 *Problem definition*

This section discusses the framework for the fatigue reliability analysis of the Venoge bridge, under the long-time effect of highway traffic. Due to the inherent randomness of traffic loading and detail fatigue strength, a probabilistic model has to be established. Probability of fatigue failure is associated with the evaluation of a limit state function that correlates the fatigue resistance and the fatigue loading for the considered critical fatigue detail.

Fatigue tests of structural steels for variable amplitude (VA) stress ranges, show that if the maximum stress range $\Delta\sigma_{max}$ stay below the CAFL of EN 1993-1-9 standard bilinear fatigue strength curves, then the life of a structural detail tends to be infinite; this observation can be used for the following verification:

$$\Delta\sigma_{max} \leq \Delta\sigma_D \tag{1}$$

Given that the stress time history at the fatigue critical detail is a stochastic process, the maximum stress range $\Delta\sigma_{\max}$ turns out to be a random variable. Regarding fatigue resistance, the CAFL value is also considered as a random variable. By considering these two random variables, a fatigue failure probability function can be defined as follows:

$$P_f = \int_{g(x,\boldsymbol{\theta}_g)\leq 0} f_{\mathbf{X}}(x,\boldsymbol{\theta}_f)dx \tag{2}$$

where $\mathbf{X} = (\Delta\sigma_D, \Delta\sigma_{\max})$ is a two-dimensional vector of random variables with continuous joint density function $f_{\mathbf{X}}(x,\boldsymbol{\theta}_f)$, where x is a realization of the random vector and $\boldsymbol{\theta}_f$ is a vector of distribution parameters. Failure is defined in terms of a limit-state function $g(x,\boldsymbol{\theta}_g) = \mathbf{X}_1 - \mathbf{X}_2$, where $\boldsymbol{\theta}_g$ is the vector of limit-state function parameters. The fatigue failure probability P_f can be related to the reliability index β as follows:

$$P_f = \mathrm{F}(-\beta) \tag{3}$$

where F is the cumulative distribution function of a standard normal distribution.

In this analysis EN 1993-1-9 double slope (m = 3, k = 5) standard fatigue strength curves are used. According to Table 8.4 in (Eurocode EN 1993, 2005), the considered fatigue critical detail is classified as FAT 56. The $\Delta\sigma_D$ can be regarded as a random variable modeled by a lognormal distribution with mean value μ_{RI} of 4.257 and standard deviation σ_{RI} of 0.113 (Technical European Convention for Constructional Steelwork – TC6, 1985); the parameters of the $\Delta\sigma_{max}$ probability distribution can be estimated through the following steps(details are given later in Section 3):

1. Randomly generate bridge load time-history samples by using the traffic simulation software and WIM -Swiss Automatic Road Traffic Data Collection (SARTC) database
2. Compute the stress-time response samples, at the fatigue critical location, using FE analysis;
3. Compute the stress-range spectrum samples, at the fatigue critical location, using the rain flow counting method;
4. Estimate the maximum stress range $\Delta\sigma_{max}$ probability distribution parameters, by using MCS.

2.2 *Reliability analysis – FORM method*

Once the probability distribution parameters of the random variables have been defined, then the problem structure is implemented in a Matlab code using the FERUM open source toolbox (Bourinet, Mattrand, & Dubourg, 2009). The fatigue reliability problem of Equation (1) is transformed from the original space of random vector $\mathbf{X}$ to a standard normal space. Following the failure probability P_f and the related reliability index β are estimated using the First-Order Reliability Method (FORM).

3 PROBABILISTIC LOAD MODEL

3.1 *Highway traffic simulation*

In order to get a realistic time-history of bridge crossing vehicles, traffic simulations were developed in the EPFL LAVOC laboratory, using the AIMSUN software. This software enables simulation of traffic flow in a road network, with the possibility to set up vehicle specifications and lane characteristics, to include driver behavior models in the software catalogue and to analyze different traffic scenarios (i.e. accidents, lane closures).In the first version of the traffic model, a linear highway network with a 3 km length,2000 vehicles per hours per lane (vph/pl) total capacity and 120 km/h speed limit was modeled; bridge is considered as a single point in the network. Following classes of vehicles were introduced in the software catalogue:

- Six classes of light vehicles (from motorbike to delivery vehicles);
- Thirteen classes of heavy vehicles with gross vehicle weight (GVW) higher than 10 tons (Table A.2 in (Meystre & Hirt, 2006));
- Two classes of heavy vehicles with GVW lower than 10tons (coaches, buses and trucks, road trains and articulated vehicles);

Since the lateral distribution of heavy vehicles on the bridge section is not currently known, a

conservative hypothesis was made: all the heavy vehicles of more than 10 tons detected by WIM circulatein the slow lane.

A statistical study based on data from Swiss Automatic Road Traffic Data Collection (SARTC) in Préverenges station (A1 Lausanne-Geneva direction, 2008) and from WIM in Denges station (A1 Lausanne-Geneva direction, 2008), was carried out to determine the class, the free flow speed distributions and the average time allocation for each vehicle class; Denges 2008 WIM database was chosen because it is the most recent available complete database.

Traffic simulation is based on origin-destination (O/D) matrices representing a standard week from year 2008; probability distribution of heavy cars was calibrated in terms of vehicle flow, by using empirical measurements for year 2008.

As it was aforementioned, a typical week of 2008 was simulated, as well as a forecasted week for 2012, assuming a 13.3% growth rate of traffic (3.3% per year), calculated from SARTC data of 2012. Simulated data (vehicle class, speed, and bridge crossing time)were used as input for fatigue analysis.

3.2 *Weekly stochastic stress response*

Simulated data for a typical week of 2008 (or forecasted week of 2012) were coupled to vehicle total length (TVL), vehicle axle spacing (AVS),vehicle gross weight (GVW) and vehicle axle load (AVW) information recorded by the WIM Denges station over the year 2008, in order to build the bridge traffic loading time history. Only heavy vehicles with a GVW over than 10 tons were involved in the calculation because lighter vehicles give a negligible contribution to the bridge fatigue damage. Simulation of one-week continuous traffic was performed using AIMSUN traffic simulator.

The simulation output is a bridge crossing-time sheet, which gives information on vehicle class, speed and arrival time. One sample of the bridge loading time history for a typical week of 2008 (or forecasted week of 2012) was calculated through the following steps:

1) The TVL and GVW histograms from WIM database were fit to standard probability distributions for each vehicle class;
2) TVL and GVW were randomly generated for each crossing vehicle by using fitted probability distributions generated at point 1);
3) the AVS and AVW histograms from WIM database were fit to the AVS-TVL and AVW-GVW relationship equations for each vehicle class, and;
4) the AVS and AVW were randomly generated for each crossing axle using equations

Generation of two hundred loading time-history samples was performed following the above steps. A3-D refined FE model of the bridge, which takes into account the effective transverse load repartition and the cracking of the concrete slab, was used to compute the nominal stress range influence line at the critical fatigue location (detail 1 in Figure 2); the FE model was calibrated and validated using experimental results from bridge static tests (Burdet, 1997). MSC/Nastran (MSC Software, 2012) was used for the analysis. The $\Delta\sigma_{norm}$ influence line and the loading time-history samples were then used to compute two hundred weekly stress response samples Tw_j both for a typical week of 2008 and for a forecasted week of 2012 (see Figure 3).

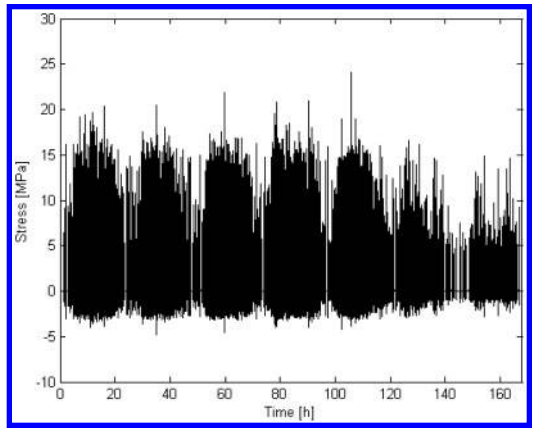

Figure 3. Sample of traffic-induced time stress response Tw_{2012}.

3.3 *Probability distribution of the maximum stress ranges*

3.3.1 *No traffic growth*

A rain flow counting algorithm and MCS were used to determine time invariant $\Delta\sigma_{max}$ probability distribution parameters at the failure critical location (detail 1 in Figure 2), assuming no future traffic evolution.

Two-hundred $Tw_{2012,j}$ were computed at the critical structural detail and two-hundred samples of $\Delta\sigma_{2012,j}$ were then obtained by application of a rain flow counting algorithm. Following, the generalized extreme value (GEV) probability distributions family was considered to model the upper bound of each stress range sample.

Type III GEV distribution (log-Weibull distribution with location parameter $\zeta = 0$) was fit to data using MLE. The scale parameter, λ_{lW}, is 3.39 and the shape parameter, k_{lW}, is 57.76. To visually assess the goodness of fit, the fitted probability density function (PDF) and the fitted cumulative distribution (CDF) function are shown in Figures 4 and 5.

3.3.2 *Linear traffic growth pattern*

Considering that the highway traffic may increase in the future, a time-dependent $\Delta\sigma_{max}$ probability distribution was computed assuming that distribution parameters have a linear growth pattern (conservative hypothesis). Using the approach described in section 3.3.1 two different $\Delta\sigma_{max}$ GEV probability distributions were estimated from $\Delta\sigma_{2008,j}$ and

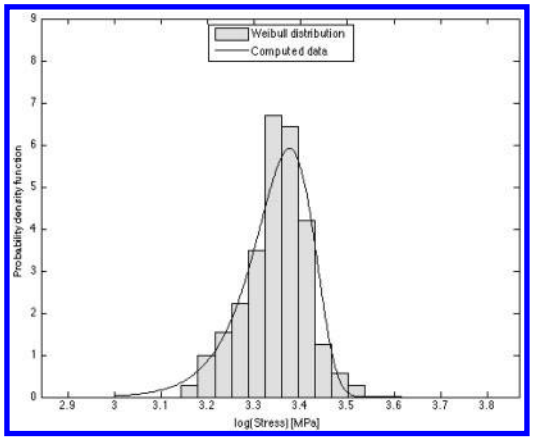

Figure 4. PDF of the $\Delta\sigma_{max2012}$ random variable.

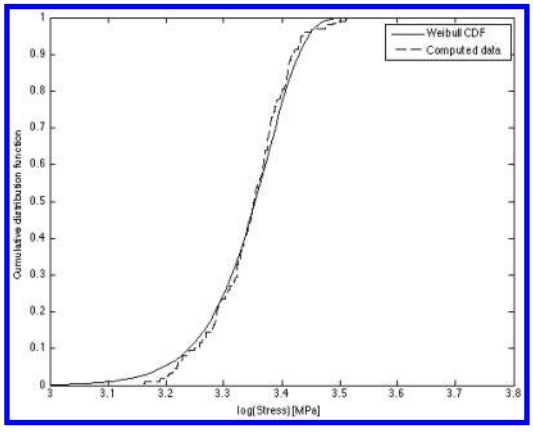

Figure 5. CDF of the $\Delta\sigma_{max2012}$ random variable.

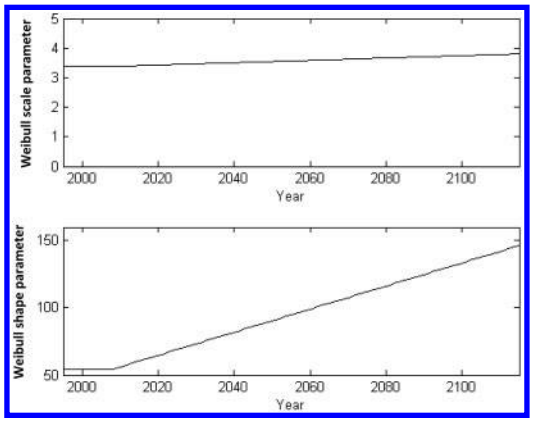

Figure 6. Time evolution of $\Delta\sigma_{max}$ distribution parameters.

$\Delta\sigma_{2012,j}$ samples. Following, the slope of the time-dependent $\Delta\sigma_{max}$ probability distribution parameters were calculated by linear interpolation.

As shown in Figures 6 and 7, no traffic growth was assumed between 1995 and 2008.

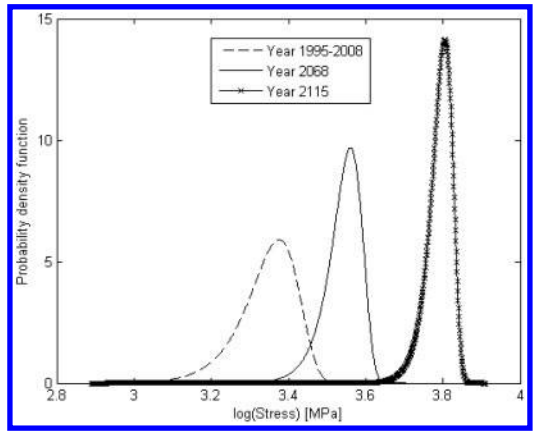

Figure 7. PDF of the time-dependent $\Delta\sigma_{max}$ random variable.

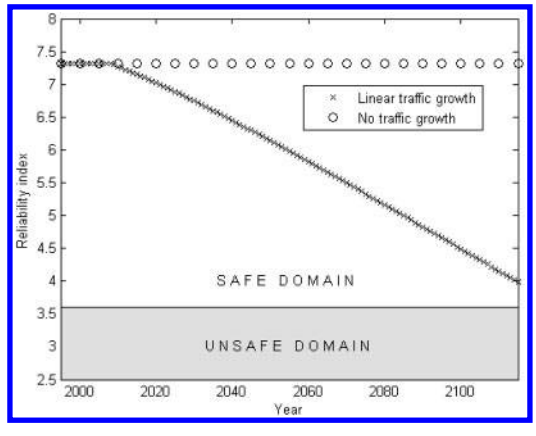

Figure 8. Fatigue reliability index evolution.

4 RELIABILITY ANALYSIS RESULTS

On the basis of the limit-state equation defined in Equation (2) and of the probabilistic load model defined in Section 3, the failure probability P_f at the fatigue critical location and the related reliability index β were computed for two considered future traffic evolution scenarios. Assuming no future traffic growth, the reliability index β at the end of the bridge design-life is equal to 7.31 (corresponding to a failure probability P_f lower than 0.0001%). When assuming a linear traffic growth pattern (see Section 3.3.2) the reliability index β at the end of the bridge design-life is 3.98 (corresponding to a failure probability P_f of 0.0035%). For reference, a target reliability index value of 3.6 is recommended from article C6 in (Eurocode EN 1990, 2001) for 120 year design life where inspections are not planned. The value of the computed β at the end of the 120 year design life is higher than the reference value, as shown in Figure 8.

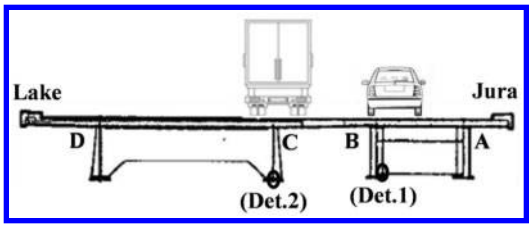

Figure 9. Future lane change.

5 TRAFIC SIMULATION DEVELOPMENTS AND POTENTIAL FOR FUTURE ADVANCES

While the AIMSUN software allows for generation of realistic traffic in a road network, the first version of the traffic model (the version used herein) is limited to linear network simulation with all heavy vehicles placed in the slow lane and it needs a post processing to include vehicle lengths, weights and axle spacing. Future versions of the model under development will overcome these limitations and allow simulation of special events like a lane closure or the opening of a new highway exit. The lateral positioning of heavy vehicles is being studied using video recording: collected data will be used to define realistic vehicle lateral distribution on the bridge section.

Particular attention has to be paid to these "special" events because they could require the re-consideration of the fatigue critical locations and or re-definition of the limit state function. A lane configuration change as shown in Figure 9, would result in FAT 40 detail 2 as the critical fatigue location and require a re-definition of the limit state function in terms of accumulated damage (given that a considerable amount of cycles could be higher than the CAFL).

The reliability analysis framework set up in this paper and the realistic traffic simulator constitute two powerful tools to perform fatigue reliability analysis of road bridges for any future traffic evolution scenario and for several special events simulation.

6 CONCLUSIONS

In this paper a framework for the fatigue reliability analysis of a highway bridge has been formulated in terms of a limit state function that describes the relationship between the fatigue strength of a selected critical detail and the maximum stress range. The framework has been applied to the Venoge bridge within the A1 Swiss Motorway. A traffic simulator tool, WIM database, and FE analysis were combined to compute the time-stress response at the fatigue critical location. MCS has been used to define parameters of the maximum stress-range probability distribution. Finally, the fatigue failure probability and a related reliability index are calculated at the end of the bridge design life. The results show that fatigue is not a concern for the Venoge bridge over the considered 120 year design life, evident by a reliability index greater than the target reliability index (3.98 compared to a target value of 3.6, see again Figure 8). Particular attention is needed however, for future changes in traffic lane configuration, which could require re-consideration of fatigue critical locations and re-definition of limit state function.

Comparing two types of fatigue and tsunami resisting medium span bridges

Ph. Van Bogaert
Ghent University, Belgium

ABSTRACT: Two alternatives of medium span steel railway bridges have been considered to be reinforced from common design conditions to resist tsunami load. The tropical cyclone method is being used to assess the effect of tsunami impact. Verification demonstrates that the effects of surge impact and the post-wave action are different for a plate girder and truss type bridge. This also applies to the effect of the debris force and overturning of the train vehicles. For moderate span, the plate girder bridge needs far less reinforcement than the truss bridge and is easier to adapt. A discussion about the scale effect is also added.

1 INTRODUCTION

1.1 *Tsunami resistance*

Although this type of disaster has been known throughout history, the major disasters of the last decades have made tsunami waves again a relevant accidental load for structures. This paper does not aim at closely simulating the effects of tsunami waves or define approaches for that purpose. It merely tries to discuss a conceptual question, whether two types of medium-span bridges are able to resist both frequent loading conditions, such as fatigue as well as an accidental situation, caused by an average tsunami impact. This problem was initiated by a steel fabricator who was asked to deliver such a comparison for a pacific railway company, renewing its oldest bridges. The results of this comparison are delivered in this paper and may show a somewhat surprising result.

1.2 *Bridge replacement conditions*

Since the railway company was replacing more than 40 bridges of various spans, the present study needed to focus on one particular span range. For this, a typical bridge of 38.1 m span has been considered. In addition, the railway loading corresponds to LM 71 according to Eurocode 1 (EN 1991-2 2003), including the requirements for fatigue resistance.

The bridges to be replaced are mostly dating from the late 19th or early 20th century, and although they have been well kept, they are showing major corrosion. In addition, the design loads are unknown and there may be doubt whether these structures comply with the requirements of modern train vehicles. Fig. 1 shows a typical bridge of the truss-type. Other bridges have plain web girders. It may be noticed that only few bridges have ballast track, wooden sleepers being mostly fixed to the steel structure.

Figure 1. Typical truss girder bridge with wooden sleepers.

2 TSUNAMI LOAD

2.1 *Tropical cyclone method*

Various methods have been developed quantify the effect of tsunami loads on buildings. The method described by in (Yeh 2007), seems at present the most complete, since it distinguishes the various origins of this type of load. This method was derived from the effect of tropical cyclones. It involves the hydrostatic force, the hydrodynamic drag, the surge impingement effect, as well as the buoyancy and debris forces. The latter forces do not necessarily occur simultaneously with other effects, since they show a delay compared to the actual impact (Yamamoto et al 2006).

2.2 *Hydrostatic force*

The equivalent hydrostatic force acting on a plain panel of width b and height h_w is given by equation 1. In this expression h is the height of the tsunami

wave, whereas ρ is the water density and g the gravity acceleration.

$$F_h = \rho g \left(h - \frac{h_w}{2} \right) b\, h_w \quad (1)$$

Elementary quantification of the tsunami force increase the value of h up to 2.5 or 3 times the actual height of the tsunami wave. In the tropical cyclone method, other parameters are used.

2.3 *Hydrodynamic drag*

The effect of the wave speed is found through the hydrodynamic flow force of equation 2. In this A is

$$F_d = \frac{1}{2} \rho\, C_d\, A\, u_p^2 \quad (2)$$

the projected area perpendicular to the direction of flow, C_d is the drag coefficient and u_p is the flow velocity. The drag coefficient depends on the shape and roughness of the object. For a rectangular shape this coefficient equals approximately 2 (Fujima et al 2009). To determine the flow velocity, it may be assumed that the tsunami wave progresses on a river and constitutes a shallow water waver. The velocity of this type of waves can be found from equation 3.

$$u_p = \sqrt{g\, d_s} \quad (3)$$

2.4 *Surge impingement force*

This is the hydrodynamic force of the leading edge of the tsunami wave. It is determined using equation 4. Herein C_I is the impingement factor and h the

$$F_I = C_I\, \rho\, g\, h^2 \quad (4)$$

In literature (Palermo et al 2008a, b) a value of 4.5 for C_I may be found. According to some authors this value is conservative and overestimates the impingement force.

2.5 *Buoyancy force*

The buoyancy force is an uplift effect due to the sudden rise of the water level below the structure. It is found from equation 5 in which V is the water

$$F_B = \rho\, g\, V \quad (5)$$

volume displaced by the bridge itself. In the case of the open, ballastless structures being discussed, the value of V is rather low and the buoyancy is limited. In fact, it is totally being compensated by the structure's dead weight.

2.6 *Debris force*

This force is caused by water-borne objects, such as boats, vehicles and driftwood, hitting the bridge. There are various methods to determine this force. Among them is the stiffness approach, which is recommended for driftwood. The debris force becomes

$$F_{debris} = C_M\, u_p \sqrt{;\, k\, m} \quad (6)$$

C_M being a mass coefficient, u_p the flow velocity, k the effective stiffness and m the mass of the debris. A reasonable value for C_M is 2 and k equals 2.4 MN/m. The Honolulu building code gives a value of 455 kg for the mass m (Santo et al 2010).

Table 1. Tsunami pressures.

Effect		Pressure
Hydrostatic	F_h	24.53 kN/m^2
Hydrodynamic drag	F_d	49.05 kN/m^2
Surge impingement	F_I	198.65 kN/m^2
Initial impact	F_{1L}	198.65 kN/m^2
Post impact	F_{1P}	73.58 kN/m^2

2.7 *Combination of tsunami effects*

The previously mentioned effects do not occur simultaneously during tsunami impact. Two phases should be distinguished : the initial impact and the post wave impact. During the initial impact, the surge impingement force is possible accompanied by the debris force, according to equation (7), whereas subsequently the combination of hydrostatic force, hydrodynamic force, buoyancy and debris force can act together, according to equation 8.

$$Phase\ 1: \ F_I + F_{debris} \quad (7)$$

$$Phase\ 2: \ F_h + F_d + F_B + F_{debris} \quad (8)$$

In this study, the tsunami height has been assumed to reach 4.5 m according to (Shoh et al 2007) the wave velocity being 7 m/s. Obviously, more extreme values may be considered. These assumptions render the pressures mentioned in table 1 and the resulting combinations.

3 PLATE GIRDER BRIDGE

3.1 *Initial design*

If no tsunami load is considered, the various effects are dead weight, permanent rail loading, vertical and horizontal train loading and wind. The analysis of the FE model shown in Figure 2, reveals that fatigue is the critical condition. This is explained by the large proportion of the variable load, since the dead loads are rather small.

The numerical model clearly shows the main girders and crossbeams, which are at the distance of 3.81 m and are connected to the vertical stiffeners. The open

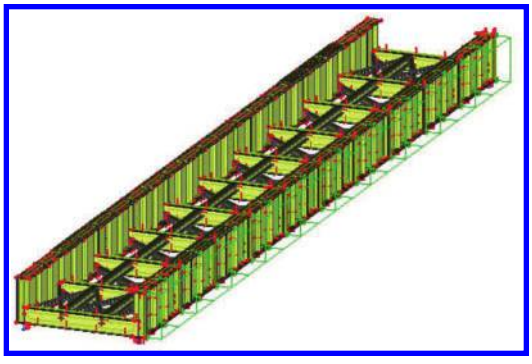

Figure 2. FE-model of plate girder bridge.

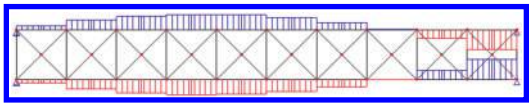

Figure 3. Lower bracing.

deck structure also contains stringers below the rails. The latter are uninterrupted at the intersection with the crossbeams.

3.2 *Adapting to resist tsunami effects*

Applying tsunami loads to the plate girder alternative shows that the critical situation occurs when the wave hits the main girder closest to the sea. This means that the opposite girder is not subjected to the wave impact. This condition is more important than the simultaneous action of wave impact on the reduced section of the second, land side girder and post impact force on the seaside girder.

The plate girder structure must be equipped with heavy horizontal bracing, since the seaside girder receives large compression, whereas the landside girder shows large tensile force. The horizontal bracing, including the normal forces is shown in Figure 2.

As can be seen in figure 3, the distribution of normal forces in the edge beams is not symmetrical. This is due to the fact that the horizontal restraining of displacements by the bearings is statically indeterminate, as the horizontal reactions influence the normal forces in the edge beams.

The most important result from tsunami loading is the heavy bending and possible crippling of the girder web. This has resulted in adding 1 or 2 vertical stiffeners to reduce the bending effect. As shown in Figure 4a, one additional stiffener does not resolve the problem, since the panel width equals its height and the panel is too large. In Figure 4b with two additional stiffeners, the ratio of width to height has been reduced sufficiently.

In addition, the local impact load of debris also necessitates reducing the panel length. The effect on plate stresses is shown in Figure 4c. However, after failure of this panel, the plate girder bridge remains

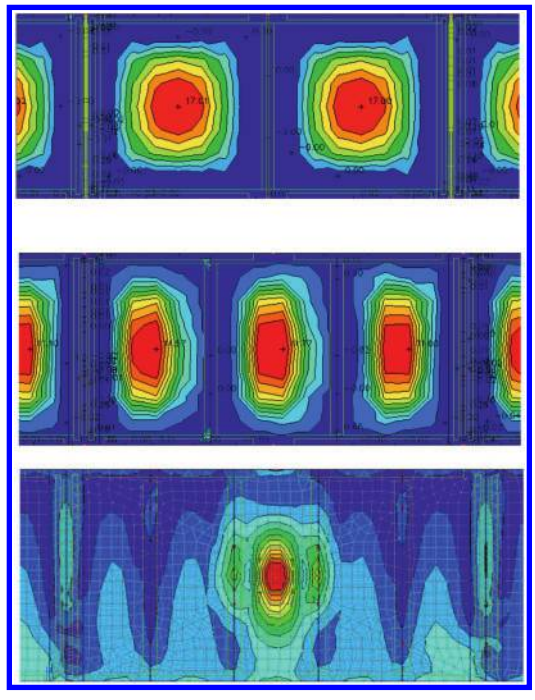

Figure 4a, b, c. Web plate stresses caused by surge load with 1 (a), and 2 (b) additional stiffeners and by debris force (c).

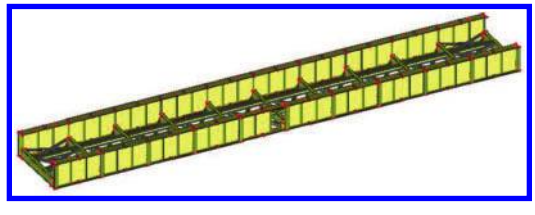

Figure 5. Bridge model with 1 plate panel failed.

capable to resist railway loading, this being verified by a numerical model with one panel being cut out as in Figure 5.

To conclude the case of the plate girder bridge, the case of simultaneous railway and tsunami loading has also been considered. However, the train loading will take a ψ-factor equaling 0.5. In this case, the additional stiffening becomes somewhat heavier. In particular, the intermediate stiffeners, which are simple vertical plates, are subjected to bending with respect to a horizontal axis.

The concept of using simple plate stiffeners for intermediate ones and more heavy stiffeners, including flanges at the location of crossbeams, shown both in Figure 6 (left and right) may seem old, yet it continues to be sensible, since the first type is easier to fabricate than the latter. Figure 6 shows for both types the stress state in case of simultaneous railway and tsunami load. It can be noticed that the plate stiffeners receive almost no contribution to resistance from the web plate.

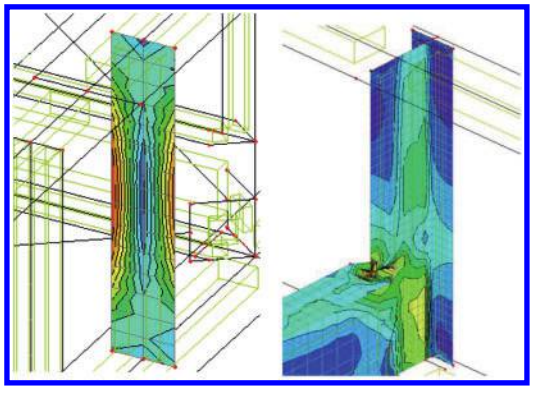

Figure 6. Plate and flange-type vertical stiffener.

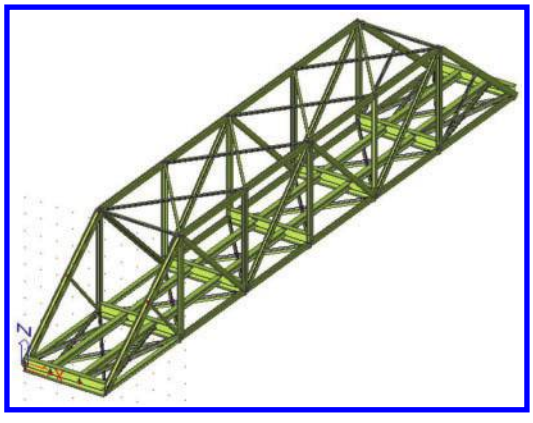

Figure 7. Truss bridge model.

4 TRUSS BRIDGE

4.1 *Initial design*

As in the former case, the design without tsunami load again shows that fatigue resistance is the critical condition. The stringers are being reinforced to resist the stress variations and crossbeams, which are at 6.1 m distance, also are determined by fatigue conditions, the category corresponding to 80 MPa.

As for the truss members, the second diagonal, as shown in Figure 7 is the most critical for fatigue.

The upper edge member is determined by buckling conditions at ultimate limit state, rather than fatigue resistance.

4.2 *Effects of tsunami load*

Calculations demonstrate that the tsunami load has maximum effect if the surge impingement hits the landside truss girder and the post-impact effects are acting on the seaside truss member. Again, the lower bracing becomes much heavier compared to the initial design and additional bars are needed. The outer diagonal members are subjected to heavy out-of-plane bending, since they act as a portal frame, together with

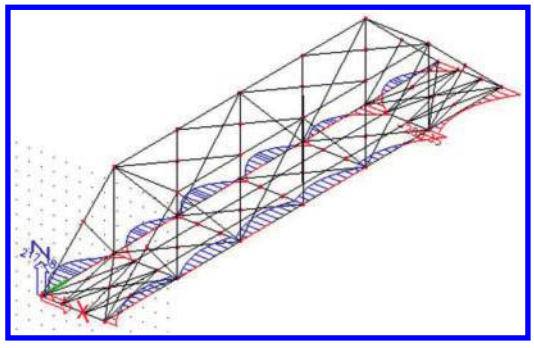

Figure 8. Lateral bending of lower truss member.

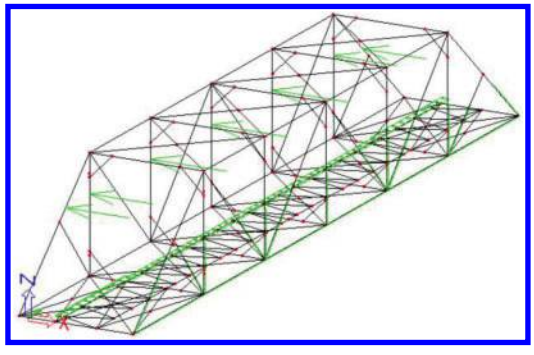

Figure 9. Truss bridge with debris force on members.

the edge crossbeams. These effects are due to global distortion of the truss bridge.

In addition, the seaside lower edge member becomes heavily compressed, a non-existing situation for the initial design. This causes a stability problem for the member, which needs excessive increase of the cross-section stiffness. The edge member is also subjected to bending, which is an unusual condition for normal truss bars. This is shown in Figure 8.

A particularly difficult problem is the debris force, causing concentrated loads on the vertical or diagonal members. Obviously, most members are indispensable and the strategy adopted for the plate girder bridge no longer applies. Hence, these members required larger reinforcement.

The combination of simultaneous train load and tsunami is more complicated for this truss bridge. As the rail vehicle is obstructing the impact of the wave, the vehicle is subjected to the surge. In these conditions, the vehicle will overturn and immediately hit the truss diagonal and vertical bars. This condition has also been considered, the loading case being shown in Figure 9.

In order to improve the distribution of loads, the width of the bridge needs to be increased, in this case up to 6.1 m. This results in higher resistance to horizontal loads.

As a result of the combined action of tsunami and railway load and the overturning of the rail vehicle is the need to add sloping bars in the edges of the portal

frames constituted of the vertical truss bars and bracings. This can also be seen in Figure 9. These additional bars are needed to resist the large bending moments at the frame angles, caused by the distortion effect.

5 DISCUSSION OF REINFORCEMENTS

5.1 *Plated girder bridge*

In this and the following sections, the overview of reinforcement of sections, due to tsunami loads are being discussed. For the case of the plated girder bridge, subjected to tsunami load without railway loading, the following members are affected.

- the longitudinal stringers are unaffected and continue to function as in the original;
- all crossbeams show sufficient resistance, apart from the edge crossbeam, which changes from HEA to HEB 700 profile;
- the primary lower bracing must be reinforced consistently from HEA 120 to HEM 220 profiles, as well as the bolted connections. However the height of secondary bars changes slightly from 100 to 120 mm.

If both the railway and tsunami loading are acting on the plated girder bridge, the following adaptations are necessary:

- the longitudinal stringers are still functioning in their original version;
- all crossbeams show sufficient resistance, apart from the edge crossbeam, which changes from HEA to HEB 700 profile;
- the primary lower bracing must be reinforced consistently from HEA 120 to HEM 240 profiles, as well as the bolted connections. However the height of secondary bars changes slightly from 100 to 120 mm

It should be remembered that debris force is critical for the web plate and will cause local damage.

5.2 *Truss bridge*

The difference between the original, fatigue resistant truss bridge and the structure, resisting to tsunami load alone, without railway loading can be summarized as follows:

- the longitudinal stringers have sufficient resistance in both cases, although the last sections near the bridge ends are heavier;
- summarized as follows:
- the edge crossbeams have to be increased, whereas normal crossbeams are satisfactory;
- the lower edge truss member needs considerable reinforcement from HEA 240 to HEM 500, also because it shows compression force instead of uniform tension;
- the upper edge truss member continues satisfying the requirements;
- the upper bracing as well as the lower bracing members become considerably heavier;
- the end portal frames and extreme diagonal bars are to be reinforced considerably.

If the same loading conditions are combined with the debris force, the following additional design revisions are necessary:

- the type of profile of the edge crossbeam needs serious revision, since a closed section of 750 mm width is needed;
- this also applies to the lower edge truss member, for which a closed section 750*300 mm becomes necessary;
- all diagonal truss members need serious reinforcement, although a change of type of profile is unnecessary;

Obviously the latter is due to the concentrated debris force, acting independently on the diagonal bars. If the combined effects of tsunami and train loading are considered, the following additional revisions proved to be necessary:

- the type of profile of all stringers needs to be changed to closed sections of 400*380
- the upper truss member also requires a hollow cross section of 300*300
- the first and last diagonal and vertical members must be changed to hollow section profiles of 600*600
- most importantly, the total width of the bridge should be increased to at least 6.1 m.

As a result of this, the tsunami and railway load resistant plate girder bridge's steel mass increases by 26%. In the case of the truss bridge adaptations to resist an identical combination, steel weight will increase by 80%, which further increases to 105% if debris force must be resisted.

5.3 *Scale effects*

The former calculations show that the plate girder alternative is more capable to be adapted to tsunami loading. However, the calculations concern a 38.1 m span bridge.

Should the span of the bridge be larger than the value being considered, under normal conditions a truss bridge should become more advantageous. The length of individual members increasing, the number of fatigue loading cycles should decrease. This particularly is in favour of the truss alternative.

Concerning the effect of tsunami loading, the height of a plate girder bridge will increase with the span, obtaining a larger impact surface for the surge wave. In addition, the span of the vertical stiffeners increases and the higher impact pressure, acting on longer stiffeners, will introduce larger stresses in these members. This will cause heavier reinforcement of the plate girder bridge.

In case of a truss bridge, the increase of span will necessarily require larger resistance of all members. The effect of tsunami will act on somewhat larger areas, although compared to the former case this size effect clearly is moderate. The same applies to the debris force and the train car overturning loads.

Consequently, the increase of steel mass for the plate girder will increase with the span more rapidly than for the truss alternative, which may very well reduce below 80 or 105%.

6 CONCLUSIONS

Two alternatives of medium span steel railway bridges have been considered to be adapted from common design conditions to resist tsunami load. These examples clearly demonstrate this aim certainly proved to be realistic.

Large uncertainty continues to exist about the magnitude of tsunami loads. The surge wave height and speed is a fundamental issue and some assumptions had to be made. In addition the debris force may be discussed, since it has large impact on both bridge types.

A plate girder bridge seems to be loaded by tsunami effects in a totally different way than the truss alternative. In the first case, the surge impact acts directly on the seaside girder, the landside girder being still unloaded. For the truss alternative the most critical condition corresponds to having initial impact on the landside truss and post-impact effect on the seaside girder.

Simulations for a 38.1 m span bridge have shown that the condition of tsunami loading, combined with railway loads will increase the steel mass by 26%, mainly due to adding vertical stiffeners of the girder webs and reinforcing the bracing. For the alternative of a truss bridge, the mass increase moves up to 105%. This demonstrates that the plate girder bridge performs better than the alternative.

Obviously, larger span bridges will show different results, and it is expected that gradually the truss bridge will perform much better.

Are short span reinforced concrete bridge girders cost effective?

T.N. Haas & D. Smith
Department of Civil Engineering, Stellenbosch University, South Africa

ABSTRACT: This study investigated the cost effectiveness of steel girders compared to the conventional reinforced concrete girders used in bridge construction in South Africa. The investigation considered an existing bridge which required widening as a result of increased traffic flow in close proximity to an industrial area. The consulting engineer specified the same reinforced concrete cross sections for the 10 m abutment and 22 m central span girders to maintain uniformity with the existing bridge. To determine the cost effectiveness of this approach, steel girders were designed for only the 10 m abutment span based on the relevant South African codes of practice. The analysis was conducted for non-composite as well as composite action between the steel girder and the reinforced concrete bridge deck. Based on the steel sections obtained a cost comparison was performed. The investigation revealed that for generally available off the shelf I-sections in South Africa, steel girders are an economically viable option, even when considering corrosion treatment. For the 10 m span, the composite girder construction proved to be more economical compared to the reinforced concrete beam over a 5 year periods. However, for the same period, the non-composite girders were economical for 2 years out of the 5 year period. Thus, bridge designers should consider steel girders as an option during the conceptual design stage for short spans, i.e. up-to 10 m in length. A survey was also conducted amongst senior bridge design engineering professionals to determine the apathy towards using steel sections as girders in bridge construction.

1 INTRODUCTION

Highway bridge elements in South Africa are usually constructed of reinforced concrete (RC). These elements include; bridge decks, girders, piers and the foundations. It is understandable that all of these elements, except for the girders, are constructed with RC since the members are in compression. When live and dead loads are applied to the bridge deck, it causes the section above the neutral axis of the girder to be in compression and the remainder of the cross section to be in tension. Thus, any material which is economically viable can be used to construct bridge girders.

For many years engineering professionals have debated which material is more economical in highway bridge construction. To emphasize this point, approximately 97% of highway bridges in the Western Cape in South Africa are constructed with RC girders, Viljoen (2012). This uncertainty led to this investigation to determine whether RC or structural steel would be better suited in highway bridge construction with particular emphasis on bridge girders. Most highway bridges in South Africa consist of two central spans and two abutment spans. The central spans are approximately 22 m long while the abutment spans are approximately 10 m long. A bridge, which required widening, in the Kuilsriver area in the Western Cape with these dimensions was used for the analysis. The widening of the existing bridge was necessitated due to the significant increase in the housing development which led to a corresponding increase in traffic volumes during peak hours.

In many countries around the world, structural steel sections are commonly used as bridge girders. However, in South Africa this is not the case. There are many factors which affect the material choice used in bridge construction. Some of the most important factors include, but not limited too, are:

- Abutment span
- Location
- Experience of the bridge engineer working with structural steel
- Cost of the structural steel and the availability of larger off the shelf steel sections
- Environmental factors
- Time constraints
- Safety requirements
- Standardized RC sections used by provincial road agencies and consulting engineers
- Norm?

To answer the aforementioned question, this investigation considered the responses of a survey completed by senior structural engineering professionals. The aim of the survey was to determine why engineering professionals are reluctant to use structural steel as bridge girders. In addition, steel girders were also analyzed and designed to perform a cost analysis to determine whether off the shelf steel sections can be used as bridge girders for abutment spans. The analysis

Table 1. Average level of agreement why composite bridge construction is not used in South Africa.

Question	% level of agreement
Required off the shelf steel sections not available	20%
Steel bridge girders are too expensive	80%
Installation of steel bridge girders are expensive	30%
High cost of maintenance	80%
Concrete beams have become the norm	70%
Steel bearing are expensive	40%
Shear connectors are expensive	40%
Aesthetic appeal	50%
Steel girders have the potential to buckle laterally	20%

considered transportation costs, corrosion treatment costs and composite construction.

2 SURVEY

A survey questionnaire, developed by Smith (2010), was sent to numerous companies who specialize in highway bridge construction to determine the reason(s) why RC girders are predominantly used in highway bridge construction. The survey questionnaire was designed as a web based survey where the respondents had to indicate their level of agreement to the questions. An explicit requirement was that only experienced bridge / structural engineering professionals complete the survey questionnaire. Only 10 responses were obtained from the survey. From the survey it was established that the respondents had an average of 21 and 16 years of experience in structural engineering and bridge design, respectively. Based on the average years of experience of the respondents, the authors felt confident that only experienced professionals took part in the survey. The authors also felt confident that the responses would be similar if a wider audience were sought. Some of the important results from the survey are now presented in Table 1.

Based on the survey we notice that the apathy toward using steel girders in bridge construction are that; steel girders as too expensive, the high cost of maintenance, concrete girders have become the norm and the aesthetic appeal of the concrete girders. The latter two factors are based on the designer's and/or client's appreciation and not on economic considerations. The first two factors however need to be investigated to have a sound economic base. The authors believe that these factors are solely based on past experience and not on a cost analysis per project.

3 PRICE INDICE OF STRUCTURAL STEEL

It is common knowledge that the price of steel fluctuates significantly over time. Erling (2012), from the

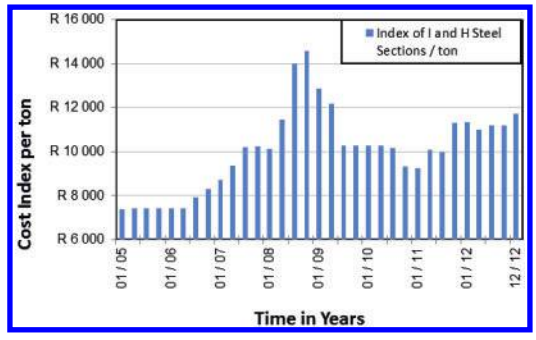

Figure 1. Cost index of steel per ton since January 2005.

Southern African Institute of Steel Construction was approached to determine the accuracy of this claim. Erling provided data which is presented in Figure 1 to monitor the price fluctuations of I and H sections since 2005.

Figure 1 shows that during 2005 the price index of steel ("raw" cost) remained constant and steadily increased from mid-2006. During 2008 the price of steel dramatically increased to a record high of approximately R14 600 per ton. Thereafter the price of steel experienced a significant decrease to stabilize at approximately R10 800 per ton during 2009 to 2012. Figure 1 shows the that the price of steel does indeed fluctuate significantly over time and that it is imperative to conduct a cost analysis to provide the client with the most affordable cost for the project.

4 DESCRIPTION OF BRIDGE

The existing reinforced concrete bridge deck is supported on two 22 m simply supported central span girders and two 10 m simply supported abutment span girders. The existing bridge had a width of 8.6 m which allowed for a single carriageway in both directions. Due to the increase in traffic volumes the existing bridge was widened to allow for a dual carriageway in both directions. To maintain conformity with the existing bridge the design engineer used RC sections for all the new elements.

5 BRIDGE LOADING

The existing bridge is located in the vicinity of an industrial area which accommodates unusually heavy traffic loading. Therefore the bridge needed to be designed for all possible traffic loads as specified in the "Code of Practice for the Design of Highway Bridges and Culverts in South Africa", TMH 7, Parts 1 to 3. TMH 7 specifies that the bridge be designed for the following load cases namely:

- NA loading – normal loading on the bridge
- NB loading – abnormal loading on the bridge
- NC loading – super loading on the bridge

Table 2. Summary of the traffic loading.

	Traffic loading		
	NA	NB	NC
SF (kN)	186	238	198
BM (kNm)	466	481	495

The maximum shear force (SF) and bending moments (BM) were obtained for the abutment spans. Based on the requirements of Kayser and Nowak (1989), wind loads were ignored from this study as it is not significant in short to medium span bridges. No allowance was made for impact and dynamic effect as specified in clause 2.6.1.3 of TMH 7. From clause 2.2.6 of TMH 7, 3 notational lanes are required for an 8.6 m wide carriageway. To determine the maximum SF and BM for each type of loading, the appropriate material and partial factors were applied to the uniform distributed loads on the abutment spans. The material factor for steel was obtained as 1.1 while the partial factors for NA, NB and NC loading are 1.5, 1.2 and 1.2, respectively.

6 RESULTS OF THE MAXIMUM SHEAR FORCE AND BENDING MOMENT

6.1 *SF and BM due to traffic loading*

The individual maximum SF and BM for each type of traffic loading are presented in Table 2.

From Table 2, we notice that the maximum SF and BM due to traffic loading are 238 kN and 495 kNm, respectively. We also notice that the maximum SF and BM are obtained from different loading conditions. An interesting observation is that the SF differs by 21.8% while the BM differs by 5.6% between the three loading conditions. The maximum SF and BM varied by less than 2% from the design engineers results.

6.2 *SF and BM due to bridge deck*

Before the girders could be designed, the dead loads due to the asphalt, concrete deck and girders were required. An asphalt thickness of 50 mm together with a density of 22.0 kN/m^3 and 1 m strip was used to determine the SF and BM, while a slab thickness of 245 mm with a density of 25.5 kN/m^3 was used for the concrete deck. Using a material load factor of 1.2, the maximum SF and BM for the 10 m span was obtained as 44 kN and 110 kNm.

6.3 *SF and BM due to girders*

The dead load of the abutment girders was also required before the beams could be designed. The final steel sizes were achieved after an iterative approached was employed to obtain the optimal steel section for composite and non-composite action.

Table 3. Maximum SF and BM

	$SF_{MAXIMUM}$ (kN)	$BM_{MAXIMUM}$ (kNm)
Non-composite action	289	623
Non-composite action	287	618

Table 4. Summary of beams obtained.

	Span	Section	Shear Connectors
Non-Composite Action	L = 10 m W = 1.0 m	533 × 210 × 122 I-section	N/A
Composite Action	L = 10 m W = 1.0 m	457 × 191 × 89 I-section	19 mm ϕ studs with 0.5 m spacing

6.4 *Maximum SF and BM*

The maximum SF and BM due to traffic and dead loads for the abutment beams are presented in Table 3.

7 DESIGN OF STEEL GIRDERS

The steel girders were designed according to the South African National Standard, SANS 10162-1 of 2005 and the Southern African Steel Construction Handbook (2005). To achieve the most economical steel sections, the beams were designed to be laterally supported. This could be achieved if a groove of equivalent width of the top flange is recessed at the bottom of the concrete deck.

For further economy, the beams were also designed for composite and non-composite action based on clause 17 of SANS 10162-1. To achieve a proper composite connection shear connectors were designed to resist the horizontal shear that form between the concrete and the steel sections.

7.1 *Summary of steel beams*

The most economical steel sections which satisfy both Ultimate Limit State and Serviceability Limit State requirements for non-composite and composite action are shown in Table 4. The design of the abutment girders were controlled by Serviceability Limit State requirements, i.e. deflection criteria.

7.2 *Cost of the steel sections for the abutment spans*

Numerous steel suppliers were contacted to provide quotations for off the shelf steel I-sections. The suppliers were limited to a 10 kilometre radius from the site to minimize transportation costs. Of the suppliers contacted only one could provide a detailed cost history of these sections since 2007. As the

supplier has branches nationally and their prices were cheaper than the other suppliers, their data was used for the analysis. I-sections are stocked in 9 m and 13 m lengths. 13 m I-sections needed to be purchased even though the abutment spans were 10 m long.

7.3 *Protective steel treatment*

It is important to protect steel from corrosion to prevent the sections from experiencing a reduction in its load carrying capacity, Kayser, (1989). Corrosion on steel sections is not uniform which leads to further uncertainty of the section's performance. In the study various commercial corrosion treatment options were considered over the design life of the bridge. Hot dipped galvanizing was found to be the most economical method of preventing corrosion on steel sections. Using information supplied from the Hot Dip Galvanized Association of Southern Africa (HDGASA) and the recommendation from Wilmot, a 150 μ m zinc coating is sufficient to protect the steel sections for 50 years. The current cost of hot dipped galvanizing steel sections is approximately R6 250 per ton. The authors could not obtain accurate prices from suppliers for hot dipped galvanizing steel since 2007. To obtain a cost history backdated to 2007, a 10% depreciation was applied to the current cost of hot dipped galvanizing.

7.4 *Cost of shear connectors*

Shear connectors are required to provide a composite action between the concrete and steel girders. Based on the design requirements, a total of 40 shear connectors of 19 mmϕ × 100 mm are required. The total cost to attach shear connectors to the top flange of the I-section was R1 440 based on 2012 prices. A 10% depreciation was applied to obtain cost estimates backdated to 2007.

7.5 *Transportation cost*

The average cost of transporting I-sections to site is approximately R450 per ton based on 2012 prices. A 10% depreciation was again applied to obtain cost estimates backdated to 2007.

8 RESULTS AND DISCUSSION

The RC beams were cast 8 kilometres off-site and needed to be transported on a lowbed to site. Since the project commenced in 2009, the contractor provided cost estimates from this time. A 10 % depreciation was applied to the RC girders to obtain a cost history for 2007 and 2008.Figure 2 shows the total cost inclusive of transportation and installation of the RC girder obtained from the contractor.

Superimposed on Figure 2 is the cost of the I-sections over a 5 year period inclusive of galvanizing, transportation and shear connectors were necessary.

Figure 2 shows a dramatic escalation in the cost of steel at the beginning of 2008. This confirms the steel cost index from Figure 1. It is observed that a composite steel girder is more economical compared to an RC beam. Since 2008, the cost difference between RC and composite steel girders increased on a yearly basis. This proves that composite construction of the abutment girders are more economical compared to RC beams.

When non-composite girder construction is considered, we notice that RC abutment beams are more economical compared to off the shelf steel sections until the mid-2009. After 2009, the non-composite construction becomes more economical with an increasing cost difference between RC and steel girders.

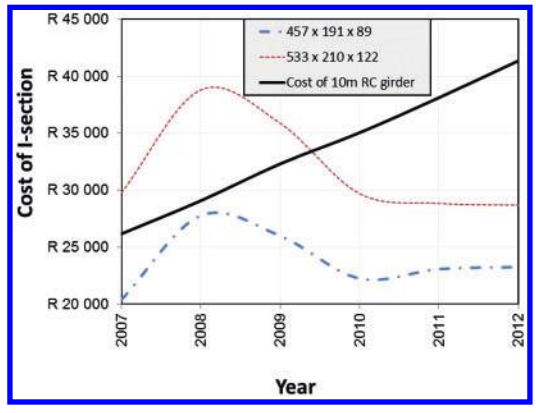

Figure 2. Girder costs.

Table 5. Total cost saving.

Year	Total cost saving for composite construction	Total cost saving for non-composite construction
2007	R115 602	R72 077
2008	R26 186	R194 359
2009	R126 578	R70 918
2010	R255 978	R107 130
2011	R300 845	R185 708
2012	R361 929	R253 374

9 CONCLUSIONS

Although the accuracy of the estimated total cost of steel girders could be questioned, the results show that using steel girders in short span bridge construction is a viable option and needs to be considered. As shown in Figure 2, it is important for design engineering professionals to conduct a cost analysis to provide the client with the most economical design. For the two abutment spans, a total of 20 beams were required. Based on this number of beams, the total cost saving is presented in Table 5 for composite and non-composite construction.

The shaded cells identifies that steel girder construction is more economical. From Table 4 it is clear that steel girders in short span bridge construction is a viable option.

Effect of constraint in-plane displacement conditions for the unloaded edges of stiffened flanges used in steel box girder bridges

P.S. Ferreira

F. Virtuoso
Technical University of Lisbon, Instituto Superior Técnico, DECivil-ICIST, Lisbon, Portugal

ABSTRACT: This paper presents a computational semi-analytical model for the post-buckling analysis and ultimate strength prediction of stiffened plates under longitudinal uniform compression. The possibility of considering fully free in-plane displacements at longitudinal edges (or unloaded edges) is the innovation of this model over existing models, where these displacements are assumed constrained to remain straight. Comparisons between the semi-analytical model results and nonlinear finite element model results are presented in order to discuss the effect of in-plane displacement boundary conditions on behavior and design of stiffened flanges used in steel box girder bridges. This study shows that the in-plane displacement boundary conditions for the unloaded edges significantly influence the post-buckling behavior and ultimate strength of stiffened flanges and this problem cannot be neglected in the definition of the design rules.

1 INTRODUCTION

Recent work in the field of semi-analytical methods used for the nonlinear analysis and design of stiffened plates with buckling problems have shown an important and alternative tool that provide an efficient and understandable response (Paik et al. 2008, Brubak & Hellesland 2008).

Nowadays two computational programs use the semi-analytical method to analyze the post-buckling behavior of plates and to predict their ultimate strength. The computer program ALPS/ULSAP (Paik & Thayamballi 2003), which uses a semi-analytical method previously known as the incremental Galerkin method (Ueda et al. 1987) and the computer program PULS (Bycklum 2002) developed at Det Norske Veritas (DNV) and accepted as general buckling code for ship and offshore platform structures as part of the DNV specifications (DNV-RP 2002).

The existing semi-analytical models are restricted to stiffened plates supported by rigid transverse and longitudinal girders. This type of arrangement is typical in ship, aircraft, tanks and offshore platform structures where it is assumed that the analyzed stiffened plate is simply supported and the in-plane displacements perpendicular to the edges are constrained to remain straight in all edges. Generally, in bottom flanges of steel box girder bridges there are no neighboring panels in the longitudinal edges to provide this kind of constraint and it is more conservative to consider the longitudinal edges with fully free in-plane displacements that are characteristic of edges free from stresses.

This paper presents a computational semi-analytical model for the post-buckling analysis and ultimate strength prediction of stiffened plates under longitudinal uniform compression. The possibility of considering fully free in-plane displacements at longitudinal edges (or unloaded edges) is the innovation of this model over existing models. Comparisons between the semi-analytical model results and nonlinear finite element model results are presented in order to discuss the effect of in-plane displacement boundary conditions on behavior and design of stiffened flanges used in steel box girder bridges.

2 METHOD OF ANALYSIS

2.1 *General*

In order to validate the results obtained by the semi-analytical model that was developed, all nonlinear simulations were performed using the semi-analytical method and the finite element method.

The simulations with both methods were performed considering a yield stress (f_y) of 355 Nmm^{-2}, Young's modulus (E) of 2.1×10^5 Nmm^{-2} and Poisson's coefficient (ν) of 0.3.

The stiffened flanges were considered simply supported under longitudinal uniform compression (σ) with the following two cases for the in-plane displacement boundary conditions: in-plane displacements perpendicular to the edges constrained to remain straight in all edges (case CC) and in-plane displacements perpendicular to the edges constrained to remain

straight at loaded edges and free at unloaded edges (case CF).

Unless otherwise indicated an equivalent geometric imperfection, including the geometric imperfections and residual stresses in accordance with European standard (EN-1993-1-5 2006), was considered for the initial imperfection. Amplitude of 1/400 of the minimum between the length and width of the half-wave of the imperfection mode was considered for the equivalent geometric imperfection with a global imperfection mode shape. For a local imperfection mode shape the same principle was considered, with amplitude of 1/200.

2.2 *Implementation of the semi-analytical method*

The semi-analytical method uses the two nonlinear fourth order partial differential equations of the large deflection theory, the equilibrium and compatibility equations derived by von Kármán in 1910 (Timoshenko & Woinowsky-Krieger 1959) for perfect plates and extended to plates with initial imperfections by Marguerre (1937). The method is called semi-analytical because in a first step an analytical solution for the Airy stress function (F) is obtained solving the compatibility equation. Trigonometric series for the out-of-plane displacements (w) and for the initial imperfections (w_0) are adopted, which satisfy the boundary conditions.

In a second step approximate solutions for the unknown amplitudes (q) of the out-of-plane displacements are obtained solving the equilibrium equation using a variational method. Based on the approximate solutions for the unknown amplitudes of the out-of-plane displacements, the kinematic and constitutive relations and the yield criterion it is possible to analyze the post-buckling behavior and to predict the ultimate strength of plates.

The computational implementation of the semi-analytical model developed in the framework of this study uses the Rayleigh-Ritz method to solve the equilibrium equation and it was implemented using the programming language of Mathematica6 (Wolfram 2007). The initial imperfections (w_0) and out-of-plane displacements (w) considered in the computational semi-analytical model, which satisfy the boundary conditions for simply supported plates, are given as follow

$$w_0 = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} q_{0,mn} \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \tag{1}$$

$$w = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} q_{mn} \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \tag{2}$$

where m = number of half-waves in the longitudinal direction; n = number of half-waves in the transverse direction; q_0 = prescribed amplitudes of the initial imperfection; q = unknown amplitudes of the out-of-plane displacement; a = plate length; b = plate width; x = longitudinal coordinate; and y = transverse coordinate. The xy plane coincides with the plate mid-surface. Figure 1 illustrates an overview of the semi-analytical model developed.

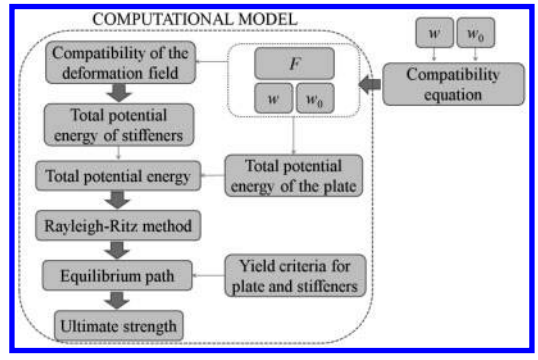

Figure 1. Overview of the semi-analytical model developed.

The stiffened plate analysis through this semi-analytical model is achieved considering the separate analyses of the plate and the stiffeners. Plate and stiffeners are modeled as an isotropic plate and as beam elements, respectively.

The compatibility equation for the isotropic plate used in the first step of the semi-analytical model to obtain the analytical solution for the Airy stress function (F) is expressed as

$$w_0 = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} q_{0,mn} \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b} \tag{1}$$

The stiffener deformations are defined through the compatibility of the deformation field between the isotropic plate and the beam elements considering the stiffener curvature (κ_{sl}) equal to the longitudinal plate curvature for bending ($-w_{,xx}$) and the stiffeners strain (ε_{sl}) equal the longitudinal plate membrane strain (ε_x^m) at their intersection. The strain of the stiffener is evaluated at transverse stiffener location (y_{sl}) and the general expression is given by

$$\varepsilon_{sl}(z) = \left[\varepsilon_x^m - (z - z_{st})w_{,xx}\right]_{y=y_{sl}} \tag{4}$$

where z = height coordinate measured from the plate mid-surface; z_{st} = geometric centre of the cross-section composed of the plate and the stiffeners.

The transverse (or lateral) displacements and the torsional rotation of the stiffeners are accounted for in the total potential energy of stiffeners. By compatibility the angle of twist (θ) and the transverse displacement at the shear centre of the single stiffener (v_{sc}) are defined as

$$\theta = w_{,y} \tag{5}$$

$$v_{sc} = -w_{,y} z_{sc} \tag{6}$$

where z_{sc} = coordinate z of the shear centre of the single stiffener.

The local buckling effect of the stiffener elements is not considered in the response. This assumption is reasonable if the local buckling problems in the stiffener elements are prevented by satisfying minimum requirements for the stiffener geometric properties as established in the European standard (EN-1993-1-5 2006). These minimum requirements are used in the standards because the collapse of stiffened plates by local buckling of the stiffeners (lateral torsional buckling of the stiffener or local buckling of the stiffener elements) may exhibit a very unstable response.

This semi-analytical model enables to take into account the initial imperfections, cases CF and CC for the in-plane displacement boundary conditions, the interaction between local and global buckling, the geometric nonlinearity and in an approximate way, the material nonlinearity associated with the stiffness reduction after reaching the yield in the extreme fiber of the plate. The von Mises yield criterion was assumed for the plate and the stiffeners.

The plate yield criterion was defined for the sum of membrane and bending stresses at one-quarter of the plate thickness. This criterion allows for the formation of plasticity through the possibility of an additional strength after yielding in outer fibers in order to take into account in an approximate way for the material nonlinearity.

The stiffener yield criterion was defined by the yield stress, in tension or compression, at the location of the maximum stiffener stress. This criterion gives conservative ultimate strength predictions for global buckling cases when the stiffener extreme fibers are compressed.

The computational semi-analytical model developed has the following assumptions: the plate has a width b, length a and uniform thickness t, it is possible to consider one or more longitudinal stiffeners positioned symmetrically or eccentrically about the middle plane of the plate, the material is considered isotropic and linear elastic, characterized by Young's modulus E, Poisson's coefficient ν and yield stress f_y and the stiffened plate is subject to uniform compression σ in the longitudinal direction.

The complete definition of each step and the procedures of the semi-analytical model developed can be found in Ferreira (2012).

2.3 *Finite element modeling*

The commercial program ADINA (Bathe 2006) was used to perform the nonlinear simulations by the finite element method. The program uses a large displacement/small strain with a Total Lagrangian formulation. The stiffened flanges were modeled using a four-node shell element for the plate and the stiffeners. This type of element allows for finite strains due to in-plane displacements (membrane) and out-of-plane displacements (bending). A collapse analysis was performed in the full range behavior of the stiffened flanges, including the post-buckling regime and assuming a von Mises yield criterion.

The nodes of each stiffener at loaded edges were connected with rigid links in order to assure their planar rotation about the supported edge. For the plate edges with in-plane displacements constrained to remain straight it was used a constraint for all nodes of the edge to ensure a uniform in-plane displacement.

The material behavior for all elements was modeled assuming elasto-plastic behavior with linear strain hardening. A value of Young's modulus/100 was adopted for the yield branch, in accordance with European standard (EN-1993-1-5 2006).

3 RESULTS AND DISCUSSIONS

3.1 *Post-buckling behavior*

To study the effect of boundary conditions for the in-plane displacements at unloaded edges on behavior and to compare the results obtained by the semi-analytical model with the results obtained by the finite element program ADINA a stiffened flange with five longitudinal equally spaced symmetric stiffeners, relative cross-sectional area δ (cross-sectional area of the stiffeners without any contribution of the plate A_{sl} to the cross-sectional area of the plate (bt) ratio) of 0.5 and relative flexural stiffness γ (second moment of area of the stiffened plate I_{st} to the second moment of area for bending of the plate corrected by the effect of the Poisson coefficient ($bt^3/[12(1-\nu^2)]$) ratio) of 65 was considered. The stiffened flange has a plate aspect ratio ϕ (ratio between the length a and the width b of the plate) of 5, plate slenderness λ_{plt} (ratio between the width b and the thickness t of the plate) of 150 and panel slenderness λ_p (ratio between the width of the panels between stiffeners b_p and the thickness t of the plate) of 25.

The reasons for choosing this stiffened flange are due to the fact that it is possible to validate the present model for the simplest case of stiffened plates with symmetric stiffeners, slender plates have a considerable post-critical resistance, which enables to study the effect of boundary conditions for the in-plane displacements on post-buckling and the panels between the stiffeners do not have problems of local buckling which reduces the number unknown amplitudes in the semi-analytical model.

The q_{21} was the unknown amplitude for the out-of-plane displacements assumed to be non-zero in the semi-analytical model. Two cases of initial imperfections were considered in the analysis: (i) an ideally perfect flange ($w_0 = 0$) and (ii) an equivalent geometric imperfection with the shape of the critical buckling mode ($m = 2$ and $n = 1$) with an amplitude ($q_{0,21}$) of $b/400$.

Figure 2 presents the three dimensional view of the critical buckling mode obtained from the semi-analytical model.

The elastic critical buckling stress (σ_{cr}) and the critical buckling mode obtained by the semi-analytical model illustrated in Figure 2 are in exact agreement

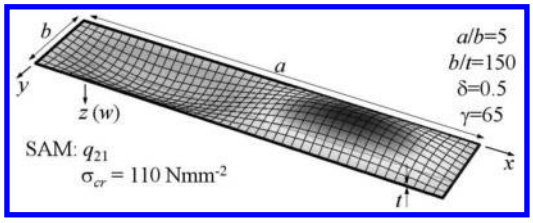

Figure 2. Three dimensional view of the critical buckling mode obtained from the semi-analytical model developed.

with the theoretical analysis exposed in reference works (Timoshenko & Woinowsky-Krieger 1959, Allen & Bulson 1980). Although Figure 2 presents an apparent mesh of elements the critical buckling mode of the semi-analytical was generated through a three-dimensional plot based on single unknown amplitude (q_{21}).

Figures 3–4 presents the comparison between the equilibrium paths obtained by the semi-analytical model and nonlinear finite element simulations for the stiffened flange considering the cases CC and CF for the in-plane displacement boundary conditions. Figure 3 shows the equilibrium path for the perfect flange and Figure 4 shows the equilibrium path for the imperfect flange. The equilibrium paths are presented in terms of normalized load (longitudinal compression σ to the yield stress f_y ratio) as a function of the normalized total deflection (ratio between the sum of out-of-plane displacement w and initial imperfection w_0 with the plate thickness t).

The load-deflection responses and the ultimate strength (σ_u) obtained by the semi-analytical model shown in Figures 3–4 are in close agreement with the finite element results for both cases of modeling the in-plane displacements at unloaded edges.

The main differences between the results obtained with the semi-analytical model and the nonlinear finite element simulations occur in large out-of-plane displacements at the end of the load-deflection response. This can be explained by the facts that the nonlinear finite element simulations allow an increase in load and the progressive extension of plastification after local yielding of the stiffened plate, while in the semi-analytical model the plastification is accounted for through the yield criterion in an approximate way and the nonlinear finite element simulations use a large number of degrees of freedom, which allow to consider the interaction between displacement modes while in the semi-analytical model only single unknown amplitude for the out-of-plane displacements was used.

Nevertheless, the differences between the semi-analytical model and the nonlinear finite element simulations for the ultimate strength are less than 4% in the flange with fully free in-plane displacements at unloaded edges (case CF) and about 1% in the flange with uniform in-plane displacements at unloaded edges (case CC). These small differences can be reduced with an increase in the number of unknown amplitudes for the out-of-plane displacements.

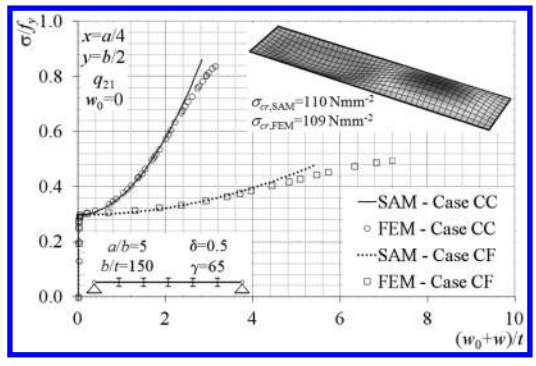

Figure 3. Comparison between the equilibrium paths obtained by the semi-analytical model (SAM) and nonlinear finite element simulations (FEM) for the perfect flange.

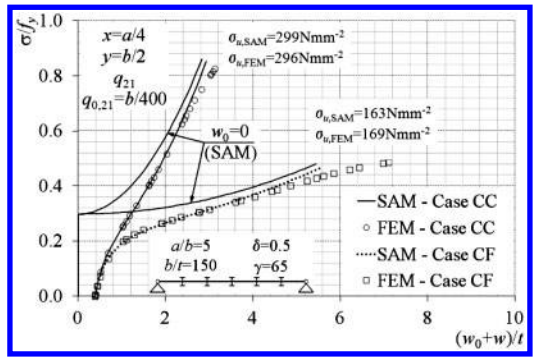

Figure 4. Comparison between the equilibrium paths obtained by the semi-analytical model (SAM) and nonlinear finite element simulations (FEM) for the imperfect flange.

Based on these results it can be verified that the post-buckling behavior and the ultimate strength differs considerably according to the in-plane displacement boundary conditions at unloaded edges. In fact with the condition of fully free in-plane displacements at the unloaded edges, the transverse stresses are significantly reduced and consequently the stiffness of the plate also decreases. This point is particularly important for plates with higher post-critical resistance.

As expected, the elastic critical buckling stress (σ_{cr}) does not depend on the in-plane displacement boundary conditions at unloaded edges.

3.2 *Ultimate strength*

The effect of boundary conditions for the in-plane displacements at unloaded edges on ultimate strength was studied considering further 20 stiffened flanges. The results obtained by the semi-analytical model were also compared with the results obtained by the finite element program ADINA. The 20 stiffened flanges were obtained based on two types of cross-sections, SF1 and SF2, and considering for each cross-section the plate aspect ratio $\phi(=a/b)$ ranging from 0.5 to 5.0 at intervals of 0.5. Both cross-sections have five longitudinal

equally spaced and single sided stiffeners, the stiffened flanges with the cross-section SF1 have a relative flexural stiffness γ ($=12I_{st}(1-\nu^2)/(bt^3)$) of 65 and the stiffened flanges with the cross-section SF2 have a relative flexural stiffness γ of 130. All stiffened flanges have a relative cross-sectional area δ ($=A_{st}/(bt)$) of 0.5, plate slenderness λ_{plt} ($=b/t$) of 150 and panel slenderness λ_p ($=b_p/t$) of 25.

In order to evaluate the ultimate strength of the stiffened flanges the following cases of equivalent geometric imperfections were considered: the shape of the first, second and third local buckling modes considered separately (cases 1–3), the shape of the first, second and third global buckling modes considered separately (cases 4–6), the combination of the local and global buckling modes with a local mode leading the imperfection (case 7) and the combination of the local and global buckling modes with a global mode leading the imperfection (case 8). In order to take into account the stiffener eccentricity the imperfection amplitude was considered with both signs (positive for imperfections in the direction of stiffeners and negative for imperfections toward the plate) for symmetrical buckling modes. The buckling modes were obtained by a linearized buckling analysis of the same stiffened flange without initial imperfection. The ultimate strength of the stiffened flange was considered as the minimum strength obtained by the several cases of equivalent geometric imperfection.

The leading imperfection in combined buckling modes was considered with the full amplitude value and the accompanying imperfection was considered with its amplitude value reduced to 70%, in accordance with European standard (EN-1993-1-5 2006).

Figures 5–6 show the comparison between the ultimate strength (σ_u) obtained by the semi-analytical model and nonlinear finite element simulations for the stiffened flanges considering the cases CC and CF for the in-plane displacement boundary conditions. Figure 5 shows the ultimate strength for the stiffened flanges with the cross-section SF1 and Figure 6 shows the ultimate strength for the stiffened flanges with the cross-section SF2. The results are presented in terms of normalized strength (mean compressive stress at peak load σ_u to the yield stress f_y ratio) for different values of the plate aspect ratio ϕ ($= a/b$).

The ultimate strength (σ_u) obtained by the semi-analytical model shown in Figures 5–6 are in close agreement with the finite element results for both cases of modeling the in-plane displacements at unloaded edges. This remark, which is based on results for the total of twenty stiffened flanges, strengthens the remark stated above based on results for one stiffened flange.

Based on results presented in Figures 5–6 it can be noted that the ultimate strength (σ_u) is similar for both cases of in-plane displacement boundary conditions in stiffened flanges with plate aspect ratio equal to or less than 1 ($\phi \leq 1$). In stiffened flanges with plate aspect ratio greater than 1 ($\phi > 1$) the ultimate strength tends to constant values for the case CF

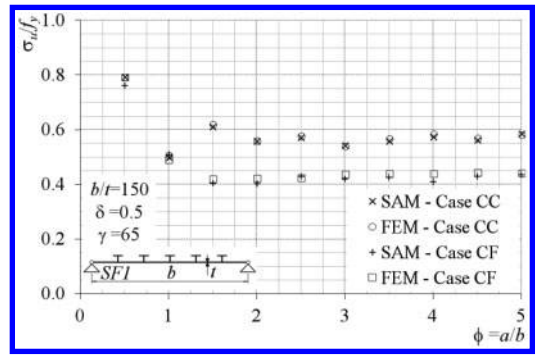

Figure 5. Comparison between the ultimate strength obtained by the semi-analytical model (SAM) and nonlinear finite element simulations (FEM) for the stiffened flanges with the cross-section SF1.

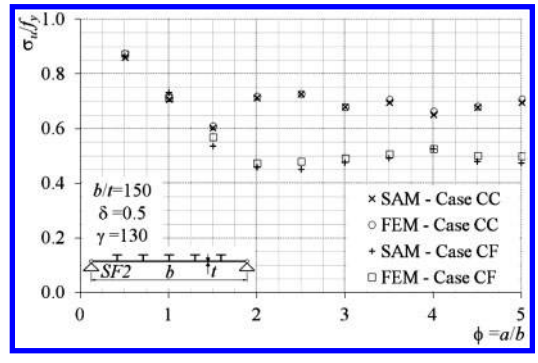

Figure 6. Comparison between the ultimate strength obtained by the semi-analytical model (SAM) and nonlinear finite element simulations (FEM) for the stiffened flanges with the cross-section SF2.

of in-plane displacement boundary conditions, it has a pronounced increase after reaching the minimum value for the case CC of in-plane displacement boundary conditions and it is considerably higher for the case CC of in-plane displacement boundary conditions than for the case CF.

These remarks show that the evaluation and definition of the type of constraint for the in-plane displacements at unloaded edges of stiffened plates is a very important issue to estimate a correct value for the ultimate strength. In European standard (EN-1993-1-5 2006) the ultimate strength of webs and internal flanges with longitudinal stiffeners used in steel box girder bridges is obtained through the same condition and this condition is independent of the in-plane displacement boundary conditions of the plate. Just apparently both elements may have the same in-plane displacement boundary conditions. Indeed, the webs are usually connected to flanges that possess sufficient rigidity to consider uniform the in-plane displacements at longitudinal edges, while the flanges are connected to webs that usually do not provide this type of constraint and it is more conservative to consider free the in-plane displacements at longitudinal

edges, as shown in the work of Ferreira & Virtuoso (2011) through a comparison between numerical and experimental results.

So if the design rules defined in the European standard are set for the case CF of in-plane displacement boundary conditions, a very conservative value may be obtained for the ultimate strength of webs with higher values of plate aspect ratio. If the design rules defined in the European standard are set for the case CC, an unsafe value may be obtained for the ultimate strength of flanges with higher values of plate aspect ratio.

4 CONCLUSIONS

From this study the main conclusions can be summarized as follows: (i) the results obtained by the computational semi-analytical model are in close agreement with the nonlinear finite element results for both cases of modeling the in-plane displacements at unloaded edges, (ii) the semi-analytical model prove to have a clear potential to provide reasonably accurate solutions require only a short computer time, (iii) the boundary conditions for the in-plane displacements at unloaded edges significantly influence the post-buckling behavior and the ultimate strength of plates and (iv) the design rules of stiffened plates cannot neglect the in-plane displacement boundary conditions of the plate.

Buckling resistance with combined shear of steel curved bridge girder webs

Ph. Van Bogaert
Ghent University, Belgium

ABSTRACT: The web curvature of a closed-section girder is gradually increased, to assess the influence of this curvature on the shear buckling resistance. Various types of numerical analysis have been used, from linear elastic, up to material and geometric nonlinear analysis, including imperfections of various amplitudes. The results show that web curvature increases the shear buckling resistance and the webs are mildly sensitive to imperfections. These conclusions are similar to those already found for bending stresses. Further steps in the research, as the effect of residual stress, are also being discussed.

1 INTRODUCTION

1.1 *Curved Bridge Panels*

This paper continues on previous research concerning the buckling resistance of curved bridge girder panels. It has been shown (Van Bogaert 2012) that in spite of the more shell-like behaviour, the curvature of bridge girder webs may increase the buckling resistance. This has been found through a model of a closed-section bridge girder in which the web curvature is increased gradually until the cross-section is close to a circle. During this previous research, nonlinear material and geometric response as well as the influence of critical imperfections of variable amplitude have been considered. However, residual stresses have not been included and the type of loading of the numerical models was mainly bending. This paper further develops the research in case shear is the main type of loading.

1.2 *Simulation tool*

A numerical model has been used, consisting of a closed box section, including diaphragm stiffeners at a distance equal to the box section height. The latter are required to prevent distortion.

A fine meshing is needed and the entire girder could not be simulated. This required limiting the model to the central part of the girder, although it should comprise several panels, since edge effects should be excluded. As the girder height was taken 3 m, the model comprises 7 fields of 3 m length and thus it represents about one third of the actual length of the girder. The boundary conditions of the model include edge bending moments and shear forces, equivalent to the stress states at the appropriate sections in the entire girder. The latter have been calculated from simple beam theory and distributed accordingly among the nodes of the edge sections. This vertical force corresponds to the reaction of bridge crossbeams, fixed to the main girders at the location of the diaphragms. These reactions may be expressed in a dimensionless manner as their individual value times the girder height divided by the applied bending moment, this ratio equals 0.0233 in the case of the model. The model mentioned has almost flat web plates. There is a slight curve, corresponding to a radius of curvature of 100 m. This allows parametric variation of the radius down to 1.65 m. However, the upper- and lower flanges have identical thickness, distinctly higher than the webs and the most curved section certainly is different from a circular tube. It is believed that these sections are relevant for the behaviour of curved panels and plates of bridge structures.

$\sigma_{E,crit}$ (MPa)	126	182	356	594	912	1503

2 RESULTS BUCKLING BY NORMAL STRESS

2.1 *Linear elastic buckling*

Calculations have resulted in values for elastic buckling loads, or elastic critical stresses. Table 1 summarizes the values of the critical bending moments, as a function of the circle segment rise to height ratio.

The critical bending moment can also be transformed to a critical elastic compression stress. The latter is obtained by multiplying the normal bending stress at the location of the top of the buckling mode, by the critical multiplier. For this, the mode shapes have been analyzed more closely.

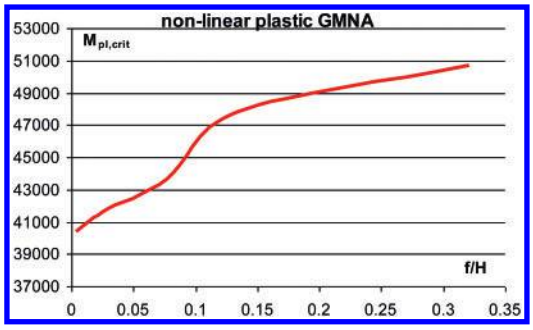

Figure 1. Nonlinear calculations results for bending moments.

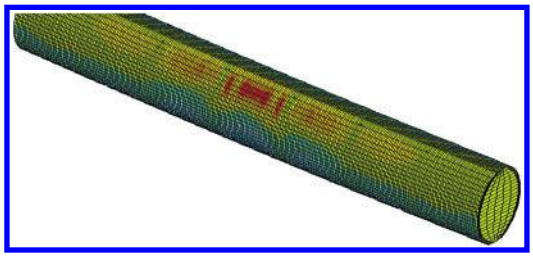

Figure 2. Nonlinear buckling – plasticity areas.

Both the critical stress and the bending moment are increasing with the web curvature. This is unexpected, since no other stress components than horizontal normal stress is appearing. Obviously the linear analysis is unable to adequately describe the buckling phenomenon.

For this reason a nonlinear plastic analysis has been conducted, including large deformation. A simple plastic law, excluding strain-hardening was used. The incremental load strategy has been used, during which the load step was optimized.

2.2 *Elastic-plastic results*

The formerly mentioned models have been used during plastic analysis, including nonlinear displacements. A simple plastic law, excluding strain-hardening was used. The incremental load strategy has been used, during which the load step was optimised. The values of these ultimate bending moments have been plotted in fig. 1. Similar to the results from elastic calculations, the load carrying capacity is increasing with the web.

However, the increase is distinctly less (1.25 instead of 6.7) then for elastic buckling. Displacements rise towards the upper flange with increasing curvature (see fig. 2). This demonstrates that the beam is acting more in a shell-like manner, the most compressed part of the shell circumference having higher resistance. Plastic buckling then occurs close to the area of change in plate thickness, in the thinner part.

2.3 *Imperfections*

Imperfections have large influence on buckling problems of thin-walled members. This is mostly true

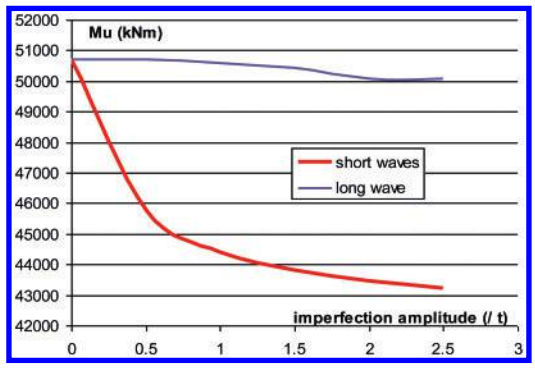

Figure 3. Ultimate bending moments with imperfections.

for shells and membranes, where meridional and circumferential compression occurs.

Some codes (EN 1993 – 2004) recommend identifying the shape of imperfections to the fundamental elastic buckling mode. However, this mode shape may well be improbable, since imperfections and tolerances are due to lack of flatness and fabrication processes. Therefore two types of imperfections have been introduced, the first one corresponding to the code and the second being more reasonable. In addition, the imperfection amplitudes have been varied.

Results of this type of GMNIAnalyses have shown that imperfections of bended curved panels have moderate influence on the failure bending moment. The short-wave imperfection type, corresponding to the elastic buckling mode shape is the most critical one. This is demonstrated in fig. 3.

The results may be compared to the use of classical web crippling procedures, similar to lateral buckling. The latter results in M_u =31743 kNm or 62.6% of the value for a perfect web to 73.5% of the case with the largest imperfection amplitude of 2.5-times the web thickness.

3 CURVED SHEAR PANELS

3.1 *Numerical model*

An identical model is being used to introduce large shear in the webs of varying curvature. However, the boundary conditions were changed to perfect clamping of one side and vertical support. Since the effects of pure shear are to be found, vertical forces have been introduced at sufficient distance from the clamped section, to avoid any local effects.

Hence, the vertical loads have been applied at the second stiffening diaphragm, which basically causes a shear force of 3000 kN and a clamping moment of 18000 kNm, considerably smaller than in the case of bending.

3.2 *Elastic buckling load*

Similar as for the panels subjected to bending, the mode shape changes gradually with increasing web

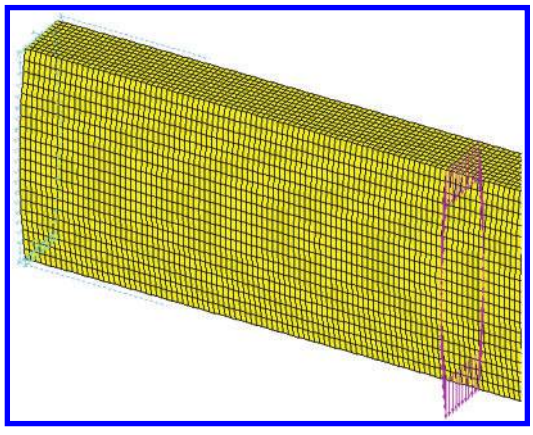

Figure 4. Load and boundary conditions of model.

Table 2. Elastic buckling moments.

Radius (m)	100	15	9	5	3	1.65
$V_{E,crit}$ (kN)	8116	13019	17340	24860	34234	50581
τ_{Ecrit} (MPa)	70.01	112.3	149.6	214.5	295.3	436.3

curvature. In fig. 5a (top) and 5b (bottom) the mode shapes corresponding to almost flat and almost cylindrical alternatives are shown. Obviously, for a flat web, a single sloping wave pattern is found, as expected. As the web curvature increases, the wave rapidly becomes double, one above the other and then gradually shifts from the first panel to the second one between vertical diaphragms.

Table 2 summarizes the results of the critical shear forces. It may be noticed that the critical shear force increases rapidly with the web curvature.

However, with exception of the value corresponding to the radius of curvature of 1.65 m, all critical shear stresses are in the elastic condition. The critical shear force increases by a factor of 6.23, which is close to the case of bending normal stresses.

Even if the critical shear stress remains elastic, elastic buckling forces do not correspond to the actual failure condition, since the web slenderness reaches 167 and plasticity may truncate the results. Hence, further plastic analysis is indispensable, including nonlinear material law and large displacements.

3.3 *Nonlinear plastic stability*

A simple plastic law, excluding strain-hardening was used. The incremental load strategy has been applied, during which the load step was optimized.

The results show that failure mostly occurs through constant shear plasticity, combined with normal stress in the clamping area. The effect of clamping gradually becomes less important as the web curvature increases. Results of the failure load are summarized in table 3 and the graph of fig. 6.

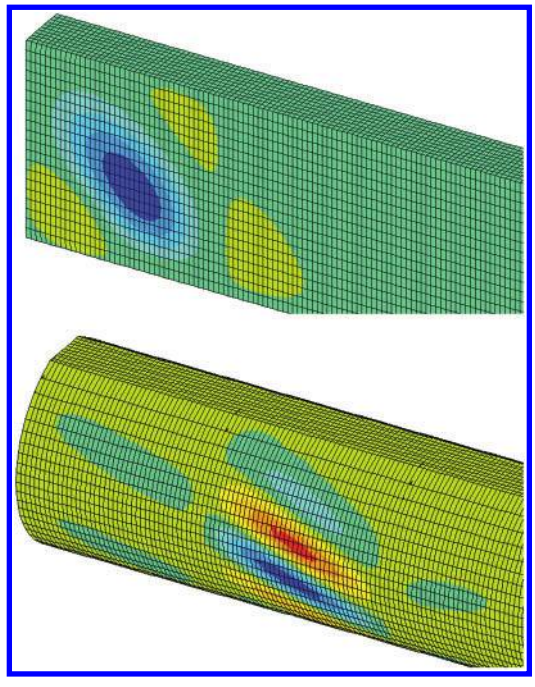

Figure 5. a and b. Elastic mode shapes (top : flat web, bottom curved web).

Table 3. Plastic failure shear load.

Radius (m)	100	15	9	5	3	1.65
VE,crit (kN)	10827	11945	12712	13004	13487	14971

An interesting result concerns the case of flat webs, where the plastic failure load is larger than the elastic buckling value. This is due to the post-critical capacity of the structure, which cannot be found from elastic theory. This appears only in nonlinear plastic analysis, causing larger failure load.

The graph of fig. 6 also shows that the increase of the failure load with curvature first rises rapidly, followed by a slower evolution. This has also been found in the former results concerning normal bending stress. The effect may be explained by the fact that a minor curvature already introduces vertical stabilizing stress and this does not contribute to a large extent beyond the first appearance of this stress state.

During the load increase, the horizontal displacements of some parts of the web may tend to reverse sign. This can be noticed in the graph of fig. 7 which shows the horizontal displacement, in this case at the single wave where plastic phase has been reached. The reversal of these deformations (limited to 3 mm) may be typical of this event.

3.4 *Imperfections*

The GMNA-procedure of paragraph 3.3 does not take into account the effect of imperfections of the

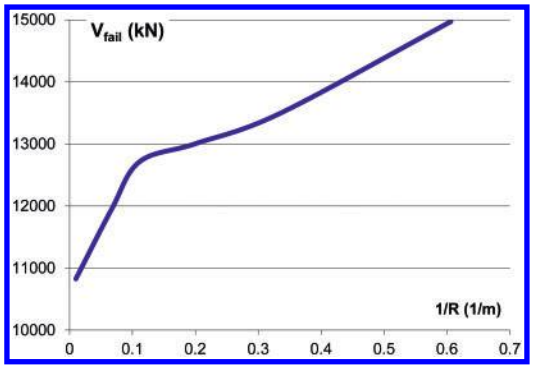

Figure 6. Failure shear load from nonlinear analysis.

Figure 7. Horizontal displacement during plastic phase.

Table 4. Imperfection amplitude according to EN 1993-1-6.

Quality Class	excellent	high	normal
$\Delta w_{0,eq,1}$	9.2 mm	14.72 mm	23 mm

structure, in particular local or general geometric errors. In the case of shell behaviour, the latter can substantially reduce the buckling resistance.

However, it may be expected that the influence of imperfections is milder than in the case of bending stresses. The effect of eccentric transmission of compression stress must be more critical than for shear. This is can be explained by the example of a buckling column, wherein normal force causes the stability issue, rather than eccentric shear, the latter introducing straightforward bending.

Since the imperfection shape, complying with the fundamental elastic buckling mode is the most critical, this type of imperfection has been introduced in the models. The amplitude has been varied by considering fractions of the web thickness. However, the amplitude is considerably larger than the values corresponding to those of EN 1993-1-6 for shells, which have been summarized in table 4.

The normally accepted amplitude corresponds to 1.28-times the web plat thickness. In the present analysis considerably larger amplitudes have been considered.

The results of the GMNIA have been assembled in the graph of fig. 8, in terms of the failure shear load.

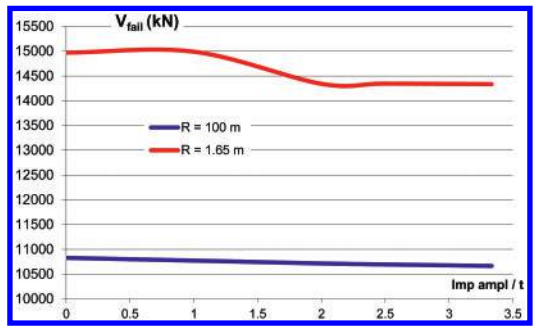

Figure 8. GMNIA failure load versus imperfection amplitude.

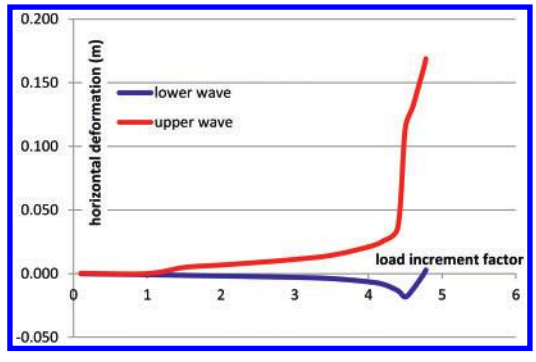

Figure 9. Horizontal web deformation of 2 buckling waves

The graph shows the evolution of the load with varying amplitudes for the two extreme cases of almost flat webs and curved webs close to cylindrical shape. Clearly, this demonstrates that imperfection amplitudes well above normal values do practically not influence the failure load.

The latter confirms the aforementioned understanding of imperfection-sensitivity for structural parts, subjected to shear. This diagram may be compared to fig. 3, where the influence of imperfections is substantial.

Evidently, the largest horizontal deformation appears in the maximum imperfection amplitude area. Fig. 5 already demonstrated that for large curvature, the width of the imperfection is rather small and may consist of a double buckle. This is found again in the GMNIAnalysis. It seems characteristic that The lower wave, as in fig. 5b, is tending to reverse change as the failure load is reached, whereas the upper wave continues its deformation in an identical direction. This is shown in the graph of fig. 9, where horizontal deformations of both waves are represented. The deformation of the upper wave is much larger than the lower one. The graph applies to the almost circular cross-section.

The vertical deformations of the waves follow closely those of the diaphragm of the vertical load. Obviously, the diaphragm section shows larger vertical displacement. Again, the values for the lower wave are considerably smaller than for the upper wave. This is shown in fig. 10.

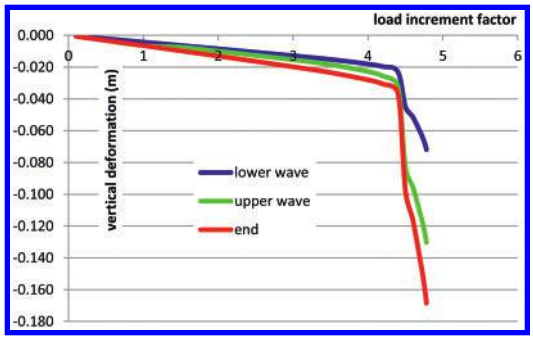

Figure 10. Vertical deformations of web waves and diaphragm.

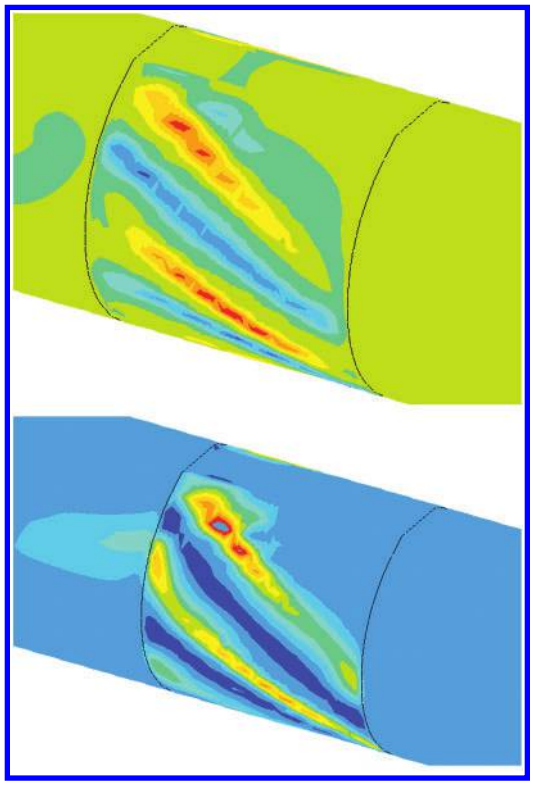

Figure 11a and b. Normal stresses (top) and shear stress (bottom) before failure.

The results of GMNIA for stresses near the failure condition should also be considered. Both the results for normal and shear stress may be considered.

The most relevant results are shown in fig. 11. Normal longitudinal stresses, as well as shear stresses are represented. Both stress types are heavily influenced by the imperfections introduced in the model. The narrow waves of the buckling mode shape directly determine the pattern of normal longitudinal stress distribution. This direct relation may be expected since local bending is introduced. However the effect of imperfections on the distribution of shear stress is less evident. Fig 11 clearly demonstrates that the maximum values of shear do not necessarily correspond to the area of maximum imperfection amplitude. In fact, as curvature increases, the maximum shear area shifts from the web centre towards the upper side of the web, near to the connection with the girder flange. All this confirms the former conclusion, that imperfections are less critical for shear loading than for bending or normal force.

A final verification may be to compare the loading condition to the use of simple bending formulas. For the flat web alternative, the slenderness reaches 167, well beyond class 3, the load carrying capacity thus being limited by web buckling. Failure occurs for a load of 10827 kN. The ultimate loads, corresponding to slenderness category 2 and 3 respectively are 13312.5 kN and 11716.2 kN. These quantities demonstrate that the failure by complete plasticization is close to the result from GMNAnalysis.

4 FURTHER DEVELOPMENTS

4.1 *Residual stress*

In the former, the effect of residual stress has not been taken into account. Nevertheless, the comparison between flat web girders and curved members is relevant, since the effect of residual stress due to welding and cold forming is expected to be similar for both situations.

Obviously, the curving of the webs is obtained by cold forming and this introduces meridional stress in the webs. This may reduce the shear failure load and further research should clarify the influence. In addition, welding stresses will have similar effect for both cases, the processes and developed heat being similar.

4.2 *Experimental verification*

The numerical results will have to be confirmed by experiments, allowing verification of the predicted values. Tests with scaled models are being considered. However, scaled models are generally too perfect and the introduction of imperfections should be considered thoroughly. In addition, the test setup will inevitably include both bending and shear loading.

At present, scaled model tests of plastic material are being considered, since this material easily allows curving of the webs. In addition, the material properties have been closely determined in the past. However, clamping of the model end is difficult to guarantee in tests. Therefore, a symmetrical model with central support and identical edge loading is being considered at present.

5 CONCLUSIONS

It was implied that, from various numerical simulations, the curvature of webs of bridge girders may

increase their buckling resistance, in spite of a more shell-like behaviour. This has been found through a model of a closed-section bridge girder in which the web curvature is increased gradually until the cross-section is close to a circle. However, the upper- and lower flanges have higher thickness than the webs and continue having higher contribution to the load carrying capacity.

Linear elastic calculations show considerable increase of the critical shear force, whereas non-linear plastic simulations show a similar tendency, however in a weakened manner. The influence of imperfections of a critical type, corresponding to the mode shape, verified during GMNIAnalysis, confirms that the curved webs are not highly sensitive to imperfections, even for amplitudes larger than normal fabrication quality.

The weathering steel bridges maintenance practice in Poland

M. Lagoda & T. Wierzbicki
Road and Bridge Research Institute, Warsaw, Poland

ABSTRACT: The weathering steel was quite often used for constructing bridges in Poland in the past. The main weathering steel bridges volume origins from the eighties of the last century. These structures are made from original Polish steel 12HNNbA. Some aspects of weathering steel itself and its history of invention are presented. During the service life some troubles in their behavior, which slightly differs from anticipated one, have occurred. Since then some administrative restriction has been put on use weathering steel in bridge construction. The paper describes day-to-day maintenance practice as well as results of investigations carried on some structures. Some results of tests on weathering resistant steel 12HNNb used for a span of railway bridge laid in the South and two highway bridges in Central Poland are presented in the paper. Worth underlying is the fact that every of those structures have different main girder structure – box, plate and T beam girders.

1 INTRODUCTION

1.1 *The origin of weathering steel*

Since the corrosion was regarded as the most severe problem in steel bridge structure maintenance, engineers were searching for the corrosion resistant material. Since the thirties of the previous century, it is believed that weathering steel might cause great savings on bridge building and maintenance.

The first documented use of weathering steel process occurred during the revolutionary war (1775–1783), when gunsmiths protected the surface of rifle and pistol barrels with a thin coat of iron oxide. This process, known as "browning" involved treating the exposed steel surfaces with chemicals to form a corrosion-resistant layer (McDad et al. 2000).

There are some tales on the first ideas of the weathering steel developing. One story says that during a London bridge demolishing, proceeded in the middle of the nineteenth century, it was discovered that some parts of the structure were in much better condition then the others. Chemical analysis showed that the well preserved structures have the 0,2% copper addition. This fact gave the idea to D. M. Buck, who reported in 1910 (or 1913 according to other sources) that carbon steel containing 0,2 % or more of copper had from 1,5 to 4 times the atmospheric resistance of carbon steel with a residual copper content. The most significant differences were found in severe industrial atmospheres, and the least improvement occurred in rural atmospheres (McDad et al. 2000), (Czyrski 1988). It was found out however that the copper presence in steel is valuable if the amount is being kept between 0,05% to 0,2%. Further copper presence increasing (over the 0,6%) does not affect atmospheric resistance, but has very negative impact on yield resistance and steel weldability. Later studies by various investigators pointed to beneficial effects from the inclusion of 2%, or less, of certain common alloying elements. Phosphorus, silicon, nickel and chromium appeared to provide atmospheric corrosion resistance to carbon steel.

The first major commercial application of weathering steel came in 1933, when it was used to build coal hopper cars. The first use of steel sheets in a building occurred in 1939 and in highway bridges in 1935. Later the wide use of the weathering steel can be observed in electrical transmission towers, guard rails and mainly in the architectural applications. Especially the last use of weathering steel made this material popular and gained public acceptance.

1.2 *Polish weathering steel*

Since weathering steels were introduced in USA, which was called corten steel there and gave the name for the whole weathering steels family, many countries were trying to adopt the idea of corrosion resistant steel in their own laboratories. Poland was between them as well, and some original steels were elaborated. In 1956 the Lenin Steelworks (Sendzimir Steelworks) has worked out the 10H steel, which was the first Polish weathering steel. This material was used for the coal miners cars only. In 1964 the next generation of weathering steels 10HA (copper, phosphorus and chromium steel) was introduced. This steel was used for railway

Al	0.06–0.15

cars. In 1971 the Institute for Ferrous Metallurgy has finished the research activity on the structural weathering steels and five new materials were put on the market, together with two welding materials dedicated for that material. This were 10HAV, 10HNAP, 12PJA, 12H1JA and 12HNNbA and welding wires SpG1Ncu and SpG2S1Ncu.

One of these steel grades were used for constructing the very first bridge structure in Poland. In 1975 the highway viaduct was erected as a part of trans European road E8 in Poznan, western Poland. The bridge structure, made of 7 10HAV steel girders was the composite one with five spans. The viaduct is kept in service till today, but the steel surface was painted shortly after the erection. Although the structure is still in service, the 10HAV was not intended for bridge structure erection. As this steel has relatively high, among the weathering steels, yield limit (390 MPa) and high tensile strength (510–650 MPa), it was intended to build mainly structures for mining industry, railway cars, steel containers and general building structures. The steel grade intended for bridges mainly was the 12HNNbA steel. This material is quite sophisticated one from the metallurgical point of view, and is composed from three main elements. These are copper, chromium and nickel. This steel has very positive plastic properties, which are high toughness in temperatures between +20°C and −40°C, high fracture toughness and good weld ability.

Those properties have made the structural engineers build some bridges in Poland in the eighties and early nineties of the previous century. These structures are presented later in this paper.

2 POLISH WEATHERING STEEL BRIDGES AT GLANCE

2.1 *General remarks*

First of all it must be stated that weathering steels were never the primary structural material in Polish bridge engineering. A few bridges, which were erected can not be compared to the structures made in the Czech Republic (former Czechoslovakia), Germany or other western European countries, not mentioning USA nor Japan. Moreover nobody has decided for this material in bridge engineering for the last twenty year. The reason for that is, that there is a practice in Poland to care about initial construction costs, not counting future savings on maintenance or traffic delays costs paid by road users. It was not mentioned here yet, but the 12HNNbA steel used to be 20% more expensive then ordinary structural steel. This extra cost was compensated with maintenance cost within the lifetime of the structure. The reason for refrain from using weathering steel could be slightly different way of designing details, which could allow for patina growing and preserving. Further some problems with weathering steel in Polish structures are presented.

Figure 1. General view of the Zakroczym Bridge.

2.2 *The Zakroczym bridge*

The road bridge is located in route of the National Road No 7 leading from Chyzne to Gdansk, which is one of the primary importance for Polish road network. The bridge was built in form of two independent structures, each leading single traffic direction placed on the isolated supports. The structure is built as a continuous box girder with the span 75.0 m+4×95,0 m+75,0 m. the box girder high is 2,7 m. The bridge was put in service in 1990 (the Gdansk direction) and 1992 (the other way). The bridge can be seen at the Figure 1.

2.3 *The Nur bridge*

The road bridge was constructed as the composite one with four steel plate girders and composite concrete slab. The girders were made of 12HNNbA steel and were left uncoated. The structure is situated in rural, non-aggressive atmosphere. The bridge structure was erected in 1987. This structure is pictured at the Figure 2.

2.4 *The Kaczawa bridge*

The bridge over the Kaczawa river in Prochowice is situated in the south-west part of Poland. This is the railway bridge located on the secondary railway line and was put out of service recently. The one span (27,0 m) structure was built in the late nineties of the

Figure 2. General view of the Nur Bridge.

Figure 3. General view of the Kaczawa Bridge.

Figure 4. General view of the DK 7 viaduct.

previous century. The span carries one railway track and is composed of two 12HNNbA steel plate girders 1,965 m high. The Kaczawa bridge is shown at the Figure 3.

2.5 *The DK 7 viaduct*

The local road viaduct over the DK 7 is situated just around 20 km away the Zakroczym bridge. The superstructure is made of two 12HNNbA steel plate girders (0,96 m high) and the concrete composite slab. The total length of the bridge structure is 77,70 m

Figure 5. General view of the DK 7 ecological viaduct.

Figure 6. General view of the Kanal Zeranski bridge.

and is composed of three spans 22,4+32,0+22,4 m. The viaduct was erected in the beginning of nineties XX century. This bridge structure is presented at the Figure 4.

2.6 *The DK 7 ecological viaduct*

This road viaduct built the same time as the Zakroczym bridge was made to allow wild life exist in the environments of the busy road. The structure is 117,60 m long, six spans 15,13+3x21,36+20,24+15,56. This is again composite structure with six 12HNNb steel plate girders in a cross section. This viaduct is presented at the Figure 5.

2.7 *Kanal Zeranski bridge*

The bridge built in mid-nineties, last century located in Warsaw. There is a continuous three span structure 27,10+38,00+27,14 m of total 92,28 m length. The cross section consists of four 10HNPA steel plate girders with variable high from 1,27 to 2,45 m over the supports. the bridge is located in a weak urbanized area, however the locals made the road authorities to paint the outer surface of the girders, as they were unlikely to see “rusty” bridge, which was addressed negative in terms of aesthetics. The bridge can be seen at Figure 6.

Figure 7. General view of the Kepno viaduct.

2.8 *Kepno viaduct*

This structure is a railway viaduct, which carries the rail track over the most busy road in Poland. This is one span structure, with the span length 15,0 m. The cross section consists of two steel plate girders 2,30 m high. There is an orthotropic deck, made, together with the girders, of 12HNNbA steel. This structure's view is presented at Figure 7.

3 THE EXPERIENCE GAINED THROUGH WEATHERING STEEL USE FOR BRIDGE STRUCTURES

3.1 *General*

As mentioned the weathering steel is not the popular structural material in Polish bridge engineering. In general the most common structural material is the concrete. If the steel is chosen the most common is the conventional S355J2 with the paint anticorrosion protection. The reason for avoiding the weathering steel is unknown. The truth is, that the former bridge designing Standard did not include the weathering steel for the material catalogue. On the other hand there were some information on temporary ban on its use in USA and German bridge engineering. Though that problem was promptly solved and the steel is widely used in both countries the suspicious atmosphere in national bridge engineering did not disappeared.

3.2 *The common problems*

The biggest problem, which faced structure administrator was, similarly to all over the world owners, preserving of the patina layer. One of the commandment in steel structure designing, and in the case of weathering steel in particular, is to avoid zones were the debris and moisture can be accumulated. That needs careful detailing. The structures were detailed in a very conservative way, the way the structures made in conventional approach. That means that the shape they made it allows for accumulation debris and destroying patina. Quite a serious problem were the devastation as well, which destroyed patina directly or through devastation of drainage system, which washed out the patina from the steel surface. There is a problem if let say aesthetic nature as well. There are often opinions meet that the bridge, although new one is already destroyed (corroded). Though this attitude is going to be changed shortly probably, as the growing non-bridge structures number utilise weathering steel for the façade for decorative purposes.

3.3 *The results of the investigation*

There were detailed investigation made on the three Polish bridges – the Zakroczym bridge, the Nur bridge and the Kaczawa bridge.

The investigation scenario was moreover similar in all three cases, however the Zakroczym bridge was under special surveillance including inside temperature and humidity monitoring, due to its extraordinary box cross section. There was a dedicated automatic monitoring system installed. It was to register the climate condition inside and outside the box girder. For nearly two years, five gauges measuring humidity and ten measuring temperature (half of them were measuring the steel surface temperature and half the air temperature) every ten minutes was monitoring and recording measured values. The cyclical structure assessment revealed that one of the steel of one bridge span did not create proper patina layer neither after three years of service nor after five years since it was produced. The girder surface was covered with thick, brittle layer of corrosion products, which were tearing apart exposing bare steel surface, which was not protected with the patina again. The specimens were examined in periodical time space, so there is a possibility to trace the particular value variation in the time.

The investigation revealed two main reasons of the steel behavior.

Firstly the steel sheets had some rolling defects, There were traces of non metallic material linear overlaps seen under the microscopic examination. They were met all over the steel sheet surface. These technological defects with no doubt explain the reason of the noticed delamination of the corrosion products found inside the girder box.

The defects found in the weathering steel structure do not explain however, why the dense, protective patina made of the corrosion products do not cover the steel surface despite exposing steel surface for few years. According to the literature and normal practice happens after a year or two. The reason for that was discovered thanks to the previously described monitoring activity. It appeared that since October 1994 till May 1995 the steel surface was practically permanently wet. In such thought condition the patina has no chance to grow. So it was the microclimate inside the box girder, which did not allow patina to cover the steel surface with the proper, protective patina.

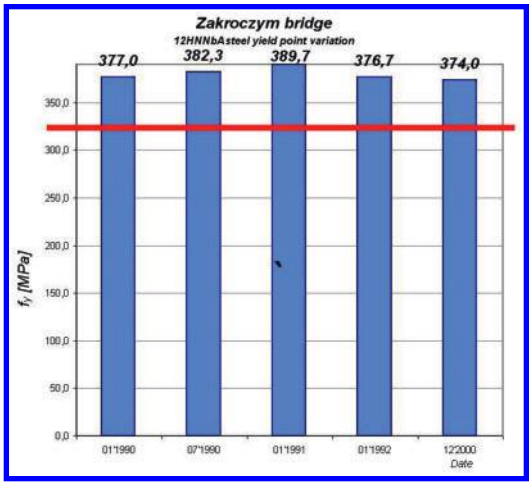

Figure 8. Psychical yield point variation at Zakroczym bridge.

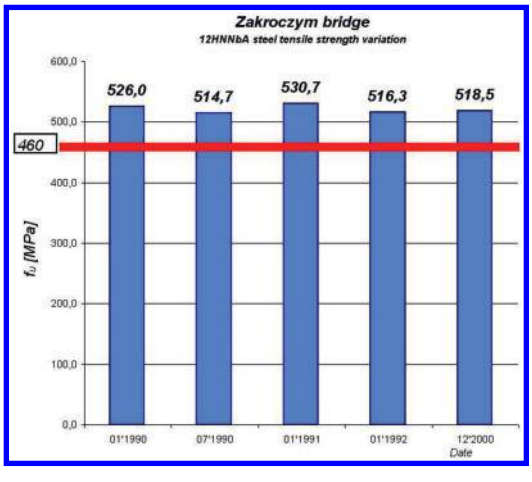

Figure 9. Tensile strength variation at Zakroczym bridge.

Anyway in case of all three brides, the investigation covered the weathering steel specimens strength testing, visual testing and metallographic investigation. And the strength test included: bending test, strength test, Charpy test both the natural and artificially matures specimens. All the specimens were prepared from the original weathering steel taken from the bridge structures at the excessive steel sheets. That means that the sample steel was under the same mature circumstances and was exposed for the same weathering conditions like the steel of the bridge.

It must be stated that all the experiments were positive in every case in terms of strength capacity. The steel despite 20 years of service was in very good condition, with no signs of cracks, excessive corrosion or any damage. All the results like psychical yield point, tensile strength, bending strength, percentage reduction of area elongation value and impact resistance were far above the limits required by the temporary production conditions (TWT 1988).

The red lines on the drawings represents the minimal values required by the (TWT 1988). In case of psychical yield point this is 325 MPa and in case of tensile strength this is 460 MPa. The other structures gave the similar results.

The only problem with the structural material was recorded in case of the Zakroczym bridge. There were two problems in fact. The first problem found in this structure was the insufficient durability of the orthotropic deck. The cracks in longitudinal ribs welded joints were found after the 18 years of service. The first idea was to blame excessive corrosion of weathering steel elements, which caused the water leakage and further destroy. Albeit the owner was trusted in this explanation there were some research activity raised to find out the reason for damage.

The other was a problem, described already, of never appearing patina inside the box girder, which lead to excessive corrosion loses. In that case, the bridge owner was forced to paint the inner surfaces of the box girder in the most destroyed sections (Wierzbicki 2012).

4 CONCLUSION

As a general conclusion one may states that the weathering steel in Polish railway and road bridges, after over twenty years of service performers reasonably well. All the strength investigations show that the structural material is strong and does not ageing. There were some problems observed in one of the bridges, with extraordinary construction (box girder with orthotropic deck) and as a result the avoidance of using this solution in weathering steel bridges is advised.

Study on high speed railway prestressed continuous rigid frame bridges

Jun-Qing Lei & Kun Zhang
School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: For high-speed railway prestressed concrete bridge, to control the deflection of the bridge as the standard, studying the key technologies of the bridge design and construction, finite element methods to calculate and analyze the Static characteristics of the beam bridge. The design of the main consideration load as: weight, temperature gradient, the settlement of bearing, the second phase load bearing (uniformly distributed load), moving load on the influence of the bridge deflection in the same bridge design provides technical reference. The construction monitoring procedure of the five-span continuous rigid frame bridge (80 m+3×145 m+80 m) of Wenzhou-Fuzhou high-speed railway, the way of construction monitoring, simulation calculation, calculation of elevation, and measurements of elevation and stress are introduced in this paper, and controlling situation of alignment and stress of the bridge is emphatically analyzed. Also, comparative analysis on the influence of changes of bulk density and elastic modulus of concrete on the final bridge line is made, which comes a conclusion that the change of bulk density of concrete is more effective. So field test of influence parameters of the final bridge line is recommended besides the calculation analysis to reduce the difference between theoretical elevation and actual elevation. Finally, this paper concludes the situation of calculation analysis and construction monitoring: formwork erected with relative elevation method can remove temporary load's effect and effects of stochastic factors and can get a smooth final bridge line; a better theoretical elevation can be calculated if parameters are corrected according to field tests. The controlling measures such as adjusting the Elevation and Control weight are taken for the construction, in accordance with the results of the analysis in order to ensure that the stresses and alignments of the beam can meet the relevant code requirements at each construction stage and the bridge is completed successfully. The reference information is provided to the another bridge.

Keywords: high-speed railway; Strain and Stress; linear control; Continuous rigid frame bridge; Construction monitoring; Influencing factors of alignment; Deflection deformation

1 INSTRUCTIONS

In recent years, with the pre-stressed technology and the transportation development, pre-stressed concrete continuous rigid-frame bridge with its construction is simple, economic and reasonable cost, comfortable and maintenance costs low unique advantage is becoming more and more applications. To ensure the continuous steel bridge design bridge is in good agreement with the linear and the structural is safety in the construction process, construction supervision is more and more attention. Construction of long-span bridge structure is aimed at monitoring the construction process through the various parts of the bridge structure, deformation, strain, stress monitoring and control, to ensure that the bridge structure during construction and bridge closure precision, linear and internal forces after the structure meet the design requirement.

White Horse River Bridge, located in Wenzhou-Fuzhou express railway Ningde section, across the White Horse River Bay, the main bridge for the cross-hole layout for the 80 m+3×145 m+80 m of large-span continuous rigid frame bridge (see Figure 1).

2 THEORY OF CONSTRUCTION MONITORING

2.1 *Construction Monitoring Ideas*

According to the continual rigid frame bridge's construction characteristic, the segments have been completed for the error can't be adjusted, and not completed segment of the state and the accurate simulation, and the completed segment of the error has nothing to do. This decided that the continual rigid frame bridge's construction control should be in the prediction that namely the accuracy for a given beam elevation end of the formwork. First, it is assumed that the structure is the ideal state of structure parameters various structural parameters are designed according to specifications or drawings of value, given the ideal state of pre-cast high to guide the construction of the superstructure.

When carries on the beam section formwork erection elevation computation, the main provider of each beam section to be poured around the end section of the height difference, absolute elevation as reference, to have complete section for stress and elevation measurement, when appears the stress and the predicted value do not tally, should analyze possibly has error's reason, the parameter identification, fixed structure parameters of calculation, construction segmental ideal. If appear displacement calculated results and actual displacement value deviation of elevation, there are fixed.

In the bridge deck height control, we should aim to ensure smooth deck, not one-sided pursuit of the theory of individual node level. When the construction of a process or beam segment elevation after pouring deviation value and the theoretical value after the occurrence, without force in the next paragraph immediately adjust the beam over, but should identify the features of Control error occurred reason, the later calculation of cantilever deflection when casting an amendment, when in the next few beam section of the cantilever pouring all late even beam deviation will gradually corrected elevation. Finally into bridge may have many practical elevation and beam design elevation error, but the overall linear deck is smooth.

2.2 *Simulation computations*

In the present stage construction the bridge simulation computational method mainly includes: orderly-erecting analysis method, inversion analytic method and un-stressing condition computation method.

The greatly cross continual rigid frame bridge usually uses cantilever cast-in-place construction method, the construction cycle is long, connected the parameter like loss of pre-stress, the concrete shrinkage continuous variation with the time and so on to be big to the construction control influence, therefore, it uses orderly-erecting analysis method to be more suitable.

The structure of discrete except in simulated stress of the pier top, cross-sectional layout of the measuring point and thin wall pier, the other is the main beam by beam segment is divided, full bridge were divided into 234 finite elements, the main beam 202 units Each cantilever casting segment as a unit, each continuous 0# block pier Department is divided into eight units, rigid frame pier Department 0# block is divided into 12 units, piers divided into 8 units. Support the construction process simulation for the temporary support, the main beam and pier use master-slave nodes the connection. When modeling the following assumptions: full-pre-stressed girder structures; does not consider the ordinary steel bar participation structure stress; pier cap bottom and constraints into account by the consolidation.

2.3 *Elevation determination*

Main beam linear control most direct and effective way is the measured value on the theoretical values to determine the box after correction segment elevation model legislation. Various errors caused by changes in the elevation and girder can be corrected by adjusting the girders during so that the main beam close alignment as possible after the bridge design of linear fit.

Box girders during the theoretical calculation formula for:

$$H_n^i = H^i + f_y^i + f_n^i \tag{1}$$

where H_n^i is the n construction stage i node formwork elevation; $H^i$is the i node design elevation; f_y^i is the i node camber; f_n^i is the i node from the n construction stage to the bridge total deflection.

As the material properties, load error, temperature changes, shrinkage and creep and relaxation tendons and other factors, the situation has some differences with the calculated. So have to constantly fixed girders during theory on. Elevation of the box the actual legislation:

$$H_n^i = H^i + f_y^i + f_n^i + f_g + \Delta f^i \tag{2}$$

where H_n^i is the i node elevation of the actual legislation f_g is the Hanging Basket elastic deformation; Δf^i is according to observations and cantilever deflection deformation of the trend adjustment to determine the value of the deflection.

Elevation of the actual legislation calculation, if the measured value and the theoretical values deviate from the small, and find out the law of deviation from the value, then the legislation can be more accurate elevation model is given; if deviation values larger or irregular, you need to by linear regression theory and gray theory to analyze and predict. White Horse River Bridge span continuous rigid frame full-bridge formwork camber curve in Figure 2.

From the Fig. 2 can see, in 12# pier or 13# pier on both sides of the arch value difference is bigger, in the near side of the cross-camber side span of almost the double camber, which mainly due to downward deflection in the span much higher than the second side span,

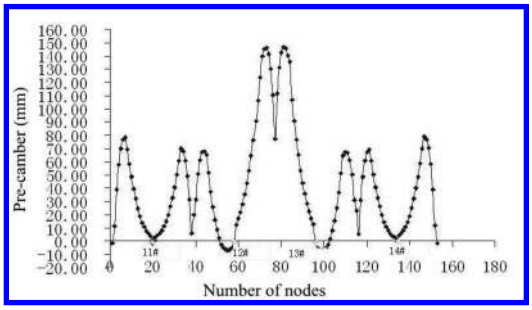

Figure 2. Bridge formwork camber curve.

the late creep across the impacts that are relatively large, these had decided when mid-span formwork erection must throw the high certain value. 11 pier# or 14# pier both ends of the camber is basically the same. For both ends of each pier Camber is then decreased, in the near Closure camber also reduces the time, this is because in the vicinity of Closure beam, post-weight is not caused by the accumulation of the beam segment under its Flexible, on the contrary will occur up rebound phenomenon because of the rigidity of a large fold.

2.4 *Density and elastic modulus of concrete*

In bridge deck construction and operational phases of impact parameters of more linear, but in general include geometric and material parameters in these two areas. The geometrical and material parameters are closely related with the construction, pre-calculated value and actual value of their existence often some differences, so when construction monitoring is necessary to analyze these differences impact on the linear. According to various parameters influence quantity size, modeling predicted ahead of time to adjust, so as to meet the design goals linear bridge.

The earlier period computation mainly involves to the concretes bulk density, elastic modulus of concrete, concrete shrinkage and creep coefficient, pre-stressed parameters, temperature field, main pier foundation settlement parameters of the 6 areas. The following analysis focused on bulk density and elastic modulus of concrete changes in the span is the elevation changes of the node.

2.4.1 *Concretes bulk density change to bridge linear influence*

In the bridge design, concrete bulk density and elastic modulus values according to specifications, but in actual construction of concrete and reinforced concrete density of sand and cement ratio of closely related. Despite the continuous bridge construction, each segment is used the same gravel concrete materials and water-cement ratio, but all segments of the concrete mixing and pouring is separate, so the differences will still exist. Based on past experience shows that construction monitoring: weight error is less than 5%. To bridge balance basis, beam weight change on the main beam linear in Table 1.

Table 1. Beam weight change on the main beam linear.

Beam weight changes /%	Δh/mm		
	A	B	C
5%	0.19	−6.72	−4.24
3%	0.13	−4.06	−2.55
0	0	0	0
−3%	−0.08	3.92	2.52
−5%	−0.14	6.59	4.21

* Note: ① h for the node elevation changes, the same; ② A, B, C respectively, cross-border, sub-side span, location across the span; ③ Figures in the table are representations on the deflection, that under the negative deflection, the same below.

Table 2. Beam weight change on the main beam linear.

E/MPa	Δh/mm		
	A	B	C
3.35×10^4	−0.55	3.19	−1.64
3.35×10^4	−0.45	2.64	−1.34
3.35×10^4	−0.36	2.09	−1.05
3.35×10^4	−0.25	1.52	−0.77
3.35×10^4	−0.17	1.02	−0.5
3.35×10^4	−0.09	0.51	−0.25
3.35×10^4	0	0	0

As can be seen from Table 1, the maximum beam weight change 5% change in the maximum deflection of the bridge 6.72 mm, so the change of beam re-alignment of the bridge obviously.

2.4.2 *The elastic modulus of concrete on the bridge of linear*

In the early design and review process of calculation, concrete elastic modulus values according to standard requirements for the bridge, the main beam is used C60 grade concrete. So, when calculated in accordance with design specifications to take concrete elastic modulus 3.65×10^4 *MPa*. However, non-linear concrete material, the elastic modulus changes with time, during the construction process, the coagulation of the elastic modulus of concrete by the impact of age and conservation does not necessarily meet the design specification to the reference value.

As can be seen from Table 2, the bridge is the change of elastic modulus of the bridge alignment is not very obvious, the biggest change to 3.19 mm.

3 ANALYSIS OF THE ACTUAL STRESS OF CONCRETE

3.1 *Effect of the Shrinkage and Creep Strain*

Concrete creep and concretes applied stress related, under the working stress, concrete elastic strain and creep strain and stress is linear. Therefore, as long as the total stress does not exceed 50% of concrete

strength in batches produced by the strain imposed by the stress superposition principle can be used. Situation for uninstall or load shedding, D. 1943 McHenry reversible creep theory proposed, will consider imposing load unload set, it generates the same time the creep load is applied in disguise, etc. creep generated, but in the opposite direction. The concretes test sample's experimental showing principle of superposition tallies very well to the basic continuous variation.

3.2 *Effect of the Temperature*

After the strain gauges embedded in concrete, the deformation occurred simultaneously with the deformation of concrete. As the concrete and the strain gauge thermal expansion coefficients of different, so when the temperature changes, strain gauges have the same passive deformation with concrete, by now the strain gauge received the concretes one kind of binding force (i.e. temperature strength), when temperature increment, the strain gauge receives the compressed stress, otherwise receives the tensile stress. The temperature elevates or reduces, will bring cantilever beams in free to elongate or shorten. This elongation or shortening the body does not produce stress in the beam changes, but the change in beam length will be embedded in the main beam reflected on the sensor, the sensor out from the concrete stress test points, including elongation of concrete caused by temperature changes or shortened.

4 MONITORING AND ANALYSIS

4.1 *Elevation Monitoring*

Elevation measurement points set in front of each block in the line, laying a 2~3 cm reinforced above the concrete. To minimize the effect of temperature, the White Horse Creek Bridge, the deflection of cantilever construction observation time normally scheduled for around 7:00 in the morning.

As the pre-stressed concrete continuous rigid frame bridge elevation observed before and after the task is to reflect the process or a specific period of time the actual deflection of the main beam changes, the elevation of the observations should be conducted before and after the procedure. Cantilever construction of the bridge, each of Cantilever Beam conditions to carry out four kinds of linear control of observations, that is, ① hanging basket in place, ② after concrete pouring, ③ tension pre-stressed steel beam before, ④ pretensile stress of steel beam is completed.

According to the method of continuous rigid-frame bridge white river Wenzhou-Fuzhou railway construction process of the deck elevations, the theoretical calculation and the actual result tallies basically, the differential value control in 5 cm, linear changes in the overall smooth main beam.

Can be learned from the previous plan, the actual level of control over the White Horse River bridge

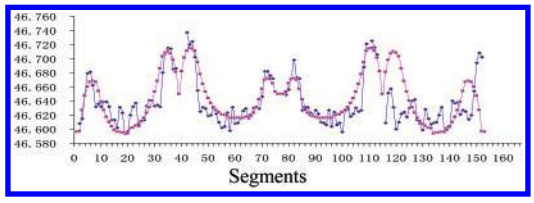

Figure 3. Measured elevation and design of the top flange should be compliance with high contrast chart.

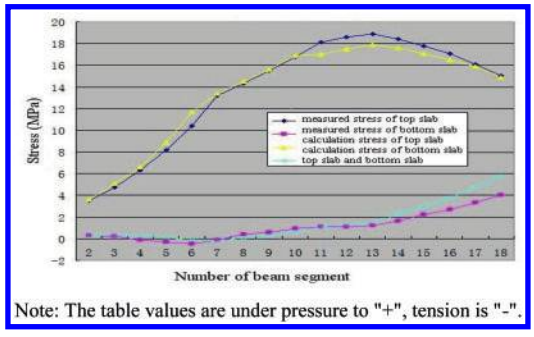

Figure 4. Caption Measured and calculated stress ratio.

is consistent with the overall design of the expected elevation linear. But because of 14 pier construction quickly, for the second side failed to timely adjust across elevation design elevation, the expected linear slightly lower than expected elevation design. And the corresponding 11 of control is perfect, good control of the line. Another Pier 12 and Pier 13 on both sides of cantilever segmental construction of elevation control in line with the design elevation.

4.2 *Stress Monitoring*

The main beam of stress and strain tests were selected in each cross-section of the fulcrum around 1/4 cross in the middle section. Beam test at the Department of the section of the roof, laid the floor of observation points, observation embedded devices (embedded concrete strain gauge steel strings). Standard beam section of each course of construction, on cradle in place, concrete pouring is completed, pre-stressed tension is complete, and on cradle mobile observation points in four operating conditions the stress test.

Each T cantilever both sides each three test section, decorate besides cantilever root 2 section 8 points, decorate the other section are six test points, a total of 40 test points. The bridge has four T-frame, total $4 \times 40 = 160$ test points. Strain sensors embedded in concrete are arranged horizontally in the direction of the bridge. Near the main pier construction phase of a cross-section measured stress values compared with the calculated values shown in Figure 4.

From the Figure 4, the measured cross section various stages of stress and stress calculation in good agreement, basically the same trend, only a slight departure from some, less than the maximum difference in 2 MPa. Error for many reasons: ① the

selection of design parameters (such as: the material properties, density and characteristic parameters); ② Construction Status Determination (working load, elastic modulus of concrete, concrete shrinkage and creep, pre-stress losses, temperature and other parameters) and measurement differences in the environment; ③ test equipment laying position, when the tension of the pre-stressing tendon closer position and test instruments, it will produce local stress concentration, the impact on test results. In general, this test is entirely reasonable, the error in a reasonable range.

5 CONCLUSIONS

(1) Concrete bulk density and elastic modulus of concrete is a continuous rigid frame bridge a greater impact on linear factors. Changing in bulk density of concrete is relatively linear effects on the more apparent. When linear control must carry on the key monitoring and the analysis to it, suggests when the computation analysis does the scene experiment to the linear influence parameter.

(2) The relative elevation method for setting formwork can eliminate the temporary load, and other random factors, obtained control of linear flow. Elevation of the legislation setting out the process, focus on the beam temperature difference changes, the measurement of time as we choose the temperature more stable periods, as short as possible formwork time.

(3) In large-span continuous rigid frame bridge construction monitoring, suggested by the structural parameters according to the standard according to the measured values, then complete the segment of the measured elastic modulus of concrete and the shrinkage coefficient to amend the method of calculating the model parameters to achieve the computing model and the actual structure of the line, in order to better predict the level of construction formwork.

(4) Stress monitoring results with the calculated error of close to 2 MPa, in addition to the scene of some random factors, the more the main reason is that individual tensioning tendons relative position and test equipment too close, and the calculation used to model creep and shrinkage the actual difference between the creep caused by the situation. There is no very consistent with China's actual situation creep model to study a better reflect the actual creep model is very necessary.

Experimental study on hybrid FRP-concrete bridge superstructure

Y.L. Wang, J.H. Ran, Y.Y. Li & M.M. Cao
School of the Civil Engineering, Dalian University of Technology, Dalian, China

ABSTRACT: The concept of the hybrid FRP-concrete design was exploited in a new type of bridge superstructure system. The proposed hybrid bridge superstructure was designed as a simply supported, 10 m singlespan, one-lane bridge. The bridge superstructure consists of two bridge decks and each deck is comprised of four Fiber Reinforced Polymer (FRP) box sections combined with a thin layer of concrete in the compression zone. This new design was proposed to reduce the initial costs and increase the stiffness of FRP composite structure. This paper presents the results from the experimental study on a one-third scale model of the hybrid FRP-concrete bridge superstructure. The scale model was subjected to four-points loading to simulate the truck load. The test results indicate that the proposed bridge model meets the stiffness requirement and has an significant reserve strength.

1 INTRODUCTION

A major concern for many bridge superstructures is the significant reduction in durability and life expectancy caused by the corrosion of the reinforcing steel and the corresponding deterioration of the concrete. These problems are accelerated by the application of de-icing salts in cold area. The corrosion will eventually cause enough damage to warrant a superstructure replacement or retrofit (Robbins 2002). According to the U.S. National Bridge Inventory, nearly 27 percent of 590,000 public bridges were either structurally deficient or functionally obsolete as of 2003. The U.S. Department of Transportation (DOT) estimates the average annual cost to improve bridge conditions for the 20-year period of 1998–2017 to be $10.6 billion in 1997 dollars (Kitane & Aref 2004, Kitane et al. 2004). The similar situation exists in China. These facts imply that it is imperative to develop and construct bridge systems that have long-term durability and require low maintenance.

As one of the solutions to this problem, structural applications of fiber reinforced polymer (FRP) composites have recently been attractive in the civil engineering community due to their superior material properties such as high corrosion resistance, high specific strength, and high specific stiffness. In terms of initial costs, FRP composites are still too expensive to compete with other conventional materials used in civil engineering applications. To make the best use of materials and reduce the initial costs, combinations of FRP and conventional materials have recently been investigated by a number of researchers (Mirmiran 2001). The advantages of the combined or hybrid structural systems include the cost-effectiveness and the ability to optimize the structural section based on material properties of each constituent material. According to Mirmiran (2001), the most effective use of FRP composites in civil structural applications is in the form of a hybrid construction with concrete.

Among the bridge maintenance items at U.S. DOT, bridge decks are ranked No.1 maintenance priority (Brailsford et al. 1995). Therefore, the concept of the hybrid FRP-concrete structural system was applied to bridge superstructure in this study. The primary objectives of this study were to propose a conceptual design of a hybrid FRP-concrete bridge superstructure, and to examine its performance under live loads by experimental investigation.

2 PROPOSED HYBRID FRP-CONCRETE BRIDGE SUPERSTRUCTURE SYSTEM

Although many configurations of the hybrid FRP-concrete bridge superstructure are possible, a conceptual design of the hybrid bridge superstructure shown in Figure 1a, where supports and substructures are not shown, was chosen. A prototype bridge was designed as a simply supported, single-span, one-lane bridge with a span length of 10 m. Geometrical parameters of the cross sections in Figure 1b were determined based on numerous finite-element analyses. The cross section of the bridge is comprised of 8 box sections, each of which has a layer of concrete in the compression zone. E-glass woven fabric reinforcement and vinyl ester matrix were selected as constituents for the GFRP laminate. In this study, the ratio of the area of concrete to the total area in the cross section is 0.4.

The bridge design is based on the traditional plank bridge concept, in which a number of individual beams

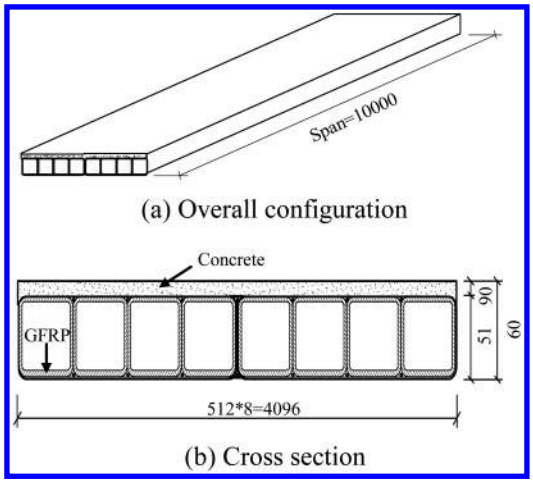

Figure 1. The proposed hybrid bridge superstructure (units in mm).

are placed side by side to create a bridge. The advantages of this concept include: (1) corrosion resistance for steel-free design; (2) initial costs reduction due to the effective use of concrete; (3) lightweight; (4) reduction of local deformation under concentrated loads that is found to be a problem in all-composite bridge; (5) no joints between decks and girders (the girders are the decks); (6) significant understanding of the bridge behaviour can be obtained by testing of individual beams; (7) the concept is well understood by bridge engineers.

Four beams make up a bridge deck with a width of 2,048 mm. The prototype bridge consists of two bridge decks. The 2,048 mm wide bridge deck can be easily transported to site on a standard truck and assembled into a bridge using simple field joints.

The design concept is similar to the concept proposed by Van Erp et al. (2002). However, there are several distinctnesses, including: (1) without utilization of CFRP due to its expensive price and lack of source in recent years in China; (2) usage of normal concrete instead of polypropylene fiber reinforced concrete; (3) the ways of assembling between two decks, and among GFRP beams in the bridge deck.

3 EXPERIMENTAL PROGRAM

3.1 *Material*

Two types of bidirectional E-glass woven fabric with a weight of 600 g/m^2, (0°/90°) and (±45°), were selected as the primary continuous reinforcement of FRP laminates. In these fabrics, fibers in 0° and 90° or +45° and −45° directions have the same weight (300 g/m^2). Vinyl-ester resin, Swancor 901, was chosen as the matrix. Vinyl-ester resins are typically used when high durability, thermal stability and extremely high corrosion resistance are required; therefore, they are very suitable for civil engineering structures.

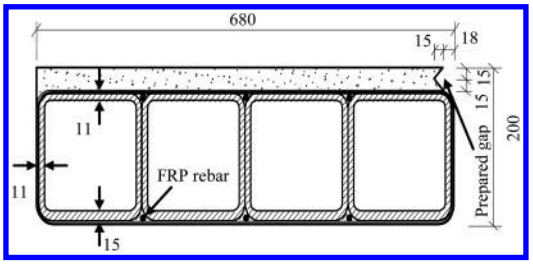

Figure 2. Cross section of 1/3 scaled hybrid bridge deck (units in mm).

Due to the size of the test specimen, coarse aggregates with maximum size of 10 mm were used in the concrete. The compressive strength of the concrete on the day of test is 51 MPa. Young's modulus of the concrete will be slightly smaller than the normal concrete due to the use of small size coarse aggregates.

3.2 *Test specimen*

The test specimen is a one-third scale model of the 10 m hybrid FRP-concrete bridge superstructure shown in Figure 1. As mentioned above, the bridge superstructure consists of two same bridge decks. Figure 2 shows the cross section of one bridge deck. The specimen (FRP part only) was fabricated at Harbin Composites Corp. of China. The box sections were fabricated by the hand lay-up process at present stage. The top flange and the webs of each box section had the same fiber architecture, which consisted of 13 layers of woven fabric reinforcement. However, the bottom flange consisted of 19 layers of woven fabric to increase the global stiffness of the section. Stacking sequences of the top and bottom flanges were $[(0°/90°)_3, (\pm45°)_2, (0°/90°)_2, (90°/0°), (\mp45°)_2, (90°/0°)_2]$, $[(0°/90°)_3, (\pm45°)_2, (0°/90°)_2, (90°/0°), (\mp45°)_2, (90°/0°), (0°/90°)_3, (90°/0°)_3, (90°/0°)_2]$, respectively. The fiber volume fraction of the FRP part is about 0.3.

The eight individual box beams were fabricated firstly. Secondly, by combining two sets of 4 box beams each using vinyl-ester resin and chopped strand mat (CSM), 2 sections with a width of approximately 680 mm were created. Thirdly, the tw2 sections were wrapped individually with a laminate having a $[(0°/90°)_2]_s$ laminate construction to strengthen the transverse stiffness of the sections. Fourthly, concrete was cast on the top surfaces of the two sections, forming the hybrid FRP-concrete bridge decks (shown in Figure 2). Finally, the 2 bridge decks were assembled together, forming the proposed hybrid bridge superstructure (shown in Figure 1). The connecting details for the 2 bridge decks are shown in Figure 3. High quality vinyl-ester resin and CSM were also used to bond the FRP parts (webs). Mortar/epoxy mortar was selected to fill the prepared gaps of the bridge decks. And FRP rebar was adopted to fill the gap at the bottom surface of the bridge superstructure. Additional FRP laminate was added to the bottom of the bridge

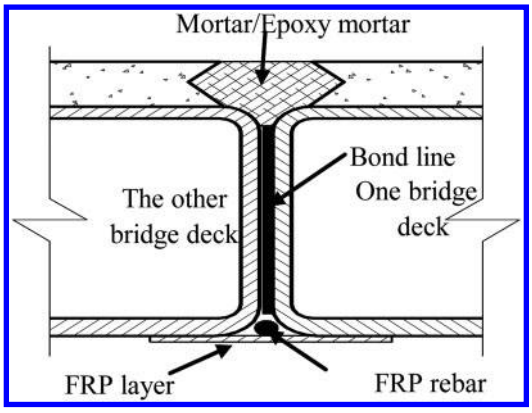

Figure 3. Connecting details for two bridge decks.

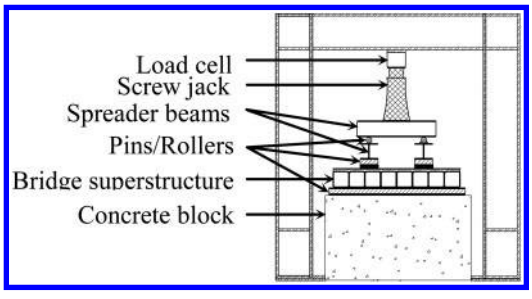

Figure 4. Experimental setup.

superstructure to give the structure some transverse stiffness. In real bridge assembling, FRP layer and FRP rebar will be neglected for simple operation.

3.3 *Test setup and apparatus*

The test setup is shown in Figure 4. Loads were applied vertically at four points on the top surface of the test specimen by three spreader beams and the screw jack supported by the top beam of a reaction frame. The load configuration simulates the two heaviest axles of the standard truck load (total 5 axles) specified in the Chinese Bridge Design Specifications (JTG D6-2004). In the specifications, the design truck load is a live load and has 5 axles. And the two heaviest axles are specified as 140 kN each, where one axle is 1.4 m away from the other. Each axle has two tires that are 1.8 m apart center-to-center, and each tire area has a length of 0.6 m and a width of 0.2 m. For the 1/3 scale model, this design truck load becomes two axles of 15.56 kN, 0.467 m apart. Two tires of axle are 0.6 m apart, and each tire area is 0.2 m long and 0.067 m wide.

The test specimen was simply supported by concrete blocks with a support length of 0.2 m at each end. To protect the bottom surface of the specimen from damage, rubber pads were placed between test specimen and the pin/roller at two ends of the specimen. Figure 5 shows the positions of the displacement and strain measurement to be acquired during the experiment.

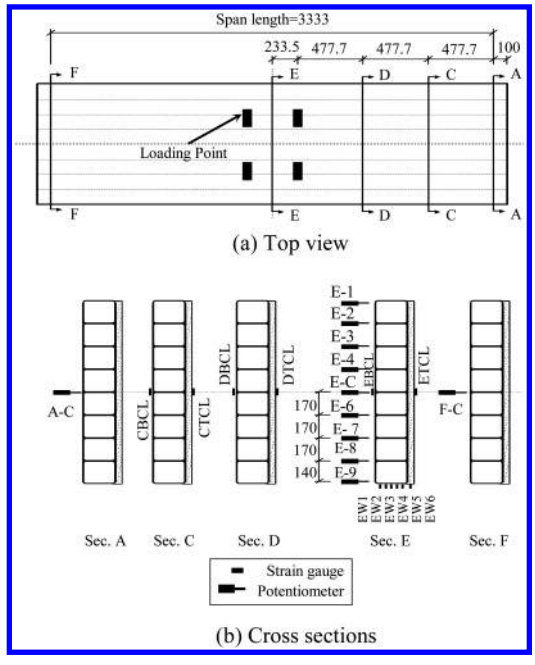

Figure 5. Instrumentation layout (units in mm).

3.4 *Test Procedures*

The hybrid FRP-concrete bridge specimen was tested by flexural and off-axis flexural loadings (shown in Figure 6) firstly. These tests were performed by force control, and the maximum load of 3 times the scaled truck load (93.3 kN) was applied. In the tests, displacement and strain were measured. Then the hybrid bridge model was tested in flexure to failure to examine its ultimate strength and failure modes. The strength test was also performed by force control, and it was divided into two steps. In the first step (Step I), a cyclic force profile was used with the amplitude gradually increased. For each cycle, the force ranged from 0 to a predetermined amplitude, and three cycles were applied for each amplitude to examine the deflection stability. In the second step (Step II), force was increased monotonically until the test specimen failed.

4 TEST RESULTS AND DISCUSSIONS

4.1 *Flexural Test*

No sound of cracking of either the concrete or GFRP was heard during the flexural test. Visual inspection after the test revealed no cracking in the surface of the test specimen. Figure 7 shows the force-displacement relationship obtained at E-C (see Figure 5 for the location). It can be concluded that the obtained force-displacement response is very much linear and has a good repeatability for the hybrid bridge specimen. The deformed shapes of the bottom surface are described in Figure 8. From this figure, we can see that the

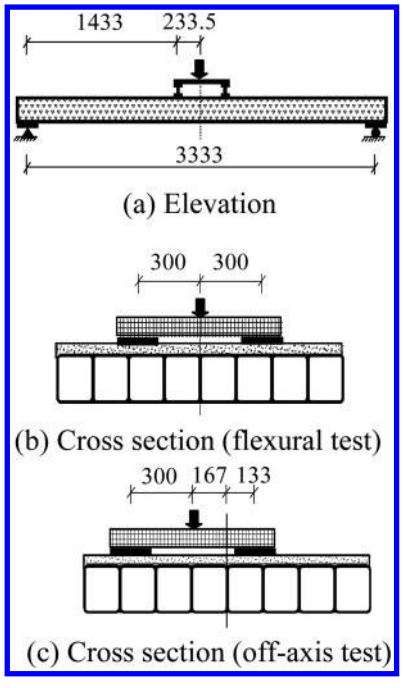

Figure 6. Loading configurations (dimensions in mm).

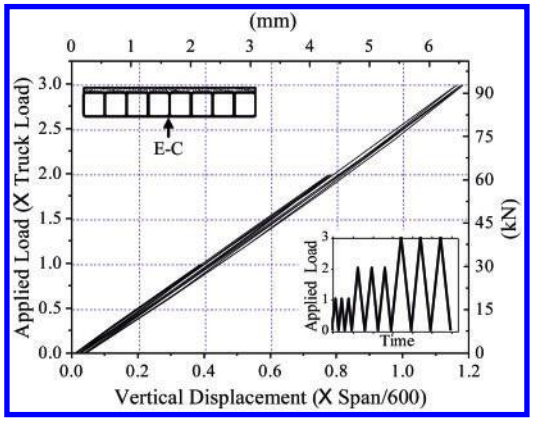

Figure 7. Force versus displacement at E-C (flexural test).

deformed shapes of bottom surface at midspan section (section E) are nearly linear, which indicates that the hybrid bridge specimen has adequate transverse stiffness and the 8 box beams can work together as a plate.

It is specified in the Chinese Bridge Design Specifications (JTG D6-2004) that the maximum deflection under live loads is smaller than $L/600$ (L = span length). The live load for this check is design truck load. As the span length of the test specimen is 3.333 m, the maximum deflection under truck load has to be smaller than $L/600 = 5.555$ mm. Deflection due to truck load measured at E-C is

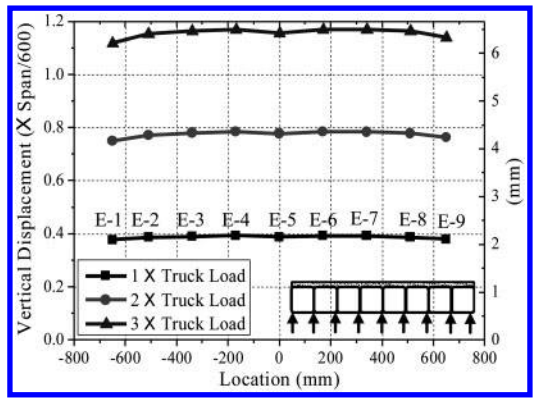

Figure 8. Deformed shapes of bottom surface at section E (flexural test).

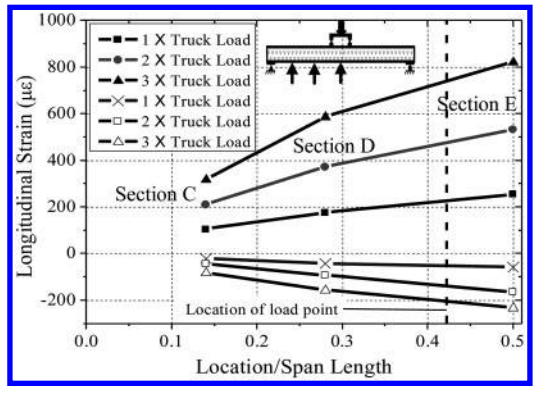

Figure 9. Longitudinal strain obtained at bottom and top center (flexural test).

$2.16\,\text{mm} = 0.39 \times L/600$. The hybrid bridge specimen well satisfied the Chinese live load deflection specification.

Longitudinal strain variations along the centerline of the bottom and top surface and over the height on the exterior web are shown in Figures 9 and 10. Figure 9 shows that longitudinal strain variations along the centerline of the bottom and top surface appear to have a good regularity with the expected results. Figure 10 shows that the bending theory for small strain can apply—i.e., the plane section before deformation remains plane after deformation. And the concrete layer is in the compressive zone, which is designed to utilize concrete effectively

4.2 *Off-Axis Flexural Test*

The screw jack and spreader beams were then moved off the centreline by 167 mm, so that the jack could apply an off-axis load, as shown in Figure 6(c). 167 mm was the largest eccentricity in the real traffic condition. Applied load history was the same as that used for the symmetrical flexural test. No sound of cracking of either the concrete or GFRP was heard during the experiment. Visual inspection after the test

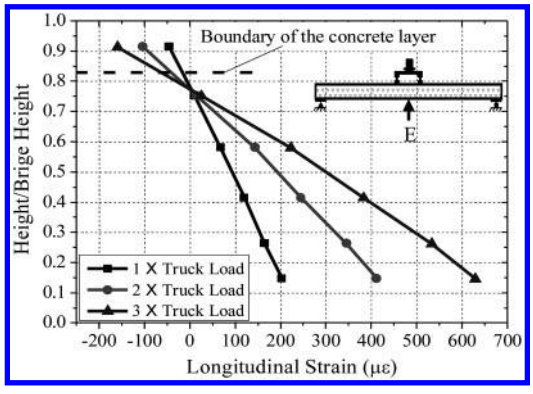

Figure 10. Longitudinal strain obtained on exterior web at section E (flexural test).

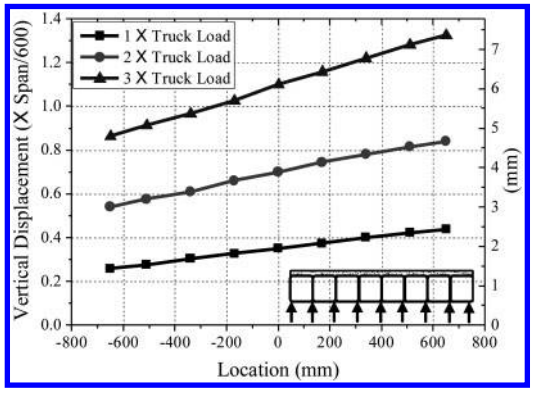

Figure 11. Deformed shapes of bottom surface at section E (off-axis test).

revealed no cracking in the surface of the test specimen. The obtained deformed shapes of the bottom surface are shown in Figure 11. Eight box sections acted together under such a load and the bonding between box sections was strong enough to keep them together. This design appears to have excellent section torsional resistance.

4.3 *Strength Test*

Figure 12 shows force-displacement responses obtained at E-C during the strength tests (Step I and II). At the load of near 16 × truck load in step II, there was a medium loud noise. It is regretted that visual inspection was not conducted in time. So the noise may be caused by the cracking of the interface between FRP and concrete or the cracking of concrete under the loading points. And at this point, the slope of force-displacement curve changes slightly. The load was 8.8 times the Chinese Bridge Design requirement of 1.4(1 + IM) × truck load for live loads in the strength limit state, where IM = dynamic load allowance, and has a value of 0.3 in this case.

The load path from Step II shows that the loading path is nearly linear until the specimen failed. A global

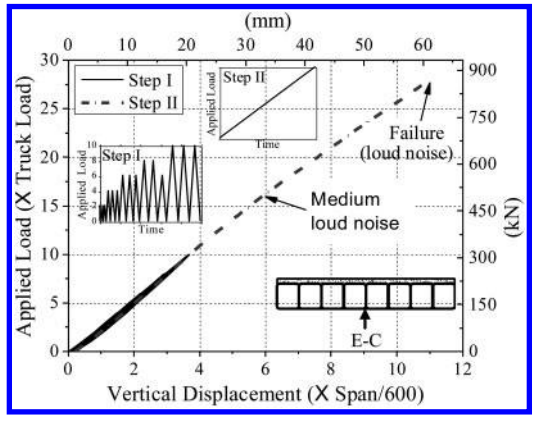

Figure 12. Force versus displacement at E-C (strength test).

failure as shown in Figure 13 occurred at 28 × truck load, which is 15.4 times the 1.4(1 + IM) × truck load. Crushing of concrete in compression near the loading points defines flexural collapse of test specimen. However, the FRP part was found to be intact. This can be described as follows. As concrete failed, large deflection occurred immediately due to the low stiffness of FRP part in comparison to the hybrid specimen, along with instantaneous reduction of the load for the quick increase of deflection, and the combined compression capacity of the FRP top flange and the residual strength of the concrete enable the specimen to carry the residual load. After unloading the residual load, the deflection of the specimen almost came back. The failure was sudden due to the nature of the concrete. However, the obtained failure mode is considered to be favorable because it did not lead to collapse of the entire bridge and the bridge can be retrofitted easily by the replacement of the concrete layer.

5 CONCLUSIONS

The experimental study presented here shows the feasibility of the proposed hybrid FRP-concrete bridge superstructure. The main features of the proposed design include: (1) the efficient use of the concrete layer in the compressive zone to increase the system stiffness, and to reduce the FRP composites and initial costs; (2) the effective implementation of aggregate coating to ensure composite action of the FRP and concrete; (3) the effective ways of assembling between two decks, and among FRP box beams in the bridge deck; and (4) the use of box sections to provide significant torsional stiffness for the cross section.

As is often the case with FRP composite bridges, the design of the proposed bridge superstructure is stiffness-control. It has been proved that the proposed hybrid bridge can be designed to meet the live load deflection requirement of Chinese Bridge Design Specifications and to have significant reserve strength (15.4 times design requirement). Therefore, the depth

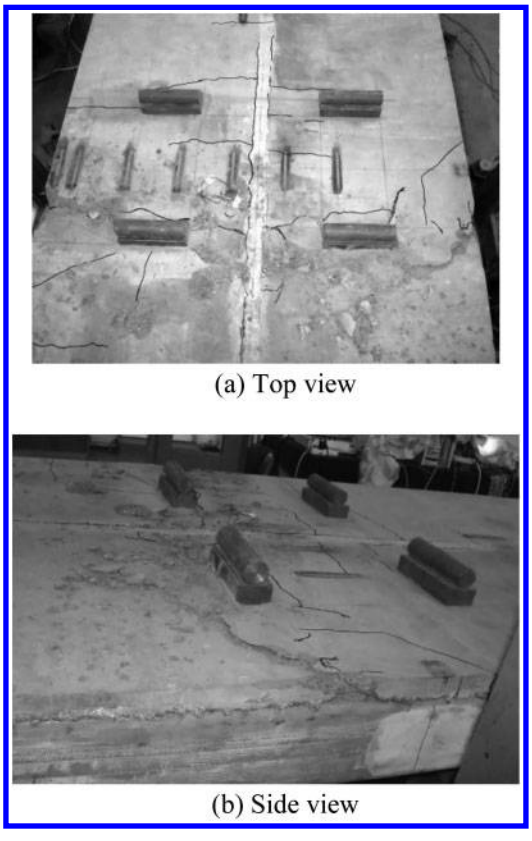

Figure 13. Failure of test specimen.

of the bridge may be increased so that the same flexural rigidity can be achieved with less material and the strength can be used more efficiently.

The concept of the hybrid design—using different materials where they perform best—is a very prudent way to design a structure. A combination of FRP composites and concrete is especially promising in civil infrastructure applications. Although the proposed hybrid FRP-concrete bridge superstructure may not be close to an optimal design, it gives an example of the hybrid design in a bridge superstructure application

Design of tension components according to Eurocode 3 Part 1-11

K. Kathage
Deutsches Institut für Bautechnik (DIBt), Berlin, Germany

ABSTRACT: This paper deals with the design rules of Eurocode 3 Part 1-11 (EN 1993-1-11) for tension components. The paper covers tension rod systems, prefabricated steel and stainless steel wire rope systems and cable systems using prestressing steel. These systems include the corresponding end connectors or anchorages as well as clamps and saddles. The design rules rules of EN 1993-1-11 are explained and introduced. If necessary the relevant reference to additional supporting documents (eg. European technical approvals or assessments) is given.

1 INTRODUCTION

Eurocode 3 Part 1-11 (EN 1993-1-11) covers the design of tension components made of steel or stainless steel which are adjustable and replaceable. The scope comprises different types of tension components which are subdivided into the three groups A, B and C according to Table 1.

Products of group A are used for simple and aesthetic architectural solutions for bracings and suspensions of filigree steel, steel-glass and timber structures.

Products of group B are used for masts, aerials and bridges, bridge hangers, suspension of membrane, steel, steel-glass and timber and roof structures, cable nets and bracings.

Products of group C are mainly used as stay cables for bridges (steel, composite or suspension bridges) or other superior suspended structures.

Additional information concerning the design of tension components according to EN 1993-1-11 is provided by Kathage & Misiek (2012).

Table 1. Groups of tension components

Group	Tension Component
A	Tension rod system: Round steel or stainless steel bars with threads and fork end connectors
B	Steel and stainless steel wire rope system: Spiral strands, locked coil strands and strand ropes including end connectors, clamps and saddles
C	Cable system using prestressing steel: Parallel wire strands, bundles of parallel wires or strands including anchorages and saddles

2 GROUP A: TENSION ROD SYSTEMS

Tension rods are made of steel or stainless steel. Most prefabricated tension rod systems have fork end connectors made of forged or cast materials. The tension rods are threaded into the fork end connectors which are connected to the corresponding gusset plates by pins (Fig. 1).

The design value of the tension resistance has to be determined according to EN 1993-1-1 in combination with EN 1993-1-8. The resistance is the minimum value of either the tension resistance of the fork end connector (including the pin and the corresponding gusset plate) or the tension rod itself.

In this paper only the determination of the tension resistance $F_{Rd,TRod}$ of the tension rod is given. The design value is determined similar to the design value of the tension resistance of bolts. It is the minimum value of the resistance of the threaded part and the unthreaded part of the tension rod.

Figure 1. Typical tension rod system

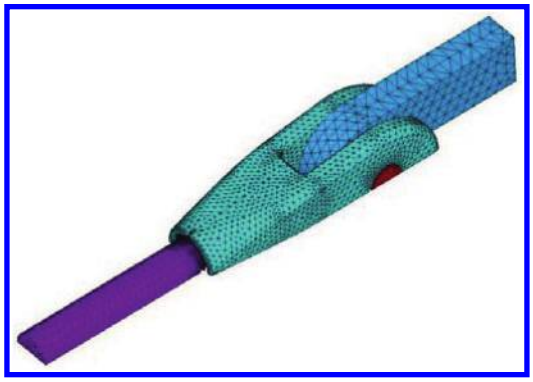

Figure 2. FE model of fork end connector

The design value $F_{Rd1,TRod}$ of the threaded part is determined according to EN 1993-1-8, Table 3.4 as follows:

$$F_{Rd1,TRod} = \frac{0.9 \cdot f_{ub,k} \cdot A_S}{\gamma_{M2}} \quad (1)$$

Where $f_{ub,k}$ = characteristic value of tensile resistance of tension rod, A_S = cross section of threaded part.

The recommended partial safety factor is $\gamma_{M2} = 1.25$. For tension rods with cut threads which are manufactured in a non-series process the value according to equation (1) has to be multiplied by 0.85.

The design value $F_{Rd2,TRod}$ of the unthreaded part is determined according to EN 1993-1-1, section 6.2.3 as follows:

$$F_{Rd2,TRod} = \frac{f_{yb,k} \cdot A}{\gamma_{M0}} \quad (2)$$

Where $f_{yb,k}$ = characteristic value of yield resistance of tension rod, A = cross section of unthreaded part.

The recommended partial safety factor is $\gamma_{M0} = 1.0$.

The minimum value min $\{F_{Rd1,TRod}; F_{Rd2,TRod}\}$ is the design tension resistance $F_{Rd,TRod}$ of the tension rod.

The design tension resistance $F_{Rd,ForkEndConnector}$ of the fork end connector (including the pin and the corresponding gusset plate) can be determined according to EN 1993-1-8, section 3. The procedure is described by Kathage (2003) and by Kathage et al (2011).

Since the determination of the design tension resistance of fork end connectors gives quite conservative results, the design tension resistance of prefabricated tension rod systems is determined in many cases by FE analysis or by tests. A typical FE model is shown in Fig. 2.

In the case of tests a European technical approval or European technical assessment is recommended as basis for the design.

For the ultimate limit state it shall be verified that

$$\frac{F_{Ed}}{F_{Rd,GroupA}} \le 1 \quad (3)$$

Figure 3. Fork socket with pin.

Where F_{Ed} is the design tension load and $F_{Rd,GroupA} = min\ \{F_{Rd,TRod}; F_{Rd,ForkEndConnector}\}$ the design tension resistance of the entire tension rod system.

For fatigue design of tension rod systems the rules given in EN 1993-1-9 shall be taken into account. The fatigue strength curves of fork end connectors made of cast materials shall be determined by tests. Usually the objective of these tests is to verify the detail category 50 (fatigue resistance $\Delta\sigma_c = 50$ N/mm^2 for $2 \cdot 10^6$ load cycles) according to EN 1993-1-9.

3 GROUP B: STEEL AND STAINLESS STEEL WIRE ROPE SYSTEMS

3.1 *General*

Tension components according to group B of EN 1993-1-11 and Table 1 are for instance steel or stainless steel wire ropes with metal or resin filled sockets (Fig. 3), swaged sockets, swaged fittings with thread, U-bolt grips or eye loops with swaged aluminium ferrule. The wire ropes may be deviated by saddles and may be connected to each other by clamps.

The materials of wires, ropes and end connectors have to fulfill the requirements of the European product standards given in section 3 of EN 1993-1-11. For steel wires a maximum nominal strength of 1770 N/mm^2 (round wires) respectively 1570 N/mm^2 (Z-wires) is recommended and for stainless steel wires a maximum nominal strength of 1450 N/mm^2.

According to section 4 of EN 1993-1-11 steel wire ropes have a corrosion protection system that should be as follows:

- Corrosion protection of individual wires,
- Corrosion protection of the interior by inner filling,
- Corrosion protection of the outer surface by sheathing or painting.

For stainless steel wire ropes no information about the corrosion resistance of the different stainless steel alloys is given in EN 1993-1-11.

Additional corrosion protection is required at end connectors, saddles and clamps.

The modulus of elasticity for the different types of wire ropes is given in Table 3.1 of EN 1993-1-11.

Unfortunately no values for the creep elongation of steel and stainless steel wire ropes are given in EN 1993-1-11. Normally creep elongation has to be taken into account for the design of stainless steel wire ropes with permanent loads of more than 40%.

3.2 *Design of steel and stainless steel wire rope systems*

3.2.1 *Ultimate limit state*

For the ultimate limit state the verification of sufficient design resistance is similar as to equation (3). It shall be verified that

$$\frac{F_{Ed}}{F_{Rd,GroupB}} \le 1 \tag{4}$$

Where F_{Ed} is the design tension load and $F_{Rd,GroupB}$ is the design tension resistance of the prefabricated steel or stainless steel wire ropes including end connectors.

The design tension resistance $F_{Rd,GroupB}$ of the prefabricated wire rope shall be determined with the recommended partial safety factor $\gamma_R = 1.0$ as follows:

$$F_{Rd,GroupB} = \min\left\{\frac{F_{uk}}{1.5 \cdot \gamma_R}; \frac{F_k}{\gamma_R}\right\} \tag{5}$$

where F_{uk} is the characteristic value of the breaking strength and F_k the characteristic value of the proof strength of the entire prefabricated wire rope.

F_{uk} is determined as follows in N:

$$F_{uk} = F_{\min} \cdot k_e = K \cdot d^2 \cdot R_r \cdot k_e \tag{6}$$

Where F_{min} is the minimum breaking force [N] of the wire rope itself (without end connector), k_e is the loss factor given in Table 2 for some types of end connectors, K is the minimum breaking force factor, R_r is the tensile strength of the wire rope [N/mm^2] and d is the diameter of the wire rope [mm].

K, d and R are specified in the relevant product standard EN 12385-2.

The loss factor should be determined by tension tests (Fig. 4). In this case a European technical approval or European technical assessment is recommended as basis for the design.

The characteristic value of the proof strength F_k can not be calculated but only determined by tests according to Fig. 4. However, normally it is not relevant for the design.

Table 2. Loss factors k_e.

End connector	k_e
Metal filled socket	1.0
Resin filled socket	1.0
Swaged socket	0.9
Swaged fitting with external thread	0.9
Eye loops with swaged aluminium ferrule	0.9
U-bolt grip	0.8

Figure 4. Tension test of wire rope with fork socket

3.2.2 *Serviceability limit state*

EN 1993-1-11, section 7 gives the relevant design criteria for the serviceability limit states. Provided that fatigue design is necessary it shall be verified for the serviceability limit state that

$$\frac{\sigma_{Ek}}{f_{SLS}} \le 1.0 \tag{7}$$

Where

$$\sigma_{Ek} = \frac{F_{Ek}}{A_m} \tag{8}$$

σ_{Ek} is the characteristic value of the stress determined by dividing the characteristic value of the tension force F_{Ek} by the metallic cross section A_m

f_{SLS} = upper stress limit for service conditions

$f_{SLS} = 0.50 \cdot k_e \cdot f_{uk}$ for fatigue design with bending stresses and

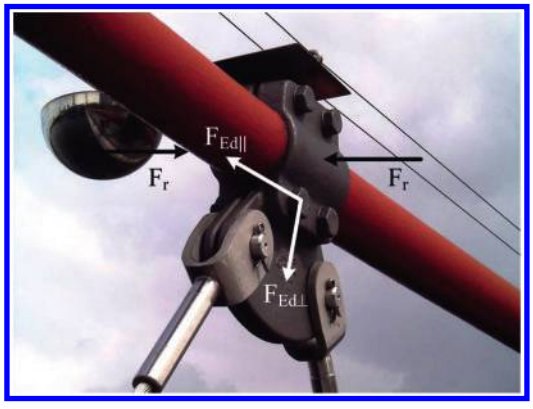

Figure 5. Clamp with corresponding forces.

$f_{SLS} = 0.45 \cdot k_e \cdot f_{uk}$ for fatigue design without bending stresses
f_{uk} = characteristic value of tensile resistance of wire rope

The stress limitation for the construction phase according to EN 1993-1-11 section 7 is already covered by the ultimate limit state design for the construction phase and thus not relevant.

3.3 *Design of clamps*

Clamps are used to connect wire ropes to each other. They transmit longitudinal forces (Fig. 5).

Slipping of clamps shall be verified as follows:

$$F_{Ed\,//} \leq \frac{(F_{Ed\,\perp} + F_r) \cdot \mu}{\gamma_{M,fr}} \tag{9}$$

$F_{Ed//}$ *und* $F_{Ed\perp}$ are the components of the design loads parallel and perpendicular to the wire rope. F_r is the radial clamping force, μ is the friction factor (unfortunately no value is given in EN 1993-1-11) and $\gamma_{M,fr} = 1.65$ is the recommended partial safety factor. Normally F_r can not be calculated, thus in most cases the design resistance of the slipping force is determined by tests. In this case a European technical approval or European technical assessment is recommended as basis for the design.

Transverse pressure could reduce the design tension resistance of the clamped wire rope. The transverse pressure due to the forces F_r and $F_{Ed\perp}$ should meet the following requirement:

$$\frac{q_{Ed}}{q_{Rd}} \leq 1 \tag{10}$$

Where

$$q_{Ed} = \frac{F_{Ed\perp} + F_r}{d' \cdot L_2} \tag{11}$$

$$q_{Rd} = \frac{q_{Rk}}{\gamma_{M,bed}} \tag{12}$$

Figure 6. Pylon with saddle

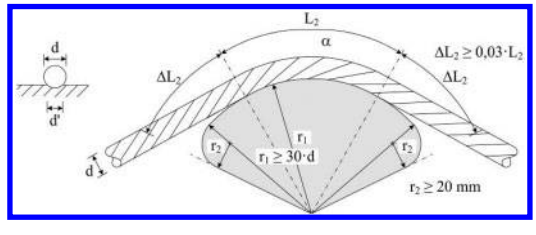

Figure 7. Curvature of a wire rope over a saddle

d' is the contact width and d the rope diameter and $0{,}6\ d \leq d' \leq d$ according to Fig. 7.
L_2 is the clamping length (Fig. 7), q_{Rk} is the limit value of the transverse pressure according to Table 6.4 of EN 1993-1-11.
$\gamma_{M,bed} = 1.0$ is the recommended partial safety factor.

Clamps shall be designed for a force equal to 1.15 times the proof strength F_k of the secondary tension component clamped to the main tension component.

3.4 *Design of saddles*

Saddles are used as support for steel and stainless steel wire ropes with curvature (eg. pylon with saddle; Fig. 6 and Fig. 7).

The transverse pressure of wire ropes with curvature over a saddle could reduce the design tension resistance of the rope. The design resistance of wire ropes with curvature over a saddle can be determined by tests. If the geometrical requirements according to Fig. 7 and section 6.3.1 of EN 1993-1-11 are met the influence of the transverse pressure on the tension

resistance of the rope at the saddle may be neglected for saddles without additional clamps.

Slipping of wire ropes on a saddle without additional clamps shall be verified with the *Euler-Eytelwein*-formula as follows:

$$\frac{F_{Ed1}}{F_{Ed2}} \le e^{\left(\frac{\mu \cdot \alpha}{\gamma_{M,fr}}\right)} \tag{13}$$

Where $F_{Ed1} > F_{Ed2}$; F_{Ed1} and F_{Ed2} are the design values of the tension forces on the left and the right side of the saddle, μ is the friction factor (unfortunately no value is given in EN 1993-1-11), α is the angle according to Fig. 7 and $\gamma_{M,fr} = 1.65$ is the recommended partial safety factor.

If equation (13) can not be satisfied, additional clamps are necessary. In this case equation (13) shall be modified as follows:

$$\frac{F_{Ed1} - \frac{k \cdot F_r \cdot \mu}{\gamma_{M,fr}}}{F_{Ed2}} \le e^{\left(\frac{\mu \cdot \alpha}{\gamma_{M,fr}}\right)} \tag{14}$$

The factor k is normally 2.0 if full friction between the saddle grooves and the clamp may be taken into account, otherwise $k = 1.0$.

If the geometrical requirements according to Fig. 7 and section 6.3.1 of EN 1993-1-11 are met the transverse pressure due to radial clamping forces F_r shall be determined as follows:

$$q_{Ed} = \frac{F_r}{d' \cdot L_2} \tag{15}$$

The requirements of equation (10) shall be verified. q_{Rd} shall be determined according to equation (12).

Saddles shall be designed for a force equal to 1.1 times the breaking strength F_{uk} of the wire rope.

3.5 *Vibrations and fatigue design*

EN 1993-1-11, section 8 gives some general information how to limit wind induced vibrations of wire ropes (eg. by using damping devices) and how to estimate possible risks. However, this information is not sufficient for the design for wind induced vibrations.

Fatigue of steel and stainless steel wire ropes usually occurs at end connectors, saddles or clamps. The detail category for fatigue design of these construction details (wire rope incl. end connector or saddle or clamp) should be determined by tests. For fatigue design of spiral strands and locked coil strands with sockets and mainly axial fatigue action bilinear fatigue strength curves are given in section 9.2 of EN 1993-1-11. These curves are for fluctuating tension loads with or without bending due to wind and rain. The detail categories refer to a fatigue resistance $\Delta\sigma_c$ for $2 \cdot 10^6$ load cycles. For spiral strands and locked coil strands with metal or resin filled sockets the detail category 150 may be used for design ($\Delta\sigma_c = 150\ \mathrm{N/mm^2}$). Additional protective measures are required to minimize bending at end connectors.

At least one test with $2 \cdot 10^6$ load cycles, $1.25 \cdot \Delta\sigma_c$ and an upper stress limit of $0.45 \cdot \sigma_{uk}$ for each diameter of the tension component (incl. end connector) is recommended according to EN 1993-1-11 Annex A section A.4 in order to verify the fatigue strength curves mentioned above. No failure of the end connectors should occur. The fatigue resistance of end connectors, clamps and saddles should be higher than the fatigue resistance of the corresponding wire ropes.

4 GROUP C: CABLE SYSTEMS USING PRESTRESSING STEELS

Cable systems using prestressing steels like parallel wire strands and bundles of parallel wires or strands are usually used as stay cables or main cables for bridges (suspension bridges, steel or composite bridges). These group C products need a special anchoring and an appropriate corrosion protection system (Fig.8).

In fact cable systems using prestressing steels can not be designed according to EN 1993-1-11 because the design resistance for static loads as well as the design for fatigue loads is not really covered by EN 1993-1-11. Tests with the corresponding anchorages are necessary to determine the design tension resistance and the design fatigue resistance.

The fatigue strength curves for group C tension components given in EN 1993-1-11 section 9.2 can not be used for design because there is no information concerning the anchorage available.

Only the breaking strength F_{uk} of group C tension components can be determined according to EN 1993-1-11 section 6.2 as follows:

$$F_{uk} = A_m \cdot f_{uk} \tag{16}$$

Where A_m is the metallic cross section and f_{uk} the tensile strength of the tension component.

For the serviceability limit state section 3.2.2 of this paper applies accordingly.

Instead of EN 1993-1-11 the fib recommendation bulletin 30 (2005) Acceptance of stay cable systems using prestressing steels" should be used for the corrosion protection, static and fatigue tests and the determination of the design resistance. This recommendation covers tests for tension components with anchorages as well as tests for saddles.

The design concept of EN 1993-1-1, section 6.2 and section 9 can be used for the necessary verifications, provided the design resistances are determined according to the fib recommendation.

However, a European technical approval or European technical assessment is recommended as basis for design.

Figure 8. Anchorage of bundle of parallel strands.

5 CONCLUSIONS

The design rules according to EN 1993-1-11 for the three different types of tension components of the product groups A, B and C according to EN 1993-1-11 are presented. This paper shows that for all product groups a determination of the design resistance only by calculation is not usual or possible. This applies for instance to the determination of the design resistance of the end connectors and anchorages. The design of group C products, which are cable systems using prestressing steels and which are mainly used for bridges is not possible according to EN 1993-1-11. For these products and in the case where tests are necessary a European technical approval or European technical assessment is recommended as basis for the design.

Extraordinary possibilities using fabric to form concrete structures

J.J. Orr, T.J. Ibell, A.P. Darby & M. Evernden
BRE Centre for Innovative Construction Materials, University of Bath, Bath, England

ABSTRACT: Concrete, our most widely used construction material, is a fluid that offers the opportunity to economically create structures of almost any geometry. Yet this unique fluidity is seldom capitalised on, with concrete instead being cast into rigid prismatic moulds to create high material use structures with large carbon footprints. This paper will demonstrate how replacing conventional orthogonal moulds with a flexible system comprised primarily of high strength, low cost fabric sheets, can utilise the fluidity of concrete to create extraordinary possibilities for highly optimised, architecturally interesting, building forms.

1 INTRODUCTION

The language and technology of concrete construction has changed dramatically over the past two thousand years – from dome of the Pantheon, through its renaissance in the 1800s, and up to the work of Nervi and other modern masters of this fluid material. Throughout this, concrete has been cast almost exclusively into wooden or steel moulds to create prismatic elements. Nervi noted that:

> *'although reinforced concrete has been used for over a hundred years and with increasing interest during the last few decades few of its properties and potentialities have been fully exploited so far …the main cause of this is a trivial technicality: the need to prepare wooden forms' (Nervi, 1956)*

This triviality pervades the minds of Engineers even today, with increased cost being associated with concrete structures that deviate from the use of flat panels of timber or steel as formwork. Despite this, concrete remains one of the most widely used man made materials in the world, with global production of cement approaching 3.4×10^9t in 2011 (USGS, 2011).

Cement accounts for a large proportion of the world's raw material expenditure, reaching nearly 33% of the total in 2008 (Orr, 2012). Although concrete has a relatively low embodied energy (Hammond and Jones, 2011) its rate of consumption means that cement manufacture alone is estimated to account for some 5% of global CO_2 emissions (Orr, 2012).

Against a backdrop of carbon dioxide emissions reduction targets, a recognition of the impact construction has on the environment and an increasing client focus on sustainability, design philosophies centred around the need to put material where it is required are becoming increasingly desirable.

Recent research has shown that for concrete structures, large reductions in embodied carbon can be achieved simply by replacing conventional orthogonal moulds with lightweight, high strength, low cost sheets of fabric. This 'flexible formwork' not only provides environmental benefits, but also provides a new form of architecture for concrete structures.

The architectural delight of fabric formed concrete is an additional advantage to the material savings achieved through the structural optimisation processes that are made possible by the use of a flexible mould.

Research undertaken at the Building Research Establishment Centre for Innovative Construction Materials (BRE CICM) at the University of Bath has shown that by following simple optimization routines and casting concrete into a flexible mould, material

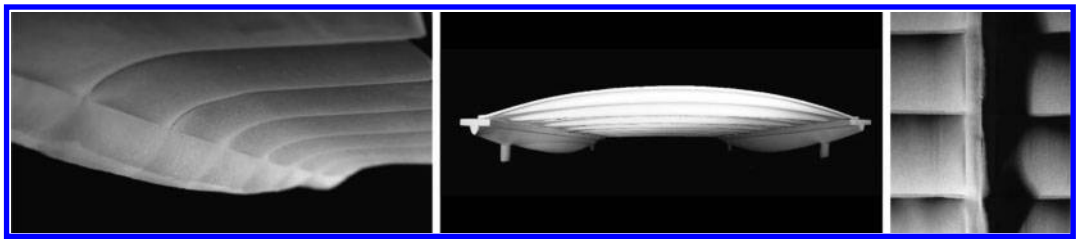

Figure 1. Possibilities with fabric formwork.

savings of up to 40% can be achieved in reinforced concrete beams (Orr, 2012, Orr et al., 2011, Orr et al., 2012c). This figure is supported by additional work showing similar reductions in material use when casting steel reinforced concrete beams.

In addition to significant material use reductions, research at the BRE CICM has demonstrated that fabric formwork can provide concrete with enhanced durability when compared to concrete cast against an impermeable surface. Significant reductions in carbonation depth and chloride ingress have been recorded (Orr et al., 2012a).

From this, it is apparent that the use of fabric formwork can provide:

- Material use reductions by replacing conventional orthogonal structures with non-prismatic, structurally efficient, alternatives;
- Enhanced durability by the provision of a permeable formwork system;
- New forms of concrete architecture.

Flexible formwork therefore has the potential to facilitate the change in design and construction philosophy that will be required for a move towards a less material intensive, more sustainable, construction industry.

2 HISTORY

The genesis of fabric formwork can perhaps be found in very early work with reinforced concrete structures, as shown in Gustav Lilienthal's patents for reinforced concrete flooring systems from the late 19th Century (Lilienthal, 1899). In the 1930s, fabric formwork became a popular method for underwater concrete construction, and remains so today.

It was, however, the introduction in the late 1960s of synthetic, high strength, fabrics that led to a second phase in fabric formwork. Initiated by architects such as Miguel Fisac, the new technique was used to create increasingly complex shapes (Fisac, 1969).

More recently, pioneering architectural research been undertaken by Professor Mark West (University of Manitoba), Professor Remo Pedreschi (Edinburgh University) and Kenzo Unno, amongst many others.

A primary research interest at the BRE CICM has been to marry the architectural achievements of fabric formwork with a desire to produce low-carbon concrete structures. This has been achieved by considering the design process afresh. In doing so, numerous challenges and exciting opportunities have been created, some of which are described in this paper.

Much of the latest research in this field was presented at the BRE CICM in June 2012, as described by Orr et al (2012c).

3 STRUCTURAL BEHAVIOUR

By replacing orthogonal concrete moulds with a system formed of flexible sheets of fabric it is possible

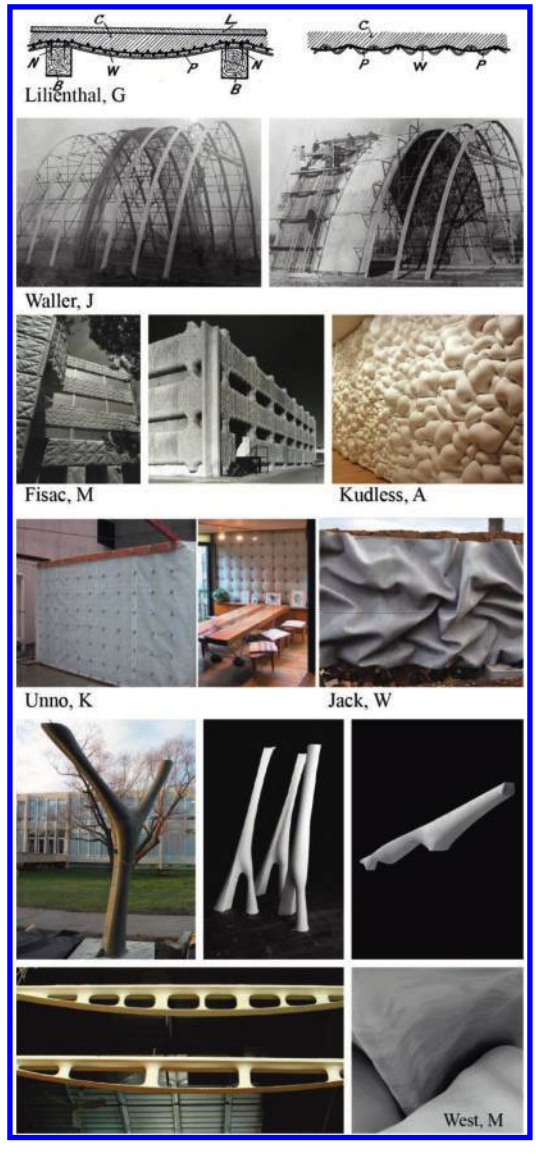

Figure 2. Fabric Formwork. Top to Bottom: Gustav Lilienthal, James Waller, Miguel Fisac, Andrew Kudless, Kenzo Unno, Walter Jack and Mark West. Figure after (Orr, 2012).

to construct optimised, variable cross section concrete elements that can provide material savings of up to 40% (Orr, 2012) when compared to an equivalent strength prismatic member.

The principle behind the design of beams using fabric formwork is illustrated in Figure 3. This process of optimization has been applied at the BRE CICM by the authors to over thirty beam specimens of varying spans and loading conditions (Garbett, 2008, Bailiss, 2006, Orr, 2012).

In essence, the optimisation process ensures that at each section along the length of the beam, the resistance of the beam (in flexure, shear, torsion and so on, R_d) matches the requirements of the design envelope

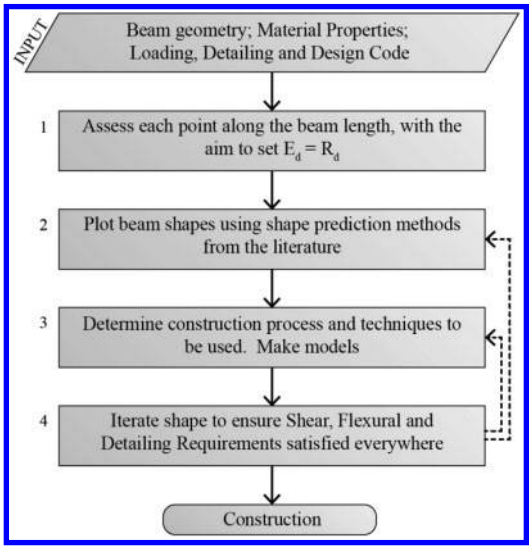

Figure 3. A design process for fabric formed beams.

(E_d). This simple principle of setting $R_d = E_d$ can create complex shapes – which can then be constructed using the flexible fabric mould.

Although much structural testing has focused on beams, this optimisation process (and fabric formwork) can be used for many other structural forms (as seen in work presented in Orr et al (2012c)).

3.1 *Flexure*

The flexural design of reinforced concrete relies primarily on the assumption that plane sections before bending remain plane after bending. This assumption forms the basis of most design codes and has been verified through extensive testing to provide a straightforward design method that gives generally unambiguous results (Bentz et al., 2006).

As optimized structures are usually not prismatic the applicability of this approach is not immediately apparent. However, work by Maki and Kuenzi (1965) and later by Davies et al (1973), as well as work by the authors showing accurate predictions of the fleuxural strength of non-prismatic beams (Orr, 2012), suggests that it is an acceptable approach for elements with moderate tapers.

The design process logically leads to elements with inclined reinforcement, and in much of the literature the theoretical contribution of this inclined bar is used in the calculation of shear capacity. However, the effective utilization of such an inclined bar has not been shown experimentally (Orr et al., 2012b).

3.2 *Shear*

There are a number of contributing factors by which a reinforced concrete beam can carry shear, as described in Figure 4. The relative importance of each

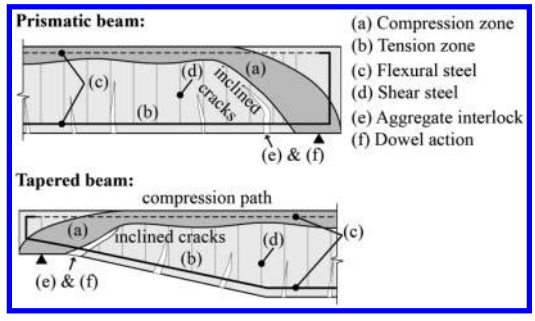

Figure 4. Contributing factors to shear resistance in tapered and prismatic section.

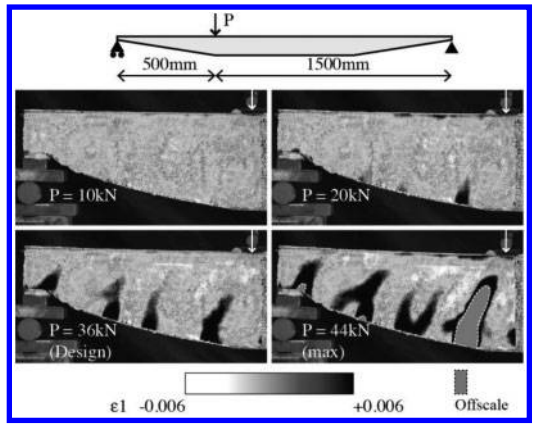

Figure 5. Digital image correlation monitoring the shear behaviour of non-prismatic beams in shear.

factor for prismatic sections is discussed in more detail elsewhere (Kotsovos, 2007, Jelic, 2002).

In the steel reinforced section, cracks form when the principal tensile stress in the concrete exceeds its tensile capacity, and inclined cracks typically propagate from the tension face of the member towards the neutral axis as the applied loads are increased. In sections that taper towards their supports, it is imaginable that the interaction of these diagonal cracks with the path of the compression force that reaches the supports is perhaps more critical.

Premature failures in shear were recorded in some early optimized beam tests, primarily designed using the empirical provisions of BS 8110 (1997).

A test program undertaken by the authors, described by Orr et al (2012b) has begun to address the provision of a design method for tapered beams that does not result in non-conservative capacity predictions and can be used in practice. Using digital image correlation to monitor concrete strains in 21 tapered beams during loading (Figure 5), a better understanding of the behavior of such sections is being developed. This research has shown good results when either a modified Compressive Force Path method, or a strut and tie model, is used.

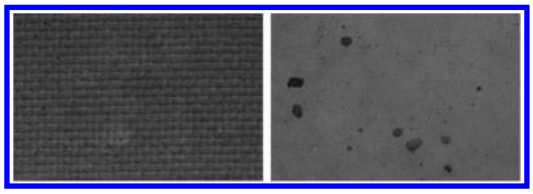

Figure 6. Comparison of concrete cast in a fabric (left) and timber (right) mould.

3.3 *Shape predictions*

Accurate shape predictions for fabric cast concrete elements (beams, column, shells and so on) are essential. Scale models (using plaster) have been successful, and new techniques have simply replaced physical models with virtual ones. Methods used include simple spreadsheets which predict the hydrostatic shape of the fluid filled fabric (mathematically explained by Iosilevski (2010)) to more complex computer programs that can automate the entire process (Veenendaal, 2008).

4 DURABILITY

By allowing water and air to be expelled from a concrete element as it cures, permeable formwork systems such as fabric formwork provide concrete with improved durability due to its denser microstructure and reduced water:cement ratio in the cover zone (Mccarthy et al., 2001). Changes in the surface appearance of such concrete can be seen in Figure 6.

Commercially available permeable formwork systems require the fixing of both permeable and draining layers to the inside of conventional structural formwork. The use of a single flexible fabric formwork system for the creation of optimised, durable structures therefore offers real advantages for designers and contractors.

In addition to tests considering structural behaviour, work at the BRE CICM has made use of accelerated testing methods to determine the effect of the permeable mould on durability.

To date, carbonation, chloride ingress, surface hardness and sorptivity tests have been undertaken, comparing permeably- and impermeably-cast concrete samples. In addition, scanning electron microscopy has been used to compare the cement contents at the surface of the cast samples.

Carbonation testing, undertaken using NordTest NT 357 (1989), exposed concrete cubes cast against fabric and steel surface to carbonation in a chamber of 4% CO_2 for up to 180 days (representing 25 years in service). Chloride ingress testing was undertaken in a similar manner, using a sodium chloride solution with a chloride concentration 5.3 times that of Atlantic seawater. Full details of the tests and their results are provided by Orr et al (2012a). A summary of the improvements seen in this work is presented in Table 1.

Table 1. Summary of durability testing (after (Orr, 2012)) representing tests undertaken on 300 concrete samples.

Test undertaken	Recorded improvement using fabric formwork
Carbonation	**50%**
(Coefficient of Carbonation – (Nordtest, 1989))	
Chloride ingress	**42%**
(Chloride Penetration Parameter, K_{cr} – (Nordtest, 1995))	
Surface hardness	up to **13%**
(Rebound Hammer – (BS EN 12504-2 (2001))	

4.1 *Discussion*

Based on experimental and analytical work undertaken at the BRE CICM it is premised that by casting concrete into a fabric mould three effects which serve to improve the durability of the fabric cast concrete occur as air and water are expelled from the mould:

- Finer material collects in the surface zone as water is expelled from the cast surface, resulting in a more tortuous surface (see Hall and Hoff (2002)) with fewer interconnected pores;
- A greater concentration of cement particles (or a reduction in the *water:cement* ratio) at the surface may result in smaller pores to both constrict the flow of gases through the structure of the concrete and provide sites for the formation of Friedel's salt;
- The macroscale surface texture provided to the concrete gives the fabric cast face a greater specific surface area when compared to the timber or steel cast face.

The Carmen-Kozeny equation has been used to begin to describe the relationships between porosity, permeability and specific surface area for fabric cast concrete, but further testing is required to confirm the precise effect of fabric formwork on the internal structure of concrete.

Faced with environmental effects, fabric cast concrete shows a number of advantages. A harder surface, as measured using a rebound hammer, suggests locally increased cement content. An increased cement content at the surface is also suggested in data from Scanning Electron Microscopy (Energy-dispersive X-ray spectrography) undertaken on small concrete samples (Orr, 2012).

A greater concentration of cement particles at the surface could have the combined effect of constricting the flow of gases through the structure of the concrete (hence providing the resistance to carbonation seen above), while also providing ample sites for the formation of Friedel's salt (which slows the ingress of chlorides). In addition a reduction in the volume of large pores at the surface (as suggested by sorptivity tests) provides a less permeable surface for both carbonation and chloride ingress. These processes thus further retard the corrosion process. Increased chloride binding by this higher cement content also prevents

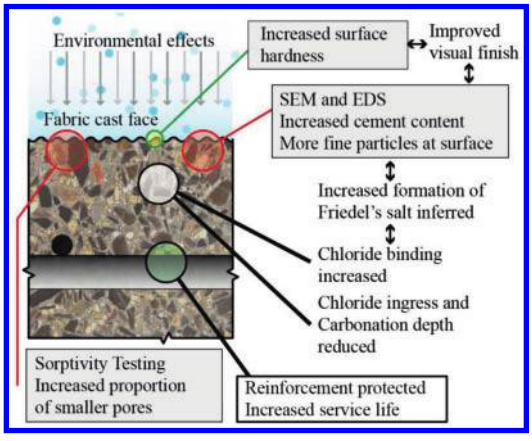

Figure 7. Web of durability advantages found through the use of fabric formwork as a permeable concrete mould.

depassivation of the steel, which is thus better protected. This web of potential advantages for fabric formed concrete is illustrated in Figure 7.

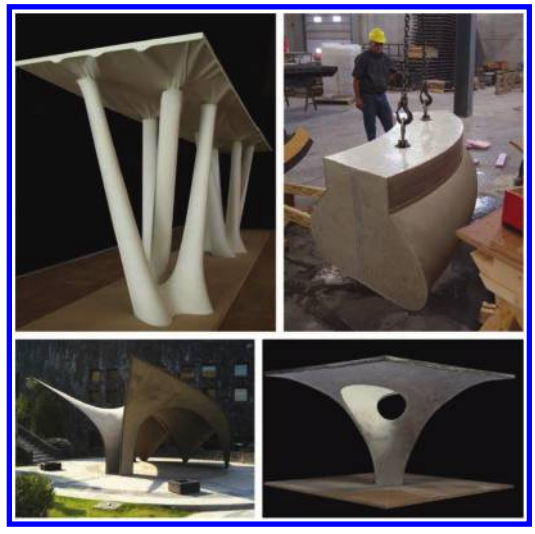

Figure 8. A sample of recent fabric formwork projects (images courtesy, clockwise from top left: (West and Araya, 2012, Araya and West, 2012, Belton, 2012, Bhooshan and El Sayed, 2012).

5 ARCHITECTURAL POSSIBILITIES

In addition to the important structural and durability-based advantages of fabric formwork, further possibilities are found in architecture.

In teaching, fabric formwork has been successfully used at multiple Universities as a means to consider not only how Engineers and Architects undertake efficient design, but also to 're-think' how concrete itself should be used as a structural material.

In practice, the use of fabric formwork in 'real' projects is, at present, quite limited. Examples, shown in Figure 8 include a Women's hospital in Winnipeg, Canada, (by Professor Mark West and Mr Ronnie Araya) shell structures, flat slabs, and columns. All of these elements have been designed and constructed using a flexible fabric mould.

6 CONCLUSIONS

This paper has summarised some of the recent research undertaken at the University of Bath. Not only is it demonstrated that fabric formwork can be used to create optimised, low carbon concrete structures, but it is also shown that the use of fabric formwork facilitates significant improvements in surface durability.

In addition, where the concrete surface is required to provide a visual finish, conventional approaches such as increases in cement content may be avoided through the use of fabric formwork. Instead, the use of a flexible formwork provides both durability and visual benefits.

The majority of testing described here has made use of just one fabric, and further work is currently underway to determine the relative advantages of other available materials in the hope of finding the optimum material that can combine flexibility, a low creep modulus, high strength and a small pore size with low cost.

By designing optimised concrete structures, significant savings in material use can be achieved, with concomitant reductions in both embodied carbon and construction cost. Fabric formwork not only provides a simple means by which such structures can be cast, but by allowing excess pore water to bleed from the surface of the concrete the resulting element is both durable and beautiful. Fabric formwork thus offers exciting opportunities for engineers and architects in the move towards a more sustainable construction industry.

7 FUTURE WORK

This paper has outlined just some of the work undertaken in the field of flexible formwork. Challenges remain – including the issue of shear behavior in elements with complex shapes, the provision of a full analysis and shape prediction computer model that can be used in industry, and solving some remaining construction difficulties.

Areas of future work for fabric formwork include the application of prestressing to the optimization process, the design and practical construction of flat slabs, permanent formwork systems and precast elements for entire building structures. In addition, the use of low-carbon concretes as an alternative to ordinary Portland cement concretes is an area that could lead to even greater savings in the embodied carbon of fabric formed concrete structures.

The Porsche Pavilion in the Autostadt Wolfsburg, Germany

H. Pasternak & T. Krausche
IPP Braunschweig/Cottbus and University of Technology, Chair of Steel and Timber Structures, Cottbus, Germany

ABSTRACT: The Porsche Pavilion is an innovative stainless steel construction using the principle, often used in ship and car design, as an advantage for building a light but stiff structure. The Pavilion is a one of a kind and outstanding construction that you can find. It fits right in the existing parts of the Autostadt within the lagoon landscape and was built in only eight months. With its curving lines and exiting bends the structure is an extraordinary work which was designed by Henn architects, Munich. The monocoque has a good balance between material and support structure. The stiffness is achieved by the upper and lower side sheathing plates and the intermediate formers. Also the roof shell has no joints and a smooth surface. The assembling of the structure requires a large time and effort cost due to many welds which are necessary to connect all section to one large shell.

1 INTRODUCTION

The Autostadt near the Volkswagen factory in Wolfsburg, Germany, was established in June 2000 by the Volkswagen Group. The Autostadt is the interface between customer and company [1]. On 28 hectares of hills and lakes, visitors are invited to a journey into the world of mobility. The pavilions of Volkswagen, Audi, SEAT, Škoda, Lamborghini are situated in the park. Each of the pavilions expresses its own brand philosophy via its architecture.In June 2012 the new Porsche pavilion with the dimensions of approximately $50 \times 35 \times 10$ [m] [length × width × height] opened. The construction time was 8 months for approximately 1400 m^2 floor area. In a unique combination of functionality and design, visitors can experience the philosophy and values of the traditional sports car brand [1].

2 ARCHITECTURAL CONCEPT

The unique shape of the roof (Fig. 1) creates a new focal point in the park and lagoon landscape which is a protected space. In line with the Porsche tradition of lightweight construction, the spatial envelope based on a monocoque design forms the self-supporting structural system. A stainless steel surface, combined with dynamically elegant lines, clearly alludes to Porsche automobile styling [1].

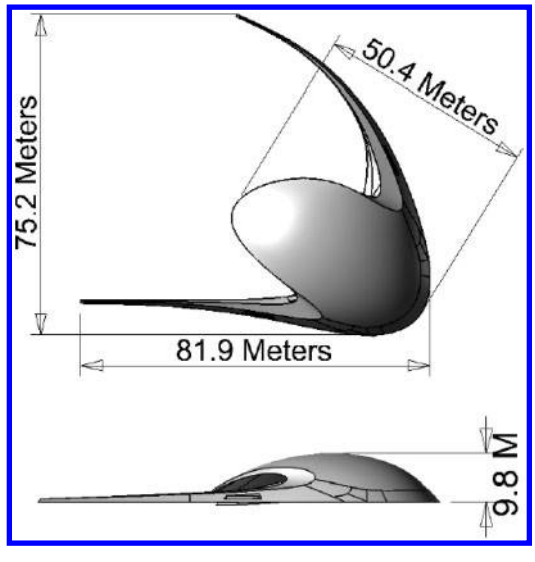

Figure 1. Upper view and elevation, dimensions[3].

3 BUILDING DESIGN

3.1 *Foundation and concrete construction*

This building part is built out of reinforced concrete C 35/45 except for the inner wall axis 1 (C45/55). Due to the soil conditions in the Autostadt, the foundation is constructed on a 50 cm thick surface. The roof parts consist of the polygon shell and the roof shell (monocoque) supported on a concrete construction. Both roofs will be supported by the wall (axle 1) and the lisenes (axle 2–9) (Fig. 2). While the monocoque is fitted on top with prestressed steel connected to the concrete, the supports for the polygon shell are on the side with shear lugs out of rolled profiles.

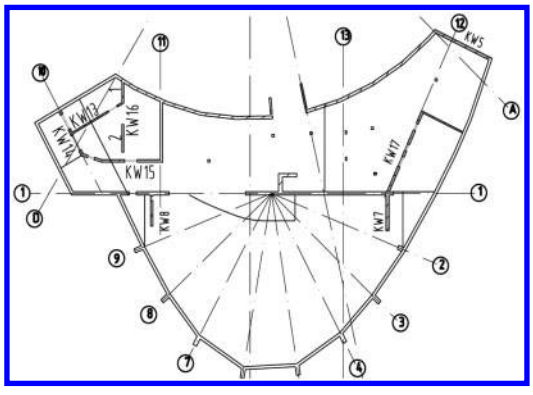

Figure 2. Ground plan concrete construction [2].

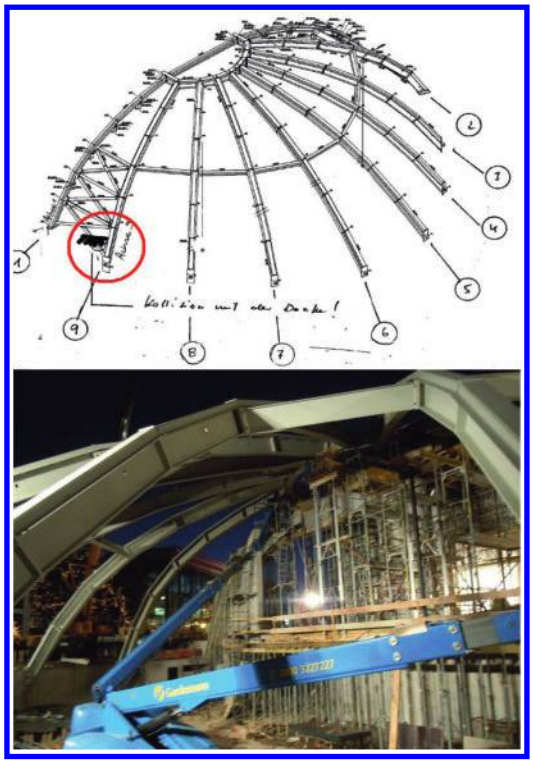

Figure 3. Top – Polygon shell 3-D drawing [2], bottom – Polygon shell during construction.

3.2 *Polygon shell*

The supporting structure is formed by 10 radially arranged steel arches out of steel S355 (HEA 700) with a rise of about 1.70 m – 1.80 m. The floor plan related spans (end support wall – bearing wreath) are from 12,09 m to 17,50 m (Fig. 3). On top of the longitudinal axes of the steel beams there are trapezoidal steel sheets. Normal to the loading direction, the sheet metal is relatively soft and can take as little curvatures perpendicular to the beads. The trapezoidal sheets are

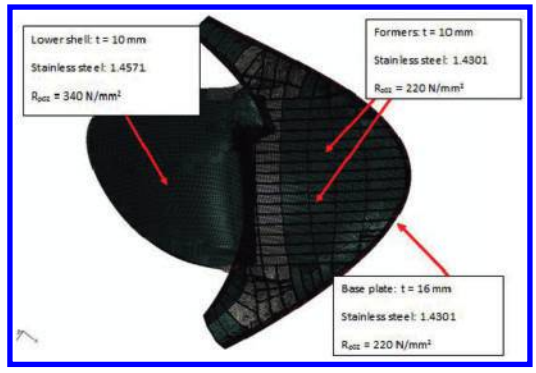

Figure 4. Upper shell, plate thickness and material.

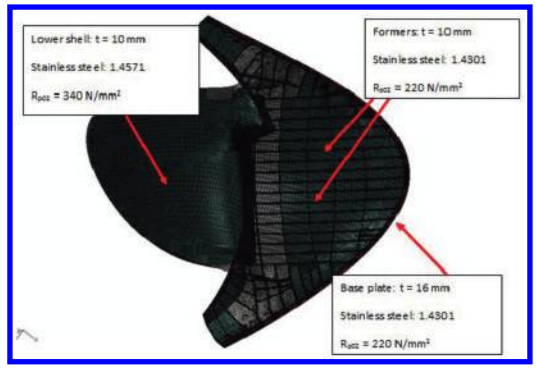

Figure 5. Lower shell, plate thickness and material.

hung on the top flange, and thus act generally as a single span. To reduce the bending of the arches there are square to axis of the free cross section in arc centre cross members (IPE 500) placed. For the presentation of the vehicles inside there are several loads such as large beamers and loudspeakers provided. Considering that on top of the polygon shell is the monocoque, there is according to the verifier [4] wind forces are expected of $\pm 0.15\,\mathrm{kN/m^2}$ because of the ventilated shells.

3.3 *Roof shell – Monocoque*

The monocoque is a construction principle you find nowadays in the machine building industry. Usually the factoring is used with cars, airplanes or ships. This type of structure has a space forming shell which will carry the loads instead of the traditional beam construction. Apparently with this type of design the whole roof is very light compared to its stiffness. The stiffness is achieved by the upper and lower side sheathing plates and the intermediate formers as you can find in a ship. The higher design expenses and manufacturing cost are the reason why this type of structure is not used more often. The whole monocoque is built out of stainless steel. While the inner parts such as the formers is stainless steel WNR 1.4301 with a yield strength of $f_{yk} = 220\,\mathrm{N/mm^2}$ the cover

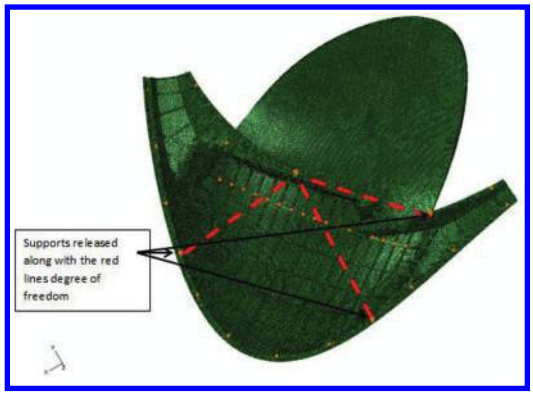

Figure 6. Boundary conditions for the resolution of the concentration of stress.

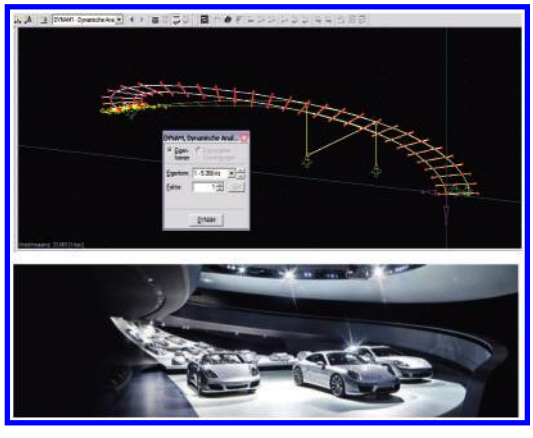

Figure 7. Top: Model of the ramp, bottom: Showroom with ramp in the background [1].

panels are WNR 1.4571 $f_{yk} = 340\,N/mm^2$. Fig. 4 and Fig. 5 show the different usage of the material and plate thickness. Basically, the monocoque is built out of 10 mm thick plates. Only in more highly stressed parts, such as the middle of the upper shell due to the cantilever arm, plates of 12 mm thickness are used. The base plate is made out of 16 mm plates. The plate thickness at the supports is 50 mm.

Due to the seamless and thereby highly statically indeterminate monocoque, it was required to reduce stress out of forced stress, such as temperature load, if possible to support the structure without constraints. In Fig. 6 the yellow dots show the supports with elastomeric bearings. All bearings are free to move except for the bearings at the red dashed line. The middle point was used as a fixed point with no horizontal movement. The other bearings along the red dashed line are movable along the line. Each bearing has a specific solution as a mounting part consisting of a base plate, tension rod and elastomeric bearing.

For verification of the calculation of the structure the FEM program ABAQUS® was used. Moreover plate buckling was analyzed according to [5]. A special significance during design was the load case wind.

Figure 8. Assembly of stainless steel sheets in the factory.

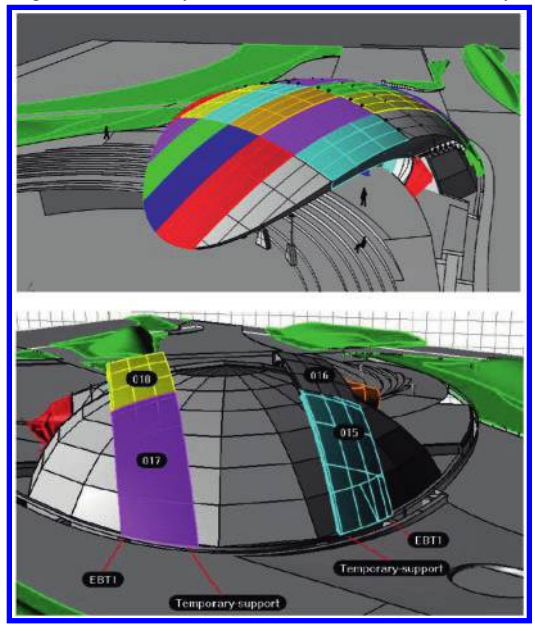

Figure 9. Top – Sections and building stages, bottom -Stage two [3].

To form the wind realistically on the model the wind was implemented based on the wind report [4]. Hereby there were 12 different wind directions (0°, 30°, …, 330°) examined.

Figure 10. Stage three – cantilever arm with temporary support.

3.4 *Ramp*

In the staging area, a ramp made of steel S355 was built as a link between the basement and ground floor (Fig. 7). The unwound ramp length is about 25 m and is designed as a double-curved pipe with 2 rolled sections as the main support members. The construction is divided into eight elements, which are connected via torsion partition plates. In the region of the third and fourth element, the ramp is supported. As supports, rolling steel beams are constructed out of S235. The ramp is designed for an audience.

4 CONSTRUCTION AND ASSEMBLY

The monocouque structure is built out of 56 prefabricated sections. All stainless steel sheets were cold formed and welded together (Fig. 8) in the factory at the plant of "Ostseestaal GmbH" in Stralsund and were transported to the site in Wolfsburg. To ensure a trouble-free mounting of the parts, measurements were taken.

On site, there were three stages of construction. Firstly, the vertical sections were placed. After the vertical parts the sections were placed above the Polygon shell (Fig. 9). The third stage was the cantilever arm (Fig. 10). Every section was elevated by a crane of 400 tons on hoisting eyes and brought into position. All sections were welded together on site. Before the structure could support its own weight, it was temporarily supported. As the last step, the deflection of the key points in the structure, such as the end of the cantilever arm, were checked in comparison with the calculation. The differences were within a construction practice range and were considered safe.

Figure 11. Final view [1].

5 CONCLUSIONS

The Porsche pavilion is a unique building consisting of a monocoque roof and a substructure (Fig. 11).

This type of roof is light compared to its stiffness. On the other hand you have higher design expenses and manufacturing costs. The innovative design was a challenge for all participants of the projects.

Computational model for simulation of rigid foldable origami structures

J.D. van der Woerd, R. Chudoba & J. Hegger
Institute of Structural Concrete, RWTH Aachen University, Germany

ABSTRACT: The paper presents a flexible and efficient modeling approach of the folding of crease patterns. The development of the model has been motivated by the need to provide support for targeted design and efficient manufacturing of shell structures exploiting the origami technique. This type of structures is becoming increasingly popular in many engineering disciplines and has been referred to as origamics.

In the present work the folding technique is used to produce spatial structures from continuously reinforced thin-walled cementitious composite plates without the need to construct curved spatial formworks. In order to support the targeted design and manufacturing of folded concrete (oricrete) structures a numerical model has been formulated and implemented. By defining different types of constraints the model can be used for several purposes. In this paper we exemplify the application of the model for the simulation of the folding and the manufacturing processes.

1 INTRODUCTION

The folding technique inspired by the traditional japanese art of origami has been used for ages to produce diverse shapes and forms of a sheet of paper. The correspondence between the crease pattern and the final shape of the product has attracted mathematicians and engineers since decades and is still a subject of ongoing research (Hull 2002, Lang 2009, Wang-Iverson 2011). Applications of the origami concepts in engineering disciplines have been realized in architecture (Sorguc et al. 2009), medicine (Kuribayashi et al. 2006) and mechanical engineering (Onal et al.).

Rigid origami, a subdomain of origami, is especially interesting for technical applications e.g. deployable mechanisms (Künstler & Trautz 2011). In rigid origami only rotations along the creases are allowed (Tachi 2010). The individual facets remain rigid and are not imposed to any deformation at any stage of the folding process. Examples for rigid foldable crease patterns are shown in an unfolded state in Fig. 1 and in folded state in Fig. 2.

By modifying the crease pattern or solely adjusting its parameters different geometrical forms can be achieved. The dependency of crease pattern and final form is only for a few cases obvious so that the design and production process of rigid foldable origami structurs calls for a computer-aided support for the simulation of the folding process. The load bearing behaviour of the final spatial structure is also impacted by the layout of the crease pattern (Trautz & Ayoubi 2011). The zero-extension condition has been used in Schenk and Guest (2011) to study the stiffness properties of the folded sheets.

Examples of models for rigid origami simulation have been reported recently by Tachi (2009). In Chudoba et al. (2013) a modeling framework for rigid origami has been proposed, formulated as an optimization problem with several types of optimality criteria and equality constraints. In the present work

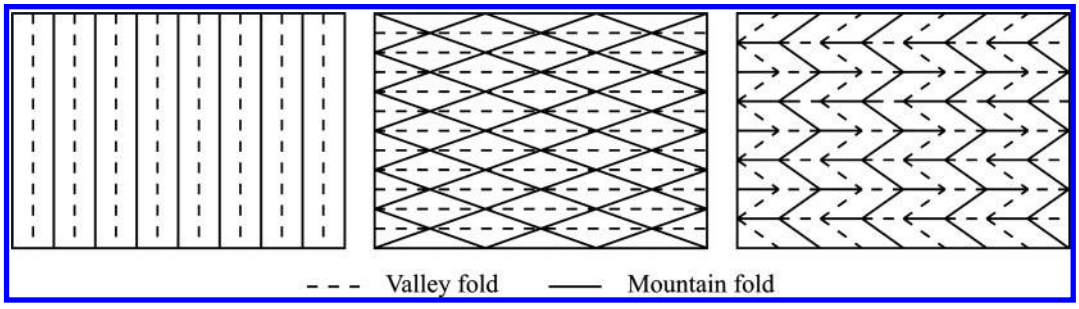

Figure 1. Rigid foldable crease patterns before folding: a) parallel folding b) Yoshimura-Pattern c) Miura-Ori-Pattern.

Figure 2. Rigid foldable crease patterns after folding: a) parallel folding b) Yoshimura-Pattern c) Miura-Ori-Pattern.

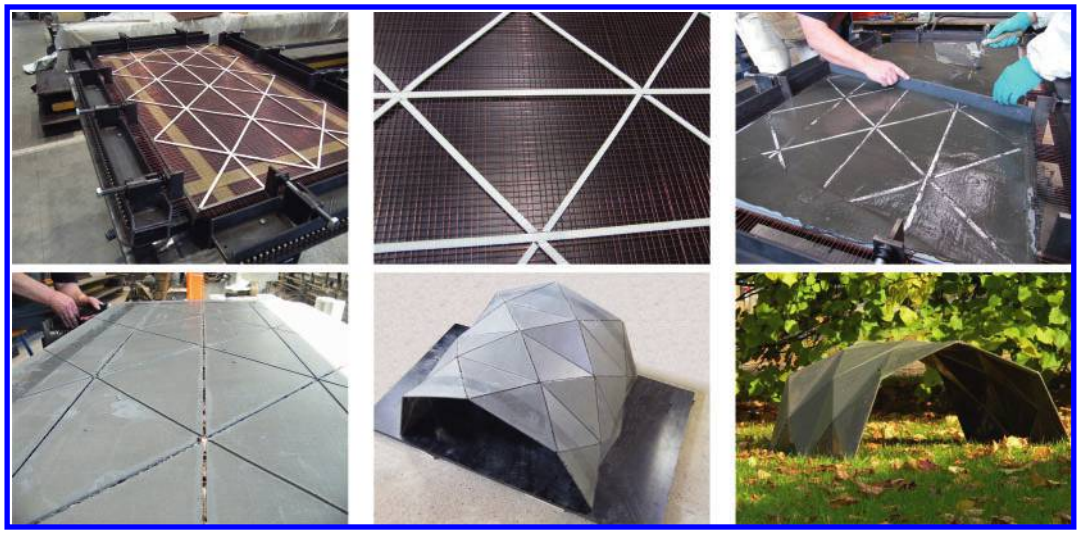

Figure 3. Production of a prototype with crease pattern introduced using linear spacers (top row), manual folding of the concreted plate and its fixation in the target shape with grout (bottom row).

we focus on the equality constraint derived from the kinematics of a rigid foldable crease pattern. The application for simulation of the folding process and for the development of folding devices is shown.

The paper is organized as follows: In Sec. 2 the oricrete method is introduced as an application of folding principle in structural concrete. The method is exemplified with the description of a realized prototype. In Sec. 3 the mathematical model is derived and its implementation is presented. Afterwards in Sec. 4 examples are shown applying the model for simulation of folding and the design of a lifting device for manufacturing.

2 FOLDING TECHNIQUE APPLIED TO CONCRETE PLATES

A crease pattern is introduced into the concrete plate using linear spacers. The continuity of the plate is provided by the textile reinforcement bridging the crease lines. After folding and reaching the desired shape the crease lines are filled with grout and the structure is fixed. By using this method spatial structures can be produced without the need to construct spatial formwork.

As a reinforcement flexible, continuous high-performance materials such as carbon and AR-glass textile fabrics are used. Textile reinforced concrete exhibits high strength and ductile behavior (Konrad & Chudoba 2009, Hegger & Voss 2008). Due to the non-corrosiveness of the textile reinforcement, no extra cover is required for its protection. Consequently, its properties can be highly exploited in thin-walled spatial and shell structures (Scholzen et al. 2012, Ehlig et al. 2012). This fact opens up the the space for the shape optimization of light-weight shell structures (Ramm & Mehlhorn 1991).

In order to demonstrate the manufacturing concept and to test its feasibility a prototype of a folded cementious shell has been produced using the Yoshimura crease pattern. Fig. 3 shows the production steps starting from the formwork with installed linear spacers and the reinforcement grid. The plate had the thickness of 6 mm and dimensions 120 × 80 cm. In spite of the simplicity and manual and improviced production, the example has shown the potential of the folding in combination with the continuous flexible reinforcement.

However, the production of the prototype has clearly emphasized the need for new concepts and

infrastructure both in the design and in the manufacturing of elements folded from a crease pattern. In order to achieve an acceptable quality and precision, concepts for the folding equipment need to be developed and exact information on the position of individual control nodes during the folding process is required. For supporting this task the use of a mathematical model is a must.

3 MATHEMATICAL MODEL

3.1 *Basic considerations*

In the following formulation of the mathematical model only crease patterns with triangular facets have been considered. Even for the simple triangular form of the facets, the design space for folded structures is large. By adding additional constraints assuring planarity of the facets, the model can be used for quadrilateral and polygonal facets.

In the folding of rigid facets the thickness of the facets has to be considered (Tachi 2011). Since the size of the oricrete plates is small and the textile reinforcement has certain flexibility, we can neglect the thickness in the model.

Regarding the crease pattern as a pin-jointed framework of the crease lines, the folding process can be modeled using kinematic equations preserving constant length of the crease lines at any stage of folding.

The model is presented in the following steps: In Sec. 3.2 the mathematical representation of the crease pattern is defined. The constant length constraint is introduced in Sec. 3.3 and additional kinematic constraints for controlling the folding process in Sec. 3.4 are added. In Sec. 3.5 the Newton-Raphson method is used for solving the system of quadratic equations and the implementation of the model is shown in Sec. 3.6

3.2 *Representation of the crease pattern*

Let us introduce a crease pattern as an enumerated set of nodes

$$\mathcal{N} \coloneqq \{i,\ i = 1 \dots N\} \tag{1}$$

and the crease lines as an enumerated set of node pairs connected by crease lines

$$\mathcal{L} \coloneqq \{l \to (i,j)\,,\ l = 1 \dots L, \wedge\, i,j \in \mathcal{N}\}\,. \tag{2}$$

In the initial configuration the position of a crease pattern node i is prescribed by a vector

$$\boldsymbol{x}_i^0 = \left\{ \begin{array}{ccc} x_i^0 & y_i^0 & 0 \end{array} \right\}^T. \tag{3}$$

with the z_i coordinate set to zero.

The vector along a crease line between two nodes i and j in the initial configuration is defined as

$$\mathbf{v}_l^0 = \boldsymbol{x}_j^0 - \boldsymbol{x}_i^0. \tag{4}$$

The displacement of a node i in an intermediate configuration t is denoted as

$$\boldsymbol{u_i}(t) = \left\{ \begin{array}{ccc} u_x & u_y & u_z \end{array} \right\}^T, \tag{5}$$

so that the current position of the node at time t can be written as

$$\boldsymbol{x}_i(t) = \boldsymbol{x}_i^0 + \boldsymbol{u}_i(t). \tag{6}$$

The corresponding vector between the nodes (i,j) at an intermediate state of folding t is expressed as

$$\mathbf{v}_l(t) = \boldsymbol{r}_j(t) - \boldsymbol{r}_i(t),\ (i,j) \in \mathcal{V}. \tag{7}$$

The unknown displacements are assembled in the global vector

$$\boldsymbol{U} = \{\boldsymbol{u}_1, \boldsymbol{u}_2 \dots \boldsymbol{u}_N\}^T. \tag{8}$$

3.3 *Constant length constraint*

By introducing the constant length constraint of a crease line a geometrically non-linear model reflecting the kinematics as a system of quadratic equations is obtained. In the initial configuration the length of a crease line l in an intermediate configuration t is evaluated as the norm of the crease line vector introduced in (Eq. 4)

$$\ell_l^0 \coloneqq \left\|\mathbf{v}_l^0\right\|. \tag{9}$$

Correspondingly, the length of a crease line l in an intermediate configuration t is expressed using the norm of the instantaneous vector (Eq. 7) as

$$\begin{aligned} \ell_l(t) &\coloneqq \|\mathbf{v}_l(t)\| \\ &= \|\boldsymbol{r}_j(t) - \boldsymbol{r}_i(t)\| \\ &= \left\|\boldsymbol{r}_j^0 + \boldsymbol{u}_j(t) - \boldsymbol{r}_i^0 - \boldsymbol{u}_i(t)\right\| \\ &= \left\|\mathbf{v}_l^0 + \boldsymbol{u}_j(t) - \boldsymbol{u}_i(t)\right\|. \end{aligned} \tag{10}$$

The length of all crease lines must remain constant during the folding process so that we require that:

$$\ell_l^0 = \ell_l(t). \tag{11}$$

In particular, the initial length (Eq. 9)

$$\ell_l^0 = \sqrt{\mathbf{v}_l^{0T}\mathbf{v}_l^0} \tag{12}$$

is set equal to the instantaneous length (Eq. 10), with t parameter omitted:

$$\ell_l = \sqrt{\begin{array}{c}\mathbf{v}_l^{0T}\mathbf{v}_l^0 + 2\mathbf{v}_l^{0T}\boldsymbol{u}_j - 2\mathbf{v}_l^{0T}\boldsymbol{u}_i + \\ +\boldsymbol{u}_j^T\boldsymbol{u}_j - 2\boldsymbol{u}_j^T\boldsymbol{u}_i + \boldsymbol{u}_i^T\boldsymbol{u}_i\end{array}}. \tag{13}$$

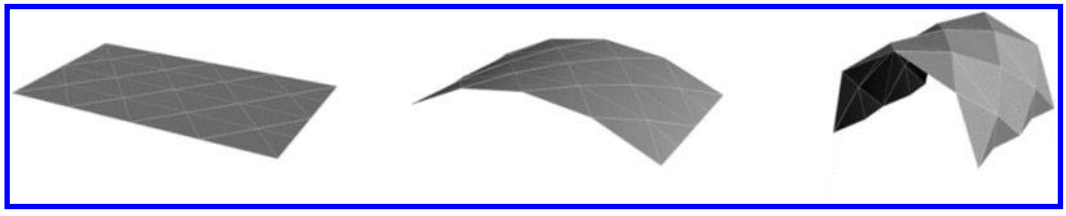

Figure 4. Simulation of folding process of the prototype by applying the model.

The constant-length constraint (Eq. 11) for a single crease line l is then obtained as

$$G_l^{(\ell)} = 2\mathbf{v}_l^{0T}\boldsymbol{u}_j - 2\mathbf{v}_l^{0T}\boldsymbol{u}_i \tag{14}$$

$$+\,\boldsymbol{u}_j^T\boldsymbol{u}_j - 2\boldsymbol{u}_j^T\boldsymbol{u}_i + \boldsymbol{u}_i^T\boldsymbol{u}_i = 0. \tag{15}$$

By applying the length-constraint to all crease lines and boundary edges of the crease pattern a system of L quadratic equations with unknown $3N$ nodal displacements assembled in the vector $\boldsymbol{U}$ is obtained in the form:

$$\boldsymbol{G}^{(\ell)}(\boldsymbol{U}) = 0 \tag{16}$$

3.4 *Kinematic constraints*

Since the constant length constraint is not sufficient for obtaining a solvable system of equations, we need $K = 3N - L$ additional constraints. Several types of kinematic constraints can be added to the model in order to provide more control over the folding and the geometrical details in the target configuration of the folded elements. They are particularly useful for the explicit specification of the boundary shapes and for the simulation of the manufactoring process. The kinematic link constraints are assembled into the vector $\boldsymbol{G}^u(\boldsymbol{U}, t)$.

3.5 *Solving by Newton Raphson technique*

In case that the total number of constraints $L + K$ is equal to the number of degrees of freedom $3N$ the model is fully constrained and can be effectively solved using standard Newton-Raphson iteration scheme. The length constraints and the kinematic constraints constitute a complete system of nonlinear equations

$$\boldsymbol{G}(\boldsymbol{U}, t) = \left\{ \begin{array}{c} \boldsymbol{G}^{(\ell)}(\boldsymbol{U}) \\ \boldsymbol{G}^{(u)}(\boldsymbol{U}, t) \end{array} \right\} = 0. \tag{17}$$

The linearized form of the system is obtained using the Taylor expansion around an admissible configuration at the instance of time

$$\boldsymbol{G}(\boldsymbol{U}) = \boldsymbol{G}(\boldsymbol{U}_t) + \left.\frac{\partial \boldsymbol{G}}{\partial \boldsymbol{U}}\right|_t \Delta\boldsymbol{U} + O^n(\boldsymbol{U}) = \boldsymbol{0}. \tag{18}$$

Neglecting higher-order terms an iterative scheme can be constructed in the form:

$$\begin{aligned} \left.\frac{\partial \boldsymbol{G}(\boldsymbol{U})}{\partial \boldsymbol{U}}\right|_k \Delta\boldsymbol{U}_{k+1} &= -\boldsymbol{G}(\boldsymbol{U}_k) \\ \boldsymbol{U}_{k+1} &= \boldsymbol{U}_k + \Delta\boldsymbol{U}_{k+1}. \end{aligned} \tag{19}$$

3.6 *Implementation*

The model has been implemented within a modeling framework using the high-level, scripting language Python together with the environment for scientific computing bundled in the Enthought Tool suite (Enthought 2013) provided as open source code. The model is accessible on the open-source management platform github.com (oricrete 2013).

In Fig. 4 the model is used to simulate the folding of the prototype shown in Sec. 2.

4 APPLICATION OF THE MODEL

For supporting the design process of the oricrete method from Sec. 2 the mathematical model is used for two tasks within this section:

- Simulate the folding of a given crease pattern,
- Simulate the manufacturing of the folded structure using explicitly imposed kinematic conditions including the lifting device for folding and identify its control parameters.

Different kinematic constraints have to be defined and implemented to use the model for these purposes.

4.1 *Folding simulation*

The simplest type of direct kinematic control of crease pattern nodes can be introduced using constraint equation linking several degrees of freedom in the form:

$$G^{(u)} := a_1 u_1 + a_2 u_2 + \ldots a_K u_K - \bar{u}(t) = 0 \tag{20}$$

where a_i are the coefficients and $\bar{u}(t)$ is the prescribed displacement. As an example of a direct kinematic control of crease pattern nodes consider

$$G_1^{(u)} := u_1 = 0, \quad G_{23}^{(u)} := u_2 - u_3 = 0 \tag{21}$$

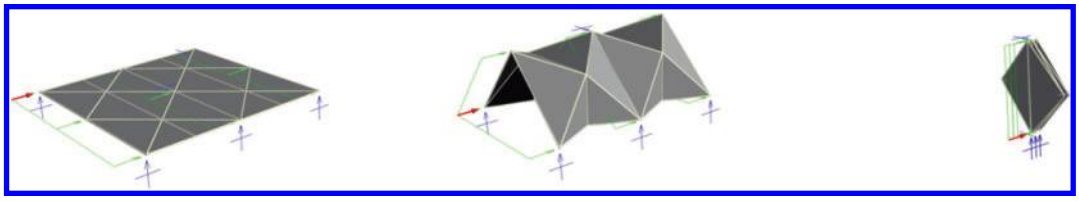

Figure 5. Direct kinematic control of crease pattern nodes: Oricrete simulation of Yoshimura crease pattern from unfolded to flat folded configuration.

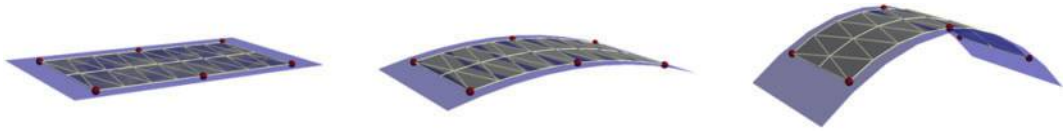

Figure 6. Kinematic control of crease pattern nodes due to deformation of a surface: Oricrete simulation of Yoshimura crease pattern.

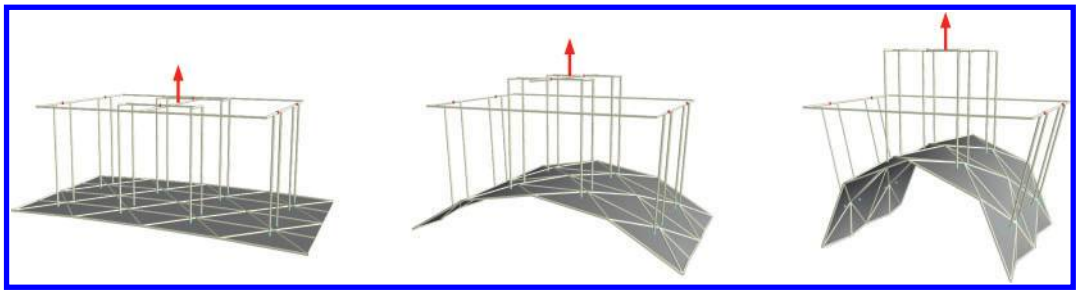

Figure 7. Simulation for designing a lifting device : Folding of the vault with 4×2 Yoshimura crease elements.

with G_1^u representing a fixed support and G_{23}^u linking two displacements together, respectively. The use of the link constraints is exemplified using the vault example in Fig. 5 by enforcing the nodes at the left-hand edge of the pattern to stay in a vertical plane.

It is also possible to attach selected crease pattern nodes to surfaces. The surface can either represent a fixed support or change its properties over time and control the folding. An example of attaching selected nodes to a single curved surface is shown in Fig. 6

4.2 *Design of a lifting device for the folding process*

For the design of simple folding equipment two additional kinematic constraints representing elements of a lifting device are defined.

- Grab points x_{ijk} on the facet with the nodes i, j, k. The position within the triangular facet is specified using the barycentric coordinates

$$\boldsymbol{G}_{(3)}^{(u)} = L_i \boldsymbol{x}_i + L_j \boldsymbol{x}_j + L_k \boldsymbol{x}_k - \boldsymbol{x}_{ijk} = 0. \qquad (22)$$

  The newly introduced node $\boldsymbol{x}_{ijk}$ can be involved in other constraints or optimality conditions.
- Sliding lines and sliding surfaces that can be used to limit the movement so that it remains on a given line ($\boldsymbol{x}_l$ on $l \in \mathcal{L}$) or a surface defined by a level set function $G^{(u)}(\boldsymbol{x}_s) = 0$.

By combining and adding these constraints to a crease pattern a raising gadget can be constructed as shown in Fig. 7.

CONCLUSIONS

We have described the formulation and implementation of a numerical model for simulation of rigid foldable origami structures. By using examples we have shown different strategies for choosing and introducing folding constraints for two different use cases:

- simulation of the folding process
- support for the design of the lifting device realizing the folding process

Further applications of the simulator include the structural analysis of the folded structure and identification of a crease pattern reproducing a desired shape. However these use cases would go beyond the scope of this paper and will be presented elsewhere.

ABSTRACT: This paper presents a qualitative investigation of the membrane roof project efficiency, in a preliminary stage of work, based on numerical and experimental data. The first stage involved the optimization procedure of the structural system of the original model under the action of load. The second stage comprised the experimental investigation of the membrane material behaviour within the structure in order to analyze the geometry of the flattened membrane. The working process adopted broadened the understanding and the evaluation of this system pointing out possibilities of improving its performance and minimizing failures during the preliminary stage of the design.

1 INTRODUCTION

This work is a qualitative investigation of the membrane roof project performance, considering a particular situation.

Structural membranes are based on the concept of surface structures with minimum thickness and weight, which withstand loads developing only tensile stress in their own plane. The three-dimensional stability of the investigated structures is a result of the geometry (double curvature in opposite directions, being referred to as anticlastic curvatures) and by the pre-stress applied at its boundaries (planar tensile forces). In addition they also work together and continuously with the support system (e.g., masts, cables, trusses, arches) allowing the development of complex buildings with large spans, low weight, high strength, fast construction process.

These structures are characterized by high complexity presenting great challenges during design and constructive process. Membranes take on forms according to the forces acting on them, similar to cable nets. They are flexible when compared to rigid-type systems such as shells, even if the working loads are within the elastic state, i.e. they present nonlinear geometric behavior (Lewis 2003), making it difficult to be analyzed by traditional methods and processes.

The designing process generally includes the stage of form finding, search for three-dimensional equilibrium of the membrane surface for certain stress distribution and boundary conditions, not considering the material behavior (Wagner 2005), the system static analysis and the patterning procedure (flattening of the three-dimensional surface for its manufacturing).

The wind is generally considered the critical load requiring a careful analysis of its action. Accurately evaluate the distribution of wind loads and their effects on membrane structures is a complex task due to the geometry and behavior of these structures and particularities of the wind load (Pauletti 2003). So, it is essential to have good information about the dynamic effects of wind in these structures, usually obtained in wind tunnel experimental tests, in order to conduct the analysis.

The material used for membranes treated herein as structural fabric, presents high strength and low weight, but, it also displays a complex behavior under tensile forces and needs to be tested.

Moreover, membrane surfaces, such as the steel components of the support system, are pre-fabricated. The surfaces, compounded of flat panels joined by seam, are just assembled and tensioned on site, which restricts major changes of its geometry.

In Brazil, architects and engineers deal with the typical challenges of this system, the uncertainties of the evaluated data and the limitations of the numerical programs used. So, it is usual to adopt simplifications in numerical simulations that could generate methodological flaws in design procedure, making the analysis less accurate and hindering performance of these structures.

These particularities reassure the motivations for investigating the efficiency of a project, trying to understand the strategies used to achieve the structural

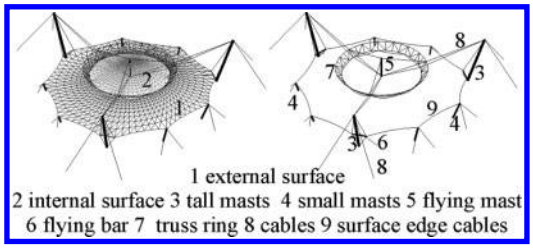

Figure 1. Membrane roof project (Nunes 2008).

efficiency of the system and the procedures that contribute to improve the structural and building performance of these structures.

1.1 *Project that guides the preliminary analysis*

The reference project for this study is the membrane roof project for the amphitheater at Federal University of Ouro Preto (UFOP) developed during the author's master research which is referred here as A1 or original model (~2000 m2), (Fig. 1).

Its system arrangement is characterized by combination and cooperation between membranes and supporting system in a pre-tension state. The supporting system is comprised of three tall masts, small masts and the spatial support system, with hinged joints. The spatial support system is formed by the spatial arrangement of the flying mast and truss ring, within a continuous net of cables forming a stable volume in space (Tensegrity principle). This model has two anticlastic membrane surfaces, with different shapes and behavior. The cone shaped external surface is fixed, while the inner surface is retractable and comprised of nine saddle shape modules arranged in a radial way. The upper part of the inner surface rests on the top of the flying mast while the base lies over the truss ring. The external surface is anchored on the truss ring, on the top of small masts and on flying bars which are hung by cables connected to the top and the base of tall masts (Nunes, 2008).

2 OPTIMIZATION PROCESS

2.1 *Variables that guided the preliminary analysis*

The first stage of the qualitative analysis comprised the optimization procedure of the structural system of the A1 model. It covered modelling and simulation of the structural system under load actions.

A set of variables (number of masts, the cable configuration and geometry of the surface) were analyzed leading to changes in the structural system arrangement and membrane geometry of the A1 model, and thus originating models with different geometries. These models were assembled in analysis cases according to the investigated variables.

The influence of the number of masts which hold the spatial support system was evaluated in the first case of analysis (Fig. 2). Configurations have also

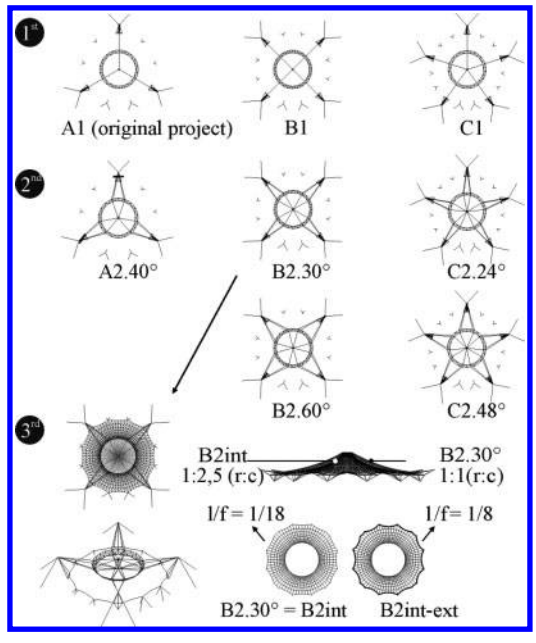

Figure 2. Cases of analysis (Nunes 2012).

been proposed with four and five tall masts originating B1 and C1 models. A pair of cables was arranged perpendicularly to the truss ring anchors in each tall mast.

The arrangement of cables that hold the flying mast and truss ring was investigated in the second case of analysis (Fig. 2). In the new cable configuration, two pairs of cables were anchored in three, four and five tall masts. It was verified the models whose angle between the pair of cable is defined by one module (A2-40°, B2-30°, C2-24° models) and two modules of the inner surface (B2-60°, C2-48° models).

The model whose spatial support system is held by two pairs of cables that are anchored in four masts (B2-30° model) was also subject of evaluation of the membrane surface geometry, shown in the third case of analysis (Fig. 2). An increase over the surfaces' curvatures was proposed. So, the pre-tensioning ratio (r:c) applied in the radial (r) and circumferential (c) directions of the inner surface was changed, originating B2int model. Then, it was also altered the ratio (f/l) of the rise of the curvature (f) and the length (l) between bottom anchor points over the outer surface, generating B2int-ext model.

2.2 *Preliminary analysis procedures and methods*

This investigation was carried out by the preliminary analysis of each model under loads and the compared study of them. The analyses were conducted in three stages: surface form finding, three-dimensional modeling of the system and preliminary analysis of the system.

The A1 model was initially defined according to physical model. So, the pre-tension forces applied to

its forms of equilibrium (represented by cable nets), in the form finding procedure, sought to approximate curvatures of cable nets to the ones of the physical model. The surface stress field of other models maintained the proportionality of A1 model surfaces, and was determinate by the pre-tension applied to the cable net elements and edge cable curvatures.

In the form finding procedure, the forms of equilibrium were carried out using Force Density Method and the software Densalfa (Oliveira 2003). Then, they were converted into surfaces and connected to the support system components, using a graphics platform (AutoCAD ®). The geometri-cally non-linear static analysis of this three-dimensional model was conducted using the Finite Element Method and Straus7 software.

The membrane material type IV (Mehler 2008) was chosen for preliminary analysis, considering its behavior as isotropic and linear. The Elastic modulus had as reference values presented by Meeß-Olsohn (2004).

The load of wind and rain were considered in these preliminary analyses. The rain load was calculated considering the water pressure of 0.01m over the surface. There was no planned wind tunnel testing. So, the wind load simulation had as reference the procedure laid down by Brazilian standard (NBR 1988) and the pressure coefficients resulted from models of membrane structures subjected to wind tunnel tests performed by Vilela (2011).

In order to perform the mapping of the wind coefficients above the surface, it was considered the tested models whose surface angle was similar to the approximate angles of the model surfaces. Then, the surfaces of the models were circumferentially sectored in accordance to the angles of the tested models. Afterwards, the wind directions were defined, i.e. global directions (−X, Y, −Y, −Y2) and local directions (in relation to surface anchor points: perpendicular to the anchor point, mid-span, and fourth portion of the span).

The dynamic pressure resultant of wind pressure calculation was multiplied by wind pressure coefficients values and applied perpendicularly to the surfaces of the models as mapping, to identify the pressures acting in surface geometry, as determined by wind directions.

The preliminary simulation of models was conducted by two performance evaluations.

The first one comprised the membrane evaluation which was based on allowable stresses, applying real load and having pre-tension values recommended by experience (Koenen 2009). It was also considered the range in which the membrane material can behave fairly linear way (Koch 2004).

The influence of magnitude and duration of long-term and short-term loads were verified. The maximum stress in the membrane surfaces under the wind action (short-term load) was limited to 25% of the material directions tensile strength; and pre-tension (long-term load) was limited to 5% of the material directions tensile strength. So, surface cutting patterns and material directions (weft and warp) considerations are required to this evaluation.

The second evaluation involved the steel support system. It was based on combination of actions, according to the American standard (AISC 2010). The following combination of actions was evaluated: 1,2D + 1,6Wdead load; W- wind; R- rain; PT-pre-tension).

The performance factor (load/ resistance) considered to the support system components was approximately 80%. The calculations performed had aimed a preliminary specification/ dimensioning of the models' support system components for their comparison, not being strictly accurate.

For the preliminary analysis and comparison of all models the same loads were considered and the same pre-tension was applied on membrane surfaces and edge cables in all models. The pre-tension applied to support system cables may change in each model, allowing to evaluate the level of pre-tension of these cables and to calculate the dimensions of the components of the support system required to support loads in each model involved.

2.3 *Preliminary analysis results*

The pre-tension applied, the surface stress field, the mass/total area and displacements of components of the models were evaluated. The wind was the critical load observed, and the most unfavorable directions were noticed directly or near anchor points of the surface causing great suction forces.

In the first case of analysis (A1, B1, C1 models), a progressive reduction of pre-tension applied to the support system cables by increasing the number of masts was observed, although these models showed similar mass/area relation. These configurations were characterized by great flexibility, since system arrangements did not offer significant restraint to displacements of support system and membrane surfaces.

The arrangement of cables proposed in the second case (A2-40°, B2-30°, C2-24° models) allowed better integration of components and increased the whole system stiffness, helping to reduce the displacements of components especially on the windward side. So, the importance of spatial arrangement of cables, reducing load path, were observed. It was observed that pre-tension applied to the support system cables also reduced progressively by increasing the number of tall masts, but the magnitude of pre-tension increased 100%. Increasing the angle between pair of cables that hold spatial support system (B2-60°, C2-48° models) helped to maximize support system stiffness, but it caused a significant raise of pre-tension magnitude applied to support system cables and the mass/area of models.

The models of the first and second cases showed similar stress distribution. In the external surface, high stress concentration was observed surrounding truss ring on the leeward side and near bottom anchor points on the leeward and windward sides. In the internal surface, the highest concentration of stress occurred only at the top of the surface surrounding the top ring,

mainly on the windward side; around this area a more homogeneous stress field with lower magnitude predominated; areas of higher stress occurred near surface anchorage points at truss ring on the windward side.

The changes of surface geometry in the third case of analysis increased membrane surface stiffness and its load bearing ability, as well as the global stability of the structural system. Greater curvatures required lower forces for the membrane surface to be in equilibrium and withstand loads, causing a significant reduction of pre-tension applied to support system cables and of system mass/area.

Among the evaluated models, C2-48° and B2int-ext showed the most favorable conditions for system equilibrium, besides having similar system mass and pre-tension magnitude applied to cables. The performance of C2-48° model resulted in large number of masts and new cable configuration. The optimal performance of B2int-ext model derived from the global stability achieved with structural system arrangement and membrane geometry. In this model, the membrane stiffness enabled support system arrangement with smaller number of masts, greater integration between components and more evenly stress distribution on membranes.

3 EXPERIMENTAL INVESTIGATION

In the first stage of qualitative analysis the form of equilibrium of the membrane was evaluated, i.e., a continuous three-dimensional surface whose definition does not consider the behavior of the material.

Thus, in the second stage of this investigation the geometry of the flattened membrane was evaluated considering the influence of material behavior.

This investigation was guided by the experimental tests of the material (biaxial test and seam tests) and the preliminary analysis of the model B2int-ext. The tests were performed at Laboratory for Lightweight structures Essen, University Duisburg-Essen, Essen, Germany, using the material PES/PVC (FR1400 Mehatop F – type IV), (Mehler 2008).

3.1 *Membrane structure that guided the tests*

This investigation had as reference the characteristics (geometry and stress field) of the external surface of B2int-ext model (Fig. 3).

Radial cutting patterns were proposed, which are aligned to surface principal curvatures. Thus, the directions of the material, warp and weft, follow radial and circumferential directions, respectively.

The trajectories of maximum stress were observed in surface circumferential direction (weft direction) on the leeward direction (caused by suction forces), and did not exceed 25% of selected material tensile strength (Fig. 3). Regarding pre-tension level, the maximum stress predicted in the surface circumferential direction (weft direction) did not exceed 5% of the selected material strength), (Fig. 3).

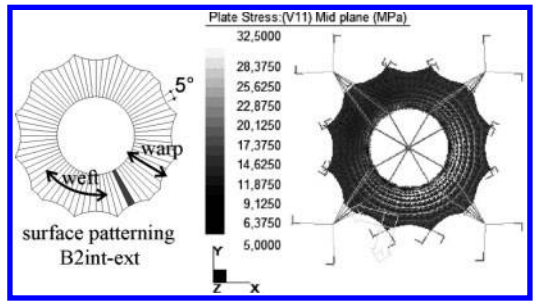

Figure 3. B2int-ext model -geometry/stress field (Nunes 2012).

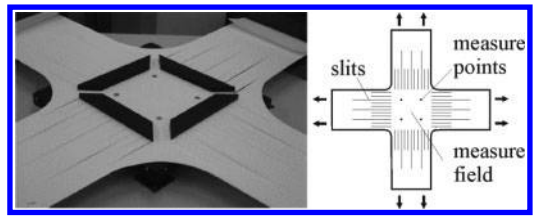

Figure 4. Biaxial test (Nunes 2012).

3.2 *Procedures and methods*

Aiming to simulate the material behavior under loads that act in the structure, the biaxial test was performed. This test is carried out under a temperature of 23°C, with cross-shaped specimen with arms extended toward material directions (warp and weft), which are cut to ensure stress transfer equally to material. Moreover, the forces are applied simulta-neously in both specimen directions of membrane material (Fig. 4).

The biaxial test was conducted according to proposed load ratio, i.e., the magnitude and duration of the loads that acts long term and short term in structure, described in a series of loads applied in warp and weft. It was performed as follows: initially the material was tensioned up to pre-tension level in both directions, maintaining a constant load. Then, the directions of warp and weft were subjected to alternated load cycles (mean and maximum values of critical load), that were intercalated with steps of constant load, simulating membrane pre-tensioning.

The influence of orientation of the material threads and of the angle between adjacent flat panels in the seam was evaluated by the seam biaxial test (Fig. 5).

The approximated angle of the cutting patterns in the investigated surface is 5°. So, threads of material (warp, weft) present a relatively small rotation compared to the seam.

In order to compare and evaluate the effect of this angle over the joint of panels by the seam, tests were performed at angles of 0°, 4° and 8°. In the first test the warp direction is parallel to seam axis, and thus, the material directions are aligned to the flow of forces. In the other tests, the warp was rotated at 2° and 4° to seam axis. In addition, the seam of specimens was performed by hot welding with overpass of 8 cm.

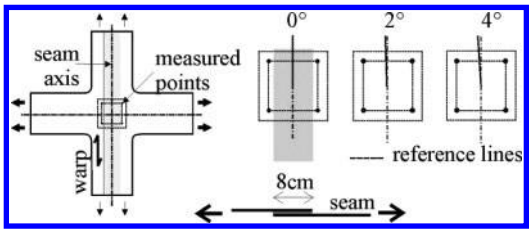

Figure 5. Seam biaxial test (Nunes, 2012).

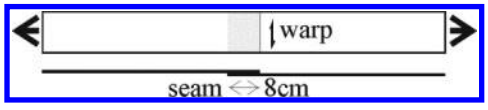

Figure 6. Uniaxial seam test (Nunes, 2012).

The pre-tension, mean and maximum values of the critical load were considered in the seam biaxial tests. The material was initially tensioned at pre-tension level in both directions. The warp direction remained constant throughout the test. The weft has been loaded in several load cycles (50% and 100% of critical load), that were in-terspersed with steps of constant load. The specimens were marked with measuring points and reference lines to favor material behavior observation.

It was also verified the temperature effect in the seam performance. So, the uniaxial seam tests were performed at angle of 0° between panels (warp parallel to seam) at the following temperatures: 23°C, 70°C and −10°C.

The seam strength was evaluated through the analysis of five specimens, considering load applied in the weft direction (transversal to seam), using specimens of 10 cm in width and seam overlap of 8cm (Fig. 6).

3.3 *Experimental analysis results*

The analysis and interpretation of tests' results were conducted according to information provided by the Laboratory, the observations and the photographic record of the tests.

The analyses of the stress and deformations that resulted of maximum load (predicted on the evaluated structure) obtained from biaxial test guided the evaluation of the elastic constants of the material.

In this preliminary investigation, the Elastic moduli (warp and weft directions) were obtained by linear adjustment of stress-strain longitudinal curves of the maximum load cycles. The stresses and strains in the warp and weft directions were replaced by their range, according to Blum (2002). The Poisson ratios (transverse deformation in the weft direction caused by the load in the warp direction, and vice-versa) were also calculated through linear adjustment of transversal deformation curve as a function of longitudinal deformation curve, as determined by Alvim & Pauletti (2004).

A small difference between the stiffness of the warp and weft was observed, i.e., there is a tendency on the material to present isotropic behavior based on the characteristics of the evaluated structure and load ratio. Moreover, these Elastic moduli had lower magnitude than Elastic modulus assumed in the preliminary analysis, something to be considered in the refined analysis.

Theoretically, Poisson's ratio for isotropic elastic materials does not exceed the value of 0.5. However, in this analysis, these ratios exceeded this value. According to MSAJ/M-02-1995, the threads and coating are not unified. So, when threads are tensioned, changes in the wave of threads, known as crimp interchange, are observed, causing geometric deformation. As a result, the material elongation and shrinkage could be associated not only to elastic deformations, but also to geometric ones as it was observed.

The analyses of the stress and deformations that derived from loads that prevail during the structure life time (mean load predicted) guided the calculation of the compensating values (adjustment values used to reduce or increase the dimensions of the flat panels according to the stretching and shrinking of the material). They were evaluated considering not only material deformations, but also cutting patterns geometry and stress distribution on membrane surface. This procedure sought to contribute to minimize the differences between the form of equilibrium and the real shape, reducing material wrinkles in such a way that the surface achieves the proposed form under pre-tension during its life time.

Analyzing the results of the seam biaxial tests, it was observed that the deformation magnitude of material (warp and weft directions) between adjacent flat panels in the seams of the evaluated angles was similar. However, comparing the lines on specimens (the beginning and during the tests), it was observed the distortion of the material. Increasing the angle between panels and the applied loads, the material distortion (shear deformation) became more intense. This behavior results from sliding movement and rotation between threads, caused by different forces acting on material directions, and thread orientation in relation to force direction, confirming the importance of limiting the angle between panels.

In the uniaxial seam tests under the temperature of 23°C, the seam breaking strength showed a higher value than the material tensile strength. The failures at the end of the seam prevailed with fabric breaking parallel to seam, which reveals high strength of seam. Reducing the temperature (−10°C) the seam breaking strength showed a small decrease comparing to test at 23°C, but still showed similar value to the material strength. The material was brittle and failures at the edge of the material prevailed. Increasing temperature (70°C) there was a significant reduction in the seam performance (approx. 50% of material strength), which is reversible with the decrease of temperature. The PVC coating softened, reducing adhesion. These analyses made it possible to observe coating behavior and its influence in seam strength, confirming the importance of evaluating seam width and weld

manufacturing process mainly in tropical regions such as Brazil.

4 CONCLUSION

The qualitative analysis of the membrane roof project, based on numerical and experimental data, make it possible to broad the understanding and the evaluation of this system, helping to minimize failures during the preliminary stage of design.

The first stage involved the optimization procedure of the structural system of the original model under the load action. This stage of study was conducted by the definition of a set of variables (related to support system arrangement and membrane geometry) to analyze the structural system of the original model, as well as by analysis methods and the performance evaluations.

The proposed procedure permitted to predict the global behavior of each model as a trend and to carry out the comparison of the models (original model and the ones originated by the proposed variables), refining and improving the geometry of the original model.

The set of variables, gradually added in each case of analysis, contributed to greater integration between components, increasing the stiffness of the whole structure. Thus, it was verified that enhancing three-dimensional stability of the whole system and membrane stiffness, as well as improving organization and joint work among all components in pre-tension state can reduce support system and membrane displacements, making possible to withstand external loads with low system mass, and thus achieving optimal performance of these structures.

The experimental analysis, in the second stage, showed that membrane material has also a flexible structure, that is, it withstands forces by movement and or deformation of threads. These movements can be observed in the deformation and or distortion of material and are influenced by fabric weaving, orientation and stiffness of material threads, as well as magnitude and duration of loads, time and temperature. Thus, to control the movements of material under load action and to improve the construction performance of these structures, the geometry of flat panels should be adjusted, according to the evaluation of the material behavior in the context of the structure.

The working procedure adopted also demonstrated that the optimal performance of these structures is a result of an optimization process that involves the analysis of three-dimensional geometry and arrangement of all components (membrane and support system) under load action, as well as the analysis of the geometry of the membrane surface formed by flat panels considering the material behavior. This procedure also leads to the best force path and appropriated use of materials.

ACKNOWLEDGEMENTS

Prof. Dr. Jochen Menkenhagen, for providing favorable conditions for the development of this work and for resources to experimental tests in the University Duisburg-Essen/ Essen Labor. Dr Reinhold Koenen, for orientation in numerical and experimental analysis, sharing great knowledge and experience. Mr. Saxe and Mr. Homm (Essen Labor), for information, valuable suggestions in experimental analysis and for conducting the material tests. Mr. Robert Schwetz and Mehler Texnologies team, for receptivity, and assignment for material sample tests. Harry Buskes (Carpro), for gentle preparation of materials for tests. Vinicius Oliveira, the kind assignment of Densalfa software. Capes, Fapemig and Fundação Gorceix, for providing the resources for this research.

Collapse behaviour of double-layer grid structures in steel

J.M. Adams & A. Zingoni
University of Cape Town, Cape Town, South Africa

ABSTRACT: The propensity of Double-Layer Grid (DLG) structures to fail suddenly, without warning, has contributed to their reduced popularity in industry. To identify DLG pre-critical yielding behaviour and increases in DLG post-critical structural resistance, which represent improvements to conventional DLG failure behaviour, a structural and geometric parametric study was undertaken of DLG symmetric collapse under distributed loading. The parametric study additionally served to identify and characterize DLG plastic failure and collapse behaviour for structures representative of those employed in practice. Finite element analysis with the Abaqus code was employed for the structural collapse analysis; the displacement-controlled analysis method was verified against a previously undertaken experimental analysis of DLG collapse. DLG geometric configurations with reduced bottom chord densities were found to be an easily implementable means of achieving stable pre-critical plastic displacement; the extent of pre-critical plastic displacement was comparable to that achieved by employing over-sized and 'soft' compression members.

1 INTRODUCTION

Flat double-layer grid (DLG) structures are efficient modular structural systems which span in two or more directions and consequently develop their resistance in three dimensions. For unobstructed roofing applications, DLG structures offer many structural, constructional and aesthetic advantages over alternative planar structures. DLG structures, however, have been observed to have a propensity for sudden collapse behaviour, as witnessed in the collapse of the Hartford Coliseum roof structure in 1978 (Parke 1988). An investigation of DLG collapse behaviour was consequently undertaken to identify if improvements to DLG collapse behaviour could be achieved through specific combinations of common structural and geometric DLG parameters (Adams 2012); pre-critical yielding behaviour and post-critical increases in DLG resistance were considered to represent improvements over conventional DLG collapse behaviour; for both cases the initiation of DLG failure is identifiable prior to collapse.

2 PREVIOUS RESEARCH

Research into the collapse behaviour of DLG structures has largely been conducted with two experimental aims in view. Initial studies, such as those presented by Schmidt et al. (1976, 1982), Collins (1981) and Saka & Taniguchi (1994) focused on establishing the collapse behaviour of DLG structures. Due to the unfavourable nature of this established behaviour, and collapses in industry, subsequent studies as presented by Parke (1988), Mwakali (1990) and El-Sheikh & McConnel (1993) focused on improving DLG structure collapse behaviour.

The highly nonlinear behaviour of structural collapse has resulted in most authors adopting physical model testing as their primary means of analysis. Experimental modelling of DLG structures has highlighted their sensitivity to structural and geometric imperfections, as observed in the divergence from symmetry in DLG failure and the variability of experimental results.

Studies into DLG collapse behaviour have additionally been accompanied by numerical collapse analysis; notable examples of such studies include the work of Collins (1981), Parke (1988), Mwakali (1990), El-Sheikh & McConnel (1993) and Saka & Taniguchi (1994). Numerical collapse analysis of DLG structures has been conducted largely through use of idealized strut implementations of DLG behaviour; Saka & Taniguchi (1994) are the exception who investigated DLG critical behaviour using a buckling analysis method.

The use of idealized strut implementations of member behaviour for the numerical analysis of DLG structures has not allowed for the continuous behaviour of DLG collapse to be established. The effect of the grid restraint on individual member behaviour has also not been captured. Furthermore, the idealized strut implementations have not accounted adequately for the effects of member bending resistance and joint rotation in the post-critical regime where changes to DLG geometry result in structures whose structural resistance can no longer be assumed to be comprised of axial stiffness only.

3 PROBLEM STATEMENT

Despite the propensity of DLG structures to fail suddenly, only limited and inconsistent results describing DLG structure failure and collapse behaviour are available. A parametric study, where the results would allow for the identification of trends in pre-critical DLG yielding behaviour and post-critical increases in DLG resistance, was therefore required.

4 METHOD

In order to identify trends in DLG collapse behaviour, results covering the full design spectrum of DLG collapse behaviour were required; the large number of analysis cases was to be developed with structural finite element (FE) analysis. The numerical method of analysis to be employed was developed and validated through comparison with published experimental results. The case of distributed loading was considered as this is consistent with the loading commonly assumed in roof structure design. Corner supports were employed to limit the effect of boundary conditions on DLG behaviour.

4.1 *Numerical analysis*

The numerical method employed for the finite element analysis of DLG structures, with the Abaqus code, was a quasi-static, geometry and material nonlinear, incremental and iterative, displacement controlled analysis (Simulia 2010). A novel application of the distributing couple element was used for the application of uniformly distributed load in a displacement controlled analysis[1]. As DLG structure failure behaviour is characterized by the compression failure of individual members, a half-sine geometric (bow) imperfection was introduced into the initial geometry of all member groups, which could potentially experience compression in the DLG elastic regime; geometric imperfections were applied in the vertical plane to negate their effect on symmetry. Member imperfections were introduced to avoid problems associated with bifurcation in the numerical analysis.

4.2 *Validation*

The comparison of the numerical results, from FE analysis, with the experimental results of Collins (1981) showed a good correlation for the entire failure path (Figure 1); the numerical analysis method was consequently considered to be validated.

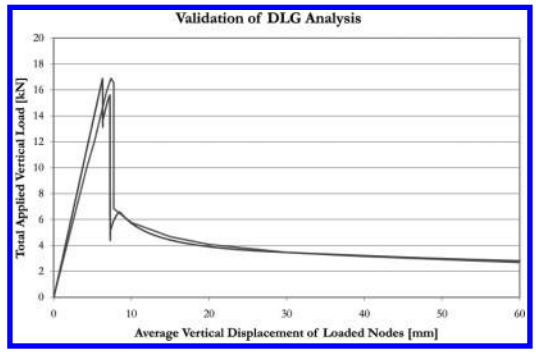

Figure 1. Validation of FE results for SOS DLG collapse through comparison with the experimental results of Collins (1981). Load redistribution between adjacent chord members was evident prior to collapse for the numerical model results.

The validation of the numerical method for the square-on-square (SOS) DLG configuration under point loading was extended to the following additional cases:

- Semi-rigid connections
- Uniformly distributed loading
- Diagonal-on-square DLG configuration

The validation of the structural parameterization employed was achieved through the consideration of DLG scale, a DLG scale of up to × 10 was considered. A maximum error between numerical results and predicted results for flexural, shear and yielding collapse mechanisms of 0.6% and 1.25% was observed when evaluating critical load and energy applied to DLG respectively; this was considered to be an acceptable error.

To increase computational efficiency and to enforce symmetric failure, one quarter of the complete DLG geometry was considered for the parameter study. A maximum error between numerical results for both numerical model representations of <3.0% was observed with respect to the energy applied to the DLG; this more significant error was attributed to deviations from a symmetric failure path for the full DLG model and was consequently not considered to be associated with the use of symmetry in the model.

4.3 *Investigation method*

Following the validation of the numerical DLG collapse analysis method, a parametric study was developed which allowed for the full design spectrum of DLG behaviour to be established. The DLGs selected for analysis (Figure 2) were limited to the cases of SOS and DOS configurations with: cornice edge detail; simple corner supports; aspect ratio of 1.0; circular hollow section (CHS) members of steel grade S355; 9 × 9 and 7 × 7 modules for the SOS and DOS DLG configurations respectively.

[1]Application of distributed load in a displacement controlled analysis was achieved as follows: a continuum distributing couple linked a control node with the reference nodes; reference nodes were located directly below the top intersection nodes on the DLG; link connector elements were defined between the reference nodes and the DLG top nodes; equation constraints were defined to equate the horizontal displacements of the reference nodes and the DLG top intersection nodes. This allowed for the force associated with a single displacement boundary condition at the control node to be distributed equally to all the DLG top intersection nodes.

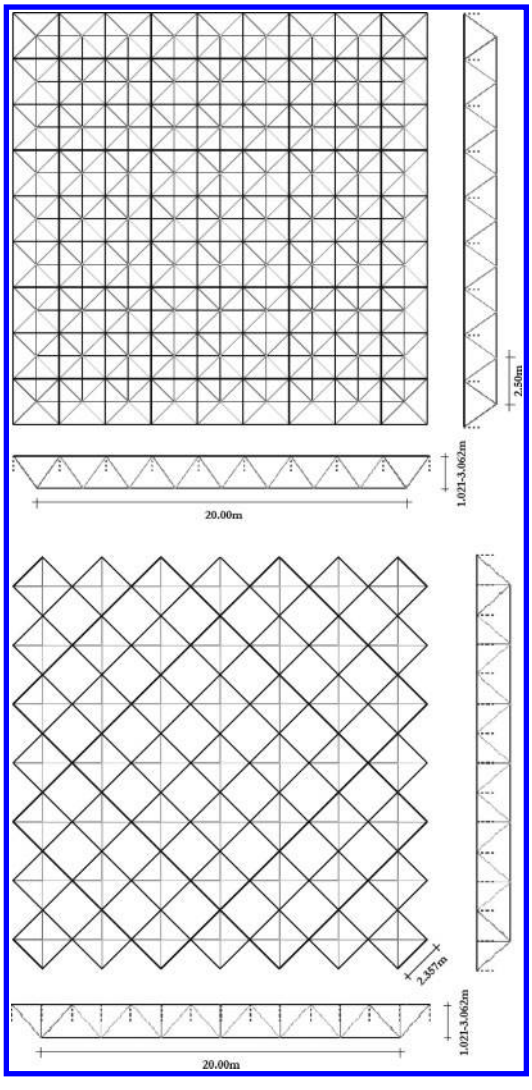

Figure 2. 20×20 m, SOS (top) and DOS (bottom) DLGs with cornice edge detail. Member groups used for analysis included top chords, bottom chords, web members and support members (four web members at each corner support). DLGs were supported at the four bottom corner nodes.

DLG member sizes were based on a design in accordance with the relevant European Standards (CEN 2003, 2005). This was undertaken such that DLGs analyzed were representative of DLG structures employed in practice; elastic, perfectly plastic material behaviour was employed.

DOS DLG geometry and section sizes were scaled to achieve an equivalent span distance for both SOS and DOS DLGs; span:depth was maintained constant between SOS and DOS DLGs by adjusting the DOS web angle. A DOS DLG with fewer modules than the SOS DLG was selected to maintain the number of load points and web member angles approximately equivalent between SOS and DOS DLGs of equal span; an odd number of top modules were selected to allow for a symmetric displacement field.

Parameterization of the DLG structures aimed to capture the complete behaviour of the structure so that the effect of scale on structural behaviour could be accurately accounted for. The parameters considered included: Span:Depth; Web:Top Chord Resistance; Chord Area Ratio; and Connection Stiffness.

Parameter values were selected which defined the typical structural and geometric ranges employed in industry. For the purpose of the parametric study, the parameter values selected were varied concurrently so that the full interaction of parametric behaviour could be observed in the results; in total 480 individual structures were analyzed.

To account for member instability and yielding behaviour, member resistance was parameterized in terms of A/λ^2 (where: A = member cross-section area, λ = member slenderness ratio) such that member resistance to instability and yielding was varied proportionally. Connection stiffness was defined, with respect to individual member capacity, between pinned and fixed bounds.

The following parameters were considered:

- DLG Configuration: SOS, DOS
- Span:Depth: 6:5, 11:3, 19:6
- Connection Stiffness: 0% (pinned), 33%, 66% and 100% (fixed)
- Web:Top Chord Resistance: 33%, 50%, 66%, 83% and 100%
- Chord Area Ratio: 50%, 66%, 83% and 100%

5 RESULTS

The nonlinear collapse analysis of the DLG structures, of SOS and DOS configuration, allowed for the failure and collapse behaviour of such structures to be observed under uniformly distributed loading. DLG behaviour resulting from the collapse analyses was divided into three regimes for the purpose of comparison: pre-critical behaviour (comprising of linear elastic and plastic behaviour); critical behaviour; and post-critical behaviour. DLG behaviour was initially identified and categorized; trends in structural behaviour were then established through comparison of post-processed representations of DLG load-displacement responses (Adams 2012). Critical and post-critical behaviour was observed to vary as a result of failure mechanism (critical behaviour), collapse mechanism (post-critical behaviour) and as a direct result of the variation of structural and geometric parameters.

5.1 *Pre-critical behaviour*

Pre-critical behaviour was dominated by plastic yielding behaviour of DOS DLG configurations. Significant plastic deformation of SOS DLGs was not observed; this was attributed to the denser layout of bottom chord members in SOS DLGs relative to DOS

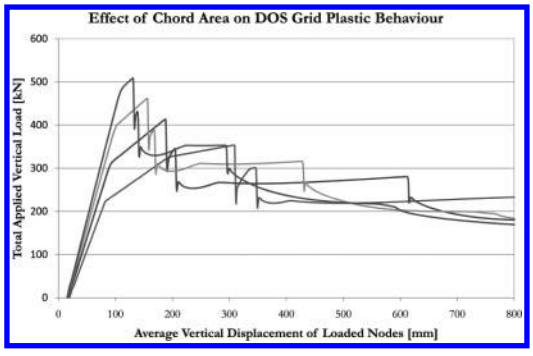

Figure 3. Variation of DOS DLG load-displacement behaviour for increasing values of the Chord Area Ratio parameter (bottom to top).

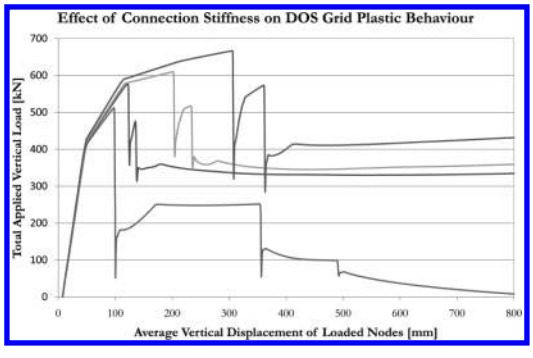

Figure 4. Variation of DOS DLG load-displacement behaviour for increasing values of the Connection Stiffness parameter (bottom to top).

DLGs. Plastic behaviour of DOS DLGs was assessed by comparing plastic and critical energy fractions; these fractions were represented by the integral of the load-displacement responses for DLG plastic and pre-critical regimes respectively.

DLG pre-critical behaviour, observed in the results of DLG collapse analysis, was summarized as follows:

- DOS DLGs were less stiff than comparable SOS DLGs.
- DLG stiffness increased for increasing values of the Connection Stiffness and Chord Area Ratio parameters.
- DLG stiffness decreased for increasing values of the Span:Depth parameter.
- Web members did not affect DLG flexural stiffness.
- DOS DLG configurations allowed for the development of significant nonlinear behaviour prior to the onset of DLG failure.
- Initiation of DLG plastic deformation was inversely proportional to the Chord Area Ratio parameter (Figure 3).
- Stability of DLG plastic deformation was dependent on the avoidance of shear and flexure failure mechanisms; plastic deformation consequently increased with Connection Stiffness (Figure 4) and Web:Top Chord Resistance parameters.

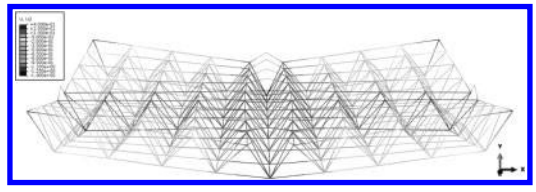

Figure 5. Flexural failure of SOS DLG, with vertical displacement field superimposed.

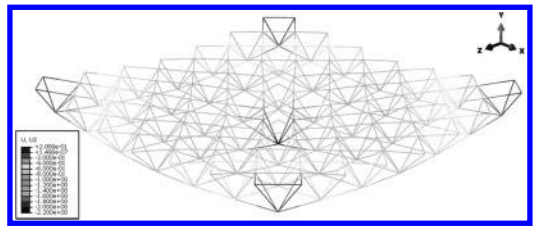

Figure 6. Flexural failure of DOS DLG, with vertical displacement field superimposed.

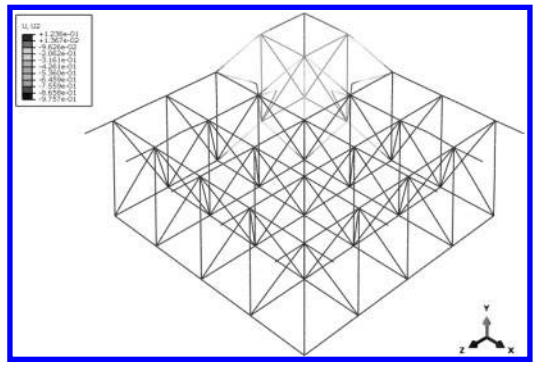

Figure 7. Shear failure and collapse of SOS DLG, with vertical displacement field superimposed.

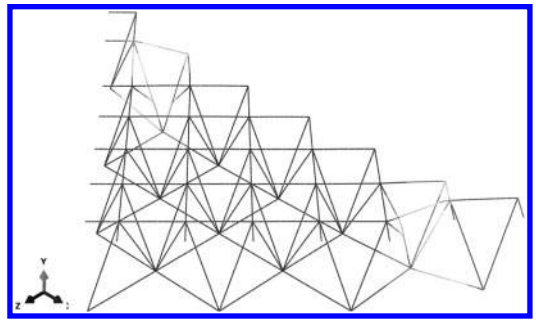

Figure 8. Shear failure and collapse of DOS DLG, with vertical displacement field superimposed.

5.2 *Critical behaviour*

Critical behaviour of DLG structures was observed to be dependent on flexural failure (Figures 5–6) and shear failure mechanisms (Figures 7–8) which were in turn dependent on Web:Top Chord Resistance and Span:Depth parameters. DLG critical resistance was

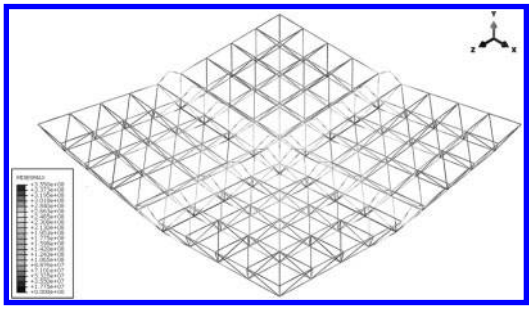

Figure 9. Flexural collapse of SOS DLGs was characterized by the development of plastic hinges in two directions across the DLG; an equivalent displacement field cannot develop for DOS DLG configurations. Max. von Misses Stresses are shown superimposed on the deformed geometry.

observed to be further dependent on Chord Area Ratio and Connection Stiffness parameters.

DLG critical behaviour, observed in the results of DLG collapse analysis, was summarized as follows:

- Shear failure of DLGs resulted in significant reductions to structural efficiency in comparison to similar DLGs which failed in flexure.
- Shear failure was observed to be dependent on Web:Top Chord Resistance, Connection Stiffness and Span:Depth parameters.
- SOS DLGs were observed to be more susceptible to shear failure than DOS DLGs due to the increased flexural resistance of SOS DLGs.
- Web:Top Chord Resistance and Connection Stiffness parameters were observed to have the most significant effect on critical load for DLGs which failed in shear.
- Chord Area Ratio, Span:Depth and Connection Stiffness parameters were observed to have the most significant effect on critical load for DLGs which failed in flexure.

5.3 *Post-critical behaviour*

The collapse of DLG structures was frequently observed to be consistent with the initial failure mechanism, although significant interaction of web, top and bottom chord member failure was also observed. Three principle collapse behaviours were identified: shear collapse (Figures 7–8), flexural collapse (Figure 9) and flexural failure with post-critical shear collapse interaction. The displacement field associated with flexural collapse was not developable for DOS DLGs due to the orientation of top chord members relative to supports. Post-critical behaviour was assessed in terms of the average post-critical load resistance and the ratio of average post-critical:critical resistance.

DLG post-critical behaviour, observed in the results of DLG collapse analysis, was summarized as follows:

- Shear collapse of DLGs was characterized by only nominal post-critical residual strength.
- Improved post-critical resistance was observed for increasing values of the Connection Stiffness parameter.
- More rapid decreases in DLG post-critical resistance resulted from reductions of the Span:Depth parameter.
- Slender top chord members resulted in sudden collapse with only nominal post-critical load resistance.
- DOS DLGs were generally observed to collapse more quickly than similar SOS DLGs.
- Flexural collapse of SOS DLGs resulted in significant, sudden decreases in DLG post-critical resistance.
- Initiation of flexural collapse was dependent on Web:Top Chord Resistance and Chord Area Ratio parameters.
- Flexural failure and post-critical shear collapse interaction was generally characterized by a gradual decrease in load resistance.

6 DISCUSSION

The results presented are for the case of symmetrical failure. In 'real' DLG structures symmetrical failure is not observed due to the sensitivity of such structures to imperfections. The results presented, therefore, provide a means of evaluating the effects of the identified structural and geometric parameters in an idealized DLG failure.

The failure of the DLG structures considered was observed to be followed by increased post-critical resistance in only a few instances and a trend in such behaviour was not established. Although exceeding the critical load of all the other structures considered results in collapse, the post-critical behaviour observed is indicative of the nature of collapse. The design of DLG structures should consequently avoid global shear failure, which results from the failure of web members adjacent to supports, as global shear failure is characterized by a sudden decrease in load resistance. Initial flexural failure followed by interaction with web member failure was observed to result in the most gradual decrease in DLG load resistance; such a collapse mechanism is consequently preferred as the failure is characterized by multiple non-critical member failures.

DLGs, with low values of the Bottom:Top Chord Area parameter, demonstrated significant nonlinear behaviour prior to failure, this therefore represents a notable improvement to DLG failure behaviour. The significant yielding behaviour observed for DOS structures was believed to be equally as effective as the use of 'soft' chord members or over-designed top chord members in improving pre-critical and critical behaviour, presented by Parke (1988). The less dense distribution of bottom chord members in the DOS configuration is an effective and simple means of introducing pre-critical yielding behaviour in DLG structures

which provides warning of structural damage prior to structural collapse.

SOS DLGs were observed to demonstrate the preferred post-critical behaviour; however, DOS DLGs were observed to demonstrate the preferred DLG pre-critical behaviour. The most significant concern regarding the behaviour of DLG structures has been their propensity to fail without warning; DOS DLGs consequently represent the most suitable DLG configuration considered for corner supported DLG structures.

7 CONCLUSION

Nonlinear analysis of SOS and DOS DLG structures was successfully undertaken to determine global pre-critical yielding and critical behaviour. Bifurcation behaviour, at a member level, was accounted for by applying initial geometric imperfections. Distributed loading was applied to the DLG structures in a displacement controlled analysis; the effect of grid restraint and connection restraint on member behaviour was accounted for.

The behaviour of DOS DLG configurations with low values of the Bottom:Top Chord Area Ratio parameter, were shown to exhibit significant stable nonlinear pre-critical behaviour resulting from the yielding of bottom chord members. The DOS DLG configuration, and potentially other DLG configurations, with less dense bottom chord arrangements, therefore represent attractive structural configurations for design purposes, provided dominant loading is applied in one direction only.

Connection Stiffness and Span:Depth parameters were observed to have the greatest effect on DLG post-critical behaviour. A general improvement in post-critical behaviour was observed for increasing values of the Connection Stiffness and Span:Depth parameters; slender top chord members were observed to result in sudden DLG collapse behaviour.

Behavior of composite bar structures: Theory and examples

J.B. Obrębski
Faculty of Civil Engineering, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The present author has elaborated complex theory for straight bars with any type of Cross-Sections (CSs) – in it homogenous and composite, too. There, was proposed, that for the bars with full – compact Cross-Section (CS), can be calculated geometrical characteristics, identically as in theory of thin-walled bars (TWBs), when the CS is modeled as set of closed tubes located each into the other (see short paper). The tubes can be of composite character with different materials concentrated in longitudinal strips located along theirs circuit. With such geometrical characteristics of full CSs is possible much more exact calculation of bars in range till now known rather in theory of TWBs. Both papers, short and full, form one whole.

1 INTRODUCTION

The paper are shows some examples of calculations for composite straight bars under combined loading. It tries to present in one place summary of created unconventional possibilities for designing of different composite bar structures. On example of simply supported bar (Fig. 1) with seven similar rectangular CSs, were compared normal stresses, cores and mechanical behavior. The six of them have identical external dimensions, but other dislocation of two materials: steel and timber. There, were presented some drawings showing position of indifferent axes (where normal stresses are equal zero) and area of calculated the CSs' cores (short paper, Fig. 3). Values of normal stresses are presented in proper tables.

For calculation of CSs warping (warping functions) and position of shearing centers, they were divided in two different manners for sets of five or six closed thin-walled, homogenous (steel or timber) or composite (having steel and timber). In consequence it gives a little different effects and results.

For strength calculations were used: own program MBK and MS Excel. The calculations are based on

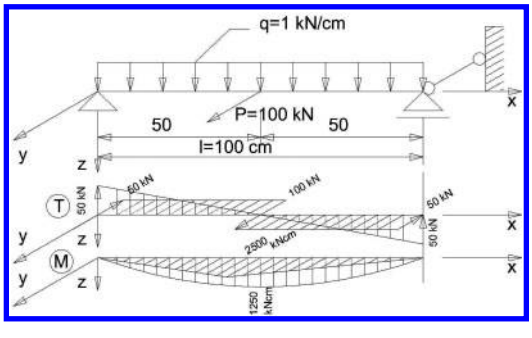

Figure 1. Scheme of investigated bar, loadings and diagrams of shearing forces and bending moments.

mentioned own theory (Obrebski 1991, 1997), next extended in some large papers published in LSCE books (1995–2012). Together both manuals forms one portion of knowledge concerning static and dynamic analyses in range of first and second order including instability of the bars which can interacting with surrounding media (dumping, aerodynamics, elastic multi-parametrical foundation etc.). There, can be straight bars with any type of CSs composed from some materials in it full and thin-walled o open or closed with one- or multi-circular and open closed. Moreover short review of previous author's researches (including SEMC), related to different aspects of strength calculations for composite straight bars are given, too.

The paper presents rather comparison of behavior considered seven similar simply supported bars. In the future works is foreseen extension of investigations on instability of such single bars and on space bar structures built from many composite bars.

In author's theory are defined "reduced principal axes" of CS, for which are equal zero some next geometrical characteristics (static moments and centrifugal moments of inertia – all reduced):

$$\overline{A} = \oint d\overline{A} \quad \& \quad d\overline{A} = \left(\frac{E_1}{E}\right)\delta\, ds = \left(\frac{E_1}{E}\delta\right) ds = \overline{\delta}\, ds \quad \& \quad \overline{\delta} = \left(\frac{E_1}{E}\delta\right) \tag{1}$$

Some essential formulae of applied theory are quoted in next chapters, only.

2 INVESTIGATED BAR

Comparative strength analyses are performed for short bar with length 100 cm, Fig. 1. There, is given external loading acting in two principal planes of bar CS. Continuous uniform loading q is given in vertical plane of symmetry and horizontal force P = 100 kN in half of CS height. The calculations were done for seven

prismatic bars with constant rectangular CS. Six CSs have external dimensions 10 × 12 cm, and the seventh is bigger – 12 × 12 cm. The first CS is made from steel, but six next besides steel (E = 205 GPa, E_1 = 225.27 GPa; G = 80 GPa; ν = 0.281) have inclusions of timber with area of its CS from 24 cm^2 up to 80 cm^2 (E = 10 GPa, G = 63 GPa; ν = 7). The all CSs are symmetrical with regard to vertical z axis The CSs A & C are bisymmetrical, (see short paper, Figs 2, 3).

3 GEOMETRICAL CHARACTERISTICS

There, key-matter is definition of so called geometrical characteristics for CS. As the first is defined reduced area:

$$\bar{I}_i = \oint (\eta_j)^2 d\bar{A}, \quad i, j=2, 3 \ \wedge \ i \neq j, \tag{2}$$

where $\bar{\delta}$ = new reduced thicknesses of the bars walls.

Similarly are defined reduced moments of inertia:

$$\bar{S}_2 = \bar{S}_2 = \bar{S}_{\hat{\omega}} = \bar{I}_{23} = \bar{I}_{2\hat{\omega}} = \bar{I}_{3\hat{\omega}} = 0 \ . \tag{3}$$

$$\bar{I}_{23} = \oint \eta_2 \eta_3 d\bar{A}, \quad \bar{I}_{\hat{\omega}} = \oint (\hat{\omega})^2 d\bar{A}, \quad \bar{I}_{j\hat{\omega}} = \oint \eta_j \hat{\omega} d\bar{A}, \quad j=2,3$$

where η_i = coordinates. Obtained in this way geometrical characteristics for considered CSs are shown in Table 1. Next, in Table 2 are given positions of reduced center of gravity, shearing center and arm of the force P generating torsion moment M_1.

As follow from Table 1, by much dense division of CS on tubes (5 on 10), is slightly changing only sectorial moment of inertia (last column). Similarly, as follow it from Table 2, by much dense division of CS on tubes (5 or 10), slightly changes torsion rigidity K_s from 87.3 % to 88% (last column). There, theoretical solution is regarded as exact.

CS A modeled as 10 tubes	14 109 447	88.0

4 "TRADITIONAL" CALCULATIONS

The calculations were started from trivial determination of graphs for internal forces – shearing T and bending moments M, (see Table 1). All seven compared calculations were led for following bending moments (in vertical and horizontal planes): $M_2 = ql^2/8 =$ 1250 kN cm, $M_3 = Pl/4 = ql^2/4 =$ 2500 kN cm.

Determination of internal forces associated with torsion needs of knowledge about position of shearing centre (see chapter 5.3). The normal stresses for each kind of bar should be calculated as follow:

$$\sigma_1 = \frac{E_1}{E}\left(\frac{T_1}{A} - \frac{M_3\eta_2}{\bar{I}_3} + \frac{M_2\eta_3}{\bar{I}_2} + \frac{B\hat{\omega}}{\bar{I}_{\hat{\omega}}}\right) \ . \tag{4}$$

There last term describes torsion. Traditionally, by strength calculations for compact CSs, the fourth term

is neglected. In such case, we have indifferent axis which for each type of CS has other inclination.

In turn, in the Table 6 are given positions of cores for particular CSs. Here, turn the attention different shape and area of each core. The coordinates of its corners were determined according to formulae:

$$z_0 = -\frac{\overline{i_2}^2}{e_3}, \qquad y_0 = -\frac{\overline{i_3}^2}{e_2},$$

where e_2 & e_3 = coordinates of the points where a longitudinal force is applied (external corners of the CS); y_0 & z_0 = coordinates of the points in which indifferent axis crosses the reduced principal axes;

$$\overline{i_2}^2 = \frac{\overline{I_2}}{A}, \qquad \overline{i_3}^2 = \frac{\overline{I_3}}{A},$$

are squares of reduced radiuses of inertia for particular CSs, Obrebski 1991, 1997.

In the Table 8, are compared deflections of particular bars depending on reduced moment of inertia.

5 TORSION IN INVESTIGATED BARS

According to theoretical derivations follows, that torsion moment M_1 is calculated with regard to shearing centre. For its determination is needed knowledge of warping of considered CS. In this moment appears necessity to modeling full – compact homogenous or composite CSs as built from some tubes located one into the other, Obrebski 1991, 1997, 2012. So, it is assumed division of CSs on generally 5 tubes, treated from this moment as thin-walled. But shearing centre, moments of inertia, center of gravity (reduced, too) are calculated as common for whole CS. Here, geometrical characteristics are calculated as sums of similar values, but calculated for particular tubes.

Especially in this paper, are shown three possible methods of CSs division. Version "a" assumes existence of closed composite tubes – built here from steel and timber. Version "b" assumes homogenous closed thin-walled tubes, only (short pap. Fig. 3). Each closed tube is represented by middle line forming closed circuits, with length L (Table 10) and with double area of closed tubes: $\Omega = 2 \times A$ (Table 9).

The warping of the each homogenous rectangular closed tube used in CS type A was calculated according to the following formula, Obrebski (1991):

$$K = a \times b \frac{b-a}{a+b}, \qquad (5)$$

where K = value of warping function in corner of each rectangular tube, a = value o half width of particular closed rectangular tube, b = value of half high of particular closed rectangular tube. For remaining tubes, homogenous and composite ones, was used the formula in its general shape (6) Obrębski 1991:

$$\hat{\omega}(s) = \hat{\omega}_A + \omega(s) - \Omega\frac{l}{L} \quad \& \quad l = \int_0^s \frac{ds}{G\delta}, \quad L = \oint \frac{ds}{G\delta}, \qquad (6)$$

where $\hat{\omega}(s)$ = value of calculated warping for closed tube; $\hat{\omega}_A$ = value of warping in starting point (s = 0); $\omega(s)$ = warping calculated for opened CS. By means of above formulae and program MS Excel, were calculated values of warping function in characteristic points of each particular tube (Table 7).

As the last step in calculations presented in this paper, are positions of shearing centers for each type of CS defined by two coordinates:

$$\eta_{zA'} = \frac{\bar{I}_{3\hat{\omega}}}{\bar{I}_2}, \qquad \eta_{yA'} = \frac{\bar{I}_{2\hat{\omega}}}{\bar{I}_3}. \qquad (7)$$

where $\bar{I}_{2\hat{\omega}}$ & $\bar{I}_{3\hat{\omega}}$ = warping-centrifugal reduced moment of inertia of the CS. All geometrical characteristics, including above formulae, are calculated as

**Division on 6 tubes.

the sums of n similar, determined for each (i) particular tube. In few tables below, are given some results of calculation of torsion bars rigidity and generated by them in task internal forces. This matter is here without comments.

It is interesting to know, what part of torsion moment carry particular tubes. It is proportional to torsion rigidity K_s of particular tubes with regard to torsion rigidity of whole CS (compare Table 13).

After determination of shearing centre, warping function $\hat{\omega}$, sectorial moment of inertia $\bar{I}_{\hat{\omega}}$, and bimoment B, we can use for calculation of normal stresses, full version of formula (3). Results for particular CSs are given in Tables 14–19. There is omitted table with normal stresses σ_x in external corners of CS type A (as homogenous built from steel).

Shearing stresses in general case should be calculated according to formula (8), where last term gives influence of torsion (bending-torsion moment).

$$\tau_{1s} = \tau_O - \frac{1}{\delta}\left(\frac{T_z\widetilde{S}_3}{\bar{I}_3} + \frac{T_y\widetilde{S}_2}{\bar{I}_2} + \frac{M_{\hat{\omega}}\widetilde{S}_{\hat{\omega}}}{\bar{I}_{\hat{\omega}}}\right). \qquad (8)$$

For the reason of limited volume of this paper, in tables 20 & 22 are given the flows of τ_o, only.

In presented bars type A & C, horizontal force P has not giving any torsion. In result in Table x torsions were equal zero. Therefore, in Table 22, below are shown

e.g. single- and multi-layer bar coverings: flat, different vaults and domes, too. So, future works should be related to such structures.

The second domain of planned comparative calculations, using as a basis presented above geometrical characteristics, is instability of composite bars under combined external loading. It was proved by author together with J.Tolksdorf, that in such situations we

can determine certain “critical surface” dependent in general case on multi parameters.

7 CONCLUSIONS

For the reason of limited volume of this paper some essential information are only enclosed. Calculated shearing stresses were here omitted. The paper shows possibility to calculate for composite bars some parameters and quantities proper rather up to the moment for TWBs: shearing centre, warping of CS and warping stresses.

Table 22. Shearing stresses flow τ_o in particular tubes of CSs A and C [kN/cm].

Tube No	when $M_1 = 1$ & CS A kN/cm	when $M_1 = 1$ & CS C kN/cm
Tube 1	0.00284	0.005
Tube 2	0.00226	3.14E-5
Tube 3	0.00167	2.33E-5
Tube 4	0.00108	1.5E-5
Tube 5	0.00043	5.99E-6

It is shown, that in five cases on seven, appears strong torsion, which by traditional analyses will be not considered at all. In consequence appears significant warping stresses, which extremely modify image of resulting stresses. In this case the shapes of warping function, longitudinal displacements and σ_x are not limited by plane surface, but are rather a complicated surface, difficult to draw. Torsion in some cases generates concentration of stresses in selected corners of the particular CSs.

After calculation, it can be observed, that proposed approach to modeling of the bars for σ_x gives rather excellent results. In the case of shearing stresses in the moment, are some questions: method of calculation is much more complicated; especially calculation of τ_o is rather laborious; obtained results well describe torsion, but are rather fare from traditional. The last problem needs much more time for recognition and observation.

A method for reconstructing the shape of highly flexible, slender objects from distributed strain measurements

ABSTRACT: This paper presents a method for determining three-dimensional global displacement (for arbitrarily-sized deformation but "small" strain) of thin rod/tether-like structures from a limited set of scalar strain measurements. The approach is rooted in Cosserat rod theory with the adoption of a material-adapted reference frame and a localized linearization approach that facilitates an exact local basis function set for the displacement as well as the material frame evolution itself. The solution set is shown to be robust to potential singularities from vanishing bending and twisting angle derivatives and from vanishing measured strain. Validation of the approach is performed through comparison with finite element simulations of a tube-like structure subjected to arbitrary deformations. The average root mean square reconstruction error of 0.01%–1% of the total length, for reasonably low sensor counts. Analysis of error due to extraneous noise sources and boundary condition uncertainty shows how error scales with those effects. The algorithm involves relatively simple operations, the most complex of which is square matrix inversion, lending itself to potential low-power embeddable solutions for structural monitoring applications requiring shape reconstruction. Experimental verification will also be shown in the presentation accompanying this paper.

1 INTRODUCTION

There are a number of applications where it is desirable to monitor long, slender, highly flexible structures such as cables, tethers, long rods, or any such system which has one dimension's length scale dimension substantially greater than any other dimension's length scale. Such systems share the common kinematic behavior of arbitrarily large deformation (bending, twisting, rotating) while experiencing relatively small (linear, elastic) strain. Euler initiated the first formal study of such objects (the elastica), followed by more modern theories (Love 1909, Cosserat & Cosserat 2001, Bishop 1975, Reisner 1981, Langer & Singer 1996).

In the monitoring applications of interest, a common objective is to obtain the displacement of the these structures from distributed measurements of some kind, whether the measurements are acceleration (requiring integration), direct non-contact measures of displacement (such as with laser vibrometry), or indirectly through distributed local measures of a kinematically-related quantity, such as strain. This last approach comprises the scope of the present paper. The main challenge in this class of monitoring problems lies in obtaining a reasonable inverse model that converts a finite number of local strain measurements into global displacement estimations. For small displacements of certain structural models (beams, plates), classical theory can be directly inverted, but no such viable method currently exists for long, highly deformable objects. This paper presents a kinematic model rooted in Cosserat theory and introduces a material basis reference frame to describe the deformation more precisely in a way that measurable strain metrics are calculable from the theory. Then, under local linearization assumptions, the resulting displacement/material frame evolution equations are integrated in terms of the strain metrics to obtain global displacement. The approach is validated against several full finite element displacement simulations of a pipe undergoing arbitrarily large deflections in this paper, and validation against an experimental hose test bed will be presented at the conference accompanying this paper.

2 KINEMATIC MODEL

2.1 *Geometry, kinematics, and strain measure*

Figure 1 shows the relevant geometry. Under the assumption that the neutral axis of the object does not

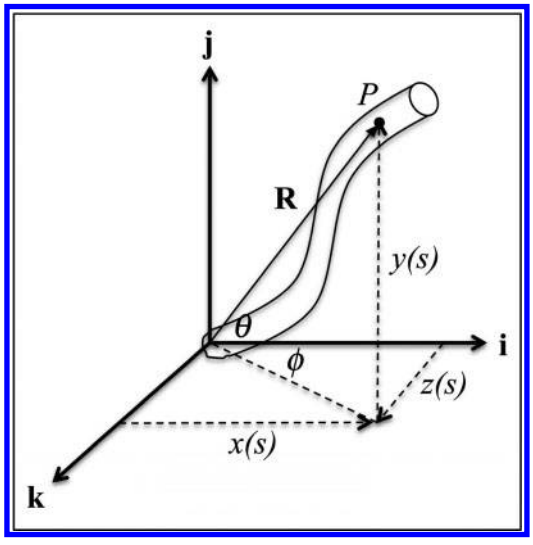

Figure 1. Fundamental geometry description of the deformed structure.

stretch appreciably, a point P on the neutral axis of the object in the deformed state may be located by the vector **R** in an inertial reference frame **i-j-k** by a pitch angle θ in the **i-j** plane and a yaw angle ϕ deviation from the **i-j** plane, each parameterized by the arc length variable s:

$$\mathbf{R}(s)=\underbrace{\left(\int_0^s \cos\theta(p)\cos\phi(p)\,dp\right)}_{x(s)}\mathbf{i}+\underbrace{\left(\int_0^s \sin\theta(p)\,dp\right)}_{y(s)}\mathbf{j}+\underbrace{\left(\int_0^s \cos\theta(p)\sin\phi(p)\,dp\right)}_{z(s)}\mathbf{k} \tag{1}$$

While the vector **R** may successfully locate P on the neutral axis through the two angle functions, it is insufficient in describing the material deformation about P, which is what generates strain. Recourse is made to a reference frame that somehow evolves with the deformed structure; one such common frame is the Frenet frame, consisting of a tangent **T**, normal **N**, and binormal **B** vector set. However, as Todd et al. (2013) discussed in earlier work, the Frenet frame suffers discontinuities, because it is not evolve according to the material's actual physical twisting and bending, but rather with the kinematic curvature and torsion. As a consequence, the Frenet frame **N** and **B** vectors can suddenly switch sign at inflection points, causing apparent (but not real) strain discontinuity in the model; since inflection points aren't known a priori, this is an undesirable restriction on use. Instead, a true material-referenced frame may be used by rotating the **N** and **B** vectors into **U** and **V** vectors through the actual local material rotation $\sigma(s)$. Figure 2 shows the relevant geometry at an arbitrary cross section, where the **U** and **V** vectors rotate with the material, and

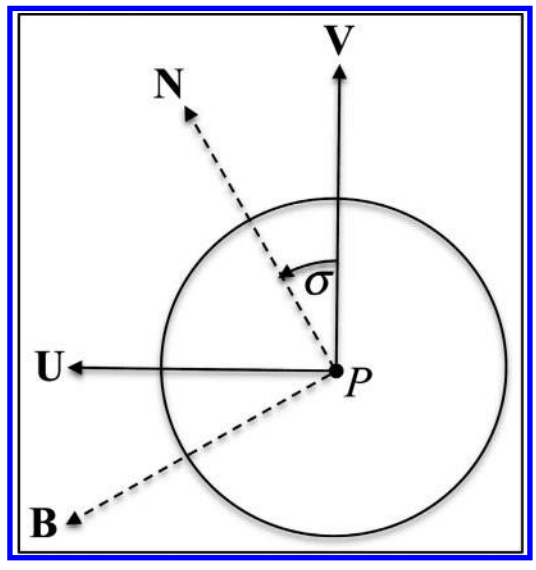

Figure 2. A material twist angle $\sigma(s)$ relating **N** and **B** vectors to material-referenced **U** and **V** vectors.

the difference between their current orientation and the Frenet frame orientation is $\sigma(s)$.

The same tangent vector **T** is retained; only the cross section is rotated, which is where the discontinuity potential is. This choice of material frame guarantees that the pitch angle θ defines the projection of **V** into **j**, or $\mathbf{V}\cdot\mathbf{j}=\cos\theta$. Using this definition and the Frenet-Serrat equations governing the Frenet frame evolution, a new set of equations may be derived for the material frame:

$$\begin{bmatrix}\mathbf{R}'\\ \mathbf{T}'\\ \mathbf{V}'\\ \mathbf{U}'\end{bmatrix}=\begin{bmatrix}0 & 1 & 0 & 0\\ 0 & 0 & \theta' & \phi'\cos\theta\\ 0 & -\theta' & 0 & -\phi'\sin\theta\\ 0 & -\phi'\cos\theta & \phi'\sin\theta & 0\end{bmatrix}\begin{bmatrix}\mathbf{R}\\ \mathbf{T}\\ \mathbf{V}\\ \mathbf{U}\end{bmatrix} \tag{2}$$

where a prime mark indicates differentiation with respect to s, and the relationships between material twist σ, traditional curvature κ, and torsion τ are given by

$$\begin{aligned}\kappa\sin\sigma&=\phi'\cos\theta\\ \kappa\cos\sigma&=\theta'\\ \sigma'&=\tau+\phi'\sin\theta\end{aligned} \tag{3}$$

The angles θ and ϕ clearly are embedded in the relationships. The last of Equations (3) shows the explicit relationship between material rotation rate and torsion; the two are not equal, and the additional term is what helps to accommodate discontinuities.

Figure 3 shows a representative curve with the **U**, **V**, **N**, and **B** vectors superimposed at several locations along it. At all inflection points, the Frenet (**N,B**) frame suddenly flips direction, while the material-referenced frame (**U,V**) smoothly follows material

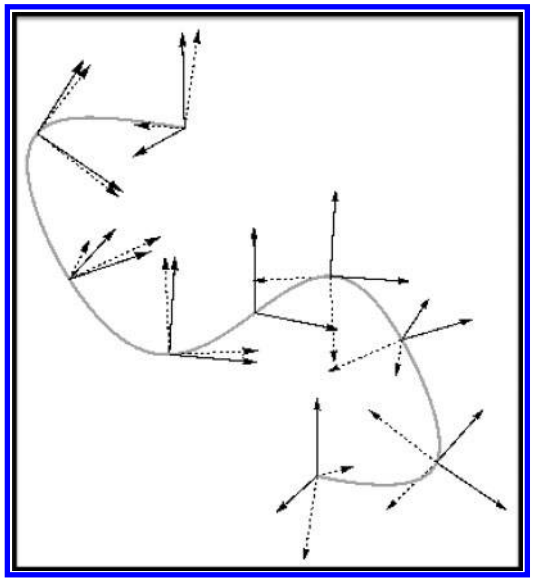

Figure 3. A curve showing the (**U**, **V**) frame (solid lines) and the (**N**, **B**) frame (dashed lines) as they evolve around the curve.

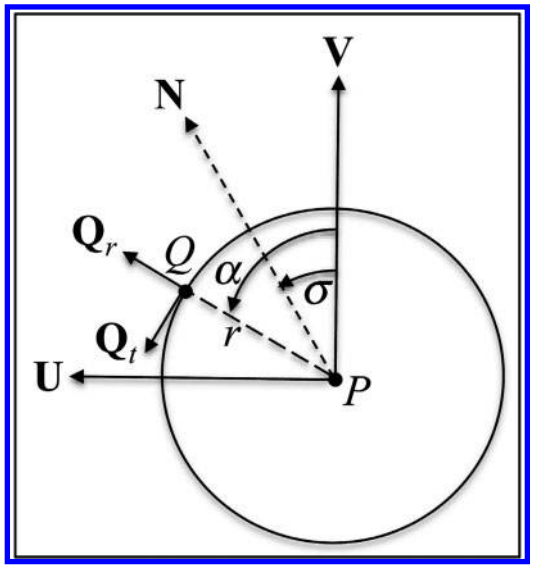

Figure 4. Cross-sectional geometry locating an arbitrary surface point Q for calculation of strain.

rotation. The Frenet frame leads to ambiguous (and thus indeterminate) strain measurements at such points of discontinuity.

Now a measure of strain may be computed from this kinematic model. Given the one-dimensional geometry of the class of objects under consideration, only strains due to changes in the s-coordinate are assumed non-negligible. Figure 4 shows the cross-sectional geometry at an arbitrary location s relative to the centerline point P and an arbitrary point on the surface of the object, Q. Since most strain measurements are obtained by a surface-mounted gage, the figure reflects this, although the theory doesn't require this; the radial distance r of the point Q relative to point P should be thought of as an arbitrary distance locating the strain point relative to P, oriented through the angle a relative to. The components of strain (the strain vector, since the rest of the components of the tensor in this formulation are zero) in the three directions **T**, **U**, and **V** may be computed by differentiating the vector locating Q relative to P:

$$\begin{aligned}\boldsymbol{\varepsilon} &= \mathbf{r}'_{Q/P} \\ &= \left(r\cos\alpha\mathbf{V} + r\sin\alpha\mathbf{U}\right)' \\ &= -r\alpha'\sin\alpha\mathbf{V} + r\cos\alpha\mathbf{V}' + r\alpha'\cos\alpha\mathbf{U} + r\sin\alpha\mathbf{U}' \\ &= \left(-r\cos\alpha\theta' - r\sin\alpha\phi'\cos\theta\right)\mathbf{T} \\ &\quad -r\sin\alpha\tau\mathbf{V} + r\cos\alpha\tau\mathbf{U} \\ &= \left(-r\cos\alpha\theta' - r\sin\alpha\phi'\cos\theta\right)\mathbf{T} + r\tau\mathbf{Q}_t\end{aligned} \tag{4}$$

where Equations (2) were used to substitute for the material frame derivatives and material continuity was imposed, i.e., changes in the location angle α must equal changes in material twist σ. For a surface-mounted strain gage at point Q, a more useful vector space is spanned by **T** (out of the page) and $\mathbf{Q}_t$, as shown in Figure 4. A gage can only be mounted in some orientation that is a combination of **T** and $\mathbf{Q}_t$ (radial direction mounting is impossible, obviously), so this transfer from (**U**,**V**) into ($\mathbf{Q}_r$,$\mathbf{Q}_t$) is represented in the final line of Equations (4).

Equation (4) is very easily interpreted in its final form, where the strain is clearly decomposed into bending strain (the **T** component) and torsional strain (the $\mathbf{Q}_t$ component). For a strain gage arbitrarily mounted, assuming an orientation angle μ from the **T** direction, the scalar strain expected at the point Q is given by

$$\begin{aligned}\varepsilon = &-r\cos\mu\cos\alpha\theta' - r\cos\mu\sin\alpha\phi'\cos\theta \\ &+r\sin\mu\tau\end{aligned} \tag{5}$$

Equation (5) is a very general model predicting the scalar strain that a surface-mounted gage would be expected to see, in terms of all the relevant kinematic parameters. The torsion τ has a highly complex, nonlinear relationship with the two angles (not explicitly shown here), so orientating a gage that is insensitive to torsion by choosing $\mu = 0$ would simplify Equation (5) to

$$\varepsilon = -r\cos\alpha\theta' - r\sin\alpha\phi'\cos\theta \tag{6}$$

As shown in the next subsection, this (final) model form, while still a nonlinear relationship between strain and kinematic displacement angles, nonetheless facilitates an approach that leads to a viable solution. Now that Equations (2) and (6) relate displacement and strain, respectively, to the kinematic variables, the solution will be proposed by combining multiple strain measurements at each cross section and local linearization.

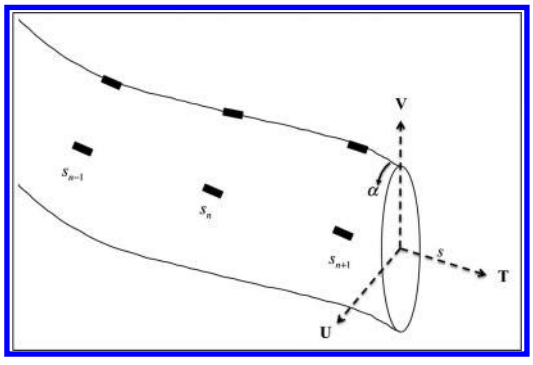

Figure 5. Assumed arrangement of discrete strain gages.

2.2 *Solution method*

The first assumption is that a finite set of discrete strain measurements is available from gages placed at locations $s = s_n$, $n = 1 \ldots N$, at multiple circumferential locations α_m, $m = 1 \ldots M$. The case of $M = 2$ is shown in Figure 5, which is the minimum number of circumferential independent readings required, as will now shown. From Equation (6), then, the strain at each gage is given by

$$\varepsilon_{n,m} = -r\cos\alpha_m \theta_n' - r\sin\alpha_m \phi_n' \cos\theta_n \tag{7}$$

and it is straightforward to show that at each cross sectional station n where two gages are located,

$$\begin{aligned} \frac{\sin\alpha_2 \varepsilon_{n,1} - \sin\alpha_1 \varepsilon_{n,2}}{\sin(\alpha_1 - \alpha_2)} &= r\theta_n' \equiv e_{n,1} \\ \frac{-\cos\alpha_2 \varepsilon_{n,1} + \cos\alpha_1 \varepsilon_{n,2}}{\sin(\alpha_1 - \alpha_2)} &= r\phi_n' \cos\theta_n \equiv e_{n,2} \end{aligned} \tag{8}$$

where it is clear that the two circumferential locations cannot be chosen 0 or π radians apart (across from each other). The second assumption made now is that, if the structure's curvature changes between from any location n to its nearest locations is small compared to the spacing between sensor locations, the strain is locally constant in the n-th so-called "neighborhood". This means the strain combinations $e_{n,1}$ and $e_{n,2}$ are constant, so the first of Equations (8) may be directly integrated to find

$$\begin{aligned} \theta_n &= a_n + (e_{n,1}/r)s \\ &\approx a_n + (e_{n,1}/r)s_n \end{aligned} \tag{9}$$

where a_n is a constant of integration, and the second line is a zero-order Taylor series approximation of θ_n about $s = s_n$, which will allow for Equations (2) to be solvable. So, with θ_n determined locally by Equation (9) and using Equations (8), the system of Equations (2), for the n-th cross-section, may be written

$$\begin{bmatrix} \mathbf{R}_n' \\ \mathbf{T}_n' \\ \mathbf{V}_n' \\ \mathbf{U}_n' \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & \frac{e_{n,1}}{r} & e_{n,2}/r \\ 0 & -\frac{e_{n,1}}{r} & 0 & -\frac{e_{n,2}}{r}\tan\theta_n \\ 0 & -\frac{e_{n,2}}{r} & \frac{e_{n,2}}{r}\tan\theta_n & 0 \end{bmatrix} \begin{bmatrix} \mathbf{R}_n \\ \mathbf{T}_n \\ \mathbf{V}_n \\ \mathbf{U}_n \end{bmatrix} \tag{10}$$

where everything in the matrix is a constant for that n-th cross section. Equations (10) may be solved exactly analytically, the solution in particular for the n-th displacement vector $\mathbf{R}_n(s)$ is given by

$$\begin{aligned} \mathbf{R}_n(s) = {} & \frac{\mathbf{c}_{n,2} r e_{n,1} + \mathbf{c}_{n,1} r e_{n,2} + \mathbf{c}_{n,4}\gamma_n^2}{\gamma_n^2} \\ & + \left(\frac{\delta_n e_{n,2}\left(-\mathbf{c}_{n,1} e_{n,1} + \left(\mathbf{c}_{n,2} + \delta_n \mathbf{c}_{n,3}\right) e_{n,2}\right)}{\gamma_n^2} \right) s \\ & + \left(\frac{\delta_n e_{n,2}\left(\mathbf{c}_{n,1} e_{n,1} - \mathbf{c}_{n,2} e_{n,2}\right) + \mathbf{c}_{n,3}\left(e_{n,1}^2 + e_{n,2}^2\right)}{\gamma_n^3} \right) r\sin\left(\frac{\gamma_n s}{r}\right) \\ & - \left(\frac{\mathbf{c}_{n,2} e_{n,1} + \mathbf{c}_{n,1} e_{n,2}}{\gamma_n^2} \right) r\cos\left(\frac{\gamma_n s}{r}\right) \end{aligned} \tag{11}$$

where the $\mathbf{c}_{n,j}$ are vector constants of integration and

$$\begin{aligned} \gamma_n &= \sqrt{e_{n,1}^2 + \left(1 + \delta_n^2\right) e_{n,2}^2} \\ \delta_n &= \tan\theta_n \end{aligned} \tag{12}$$

with θ_n given by Equation (9). Similar expressions are found for $\mathbf{T}_n$, $\mathbf{U}_n$, and $\mathbf{V}_n$.

The total number of unknowns in the solution, given by the combination of Equations (9), (11), and (12) is $13N$, with $12N$ coming from the three components of the four vector quantities and N more from θ_n. Table 1 summarizes all the continuity and boundary conditions imposed to make the solution unique. In general, continuity is imposed in each kinematic variable (the four vector quantities and θ_n) at each segment boundary, defined to be s_n* in the table, and five remaining boundary conditions are drawn from some combination of those five same variables. In general, the choice of s_n* is made to coincide with the midpoint between s_n and s_{n+1}, although the choice could be any value in that range.

With the problem now completely determined and unique, Equation (11) explicitly provides the Cartesian coordinates of the three-dimensional displacement of the structure at any point along it within a neighborhood of the n-th cross-section; these individual "local" solutions are just added over their respective ranges of validity using Heaviside functions $u()$ to obtain the global displacement for any s:

$$\mathbf{R}(s) = \sum_{n=1}^{N} \mathbf{R}_n(s)\left[u\left(s - s_{n-1}^*\right) - u\left(s - s_n^*\right)\right] \tag{13}$$

Table 1. Summary of constraints imposed to make solution unique.

Condition or constraint description	Number of imposed constraints
Continuity in $\mathbf{R}_n$: $\mathbf{R}_n = \mathbf{R}_{n+1}$ at some s_n*	$3N$-1
Continuity in $\mathbf{T}_n$: $\mathbf{T}_n = \mathbf{T}_{n+1}$ at some s_n*	$3N$-1
Continuity in $\mathbf{U}_n$: $\mathbf{U}_n = \mathbf{U}_{n+1}$ at some s_n*	$3N$-1
Continuity in $\mathbf{V}_n$: $\mathbf{V}_n = \mathbf{V}_{n+1}$ at some s_n*	$3N$-1
Continuity in θ_n: $\theta_n = \theta_{n+1}$ at some s_n*	N-1
Any five boundary conditions	5
TOTAL	$13N$

Close inspection of Equation (11) shows that a possible singularity might occur if both measured strains were zero, or $e_{n,1} = e_{n,2} = 0$. However, evaluating the limit of the solution in this condition reveals that

$$\lim_{e_{n,1},e_{n,2}\to 0} \mathbf{R}_n(s) = \mathbf{c}_{n,4} + \mathbf{c}_{n,3}s \tag{14}$$

which is a smooth, continuous result. Thus, in any practical algorithm, either Equation (11) or (14) would be used as the basis function selected for the displacement at each neighborhood n, depending on the tolerances of the measured strains to zero.

Finally, in the case of purely planar (two-dimensional) deformation, where $\tau = 0$ (and thus $\phi = 0$), the strain model reduces to

$$\varepsilon_{n,m} = -r\cos\alpha_m\theta'_n \tag{15}$$

Since the dependence upon ϕ is eliminated, technically only one strain reading is required at each cross section ($M = 1$). However, since it is not generally known a priori where the plane of bending is, it is advantageous to retain two strains at each cross and only computing the strain measure $e_{n,1}$ to ensure a more robust solution. If the plane of bending is known a priori, in contrast, then only a single strain is required, as $e_{n,1}$ is not needed, with the only constraint that it not be placed at a circumferential direction corresponding to the initial **B** direction. The planar bending simplification of Equation (11) is

$$\mathbf{R}_n(s) = \mathbf{c}_{n,4} + \mathbf{c}_{n,2}\frac{r\left(1-\cos\left(e_{n,1}s/r\right)\right)}{e_{n,1}} + \mathbf{c}_{n,3}\frac{r\sin\left(e_{n,1}s/r\right)}{e_{n,1}} \tag{16}$$

and this solution is also easily shown in the limit of vanishing $e_{n,1}$ to be Equation (14), so no singularities are present in the planar version either. Thus, the two-dimensional solution is a natural subset of the full three-dimensional version, and no separate theories distinguishing between the two classes of problems is required.

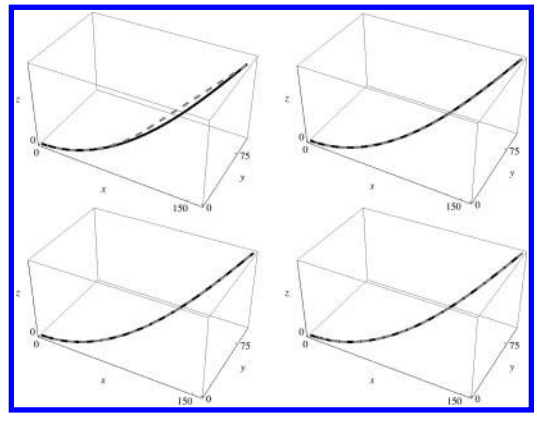

Figure 6. Comparison of exact finite element simulation (black solid line) and shape reconstruction approach (gray dashed line) of the first simulation shape, for, left-to-right then top-to-bottom, $N = 2, N = 5, N = 10$, and $N = 20$ sensor locations.

3 MODEL VALIDATION EXAMPLES

3.1 *Validation via finite element simulations*

The proposed model was validated by using finite element-based simulation of the large deformation of a hollow steel cylinder with a length of 212 m, inner diameter of 20 cm, and outer diameter of 30 cm. The material constants were chosen consistent with linear elastic theory, with a Young's modulus of 200 GPa and Poisson's ratio of 0.3. Abaqus S4R general-purpose shell elements were employed to model this structure, given their superior capability and computational efficiency in modeling large-scale bending and torsional behavior. Two three-dimensional deformations were simulated, and strains in the **T**-direction were retained at $\alpha = 0$ and π, each averaged over 1 cm of elements to simulate the average gage length of many types of strain gages.

Figure 6 shows the results for the first shape, which only contained one substantial change in curvature. The exact centerline of the hollow cylinder, as simulated by Abaqus, is shown as a solid black line, while the reconstructed shape from the algorithm presented in Section 2 is shown as a gray dashed line, for different numbers of sensor locations N. For this first shape, even for just N = 2 (4 total sensors), fairly good reconstruction is observed, with an average (over the total length) rms error of about 7 m (3% of the length); this error decreases quite rapidly, and for $N = 20$ (40 total sensors), the average rms error is only 1 mm. The spacing between each pair of sensors along s was chosen to be uniform over the 212 m (i.e., the spacing is about $212/N$ m).

Figure 7 shows results for a substantially more complex shape. This complexity inherently degrades detection performance compared to the previous test shape; the same sensor count will not result in the same reconstruction performance here. Nonetheless, with about 50 sensor locations, only a few cm of rms

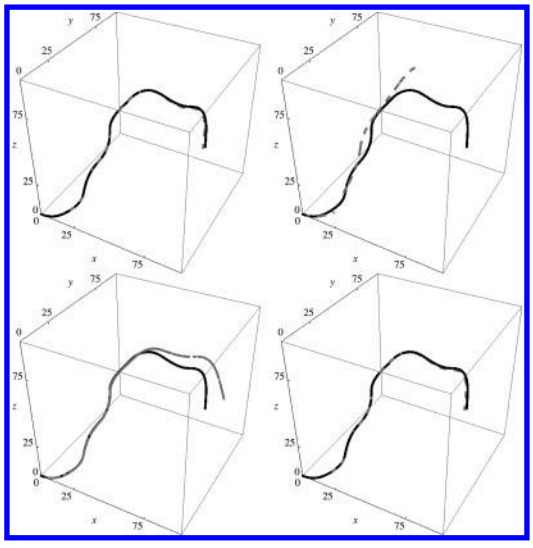

Figure 7. Comparison of exact finite element simulation (black solid line) and shape reconstruction approach (gray dashed line) of the second simulation shape, for, left-to-right then top-to-bottom, $N = 2$, $N = 5$, $N = 10$, and $N = 20$ sensor locations.

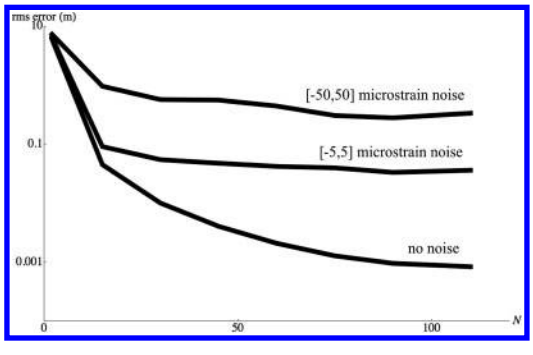

Figure 8. RMS error for the first simulation shape for various noise levels as a function of sensor locations N.

error—approximately 0.01% of the total length—is observed.

3.2 *Noise robustness*

In practical applications, the measurements of strain from a real sensor array contain noise, and additionally other sources of external uncertainty can corrupt the algorithm's performance. To address robustness, Monte Carlo simulations on both shapes were performed with uniform noise added at both the $[-5,5]$ microstrain and $[-50,50]$ microstrain levels. The resulting rms errors are shown, as a function of N, for the first shape in Figure 8 and the second in Figure 9. As expected, the reconstruction performance is degraded, although eventually the noise saturates the

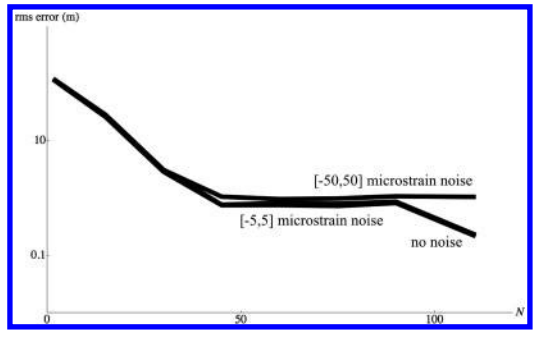

Figure 9. RMS error for the second simulation shape for various noise levels as a function of sensor locations N.

performance, as the error does not appear to decrease with additional sensors past a certain point.

4 SUMMARY AND ACKNOWLEDGEMENT

This paper proposed a method for obtaining the global three-dimensional displacement of rod-like from discrete strain measurements. The method is rooted in Cosserat rod theory using a material-adapted reference frame whose evolution equations are locally linearized in segments and subsequently solved analytically. The solution set was shown to be robust to singularities and was validated with two finite element models of a 212 m hollow steel tube undergoing significant three-dimensional deformation. Depending on the number of measurement points and shape complexity, average rms errors from tens of m down to a few mm were obtained. Preliminary noise tolerance studies showed the rms error trends with extraneous noise due to measurement uncertainty.

This work was performed under an Office of Naval Research (ONR) Small Business Technology Transfer (STTR) Program contract #N00014-10-C-0200.

Rod-in-tube buckling – Comparative analysis of numerical and test results

V.S. Tikhonov
Weatherford Int, Moscow, Russia

O.S. Bukashkina
Weatherford Int, St.-Petersburg, Russia

ABSTRACT: Buckling is considered to be a deleterious phenomenon because it can cause locking-up of a drillstring in a wellbore. Notwithstanding the numerous works devoted to numerical analysis and experimental investigations, the problem of buckling continues to be the urgent one. It is explained by the fact that the results of many numerical analysis correlate badly to the results of the laboratory experiments conducted with a rod-in-tube simulating drillstring in a wellbore. Present investigation tries to explain the character of these distinctive features on the basis of the improved dynamic model of a drillstring. The model includes effects of wellbore wall stiffness and multicomponent friction, it accounts for initial rod curvature and other factors. The analysis is made on the basis of the DYNTUB software, which allows carrying out numerical simulation of nonlinear 3D dynamics for long drillstring in the 3D well. The results of the laboratory experiments performed by McCann & Suryanarayana (1994) are used as the basis for comparison. The simplified analytical expressions developed in the paper to evaluate buckling loads are additional proofs of correct analysis. The results of the work allow to understand better the nature of buckling and to predict better the objectionable effects occurring in drilling.

1 INTRODUCTION

Buckling of compressed sections of the drillstring and coiled tubing is typical for horizontal and inclined intervals of wells at extended reach drilling. The buckling may lead to undesirable effects:

- Crooking of the well from the direction of drilling;
- Decreased axial load transferred to the bit up to the drillstring lockup;
- Failure of the drill pipes under action of bending moment at contact points of connectors with the wellbore wall.

The main areas of buckling investigation are related to development of analytical expressions to calculate buckling loads, numerical simulation methods and small-scale tests of the rod-in-tube samples modeling the drillstring in the wellbore. Their detailed overview was presented by Hajianmaleki et al. 2012. Despite numerous investigations in this area, there is still no understanding of the process behavior. It is in many ways due to inconsistency of the rod-in-tube test results. The actual rod behavior during buckling is strongly affected by such "fine" factors as friction, rod length, initial curvature, etc.

The paper describes these variables impact based on DYNTUB software analysis that simulates the time-domain dynamics of the drillstring (Tikhonov et al. 2006, Tikhonov & Safronov 2011). This software is efficient for simulating various drillstring operation regimes (Tikhonov et al. 2013). However its verification by comparison with the results obtained using conventional analytical expressions for critical sinusoidal and helical buckling forces (Wu & Juvkam-Wold 1993) and experimental data revealed rather poor accuracy. To understand the reason, DYNTUB software was specially upgraded to compare the simulation results with the rod-in-pipe buckling test results.

The comparison is based on the results of the laboratory experiments performed by McCann & Suryanarayana (1994). The authors obtained the rod-in-tube test results with high reproducibility. The paper was the first to recognize poor correlation of the common buckling loads formulae with experimental results and state one of the primary reasons of poor accuracy as neglecting the hoop component of the friction force. It is curious but long after the above paper had been published other researchers still failed to consider the friction force effects and kept on using the same formulae introduced by Dawson & Paslay (1984). Only 2–3 years ago Gao & Miska (2009, 2010) again paid attention to the friction phenomenon during buckling.

This paper provides a brief description of DYNTUB model and represents the results of numerical simulation for the compressed rod in horizontal tube analysis vs the friction factor, rod length and initial curvature. Comparative analysis of the numerical simulation and test results is carried out. The results are supported with simplified expressions for sinusoidal and helical buckling loads.

2 MATHEMATICAL MODEL OF THE ROD DYNAMICS

The detailed description of the mathematical model of drillstring dynamics in the 3D well was provided by Tikhonov et al. 2010. It is a set of equations for lateral, axial and torsional motion of the rod. The specified model was upgraded for the purpose of buckling test result analysis:

- The multicomponent friction model was improved;
- The bottomhole stiffness was introduced, which allowed to enhance the efficiency of the algorithm for the axial force acting on the rod at kinematic loading of the top end;
- The initial curvature of the rod was considered.

To describe the rod motion in the tube, introduce the righthand coordinate system *OXYZ* with *OX* axis connected with the tube center line and *OY* axis directed along the normal to the tube wall (Fig. 1). For straight-line tube, the equations of motion for the uniform rod in projections on *OXYZ* axes are as follows (Tikhonov et al. 2010):

$$m\ddot{x} = -Q' + f_x, \tag{1}$$

$$m^*\ddot{\mathbf{r}} = Q\mathbf{r}'' - EI(\mathbf{r}'' + j\boldsymbol{\kappa}_0)'' + j[M(\mathbf{r}'' + j\boldsymbol{\kappa}_0)]' + \mathbf{f}_\mathbf{n}, \tag{2}$$

$$\rho I_p \ddot{\Psi} = M' + \mu, \tag{3}$$

where $\mathbf{r} = y + jz$; x, y and z are projections of the rod center line onto *OX*, *OY* and *OZ,* respectively; m = rod mass per unit length; *AE*, *EI* and *GI p* are axial, bending and torsional stiffness of the rod; ρIp = moment of inertia relative to the rod axial line; $Q = AE(x' - 0.5|\mathbf{r}'|^2$ = axial compressive force; ψ = torsion angle; $M = GI_p\Psi'$ = torque; $\boldsymbol{\kappa}_\mathbf{0} = \kappa_{y0} + j\kappa_{z0}$, κ_{y0} and $j\kappa_{z0}$ are projections of the rod initial curvature vector $\boldsymbol{\kappa}_\mathbf{0}$ onto axes *OY* and *OZ*; $\mathbf{f_n} = fy + jf_z$; f_x, f_y and f_z are projections of the external force $\mathbf{f_n}$ per unit length onto axes *OX*, *OY* and *OZ*; μ = external torque per unit length; $j = (-1)^{1/2}$; the prime means a derivative with respect to rod arc length s, and the point is derivative with respect to time t; bold type means the complex variable (vector in *OYZ* plane), which real part is the vector projection on axis *OY*, and imaginary part is the projection on axis *OZ*.

Major components of external force$_\mathbf{f}\mathbf{n}$ include weight per unit length w, and vectors of normal contact force $\mathbf{p}$ and friction force $\mathbf{f_t}$ per unit length (Fig. 1).

Assume that the absolute value of p vector of the normal contact force $\mathbf{p}$ is determined by tube wall deformation $\Delta = \sqrt{y^2 + z^2} - \delta$ and $p(\Delta)$ dependence is quadratic-elastic (Fontaine et al. 2002), where δ = gap between the tube wall and the rod.

A multicomponent friction model was developed for the complex motion of the rod in the wellbore and axial movement with simultaneous rotation around mass center and wellbore center line, Tikhonov et al. (2012). Neglecting the force of rolling friction, represent the components of the sliding friction force as

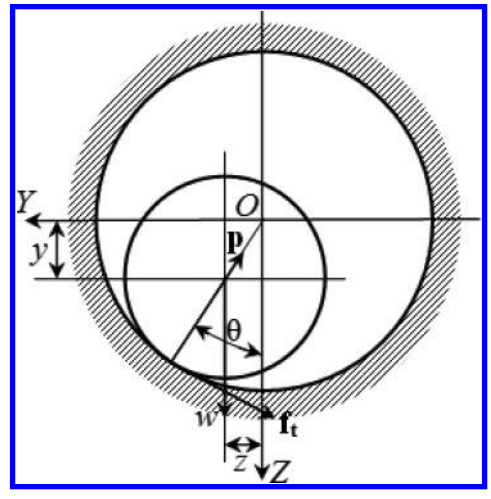

Figure 1. Coordinate system and external forces acting on the rod.

projections on axis *OX*, f_x and on the tangent to the wellbore wall in *OYZ* $\mathbf{f_t}$ plane:

$$f_x = k_a \frac{\dot{x}}{v}, \quad \mathbf{f_t} = k_\theta \frac{\mathbf{v_\theta}}{v}, \tag{4}$$

where k_a and k_θ are friction factors in axial and circumferential directions, respectively; $\mathbf{v_\theta}$ = vector of relative circumferential velocity of the rod, which absolute value is the ratio of the difference between the hoop velocities of the rod surface points relative to its center of mass and wellbore center line to their sum, $v_{\theta m}$; $v = \sqrt{\dot{x}^2 + (v_{\theta m}/\gamma)^2}$; γ = factor of transition zone width from sliding to rolling friction in the zone of low speed v_θ.

All the above considered, the external forces vector:

$$\mathbf{f_n} = w\sin\alpha - p\mathbf{r}/|\mathbf{r}|\left(1 - jk_\theta v_\theta / v\right), \tag{5}$$

where α = inclination angle of the tube axis relative to the vertical.

The boundary conditions for the Equations (1)–(3) are defined by the specified displacement of end points in the cross-sectional plane of the tube, fixity conditions (hinge/cantilever) as well as loading conditions at compression and torsion. Assume the following:

1) Rod compression is achieved under kinematic load of the top end with the specified velocity vg, $\dot{x}(L, t) = v_g(t)$, where L is the rod length;
2) The bottom end of the rod elastically supports on the bottomhole: $Q(0, t) = \lambda x(0, t)$, where λ = stiffness of the bottomhole;
3) The torque in the bottom end $M(0, t) = 0$;
4) The top end is fixed to prevent rotation: (in general rotating rod buckling case, the condition determining variation of angular velocity of the top end in time).

The solution method for the set of Equations (1)–(3) is described in detail by Tikhonov et al. (2010) and

consists in approximation of partial derivatives with respect to length s by finite differences and in integrating of the net set of ordinary differential equations derived in this way with the explicit scheme.

3 ANALYSIS OF NUMERICAL SIMULATION RESULTS

The results of the aluminium rod test in a horizontal wellbore performed by McCann & Suryanarayana (1994) were used as a basis for comparative analysis:

- Outer rod diameter = 6.3754 mm;
- Inner tube diameter = 38.15 mm;
- Rod length, $L = 3.683$ m;
- Hoop friction factor = 0.331;
- Loading speed = 0.1016 mm/sec.

The rod ends are fixed in hinges in the bottom surface of the tube.

Figure 2 shows load curves of the rod as the bottom load vs top displacement.

The curves marked with geometric figures are borrowed from McCann & Suryanarayana (1994) for eight different tests (as rescaled from inch-lbs to mm-N). The curve marked with a solid line was calculated by DYNTUB. For the largest part of the top distance range, the difference between the load curves does not exceed 15%. At the same time there is a rather large difference between the curves at the initial loading phase, correlating with elastic deformation of the rod. However, simple calculations demonstrate that the value of the theoretical slope of the curve in this phase,

$$\frac{\partial Q(L)}{\partial x_g} = \frac{AE}{L} = 6.067 \text{ N/m},$$

is far from the slope evaluated based on the test results and is close to the calculated value.

Upon completion of the elastic deformation phase, there is a transition from the straight-line to sinusoidal shape of the rod. According to the test data, the sinusoidal buckling load is 70 N and according to the numerical simulation results – 76 N. The conventional value of the sinusoidal buckling load by Dawson & Paslay (1984),

$$Q_{\sin} = 2\sqrt{\frac{EIw}{\delta}} = 35.7 \text{ N}, \quad (6)$$

is significantly lower than both these values. This formula derivation process does not consider friction.

The formula (A-7) for sinusoidal buckling load calculation with allowance for friction is given in the Appendix. In compliance with it, $Q_{\sin} = 59.6$ N at the friction factor of 0.331 (Fig. A-1). This formula has been derived for deduced buckling while the test was performed with $L = 3.683$ m rod close to the sinusoidal buckling $l = 3.228$ m. It is natural that in this case the boundary conditions will act the essential part for the rod shaping. This can be demonstrated by comparison of the load curves for L, $2L$, $3L$ and $4L$ rods (Fig. 3).

It is obvious that with increase of the rod length the sinusoidal buckling load tends to decrease reaching 53 N at the fourfold length of the rod. Periodic drops of the bottom load (points A, B1-B2, C1-C2-C3, the last is not shown) which occur with increase of top displacement, are typical for generation of successive turns of helix near the rod ends and propagating to its middle. With the minimum length of the rod, $L \sim l$, there is almost no drop of the bottom load. Immediately after helical buckling the rod assumes a spring shape and the bottom load is steadily growing. With increase of the rod length such growth settles only upon turns development along the whole length of the rod.

Note that in the process of turns generation the helical buckling load does not change much, it is within 59–64 N. For comparison, the helical buckling load by Dawson & Paslay (1984)

$$Q_{\text{hel}} = 2\sqrt{\frac{2EIw}{\delta}} = 50.5 \text{ N}. \quad (7)$$

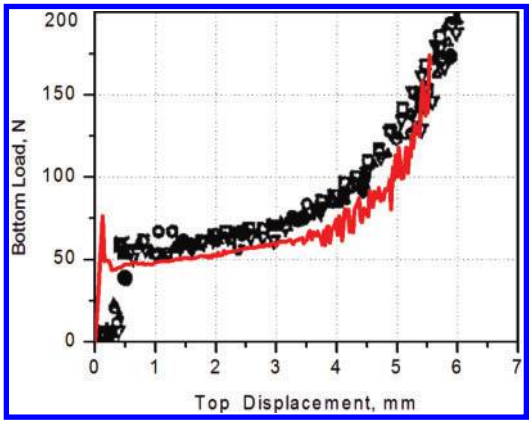

Figure 2. Experimental vs calculated load curves.

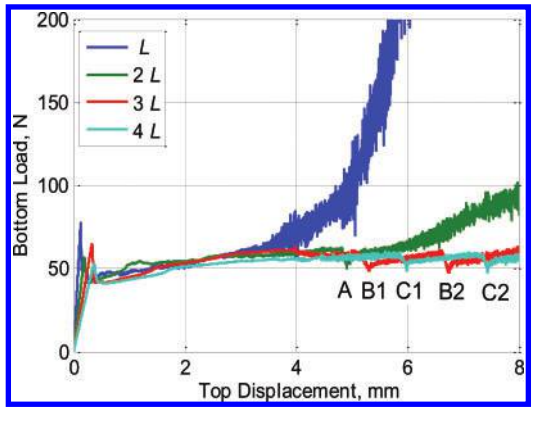

Figure 3. Influence of the rod length on the load curve.

Table 1. Comparative analysis of buckling loads for various rod lengths.

Buckling Load, N	Experiment (L)	Numerical simulation L	$2L$	$4L$	Formula
$Q_{\sin}$	70	76	57	53	60
Q_{hel}	79	79	63	59	51

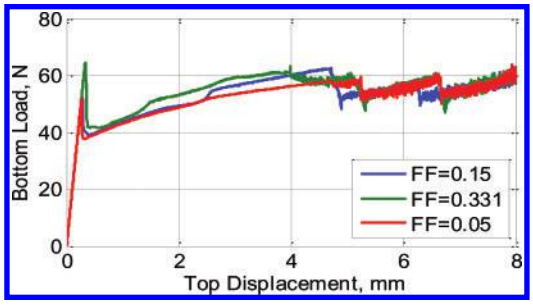

Figure 4. Influence of the friction factor on the load curve.

The results of the comparative analysis of the sinusoidal and helical buckling loads for various rod lengths at friction factor 0.331 are shown in the Table.

Figure 4 shows the load curves plotted for various friction factors of triple rod length, $3L$. It is obvious that with decrease of the friction factor the sinusoidal buckling load also decreases tending to the conventional value $Q_{\sin}$ (6). Meanwhile the helical buckling load remains almost constant.

In the investigation of the effect of the initial bending, the initial shape of the rod was given in the form of a sine wave:

$$z_0 = A \sin \frac{2\pi n s}{L},$$

where $A =$ amplitude of the sine; $n =$ the number of sine waves along the length of the rod. In this case $\kappa_{y0} = z_0''$, $\kappa_{z0} = 0$.

Figure 5 shows the load curve for the threefold length of the rod, $3L$, bent of the three sinusoids shape ($n = 3$) with the amplitude $A = 1$ mm.

As shown from Fig. 5, the initial bending significantly increases the sinusoidal buckling load. A similar effect was observed at a buckling of the straight-line rod in curved wellbore (Wu & Juvkam-Wold 1995).

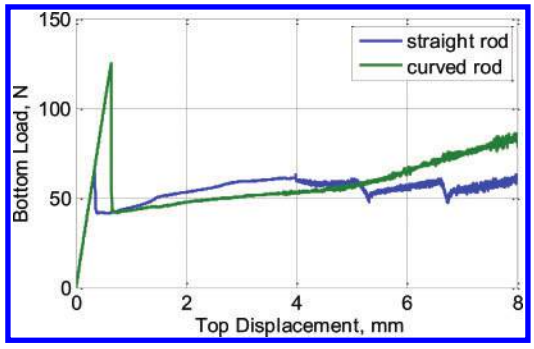

Figure 5. Influence of initial bending on the load curve.

4 CONCLUSIONS

1) The comparative analysis results confirmed DYNTUB software capability and feasibility for drillstring buckling analysis.
2) With increase of the friction factor, sinusoidal buckling load increases and helical buckling undergoes minor changes. As a result, with rather high friction factor, sinusoidal buckling load can exceed helical buckling load. This conclusion alters the existing understanding of sinusoidal and helical buckling relation.
3) The load curve character for rod buckling essentially depends on the rod length due to boundary conditions effect. It shall be considered when performing buckling experiments.
4) Subject to initial rod bending, sinusoidal buckling load increases and helical buckling load undergoes slight changes.
5) The derived simplified formulae of sinusoidal and helical buckling loads with allowance for friction can be used for improvement of buckling load values for practical drilling operations.

APPENDIX – DERIVATION OF FORMULAE FOR DEVELOPED BUCKLING WITH ALLOWANCE FOR FRICTION

Assume that at the sinusoidal buckling, the rod rests on the bottom wall of the tube and bends in a shape of a sinusoid with the period, within which the compression force can be considered constant. Then according to the Langrange-Dirichlet theorem, any equilibrium rod bending shape can be determined subject to minimal energy functional with all possible movements, preset limitations of its buckling in the tube and boundary conditions. Total rode bending energy is composed of elastic bending energy, work of axial load, weight and friction force. In this case the energy functional can be represented as:

$$J_{\sin} = \int_0^l \left[\begin{array}{l} 0.5EI(y''^2 + z''^2) - 0.5Q(y'^2 + z'^2) \\ + w\sin\alpha(\delta - y) + k_\theta w\delta|\theta|\cos\theta \end{array} \right] ds, \quad \text{(A-1)}$$

where $\theta = \theta_0 \sin(2\pi x/l)$ is rod axis offset angle relative to vertical (Fig. 1); θ_0 = amplitude of sinusoid.

Coordinates y and z with sinusoidal buckling:

$$y = \delta\cos\theta, z = \delta\sin\theta. \quad \text{(A-2)}$$

With medium low values of the angle $\theta_0 < 1$ the Equations (A-2) can be approximately represented in the form of the series expansion:

$$y = \delta\left(1 - 0.5\theta_0^2 \sin^2\frac{2\pi x}{l}\right), z = \delta\theta_0 \sin\frac{2\pi x}{l}\left(1 - \frac{\theta_0^2}{6}\sin^2\frac{2\pi x}{l}\right). \quad \text{(A-3)}$$

Substituting y, z (A-3) as well as their derivatives in the Equation (A-1) and integrating, we'll get the expression for the rod energy functional with sinusoidal buckling:

$$J_{\sin} = \frac{EI\delta\pi^4\theta_0^2}{l^3}(4 + 3\theta_0^2) - \frac{Q\delta\pi^2\theta_0^2}{l} + 0.25wl\theta_0\left(\theta_0 + \frac{8k_\theta}{\pi}\right)\sin\alpha. \quad \text{(A-4)}$$

At the critical point of transition from the straight-line to sinusoidal rod shape $J_{\sin} = J_s$, where J_s = energy of the straight-line shape. It is obvious that $J_s = 0$, and $J_{\sin} = 0$ respectively. Then based on the Langrange-Dirichlet theorem, we'll get two conditions:

$$\frac{\partial J_{\sin}(Q,\theta_0,l)}{\partial\theta_0} = 0 \text{ (a)}, \frac{\partial J_{\sin}(Q,\theta_0,l)}{\partial l} = 0 \text{ (b)}, \quad \text{(A-5)}$$

Transformation of the system composed of three equations: $J_{\sin} = 0$ (A-4), (A-5a) и (A-5b) results in equation in angle $\theta 0$:

$$-4.5\mu\theta_0^4 + 3\theta_0^3 + 4\mu\theta_0^2 - 8\mu = 0, \quad \text{(A-6)}$$

where $\mu = 2k_\theta/\pi$.

The solution of the Equation (A-6) determines the angle θ_0 corresponding to the minimal energy of rod sinusoidal buckling. The determined θ_0 value can be used for calculation of sinusoidal buckling load with allowance for friction:

$$Q_{\sin} = k_{\sin}(\mu)\sqrt{\frac{EIw\sin\alpha}{\delta}}, \quad \text{(A-7)}$$

where the sinusoidal buckling factor is

$$k_{\sin} = \sqrt{\frac{(4 + 3\theta_0^2)[\theta_0 + \mu(4 - \theta_0^2)]}{\theta_0}}. \quad \text{(A-8)}$$

Without friction, $\mu = 0$, functional $J_{\sin}$ does not depend on angle θ_0 and factor $k_{\sin}$ (A-8) assumes a value of 2 similar to those derived by Dawson & Paslay (1984).

Sinusoid period

$$l = \pi\sqrt[4]{\frac{4EI\delta\theta_0(4 + 3\theta_0^2)}{w\left(\theta_0 + \frac{8\mu}{\pi}\right)}}. \quad \text{(A-9)}$$

Helical buckling energy:

$$J_{\text{hel}} = \int_0^\ell \left[\begin{array}{l} 0.5EI(y''^2 + z''^2) - 0.5Q(y'^2 + z'^2) \\ + w\sin\alpha(\delta - y) \end{array} \right] ds, \quad \text{(A-10)}$$

where $y = \delta\cos(2\pi x/\ell)$, $z = \delta\sin(2\pi x/\ell)$; ℓ – helix pitch.

At the critical point of transition from the sinusoidal to helical rod shape $J_{\text{hel}} = J_{\sin}$. Then, making expression $J_{\sin}$ (A-1) equal to J_{hel} (A-10), integrating and using conditions resulting from Langrange-Dirichlet theorem, similar to the above calculations we'll get the equation for angle θ_0 corresponding to

rod helical shape. The expression for helical buckling force with allowance for friction is as follows:

$$Q_{\text{hel}} = k_{\text{hel}}(\mu)\sqrt{\frac{EIw\sin\alpha}{\delta}}. \qquad \text{(A-11)}$$

The dependence of the sinusoidal and helical buckling coefficients, k_{sin} and k_{hel}, on the friction factor, μ, is shown in Figure A-1. It shall be noted that with increase of the friction factor the helical buckling coefficient k_{hel} decreases, and with $\mu > 0.139$ the helical buckling energy becomes lower than the sinusoidal buckling energy. In this case the helical buckling load will be lower than the sinusoidal buckling load.

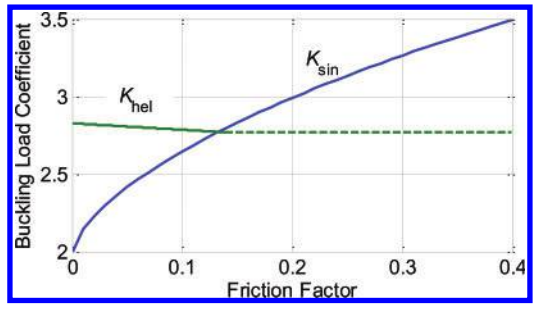

Figure A-1. Dependence of the sinusoidal and helical buckling coefficients on the friction factor.

On load drop phenomenon in axially compressed elasto-plastic columns

L. Kwasniewski
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The phenomenon of Finite-Disturbance Buckling instability (FDB), i.e. sudden critical load drop, is commonly associated with buckling of thin elastic cylindrical and spherical shells but rarely related with buckling of columns. Ziolkowski & Imielowski's (2011) recent experimental study, revealing appearance of FDB in aluminum columns with slenderness remaining within a specific range only, raises questions about its physical sources and mechanism. The present study is a continuation of the work of Kwasniewski & Ziolkowski (2013) which provided a theoretical explanation and quantitative evaluation on the phenomenon of finite-disturbance buckling of columns with rectangular cross-section made of linearly elastic-perfectly plastic material. Here an effort is focused on effects resulting from cycling loading and unloading performed in the post-buckling regime and generating residual stress distributions. The results from FE numerical simulations are compared with experimental evidence.

1 INTRODUCTION

Different post-buckling behavior scenarios are often attributed to specific classes of structures such as columns, shells or plates. The post-buckling response of structures has strong implications on their load carrying capacity, imperfection sensitivity, and structural safety and has an important bearing on today's design procedures.

Ziolkowski & Imielowski's (2011) recent experimental study, revealing appearance of FDB in aluminum columns with slenderness remaining within specific range only, raises questions about its physical sources and mechanism. The present study is the continuation of the work of Kwasniewski & Ziolkowski (2013) which provided a theoretical explanation and quantitative evaluation on the phenomenon of finite-disturbance buckling of columns undergoing elasto-plastic deformation and expressing itself in the form of critical load drop. A simplified, analytical model of buckling of linearly elastic-perfectly plastic column with rectangular cross-section was developed to explain the phenomenon of sudden load drop appearing in the columns with slenderness remaining in the neighborhood of critical slenderness, Kwasniewski & Ziolkowski (2013). The theoretical study was accompanied by a numerical investigation using finite element (FE) models built of brick and shell elements, dedicated for two selected FE code packages.

The present study is focused on effects of cycling loading and unloading performed in the post-buckling regime and generating residual stress distributions. The paper presents comparison of numerical results for the simplified problem defined in the previous paper for analytical consideration. The results of numerical studies are compared with experimental data. In the present study attention is focused on the effect of Return Point Memory (RPM) and the effect of generated residual stress distributions on the character of post-buckling equilibrium paths. Considered case was investigated numerically based on the FEM models formulated in the previous study of Kwasniewski & Ziolkowski (2013).

2 SIMPLIFIED COLUMN MODEL

2.1 *Idealized column*

The considered case refers to the theoretical example of idealized column with critical slenderness $\lambda = \lambda_0$, i.e. critical stress σ_{cr} is equal to the yield stress σ_Y. The problem was investigated analytically in Kwasniewski & Ziolkowski (2013) but without consideration of subsequent post-buckling loading and unloading stages. For this case a prismatic strut with a rectangular cross-section made of elastic–perfectly plastic material, is considered. The idealization is due to the material, which can be considered as a limit case for the materials with a clear plastic plateau and a small "knee" that is a small difference between the proportional and the yield limits, Galambos (1988). The present study is focused on analysis of the return point memory (RPM) and the effect of residual stresses on the equilibrium path, Gere & Goodno (2009). This is the case in which loss of strength will be greater than in real materials with a nonlinear stress-strain relationship and strain hardening, but the mechanism of the phenomenon will be the same, i.e., nonuniform increase of stresses in the cross-section due to simultaneous bending and axial loading within the inelastic range. Majority of

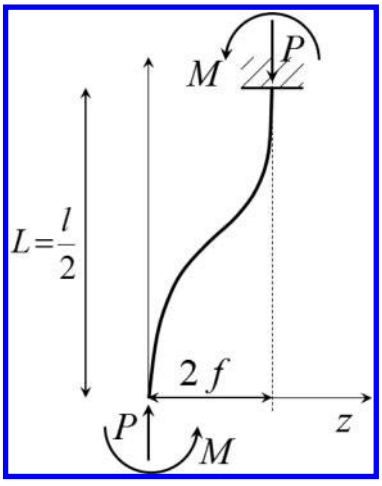

Figure 1. Schematic view of column deformation, boundary conditions and loading.

investigated problem parameters such as geometrical dimensions, loading conditions, material parameters values are taken the same as those identified for specimen tested by Ziolkowski & Imielowski's (2011). The only major difference is that instead of Ramberg-Osgood material model, linear elastic–perfectly plastic material model has been adopted with the bilinear characteristics of $\sigma-\varepsilon$ and with material data: yield stress $\sigma_Y = 189$ MPa, Young modulus E = 63300 MPa, Poisson ratio v = 0.45. Due to problem symmetry only half of the specimen has been considered in numerical simulations, Figure 1. The cross-section is rectangular with the following dimensions taken for numerical calculations: width b = 19.98 mm, height h = 5.88 mm, total length l = 195.18 mm. The applied boundary conditions result in column effective slenderness $\lambda = \lambda_0 = 57.49$ ($\sigma_{cr} = \sigma_Y$). The column maximum lateral deflection takes place in its middle height and is denoted by $2f$. It is assumed that the post-buckling bending results in linear distribution of strains in the column cross-sections, i.e. satisfies classical assumption on planar sections. In Kwasniewski & Ziolkowski (2013) two FEM models of buckling column were prepared one composed of shell and of solid elements. Subsequently relevant numerical tasks for one loading-unloading cycle have been solved using two FEM commercial codes ABAQUS, Abaqus (2007) and LS-DYNA®, Hallquist (2007).

The numerical results are compared with predictions of a simplified analytical model recalled succinctly in the next section of this work and with the experimental results.

2.2 *Simplified analytical model of FDB*

In order to understand essential features of FDB instability in columns a relatively simple analytical model of column buckling was formulated in Kwasniewski & Ziolkowski (2013). The key result predicted by this model, i.e. buckling and post-buckling equilibrium deformation path of a column exhibiting FDB is schematically presented in Figure 2. On x-axis of Figure 2 there are placed values of normalized axial contraction $\Delta l/\Delta l_{cr}$ of effective length of the column. The Δl_{cr} denotes the yield contraction, here corresponding also to Euler's buckling contraction ($\sigma_{cr} = \sigma_Y$). On y-axis there are values of normalized loading parameter σ/σ_Y, where $\sigma = P/A$; P is compressive loading force. In order to make the present paper self-contained, the simplified analytical model relations are presented succinctly below. At any moment and in any location of the column the axial force P and the bending moment M must satisfy global equilibrium equation, Figure 1

$$\mathrm{Pf} - \mathrm{M} = 0 \tag{1}$$

It is convenient to divide column post-buckling behavior into two phases of deformation. The phase I is characterized by condition $\sigma_2 \le 2\sigma_Y$, where σ_2 is the maximum negative tensile stresses increment due to bending, on the convex side of the middle cross-section. The moment M_I and axial force P_I, in the middle of the column, resulting from combined compression and bending, i.e. with asymmetric distribution of stresses in the cross-section, can be expressed as follows, Kwasniewski & Ziolkowski (2013)

$$P_I = \sigma_y bh - \frac{1}{2}\sigma_2 b\left(\frac{h}{2} + z_0\right) \tag{2}$$

$$M_I = \frac{1}{6}\sigma_2 b\left(\frac{h}{2} + z_0\right)(h - z_0) \tag{3}$$

z_0 denotes a distance from the cross-section centroid to the fiber undeformed by bending. Upon substitution of (2) and (3) into (1), it becomes

$$\sigma_y h 2f - \sigma_2 f\left(\frac{h}{2} + z_0\right) - \frac{1}{3}\sigma_2\left(\frac{h}{2} + z_0\right)(h - z_0) = 0 \tag{4}$$

At moderate lateral deflections, when the buckled column shape can be well approximated with sine function, σ_2 can be expressed as, Kwasniewski & Ziolkowski (2013)

$$\sigma_2 = \frac{\mathrm{E}\pi^2 \mathrm{f}}{\mathrm{L}^2}\left(\frac{\mathrm{h}}{2} + \mathrm{z}_0\right) \tag{5}$$

One can determine z_0 as a function of lateral deflection f, by solving constraint relation (4) after replacing σ_2 with the aid of (5). Subsequently $\mathrm{P_I}$ and $\mathrm{M_I}$ can be expressed in terms of f. In the present study, the most unfavorable material characteristic is considered, regarding FDB instability. When column is made of material exhibiting strain hardening (e.g. aluminum), the additional bending strength can origin from stress increase in a part of the cross section already in plastic range of deformation. Thus axial load drop will be smaller in such a case.

The phase II begins, when the value of stress σ_2 is equal or greater than $2\sigma_Y$. Then, the axial force P_{II} and the moment M_{II} in the middle of the buckling column can be expressed as, Kwasniewski & Ziolkowski (2013)

$$P_{II} = \sigma_y bh - \frac{\sigma_2 b}{2}\left(\frac{h}{2}+z_0\right) + \frac{(\sigma_2 - 2\sigma_y)b}{2}\left(\frac{h}{2}-z_1\right) \tag{6}$$

$$M_{II} = \frac{\sigma_2 b}{6}\left(\frac{h}{2}+z_0\right)(h-z_0) - \frac{\sigma_2 - 2\sigma_y}{6} b\left(\frac{h}{2}-z_1\right)(h+z_1) \tag{7}$$

where z_1 denotes a distance of a fiber, closest to the cross-section centroid in which tensile stress increment reached $2\sigma_Y$. The following relation must be satisfied upon the assumption of flat cross sections in bending, Kwasniewski & Ziolkowski (2013)

$$z_1 = \frac{2\sigma_y}{\sigma_2}\left(\frac{h}{2}+z_0\right) - z_0. \tag{8}$$

The value of z_0 as a function of lateral deflection f in the phase II of buckling deformation can be determined, by solving equilibrium equation (1) after substituting into it (6), (7), and (8).

The strut tracing subsequent equilibrium states, i.e. subjected to ideal constraints, changes its length at the time of buckling, as the result of interaction between two effects. On the one hand, there is a reduction of the distance between the end cross-sections (the chord) caused by bending (treated as positive), and calculated from the known formula, Timoshenko & Gere (1961), valid for small deflections

$$2\Delta l_1 = 2\int_0^L L\left(\frac{dz}{dy}\right)^2 dy \tag{9}$$

where L denotes the effective length of the column. On the other hand, an opposite effect takes place in the form of (negative) growth of the total fiber length. In the case considered here, because of the symmetry, both the upper and the middle cross-sections (see Fig. 1) remain in a horizontal position, and all the fibers change their lengths in the same way. Distribution of the strain along the length of a selected fiber is not uniform, for the strain increments at the ends of the fibers (for a half of the bar) are different because of the shift of the rotation axis. In the case of elastic buckling, the rotation axis keeps the centroid position, the strain distribution is asymmetrical, and the fiber elongation due to bowing does not take place. This change of the fiber's length (negative for extension) was approximated in Kwasniewski & Ziolkowski (2013) by

$$2\Delta l_2 = -2\int_0^L \epsilon_m dy = -\frac{2z_0 L\epsilon_2}{\left(\frac{h}{2}+z_0\right)}. \tag{10}$$

where ϵ_2 is the absolute value of the maximum tensile strain (increment). The mean strain is different from zero and is

$$\epsilon_m = \frac{\epsilon_U + \epsilon_M}{2} = \frac{z_0}{\left(\frac{h}{2}+z_0\right)}\epsilon_2. \tag{11}$$

where ϵ_U and ϵ_M are strains at the fiber ends, in the upper and middle cross-sections respectively. In the case of sine approximation for deformed axis, the shortening of the column along the y-axis can be expressed with the formula

$$2\Delta l = 2\Delta l_1 + 2\Delta l_2 = \frac{\pi^2 f^2}{L} - \frac{4\pi^2 f z_0}{L}. \tag{12}$$

Closed form solutions for P_I, P_{II}, M_I, M_{II} are unavailable to the author, hence in order to reach some tangible results, computer program MathCAD was used to effectively determine solutions of nonlinear constraint relations in phase I and II. Results of this computation in the form of equilibrium path of buckling column are shown in Figure 2. They very clearly illustrate the source and the essence of FBD instability. The point P_{12} in Figure 2 indicates a transition between Phase I and II, as defined previously. The 40% load drop, marked in Figure 2 as a difference between P_{crU} and P_{crD}, can be considered as a sort of limiting case, as columns with the same geometry but made of material with strain hardening exhibits lesser drop. The phenomenon of FDB in the considered simplified case is associated with three effects occurring simultaneously, Kwasniewski & Ziolkowski (2013). These are the post-buckling load drop accompanied by the rod's elongation, and the contraction due to bowing in the first post-buckling phase, just after buckling. The load drop is due to the unsymmetrical distribution of strain increments caused by buckling (bowing) in plastified regions represented by middle and end cross-sections for a fixed column. Unsymmetrical means that the rotation axis is not in the centroid position. The load drop is directly caused by nonuniform stress distribution in the cross-section, magnified by perfect plasticity, which does not allow for positive (compressive) stress increments (when $\lambda = \lambda_0$). The asymmetry of strain distribution in the (middle and end) characteristic cross-sections also causes unbalanced strain variation along the fibers, with negative (elongation) average strain and total fiber elongation. This effect is accompanied by the cord contraction due to bending of the axis. The cord contraction is nonlinearly dependent on the magnitude of the axis deformation and dominates for larger deflection when the bar's overall chord shortens. Therefore, after buckling, a rod equipped with the ideal restrains allowing the adoption of successive positions of equilibrium, would experience a simultaneous decrease in strength (axial load drop) and a reduction of shortening (elongation). This behavior is reflected by a specific shape of the secondary equilibrium path with negative increments of both, the

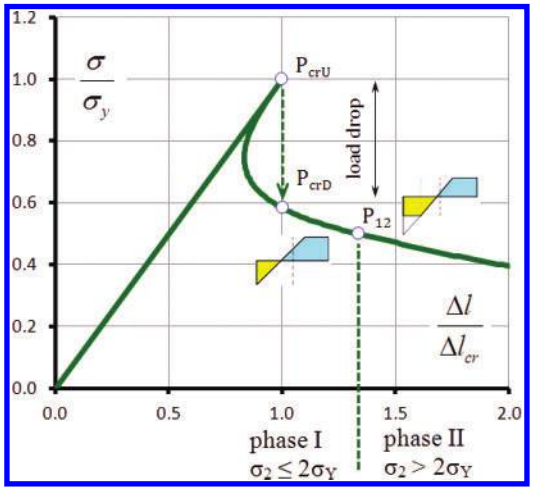

Figure 2. Equilibrium path for an ideal column with intermediate slenderness, Kwasniewski & Ziolkowski (2013).

load and the vertical displacement (captured by analytical and ABAQUS solutions), Figure 2. The load drop is indicated by the ordinate difference between two points P_{crU} and P_{crD}, representing two equilibrium states, for the strait and deflected bar. The equilibrium state represented by P_{crD} refers to the situation where both mentioned before effects: shortening of the chord and elongation of fibers, are balanced so the distance between characteristic cross-sections, upper and middle, is the same as at the critical state depicted by P_{crU}. The arrow between points P_{crU} and P_{crD} show a transition experienced during an experiment controlled by displacement.

2.3 *FE models*

Figure 3 shows FE model built of solid elements, applied in the calculations using LS-DYNA code. Numerical model represents only upper half of the column. The imposed boundary conditions reflect fixing conditions present during actual buckling experiments and symmetry of the investigated problem. The load was applied as a forced vertical displacement of the upper end. In the sequel of this study LS-DYNA code computations were performed employing solver with implicit solution algorithm (BFGS) dedicated for static analyses, Hallquist (2007). A variant case of basic buckling problem was examined with geometrical imperfection in the form of a small initial curvature defined by a sine function with the maximum amplitude of 0.001 mm (on both sides in the direction of buckling).

2.4 *Loading vs. unloading*

Figure 4 shows equilibrium paths obtained using FE solid model and LS-DYNA calculations for the considered simplified column with critical slenderness. The loading is applied as a prescribed displacement of the

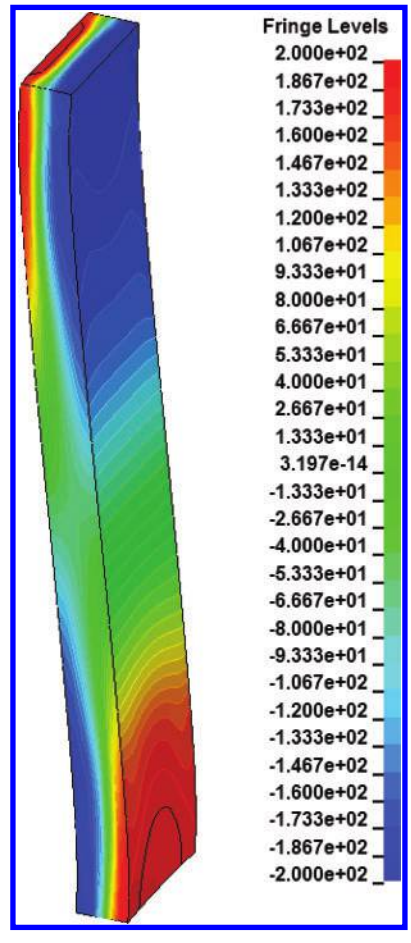

Figure 3. Contours of normal stress for the phase II deformation. FE solid element model.

upper end. The regular loading is accompanied by two unloading steps, identified with the numbers 1 and 3 in Figure 4 and followed by repeated loading marked as steps 2 and 4. The unloading is performed until the original length of the strut is reached so it covers also tensioning, leading to generation of additional residual stress. As it can be seen from Figure 4 the repeated loading (steps 2 and 4) follow different paths than unloading (steps 1 and 3), creating typical hysteresis loops, but the meeting points on the principal equilibrium path, identified as return point memory RPM1 and RPM2, are the same for loading and unloading paths. After reaching the RPM the behavior of the strut follows the principal equilibrium path until the prescribed displacement is reduced again.

Figure 5 shows normal stress and Figure 6 effective plastic strain distributions for four selected equilibrium states, three marked with triangles at the paths presented in Figure 4, and forth corresponding to RPM1. Figures 5 and 6 depict evolution of plastic regions in the vicinity of upper and middle cross-sections, where bending due to buckling is the largest.

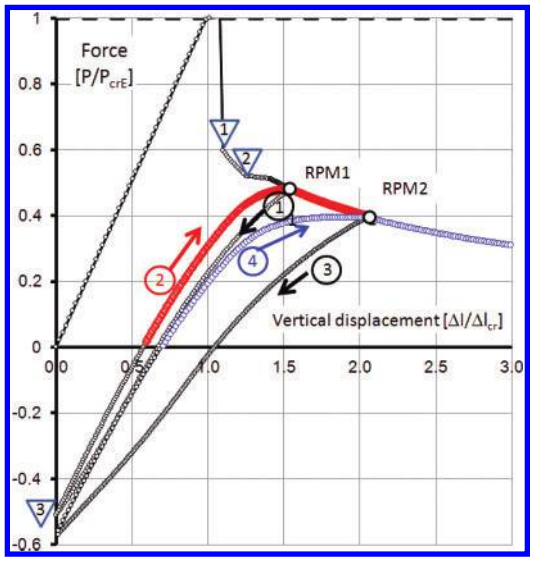

Figure 4. Equilibrium paths for alternate loading and unloading, obtained using FE solid model and LS-DYNA calculations.

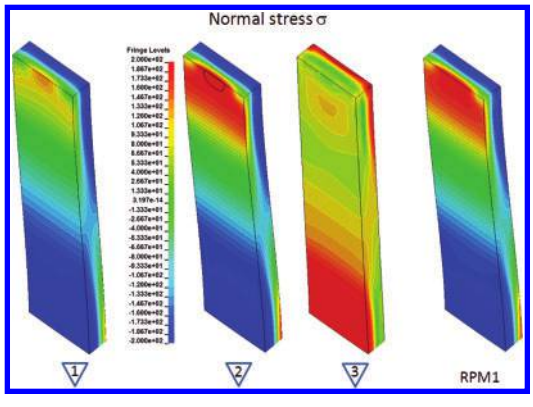

Figure 5. Contours of normal stress for four selected equilibrium states indicated in Figure 4.

There is also visible variation of normal stress distribution in both cross-sections during successive loading and unloading. Presented numerical results for 3D FE models provide a good complement to the experimental data and give a good insight in the mechanism of considered FDB phenomenon.

Figure 7 shows two selected segments of equilibrium paths presented in Figure 4 for repeated loading steps 2 and 4. Only segments for compression are shown, starting from the state for which P = 0. Additionally, the curves are translated to the origin of the coordinate system to represent a potential compressive test on a column which before the test was subjected to successive loading and unloading, reaching beyond the elastic range. Such a column possesses some permanent deformation and self-equilibrated residual stresses. Thus it can be stated that the curves shown in Figure 7 depict a performance of a column with

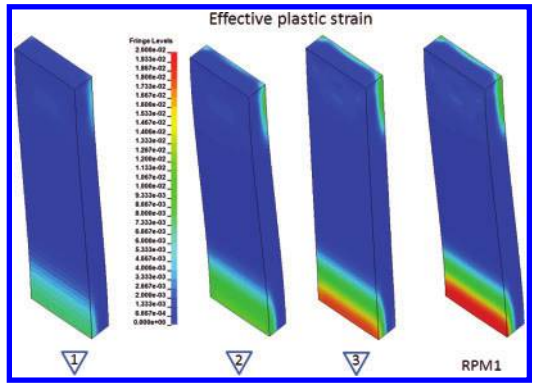

Figure 6. Contours of effective plastic strain for four selected equilibrium points indicated in Figure 4.

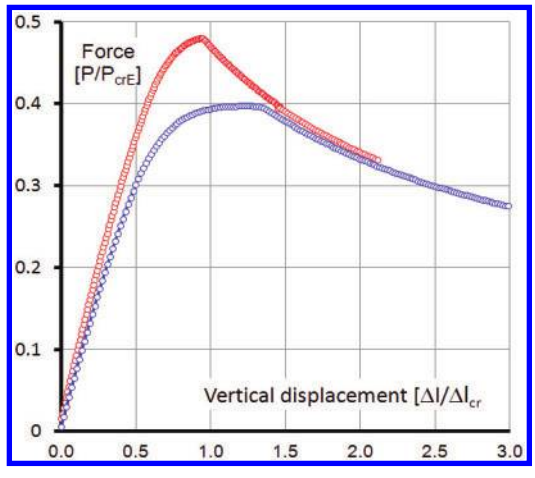

Figure 7. Segments of equilibrium paths for alternate loading and unloading, obtained using FE solid model and LS-DYNA calculations.

imperfection and residual stresses, during a compressive test. The difference between curves in Figure 7 comes from different loading history resulting in the different level of residual stress.

Due to assumed material model and because of the extensive unloading reaching to the original length of the column, the considered case is extreme. In real columns such large reduction of critical loading is rear.

3 COMPARISON WITH EXPERIMENT

Qualitative comparison of the numerical results with experimental data is presented in Figure 8. The experimental data was obtained by Ziolkowski & Imielowski's (2011) for an aluminum column with slenderness $\lambda = 53$. Except the length, the actual column differ from the numerical FE model mainly in terms of material which shows strain hardening and nonlinear transition between elastic and plastic ranges. Even though compared cases differ and additionally

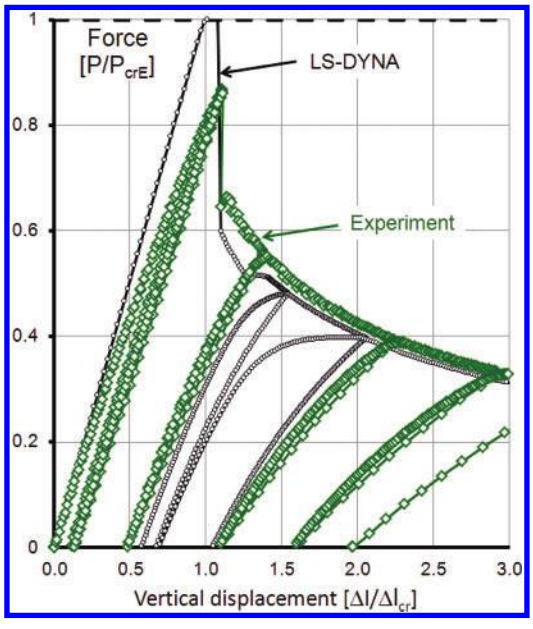

Figure 8. Comparison of equilibrium paths for numerical and experimental data Ziolkowski & Imielowski's (2011).

the experimental data is subjected to some uncertainties, both curves in Figure 8 show many similarities. The main difference is for pre-buckling phase, where the actual column shows bigger reduction of critical loading and also more nonlinear behavior comparing to the performance of the ideal FE model.

4 SUMMARY

Besides imperfection the effect of residual stress is recognized as one of the main features reducing critical loading of actual columns. Even though residual stresses can have many different sources, such as manufacturing, their quantitative effect on compressive behavior maybe similar as it is in the case of imperfections. The residual stress reduces critical loading and leads to more nonlinear response in the pre-buckling phase. To analyze this phenomenon quantitatively, first they have to be included in the computational model. The theoretical residual stress distribution is well known for beams with simple cross-sections, subjected to elastic-plastic bending. In the cases considered here residual stresses are generated through successive loading – unloading, reaching tension. The results were obtained using FE model built of solid elements which enable tracing stress and strain distributions through the column's cross-section. The numerical results were partially verified and validated. The verification was performed through comparison with analytical solutions for loading phase. The validation included quantitative comparison with experimental data for an actual column with similar characteristics. Presented methodology shows potential for further qualitative investigation of effects of residual stress on buckling of metal columns.

ACKNOWLEDGEMENTS

The author wishes to thank Andrzej Ziolkowski D.Sc. for making available the experimental results, presented in the paper. These results were obtained as a part of the research project supported by Polish Ministry of Science and Higher Education, Grant PB N50104131/2765 "The analysis of critical and post-critical states of structures under conservative and non-conservative loads. Experimental and theoretical investigation, verification of existing design codes".

ABSTRACT: This paper reformulates the governing equations of an extensible elastic rod by reference to a given spatial curve. This Eulerian formulation is motivated by the need to solve efficiently the constrained elastica problem encountered in many medical and engineering applications, in which a thin rod is inserted in a tortuous conduit. The Eulerian reformulation of the equations hinges on the restatement of the rod local equilibrium in terms of derivatives with respect to the curvilinear coordinate associated with the reference curve and the description of the rod deflection as a perturbation of this curve. The originality of the proposed formulation lays in the axially unconstrained character of the resulting system such that the determination of the rod configuration between two fixed points reduces to the resolution of a classical boundary value problem.

1 INTRODUCTION

The general problem of a slender elastic body constrained to deform inside a straight or sinuous conduit is widely encountered in medical and engineering applications. Examples include the insertion of miniature instruments into blood vessels for the treatment of vascular and cerebrovascular pathologies (e.g. abdominal and thoracic aortic aneurism, stroke) as well as the endoscopic examination of internal organs (e.g. colonoscopy, fibroscopy, rhinoscopy), see for instance Schneider (2003). Another application concerns the petroleum industry which relies on several kilometers long drillstrings to transmit the axial force and torque necessary to drill the rock formations and reach deep hydrocarbon reservoirs (Inglis 1988, Sampaio 2008). The assessment of the energy loss along the drill string, known as the *torque and drag problem*, plays an essential role in drilling and well design as the friction appearing at the contacts between the drillstring and the borehole may dramatically increase the costs or, even, be a limiting factor in some configurations (Mason and Chen 2007). The identification of the number of contacts between the rod and the conduit (e.g. blood vessel or borehole) as well as their position and extent constitutes the central concern of this relatively broad class of problems. The nonlinearities associated with the large deflection of the rod and the unilateral contact condition as well as the *a priori* unknown number of contacts, however, make the use of conventional numerical tools rather inefficient. Additionally, the commonly adopted division of the problem in rod segments bounded by two contacts (Chen & Li 2007, Denoël 2008) requires to solve the governing equations on domains which are initially unknown and, therefore, leads to the establishment of integral constraints on the unknown length of a rod forced to go through fixed points in space. Finally, the assessment of the unilateral contact condition, which requires in principle the comparison of two curves parametrized by distinct curvilinear coordinates (e.g. the rod centroid and the conduit axis), prove to be a rather intensive computational task.

To circumvent the above-mentioned difficulties, an Eulerian reformulation of the rod governing equations is proposed and the strategy initiated by Denoël & Detournay (2011) for the planar elastica is generalized to three-dimensional configurations and extensible rods. Modeling the elastic body by means of the special Cosserat rod theory, its deflection is described as a perturbation of a reference curve (e.g. the conduit axis) while the rod local equilibrium is formulated within the Eulerian reference frame associated with this curve. Consequently, the determination of the rod configuration between two adjacent contacts reduces to the resolution of a classical boundary value problem for which, in addition to the axial components of the internal force and moment at one end, the rod

eccentricity as well as its inclination with respect to the reference curve are prescribed at both extremities of the domain.

The originality of the proposed formulation lays in the axially unconstrained character of the resulting system. Indeed, as the reference curve is substituted for the domain of the problem, the unstressed length of the rod is not prescribed and, therefore, freely evolves as a result of the loading. This particular aspect is encountered in various additional applications in which the length of the domain is *a priori* unknown or susceptible to self-adjustment such as the continuous casting process, the extrusion of plastic through a draw plate or the laying of cables and pipelines. We will refer to the ability of the proposed method to handle this particular class of axially unconstrained problems, as *self-feeding*.

2 PROBLEM DEFINITION & GOVERNING EQUATIONS

The canonical problem considered in this paper consists in the determination of the deformed configuration adopted by an extensible rod forced to go through two fixed points in space and subjected to a known external loading (e.g. weight, applied torque and tension at an extremity). Consequently, the length of the rod, which satisfies the boundary conditions and is in equilibrium with the external loading, is unknown.

To solve this problem, let us define the right-handed orthonormal basis $\{e_k\}$ for the Euclidean space $\mathbb{E}^3$ and denote by $R(S) = X_k\, e_k$ the position vector of the point lying on the reference curve $\mathscr{C}$ at S. The arc-length parameter S, referred to as the Eulerian coordinate, identifies a *section* along $\mathscr{C}$ which consists of all points whose reference positions are on the plane perpendicular to the reference curve at S. For the sake of clarity, the parametrization of this curve is assumed to be natural such that $\mathscr{C}$ is said to be unit-speed (Pressley 2010).

Having defined the global $\{e_k\}$–basis, the position vector of the rod cross section centroid with curvilinear coordinate s is denoted by $r(s) = x_k\, e_k$. The parameter s, which is referred to as the (natural) Lagrangian coordinate in contrast to the Eulerian coordinate S, identifies the rod cross section in its unstressed configuration $r^0(s)$. To fully characterize the spatial configuration of the rod, one has to additionally supply this space curve $\mathscr{E}$ with a pair of orthonormal vectors $d_1(s)$, $d_2(s)$ characterizing the configuration of a pair of orthogonal material lines of the section (Antman 2005). The rod is therefore entirely defined by the three-vector valued functions

$$[s_a, s_b] \ni s \mapsto \boldsymbol{r}(s),\, \boldsymbol{d}_1(s),\, \boldsymbol{d}_2(s) \in \mathbb{E}^3 \tag{1}$$

with $s = s_a$ corresponding to the origin of the canonical problem located at $S = S_a$, and $s = s_b$ corresponding to its extremity located at $S = S_b$, see Figure 1(a).

The cross section orientation is then naturally described by its normal $d_3(s) = d_1 \times d_2$ such that the resulting triplet of *directors* $\{d_k(s)\}$ constitutes a right-handed orthonormal basis for $\mathbb{E}^3$ for each cross section s. The rod change of shape is measured by the twist and stretch vectors, $u = u_k\, d_k$ and $v = v_k\, d_k$, which are defined as

$$\mathrm{d}_s \boldsymbol{d}_k = \boldsymbol{u} \times \boldsymbol{d}_k \qquad \mathrm{d}_s \boldsymbol{r} = \boldsymbol{v} \tag{2}$$

respectively. Their components in the directors basis, u_k and v_k, are referred to as strain variables.

Considering only local interactions between adjacent cross sections of the rod and defining the internal force $F(s) = F_k\, d_k$ and moment $M(s) = M_k\, d_k$, the conservation of linear and angular momenta yields (Antman 2005)

$$\mathrm{d}_s \boldsymbol{F} + \boldsymbol{f} = 0 \tag{3}$$

$$\mathrm{d}_s \boldsymbol{M} + \mathrm{d}_s \boldsymbol{r} \times \boldsymbol{F} = 0 \tag{4}$$

where $f(s) = w\, e_3$ is the body force per unit reference length with w the rod specific weight.

For an unshearable rod of circular cross section made of linearly elastic material, the components of the internal force and moment are related to the strain variables by means of the following constitutive equations

$$\boldsymbol{M}(s) = EI\,(u_1\, \boldsymbol{d}_1 + u_2\, \boldsymbol{d}_2) + GJ\, u_3\, \boldsymbol{d}_3 \tag{5}$$

$$\boldsymbol{F}(s) = F_1\, \boldsymbol{d}_1 + F_2\, \boldsymbol{d}_2 + EA\,(\alpha - 1)\, \boldsymbol{d}_3 \tag{6}$$

with the bending stiffness EI, the torsional stiffness GJ and the axial stiffness EA. To close the formulation, one must additionally consider the material restraint $v(s) = \alpha\, d_3$ which expresses that the centroid tangent vector is aligned with the normal to the rod cross section and where the stretch $\alpha(s) > 0$.

2.1 *Parametrization of the rotation group SO(3)*

The use of six components for the directors d_1 and d_2 may appear clumsy since these components are subject to three orthonormality constraints. The introduction of unit quaternions to parametrize the three-dimensional rotation group $SO(3)$ is an alternative to the habitual Euler angles subject to gimbal lock (Kuipers 1999). It is motivated by the desire to resort to a regular representation of the rotation tensor.

According to Euler's rotation theorem, the orientation of the triplet of directors $\{d_k(s)\}$ can be defined by specifying its rotation about the unit axis of rotation a through the angle ω with respect to the global $\{e_k\}$–basis. The set $\{\omega, a\}$ can advantageously be replaced by the so-called quaternion $\mathbf{g}(s) = (g_0, g_1, g_2, g_3)^T$ with $\|\mathbf{g}\| = 1$ and whose components are defined as

$$g_0(s) = \cos(\omega/2) \qquad \boldsymbol{g}(s) = \sin(\omega/2)\, \boldsymbol{a} \tag{7}$$

(Kuipers 1999). Additionally to being regular, the quaternion components vary continuously as the orientation changes.

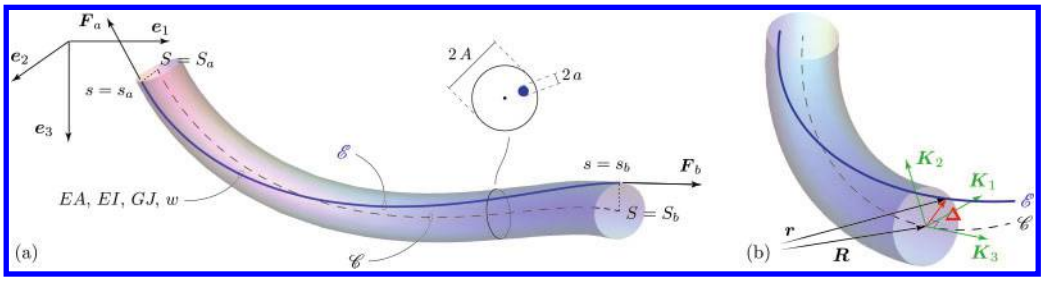

Figure 1. (a) Description of the canonical problem, and (b) Decomposition of the position vector $r(s) = R(S) + \mathbf{\Delta}(S)$. For the sake of readability, the region in which the solution is expected be found is represented (for the constrained problem, this region corresponds to the conduit centered on the reference curve).

2.2 *Shortcomings of the Lagrangian formulation*

As already emphasized in the introduction, the canonical problem under consideration consists in a two points boundary value problem for which the rod location and inclination are prescribed at both extremities s_a and s_b of the domain. However, as the parametric coordinates of the rod $x_k(s)$ in the absolute reference frame $\{e_k\}$ are given by

$$x_k(s) = x_k(s_a) + \int_{s_a}^{s} \mathrm{d}_s \boldsymbol{r} \cdot \boldsymbol{e}_k \, \mathrm{d}s \tag{8}$$

with $\mathrm{d}_s r = v$, the boundary conditions associated with the canonical problem reduce to a set of three integral constraints on the unknown length of the rod forced to go through two fixed points in space. These stiff isoperimetric constraints result in ill-conditioned equations requiring an excessive amount of iterations, provided that convergence is reached, which worsens with decreasing bending stiffness (Denoël & Detournay 2011).

For the constrained problem, a further difficulty is related to the assessment of the unilateral contact condition which ensures that the computed deformed configuration of the rod is contained within the conduit. This constraint indeed requires the evaluation of the distance Δ between the reference curve (*i.e.* the conduit axis), parametrized as

$$X_k(S) = X_k(S_a) + \int_{S_a}^{S} \mathrm{d}_S \boldsymbol{R} \cdot \boldsymbol{e}_k \, \mathrm{d}S \tag{9}$$

in the absolute reference frame $\{e_k\}$, and the rod cross section centroid $\mathscr{E}$ given in Equation (8). As these two curves are parametrized by two distinct curvilinear coordinates (S and s respectively), this task turns out to be computationally intensive.

Finally, the ill-conditioning of the governing equations for small flexural rigidity, the existence of spurious solutions associated with curling of the rod as well as the demand for increasing accuracy of the solutions with decreasing clearance, are sources of various additional complications or other bottlenecks, with the consequence that the Lagrangian formulation of the problem is particularly ineffective and laborious to solve.

3 EULERIAN FORMULATION

To circumvent the above-mentioned shortcomings of the Lagrangian formulation and on account of the nature of the problem, which is characterized by relatively close spatial curves $\mathscr{C}$ and $\mathscr{E}$, the proposed formulation hinges on the introduction of the *eccentricity vector* $\mathbf{\Delta}(S)$, characterizing the rod deflection with respect to the reference curve. The description of the problem is further expressed in terms of the Eulerian coordinate S rather than the natural Lagrangian coordinate s of the rod. As presented in Figure 1(b), the position vector of the rod cross section centroids $r(s) = x_k\, e_k$ can, naturally, be expressed as

$$\boldsymbol{r}(s) = \boldsymbol{R}(S) + \mathbf{\Delta}(S) \tag{10}$$

where the position vector of the reference curve $R(S) = X_k\, e_k$ is known, and the eccentricity vector is perpendicular to $\mathscr{C}$, *i.e.* $\mathrm{d}_S R \cdot \mathbf{\Delta} = 0$. The former expression describes the rod configuration as a perturbation of the reference curve, such that the eccentricity vector can be interpreted as a measure of the rod deflection and rotation with respect to $\mathscr{C}$ in the *section* of curvilinear coordinate S.

From now on, derivatives of scalar and vector valued functions with respect to the Eulerian coordinate S will be denoted by the apposition of a prime while derivatives with respect to the Lagrangian coordinate s are explicitly specified.

3.1 *Definition of the reference curve*

With each point of the reference curve, one may associate a triplet $\{K_j(S)\}$ constituting a right-handed orthonormal basis with $K_3 = R'$ defined as the unit vector tangent to $\mathscr{C}$. The orientation of this triplet can be defined through a unit quaternion $\mathfrak{Q}(S)$ specifying its rotation with respect to the global $\{e_j\}$–basis. Additionally imposing the component of this rotation about K_3 to be null, one has

$$\mathfrak{Q}(S) = (Q_0, Q_1, Q_2, 0)^T \tag{11}$$

with $Q_0^2 + Q_1^2 + Q_2^2 = 1$. This arbitrary definition of $Q_3(S) = 0$ simply reflects that the reference curve

needs only to be specified through the inclination of its tangent vector $\boldsymbol{K}_3(S)$ on the global axes; in other words the possible rotation of a pair of vectors spanning the plane perpendicular to the reference curve is irrelevant. An alternative definition of the unit quaternion $\mathfrak{Q}(S)$ would be to specify its components such that the triplet $\{\boldsymbol{K}_j(S)\}$ coincides with the Frenet basis attached to the reference curve. However this would lead to uniqueness and continuity issues for reference curves with vanishing curvature.

As a result of the previous definition, the pair $\{\boldsymbol{K}_1, \boldsymbol{K}_2\}$ constitutes an orthonormal basis for the plane perpendicular to the reference curve in which the eccentricity vector reads

$$\boldsymbol{\Delta}(S) = \Delta_1 \boldsymbol{K}_1 + \Delta_2 \boldsymbol{K}_2 \tag{12}$$

with $\Delta_1 = \Delta \cos\beta$ and $\Delta_2 = \Delta \sin\beta$. The components of the position vector in the global basis may, therefore, be expressed as

$$x_1(s) = X_1 + \Delta_1\left(1 - 2Q_2^2\right) + 2\Delta_2 Q_1 Q_2 \tag{13}$$

$$x_2(s) = X_2 + 2\Delta_1 Q_1 Q_2 + \Delta_2\left(1 - 2Q_1^2\right) \tag{14}$$

$$x_3(s) = X_3 - 2Q_0\left(\Delta_1 Q_2 - \Delta_2 Q_1\right) \tag{15}$$

in which each variable is a function of the Eulerian coordinate S and where the X_j's are obtained by integration of the reference curve local inclination expressed in terms of the quaternion components $Q_j(S)$.

3.2 *Definition of the rod*

By analogy with the definition of the reference curve and for reasons that will become clear in the following section, the orientation of the rod cross section is described by means of two unit quaternions

$$\mathbf{q}(s) = (q_0, q_1, q_2, 0)^T \qquad \mathbf{t}(s) = (t_0, 0, 0, t_3)^T \tag{16}$$

representing two successive rotations and such that the quaternion corresponding to the total rotation is given by the quaternion product $\mathbf{g}(s) = \mathbf{q} \cdot \mathbf{t}$. This parametrization of the rotation tensor allows to uncouple the attitude of the director $d_3(s)$ from the rotation of the section about this director.

Expressing the directors in terms of the unit quaternion $\mathbf{g}(s)$, one may compute their derivatives $\mathrm{d}d_k/\mathrm{d}s$ and identify the components of the twist vector, $u = u_k\, d_k$, in the directors basis.

3.3 *Jacobian of the mapping*

To complete the reformulation of the local equilibrium (3–4) within the reference frame associated to $\mathscr{C}$, one has to further express the natural derivatives $\mathrm{d}\cdot/\mathrm{d}s$ in terms of derivatives with respect to the Eulerian curvilinear coordinate $\mathrm{d}\cdot/\mathrm{d}S$. The function $s(S)$, which maps the Eulerian coordinate of the reference curve on the Lagrangian coordinate of the rod, is therefore introduced. Considering the definition (2) of the centroid tangent vector $\mathrm{d}\boldsymbol{r}/\mathrm{d}s$ in terms of the stretch vector components and applying the chain rule differentiation, the Jacobian $s'(S)$ of this transformation can be expressed as

$$\frac{\mathrm{d}s}{\mathrm{d}S} = \pm \left\|\boldsymbol{R}' + \boldsymbol{\Delta}'\right\| / \|\boldsymbol{v}\| \tag{17}$$

where the positive sign is selected in order to prevent the appearance of parasitic solutions associated with curling of the rod. This expression emphasizes that the origin of the drift existing between the two curvilinear coordinates is two-fold: (i) the eccentricity between the rod and the reference curve, and (ii) the stretch $\|v\| = \alpha$ of the rod itself.

Defining the function $J_1(S) = 1/s'$ as the Jacobian of the inverse mapping $S(s)$, *i.e.* from the Lagrangian to the Eulerian coordinate, one may compute its successive derivatives using the following recursive relation

$$J_k(S) = \left.\frac{\mathrm{d}^k S}{\mathrm{d}s^k}\right|_{s=s(S)} = J'_{k-1}\, J_1 \tag{18}$$

for $k > 1$.

3.4 *Rod attitude*

The next step in the Eulerian reformulation of the problem consists in rewriting the quaternion $\mathbf{g}(s)$, representing the directors orientation, in terms of the quaternion $\mathfrak{Q}(S)$, expressing the reference curve local inclination, and the components (Δ_1, Δ_2) of the eccentricity vector in the section S.

Using expressions (13–15) for the position vector components and the definitions of the directors $\{d_k\}$ in terms of the quaternion $\mathbf{g} = \mathbf{q} \cdot \mathbf{t}$ in the kinematic relation (2), one may obtain the following set of equations

$$2\alpha\, q_0\, q_2 = J_1\, \boldsymbol{r}' \cdot \boldsymbol{e}_1 \tag{19}$$

$$-2\alpha\, q_0\, q_1 = J_1\, \boldsymbol{r}' \cdot \boldsymbol{e}_2 \tag{20}$$

$$\alpha\left(2q_0^2 - 1\right) = J_1\, \boldsymbol{r}' \cdot \boldsymbol{e}_3 \tag{21}$$

with the stretch $\alpha > 0$ and where the uncoupling between the representation of d_3 attitude and the rotation of the section about this director has been advantageously used. Solving this set of equations, one may relate the Lagrangian quantities $q_j(s)$ function of the rod curvilinear coordinate s to the Eulerian quantities $Q_j(S)$ and $\Delta_1(S)$, $\Delta_2(S)$ function of the reference curve curvilinear coordinate S.

3.5 *The excess of twist*

Finally, the second quaternion $\mathbf{t}(s)$ characterizing the rotation of the rod cross section about the director $d_3(s)$ cannot be related to the eccentricity vector and, therefore, to the Eulerian quantities $\Delta_1(S)$ and $\Delta_2(S)$. The angle $\varphi(S)$ is consequently introduced such that $t_0 = \cos(\varphi/2)$ and $t_1 = \sin(\varphi/2)$ with

$$\varphi_{,s} = J_1\,\varphi' \qquad \varphi_{,ss} = J_1^2\,\varphi'' + J_2\,\varphi' \tag{22}$$

and where $\varphi_{,s}$ can be interpreted as the internal torsion or the excess of twist of the rod. Similarly, additional Lagrangian quantities appearing in the conservation of linear and angular momenta, such as the internal force $\boldsymbol{F}(s)$ or the stretch $\alpha(s)$, are re-written as functions of the Eulerian coordinate and their derivatives are evaluated using the same scheme.

3.6 *Boundary conditions*

In conclusion, one obtains a mixed order system of six ODE's involving exclusively Eulerian quantities. This system being first order in the components $F_k(S)$ of the internal force, second order in the angle $\varphi(S)$, and third order in the components $\Delta_k(S)$ of the eccentricity vector, a total of eleven boundary conditions is required.

In addition to the rod eccentricity and inclination with respect to the reference curve, which must be prescribed at both extremities of the boundary value problem, the axial component of the internal force and the torque need to be specified at one extremity of the domain. The eccentricity vector $\boldsymbol{\Delta}(S)$ and its derivative $\boldsymbol{\Delta}'(S)$ are, therefore, imposed at both $S = S_a$ and $S = S_b$ while the stretch $\alpha(S)$ as well as the angle $\varphi(S)$ and its derivative $\varphi'(S)$ are prescribed at either $S = S_a$ or $S = S_b$, depending on the nature of the problem under consideration.

4 NUMERICAL IMPLEMENTATION

To solve numerically the resulting nonlinear boundary value problem, a collocation method has been implemented. Defining a partition π of $[S_a, S_b]$ constituted of N subintervals, we seek an approximate solution $(\boldsymbol{\Delta}^*, \varphi^*, F^*)$ such that

$$\boldsymbol{\Delta}^* \in \mathcal{P}_{k+3,\pi} \cap C^2[S_a, S_b] \tag{23}$$

$$\varphi^* \in \mathcal{P}_{k+2,\pi} \cap C^1[S_a, S_b] \tag{24}$$

$$\boldsymbol{F}^* \in \mathcal{P}_{k+1,\pi} \cap C^0[S_a, S_b] \tag{25}$$

where $k \geq 3$ is the number of collocation points per subinterval and $\mathcal{P}_{n,\pi}$ is the set of all piecewise polynomial functions of order n on the partition π. For reasons of efficiency, stability, and flexibility in order and continuity, B-splines are chosen as basis functions while collocation is applied at Gaussian points (Ascher et al. 1979).

The unknown B-splines coefficients are then determined by solving the nonlinear system of 6 kN collocation equations and imposing the 11 boundary conditions. This method has been implemented in MATLAB using the nonlinear solver `fsolve` as well as the *Spline Toolbox* (De Boor 2005) to evaluate the B-splines and their derivatives.

5 APPLICATION

As an implementation of the proposed formulation, we consider the progressive twisting of a clamped-clamped beam subject to its specific weight w as well as a prescribed tension T, see Figure 2(a). The particularity of the present loading, which results from the Eulerian reformulation of the problem, is that the unstressed length of the rod ℓ^0 is actually not prescribed but freely evolves as the loading progress (c.f. *self-feeding*); the length L of the straight reference curve remaining however constant.

The response diagram presented in Figure 2 pictures the twist angle $\varphi(L)$, imposed at the rod extremity, versus the dimensionless stretched length $(\ell - L)/L$ for various values of the loading parameter $\Gamma = T/wL$. This diagram was obtained for a unitary distance between supports, *i.e.* $L = 1$, and a specific weight $w = 10$ while the rod stiffnesses were chosen such that $EI = 4\,GJ/3 = EA/255 = 1$. These relations as well as the deformed configurations graphed in the figure were obtained using the numerical implementation presented in the previous section with $k = 5$ gaussian points in each of the $N = 15$ uniformly spaced subintervals.

Observe that, while the number of helical waves in the deformed configuration clearly increases with the imposed end rotation $\varphi(L)$, foldings in the relation between the end rotation and the dimensionless stretched length are triggered by the development of additional helical waves in the rod deformed configuration. Eventually, material flows inside the domain either for compressive axial force (buckling) or insufficient tensile force (regarding the imposed end rotation) as more rod is required to maintain the equilibrium state.

6 CONCLUSIONS

The Eulerian reformulation of the equations governing the three-dimensional deflection of an extensible rod has been achieved by (i) the introduction of the eccentricity vector $\boldsymbol{\Delta}(S)$, characterizing the rod deflection with respect to a given reference curve, (ii) the uncoupling of the attitude of the rod centroid tangent vector form the rotation of the cross section about it, and (iii) the expression of the rod local equilibrium in terms of derivatives with respect to the reference curve curvilinear coordinate. The originality of the proposed

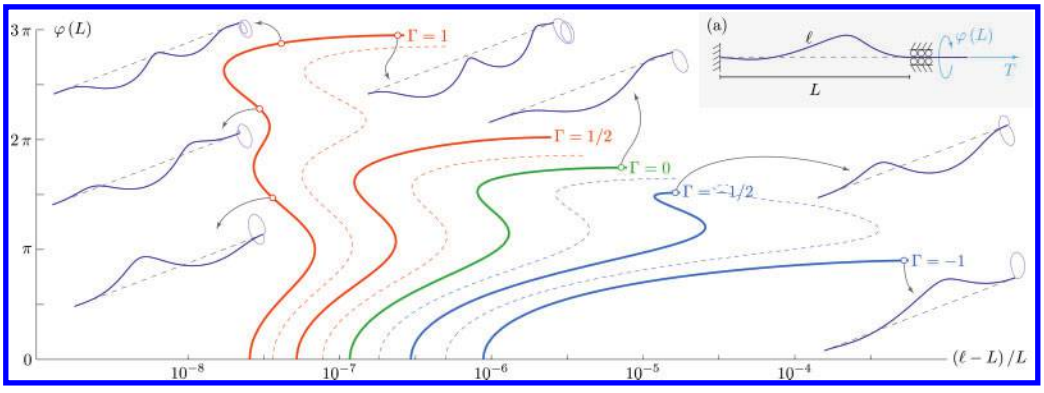

Figure 2. Response diagram of a clamped-clamped beam subject to progressive twisting as well as its specific weight $w = 10$ and a prescribed tension T. The imposed end rotation $\varphi(L)$ is plotted as a function of the dimensionless stretched length $(\ell - L)/L$ for various values of the loading parameter $\Gamma = T/wL$ and a unitary distance between support $L = 1$; the rod stiffnesses were chosen such that $EI = 4GJ/3 = EA/255 = 1$.

formulation, which resolves in one stroke a series of issues that afflict the classical Lagrangian approach (isoperimetric constraints and potential contact detection with the wall of a conduit), lays in the *self-feeding* character of the resulting system as the unstressed length of the rod is subject to self-adjustement in response to the loading. Finally, the response of a clamped-clamped beam subject to progressive twisting is obtained using the proposed formulation and its numerical implementation.

Some results of experimental investigations of thin-walled bars

J.B. Obrębski
Faculty of Civil Engineering, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The present author has elaborated complex theory for general analysis of space bar structures, composed from straight bars including any type of Cross-Sections (CSs) – in it compact, thin-walled and composite, too. Specially, theory for thin-walled straight bars (TWBs) has some assumptions, which accuracy was verified experimentally. Moreover, in literature we can find, that sometimes calculated results are dramatically different from reality. So, it can be concluded, that especially computer analysis is certain simulation, only (Pruki R.P. & Lopez P.M. SEMC-2001). More adequate results to reality can be obtained after its verification or calibration by experiments. The author by himself and in cooperation with his co-worker has perform some wide series of experiments over TWBs, described below.

1 INTRODUCTION

So, the author perform by himself and in cooperation with Z. Urbaniak, P. Flont, S. Wichniewicz, N. Jankowska, M.E. El Awadi (Egypt) some series of experiments for thin-walled structures: cantilevers under combined loading – bended eccentrically; instability effects also by loading bar by pure bimoment; transmission of torsion forces (bimoment and bending-torsion moment) through plane nodes connecting 2 or 3 TWBs and some simple experiments for presentation for students during lectures. The attention is there focused on some examples of visible bimoment influence on instability of thin-walled bars (TWBs).

Shown photographs and drawings presents observed effects. In the light of these experiments, the bimoment is evidently real internal force, very dangerous for structures, which should be seriously considered by designing objects composed of TWBs. The paper presents mainly experiments performed in years 1988–1992 and elaborated partially a little latter. Some observations concerning considered phenomena were quoted in author's books. The others materials were not published up to the moment.

Especially valuable are results of measurements done by electro-resistance methods and different approaches to elaboration of obtained results.

Moreover, are compared results of investigations presented in the book of A.I. Strielbitska & G.I. Jewsiejenko and the other measurements done much later by A. Glinicka – all concerning of some thin-walled elements used by designing of civil engineering structures. In all mentioned examples, are pointed visible influences of applied methods and input data to numerical analyses, on quality of obtained results.

To comparative analyses, including experiments, were used large brazen models: cantilevers – for bending-torsion loadings (Figs 1, 2, 5, 6), short bar

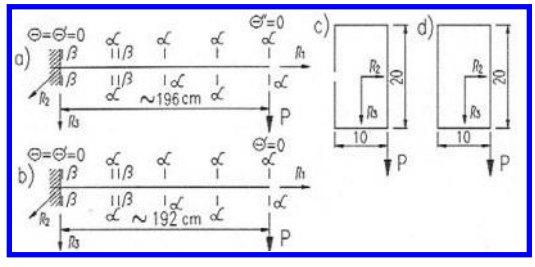

Figure 1. Scheme of the cantilevers with free end a), planar constrained displacements b); loading system for **TWB**s with rectangular **C**Ss: open c), closed d).

for loading by pure bimoment (Figs 7, 8) and simple frames (Figs 9, 11). All these models were having rectangular **CS**s with approximate dimensions 10×20 cm.

2 CANTILEVERS UNDER COMBINED LOADING

2.1 *Applied models and measuring method*

There, was investigated cantilever beams behaviour under bending-torsion loading with schemes given in Figures 1, 2. As specimens were used natural scale brazen **TWB**s with approximate dimensions $10 \times 20 \times 196$ cm, with wall thicknesses 0.5 mm, 1.5 mm and 2.5 mm. Strains in two **CS**s β-β, displacements in **CS**s α-α and load capacity of the bar were measured. Moreover, behaviour of the beam was observed and documented carefully.

2.2 *Observed effects*

There, 17 bars were investigated. Out of these, 13 with a vertical position (as in Figs 1, 2) and rectangular

CS (with Urbaniak, 1992, 2009) and 4 with a horizontal orientation (together with Flont, 1995)). In all of the above experiments, before bar damage (breaking) some waves appeared at the fixed end (Figure 2c, 5) on both bar sides and in the bottom wall. Some waves appear at loaded bar end, too, where longitudinal displacements were constrained by a rigid cork, Figure 2c. Development of waves during this type of experiments was observed, too.

In the Figure 5d are compared four similar bars with identical wall thickness. Two of the bars have an open **CS** and the opposite loaded end is totally free, or constrained by a cork. Similarly, the other two bars with a closed **CS** have the opposite end free or constrained by a cork, too. The different distances of breaking from the fixed end on the bottom wall and its inclination are interesting, Figure 6a-d. Here we should remember that for open type **CS**s, warping stresses are much higher. Also, the distribution of normal longitudinal stresses for bars with open and closed **CS**s is dramatically different.

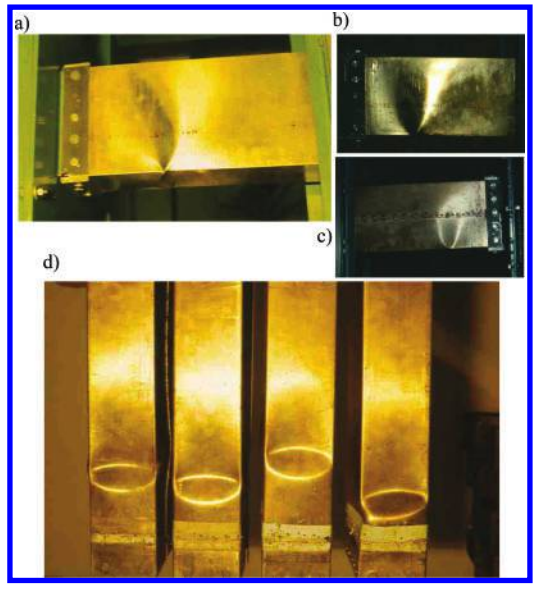

Figure 5. View of hinge (breaking point) of cantilever beams with planar constrained fixed end a); waves on lower wall and on both sides of the bar b, c); four cases of bars (Fig. 1) seen from down (wall thickness $\delta = 0.5$ mm) d).

	measured	848.475	−2.175
Model 22*	analytically	−4.826	2.189
	measured	9.65	3.35

*Errors in range of calculation accuracy.

2.3 *Elaboration of experimental results*

Strains were measured experimentally by electro-resistance method. Then were calculated: a) bimoment B and bending-torsional moment M_ω, shown in the Table 13 (method proposed by Obrębski (1994). There, were applied closed formulae:

$$B = \oint \sigma_1 \hat{\omega}\, d\bar{A} \quad , \quad M_{\bar{\omega}} = \oint \tau\, d\hat{\omega} \quad , \tag{1}$$

where σ_1 = normal stresses, $\hat{\omega}$ = warping function, τ = flow of shearing stresses, $\bar{A}$ = reduced area of CS.

Next, by MS Excel were calculated geometrical characteristics of **CS**s, normal stresses, shearing stresses, principal strains and stresses, angle of shape deformation. Some selected results are presented in the Tables 2 to 9.

It is interesting, what shows Table 1, that on basis of known experimentally obtained strains, were calculated B & M_ω with satisfying accuracy. This tests were

repeated later by Jankowska (2006) and than exploited by investigation of plane TW frames.

3 TRANSMISSION OF TORSION FORCES THROUGH NODES

3.1 *Reason and method of measurements*

The problem of computer analysis of space frames taking into consideration of bimoments, too, was numerically investigated by some authors. There, can be mentioned e.g. works by J. Rutecki [18], J.H. Argyris and D. Radaj (1971), R. Dziewolski (IASS, Kielce 1973), Obrebski [8, 9, 13, 15, 17] (1985, 1991), K. Grygierek (Ph.D. dissertation, Gliwice, 2003), and C. Szymczak et al. (2003).

There, still is serious question about real behaviour of space bar frames. Therefore, N. Jankowska (2006) in she's Ph.D. dissertation (supervised by J.B.Obrebski), has investigated 8 models of simple thin-walled frames, type L, T and Y (Figs 6, 7). The frames were composed of the 2 or 3 **TWB**s, made of the brass, connected with one central node, only. By both ends of each bar, in distance of 2.5 cm were glued 25 electro-resistance rosettes. There was applied very modern in that time electronic bridge of the firm VISHAY, system 5000, Figure 3c. All together, were investigated 32 **CS**s, in it most of them placed by central node.

3.2 *Some results and its evaluation for series of thin-walled frames*

Jankowska [2] has presented proper diagrams of shearing and normal stresses (e.g. Figure 9b), and calculated among the other, internal forces, associated

with torsion: B – bimoment and $M_{\hat{\omega}}$ – bending-torsion moment, according to formulae (1), by method proposed by J.B. Obrębski.

Some next results are given in the Table 10. So, the transmission of bimoment through node is from 16.57% to 33.35 and its dependence on node rigidity was confirmed. It is important, that similar observation concerning of bimoments transmission, obtained numerically by super-elements technique, was reported by C.Szymczak et al., too.

4 STABILITY OF THIN-WALLED BARS LOADED BY PURE BIMOMENT

4.1 *Applied models an method of measuring*

In this type of experiments, the short bar was loaded by pure bimoment only, Figure 10a. There, pure bimoment was applied at the bottom end of the bar. At the top of the specimen, in each case was applied a rigid cork to constrain longitudinal displacements and to stiffen the whole mode (Fig. 10b). Also, three different types of longitudinal slits were applied: in the middle, in one quarter of the wider wall and in the bar corner (Fig. 10c). Moreover, three wall thicknesses were applied: 0.5 mm, 1.0 mm, 1.5 mm.

Waves appeared along the longitudinal slit, at a certain value of bar loading P. The value of force P when waves appeared, was noted as critical loading by bimoment B. Beside slit edge waving, certain rotations of the top end of the bars were observed. So, when bimoment is applied, torsion appears. In this series of experiments, without any doubt, waves and critical loading were the result of pure bimoment application, only. So, it all confirms the thesis that bimoment is significantly responsible for wavy effects on side walls and along slits, too Fig. 4a.

4.2 *Some obtained results*

In the Figure 10c are shown a few diagrams of compared curves obtained experimentally and theoretically (Obrębski 1997). Especially for model with thin bar walls, accuracy of calculated results seems to be enough.

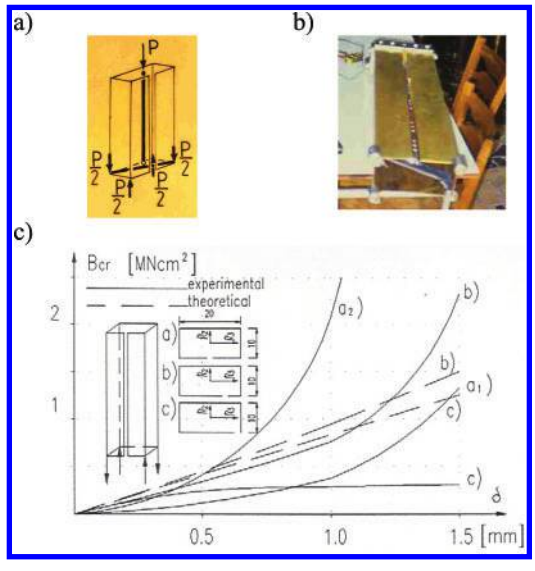

Figure 10. Scheme of experiment for critical bimoment a); planarly constrained displacements by strong steel cork at top b); loading system by pure bimoment at bottom bar end a,b); diagrams of measured and calculated critical bimoments c).

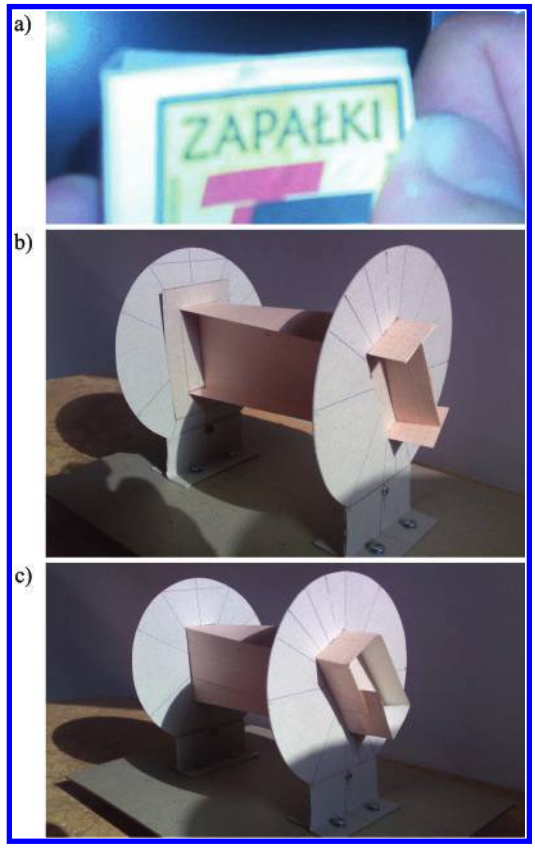

Figure 11. Three simple experiments with torsined models: match box a), I cross-section and strongly lipped open cross-sections.

5 EXPERIMENTS FOR DIDACTIC PURPOSES

There, were performed some very simple experiments, which each student can do at home. They show, the phenomena, which are computed by means of theory. It is interested, that model in the Figure 11b represents closed tube . . .

6 CONCLUSIONS

The more important conclusions are listed below. For wider information and literature, please, see to Obrębski (2009).

□ Bimoment is real internal force as longitudinal force, shearing force, bending and torsion moments, and can be calculated their critical values including combined loadings.

□ Bimoment can be measured experimentally, especially for open **CS**s.

□ In bars torsion always appears together with bimoment and bending-torsion moment.

□ Any type of loading and combined loading can lead to the critical state of bar behaviour.

□ Circuital normal stresses for **TWB**s can reach up to 98.17%, ($\eta = 2$ cm) & 11.4–47.1%, ($\eta = 55$ cm) of longitudinal normal stresses (see Tabl. 2, 3).

□ Shearing stresses for **TWB**s can reach $6.25 \div 67.92\%$, ($\eta = 2$ cm, Table 2) & $13.41 \div 61.99\%$, ($\eta = 55$ cm, Table 3) of longitudinal normal stresses.

□ In investigated cantilevers the angles of shape deformation (non-dilatation strain) for open **CS**s reach up to $-0{,}034^0$ and for closed **CS**s $+0.032^0$ (93,20% when $\eta = 2$ cm or 71,45% when $\eta = 55$ cm – of similar angles for closed **CS**s, Tables 2, 3). In Vlasov's theory (1940 & 1959) it was assumed zero!

□ The analytically obtained stresses were for cantilever bars close to experimental ones, than similar calculated by FEM (compare Tables 6–9).

□ Calculation of critical forces is possible for composite bars, under combined loading, too Obrebski (1991, 1997, 2001, 2008).

□ Many effects observed in behaviour of **TWB**s, considered in standards by means of certain coefficients, can be calculated simply by author's theory.

□ Assumptions and possibilities of theory of **TWB**s elaborated by Obrebski (1989, 1991, 1997, 2008) seem to be well confirmed by experiments, much better than in the others mentioned below.

□ So, computer algorithms together with good theory, are giving the best solutions.

In this paper only the more important remarks and conclusions are presented. It should be pointed out that nowadays, in standards, torsion and bimoment are almost completely neglected. There is a strong tendency to eliminate stresses calculation from the dimensioning process. It seems to be highly dangerous. **Investigations are continued.**

Bending and buckling of circular sandwich orthotropic plates with corrugated cores

K. Magnucki & M. Walachowski
Institute of Applied Mechanics, Poznan University of Technology, Poznan, Poland

E. Magnucka-Blandzi
Institute of Mathematics, Poznan University of Technology, Poznan, Poland

ABSTRACT: The subject of the study is a circular sandwich plate with corrugated main core and three-layer faces. The cores of the faces are made of homogeneous isotropic polyurethane foam. The plate is a thin-walled structure with three cores: one main – in the middle, and two others – internal layers of faces and four sheets. The corrugation of the main core is along the radius. The field of displacements, strains, and stresses are formulated basing on the Zig-Zag hypothesis. The system of partial differential equations of equilibrium for the circular sandwich plate is derived based on the principle of stationary total potential energy. Moreover, for verification of the results a Finite Element Model (FEM – ANSYS – system) for the plate is formulated. The bending and buckling analysis was carried out to determine the critical load and buckling shape. Comparison of the results obtained in the analytical and numerical (FEM) analysis is shown in figures.

1 INTRODUCTION

Sandwich structures are well-known since the mid of 20th century. Modelling and design of these structures was a basic problem. Elastic constants for corrugated cores of the sandwich structures were elaborated by Libove & Hubka (1951). Objective basic researches for sandwich structures were intensively conducted in further decades. Allen (1969) elaborated fundamental monograph for sandwich structures. Noor et al (1996) and Vinson (2001) presented a review of selected problems of sandwich structures. Strength and stability problems of sandwich structures are the subject of contemporary studies. Carrera (2003) elaborated a review of theories for multilayers plates and shells. Carlsson et al (2001) elaborated the elastic stiffnesses of corrugated core sandwich. Analytical modeling and FEM calculations of sandwich structures were presented by Steeves & Fleck (2004), Talbi et al (2009), Kazemahvazi & Zenkert (2009), Seong et al (2010), Jasion et al (2012), Magnucka-Blandzi et al (2012) and Magnucki et al (2013). Modeling and analysis of buckling problems of circular sandwich plates were presented by Jasion et al (2012), Luo et al (2004), Luwu & Changjun (1992), Pawlus (2006), (2008) and Wang & Chen (2003).

The subject of the paper is a circular sandwich plate composed of seven layers: two outer flat sheets, two inner flat sheets, two isotropic polyurethane foam cores of the faces and one main corrugated core (Fig. 1). The plate is under a uniform pressure p_0 or uniform distributed radial compression load of intensity N_r^0.

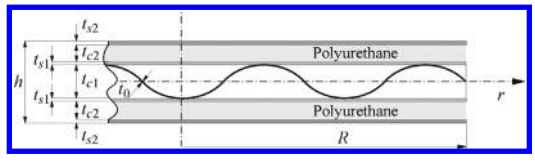

Figure 1. Scheme of the circular sandwich plate.

The analytical and numerical FEM analyses for axisymmetric bending or buckling of the plate are presented.

2 ANALYTICAL STUDY

2.1 *Analytical model*

The assumption: the straight line – normal to the middle plane of the plate before bending, does not remain straight and normal after axisymmetric bending, but becomes a broken line (Fig. 2).

The hypothesis makes a basis for formulation of the field of displacements, strains and stresses. Displacements are as follows:
the outer sheets of thicknesses t_{s1}

$$u(r,z) = -t_{c1}\left[\zeta\frac{dw}{dr} \pm \psi_1(r) \pm x_2\psi_2(r)\right], \tag{1}$$

the polyurethane foam cores of faces – t_{c2}

$$u(r,z) = -t_{c1}\left\{\zeta\frac{dw}{dr} \pm \psi_1(r) - \psi_2(r)\left[\zeta \pm \left(\frac{1}{2} + x_1\right)\right]\right\}, \tag{2}$$

the inner sheets of thicknesses t_{s2}

$$u(r,z) = -t_{c1}\left[\zeta \frac{dw}{dr} \pm \psi_1(r)\right], \tag{3}$$

the main core of thickness t_{c1}

$$u(r,z) = -t_{c1}\zeta\left[\frac{dw}{dr} - 2\psi_1(r)\right]. \tag{4}$$

The upper sign is related to upper layers, and lower sign is related to lower layers. The following dimensionless coordinate and parameters are introduced:

$$\zeta = \frac{z}{t_{c1}}, \quad x_1 = \frac{t_{s1}}{t_{c1}}, \quad x_2 = \frac{t_{c2}}{t_{c1}}, \quad x_3 = \frac{t_{s2}}{t_{c1}}. \tag{5}$$

Moreover, two dimensionless functions are defined:

$$\psi_1(r) = \frac{u_1(r)}{t_{c1}}, \quad \psi_2(r) = \frac{u_2(r)}{t_{c2}}. \tag{6}$$

Strains for each layer of this circular plate are defined as follows:

$$\varepsilon_r = \frac{\partial u}{\partial r}, \quad \varepsilon_\varphi = \frac{u}{r}. \tag{7}$$

Stresses for each layer of this circular plate are defined as follows.

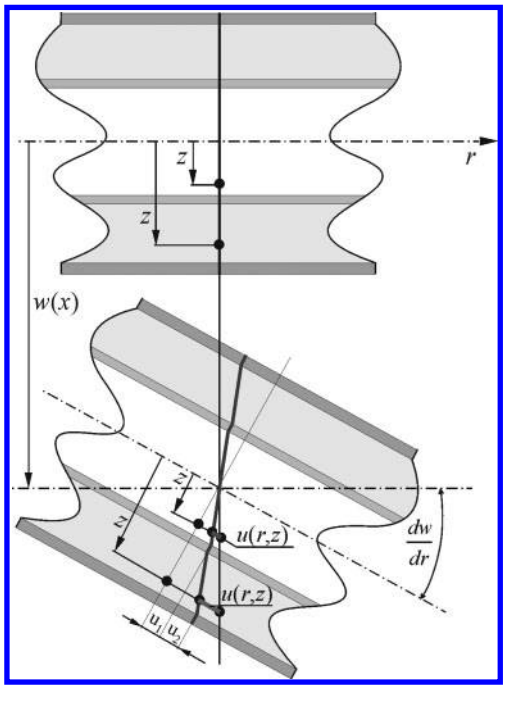

Figure 2. The hypothesis of deformation of the normal to the middle plane of the circular sandwich plate.

the flat sheets

$$\sigma_r = \frac{E}{1-\nu^2}\left(\varepsilon_r + \nu\varepsilon_\varphi\right), \quad \sigma_\varphi = \frac{E}{1-\nu^2}\left(\varepsilon_\varphi + \nu\varepsilon_r\right), \tag{8}$$

$$\tau_{rz} = \tau_{r\varphi} = 0, \tag{9}$$

the cores of the faces

$$\sigma_r = \frac{E_{c2}}{1-\nu_{c2}^2}\left(\varepsilon_r + \nu\varepsilon_\varphi\right), \quad \sigma_\varphi = \frac{E_{c2}}{1-\nu_{c2}^2}\left(\varepsilon_\varphi + \nu\varepsilon_r\right), \tag{10}$$

$$\tau_{rz} = G_{c2}\gamma_{rz}, \quad \tau_{r\varphi} = 0, \tag{11}$$

the main core

$$\sigma_r = \frac{E_r^{(c1)}}{1-\nu_{c2}^2}\left(\varepsilon_r + \nu\varepsilon_\varphi\right), \quad \sigma_\varphi = E_\varphi^{(c1)}\varepsilon_\varphi, \tag{12}$$

$$\tau_{rz} = G_{rz}^{(c1)}\gamma_{rz}, \quad \tau_{r\varphi} = 0, \quad \nu_r = 0, \quad \nu_\varphi = \nu. \tag{13}$$

Elastic constants for corrugated core are elaborated similarly to the ones presented by Libove & Hubka (1951) and Kazemahvazi & Zenkert (2009).

2.2 *Equations of equilibrium*

The elastic strain energy of the plate is a sum of energy of the following layers: two outer sheets, two face polyurethane cores, two inner sheets and one main corrugated core

$$U_\varepsilon = 2U_\varepsilon^{(os)} + 2U_\varepsilon^{(fc)} + 2U_\varepsilon^{(is)} + U_\varepsilon^{(mc)}. \tag{14}$$

The work of the load

$$W = 2\pi\int_0^R\left[p_0 w(r) + \frac{1}{2}N_r^0\left(\frac{dw}{dr}\right)^2\right]rdr. \tag{15}$$

From the theorem of stationary total potential energy

$$\delta\left(U_\varepsilon - W\right) = 0, \tag{16}$$

one obtains three equilibrium equations:

$$\Re_{10}(w) - \Re_{11}(\psi_1) - \Re_{12}(\psi_2) = Q_r(r) - N_r^0\frac{dw}{dr}, \tag{17}$$

$$\Re_{20}(w) - \Re_{21}(\psi_1) - C_{\psi 1}\psi_1(r) = 0, \tag{18}$$

$$\Re_{30}(w) - \Re_{31}(\psi_1) - \Re_{32}(\psi_2) + C_{\psi 2}\psi_2(r) = 0, \tag{19}$$

where the differential operators are composite, for example

$$\Re_{10}(w)= D_{c1}\left[C_{w101}\Im_0(w)+\frac{1-\nu^2}{6}\Im_1(w)\right]+D_{c2}C_{w102}\Im_0(w) \quad (20)$$

and

$$\Im_0(w)=\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}\left(r\frac{dw}{dr}\right)\right], \quad (21)$$

$$\Im_1(w)=\tilde{E}_r^{(c1)}\frac{1}{r}\frac{d}{dr}\left(r\frac{d^2w}{dr^2}\right)-\tilde{E}_\varphi^{(c1)}\frac{1}{r^2}\frac{dw}{dr}. \quad (22)$$

2.3 *Analytical solution*

The circular plate of radius R with clamped edge is under a uniform pressure p_0 or uniform distributed radial compression load of intensity N_r^0 (Fig. 3).

The equilibrium equations (17), (18) and (19) for the plate are approximately solved assuming the three unknown functions in the following forms

$$w(r)=w_a\left[1-2\left(\frac{r}{R}\right)^2+\left(\frac{r}{R}\right)^4\right], \quad (23)$$

$$\psi_1(r)=\psi_{1a}\left[\frac{r}{R}-\left(\frac{r}{R}\right)^3\right],\ \psi_2(r)=\psi_{2a}\left[\frac{r}{R}-\left(\frac{r}{R}\right)^3\right], \quad (24)$$

where: w_a, ψ_{1a}, ψ_{2a} – parameters of the functions.

Substituting these expressions into (17), (18) and (19), one obtains the deflection and the critical load in complicated forms.

Example. The corrugation of the core consist of circular arcs – semicircles (Fig. 4).

Data for the plate: $R=1000$ mm, $h=39.7$ mm, $R_0=10$ mm, $t_0=0.5$ mm, $t_{c1}=20.5$ mm, $t_{s1}=0.6$ mm, $t_{c2}=8$ mm, $t_{s2}=1$ mm, $E_{c2}=50$ MPa, $\nu_{c2}=0.2$, $E=200$ GPa, $\nu=0.3$.

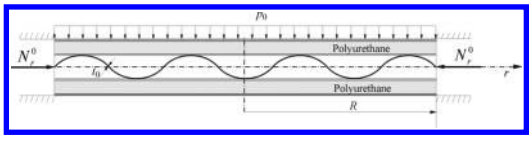

Figure 3. Scheme of the load of the plate.

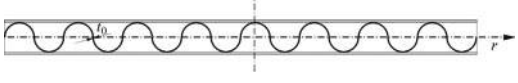

Figure 4. Scheme of the corrugated core.

3 NUMERICAL – FEM STUDY

3.1 *FEM model*

The FEM model was built as the shell structure and body structure. The main core, the outer sheets and the inner sheets were modelled as the shell structure. The polyurethane foam cores of faces were modelled as the body (Fig. 5).

The model was built as the axial symmetrical, thanks to that only the one fourth of the plate were taken into account (Fig. 6).

The mesh for each part was built as the quadrilaterals and the sizing was decided as the 50 mm for each elements (Fig. 7).

The contact between the parts were defined as the bounded.

The boundary conditions for the circular sandwich plate were defined on the edge of the plate (Fig. 8). The horizontal displacements and X, Y, Z rotation were blocked.

The uniform presser p_0 was added on the top surfaces (Fig. 9), and the uniform distributed radial

compression load of intensity N_r^0 was added on the edge of sheets (Fig. 10).

3.2 *Numerical – FEM calculations*

FEM calculations were divided for two analysis. First one the static structural analysis, and the second one lineal buckling analysis.

Total deformation (Fig. 11), equivalent elastic strain (Fig. 12) and equivalent stress (Fig. 13) were calculated in the static structural analysis. The uniform pressure p_0 and uniform distributed radial compression load of intensity N_r^0 were considered.

In the lineal buckling analysis only the uniform distributed radial compression load of intensity N_r^0 was considered. Total deformation was calculated in lineal

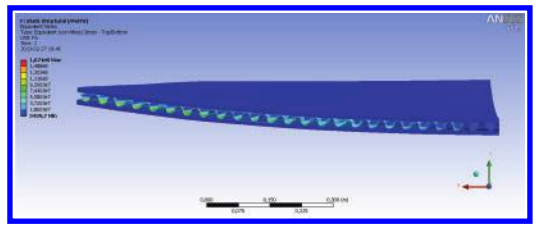

Figure 13. Equivalent stress.

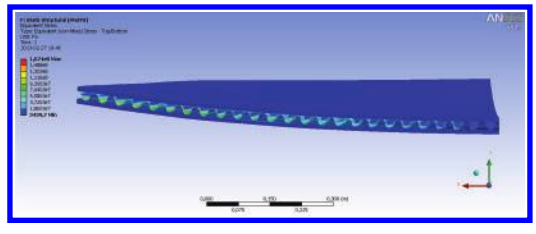

Figure 14. First mode of total deformation.

buckling analyse. The first mode of total deformation is presented (Fig. 14).

Results of numerical FEM Calculations are following:

Total deflection

$$w_a^{(FEM)} = 0.00149\ m$$

$$w_a^{(ANALYT)} = 0.00119\ m$$

The critical load

$$N_a^{(FEM)} = 1107.5\ \frac{kN}{m}$$

$$N_a^{(ANALYT)} = 1240.7\ \frac{kN}{m}$$

4 CONCLUSION

The subject of a study is the variety of classic sandwich plate. The mathematical and numerical models of the plate are presented, as well as the results obtained by these methods. The shirring effect is a sum of shirring of the main core and the polyurethane core of the outer layers. The bending and critical forces are closely related to the shirring effect.

Modeling and simulation of large amplitude vibrations of layered composite and smart structures

R. Schmidt, M.N. Rao & T.D. Vu
RWTH Aachen University, Institute of General Mechanics, Germany

ABSTRACT: This paper presents a numerical study on dynamics of layered composite and smart structures. The shell element is based on the Reissner-Mindlin first-order shear deformation theory and strain-displacement relations are valid for small strains but finite rotations. The electromechanical coupling is considered by introducing three additional electrical degrees of freedom for each electrode pair. Nonlinear transient analysis is carried out for a layered angle-ply cylindrical shell and a smart piezolaminated composite plate. The present simulations are compared with those obtained by finite element analyses based on first-order transverse shear deformation moderate or refined von Kármán-type theories in earlier literature.

1 INTRODUCTION

Modeling and numerical simulation of both the nonlinear dynamic response of layered composite structures and of adaptive structures with integrated distributed control capabilities has attracted considerable research interest in recent years. While geometrically linear theories for structures with piezoelectric layers and associated numerical methods have been developed by a number of authors, geometrically nonlinear problems have been treated considerably less in literature.

Most of the available papers treat the nonlinear transient response of composite structures with simplified geometrically nonlinear theories based either on the first (Reddy (1983), Reddy & Chandrashekara (1985), Palmerio et al. (1990), Ganapathi & Vardhan (1996), Klosowski et al. (1996), Sansour et al. (1997), Pellicano et al. (2002)), or third-order (Khdeir et al. (1989)) transverse shear deformation theory, using the refined von Kármán-type or moderate rotation theories. Concerning nonlinear vibrations of adaptive structures, Yi et al. (2000) used solid elements for geometrically nonlinear analysis of sensor voltage output of surface bonded patches on beams, plates and shells. Mukherjee & Chaudhuri (2005) analyzed nonlinear vibrations of piezolaminated beams by adopting von Kármán-type nonlinearity in the framework of first-order shear deformation theory. Marinkovic et al. (2009) investigated geometrically nonlinear vibrations of active thin-walled structures using a degenerated shell element. Nonlinear transient analysis, vibration control of smart isotropic or composite laminated beams, plates and shells with integrated piezoelectric actuator and sensor layers was considered in our previous works (Lentzen & Schmidt (2005a, b)) accounting for moderate rotations in the framework of first-order shear deformation theory. Schmidt & Vu (2009) and Vu (2011) considered the refined von Kármán-type nonlinearity in the framework of third-order shear deformation hypothesis to analyze nonlinear vibrations of smart structures.

The present paper deals with geometrically nonlinear transient analysis of composite laminated structures and adaptive structures in the framework of the first-order transverse shear deformation theory (FOSD). The theory and the finite element method account for full geometrical nonlinearity, thus they account for arbitrary, finite rotations. The finite rotation theory (FRT) finite element formulation developed by Lentzen (2009) and extended to nonlinear vibration analysis in Schmidt et al. (2010) is applied and further extended to dynamic analysis of composite plates and shells with integrated piezoelectric layers and patches. For comparative purposes, finite element methods with the refined von Kármán-type (RVK) and the moderate rotation first-order shear deformation (FOSD MRT) shell theories (Schmidt & Reddy (1984), Palmerio et al. (1990), Kreja et al. (1997), Lentzen et al. (2007)) are also used.

The developed composite piezolaminated shell element is deployed in a few numerical examples dealing with large amplitude vibrations of composite and adaptive structures in the geometrically nonlinear range of deformation.

2 FINITE ROTATION SHELL THEORY AND FINITE ELEMENT METHOD

Concerning the underlying theory and finite element method, the present paper is based on the FOSD shell theory for small strains and finite rotations of Habip (1965) and the FE implementation of Gruttmann & Wagner (2006) and Lentzen (2009).

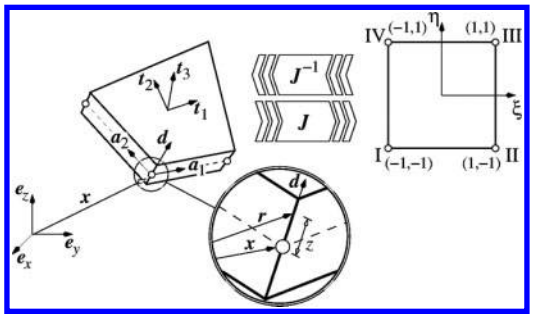

Figure 1. Definition of the coordinate systems in the FRT-element.

Figure 1 shows the four-node element with the global $\mathbf{e}_i$, the local $\mathbf{a}_\alpha$, the natural $\xi-\eta$ and the orthonormal material $\mathbf{t}_i$ coordinate systems. The position vector to the reference surface in the initial configuration at node I is denoted as $\mathbf{x}_I$.

Figure 1 also shows that a linear displacement field is assumed by introducing the inextensible director d which is a unit vector perpendicular to the reference surface in the undeformed configuration. For the FOSD or Reissner-Mindlin hypothesis, the position vector r to an arbitrary point on the director at the position (ξ,η) is described as

$$\boldsymbol{r}=\boldsymbol{x}(\xi,\eta)+z\boldsymbol{d}(\xi,\eta) \tag{1}$$

where z denotes the thickness coordinate ranging from the bottom to the top of the considered shell.

In the framework of this hypothesis, the Green strain-tensor components for fully nonlinear finite rotation strain-displacement relations are obtained as (see Habip (1965))

$$\begin{aligned}
\varepsilon_{\alpha\beta}&=\overset{0}{\varepsilon}_{\alpha\beta}+\zeta\overset{1}{\varepsilon}_{\alpha\beta}+\zeta^2\overset{2}{\varepsilon}_{\alpha\beta}\\
\varepsilon_{\alpha 3}&=\overset{0}{\varepsilon}_{\alpha 3}+\zeta\overset{1}{\varepsilon}_{\alpha 3}\\
\varepsilon_{33}&=0
\end{aligned} \tag{2}$$

where

$$\begin{aligned}
\overset{0}{\varepsilon}_{\alpha\beta}&=\frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{x}}_{,\beta}-\boldsymbol{x}_{,\alpha}\cdot\boldsymbol{x}_{,\beta}\right)\\
\overset{1}{\varepsilon}_{\alpha\beta}&=\frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{d}}_{,\beta}+\bar{\boldsymbol{x}}_{,\beta}\cdot\bar{\boldsymbol{d}}_{,\alpha}-\boldsymbol{x}_{,\alpha}\cdot\boldsymbol{d}_{,\beta}-\boldsymbol{x}_{,\beta}\cdot\boldsymbol{d}_{,\alpha}\right)\\
\overset{2}{\varepsilon}_{\alpha\beta}&=\frac{1}{2}\left(\bar{\boldsymbol{d}}_{,\alpha}\cdot\bar{\boldsymbol{d}}_{,\beta}-\boldsymbol{d}_{,\alpha}\cdot\boldsymbol{d}_{,\beta}\right)\\
\overset{0}{\varepsilon}_{\alpha 3}&=\frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{d}}-\boldsymbol{x}_{,\alpha}\cdot\boldsymbol{d}\right)\\
\overset{1}{\varepsilon}_{\alpha 3}&=\frac{1}{2}\left(\bar{\boldsymbol{d}}_{,\alpha}\cdot\bar{\boldsymbol{d}}-\boldsymbol{d}_{,\alpha}\cdot\boldsymbol{d}\right).
\end{aligned} \tag{3}$$

Here ζ denotes the thickness coordinate and an overbar indicates the deformed configuration. Due to thinness of the regarded plates and shells the components $\overset{2}{\varepsilon}_{\alpha\beta}$ and $\overset{1}{\varepsilon}_{\alpha 3}$ are neglected.

There are no kinematical restrictions with respect to the range of rotations. The director is assumed to be inextensible and the rotations are parameterized with the Rodriguez formulation. In order to overcome various types of locking, the ANS procedure suggested by Bathe & Dvorkin (1985), Hughes & Tezduyar (1981) combined with EAS (Lentzen (2009)) has been used.

2.1 *Electric potential distribution*

For this finite element, the electric potential is assumed to vary quadratically through the thickness by introducing three electrical degrees of freedom per layer

$$\varphi(\zeta)=\overset{0}{\varphi}+\zeta\overset{1}{\varphi}+\zeta^2\overset{2}{\varphi} \tag{4}$$

where φ denotes the electric potential.

The above mentioned electrical degrees of freedom are converted into the electric potential on the lower electrode, in the middle of the piezoelectric layer and on the top electrode, respectively, denoted by $\bar{\varphi}$, $\overset{m}{\varphi}$ and $\overset{+}{\varphi}$. The conversion is performed by inverting the following matrix-vector representation of the boundary conditions.

$$\begin{Bmatrix}\bar{\varphi}\\ \overset{m}{\varphi}\\ \overset{+}{\varphi}\end{Bmatrix}=\begin{pmatrix}1 & \bar{\zeta} & \bar{\zeta}^2\\ 1 & \overset{m}{\zeta} & \overset{m}{\zeta}^2\\ 1 & \overset{+}{\zeta} & \overset{+}{\zeta}^2\end{pmatrix}\begin{Bmatrix}\overset{0}{\varphi}\\ \overset{1}{\varphi}\\ \overset{2}{\varphi}\end{Bmatrix} \tag{5}$$

leading to

$$\begin{Bmatrix}\overset{0}{\varphi}\\ \overset{1}{\varphi}\\ \overset{2}{\varphi}\end{Bmatrix}=\frac{1}{k_1}\begin{pmatrix}\overset{m}{\zeta}\overset{+}{\zeta}t_1 & -\bar{\zeta}\overset{+}{\zeta}t_2 & -\overset{m}{\zeta}\bar{\zeta}t_3\\ \left(\overset{+}{\zeta}+\overset{m}{\zeta}\right)t_3 & \left(\overset{+}{\zeta}+\bar{\zeta}\right)t_2 & \left(\overset{m}{\zeta}+\bar{\zeta}\right)t_3\\ t_1 & -t_2 & -t_3\end{pmatrix}\begin{Bmatrix}\bar{\varphi}\\ \overset{m}{\varphi}\\ \overset{+}{\varphi}\end{Bmatrix} \tag{6}$$

$$\text{where } k_1=-\overset{m}{\zeta}\overset{+}{\zeta}t_1-\overset{+}{\zeta}\bar{\zeta}t_2-\bar{\zeta}\overset{m}{\zeta}t_3, \tag{7}$$

$$t_1=\left(\overset{+}{\zeta}-\overset{m}{\zeta}\right),\ t_2=\left(\overset{+}{\zeta}-\bar{\zeta}\right),\ t_3=\left(\bar{\zeta}-\overset{m}{\zeta}\right). \tag{8}$$

2.2 *Constitutive equations*

The mechanical and electrical quantities are coupled to each other by two linear constitutive relations describing the direct and the converse piezoelectric effect, respectively,

$$\begin{aligned}
\{D\}&=[e]\{\varepsilon\}+[\delta]\{E\}\\
\{S\}&=[c]\{\varepsilon\}-[e]^T\{E\}
\end{aligned} \tag{9}$$

where $\{S\}$ denotes the stress vector, $\{\varepsilon\}$ the strain vector, $\{D\}$ the electric displacement vector and $\{E\}$ the electric field vector:

$$\{S\}=\begin{Bmatrix}\sigma_{11}\\ \sigma_{22}\\ \tau_{12}\\ \tau_{23}\\ \tau_{13}\end{Bmatrix},\{\varepsilon\}=\begin{Bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ 2\varepsilon_{12}\\ 2\varepsilon_{23}\\ 2\varepsilon_{13}\end{Bmatrix} \qquad (10)$$

$$\{D\}=\begin{Bmatrix}D_1\\ D_2\\ D_3\end{Bmatrix} \text{ and } \{E\}=\begin{Bmatrix}E_1\\ E_2\\ E_3\end{Bmatrix}.$$

Further $[\mathrm{e}]=[d][c]$ and $[\mathrm{e}]^T=[c][d]^T$, where $[c]$ denotes the elasticity matrix for anisotropic material, $[d]$ the piezoelectric constant matrix and $[\delta]$ the dielectric constant matrix

$$[c]=\begin{bmatrix}c_{11}&c_{12}&c_{13}&0&0\\ c_{12}&c_{22}&c_{23}&0&0\\ c_{13}&c_{23}&c_{32}&0&0\\ 0&0&0&c_{44}&c_{45}\\ 0&0&0&c_{45}&c_{55}\end{bmatrix}=\begin{bmatrix}[C_1]&0\\ 0&[C_2]\end{bmatrix}, \qquad (11)$$

$$[d]^T=\begin{bmatrix}0&0&d_{31}\\ 0&0&d_{31}\\ 0&0&0\\ 0&d_{15}&0\\ d_{15}&0&0\end{bmatrix} \text{ and } [\delta]=\begin{bmatrix}\delta_{11}&0&0\\ 0&\delta_{22}&0\\ 0&0&\delta_{33}\end{bmatrix}.$$

2.3 *Variational formulation*

The finite element developed by Lentzen (2009) is based on the shell element of Gruttmann & Wagner (2006) and extended with the electromechanical coupling. In the present element a displacement based variational principle is chosen in order to reduce the number of internal variables. The variational formulation reads

$$\int_V \left(\boldsymbol{S}:\delta\boldsymbol{\varepsilon}-\boldsymbol{D}\cdot\delta\boldsymbol{E}\right)dV=\int_A\left(\boldsymbol{T}\cdot\delta\boldsymbol{\upsilon}+Q\,\delta\varphi\right)dA +\int_V\left(\rho(\boldsymbol{b}-\ddot{\boldsymbol{\upsilon}})\right)\cdot\delta\boldsymbol{\upsilon}\,dV \qquad (12)$$

where S is the second Piola-Kirchhoff stress tensor, D is the electric displacement vector, $\boldsymbol{\varepsilon}$ is the Green-Lagrange strain tensor, E is the electric field vector, $\delta\boldsymbol{\upsilon}$ is the virtual displacement vector, T is the traction vector on the boundary, Q is the surface related charge density, ρ is the mass density, b is the body force density and $\ddot{\boldsymbol{\upsilon}}$ is the acceleration vector. Here a total Lagrangian approach is adopted.

The variation of the Green-Lagrange strain tensor components are

$$\begin{aligned}\delta\overset{0}{\varepsilon}_{\alpha\beta}&=\frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{x}}_{,\beta}+\bar{\boldsymbol{x}}_{,\alpha}\bullet\delta\bar{\boldsymbol{x}}_{,\beta}\right)\\ \delta\overset{1}{\varepsilon}_{\alpha\beta}&=\frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{d}}_{,\beta}+\delta\bar{\boldsymbol{x}}_{,\beta}\bullet\bar{\boldsymbol{d}}_{,\alpha}+\bar{\boldsymbol{x}}_{,\alpha}\bullet\delta\bar{\boldsymbol{d}}_{,\beta}+\bar{\boldsymbol{x}}_{,\beta}\bullet\delta\bar{\boldsymbol{d}}_{,\alpha}\right) \qquad (13)\\ \delta\overset{0}{\varepsilon}_{\alpha 3}&=\frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{d}}+\bar{\boldsymbol{x}}_{,\beta}\bullet\delta\bar{\boldsymbol{d}}\right).\end{aligned}$$

with $\bar{x}=x+\upsilon$, it follows that $\delta\bar{x}_{,\alpha}=\delta\upsilon_{,\alpha}$. The variation of the director and its linearization developed by Gruttman & Wagner (2006) has been used.

2.4 *The system matrices and vectors*

The electric field is assumed to be homogeneous over the electrode and exists only in transverse direction. In addition to the mechanical degrees of freedom at each node, three electrical degrees of freedom have to be introduced per electrode pair.

After introducing the shape functions to interpolate mechanical and electrical quantities, the generalised displacements $\{q\}$ and electric potential $\{\varphi\}$, integrated constitutive matrices $[H_1]$ for the elastic material, $[H_2]$ for the piezoelectric constants, $[H_3]$ for the dielectric constants, and the following set of equations can be derived on element level from the variational formulations

$$\begin{bmatrix}[M_{qq}]&0\\ 0&0\end{bmatrix}^e\begin{Bmatrix}\{\ddot{q}\}\\ \{\ddot{\varphi}\}\end{Bmatrix}^e +\begin{bmatrix}[K_{qq}]&[K_{q\varphi}]\\ [K_{\varphi q}]&[K_{\varphi\varphi}]\end{bmatrix}^e\begin{Bmatrix}\{\Delta q\}\\ \{\Delta\varphi\}\end{Bmatrix}^e=\begin{Bmatrix}\{f_q\}\\ \{f_\varphi\}\end{Bmatrix}^e \qquad (14)$$

where

$$\begin{aligned}[K_{qq}]^e&=[K^\sigma]^e+\int_{\Omega^e}[B_q]^T[\mathrm{H}_1][B_q]\,d\Omega,\\ [K_{q\varphi}]^e&=[K_{\varphi q}]^{eT}=\int_{\Omega^e}[B_q]^T[\mathrm{H}_2][B_\varphi]\,d\Omega, \qquad (15)\\ [K_{\varphi\varphi}]^e&=\int_{\Omega^e}[B_\varphi]^T[\mathrm{H}_3][B_\varphi]\,d\Omega.\end{aligned}$$

The incremental stiffness matrix $[K_{qq}]$ is the only matrix containing the geometrical nonlinear stiffness $[K^\sigma]$. Further $[K_{q\varphi}]$ denotes the electromechanical coupling matrix, $[K_{\phi\varphi}]$ is the piezoelectric capacity matrix, $[M_{qq}]$ is the mass matrix, $\{f_q\}$ is the vector containing the nodal forces, moments and in-balance forces, $\{f_\varphi\}$ is the vector containing the nodal charges and in-balance charges, $[B_q]$ is the strain-displacement matrix and $[B_\varphi]$ is the electric field matrix.

3 NUMERICAL EXAMPLES

3.1 *Angle-ply cylindrical shell subjected to impulsive internal pressure*

This numerical example deals with a two layer angle-ply [−45°/45°] clamped cylindrical shell as shown in Figure 2 subjected to impulsive internal pressure in form of a step load. The material properties of the shell are taken as $E_{11} = 7.5e6$ psi, $E_{22} = 2.0e6$ psi, $\nu_{12} = 0.25$, $G_{12} = G_{13} = G_{23} = 1.25e6$ psi, $\rho = 1.0\,\text{lb} \cdot \text{s}^2/\text{in}^4$.

Here, simulations of the dynamic behavior of the cylindrical shell corresponding to two different finite element methods, FOSD MRT and FOSD FRT are carried out. Following Reddy & Chandrashekara (1985), for this example, one quadrant of the shell was modeled. An equivalent density of nodes and the Newmark method was used in both FOSD FRT and FOSD MRT theories.

Figure 3 shows the predictions of deflections at the center of the shell with different time steps for both theories. The present results are compared with those given in the existing literature by Reddy & Chandrashekara (1985) using FOSD RVK theory. Figure 4 and 5 show the velocity and accelerations of the cylindrical shell at the center, respectively. It can be observed that the responses predicted by FOSD FRT, MRT and RVK are remarkably different from each other.

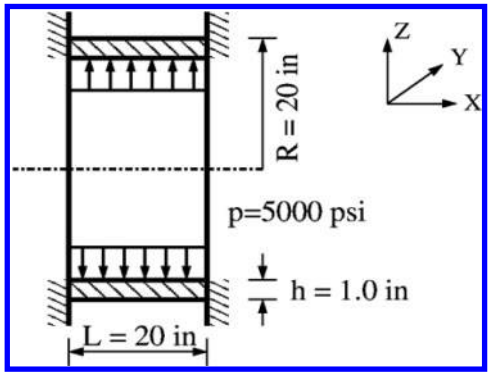

Figure 2. Clamped angle-ply cylindrical shell.

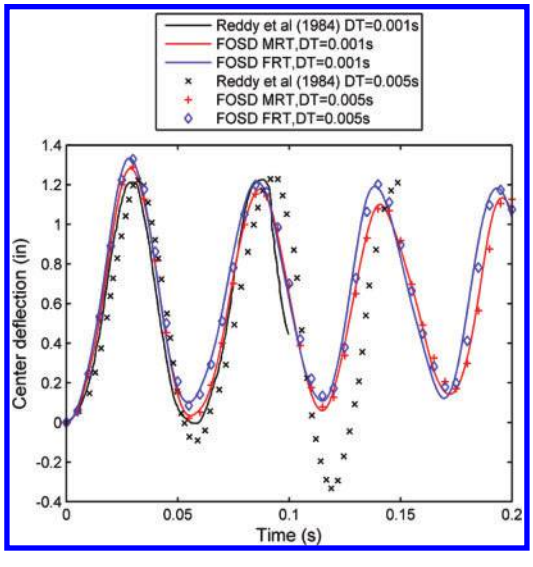

Figure 3. Center deflection of the clamped cylindrical shell.

3.2 *Two edge simply supported piezolaminated composite plate*

The numerical example considered here is the two sides hinged composite piezolaminated plate as shown in Figure 6. The transient behavior of the structure is simulated when an input voltage in form of a harmonic

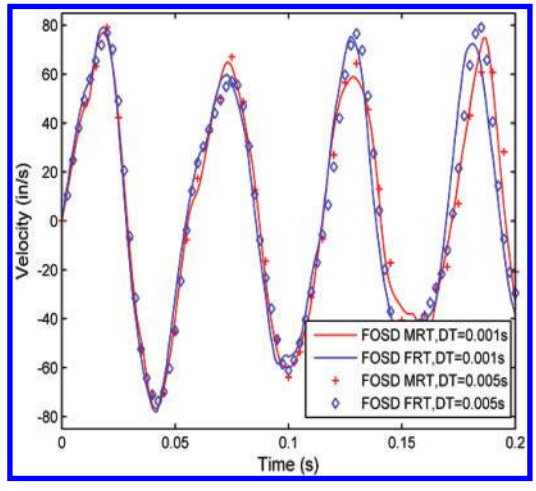

Figure 4. Velocity at the center of the clamped cylindrical shell.

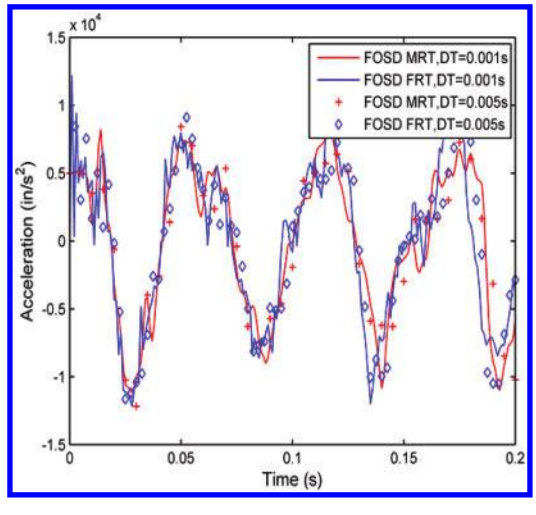

Figure 5. Acceleration at the center of the clamped cylindrical shell.

time function is applied to the two actuator layers. The middle layer is a graphite-epoxy T300/976 layer with the fiber orientation of 90° covered by two PZT G1195 layers.

The in-plane dimensions are 40×40 mm. The thickness of the PZT layers is 0.15 mm each and that of the composite layer is 0.2 mm. The material properties of the graphite-epoxy are taken as $E_{11} = 150$ GPa, $E_{22} = 9$ GPa, $\nu_{12} = \nu_{23} = 0.3$, $G_{12} = 7.1$ GPa, $\rho = 3.95$ g/cm^3 and those of the PZT are taken as $E = 63$ GPa, $\nu = 0.3$, $e_{31} = 2.286$e-05 Cmm^{-2}, $\rho = 7.85$ g/cm^3.

Here, the actuator layers are subjected to electric voltage in sine form with the amplitude of 300 V and a frequency of 100 Hz. The PZT layers are oppositely polarized, which results in moments that are uniformly distributed over the edges of the piezolayers. The response at the mid-point of the structure is observed over a time period of 0.05 s. The linear and nonlinear predictions of FOSD FRT are obtained by the Newmark method with a time step 10^{-5} s. From Figure 7, it can be seen that both the linear and nonlinear prediction of the dynamic response of the structure yield oscillations driven at the frequency of excitation. The amplitudes predicted by the nonlinear simulation are lower than those of the linear simulation because of the stress stiffening due to the von Kármán effect in the geometrically nonlinear range of deformation.

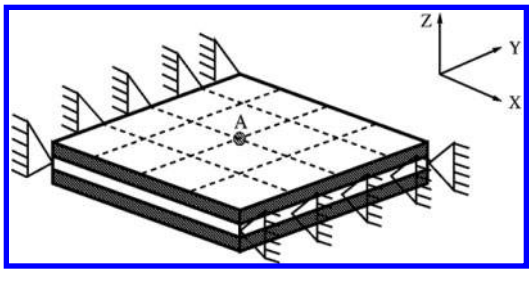

Figure 6. Two edge simply supported piezolaminated plate.

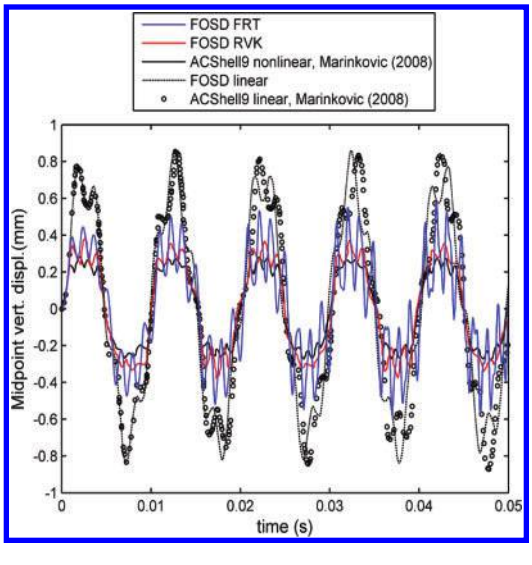

Figure 7. Mid-point vertical displacement to harmonic electric excitation.

The present predictions (FOSD FRT) are compared to those in the existing literature given by Marinković et al. (2009), in which a degenerated 9-node active shell element (ACShell9) obtained through the degeneration process from a 27-node solid element was used and by Vu & Schmidt (2011), in which FOSD RVK theory was used. The amplitudes predicted by FOSD FRT are much higher than those obtained by the degenerated element.

4 CONCLUSIONS

In this paper, large amplitude vibrations of a two layered angle-ply composite cylindrical shell with impulsive internal pressure and a two edges simply supported piezolaminated plate with harmonic electric excitation have been examined by different nonlinear models (FOSD FRT, FOSD MRT). The present simulations show that due to the thinness of the considered smart structures FRT is necessary in many cases.

Simplified modelling of stiffened panels for simultaneous static and dynamic optimisation

L. Weiß, H. Köke & C. Hühne
Institute of Composite Structures and Adaptive Systems,
DLR German Aerospace Center, Braunschweig, Germany

ABSTRACT: In this paper a novel simplified structural modelling approach for stiffened panels is presented. It specifically addresses structural response of aircraft fuselage components made from Carbon Fibre Reinforced Plastics (CFRP). The proposed method considers structural modelling requirements necessary for structural optimisation with respect to system response under simultaneous static and dynamic loads. The standard explicit Finite Element (FE) solver LS-Dyna is utilised, providing the framework to regard statics and dynamics as well as non-linearities by material, large deformation and contact. The simplified model is fundamentally composed of shell, beam, and discrete elements. Simulating the structural collapse behaviour of thin-walled CFRP sections under bending load the detailed model provides input parameters for the discrete elements. Furthermore, skin-frame-interaction attributes immanent to the present fuselage configuration are reviewed and considered by idealised deformation characteristics. Finally, the present approach is verified through analyses of the detailed model. The results illustrate the benefits of model simplification. Replacing detailed shell model features by beam and non-linear spring elements significantly reduces computational effort. At the same time the accuracy deduction is acceptable considering topological optimisation requirements.

1 INTRODUCTION

Research and technology projects on aircraft fuselage pursue the application of lightweight materials to endeavour improved structural efficiency. Especially thermoset fibre reinforced plastics (FRPs) comply with the designer's need for excellent specific material properties. Structural designs applying such composite materials need to satisfy the authorities airworthiness code for 'equivalent level of safety' EASA (2003).

Due to plastic deformation capacity of state-of-the-art metallic fuselage designs, those certification requirements are achieved almost naturally by the design's intrinsic energy absorption capabilities. In contrast to metallic materials, thermoset FRPs exhibit brittle fracture behaviour when loaded beyond their elastic limits. Thus energy absorption by plastic deformation is unsatisfactory limited. Considering FRP constitutive non-linearities in dynamic loading conditions at early design stages, however, induce alternative principles of energy absorption.

At early design stages only static or quasi-static loads are accounted for in the structural layout. If at all, common engineering practice simplifies dynamic loading conditions for consideration in the initial phase of the design process. Such, dynamic structural behaviour (e.g. energy absorption characteristics) of composite design is an inappropriate result of static structural layout. This suggests that composite fuselage design requires simultaneous consideration of static and dynamic loading conditions at the preliminary design stage. An appropriate optimisation procedure is essential for determining an efficient structural layout. Following Eschenauer (2006) the proposed optimisation scheme depicted in figure 1 consists of three constituents: a structural analysis, an optimisation model, and an optimisation algorithm.

A typical approach of structural optimisation for severe dynamic objectives applies a detailed continuum FE model in association with metamodelling schemes as studied in Fang et al. (2005). Usually, the required detailed continuum FE model is not available in the initial phase of the design process. Alternatively discrete modelling techniques are applied. Appropriate representation of the governing collapse mode is their uniting feature. Analytical or hybrid modelling has been proposed by Wittlin and Lackey (1983) in order to obtain floor pulse characteristics of transport aircraft in hard landings. To represent the response to severe dynamic load of a metallic frontal impact structure of a car Lust (1992) and Hamza and Saitou (2005) apply spring-mass-models for sizing optimisation. Multibody modelling with rigid-flexible links is used by Ambr'osio and Dias (2007) for road vehicles and Pereira et al. (1997) for train vehicles. In the later case shape optimisation is carried out based on the structural response. Discrete modelling for topology optimisation is developed by Pedersen (2004) for metallic structures, and by Hajela and Lee (1997) and Bisagni et al. (2002) for composite structures respectively. Recently, Waimer et al. (2010) developed

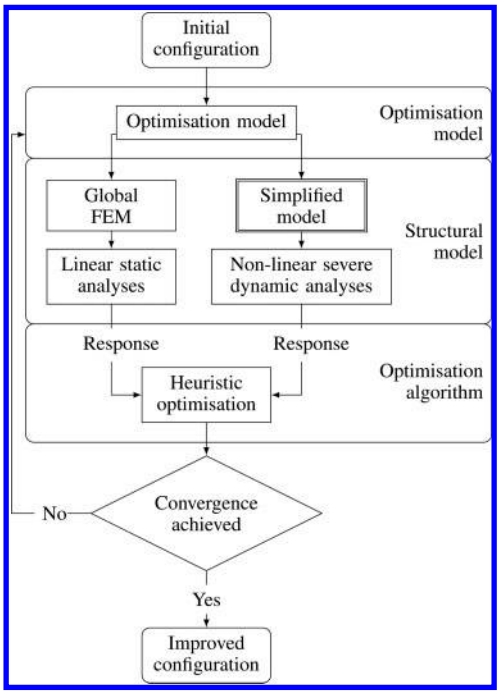

Figure 1. Optimisation scheme indicating the relevance of simplified modelling.

a method placing macro elements within a fuselage shell model to obtain the kinematic response of fuselage cross sections subjected to typical severe dynamic loads.

Most promising, however, appears the simplified modelling approach suggested by Liu and Day (2008) with respect to the obtained accuracy in relation to the computation time saved. It is verified for aluminium frame structures based on analytical formulations of plastic hinge development in impact loaded structures. Nevertheless, it contains inspiring features such as adjustable non-linear springs.

Yet, current discrete modelling techniques are applied either to metallic structures forming plastic hinges due to bending deformation or to axially loaded composite structures. In this paper a novel simplified structural modelling approach for stiffened CFRP panels is presented. As such it classifies in between spring-mass models and kinematic models.

Reconsidering the integration of the simplified modelling technique within the proposed topological optimisation scheme, the requirements remain open.

In essence there are two essential prerequisites:

1. elapsed computer time per calculation less than 60 seconds
2. less than 20% deviation on severe dynamic indicees such as displacement or energy absorption.

Where displacement implies significance on collapse mechanism and deformation pattern prediction, energy absorption indicates the suitability of an obtained solution.

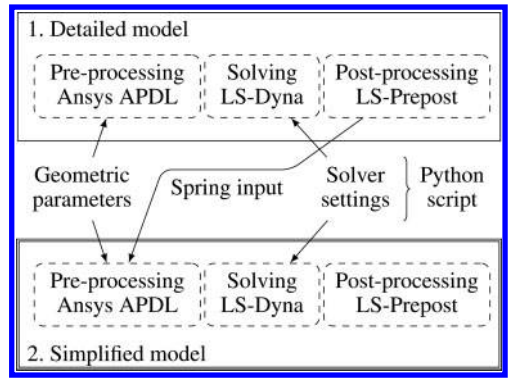

Figure 2. Shared data and data handling between models.

With the optimisation framework set, the aim of this paper is to propose a simplified modelling approach for stiffened CFRP panels. The following sections will guide the reader starting from the analysis of a detailed model via the examination of the governing collapse mechanism to the derivation of discrete element characteristics. This data is put forward to the simplified model as depicted in figure 2. Results of relevant indices are compared for both models before conclusions on the proposed modelling scheme complete this paper.

2 DETAILED MODEL

The detailed model describes a generic arrangement of aircraft composite fuselage design. The modelled section features a skin, stringers (longitudinal supports), frame (circumferential supports), and the interconnecting clips. It represents a 6° angular sector of an 650 mm wide circular configuration with 1800 mm radius. Such, it features roughly 16.5k elements. Except the aluminium rivets, the model entirely consists of CFRP components.

The corresponding material properties for standard aluminium (MAT1) and T700 carbon fibre/2510 epoxy prepreg (MAT54) are summarised in table 1 as published in Feraboli et al. (2011). Shells of type Belytschko-Tsay (ELFORM 2) are used to mesh the mid-surface geometry with an average size of 10 mm element edge length. Shell elements on the clip geometry are refined to an average edge length of 5 mm. Table 2 shows the stacking sequences and respective section properties of the individual parts. Beam elements of type Hughes-Liu (ELFORM 1) of 5 mm diameter are in place to connect the clips with the frame and the skin which are actually riveted. For the present approach rivet failure is assumed of negligible influence for the global deformation pattern, as will be shown later. Thus, an idealised modelling is applied using a solid circular cross-section with linear elastic properties.

However, as large deformations are considered parts may get in contact during the featured calculation time. Thus, three different contact definitions are

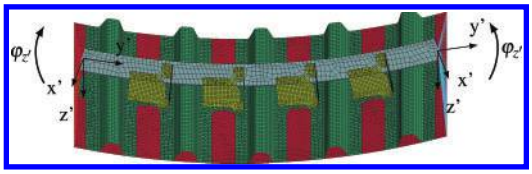

Figure 3. Detailed model with its constituents: skin (red), stringer (green), frame (grey), clips (yellow), and nodal rigid bodies on either side.

Table 1. Material properties of aluminium and CFRP. Subscripts T and C denote tension and compression respectively.

Property	Symbol	Value
Aluminium		
Density	ρ_{Alu}	2.78 g/cm^3
Modulus	E	70.0 GPa
Poisson's ratio	ν	0.33 –
CFRP		
Density	ρ_{CFRP}	1.52 g/cm^3
Modulus in 1-direction	E_1	127.00 GPa
Modulus in 2-direction	E_2	8.41 GPa
Shear modulus	G_{12}	4.21 GPa
Minor Poisson's ratio	ν_{21}	0.02049 –
Strength in 1-direction	X_T	2200.0 MPa
Strength in 1-direction	X_C	1470.0 MPa
Strength in 2-direction	Y_T	48.9 MPa
Strength in 2-direction	Y_C	199.0 MPa
Shear strength	S_{12}	154.0 MPa
Cured ply thickness	t	0.1667 mm

Table 2. Stacking sequences and resulting laminate thickness for individual parts ($[]_S$ denotes symmetry plane).

Part	Stacking sequence	Thickness mm
Skin	[45/-45/0/90/-45/45/90/0/-45/45]	1.667
Stringer	$[45/-45/0/90]_S$	1.334
Frame	[45/-45/0/90/-45/45/90/0/-45/45]	1.667
Clip	[45/-45/0/90/-45/45/90/0/-45/45]	1.667

set between the individual parts. First, stringers are tied to the skin with a TIED_NODES_TO_SURFACE algorithm. Second, AUTOMATIC_SURFACE_TO_SURFACE contacts are established between clip and frame, clip and stringer as well as frame and stringer. And third, an AUTOMATIC_SINGLE_SURFACE contact is defined in case of frame failure and subsequent shell contact under large deformations.

Nodal rigid bodies are utilised to apply boundary conditions to the near and far end of the modelled section. The boundary conditions are defined with respect to local coordinate systems (see figure 3). The near end is fixed in all degrees of freedom (DOFs) except the rotation about the local z-axis where a rotational displacement of 2.75° is prescribed as shown in figure 4. The same applies to the far end except the nodal rigid body is allowed to displace freely across the local y-z-plane. Furthermore, the nodes along the curved free

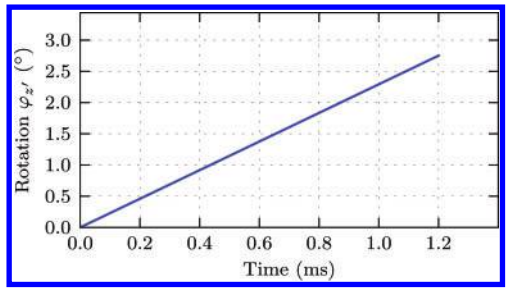

Figure 4. Prescribed rotational displacement applied at both ends of the section.

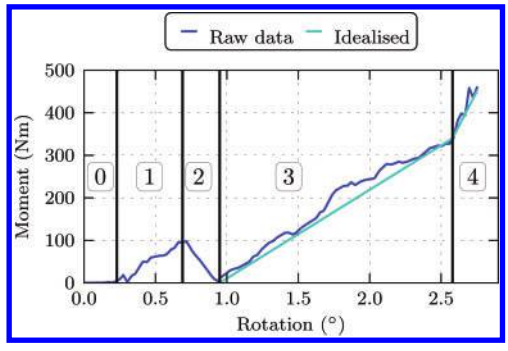

Figure 5. Bending moment about global z-axis vs. rotation response of frame section. The cyan curve shows the idealised spring characteristic used for model simplification. Numbers 0–4 denote stages as described in section 3.

edges of the skin and stringer shells are fixed in the global z-direction.

3 COLLAPSE MECHANISM

Due to the curved shape and the rotational displacement applied the frame is under compression forming a closing hinge. Closing hinge describes a deformation pattern where the curvature of a the structure increases upon load application. In total, five stages are determined in the evolution of the deformation mechanism as emphasised in figure 5.

(0) As the results are obtained from an explicit calculation with a time integration scheme, time elapses in the 'initial stage' until the entire structure is loaded. Since the section for response retrieval is located at central position (see figure 6) the far ends have already been rotated before a bending moment is obtained.

(1) In the 'elastic stage' the fuselage section deforms in a linear elastic manner with the frame displacing towards the skin. Therefore, the clips are under compression transferring the load onto the skin, which locally deforms.

(2) As the calculation progresses beyond 0.69° rotation the 'twisting stage' is initiated, with the clip walls starting to deform out-of-plane allowing the frame to twist and bend out of its initial planar shape. This distortion is eventually restrained by the clips holding the frame back.

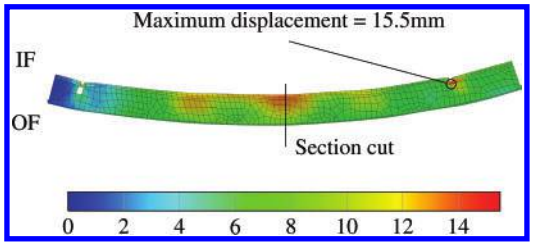

Figure 6. Contours of resultant displacement in global coordinates of frame. Element deletion indicates material failure progressing from inner flange (IF) radius towards outer flange (OF). The left side is globally constrained.

(3) In the 'buckling stage' the overall deformation increases resulting in local buckling on the inner flange of the frame (see figure 6). Induced by the inner flange buckling the frame's web and outer flange buckle locally. Deformation continues until the initial clearance between frame and stringer is entirely closed and the parts are getting in contact, with the frame then partially resting on the stringer.

(4) At 2.58° rotation the 'failure stage' of the progressing collapse mechanism is reached. It culminates in material failure initiation at the inner flange radius and failure progression towards the frame's web.

However, the observed deformation pattern is entirely based on relative part stiffness. The collapse mechanism outlined is only true for the geometry, material properties, and boundary conditions specified. With one of them being subject to modification different collapse modes may be observed.

4 DISCRETE ELEMENT CHARACTERISTICS

For the simplified modelling it is crucial to determine representative discrete element characteristics. In order to obtain those the frame and the clips are examined in detail. The section plane functionality in LS-Prepost assists that approach. It is used to perform section cuts of the model for analysis. The section cuts are fixed to the model and not fixed in space which is important when large deformations are present. Such, the bending moment of the frame is used to define the behaviour of rotational springs, and the axial forces of the clip are obtained to specify the performance of discrete beams.

The rotational spring characteristic is directly derived from figure 5. The response of stages 3 and 4 is idealised by a bi-linear law representing the bending moment vs. rotation characteristic. The first part is governed by the frame deformation whereas the increased stiffness of the second part results from the frame getting in contact with the stringers.

The discrete beam input for the frame-skin-interaction is evaluated locally at the clips. The axial force components are then applied to the respective DOF of the discrete beam. The graphs in figure 7 depict the idealised piecewise linear laws. The relation in x-direction is extended in order to account for

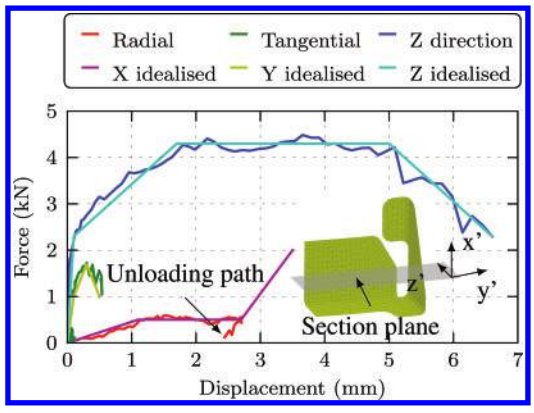

Figure 7. Force vs. displacement characteristics for the clip obtained from the detailed model. The lighter colours denote the idealised representatives forwarded to the simplified model.

the contact between frame and stringer as described in stage three of the collapse mechanism. As a first assumption the contact stiffness is estimated to be equal to the modulus of the curve's unloading part.

As the idealised relations are obtained from resultant responses they are defined in the first quadrant. This, however, describes the response to tensile load only. To account for compressive loading, all idealised relations are extended into the third quadrant by symmetry operation to the point of origin.

5 SIMPLIFIED MODEL

At early stages of the design process simplified modelling approaches are common practise. Inspired by the global finite element modelling technique (GFEM) applied in aircraft industry the proposed method uses beam and shell elements. Similar to the detailed modelling the shells are of type Belytschko-Tsay and the beams are of type Hughes-Liu. In addition, discrete beams replace the clips for translational coupling of frame and skin, as shown in figure 8. Different to the detailed model, the discrete elements are not located between the stringers but in fact share nodes with stringer beams. This modelling assumption is made to reduce number of elements to a minimum. Such, it features 43 elements only.

However, figure 9 illustrates the nodal coupling defined at the hinge positions. The DOFs of each individual node triple are coupled or conditioned according to table 3. The numerical code denotes $0 =$ free, $-1 =$ coupled, $1 =$ constrained, and $2 =$ fixed. Fixed and free refers to DOFs in global coordinates. Upper case *d* denotes the application of discrete beams (ELFORM 6, MAT119), whereas upper case *s* denotes the use of discrete springs (MATS04). Constrained describes a nodal constraint using the CONSTRAINED_NODE_SET keyword. Coupled refers to the application of discrete elements of either non-zero length for the translational springs coupling the frame to the skin or zero length for the translational

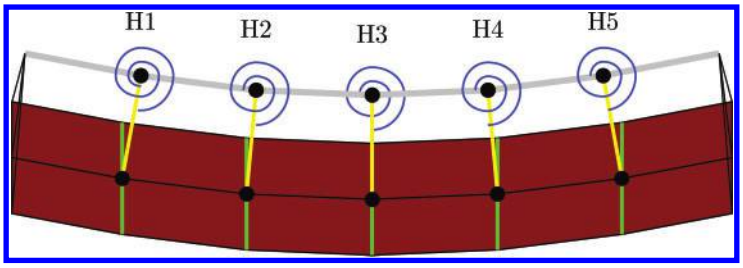

Figure 8. Simplified model with its constituents: skin (red), stringer (green), frame (grey), rotational springs (blue), discrete beams (yellow), and nodal rigid bodies on either side. H1-5 denote hinge positions.

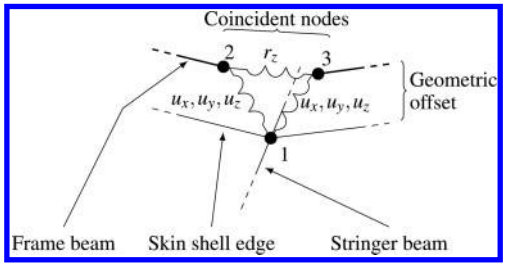

Figure 9. DOF coupling with discrete elements. Node numbering specified for interaction matrix 3.

Table 3. Interaction matrix for DOF coupling and conditioning. The numerical code reads as: free (0), coupled (−1), constrained (1), and fixed (2). Compare figure 9 for node numbering. -1^d denotes discrete beam and -1^s denotes spring element.

Global DOF		nodes 1-2	nodes 1-3	nodes 2-3
translation in x	u_x	-1^d	-1^d	1
translation in y	u_y	-1^d	-1^d	1
translation in z	u_z	-1^d	-1^d	1
rotation about x	r_x	0	0	2
rotation about y	r_y	0	0	2
rotation about z	r_z	0	0	-1^s

rotational non-linear springs acting between the frame nodes only.

In relation to the detailed model material properties and section definitions for the shell elements remain the same. In contrast linear elastic properties (MAT1) are assigned to the beam elements. It is assumed that all contribution to structural response beyond the elastic limit such as buckling and failure may be lumped in distinct positions evenly distributed along the frame. Hence, the sections in between act linear elastic. Yet, only homogenised properties may be specified in MAT1. The classical laminate theory (CLT) is used to obtain the desired properties according to Kollár and Springer (2003). For the stringer the elastic properties used are $E_{stringer} = 48.6$ GPa and $\nu_{stringer} = 0.314$. The elastic properties of the frame are $E_{frame} = 43.4$ GPa and $\nu_{frame} = 0.387$ accordingly.

Finally, with respect to the detailed model, nodal rigid bodies transfer the characterised boundary conditions to the structure.

Table 4. Comparison of results from both models.

Parameter	Detailed model	Simplified model	Difference (%)
Displ. global (mm)	7.02	6.85	2.5
Displ. hinge 5 (mm)	3.54	3.08	14.9
Displ. hinge 4 (mm)	3.54	3.29	7.6
Displ. hinge 3 (mm)	3.70	3.59	3.1
Displ. hinge 2 (mm)	3.51	3.67	4.4
Displ. hinge 1 (mm)	3.67	3.96	7.3
Absorbed energy (J)	125.8	159.1	20.9
Computer time (s)	2316	2	99.9

6 RESULTS AND COMPARISON

The results of this study are summarised in table 4. LS-Dyna version 971 in double precision mode is utilised for all calculations. The timing information provided are based on the usage of an dualcore i7 CPU M620 machine at 2.67 GHz with 4 CPUs specified for the calculation runs.

Comparing the computer time used for the solution of the detailed and simplified model significant savings are obvious.

Examining the timing information provided for the detailed model, the element processing holds about 92% and the contact algorithm about 7% of the total CPU time. Simplifying the model towards a minimal amount of elements and omitting contact definitions contributes substantially.

Displacements and energy absorption are relevant indices in severe dynamic structural response. Therefore the resultant displacement at the hinge positions as well as the global deformation are compared. Surveying all displacements, the discrepancies are indeed less then 15% which is well within the range initially specified. Figure 10 contains the chronological sequence of the overall displacement of both, the detailed and the simplified model which are in adequate agreement. This, however, proofs the assumption of lumping non-linear structural response in distinct positions right.

Comparing the overall energy absorption featured in figure 11 reveals moderate agreement. Between 3–5 mm global resultant displacement the energy response diverges. This displacement range coincides with the twisting stage outlined in section 3. Yet, the

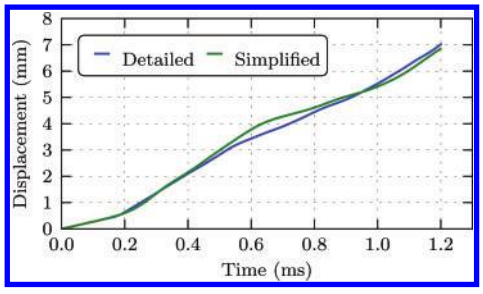

Figure 10. Comparison of the global resultant displacement at the nodal rigid body master nodes.

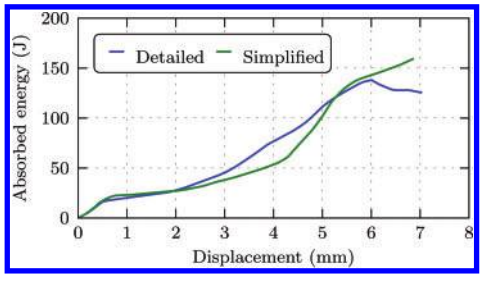

Figure 11. Comparison of overall energy absorption.

offset is recovered up to the failure stage where graphs separate again. The difference on energy absorption between the detailed and the simplified model is 20.9% at termination time. Although being more then initially sepcified, this offset is still acceptable considering the requirements of simultaneous static and dynamic optimisation. Hence, particular attention is to be paid on the failure stage with respect to further verification of the proposed method.

7 CONCLUSIONS

This paper established a novel simplified structural modelling approach for stiffened panels. The results illustrate the benefits of model simplification and findings are summarised as:

1. Representing skin-frame-interaction as well as collapse modes immanent to CFRP fuselage constituents by idealised deformation characteristics is a feasible approach.
2. All contribution to structural response beyond the elastic limit such as buckling and failure may be lumped in distinct positions evenly distributed along the frame.
3. Replacing detailed shell model features by beam and discrete elements significantly reduces computational effort. At the same time the accuracy deduction is acceptable considering system response optimisation requirements.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to AIRBUS Operations GmbH for supporting this work. The present work benefited from the input of Dr Dieter Hachenberg, Dr Lars Fiedler, and Mr Lars Margull who provided valuable assistance and thoughtful comments to the undertaking of the research summarised here.

ABSTRACT: The dynamic analysis of poles made of advanced composite materials is carried out for different length-thickness ratios and layup sequences. The numerical results using ABAQUS obtained for plates and shells are in good agreement with those reported by other investigators. The new results for laminated composite pole structures in this study mainly show the effect of the interactions between the radius-length ratio and other various parameters. The effect of fiber angles of long composite poles also investigated. Key observation points are discussed and a brief design guideline is given.

1 INTRODUCTION

With the advancement of technology in composite materials, applications of laminated composites to pole structures are advantageous because of their light weight, high specific stiffnesses and high specific strengths. However, laminated poles with a long length may result in a significant change of the dynamic characteristics during various external loading. Therefore, it is essential to study the effect of fiber angles and geometries simultaneously on the frequency of layered poles.

Numerous theories exist for laminated composite plates or structures. Many these theories were developed originally for thin shells and are based on the Kirchhoff-Love kinematic hypothesis (Sanders, 1963). However, these classical theories are inadequate to describe accurately the kinematic behavior of anisotropic composite shells. The first-order shear deformation theory (FSDT) has been extended by other investigators to deal with those problems (Kraus, 1967; Sanders, 1059; Zukas and Vinson, 1971). In general, a first order shear deformation theory can describe easily and accurately the kinematic behavior of a thin composite structure (Reddy, 2004). The composite pole types can be practically applied to wind turbine towers. Polyzois et al. (2009) studied static and dynamic characteristics of multi-cell jointed glass fiber-reinforced polymer (GFRP) wind turbine towers.

In this paper, we performed a finite element analysis based on FSDT to analyze the free vibration of laminated poles with a long length. Very little research has been studied to identify the interaction between vibrations and layup sequences for long composite pole type structures. The length-thickness ratio and layup sequence of laminated poles with different geometries could play a dominant role in determining and efficiently controlling the dynamic characteristics of the composite structure without causing a change in its material properties. Numerical examples are focused on the changes in natural frequencies for different radius-length ratios, layup sequences, shapes of the cross-section and interactions between these parameters.

2 BASIC THEORY

In the laminated structures, the stiffness properties are function of the normal coordinate. In Figure 1 a cross-section of laminated plate composed of N layers is presented. A linear elastic properties of the anisotropic layers are characterized by the tensor of elasticity C_{ijkl}. In many applications, it can be assumed that calculations of shell stiffness properties can be performed neglecting the differences in spatial and shell mid-surface metrics. In this case, the Hook's law for each layer can be written by

$$S_{ij} = C_{ijkl} E_{kl} \tag{1}$$

Since the present formulation is based on the natural coordinate reference frame, we introduce here an explicit transformation scheme between natural coordinates and the global coordinate system, to obtain a natural coordinate based constitutive equation. The stress tensor in the natural coordinate can be written as follows:

$$\tilde{S}_{ij} = \tilde{C}_{ijkl} \tilde{E}_{kl} = \tilde{J}_0 \mathbf{T} \tilde{D}_{ijkl} \mathbf{T}^{\mathrm{T}} \tilde{E}_{kl} \tag{2}$$

where $\tilde{J}_0$ is the determinant of the Jacobian matrix and $\tilde{D}_{ijkl}$ is the constitutive matrix for orthotropic materials with the material angle θ. The transformation matrix $\mathbf{T}$ in Eqation 2 is given by Han *et al.* (2004). The strain energy U can be expressed by

$$U = \frac{1}{2} \int_A \int_{-h/2}^{h/2} \tilde{C}_{ijkl} \tilde{E}_{ij} \tilde{E}_{kl} \, d\xi_3 \, dA \tag{3}$$

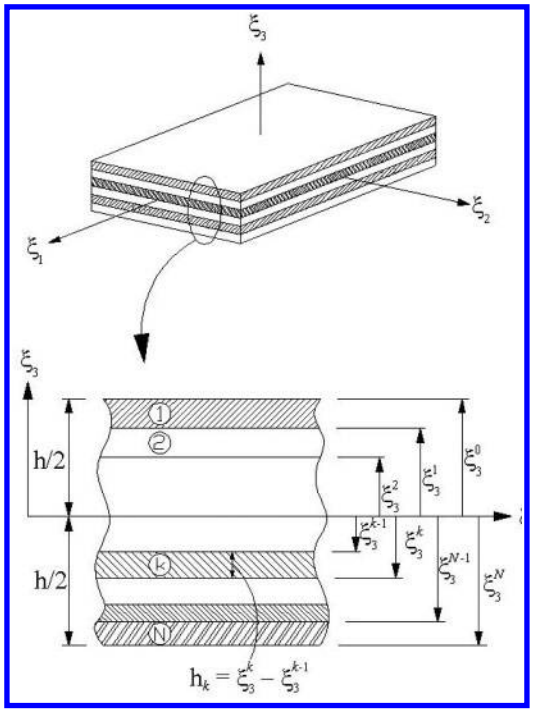

Figure 1. Cross-section of laminated plate composed of N layers.

After integration, throughout the thickness, the strain energy can be obtained in terms of shell quantities: stress resultants and couples and laminated shell stiffness characteristics

$$A_{\alpha\beta\gamma\delta}, B_{\alpha\beta\gamma\delta}, D_{\alpha\beta\gamma\delta} = \int_{-h/2}^{h/2} \tilde{C}_{\alpha\beta\gamma\delta}(1, \xi_3, \xi_3^2)\, d\xi_3 \quad ,$$
$$A_{\alpha 3\beta 3} = k_s \int_{-h/2}^{h/2} \tilde{C}_{\alpha 3\beta 3}\, d\xi_3 \quad . \tag{4}$$

The Reissner's value of 5/6 is used as the transverse shear correction factor in the FE formulation based on the first shear deformation theory.

The shell element displays resultant forces acting on a laminate which are obtained by integration of stresses through the laminate thickness. In this study, we impose the plane state on the natural constitutive equation of Equation 2 before forming the equivalent constitutive equation. The constitutive relations of the composite laminate are as follows:

$$\begin{Bmatrix} N_{\alpha\beta} \\ M_{\alpha\beta} \\ Q_{\alpha 3} \end{Bmatrix} = \begin{bmatrix} A_{\alpha\beta\gamma\delta} & B_{\alpha\beta\gamma\delta} & 0 \\ B_{\alpha\beta\gamma\delta} & D_{\alpha\beta\gamma\delta} & 0 \\ 0 & 0 & A_{\alpha 3\beta 3} \end{bmatrix} \begin{Bmatrix} \tilde{E}^m_{\gamma\delta} \\ \tilde{E}^b_{\gamma\delta} \\ \tilde{E}^s_{\beta 3} \end{Bmatrix} \tag{5}$$

3 FINITE ELEMENT MODEL

In the current study, the ABAQUS program was used to develop finite element models for simulating the structural behavior of laminated composite poles. The poles tested had an average height of 5.00 m from the base.

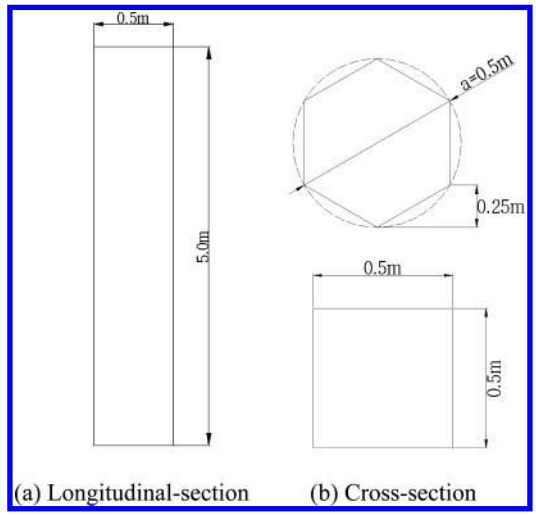

Figure 2. Two type test models.

The sectional properties are shown in Figure 2. Each ply of the laminates has equal thickness. The material properties of the plies are $E_1 = 40.0E_2$, $G_{12} = 0.5E_2$, $G_{23} = 0.6E_2$ $G_{13} = 0.5E_2$, and Poisson's ratio = 0.25. The produced natural frequencies are normalized. Figure 3 shows finite element laminated composite models using different element types in ABAQUS program. The mass density is assumed for convenience to have a unit value. The boundary conditions are free-clamped supported such as a cantilever beam.

4 NUMERICAL EXAMPLES

4.1 *Quadrangle poles*

Table 1∼3 show non-dimensional natural frequencies of quadrangle poles for different layup sequences and length-thickness ratios (a/h). It can be observed from the tables that the use of different layup sequences (symmetry or anti-symmetry) has a negligible effect on the laminated poles, regardless of the fiber angles and length-thickness ratios. On the other hand, the induced frequency for the same layup sequence is strongly dependent on the fiber angle, especially for $[0/90]_s$ and $[15/-75]_2$.

4.2 *Hexagon poles*

Table 4∼6 show non-dimensional natural frequencies of hexagon poles for different layup sequences and length-thickness ratios (a/h). The produced natural frequencies for hexagon poles show a similar trend with those of quadrangle poles. The highest frequency occurs for the laminate with a layup sequence of [0/90/90/0] or [0/90/0/90] because its stiffness is greater than that of the others. The differences between the layup sequences for different fiber angles depend on many geometrical parameters such as shape of the cross-section, length-to-thickness ratio, and boundary conditions.

4.3 *Mode shapes*

Figures 5∼6 show the mode shapes of symmetric cross-ply laminated quadrangle and hexagon poles with free-clamped ends. Each figure represents (a) symmetric vertical bending, (b) symmetric horizontal bending, (c) torsional, and (d) antisymmetric horizontal bending modes, respectively. As shown in the figures, some peculiar and complex mode shapes are produced due to the combined effect of both shapes of the cross-section of and layup stacking sequences.

5 SUMMARY AND CONCLUSION

A technique based on the first-order shear deformation plate theory is developed to analyze the static and free vibration behavior of pole structures made of laminated composite materials. The usage of composite for poles could be an attractive approach from the practical point of view, not only because it has high stiffness but also because we can avoid the undesirable corrosion occurred in steel structures.

The technique is then implemented for quadrangle and hexagon poles of various layup sequences and end conditions to compare the results obtained

from different length-to-thickness ratios. It is observed that the use of different layup sequences make little difference regardless of fiber angles, but the produced frequencies for different fiber angles become significant for various length-to-thickness ratios.

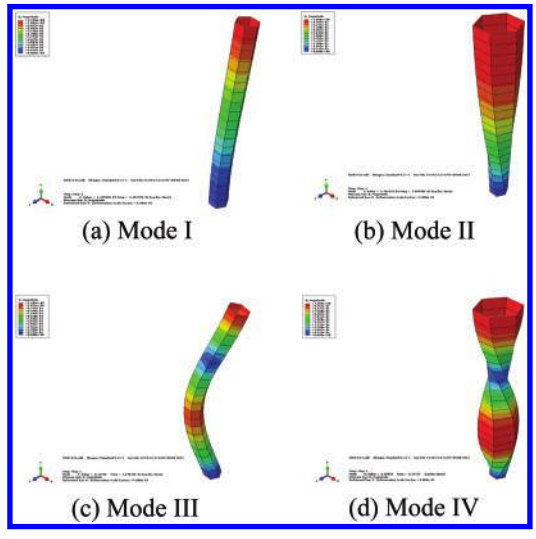

Figure 5. Mode shapes of hexagon laminated composite poles (0/90/90/0).

For composite poles with the closed section, e.g., quadrangle or hexagon box, the significance could be greater, because it is not only the properties of the materials but also the sectional properties of the member that makes large contributions to the overall behavior of the structure. The results of this study may serve as a benchmark for future guidelines in designing composite pole structures. But our parametric study is only an example and more studies should be carried out for individual design cases.

Experiments on fatigue behaviour of sandwich panels

Harald Nelke & Jörg Lange
Institut für Stahlbau und Werkstoffmechanik, Technische Universität Darmstadt

ABSTRACT: Sandwich structures are widely used in structural engineering. Sandwich panels for building construction differ strongly from sandwich structures in mechanical engineering: The core material is lighter, the face sheets are thinner and the panel width is greater. So far applications for these sandwich panels are limited to installations where static or quasi-static loads occur. In this paper primary results of high-cycle fatigue behaviour are presented for the core materials polyurethane (PU) and mineral wool (MW). The tests are carried out on a three-point-bending test setup. Samples measure 168 cm × 70 cm × 20 cm. The following failure types are observed: Shear failure (MW), Wrinkling (PU & MW) and indentation of face sheet (PU). By comparing the cyclic results to the static tests, it can be pointed out that the face sheet failures are related to a cyclic damage of core material in compression.

1 INTRODUCTION

The advantages of sandwich panels in structural engineering are obvious. They are light in weight and combine a core which is structural member and thermal insulation. And most important, they are cost effective in production and easy to mount. Two different types of core material are examined in this paper: Mineral wool (MW) and polyurethane foam (PU). Mineral wool is incombustible and can be fully recycled. Polyurethane is lighter, cheaper and better in insulation than mineral wool, but only flame retardant.

Sandwich panels are automatically fabricated in production lines: Coils deliver the steel for both face sheets on which the mineral wool has to be glued whereas the polyurethane glues on its own. Detailed information about the production process, constructional solutions and mounting can be found in Pöoter(2010). Sandwich panels are used as wall or roof panels. The thickness normally varies between 40 mm and 200 mm. This paper focuses on wall panels of 200 mm. The face sheets are usually made out of steel with a minimum yield strength of $f_{y,k} = 220$ MPa. The thickness is typically between 0.4 mm and 1.0 mm. The construction and calculation of sandwich panels is regulated in Europe according to EN 14509.

On structural point of view sandwich panels can be assessed according to the sandwich theory formulated in Stamm & Witte (1974). A brief derivation and more information about sandwich panels is given in Lange & Berner (2010). This theory states that sandwich elements with planar or quasi-planar face sheets can be divided into two structural parts: The face sheets act as a two-point cross section and take over the bending moment whereas the core carries all the shear force. Typical failure modes are: Wrinkling or yielding of face sheets, shear or compression failure of the core and delamination between face sheet and core.

Under normal conditions static or quasi-static loads dominate in structural engineering. But there is number of applications where loading occurs cyclic and the fatigue strength becomes important. Indeed, sandwich structures have already been used for applications requiring resistance to cyclic loads such as offshore structures, wind energy converters, shipbuilding or aerospace. One of the most renowned systems is probably the Sandwich Plate System (SPS) (Kennedy 2007). But all these sandwich structures differ strongly from sandwich panels used in building construction. Mostly the face sheet material is different[1] the ratio of face sheet thickness to element width is far higher and the core material is much denser (compare e.g. Mathieson & Fam 2011, Kennedy 2007, Roosen 2005, Sharma, Narasimha Murthy, & Krishna 2004, Burman 1998).

Mineral wool as core material in fatigue tests has almost not been investigated. Buska, Lybye, & Maciulaitis (2008) analysed the effect of point loads on mineral wool boards. In their studies the mineral wool is not included in a sandwich construction, but it works as a pure insulation board on flat roofs which are usually loaded for service reasons only.

2 EXPERIMENTAL SETUP

The experiments can be regarded as pretests to examine in which way sandwich elements perform under cyclic load. The test setup is a three-point-bending test with 140 cm of inner length and 168 cm of outer length

[1] E.g. fibre reinforced polymers instead of steel.

(figure 1). Loads were applied via a Schenck servo hydraulic testing machine for tension with a maximum load of 200 kN (figure 2).

The samples measured 168 cm × 70 cm × 20 cm (length × width × thickness). The local conditions limited the length and the width to the chosen values (see figure 2). The thickness of 20 cm results from the maximum thickness which is usually produced. The maximum thickness is necessary since the testing machine worked at its minimum level of force: Smaller elements might not have withstand the minimum loads.

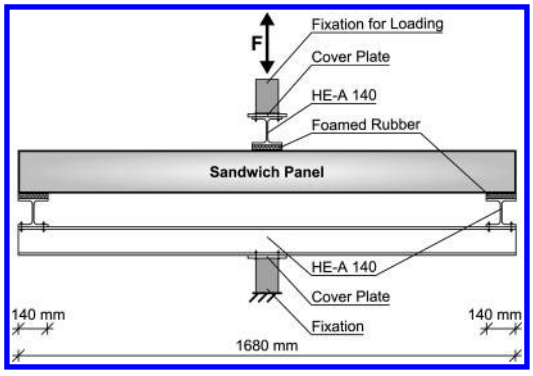

Figure 1. Three-Point-Bending Test: Schematic Test Setup.

Figure 2. Three-Point-Bending Test: Photograph of the Test Setup.

The samples were cut out of whole elements measuring 6,00 m × 1,00 m (MW) and 6,00 m × 1,10 m (PU) respectively. Samples with a core of rock wool originate from tested elements (Six-Point-Bending-Test for wrinkling failure) and were cut out by hand with a jig saw. Samples with a core of polyurethane foam originate from brand new elements and were cut out manually with a band saw.

Table 1 lists the profiling and the main material properties of tested samples. Material properties for samples with mineral wool as core material were fully determined according to EN 14509. For samples with a core of polyurethane foam instead, material properties from the same product line but from a different batch had to be used. But still, they were determined according to EN 14509. So the material properties for samples with a core of PU can only serve as an estimate. A "positive" orientation means that the bottom side during production is placed in the compression area whereas a "negative" orientation stands for the opposite.

The samples were subjected to cyclic loads according to table 2. Where possible, the maximum load was increased by 15% after the given number of cycles. The capabilities of the hydraulic system limited the frequencies f. The frequencies were chosen as high as possible.

3 EXPERIMENTAL RESULTS

In table 2 the maximum number of cycles is given when the sample failed. Figures 3 to 7 show the failure

Figure 3. S-1: Wrinkling.

modes[2]. The wrinkling failure (S-1, S-4, S-5) and the shear crack failure with delamination (S-2) are typical failure modes of sandwich elements under static loads[3]. In contrast, the failure of S-3 (indentation of face sheet) is similar to wrinkling failure, but has not been observed in static tests yet.

During the tests the samples S-3, S-4 and S-5 had not shown any kind of damage such as cracks or delamination until failure. Sample S-1 was immediately near its bearing capacity and showed heavy deformations allover. The development of damage was observable for sample S-2. The delamination of both face sheets

[2] Note that in figure 3 and 4 the edges of face sheets are still capped with a silver tape which was necessary for mounting.

[3] E.g., wrinkling failure is normally enforced in a six-point-bending test on full elements, shear failure in a four-point-bending test on short beams (both according to EN 14509).

Figure 4. S-2: Shear Crack with Face Delamination (Both-Sided).

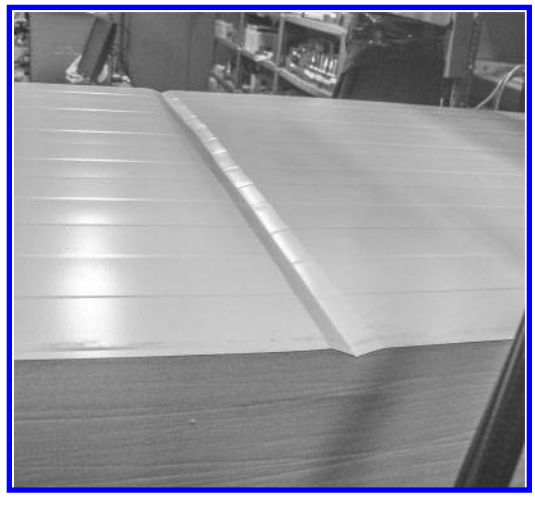

Figure 5. S-3: Indentation of Face Sheet.

increased slowly with an ongoing number of cycles. The shear crack appeared at about 350,000 cycles.

4 CALCULATION OF STRESSES

The loads and stresses from the fatigue test were compared to the results from the static tests to classify the results. As mentioned before the results from static tests for the samples S-3 to S-5 were obtained from a different batch. So variations in production are not covered within the comparison.

The static system of the test setup is a simply supported beam with a point load in the middle (figure 8). The span length cannot be clearly identified since the foamed rubber at both supports changed its characteristic during the tests. At the beginning it was still

Figure 6. S-4: Wrinkling.

Figure 7. S-5: Wrinkling.

stiff so that the supports were not fully under compression: A gap could be recognized of about half of the support width. With ongoing number of cycles the length of the gap first decreased and then disappeared at about 100,000 cycles. So in the calculations, there is a differentiation between two span lengths: Assuming a triangular distribution, the span length arises to approximately 145 cm for half of the support width under compression (N < 100,000 cycles) and to approximately 149 cm for a completely compressed support (N ≥ 100,000 cycles). For these two span lengths the following calculation is carried out.

The compressive stress, the shear stress and the normal stress in the upper face sheet are calculated for both, the maximum applied load and the cyclic load. All stresses are compared to the strength from the static tests (compare table 1) by calculating the stress-strength-ratio[4]. Table 3 shows the results. The stress

[4] For PU the compressive strength of core material (f_{Cc}) at elastic limit is chosen.

$L_S = 140$ mm	(Width of HE-A 140)

5 DISCUSSION OF RESULTS

Samples S-1 and S-4 withstood only a few hundred cycles in their maximum load range. The maximum load, not the cyclic load, is close to or even above the failure strength in static tests. Therefore the maximum loads are examined as well. Nevertheless, the failures were caused by cyclic load since the samples would had broken otherwise after one cycle.

Samples S-1, S-4 and S-5 failed in the same way; they all wrinkled. But table 3 shows that actually the stress-strength-ratios of differential normal stress in the upper face sheet were less than 50 % whereas

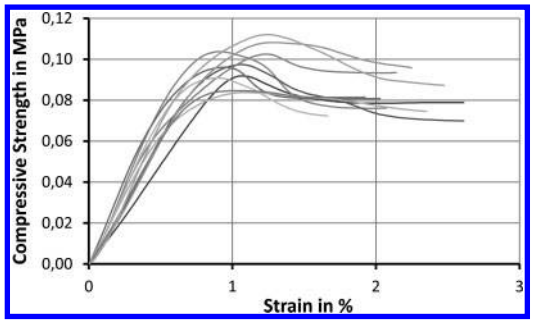

Figure 10. Compressive Strength Test of Core Material (MW).

the stress-strength-ratio for differential compressive stress was 92%, 127% and 109 % respectively. So it is assumed that the high level of compressive stress and, additionally for sample S-4 and S-5, the 60,000 cycles on lower load levels damaged the range in the middle where the load was applied. Due to this damage the continuous elastic support for the face sheet was reduced and therefore the face sheet wrinkled.

For samples S-1 (MW), S-4 and S-5 (both PU) the stress-strength-ratio for compressive stress even exceeded 100 %. Nevertheless, the samples did not fail immediately. The static compressive strength was determined from a test item measuring 10 cm × 10 cm. In the cyclic test the sample was much larger so that a three dimensional stress state could spread out which led to higher strength. For sample S-4 the stress-strength-ratio even reached 127 %, for sample S-5 still 109 %. There again the three dimensional stress state increased the compressive strength, but the characteristic stress-strain relation for PU shows another helping effect: After the elastic limit is reached (at about 3 %) the compressive strength still increases with a lower slope (figure 9). So exceeding the elastic limit will not lead to immediate failure. For MW the stress-strain relation for compression is totally different (figure 10): After the elastic limit and thereby the compressive strength is reached the curves decrease.

The failure mode for sample S-3 is similar to S-1, S-4 and S-5. There again the face sheet failed. It did not wrinkle though. Instead of that, the face sheet was pressed into the foam of PU. Looking at the stress-strength-ratios reveals that again a high level of differential compressive stress was reached. With 81 % the differential compressive stress (and with 89 % the maximum compressive stress, too) are still in the elastic range. There again this stress level damaged the range in the middle where the load was applied. Since the applied stress-strength-ratio was lower the damage might not spread as far as in samples S-4 and S-5 and in the adjacencies the foam was still strong enough to prevent the face sheet from lifting. Indeed, a video analysis watched in slow motion revealed that in sample S-4 the foam softened at first and afterwards the face sheet was lifted up (figure 11). The dark part in this figure indicates the flange of HE-A 140 in the middle of the sample.

Only Sample S-2 failed in shear. The damage underneath the location of load application[5] was not the decisive factor although the stress-strength-ratio for differential compressive stress reached 81% (as high as for sample S-3). On the one hand, the stress-strength-ratio for differential normal stress was quite low (24%). On the other hand, the face sheets started to delaminate due to the influence of shear from the beginning on. Regarding the shear crack in the mineral wool itself, it is assumed that a combination of shear

[5] From early on in the test, some cracks in the mineral wool were visible which slowly increased in length.

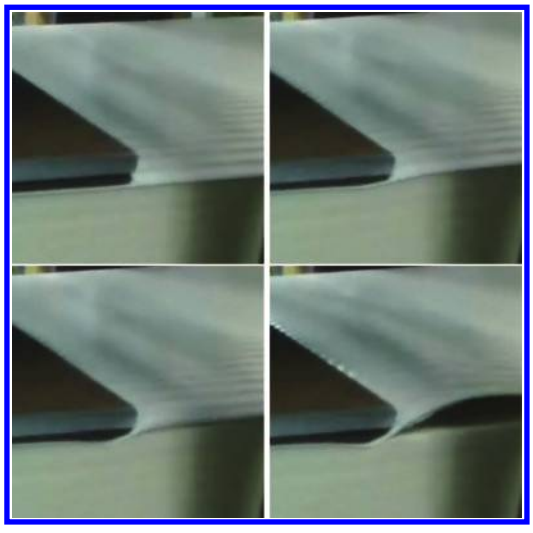

Figure 11. Sample S-4: Sequence of Failure.

crack and a loss of glue between the face sheet and the mineral wool encouraged the failure.

6 SUMMARY AND OUTLOOK

The sandwich system has many benefits in structural engineering. Sandwich panels used in building construction differ from sandwich structures in mechanical engineering since the insulation plays a decisive role for use as building envelope. So far the fatigue behaviour of these panels had not been studied yet. The main characteristics of sandwich panels are the thin face sheets (normally made out of steel), the light core material and a relative large thickness due to insulation.

A three-point-bending test was chosen for test setup. Due to local conditions the size of the samples was limited to 168 cm × 70 cm × 20 cm (length × width × thickness). The samples were loaded according to results of the static tests. After a certain number of cycles was exceeded (30,000 to 100,000 cycles) the initial cyclic load was increased by increasing the maximum load by 15%. The maximum number of cycles varied between a couple of 100 and over 400,000 depending on load and core material. Three failure modes occurred: Two known ones from static tests (shear failure with delamination of face sheet for MW and wrinkling of face sheet for PU and MW) and a new one similar to wrinkling (indentation of face sheet for PU).

Differential stresses from the cyclic load were calculated and compared to the static results. The mineral wool sample obviously failed in shear on account of a combination of loss of adhesive bond leading to delamination of both face sheets and a shear crack in the core material. It was pointed out that the samples where wrinkling and the indentation appeared failed for the same reason: Due to cyclic load, the compression strength of the core material was decreased and hence, the core material could not provide enough elastic support to prevent the face sheet from instability.

The presented tests form the basis to evaluate fatigue behaviour of sandwich panels in detail. The basic results are given to set up a test series: Fundamental failure modes are described, for different load levels the maximum number of cycles is determined (for both core materials) and the reasons for failure are discussed. Variations of span length, width, profiling of face sheet, producer and static system should now be tested. The following step will be the development of a mathematical model with the obtained results.

Modeling and nonlinear FE analysis of composite shells at finite rotations

R. Schmidt, M.N. Rao & T.D. Vu
RWTH Aachen University, Institute of General Mechanics, Germany

ABSTRACT: This paper presents a numerical study on static and stability analysis of layered composite structures. The shell element is based on the Reissner-Mindlin first-order shear deformation theory and strain-displacement relations are valid for small strains but finite rotations. Finite rotations are treated by Rodrigues parameterization. Two types of examples, static analysis of a composite laminated plate with hinged edges and stability analysis of a layered cross-ply cylindrical shell are carried out in the range of geometrically nonlinear deformation. The present simulations are compared with those obtained by finite element analyses based on first-order transverse shear deformation moderate or large rotation or refined von Kármán-type theories in earlier literature.

1 INTRODUCTION

Most of the available papers treat the nonlinear static response of composite structures with simplified geometrically nonlinear theories based either on the degenerated solid approach (Stander et al. (1989), Chang & Sawamiphakdi (1981)) or on various shell theories, such as the classical Kirchhoff-Love theory (Saigal et al. (1986)), the first- (Schmidt & Reddy (1988), Palmerio et al. (1990), Brank et al. (1995), Sansour & Bednarczyk (1995)) or third-order (Reddy (1990),Tsai et al. (1991)) transverse shear deformation theory, respectively, using the refined von Kármán-type or moderate rotation theories. Very less literature can be found on the geometrically nonlinear problems dealing with large rotations (e.g. Basar et al. (1993), Masud et al. (2000), Kreja & Schmidt (2006), Arciniega & Reddy (2007)).

The present paper deals with geometrically nonlinear static and stability analysis of composite laminated structures in the framework of the first-order transverse shear deformation theory (FOSD). The theory and the finite element method account for full geometrical nonlinearity, thus they account for arbitrary, finite rotations. The finite rotation theory (FRT) finite element formulation developed by Lentzen (2009) and extended to nonlinear vibration analysis in Schmidt et al. (2010) is applied. Here we deal with geometrically nonlinear static and stability problems of composite laminated structures. The Riks–Wempner arc-length control method is used to trace equilibrium paths in the pre- and post-buckling range of deformation.

We consider standard benchmark problems of composite laminated plate and shell structures. In particular, we compare the results with those that have been obtained in our earlier paper Kreja & Schmidt (2006) and Kreja (2007) where comparative finite element analysis has been performed using a variety of geometrically nonlinear shell theories.

2 FINITE ROTATION SHELL THEORY AND FINITE ELEMENT METHOD

Concerning the underlying theory and finite element method, the present paper is based on the FOSD shell theory for small strains and finite rotations of Habip (1965) and the FE implementation of Gruttmann & Wagner (2006) and Lentzen (2009).

Figure 1 shows the four-node element with the global $\boldsymbol{e}_i$, the local $\boldsymbol{a}_\alpha$, the natural $\xi-\eta$ and the orthonormal material $\boldsymbol{t}_i$ coordinate systems. The position vector to the reference surface in the initial configuration at node I is denoted as $\boldsymbol{x}_\mathbf{I}$. The position vector $\boldsymbol{r}$ to an arbitrary point in shell space is described as

$$\boldsymbol{r} = \boldsymbol{x}(\xi,\eta) + z\boldsymbol{d}(\xi,\eta) \tag{1}$$

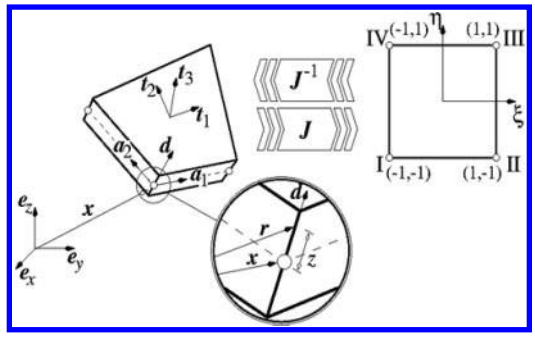

Figure 1. Definition of the coordinate systems in the FRT-element.

where z denotes the thickness coordinate ranging from the bottom to the top of the considered shell and $\boldsymbol{d}$ is the shell director.

In the framework of FOSD or Reissner-Mindlin hypothesis, the Green strain-tensor components for fully nonlinear finite rotation strain-displacement relations are obtained as (see Habip (1965))

$$\begin{aligned}
\varepsilon_{\alpha\beta} &= \overset{0}{\varepsilon}_{\alpha\beta} + \zeta \overset{1}{\varepsilon}_{\alpha\beta} + \zeta^2 \overset{2}{\varepsilon}_{\alpha\beta} \\
\varepsilon_{\alpha 3} &= \overset{0}{\varepsilon}_{\alpha 3} + \zeta \overset{1}{\varepsilon}_{\alpha 3} \\
\varepsilon_{33} &= 0
\end{aligned} \tag{2}$$

where

$$\begin{aligned}
\overset{0}{\varepsilon}_{\alpha\beta} &= \frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{x}}_{,\beta} - \boldsymbol{x}_{,\alpha}\cdot\boldsymbol{x}_{,\beta}\right) \\
\overset{1}{\varepsilon}_{\alpha\beta} &= \frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{d}}_{,\beta} + \bar{\boldsymbol{x}}_{,\beta}\cdot\bar{\boldsymbol{d}}_{,\alpha} - \boldsymbol{x}_{,\alpha}\cdot\boldsymbol{d}_{,\beta} - \boldsymbol{x}_{,\beta}\cdot\boldsymbol{d}_{,\alpha}\right) \\
\overset{2}{\varepsilon}_{\alpha\beta} &= \frac{1}{2}\left(\bar{\boldsymbol{d}}_{,\alpha}\cdot\bar{\boldsymbol{d}}_{,\beta} - \boldsymbol{d}_{,\alpha}\cdot\boldsymbol{d}_{,\beta}\right) \\
\overset{0}{\varepsilon}_{\alpha 3} &= \frac{1}{2}\left(\bar{\boldsymbol{x}}_{,\alpha}\cdot\bar{\boldsymbol{d}} - \boldsymbol{x}_{,\alpha}\cdot\boldsymbol{d}\right) \\
\overset{1}{\varepsilon}_{\alpha 3} &= \frac{1}{2}\left(\bar{\boldsymbol{d}}_{,\alpha}\cdot\bar{\boldsymbol{d}} - \boldsymbol{d}_{,\alpha}\cdot\boldsymbol{d}\right).
\end{aligned} \tag{3}$$

Here ζ denotes the thickness coordinate and an overbar indicates the deformed configuration. Due to thinness of the regarded plates and shells the components $\varepsilon^2_{\alpha\beta}$ and $\varepsilon^1_{\alpha 3}$ are neglected.

There are no kinematical restrictions with respect to the range of rotations. The director is assumed to be inextensible and the rotations are parameterized with the Rodriguez formulation. In order to overcome various types of locking, the ANS procedure suggested by Bathe & Dvorkin (1985), Hughes & Tezduyar (1981) combined with EAS (Lentzen (2009)) has been used.

2.1 *Variational formulation*

The finite element developed by Lentzen (2009) is based on the shell element of Gruttmann & Wagner (2006). In the present element a displacement based variational principle is chosen in order to reduce the number of internal variables. The variational formulation reads

$$\int_V \boldsymbol{S} : \delta\boldsymbol{\varepsilon}\, dV = \int_A \boldsymbol{T}\cdot\delta\boldsymbol{v}\, dA + \int_V \left(\rho(\boldsymbol{b} - \ddot{\boldsymbol{v}})\right)\cdot\delta\boldsymbol{v}\, dV \tag{4}$$

where $\boldsymbol{S}$ is the second Piola-Kirchhoff stress tensor, ε is the Green-Lagrange strain tensor, $\delta\boldsymbol{v}$ is the virtual displacement vector, $\boldsymbol{T}$ is the traction vector on the boundary, ρ is the mass density, $\boldsymbol{b}$ is the body force density and $\ddot{\boldsymbol{v}}$ is the acceleration vector. Here a total Lagrangian approach is adopted.

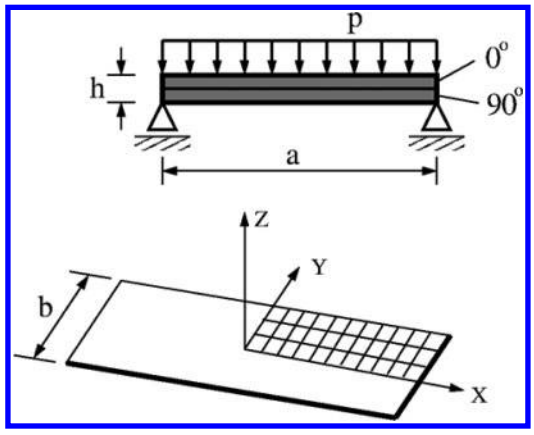

Figure 2. Two edges hinged composite laminated plate.

The variation of the Green-Lagrange strain tensor components are

$$\begin{aligned}
\delta\overset{0}{\varepsilon}_{\alpha\beta} &= \frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{x}}_{,\beta} + \bar{\boldsymbol{x}}_{,\alpha}\bullet\delta\bar{\boldsymbol{x}}_{,\beta}\right) \\
\delta\overset{1}{\varepsilon}_{\alpha\beta} &= \frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{d}}_{,\beta} + \delta\bar{\boldsymbol{x}}_{,\beta}\bullet\bar{\boldsymbol{d}}_{,\alpha} + \bar{\boldsymbol{x}}_{,\alpha}\bullet\delta\bar{\boldsymbol{d}}_{,\beta} + \bar{\boldsymbol{x}}_{,\beta}\bullet\delta\bar{\boldsymbol{d}}_{,\alpha}\right) \\
\delta\overset{0}{\varepsilon}_{\alpha 3} &= \frac{1}{2}\left(\delta\bar{\boldsymbol{x}}_{,\alpha}\bullet\bar{\boldsymbol{d}} + \bar{\boldsymbol{x}}_{,\beta}\bullet\delta\bar{\boldsymbol{d}}\right).
\end{aligned} \tag{5}$$

With $\bar{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{v}$, it follows that $\delta\bar{\boldsymbol{x}}_{,\alpha} = \delta\boldsymbol{v}_{,\alpha}$. The variation of the director and its linearization developed by Gruttman & Wagner (2006)

$$\delta\bar{\boldsymbol{d}} = \boldsymbol{\delta w}\times\bar{\boldsymbol{d}}\ , \tag{6}$$

has been used, where $\boldsymbol{\delta w}$ is the axial vector of rotation expressed in terms of virtual rotations as

$$\delta\boldsymbol{w} = \boldsymbol{H}\delta\boldsymbol{\omega} \tag{7}$$

and $\boldsymbol{H}$ is determined as

$$\boldsymbol{H} = \boldsymbol{I} + c_1\boldsymbol{W} + c_2\boldsymbol{W}^2 \tag{8}$$

with $c_1 = \frac{1-\cos\psi}{\psi^2}$ and $c_2 = \frac{\psi-\cos\psi}{\psi^3}$,
where $\boldsymbol{W}$ is the rotation tensor and ψ is the rotation angle.

3 NUMERICAL EXAMPLES

3.1 *Asymmetric cross-ply laminated plate strip under uniformly distributed transverse load*

Here, the considered example is an asymmetric cross-ply laminated plate with hinged edges as shown in Figure 2. The geometry is defined by a = 9.0 in, b = 1.5 in, h = 0.04 in and the material properties are taken as $E_{11} = 2.0 \cdot 10^7$ psi, $E_{22} = 1.4 \cdot 10^6$ psi, $\nu_{12} = 0.3$, $G_{12} = G_{13} = G_{23} = 0.7 \cdot 10^6$ psi.

The deflection at the center of the plate is simulated by the present FOSD FRT model. Due to the

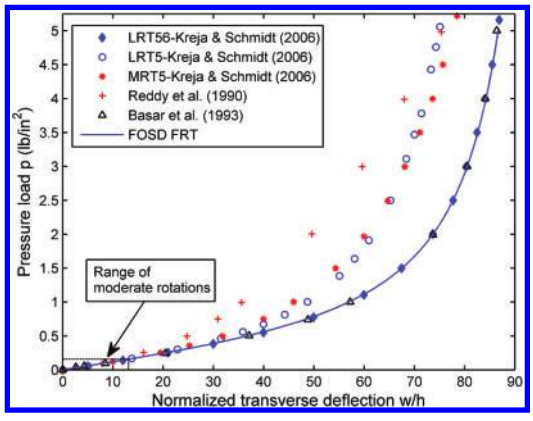

Figure 3. Normalized center deflection of the plate strip under pressure load.

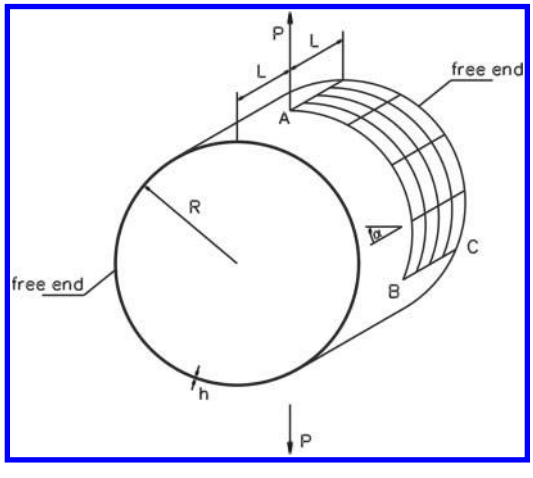

Figure 4. Cross-ply laminated short cylinder.

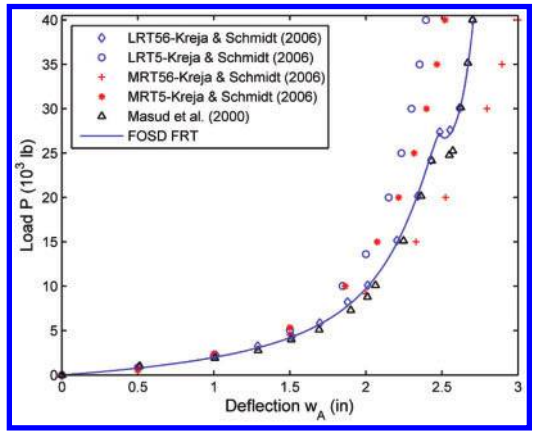

Figure 5. Radial deflection at point A for (0°/90°) plies lay-up.

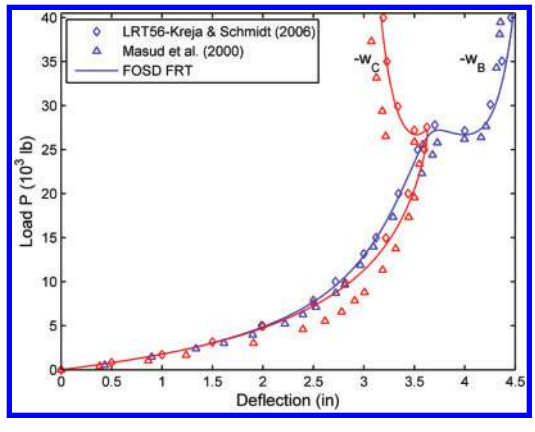

Figure 6. Radial deflection at points B and C for (0°/90°) plies lay-up.

dual symmetry of the analyzed structure, a quarter of the plate is modeled. In Figure 3 the normalized transverse deflection is compared with the existing literature given by Kreja & Schmidt (2006) (LTR56, LRT5, MRT5) together with the reference solutions of Reddy (1990) and Basar et al. (1993).

The von Kármán-type model of Reddy (1990) and the MRT5-Kreja & Schmidt (2006) model are capable of dealing with deflections in the range of moderate rotations marked in Figure 3. Our (FOSD FRT) results agree very well with those of Basar et al. (1993) and LRT56-Kreja & Schmidt (2006).

3.2 *Stretching of a composite laminated short cylinder*

The considered example is a well-known nonlinear benchmark problem of a composite laminated short open cylindrical shell stretched by two opposite point loads as shown in Figure 4. The material properties of each layer are $E_{11} = 30500$ ksi, $E_{22} = 10500$ ksi, $G_{12} = G_{13} = G_{23} = 4000$ ksi and $\nu_{12} = 0.3125$. Here two different cases of stacking sequences of the composite shell are analyzed. Due to the symmetry, only one octant of the shell is modeled using 20×32 elements (20 along the length and 32 along the periphery).

In the first simulation, the composite shell with fiber orientations (0°/90°) is analyzed. In Figure 5 the radial displacement at point A obtained from the present FE formulation is compared with reference solutions of Masud et al. (2000) and Kreja & Schmidt (2006), who use two large (LRT5, LRT56), and two moderate rotation (MRT5, MRT56) theories. The results of the present FE model (FOSD FRT) are in excellent agreement with those of the LRT56 model. The result of Masud et al. (2000) differs in the snap-through region, while the LRT5 model fails to predict the buckling phenomenon at all. As expected, the moderate rotation theories (see Librescu & Schmidt (1988), Schmidt & Reddy (1988), Palmerio, Reddy & Schmidt (1990), Kreja, Schmidt & Reddy (1997)) yield good results only in the range of moderate rotations.

Figure 6 show the radial displacements at points B and C obtained from the present simulation compared

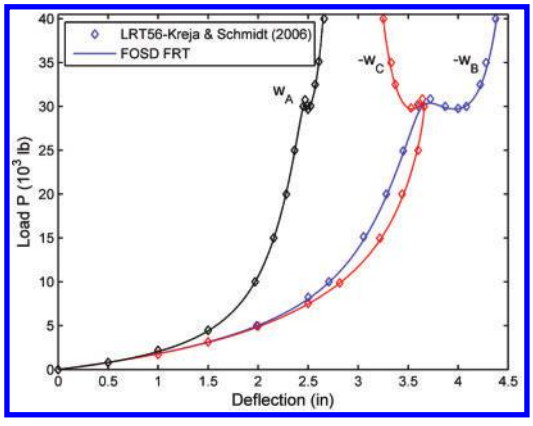

Figure 7. Radial deflection at points A, B and C for (90°/0°) plies lay-up.

with those of the existing literature. The present simulations are in very good agreement with the LRT56-Kreja & Schmidt (2006) model but differ from Masud et al. (2000), especially for point C.

In the second case, the numerical investigation is performed for the composite laminated short cylinder with lay-up (90°/0°). Figure 7 shows the radial displacements at points A, B and C, respectively. In Figure 7 the present simulations by FOSD FRT agree very well with those of LRT56-Kreja & Schmidt (2006). From Figures 3, 4 and 5, it can be observed that the snap-through load for stretching the composite laminated cylinder increases significantly, when the stacking sequence is changed from (0°/90°) to (90°/0°).

4 CONCLUSIONS

In this paper, nonlinear static analyses of a composite laminated plate strip subjected to uniform distributed load and stability analysis of cross-ply cylindrical shells with different stacking sequences are simulated by FOSD FRT model. The present simulations demonstrate the importance of the finite rotation models concerning a reliable consideration of nonlinearities.

ABSTRACT: The problem of non-destructively detecting delamination in laminated composite plates is addressed in this article. As the presence of a delamination causes a discontinuity in the first derivative of the mode shapes, a numerical method for detecting discontinuities in smooth piecewise functions and their derivatives, based on a polynomial-annihilation technique, has been proposed and applied to the problem of damage detection and localisation in plate-like structures for which only post-damage mode shapes are available. Mode shapes of the test structure can be obtained by measuring the dynamic response on a regular grid of points on the surface of the plate. In this study, numerical simulations have been performed using the FE method of the dynamic behaviour of orthotropic multilayered composite plates with delaminations; two cases have been analysed in which the delamination considered is between different layers of the composite plate. Results indicate that further development of the technique for non-destructive testing of composite structures would be highly worthwhile.

1 INTRODUCTION

In quite recent years there has been a significant effort to employ vibration-based inspection methods for identifying various types of structural damage. Since the occurrence of damage modifies the stiffness, the mass and the damping properties of a structure, its vibrational response will also change as a result of damage occurring. By appropriately assessing the eigen-parameters of a damaged structure, it may be possible to detect, locate, and even quantify the extent of damage. One class of damage identification techniques is based on the modifications of mode shapes due to damage or, alternatively, on the changes of the mode shape second derivatives ie. curvatures. These methods appear to be more sensitive than methods based on the modal frequency changes (Doebling et al. 1996).

Most of the techniques have been mainly applied to beam-like structures but more recently the attention has been focused also on two dimensional structures such as plates or shells.

Cornwell et al. (1999) extended the technique developed by Stubbs et al. (1996), based on the decrease in modal strain energy as defined by the curvature of the measured mode, to isotropic plates. One of the drawbacks of these methods is that data from the undamaged structure are required for the necessary comparison with the data of the damaged structure.

Ratcliffe (2000) proposed the so-called 'Gapped-Smoothing Technique' that enables damage detection in beam structures by evaluating a damage index which is a function only of the modal curvature calculated for the damaged state. The advantage is that no a-priori knowledge regarding the undamaged state is required. Battipede et al. (2001), simultaneously with Yoon et al. (2001) extended the 'Gapped-Smoothing Technique' to plate-like structures, publishing the latest developments and results in (Yoon et al. 2005).

Evolving the idea of an interpolation technique that can smooth the discontinuities in the data due to delamination, Smoothing Element Analysis (SEA) has been used and a damage index, that considers the change in strain energy due to the delamination in the laminated panel, has been formulated (Gherlone et al. 2005).

In general, methods based on modal curvatures often seem to demonstrate a high level of sensitivity to damage than those based on mode shapes. Unfortunately the weakness of these methods is that as they are based on a differentiation procedure making them highly sensitive also to the presence of measurement noise. Although the displacement mode shape is generally not sufficiently sensitive to small damage (Salawu & Williams, 1994), recently new methods

based on spatial wavelet analysis have emerged as a potential way of overcoming this problem thanks to their high-resolution: Indeed, although local changes in the mode shapes due to cracks or defects are not easily detectable, it may be possible to identify singularities in the signal by applying the wavelet transform to the mode shapes. This procedure has been applied to both one (Douka et al. 2003a, Chang, & Chen, 2003, Chang & Chen, 2005) and two-dimensional structures (Douka et al. 2003b). Latterly a method based on Gaussian Process Regression has been proposed by Hensman et al. (2011) and applied to the displacement mode shape of a cracked beam to identify damage.

In this paper a new methodology to localise damage in plate-like structures for which only few post-damage mode shapes are available is proposed. It is well known that a kind of damage such as a crack or a delamination, causes a discontinuity in the rotations and consequently in the first derivatives of the mode shapes. On this basis, the Polynomial Annihilation Edge Detection (PAED) technique (Archibald et al. 2008, Saxena, 2008), a numerical method for detecting discontinuities in smooth piecewise functions and their derivatives, already applied by Surace et al. (2013, in press a,b) to the problem of damage detection and localisation in beam-like structures, has been extended to bi-dimensional case.

The specific aim of this work is to detect the presence of delaminations in composite panels; due to this kind of damage, two sub-laminates are created respectively. Consequently, especially at high frequencies, the local modes exhibit discontinuities in the rotation function where the sub-laminates are separated. For this purpose a FE model of a delaminate composite plate has been simulated and some results are given for increasing amount of noise.

2 POLYNOMIAL ANNIHILATION EDGE AND DERIVATIVE DISCONTINUITY DETECTION IN THE 2-DIMENSIONAL CASE (PAED2)

In this section formulation for detecting edges and derivative discontinuities proposed by Archibald et al. (2008) for the mono-dimensional case, will be briefly presented for the 2-dimensional case:

Let's $f(x,y)$ be a piecewise smooth function,

$$\Omega = ([a,b] \times [a,b]) \subseteq R^2 \quad (1)$$

known only on the set of discrete points,

$$S = \{(x_1,y_1),\dots,(x_j,y_i),\dots,(x_M,y_N)\} \subseteq \Omega. \quad (2)$$

The method focuses on fixing a certain dimension, for instance y, and then applying the polynomial annihilation edge detection method along each line $y = y_i$ in the set S already considered.

Starting from this fact, the study becomes mono-dimensional through the M lines corresponding to N points in S.

For $y = y_i : i = 1,\dots N$
consider the set

$$S_i = \{(x_1,y_i),(x_2,y_i),\dots,(x_M,y_i)\} \subseteq [a,b] \times \{y_i\} \quad (3)$$

The function $f(x,y_i)$ is known in this set.

Consider the γ-derivation jump discontinuity in $f(x,y_i)$ so that $\frac{\partial^{(\gamma-1)}f}{\partial x^{\gamma-1}}(x,y_i)$ are continuous in $[a,b] \times \{y_i\}$, and jump discontinuity first appears in $\frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x,y_i)$.

It's also assumed that at any point (x,y_i) in the domain, $\frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x,y_i)$ has a well defined one-sided limits.

Let J_γ be the set of jump discontinuities in the γ^{th} partial derivative, that is:

$$J_\gamma = \left\{(\varepsilon,y_i): \frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x^+,y_i) \neq \frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x^-,y_i)\right\} \quad (4)$$

The local jump of γ^{th} partial derivatives defined as:

$$\left[\frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}\right](x,y_i) = \frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x^+,y_i) - \frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}(x^-,y_i).$$

An approximation to $\left[\frac{\partial^{(\gamma)}\mathrm{f}}{\partial \mathrm{X}^{\gamma}}\right](x,y_i)$ is sought that converges rapidly to zero away from the set of discontinuities.

To this end let (x,y_i) be a reconstruction point in the domain i.e. $(x,y_i) \in (a,b) \times \{y_i\}$.

For a given positive integer $m > \gamma$, a local stencil:

$$S_x^{y_i} = \{(x_j,y_i)\backslash(x_j,y_i) \in S_i\} = \{(x_1,y_i),(x_2,y_i),\dots\dots\dots,(x_{m+\gamma+2},y_i)\}, \quad (5)$$

is chosen so that

$$\min\left(\left|S_x^{+y_i}\right|,\left|S_x^{-y_i}\right|\right) > \gamma, \quad \text{with } S_x^{+y_i} = \{(x_j,y_i)\backslash(x_j,y_i) \in S_i \cap x_j x\} \text{ and } S_x^{-y_i} = S_x^{y_i}\backslash S_x^{+y_i}. \quad (6)$$

It is desirable to construct $L_{m,\gamma,S_x^{y_i}}f(x,y_i)$ to be an approximation *to* $\left[\frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}\right](x,y_i)$ such that:

$$L_{m,\gamma,S_x^{y_i}}f(x,y_i) \begin{cases} \left[\frac{\partial^{(\gamma)}f}{\partial x^{\gamma}}\right](\varepsilon,y_i), & \text{if } x_j \le x,\varepsilon \le x_{j+1}, \quad y = y_i \\ & \text{for some } (\varepsilon,y_i) \in J_\gamma \\ 0 & \text{otherwise} \end{cases}$$

$$\text{for } i = 1,\dots\dots\dots,N \quad (7)$$

The γ^{th} partial derivative edge detector, and original edge detector in the case $\gamma = 0$, of order m for stencil $S_x^{y_i}$ at $y = y_i$ is then defined as:

$$L_{m,\gamma,S_x^{y_i}}f(x,y_i) = \frac{1}{q_{m,\gamma}((x,y_i))}\sum_{(x_j,y_i)\in S_x^{y_i}} c_j((x,y_i))f(x_j,y_i). \quad (8)$$

The coefficients c_j are obtained by annihilating one-dimensional polynomials of degree up to *m-1* in the x direction by solving the linear system:

$$\sum_{(x_j,y_i)\in S_x^{y_i}} c_j(x,y_i)p_l(x_j,y_i) = p_l^m(x,y_i), \quad l = 1,\dots,m \tag{9}$$

subjected to constraints:

$$\sum_{(x_j,y_i)\in S_x^{+y_i}} c_j(x,y_i)p_l(x_j,y_i) = h^{-m+\gamma}(x)\, p_l^{\gamma}(x,y_i), \quad l = 0,\dots,\gamma; \tag{10}$$

where the density h or the maximum separation distance is defined as:

$$h(x) = \max\{|x_i - x_{i-1}| : x_i, x_{i-1} \in S_x^{y_i}, \quad y = y_i\} \tag{11}$$

Here p_l, $l = 1\dots m$, is a basis of π_m, the space of all polynomials of degree $\leq m$.

In the case of $\gamma = 0$, the constraint equations are not required.

The normalizing factor $q_{m,\gamma}((x,y_i))$ is given by:

$$q_{m,\gamma}((x,y_i)) = \sum_{(x,y_i)\in S_x^{+y_i}} c_j(x,y_i).\frac{(x-x_j)^{\gamma}}{\gamma!}. \tag{12}$$

The constraints guarantee that this factor is non-zero.

The annihilation of polynomials up to degree m results in all the first m terms in the Taylor expansion of $f(x,y_i)$ becoming zero.

When the remainder of the Taylor expansion is divided by the scaling factor$q_{m,\gamma}((x,y_i))$, a high order of convergence is achieved in the smooth regions.

The polynomial edge and derivative detector may lead to false jumps when using a low order of m, while selecting a large m causes oscillations near the discontinuities.

A *min-mod limiter* over multiple stencils and orders can be used on $L_{m,\gamma,S_x^{y_i}} f(x,y_i)$ to better resolve discontinuities.

Of course the same procedure can be applied also along each line $x = x_j$ (y direction) in the set S already considered in order to localise the discontinuity with more accuracy.

3 NUMERICAL RESULTS

The method has been applied to a delaminated multilayered composite plate in order to demonstrate its effectiveness. The in-plane dimensions of the plate are 300 × 300 mm and the lower horizontal edge is clamped. QUAD4 shell elements (5 × 5 mm) have been employed to discretise the plate domain with the use of the FEM code Nastran.

The stacking sequence of the composite plate is $(0°/45°/–45°/90°)_S$ for a total thickness of 2 mm, the material of each layer is a carbon-epoxy unidirectional composite ($E_1 = 111000$ MPa, $E_2 = 7857$ MPa, $G_{12} = G_{13} = G_{23} = 3290$ MPa, $\nu_{12} = 0.33$, $\rho = 1496$ Kg/m^3). The delamination size is 20 × 20 mm and two through-the-thickness positions:

Damage case A: between 1° and 2° layer

Damage case B: between 3° and 4° layer

have been tested. The geometric centre of the delaminated area is positioned as shown in Figure 1.

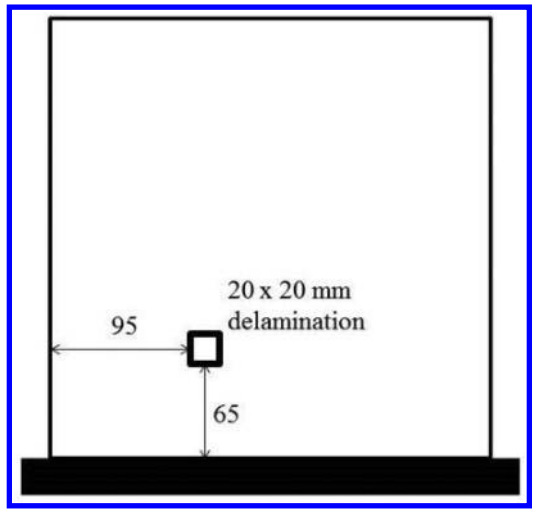

Figure 1. Delaminated multilayer composite plate.

Delaminations have been simulated using a shell element for each of the two thickness domains and attributing to them the correct offset with respect to the reference surface of the whole plate.

The first 36 mode shapes of the plate have been calculated and then to simulate the noise of experimental data white Gaussian noise was added to the data at various signal-to-noise ratios (SNR), utilising the *awgn*() MatLab function.

The PAED2 method has been applied firstly considering a grid of 61x61 points

Figures 2 and 3 illustrate indicative results for the method applied, respectively, to the first mode shape for damage case A and to the tenth mode shape for damage case B.

The subplots (a) and (b) of each figure show the contour plots of jump function approximation calculated respectively in the × and y directions for order $m = 5$ with the use of a central stencil.

In order to clearly visualise the results, a threshold t, has been applied to this function that only data greater than 70% of the maximum value are displayed.

The study reveals that the method is able to determine the location of the delamination in each case. In particular, two ridges appear in correspondence of the two sides of the rectangular delamination orthogonal to the direction in which the procedure has been applied since the discontinuity in the rotation occurs on the boundary of the delamination area

Thus in figure 2 the delamination is correctly located by employing the method with the first mode

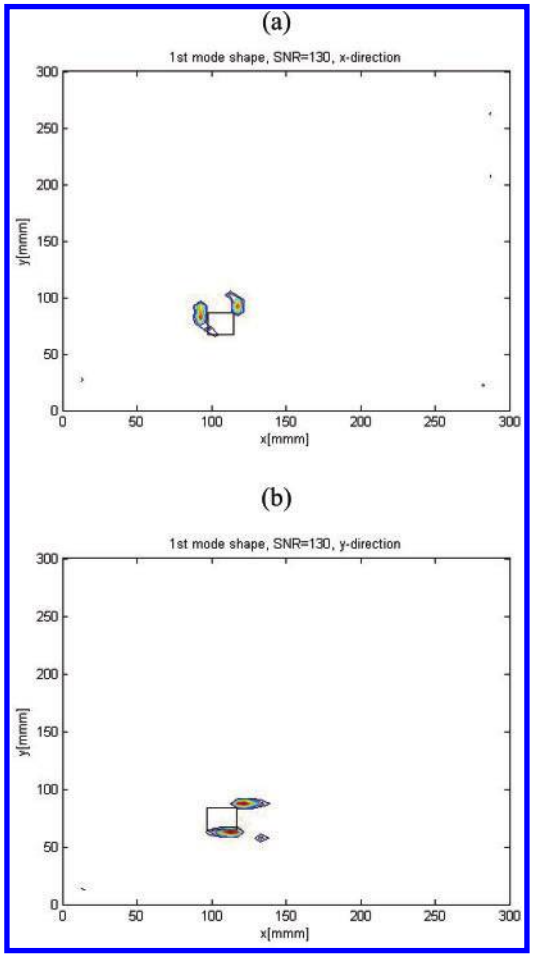

Figure 2. Contour plots of the jump function approximation in damage case A – 1st mode shape – SNR = 130. Grid: 61 × 61 (a) PAED2 method applied in x-direction; (b) PAED2 method applied in y-direction.

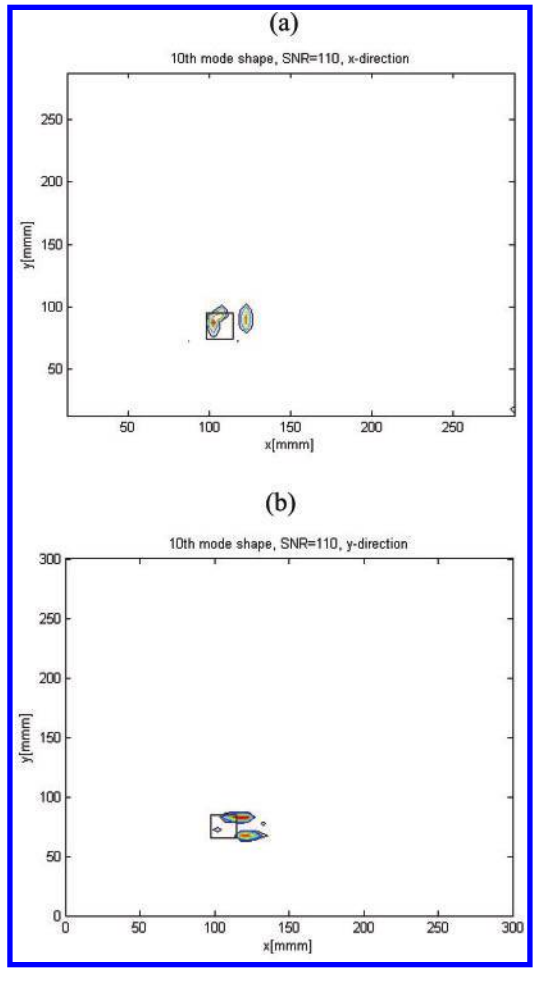

Figure 3. Contour plots of the jump function approximation in damage case B – 10th mode shape – SNR = 110. Grid: 61 × 61 (a) PAED2 method applied in x-direction; (b) PAED2 method applied in y-direction.

shape, when the maximum value of the signal to noise ratio is SNR = 130 while in figure 3 the method has been successfully applied to the 10th mode shape for a SNR = 110.

Afterwards the PAED2 procedure was applied considering a reduced grid of 31 × 31 points.

In figures 4 and 5 the results are reported for damage case B and A respectively. In particular in figure 4 the 20th mode shape polluted by a noise with SNR = 110 has been analysed while in figure 5 the 35th mode shape has been considered with a superimposed noise characterised by a SNR = 70. As the number of grid points is reduced, the method is still able to locate the damage zone but less precisely.

The analysis has been performed with all the 36 mode shapes and, in general it can be said that the modes more sensitive to delamination are the higher as they are local modes.

4 CONCLUSIONS

In this paper a numerical method for detecting discontinuities in smooth piecewise functions and their derivatives, based on a polynomial annihilation technique, has been applied to the problem of delamination detection and localisation in multilayered composite plates. This procedure is based on the fact that in correspondence of the boundary of the delamination area the rotation and hence the first derivative of the mode shapes presents a discontinuity. The performance of this methodology has been analysed with respect to simulated data using a finite element model of the plate for two cases of damage and increasing amounts of noise This method only requires post-damage mode shapes, which is very beneficial to real-world structures, as pre-damage information may not be available in many practical applications.

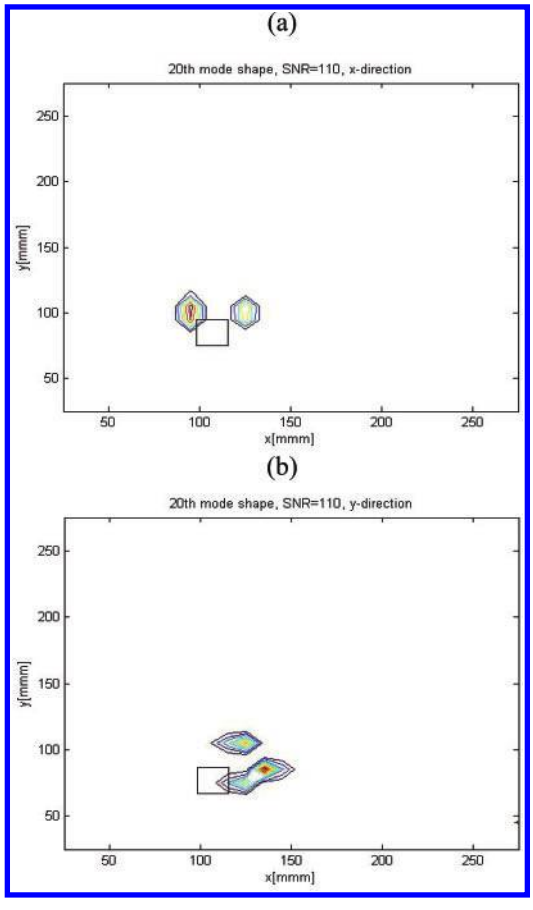

Figure 4. Contour plots of the jump function approximation in damage case B – 20th mode shape – SNR = 110. Grid: 31 × 31 (a) PAED2 method applied in x-direction; (b) PAED2 method applied in y-direction

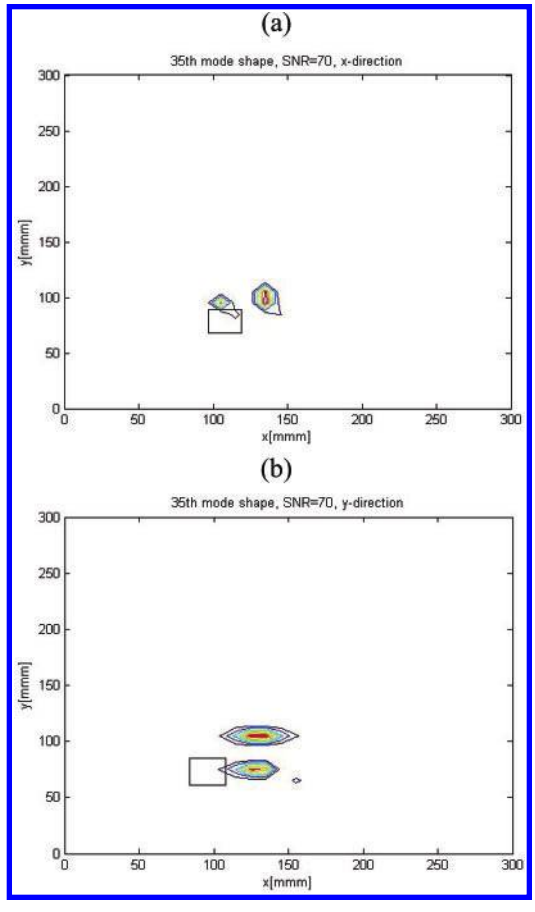

Figure 5. Contour plots of the jump function approximation in damage case A – 35th mode shape – SNR = 70. Grid: 31 × 31 (a) PAED2 method applied in x-direction; (b) PAED2 method applied in y-direction.

The approach requires a reasonably high spatial resolution of the measurement points on structures. This requirement can be addressed employing advanced measurement instrumentation, such as a scanning laser vibrometer, capable of acquiring data in a great number of observation points.

Future work would include experimental validation of the proposed method on a delaminated panel. Different numbers of sensor will be considered to investigate the influence of the sensor distribution density on the effectiveness of the proposed approach.

Finally more further research would comprise improving the derivative edge detection algorithm to make it more robust against noise.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Saxena for the useful suggestions and discussions.

ABSTRACT: The internal pressure and the serviceability limit determine the plate thickness and the stiffener spacing associated with industrial duct, which are currently designed based on elastic large deflection plate theory. The first part of this paper establishes relations between internal pressure and stiffener spacing recognizing the partial yielding, which may result in an economical and efficient duct system. This investigation is based on finite element analysis of long plates made of elastic-plastic steel. Based on a parametric study, the paper presents design equations for industrial plates for three different design scenarios namely; 0%, 16.5% and 33% of through thickness yielding of the plate. The stiffeners are often wide flanged steel beam sections, where one flange is connected to the side panel and the other flange is unsupported. Under suction situation, the unconnected flange is in compression and the duct panel is in tension. Since the tension flange is connected to the remaining system, the duct panel and the web may provide a partial rotational restraint to the compression flange of the stiffeners, which is often not considered in the design. The second part of the paper establishes the bending capacity of such stiffeners. This investigation discovered that the stiffener web slenderness and the overall stiffener slenderness dominate the behavior and the capacity of stiffeners of industrial ducts. The paper establishes the ranges of parameters for different failure modes and it establishes the corresponding bending strengths of the stiffened steel panels.

1 INTRODUCTION

The industrial duct systems, which are often of rectangular cross-section and transport large amounts of pressurized air or flue gases, can be considerably large steel structures. Figure 1 shows the sketch of such a duct system. The positive or negative pressure inside the ducts may be in the range of 10 to 15 kPa. The cross-section is formed by welding together thin steel plates which are stabilized by regularly spaced stiffeners. The cross-sectional dimensions of such industrial rectangular ducts may be 5–15 m. The practical spacing of the stiffeners (B) may be 1–2 m, which results in side wall plate elements with aspect ratio greater than 2, and thus the plate-stiffener system can be treated as a one-way slab system. The selection of stiffener spacing goes hand in hand with the plate thickness, which are determined by considering the allowable stress and deflection of a plate strip between stiffeners. The stress and deflection of the strip of the plate is generally calculated by utilizing the elastic large deflection plate theory which includes the bending stress and the diaphragm stress. However, a stiffened plate can carry loads beyond those causing the first yielding, occurring at the outer fibers at the stiffener locations, due to formation of plastic hinges and the resulting redistribution of stresses. In the first part of this paper, we create design charts and equations for relations between transverse pressure loads, transverse deflections, plate thickness and stiffener spacing, recognizing the benefit of yielding and the deflection limit of side walls of industrial ducts.

In view of the size and in view of the high loading, often, wide flanged structural sections are used as stiffeners, where one of flanges is weld connected to the side walls, whereas the other flange is unbraced and unsupported. When the duct is under suction (negative pressure) the unconnected/unbraced flange would be in compression and the connected flange and the side wall plate would be in tension. Under such loading, the distortional buckling of the stiffener may govern the strength of the stiffened panel. The second part of the paper concerns with the bending capacity and the design of such stiffeners, recognizing the benefits of rotational restraints provided by the duct panels and the web.

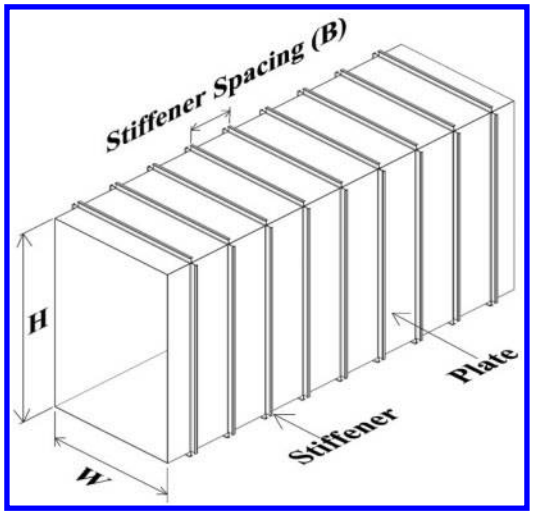

Figure 1. The sketch of a typical rectangular industrial duct.

2 THE CAPACITY OF THE SIDE WALLS (PLATE)

As shown in Figure 1, the plate element under consideration is supported by stiffeners along two of its edges and it is customary to assume that the plate is transversely and rotationally fixed supported, and in-plane held at these edges. Since the length of the plate elements (dimensions H or W) is often considerably larger than the dimension b (clear spacing between the stiffeners), these plate elements are treated as long plates. Therefore, the analysis and design of the plate elements can be based on consideration of a unit width of the plate element subjected to a pressure p. A total of 8 fundamental parameters, plate length b, thickness t, Young's modulus E, yield stress Fy, lateral pressure p, lateral deflection at mid-span δ, the total stress σ_t and the membrane stress σ_m, characterize the behavior, including the strength and the deformation, of laterally loaded plate. Note that the total longitudinal stress is the sum of the longitudinal bending stress σ_b and longitudinal membrane stress σ_m. The Poisson's ratio for a steel plate can be taken as 0.3. Without going into details, through dimensional analysis, these variables have been reduced to five non-dimensional parameters of significance that have been used in this investigation so that the results may be applied to a wider range of problems. They are; load parameter $Q = pE/(Fy^2)$, plate slenderness parameter $\beta = (b/t)(\sqrt{(Fy/E)}$, normalized deflection $\Delta = \delta/t$, normalized total stress $T = \sigma_t/Fy$, and normalized membrane stress $U = \sigma_m/Fy$. The validity (i.e. independence from scale and material characteristics) of these parameters for strength analysis, including partial yielding, was confirmed through nonlinear finite element analyses of plates (Thanga 2012).

A finite element model for the side wall plate, represented as a long plate was developed using the commercial multi-purpose nonlinear finite element program ADINA (2009). Figure 2 shows the overview of the plate under consideration. In this study, incremental nonlinear static finite element analysis was performed. In the finite element model the strip of plate was assumed to be fixed in such a manner that they cannot rotate nor pull in from two edges attached to stiffeners. The plate was subjected to increasing uniform lateral pressure p. The plate material was chosen to be carbon steel Grade A36 and assumed to be elastic-perfectly plastic material. The material properties of Grade A36 carbon steel are Elastic Modulus E = 200,000 MPa, Poisson Ratio $\upsilon = 0.3$ and Yield Strength Fy = 250 MPa. A four-node nonlinear shell element based on Mindlin/Reissner plate theory was used, which can be employed to model thick and thin general shell structures. von Mises yield criterion and isotropic hardening rule captured the yielding behavior. Furthermore, in order to simulate through thickness yielding, Newton-Cotes integration scheme with seven integration points were used in the thickness direction. From the results, the x directional stresses and strains at the support for each time step and for all integration points through thickness were obtained. The membrane stresses for each time step were calculated from the stress obtained at seven integration points through thickness. The pressure load and deflections for the case of onset of yielding at the first, second and third integration points were obtained. These correspond to 0%, 16.5% and 33% of through thickness yielding of the plate.

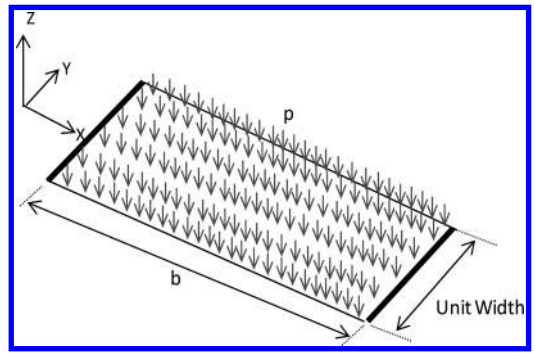

Figure 2. Side wall idealized as a long plate.

In practice, the ratio of stiffener spacing to plate thickness b/t is generally in the range of 125 to 350, thus analysis considered plate models having b/t = 125, 150, 175, 200, 225, 250, 275, 300, 325 and 350. Based on these parametric analyses, the limiting load parameters corresponding to different stages of partial yielding and the corresponding normalized peak deflections (at mid-span) and the normalized membrane stresses were established, and are graphically presented herein as Figures 3, 4, and 5. The relationship between the plate slenderness parameter $\beta = (b/t)/\sqrt{(Fy/E)}$ and the dimensionless limiting load parameter $Q = pE/(Fy^2)$, corresponding to three strength criteria, namely, onset of top fibre yielding and 16.5% and 33% of plate

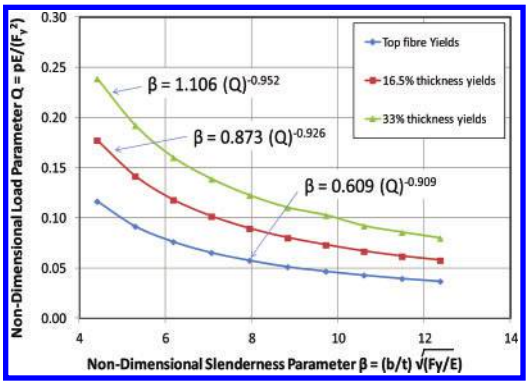

Figure 3. Load versus plate slenderness relations.

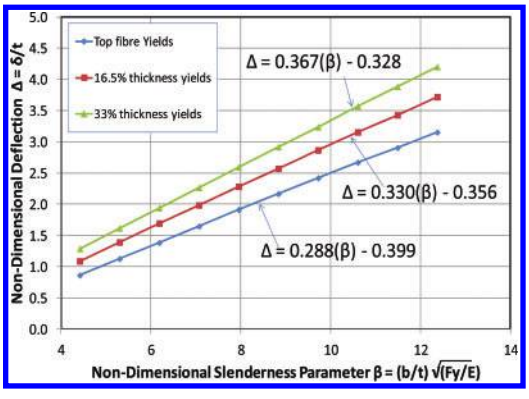

Figure 4. Deflection versus plate slenderness relations.

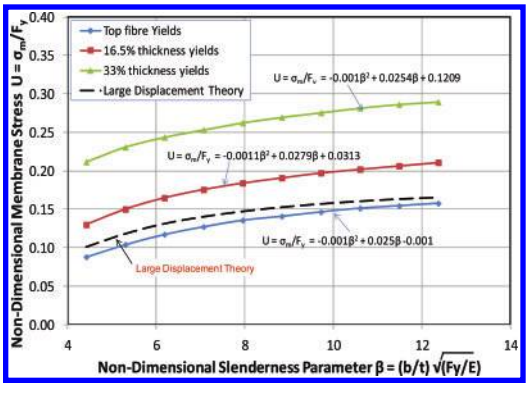

Figure 5. Membrane stress versus plate slenderness relations.

thickness yielding, are shown in Figure 3. It is evident from this figure that if the strength criterion permits plates undergoing partial yielding then the plates can carry higher lateral loads. For a given slenderness, the load resistance can be increased by approximately 55% for 16.5% partial yielding, and it can be increased by 113% by permitting 33% partial yielding. Power law based trend line equations for these plots were generated for designer's convenience and are also shown in this figure. Thus, a designer can decide on a strength criterion and choose the required slenderness (stiffener spacing) for a known load parameter. For example, if the strength criterion of 16.5% thickness yield is used to design a 5 mm thick steel (Grade A36 - Fy = 250 MPa) duct for a design internal pressure of 20 kPa (non-dimensional load parameter value of 0.064), the necessary slenderness parameter is $\beta \leq 11.13$, and the corresponding stiffener spacing is $b \leq 1575$ mm. The load corresponding to $\beta = 11.13$ at which the first yield occurs can be obtained from the graphs or through inverse relations given in Figure 3 as $Q = 0.041$, which corresponds to a pressure of 12.78 kPa. Therefore, the duct plate will not yield under service conditions, provided the service operating pressure is less than 12.78 kPa.

Figure 4 shows the relations between normalized peak deflection versus plate slenderness parameter corresponding to the three strength criteria under consideration. These relations are linear and the corresponding design equations are also given in Figure 4. The peak deflection of the plate corresponding to slenderness of the side wall plate of 11.13 at first yield can be obtained either from Figure 4 or from the relations $\Delta = 0.288(\beta) - 0.399$ as $\Delta = 2.806$. The corresponding deflection is 14.0 mm. Assuming an operating pressure of 12 kPa, the deflection at the operating pressure can be proportioned as 13.2 mm. In the design of rectangular industrial ducts under consideration, the generally accepted deflection limit is one hundredth of the stiffener spacing (b/100) or for this example 1575 mm/100 = 15.8 mm, therefore the partially yielding plate satisfies the serviceability limit. The deflection at ultimate limit state, that is when the pressure is 20 kPa or $Q = 0.064$, can be obtained either from Figure 4 plot corresponding to 16.5% yielding or from the relations $\Delta = 0.330(\beta) - 0.356$ as $\Delta = 3.317$ or 16.6 mm.

Figure 5 shows the relations between the non-dimensional membrane stress $U = \sigma_m/Fy$ and the slenderness parameter. It can be observed that the slender plates experience larger membrane stresses since such plates tend to resist the transverse loads through catenary action than bending action. It can also be observed that partial yielding causes increased membrane stresses. As presented earlier, the selection of plate thickness and stiffener spacing is based on total stress, which is the combination of the membrane stresses σ_m and the bending stress σ_b, and thus it is not really necessary to focus on the membrane stresses, except for the membrane stress σ_m in the end panel. In an interior panel, the in-plane forces due to the membrane stress σ_m are balanced by similar stresses that exist in the plates on either side of the interior plate under consideration. However, the membrane stress σ_m associated with the end panel needs to be externally resisted as the plate discontinues at the last stiffener.

3 THE CAPACITY OF THE STIFFENER

In view of the high loading and large size often, wide flanged structural sections are used as stiffeners. Figure 6 shows the general arrangement of the stiffened panel under suction and the repetitive pattern a structural engineer may consider for analysis and design of the stiffener. Under such loading, it appears that the strength of the stiffened panel may be controlled by lateral-torsional buckling of the stiffener. However, because of the constraints provided by the sidewalls, the stiffeners of the industrial duct may be treated as fully restrained against lateral translation and perhaps elastically restrained against twist. Under this scenario, the stiffener may undergo elastic or inelastic distortional buckling of the web rather than overall lateral-torsional buckling. Various researchers (Hancock, et al. 1980, Bradford and Trahair 1981, Bradford 1999) have built beam type finite elements to capture the web distortional buckling of beams. With the available plate/shell finite elements and the computing power, more precise modeling of stiffened steel plate panels can be achieved, where factors such as residual stresses and initial imperfections can be explicitly incorporated into such numerical models. Here we describe such a finite element model built for this study using Finite Element (FE) software package ADINA (2009).

The stiffeners in the duct are often equally spaced on the sides of the industrial duct. Because of the symmetry of stiffeners, only one repetitive panel as shown in Figure 6, i.e. a portion of the plate of width B with the stiffener centered on the plat strip, need to be modeled. The large deflection of laterally loaded stiffened plate panel involves in-plane and out-of-plane displacements. Therefore, shell element was used to study the behavior of the laterally loaded plate. The 4-node nonlinear shell element with the shell mid-surface nodal points was formulated with the assumptions used in the Timoshenko beam theory and the Mindlin/Reissner plate theory. The shell element used in this study can be employed to model thick and thin general shell structures, undergoing large displacement/small strains. The material model selected for the elements was elasto-plastic-multilinear material model with von Mises yield criterion, associated flow plasticity based on isotropic hardening rule. In order to capture the onset and spread of material yielding through thickness the Newton-Cotes rule with seven integration points was chosen. The Load Displacement Control (LDC) method of ADINA(2009) was used to capture the loading and unloading regions of the pressure load-lateral deflection response. The LDC method uses the load magnitude as the unknown and controls the incremental displacement from the load-displacement response. This method will terminate the computations at a user defined displacement.

Geometric imperfections may exist in plate elements of stiffened plate panels, thus the current study incorporated a double sine wave geometric imperfection. In general, the lines of web/flange intersections were defined to be straight, and either the middle line or the free edges along the length direction was defined to form a number of half sine waves. The Canadian standard for general requirements structural quality steel (CISC 2010) permits a maximum variation in straightness of the plate of 0.001 times of length of half sine wave, which was assigned here as the peak imperfection. The stiffener residual stresses were taken to be of a linear pattern with a peak compressive and tensile stresses of 0.3Fy, where Fy is the yield strength. The welding operations cause tensile stresses at the weld location and compressive stresses in adjacent areas. Staggered intermittent fillet welds are widely used in industrial ducts to connect the flange tip of the stiffener to the plate. In this analysis, a linearly varying tensile stresses (peak value of 0.5Fy) were assumed to exist in the plate to a distance of bf/6 on either side of the flange tip, where, bf is the flange width of the stiffener. Equilibrating compressive stresses were assumed to be of uniform distribution of value 0.125Fy over a distance of bf/3 on either side of the tensile stresses. The residual stresses were incorporated into the FE model as initial strains at nodal points.

Due to the severe nature of the material and geometric nonlinearities involved in the current analyses, a very dense mesh of shell elements was desirable in order to trace the nonlinear equilibrium path into the unloading regime. Based on a mesh density convergence study a dense mesh containing 5920 elements were used in the analysis. In actual physical dimensions, each element in this mesh is of size 50 mm × 20 mm. Figure 7 shows such a FE model.

The proposed finite element model was applied to an experimental study Udall (2007) conducted on such stiffened plates. To simulate the loading and the boundary condition of industrial duct, Udall (2007)

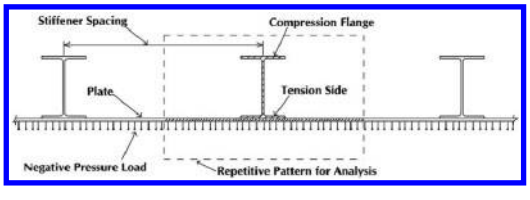

Figure 6. Configuration of an industrial duct stiffener.

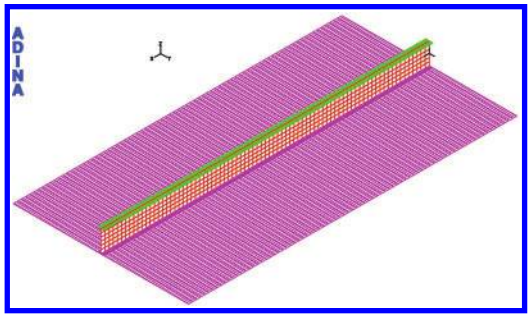

Figure 7. The finite element model of stiffener and side wall.

made a shallow box with removable top, which contained the plate and a stiffener. The box was made air tight and a vacuum pump caused suction pressure load. This arrangement simulated a single stiffener and plate between adjacent stiffeners subjected to lateral pressure. The size of the box was 4572 mm × 2438 mm in plan area and 152 mm deep. The thickness of plate was 4.76 mm and was made of ASTM 44 W steel having 300 MPa nominal yield strength. The test stiffeners were W8 × 18 wide flange sections made of A992 steel having 345 MPa nominal yield strength. W8 × 18 stiffener is considered a slender sections. The experiment was repeated two times. In the FE materials models for A992 and 44W steel grades the Young Modulus E for both grades was taken as 200 GPa, giving a corresponding yield strains of 0.001725 and 0.0015, respectively. An yield plateau was considered, and the strains at initiation of strain hardening for these steel grades were taken as 0.0345, and 0.03, respectively. The strain hardening slope E_{st} was considered to be (E/30 = 6.67 GPa). The ultimate strength of A992 and 44W steel grades were taken to be 450 MPa, and 400MPa, respectively.

The nodes along the four edges of the plate were constrained against translations and rotations, thereby creating fixed boundary conditions. The out-of-plane and in-plane lateral translation of flange and web of the stiffeners were not prevented, during the experiment and in the analysis, in order to create the case of an actual industrial duct structure. The analytical and experimental results for stiffened plate panel consisting of W8 × 18 stiffener are shown in Figure 8. The vertical and horizontal axes represent the pressure load in kPa and mid-span deflections in mm, respectively. It could be observed that the FE analysis results agree very well with the experimental results. The shapes of the curves are similar and the measured and the analytical strengths are comparable.

The failure of stiffened plate is primarily due to distortional buckling of the stiffener compression flange leading to section reaching its flexural capacity. The fundamental geometric and mechanical parameters affecting the behavior and strength of stiffener of the rectangular industrial duct are; B width of the plate (stiffener spacing), t plate thickness, h_w stiffener web height, t_w stiffener web thickness, b_f stiffener flange width, t_f stiffener flange thickness, L stiffener length, F_{ys} yield stress of stiffener material, F_{yp} yield stress of plate material, E Young's modulus of steel and M_a applied bending moment. Without going into details, through a dimensional analysis, it can be shown that the following five non-dimensional parameters, namely, β_1, β_2, β_3, β_4, M govern the behavior of a stiffened plate, where;

$\beta_1 = (b_f/t_f)\sqrt{(F_{ys}/E)}$ – stiffener flange flexural slenderness

$\beta_2 = ([h_w - 2t_f]/t_w)\sqrt{(F_{ys}/E)}$ – web flexural slenderness

$\beta_3 = (B/t)\sqrt{(F_{yp}/E)}$ – side wall plate slenderness

$\beta_4 = (L/r)\sqrt{(F_{ys}/E)}$ – stiffener overall slenderness

and M = Ma/My, where My is the yield moment capacity of the stiffened plate panel.

Eight models of stiffened plate panels each having identical dimensionless parameters $\beta_1 = 0.654$, $\beta_2 = 1.749$, $\beta_3 = 7.701$ and $\beta_4 = 7.889$ with different actual values for B, t, h_w, t_w, b_f, t_f, L, F_{ys} and F_{yp} were analyzed. The initial geometric imperfections and residual stresses were the same in all models. Figure 9 shows the non-dimensional applied bending moment (Ma/My) versus mid span vertical deflection Δ responses for all eight models. The ultimate moment can be easily obtained from these graphs, however, the Southwell plot method was used to obtain the distortional buckling moment Mcr of the stiffeners. Even though the yield moment My of these cases range between 93.4 kN.m. and 188.3 kN.m, the mean and standard deviation of normalized moments Mcr/My for all analysis models were found to be 1.138 and 0.002, respectively. Similarly, the mean and standard deviation for Mu/My of all models were found to be 1.159 and 0.002, respectively.

Therefore, it can be concluded that the dimensionless parameters identified above completely represent the behavior of stiffened plate panels associated with the industrial ducts. The impact of each of the parameters were investigated and the observations are summarized here in brief. For all intents and purposes,

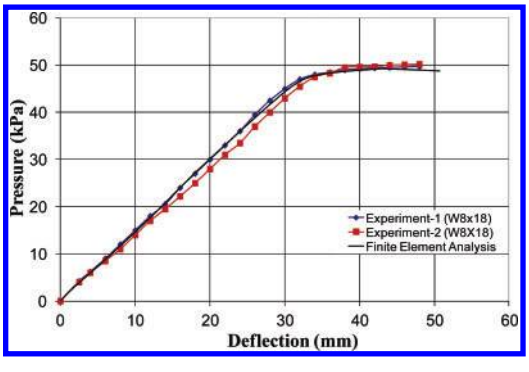

Figure 8. Pressure versus mid-span deflection of duct.

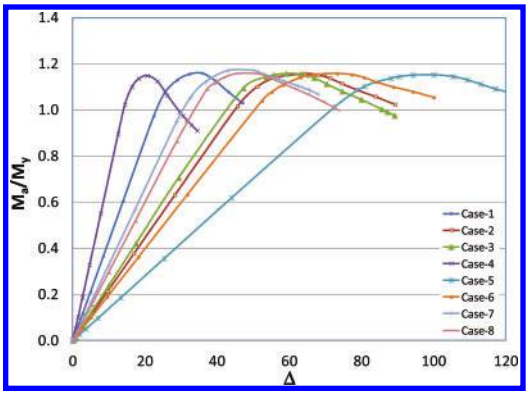

Figure 9. Normalized applied moment versus deflection.

the plate slenderness parameter β_3 did not influence the distortional buckling capacity or the flexural strength of stiffened plate panels subjected to negative pressure. Parametric studies indicated that when the stiffener slenderness parameter β_1 is less than one the system experiences distortional buckling at a moment of 1.163 My. When β_1 is greater than one, the stiffener flange experiences lo cal buckling resulting in reduced overall buckling strength and moment capacity. It was observed that most of the rolled steel sections contain compact flanges, and thus the value of stiffener flange slenderness parameter β_1 for these sections were noted to be less than 1. Therefore, it was concluded that for practical steel sections stiffener flange slenderness parameter β_1 did not influence the distortional buckling capacity or the flexural strength of stiffened plate panels subjected to negative pressure.

It was observed that the distortional buckle has a wave length (and an associated buckling moment) whose value depends on web flexural slenderness parameter β_2. It was also observed that there is a corresponding value of stiffener overall slenderness parameter, say, $\beta_{4(\text{critical})}$. There is no change in buckling moment for stiffeners having β_4 greater than the critical value $\beta_{4(\text{critical})}$. Thus, it was concluded that $\beta_4 > [\beta_{4(\text{critical})} = 3.33\ \beta_2 + 0.145]$ do not change the failure mode. It was further concluded that the stiffened plate system reaches the yield moment My, if $\beta_2 > 2$ and $\beta_4 > 3.33\ \beta_2 + 0.145$. For system having $\beta_2 < 2$ and $\beta_4 > 3.33\ \beta_2 + 0.145$ the distortional buckling moment can be established as Mcr = (1.51–0.275 β_2) My. Further details of this investigation are available in the thesis by Tharani (2012).

4 REMARKS

Based on finite element analysis of long steel plates subjected to pressure, this paper established the relations between pressure and plate slenderness parameter and between plate deflections and the slenderness parameter for three different design scenarios namely; 0%, 16.5% and 33% of through thickness yielding of the plate. Based on these results design equations have been derived for the convenience of designers of rectangular industrial ducts.

Under negative pressure (suction) situation, the unconnected flange of the stiffener of rectangular industrial duct side panels is in compression and the duct panel is in tension. The tension flange, which is connected to the duct panel, and the web may provide a partial rotational restraint to the compression flange of the stiffeners, thus the establishment of the bending capacity and the design of such stiffened steel panels are not straightforward. Finite element analysis models were built using the finite element software ADINA(2009). The finite element model included reasonable geometric imperfections and residual stresses. In order to capture the onset and spread of material yielding through thickness the Newton-Cotes rule with seven integration points was used. The Load Displacement Control (LDC) method was used to capture the loading and unloading regions of the pressure load-lateral deflection response. The finite element model was validated through comparison with experimental results. The difference between the predicted bending capacity and the measured capacity for the stiffener W8 × 18 is about 1%. Based on dimensional analysis the five non-dimensional parameters, namely, β_1, $\beta_2, \beta_3, \beta_4$, M those govern the behavior of a stiffened plate were identified. The finite element model discussed in this paper was used in a parametric study which resulted in design guidelines for such industrial ducts. However, in the interest brevity, these details are not given in this paper but may be available in future publications.

Structural behaviour of flexible straws

B. Zhang & Z. You
Department of Engineering Science, University of Oxford, Oxford, UK

ABSTRACT: The structural behaviour of flexible straws is investigated. Finite element models of conical frustum shells with reference to a real flexible straw are built and analysed. Moreover a parametric study is carried out. The results show that the collapse mechanism can vary due to different geometric configurations. The critical load which causes the snap-through is dependent of the geometric configurations as well.

1 INTRODUCTION

1.1 *Background*

Fascinating structural behaviour can be found on commonly-used utensils. A drinking straw is a thin-walled tube that a drinker uses to suck a beverage from its container. Flexible straws, or bendy straws, contains a corrugated portion that allows a kink being created and hence the flexibility. Modern flexible straws are normally made of Polypropylene (PP) and the corrugated portion has a shape shown in Figure 1.

Flexible straw belongs to a family of multi-stable thin-walled structures, such as Ping-Pong balls and a type of candy box, where inversion could occur under certain loadings. This behaviour is highly dependent on the ductility of the materials, e.g. it is impossible to push an egg, which is geometrically similar to a ping pong ball, into an inverted shape without fracturing it.

1.2 *Past Work*

1.2.1 *Snap-Through*

The snap-through behaviour is related to the flexible straw performance and is best illustrated by a 2D truss structure (Fig. 2) that consists of two identical rigid rods of length L connected with a pin joint at one end and supported by a pin joint and a roller with a horizontal linear spring of stiffness k at the other, respectively (Thompson and Hunt, 1973).

Initially, they are at an angle α to the horizontal line. When a concentrated load P is applied at the middle joint, angle α decreases to θ and the length of the spring decreases as well. The force due to the change in length of the spring is

$$F = 2kL(cos\theta - cos\alpha) \tag{1}$$

From the force equilibrium in the vertical direction, the downward force P can be written in terms of θ as

$$P = 4kL(sin\theta - cos\alpha\ tan\theta) \tag{2}$$

If we plot P against θ, the graph shown in Figure 3 is obtained. Starting at $\theta = \alpha$, the loading path is stable until the 'limit point' is reached. The model

Figure 1. The corrugated portions of flexible straws.

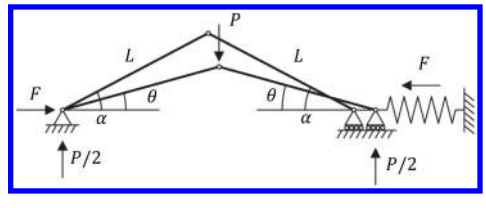

Figure 2. A basic 2D snap-through model.

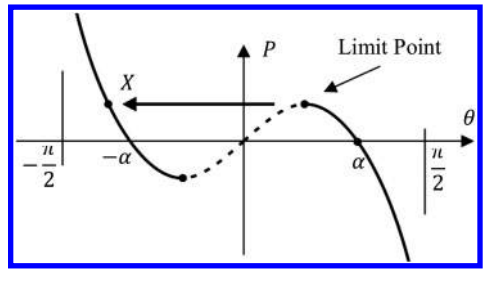

Figure 3. Plot of P againstθ in snap-through model.

snaps through to the point X. Though the path (dashed line in Figure 4) satisfies force equilibrium, they will not exist during an increasing force loading as the stability criteria cannot be met. The limit point is at $dP/d\theta = 0$, so

$$P_{cr} = 4kL[1 - (cos\alpha)^{2/3}]^{3/2} \quad (3)$$

If the load is released at point X, the model does not go back to its original shape. It follows the path back to the point at $\theta = -\alpha$, which is the second stable state of the model.

1.2.2 *Inversion of a Spherical Shell and a Egg-box*

Calladine (1985) summarised the inversion behaviour of some of the shell structures with large plastic deformations. One of his cases was the progressive inversion of a spherical shell. He proposed a plastic travelling hinge model to describe the progressive inversion behaviour of a spherical shell under downward point load.

A common egg-box consists of many close-top conical frusta which are arranged in lattice pattern. Deshpande & Fleck (2003) analysed the structural behaviour of an egg-box based on a modified plastic travelling hinge model.

As shown in Figure 4, the dash and solid lines represent the original and deformed shapes, respectively. The frustum is compressed between two frictionless rigid plates. They gave a following relationship between P and u,

$$\frac{P}{Yt^2} = \frac{2\pi tan\omega}{(2\omega - sin2\omega)^{1/2}}\left[\frac{a}{t} + \frac{u}{t}cot\omega\right]^{1/2} \quad (4)$$

It is noticed that Equation 4 is not applicable around the origin due to the assumption of the model. Hence the force that initiates the snap-through cannot be found by this model.

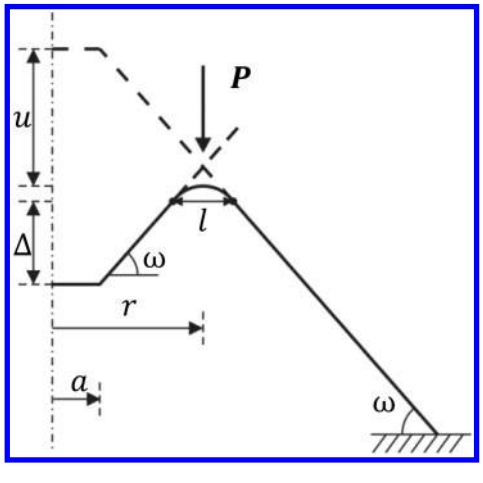

Figure 4. Cross-section of a closed-top conical frustum shell with thickness t.

1.3 *Objectives and Layout*

This paper examines the inversion behaviour of the flexible straw with the aim to utilise this feature in the design of energy absorption and multi-stable structures.

The layout of this paper is as follows. First in Chapter 2, the characteristics of flexible straws and a simplified geometrical model is presented, which are used in the subsequent analysis. Numerical analysis based on the finite element simulation is introduced in Chapter 3, followed by results and discussion in Chapter 4. Finally, final remarks and further work are given in Chapter 5, which concludes the paper.

2 GEOMETRIES

2.1 *Characteristics of a Flexible Straw*

A corrugated portion of a flexible straw shown in Figure 5a can be transformed into two states. It can shrink into that of Figure 5b, or be bent into that of Figure 5c. All of these three states are stable. The basic element of the flexible straws is a pair of conical frustum shells which are joined together. During each transformation, the deformation of the taller frustum is negligible hence it is reasonable to treat the taller frustum as a rigid body. Therefore, the deformation of the shorter frustum is considered lonely in this paper. The geometry of a frustum shell can be defined by tilting angle ω, bottom radius R_b, top radius R_t and shell thickness t, hence the height of the frustum h can be found in terms of ω, R_b and R_t, as shown in Figure 6. By observation, it was found that no distinct progressive inversion occurs during the transformation of the flexible straw, i.e. no formation of travelling hinges. It was expected that this was due to its dimensions and materials of the structure. We set out to prove this.

2.2 *Configurations for the Default Frustum and Variations*

The geometrical data of a typical flexible straw, given in Table 1, was measured and treated as a default frustum. Subsequently geometric parametric study was carried out by varying the height h, the tilt angle ω and the thickness t of the default frustum.

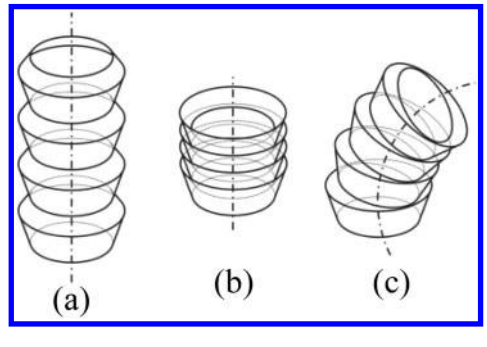

Figure 5. Three stable states of a corrugation portion of a flexible straw.

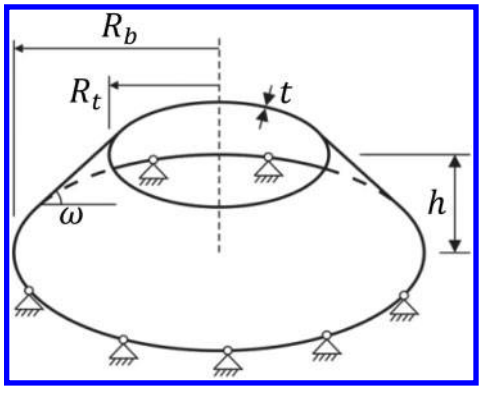

Figure 6. Configuration of a conical frustum shell.

Table 1. Typical data of the shorter frustum of flexible straws.

Dimension Type	Value & Units
Bottom Radius, R_b	2.95 mm
Top Radius, R_t	2.4 mm
Tilt Angle, ω	38.02°
Shell thickness, t	0.15 mm
Height, h	0.43 mm
Side length	0.698 mm

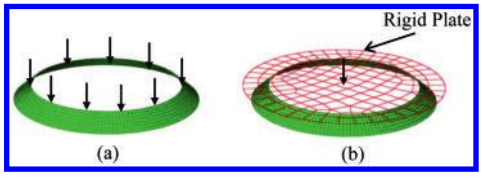

Figure 7. Two loading methods for the FE simulations.

3 NUMERICAL SIMULATION

Finite element (FE) simulations were performed using the general purpose finite element package ABAQUS Ver.6.10 (DSS 2010). A default frustum and several variations were built using shell elements according to the dimensions provided previously. The base of the frustum was constrained to have no relative displacement but free to rotate.

3.1 *Loading Methods*

In order to simulate the transformation of the shorter frustum and capture the inversion process, where a decrease in force has to be allowed in the loading history, the displacement-control loading was used in the simulations and the corresponding reaction force caused by the displacement was monitored and recorded. Two loading methods were considered: ring loading (Fig. 7a) and plate loading (Fig. 7b).

Table 2. Properties of Polypropylene (PP)

Property Name	Value & Units
Young's Modulus, E	1300 N/mm^2
Poisson's Ratio, ν	0.45
Yield Stress, σ_y	25 N/mm^2
Yield Strain, ε_y	1.9%
Density, ρ	940 kg/m^3

3.2 *Material Models*

Measuring the materials properties of this particular kind of straws is difficult. It was decided to use mean values of the PP's properties. Table 2 lists the values which are used in the simulation. The material was treated as an isotropic material. Two material models were used in the simulation: linear elastic (LE) and elastic-perfectly plastic (EPP).

3.3 *Solving Scheme*

The inversion was assumed to be a quasi-static problem, and hence no kinetic energy was associated with the problem. An implicit analysis was the best fit of the requirement. In this method, the stiffness matrix must be updated and reconstructed at each iteration due to the high non-linearity of the problems, and thus the analysis was computationally costly. An explicit analysis was used instead when the computational time was too long. In the implicit FE analysis, two nonlinear different iterative solution methods, the full Newton method and Riks method were used and the results were compared.

3.4 *Meshing*

The size of each shell element was controlled to be approximate 0.1 mm on the frustum. Hence, the default frustum had a total of 1141 shell elements. For the frusta with various tilt angles or thicknesses, the mesh has no difference from the default frustum. More elements of the same size were seeded for the frusta of various other heights accordingly.

4 SELECTED RESULTS AND DISCUSSION

4.1 *The Default Frustum*

Five simulations were carried out for the default frustum itself. The results are plotted at Figure 8.

As expected, the snap-through behaviour during the inversion has been captured in the analysis since the plots are quite similar to that shown in Figure 3.

No matter what loading method or solving scheme was used, the results were similar for same material model, which means the explicit scheme did a fair job on quasi-static simulations and the loading method did not affect the response. It is showing clearly on the graph that the critical force was larger for an LE material than that of an EPP one, given that Young's Modulus was the same. They followed the same loading path at the beginning and separated after the EPP

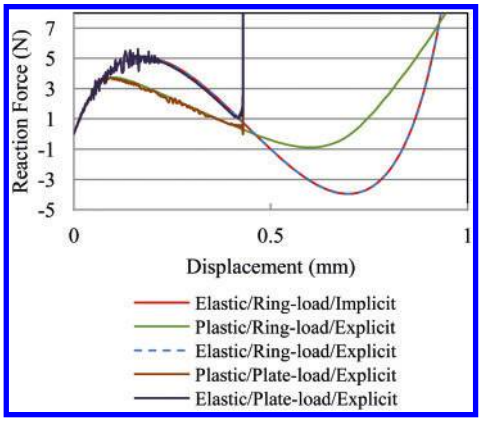

Figure 8. The default frustum results using different solving scheme.

material yielded. Afterwards, the reaction forces of EPP frusta started to drop while forces of the elastic frusta kept rising until its critical forces were reached.

For both plate-load/explicit cases, a sudden force increment to infinity was observed when the displacement was about 0.43 mm, which was the height of the frustum. This happened when the loading plate touched the bottom plane of the frustum, which could not be penetrated according to the boundary conditions.

4.2 *Frusta of Various Heights*

Including the default configuration, frusta with five different heights were analysed. The ring-load method was used for the LE material and the plate-load method was used for the EPP material.

4.2.1 *LE Material*

The results are plotted in Figure 9. Results from the Newton method and Riks method agreed well with each other at the beginning. Some of the load history started to split then. This was because the Newton method used displacement as increment while the Riks method used a varying load-factor which was modified at each iteration until convergence was achieved. The load history obtained by the Riks method indicated other possible equilibriums but was not energetically favourable in this case, and hence these paths could not exist in reality.

As the height increased, the value of the critical forces varied. The shape of the loading path changed as well. Initially, the default frustum gave a sine-like curve; as the height went larger, a rather flat zone in the force graph was formed and the zone expanded when the initial height increased. Figure 9b shows the deformed shape of the case of a 1.65 mm high frustum at point I, II and III.

4.2.2 *EPP Material*

The results are shown in Figure 10. The critical force increased as the height increased until the height reached 1.15 mm. A knuckle region was formed on the structure afterwards. A second local peak of force

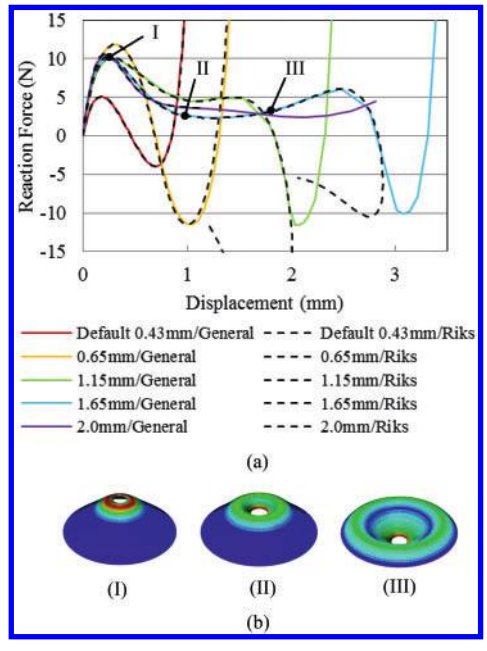

Figure 9. Results from LE frusta with various heights.

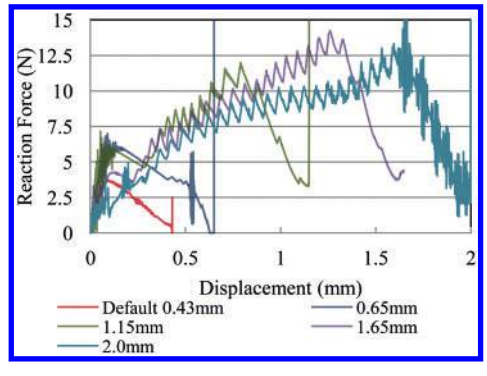

Figure 10. Results from EPP frusta with various heights.

started to appear on the graph and overtake the initial critical force. In other words, the one-off snap was replaced by two snaps at the beginning and the end, and progressive inversion in the middle of the deformation history. It is also noticed that first local force peak disappeared when the height reached 2.0 mm. Figure 11 summarises these changes of loading histories as height increased schematically. The collapse mechanism changes to different modes as the height increases.

The FE results of reaction forces within the progressive inversion region fits well with what the Deshpande & Fleck's model describes. A detailed comparison between FE results and analytic predictions is given later in this Chapter.

4.3 *Frusta of Various Tilt Angles*

Including the default configuration, frusta with five different tilt angles were analysed. They were 38.02°

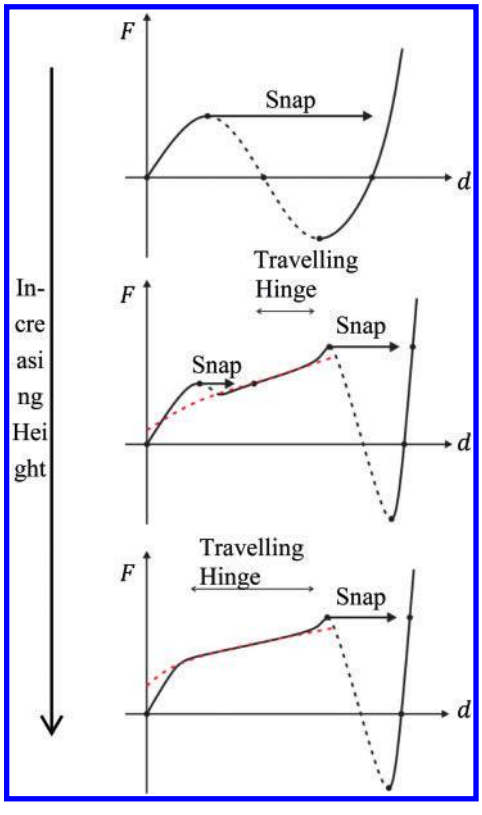

Figure 11. Schematic diagram about effects of increasing height. (Red dosh lines represent the travelling hinge model predictions).

(default), 20°, 30°, 50° and 60°. Again, the ring-load method was used for the LE material and the plate-load method was used for the EPP material.

A switch of collapse mechanism is expected before the tilt angle increases to 90°, hence the problem becomes cylindrical shell buckling under axial compressive load. It has been investigated by many people due to its widespread use in industry.

4.3.1 *LE Material*

The results are shown on Figure 12. Results from Newton method and Riks method agreed well with each other.

Figure 12 shows that the critical forces increased as the tilt angle increased. The snap-through behaviour was found on all frusta simulated. Therefore, varying the tilt angle of the frustum around current configuration, did not affect the collapse mechanism.

4.3.2 *EPP Material*

The plotted results are shown on Figure 13.

The critical force shows a clear trend of increasing as the tilt angle increases. The snap-through behaviour was found on all frusta which were simulated. Therefore, varying the tilt angle of the frustum, did not affect the collapse mechanism at current configuration.

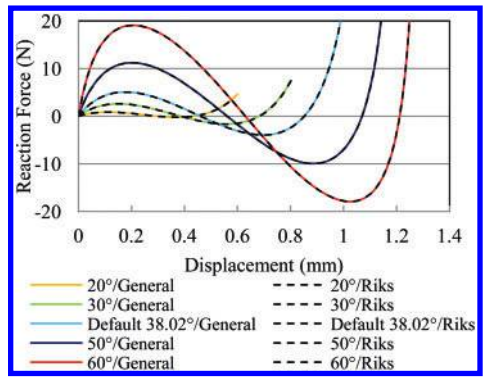

Figure 12. Results from LE frusta with various tilt angles.

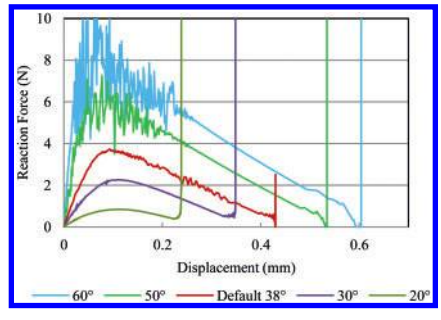

Figure 13. Results from EPP frusta with various tilt angles.

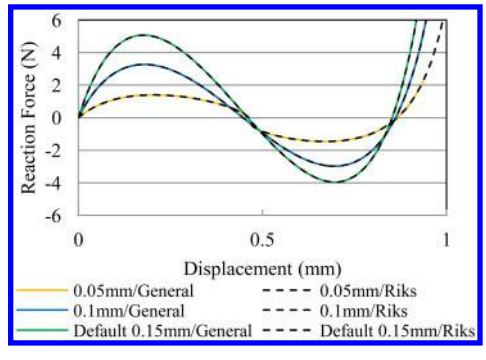

Figure 14. Results from LE frusta of various thicknesses.

The fluctuating force curves for the cases of 60° and 50° tilt angles are caused by the vibration of the frustum due to the impact of the loading plate.

4.4 *Frusta of Various Thicknesses*

Including the default configuration, frusta of four different thicknesses, 0.15 mm (default), 0.1 mm and 0.05 mm, were analysed. The ring-load method was used for the LE material and the plate-load method was used for the EPP material.

4.4.1 *LE Material*

The results are shown on Figure 14. The Newton method and Riks method agreed well with each other.

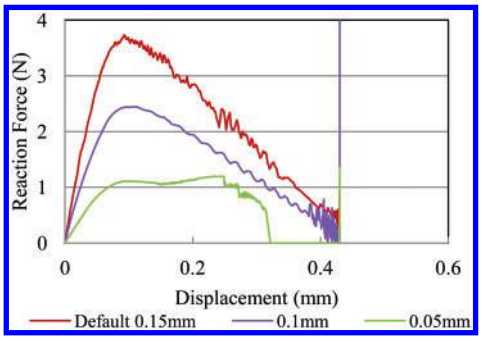

Figure 15. Results from EPP frusta of various thicknesses.

Figure 14 shows similar results comparing with Figure 12. The critical forces increased as the thickness increased. The snap-through behaviour was found on all frusta which were simulated. Therefore, varying the thickness of the frustum, did not affect the collapse mechanism at current configuration.

4.4.2 *EPP Material*

The results are shown on Figure 15. For the frustum of 0.05 mm thickness, the mesh size was reduced to 0.05 mm since the artificial strain energy of the system had to be controlled below 2% of the total internal energy to reduce the hour-glassing and shear locking effect.

It is noted that local buckling along the top circle of the frustum happened before the snap-through when the thickness reduced to 0.05 mm. This is why that the 0.05 mm frustum has rather strange force curves comparing with others. Furthermore, the sudden force drop for the frustum of 0.05 mm thickness at around 0.38 mm displacement occurred when the loading plate lost its entire contact to the frustum and the loading forces reduced to zero. This collapse mechanism for 0.05 mm thickness frustum was much more complicated than the one of the default frustum and needed further investigation.

The linear elastic material had no local buckling because the ring-load method forced top circle lines of the frusta to move downwards at the rate in the boundary condition setting. A hoop stiffener around the top edge could be added to stop the structure from buckling at this mode.

4.5 *Comparison between FE Results and Analytic Predictions*

The default frustum and its variation when height was 2.0 mm with EPP materials were chosen to be compared with the analytic predictions by Deshpande & Fleck's model. The results are plotted in Figure 16. The analytic model failed to give valid predictions for the default frustum. For the 2.0 mm high frustum, the analytic model gave fair predictions of forces during the progressive inversion but failed to give good estimate at the beginning or around the snap. In general, the analytical results are slightly larger than the FE

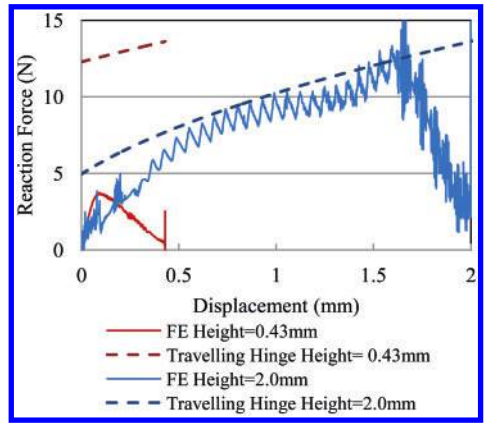

Figure 16. Comparison of FE results and Analytical Predictions.

results. This is due to the small difference of boundary conditions between my FE settings and Deshpande & Fleck's model.

5 CONCLUSIONS

In conclusion, under certain range of geometric and material configuration, the critical force for a frustum to invert can be increased by increasing the tilt angle or the thickness. The influence of height is more complex, as the collapse mechanism would switch to a different mode under certain conditions. For an EPP material, this paper demonstrates how the collapse mechanism and critical forces could change. When travelling hinge lines are formed, the force response fits well with Deshpande & Fleck's prediction. However, the plastic travelling hinges do not always form.

For a real flexible straw, the taller frustum has a larger tilt angle and a larger height compared to the shorter one, hence requires a larger critical force to snap through. The shorter frustum reaches its critical force and snaps before the taller one does, thus the corrugation could invert into a shape shown in Figure 2b.

Though only results of the FE simulation is presented in this paper, we are setting up experiments to verify the results in the future.

A strain gradient Reissner-Mindlin micro-plate model obtained through an asymptotic analysis

M. Serpilli
Department of Civil and Building Engineering, and Architecture, Università Politecnica delle Marche, Italy

ABSTRACT: In this paper we derive a strain gradient plate model from the three-dimensional equations of strain gradient linearized elasticity. The deduction is based on the asymptotic analysis with respect of a small real parameter being the thickness of the elastic body we consider. The body is constituted by a second gradient isotropic linearly elastic material. The obtained model is recognized as a strain gradient Reissner-Mindlin plate model.

1 INTRODUCTION

Higher order gradient continuum theories in linear and nonlinear elasticity have recently raised the interest on many scientists, since modern technologies involving multi-scale materials exhibit size effects and a strong dependence on internal (material) lengths.

A possible generalization of Cauchy model has been proposed in the pioneering works by Mindlin (1964) and Germain (1973). In these papers, the stored deformation energy is assumed to depend not only on the strain, but also on the strain gradient. These general continua are called second gradient continua by Germain, or strain gradient continua. In strain gradient continua approaches it is necessary to generalize the concept of Cauchy contact actions, see dell'Isola et al. (2012), and the constitutive laws, see dell'Isola et al. (2009).

In recent years plate theories have found several applications in the areas of micro-mechanics and nano-mechanics. Micro-mechanical systems and nano-mechanical systems show size effects and non local behavior. The lack of an intrinsic length scale implies that this kind of phenomena cannot be captured by classical continuum theory; therefore strain gradient elasticity theories, containing length scale parameters, find their natural and appropriate application. In order to deeply understand the effect of the internal length scale parameters in strain gradient elasticity, the authors recommend, for instance, the works by Lam et al. (2003) and by Yang et al. (2002).

For what concerns with strain gradient plate theories, Lazopoulos presented the first formulation of the Kirchhoff-Love model, respectively, for plates, (Lazopoulos 2009), and shallow shells, (Lazopoulos 2011), based on the strain gradient elasticity. More recently, in Ramezani (2012), the author proposed a micro-plate model taking into account shear deformations, based on a general strain gradient elasticity theory. All those plate models have been derived by using classical variational tools.

In the present work we derive a strain gradient micro-plate model starting from the three-dimensional equations of strain gradient linearized elasticity through an asymptotic analysis. We consider a plate-like domain filled by an isotropic second gradient linearly elastic material. By defining a small real parameter ε, which represents the thickness of the plate-like domain, we apply the asymptotic expansion method, following the approach by Ciarlet (1997). Then, we characterize the leading terms of the asymptotic expansion, and the associated limit problems. The obtained model corresponds to a strain gradient Reissner-Mindlin plate model.

The asymptotic analysis is a widely used technique for the formal derivation and justification of classical theories of thin structures, starting from the classical three-dimensional elasticity, (see Ciarlet (1997), in the case of plate models). For what concerns with the derivation of plate models, it is well-known that if we apply the asymptotic methods to the classical linear or nonlinear elasticity equations, we are capable to derive only Kirchhoff-Love plate models. In order to obtain and justify the Reissner-Mindlin plate model through an asymptotic analysis or variational convergence we need to generalize the initial three-dimensional stored elastic energy. For instance, Pa-roni et al. (2007) obtain the Reissner-Mindlin plate model via Γ-convergence by adding some specific second gradient terms to the classical linear elasticity equations. Another way to proceed in the justification of Reissner-Mindlin equations is the one proposed in the pioneering work by Erbay (2000) in which the author uses the asymptotic expansion method starting from the Cosserat elasticity equations. More recently, within two different functional frameworks, Aganovič et al. (2006) and Neff et al. (2010) consider the Cosserat elasticity as "parent" model and, respectively, derive the

Reissner-Mindlin model for rods, plates and shells by means of variational and Γ-convergence arguments.

2 STATEMENT OF THE PROBLEM

In the sequel, Latin indices range in the set $\{1,2,3\}$, while Greek indices range in the set $\{1,2\}$ and the Einstein's summation convention with respect to the repeated indices is adopted.

Let $\omega \in \mathbb{R}^2$ be a smooth domain in the plane spanned by vectors $\mathbf{e}_\alpha$, let γ_0 be a measurable subset of the boundary γ of the set ω, such that length $\gamma_0 > 0$, and let $0 < \varepsilon < 1$ be an dimensionless *small* real parameter which will tend to zero. For each ε, we define

$$\Omega^\varepsilon := \omega \times (-\varepsilon h, \varepsilon h),$$
$$\Gamma_0^\varepsilon := \gamma_0 \times [-\varepsilon h, \varepsilon h], \quad \Gamma_\pm^\varepsilon := \omega \times \{\pm \varepsilon h\}.$$

Hence the boundary of the set Ω^ε is partitioned into the lateral face $\gamma \times [-\varepsilon h, \varepsilon h]$ and the upper and lower faces Γ_+^ε and Γ_-^ε, and the lateral face is itself partitioned as $\gamma \times [-\varepsilon h, \varepsilon h] = (\gamma_0 \times [-\varepsilon h, \varepsilon h]) \cup (\gamma_1 \times [-\varepsilon h, \varepsilon h])$, where $\gamma_1 := \gamma - \gamma_0$. In order to avoid inessential complications in the sequel we suppose that $\gamma = \gamma_0$, and thus $\gamma_1 = \emptyset$.

We assume that the set $\overline{\Omega}^\varepsilon$ is the reference configuration of a strain gradient linearly elastic plate of thickness $2\varepsilon h$ and middle surface $\overline{\omega}$. We study the physical problem corresponding to the mechanical behaviour of a strain gradient plate. The plate is completely clamped on $\Gamma_0^\varepsilon = \Gamma^\varepsilon$, in the sense that the boundary conditions of place, imposed to the displacements, are $u_i^\varepsilon = 0$ and $\partial_n^\varepsilon u_i^\varepsilon = 0$ on Γ_0^ε, where ∂_n^ε represents the derivative operator with respect to the unit outer normal vector (n_i^ε) along the boundary Γ_0^ε. Moreover, we supposed that the plate is subjected to body forces $(f_i^\varepsilon) : \Omega^\varepsilon \to \mathbb{R}^3$, and surface forces $(g_i^\varepsilon) : \Gamma_+^\varepsilon \cup \Gamma_-^\varepsilon \to \mathbb{R}^3$.

We finally assume that the strain gradient linearly elastic material constituting the plate Ω^ε is homogeneous and isotropic. The constitutive laws for this kind of material (see dell'Isola et al. (2009)) take the following form:

$$\sigma_{ij}^\varepsilon := \lambda^\varepsilon e_{pp}^\varepsilon \delta_{ij} + 2\mu^\varepsilon e_{ij}^\varepsilon,$$
$$p_{ijk}^\varepsilon := c_1^\varepsilon (e_{ppj}^\varepsilon \delta_{ik} + 2e_{kpp}^\varepsilon \delta_{ij} + e_{ppi}^\varepsilon \delta_{jk}) + c_2^\varepsilon e_{ppk}^\varepsilon \delta_{ij} +$$
$$+ 2c_3^\varepsilon (e_{jpp}^\varepsilon \delta_{ik} + e_{ipp}^\varepsilon \delta_{jk}) + 2c_4^\varepsilon e_{ijk}^\varepsilon + 2c_5^\varepsilon (e_{ikj}^\varepsilon + e_{jki}^\varepsilon),$$

where $(\sigma_{ij}^\varepsilon)$ is the classical Cauchy stress tensor, (p_{ijk}^ε) is the hyperstress tensor, $(e_{ij}^\varepsilon(\mathbf{u}^\varepsilon)) := (\frac{1}{2}(\partial_i^\varepsilon u_j^\varepsilon + \partial_j^\varepsilon u_i^\varepsilon))$ is the linearized strain tensor and $(e_{ijk}^\varepsilon(\mathbf{u}^\varepsilon)) := (\partial_k^\varepsilon e_{ij}^\varepsilon(\mathbf{u}^\varepsilon))$ is the gradient of $(e_{ij}^\varepsilon(\mathbf{u}^\varepsilon))$. It is important to stress out that the ratios between the second gradient elastic moduli c_k^ε and the Lamé's constants, λ^ε and μ^ε, have the dimensions of square length, i.e. $c_k^\varepsilon/\mu^\varepsilon \propto (\ell^\varepsilon)^2$. The length scale parameter ℓ^ε is a material property associated with the heterogeneity of the material and it measures the size of the internal microstructure of the material.

The displacement field $\mathbf{u}^\varepsilon = (u_i^\varepsilon)$ satisfies the following variational problem defined over the variable domain Ω^ε:

$$\int_{\Omega^\varepsilon} \left\{ \sigma_{ij}^\varepsilon(\mathbf{u}^\varepsilon) e_{ij}^\varepsilon(\mathbf{v}^\varepsilon) + p_{ijk}^\varepsilon(\mathbf{u}^\varepsilon) e_{ijk}^\varepsilon(\mathbf{v}^\varepsilon) \right\} dx^\varepsilon = l(\mathbf{v}^\varepsilon), \quad (1)$$

for all $\mathbf{v}^\varepsilon \in V(\Omega^\varepsilon)$, where

$$V(\Omega^\varepsilon) := \left\{ \mathbf{v}^\varepsilon \in H^2(\Omega^\varepsilon; \mathbb{R}^3);\ \mathbf{v}^\varepsilon = \partial_n^\varepsilon \mathbf{v}^\varepsilon = \mathbf{0} \text{ on } \Gamma_0^\varepsilon \right\},$$

and

$$l(\mathbf{v}^\varepsilon) = \int_{\Omega^\varepsilon} f_i^\varepsilon v_i^\varepsilon dx^\varepsilon + \int_{\Gamma_+^\varepsilon} g_i^\varepsilon v_i^\varepsilon d\Gamma^\varepsilon.$$

For a more general formulation of the three-dimensional strain gradient non linear elasticity theory, the reader can refer to the works by dell'Isola et al. (2009) and dell'Isola et al. (2012).

In order to perform an asymptotic analysis, we need to transform problem (1) posed on a variable domain Ω^ε onto a problem posed on a fixed domain Ω (independent of ε). Accordingly, we let

$$\Omega := \omega \times (-h, h),$$
$$\Gamma_0 := \gamma_0 \times [-h, h], \quad \Gamma_\pm := \omega \times \{\pm h\}.$$

We suppose that the thickness of the plate h^ε depends linearly on ε, so that $h^\varepsilon = \varepsilon h$. Hence, we define the following change of variables (see Ciarlet (1997)):

$$\pi^\varepsilon : x := (\tilde{x}, x_3) \in \overline{\Omega} \mapsto x^\varepsilon := (\tilde{x}, \varepsilon x_3) \in \overline{\Omega}^\varepsilon,$$

with $\tilde{x} = (x_\alpha)$. By using the bijection π^ε, one has $\partial_\alpha^\varepsilon = \partial_\alpha$ and $\partial_3^\varepsilon = \frac{1}{\varepsilon}\partial_3$.

With the unknown displacement field $\mathbf{u}^\varepsilon = (u_i^\varepsilon) \in V(\Omega^\varepsilon)$ and test functions $\mathbf{v}^\varepsilon = (v_i^\varepsilon) \in V(\Omega^\varepsilon)$, we associate, respectively, the scaled displacement field $\mathbf{u}(\varepsilon) = (u_i(\varepsilon)) : \overline{\Omega} \to \mathbb{R}^3$ and the scaled test functions $\mathbf{v} = (v_i) : \overline{\Omega} \to \mathbb{R}^3$, for all $x^\varepsilon = \pi^\varepsilon x \in \overline{\Omega}^\varepsilon$, defined by the scalings:

$$u_\alpha^\varepsilon(x^\varepsilon) = \varepsilon u_\alpha(\varepsilon)(x) \text{ and } u_3^\varepsilon(x^\varepsilon) = u_3(\varepsilon)(x),$$
$$v_\alpha^\varepsilon(x^\varepsilon) = \varepsilon v_\alpha(x) \text{ and } v_3^\varepsilon(x^\varepsilon) = v_3(x).$$

We make the following assumptions on the data, and, thus, we require that the Lamé constants and the second gradient elastic moduli satisfy the following relations:

$$\lambda^\varepsilon = \lambda, \quad \mu^\varepsilon = \mu, \quad c_k^\varepsilon = c_k, \ k \in \{1,2,3,4,5\}.$$

In terms of the internal length parameter ℓ^ε, this means that $\ell^\varepsilon := \ell$ is independent of ε, and so the actual thickness of the plate $h^\varepsilon = \varepsilon h$ is an order of magnitude smaller than the internal length ℓ^ε. As it is shown in Lam et al. (2003) and Yang et al. (2002), the influence

of the microstructure is predominant when $h^\varepsilon \ll, \ell^\varepsilon$. This assumption on the dependences of ℓ^ε and h^ε on ε is aimed at emphasizing the effect of the microstructure in the simplified model.

We can now reformulate the problem on the fixed domain Ω. The rescaled displacement field $\mathbf{u}(\varepsilon) \in V(\Omega)$ is the unique solution of the following rescaled problem:

$$\begin{aligned}&\frac{1}{\varepsilon^4}a_{-4}(\mathbf{u}(\varepsilon),\mathbf{v})+\frac{1}{\varepsilon^2}a_{-2}(\mathbf{u}(\varepsilon),\mathbf{v})+a_0(\mathbf{u}(\varepsilon),\mathbf{v})+\\&+\varepsilon^2 a_2(\mathbf{u}(\varepsilon),\mathbf{v})=l_0(\mathbf{v})+\varepsilon^2 l_2(\mathbf{v}),\end{aligned} \tag{2}$$

for all $\mathbf{v} \in V(\Omega)$, where

$$V(\Omega) := \left\{\mathbf{v} \in H^2(\Omega;\mathbb{R}^3);\ \mathbf{v} = \partial_n \mathbf{v} = \mathbf{0} \text{ on } \Gamma_0\right\}.$$

The bilinear forms a_{-4}, a_{-2}, a_0, $a_2 : V(\Omega) \times V(\Omega) \to \mathbb{R}$ depend on the scaled components of the linearized strain tensor $e_{ij}(\mathbf{u}(\varepsilon))$ and of its gradient $e_{ijk}(\mathbf{u}(\varepsilon))$.

3 ASYMPTOTIC EXPANSIONS

We can now perform an asymptotic analysis of the rescaled problem (2). Since it has a polynomial structure with respect to the small parameter ε, we can look for the solution of the problem as a series of powers of ε:

$$\mathbf{u}(\varepsilon) = \mathbf{u}^0 + \varepsilon^2\mathbf{u}^2 + \varepsilon^4\mathbf{u}^4 + \varepsilon^6\mathbf{u}^6 + \dots\ . \tag{3}$$

By substituting (3) into the rescaled problem (2), and by identifying the terms with identical power of ε, we obtain, as customary, the following set of problems, defined for all $\mathbf{v} \in V(\Omega)$:

$$\begin{aligned}&\mathcal{P}_{-4}: \quad a_{-4}(\mathbf{u}^0,\mathbf{v}) = 0,\\&\mathcal{P}_{-2}: \quad a_{-4}(\mathbf{u}^2,\mathbf{v}) + a_{-2}(\mathbf{u}^0,\mathbf{v}) = 0,\\&\mathcal{P}_{2}: \quad a_{-4}(\mathbf{u}^4,\mathbf{v}) + a_{-2}(\mathbf{u}^2,\mathbf{v}) + a_0(\mathbf{u}^0,\mathbf{v}) = l_0(\mathbf{v}),\end{aligned}$$

By solving each variational subproblem we characterize the limit displacement field $\mathbf{u}^0$ and the associated limit problem.

The displacement field $\mathbf{u}^0$ takes the following form:

$$\begin{cases} u^0_\alpha(\tilde{x},x_3) = x_3\varphi^0_\alpha(\tilde{x}),\\ u^0_3(\tilde{x},x_3) = w^0(\tilde{x}).\end{cases}$$

The above displacement field corresponds to the well-known Reissner-Mindlin kinematics assumptions for a plate, where w^0 and φ^0_α are, respectively, the transverse displacement and the free rotation of the normal fiber to the middle plane of the plate.

The limit displacement field verifies the following limit variational problems:

$$\begin{aligned}&\int_\omega \left[(C_1\partial_{\beta\beta}w^0 + C_2\partial_\beta\varphi^0_\beta)\partial_{\alpha\alpha}\eta_3 + \right.\\&+\left(c_4(\partial_{\alpha\beta}w^0+\partial_\beta\varphi^0_\alpha)+c_5(\partial_\alpha\varphi^0_\beta+\partial_\beta\varphi^0_\alpha)\right)\partial_{\alpha\beta}\eta_3+\\&\left.+\mu(\partial_\alpha w^0+\varphi^0_\alpha)\partial_\alpha\eta_3\right]d\tilde{x} = \frac{1}{h}\int_\omega q\eta_3 d\tilde{x},\\&\int_\omega \left[\left(C_2\partial_{\beta\beta}w^0 + C_3\partial_\beta\varphi^0_\beta\right)\partial_\alpha\eta_\alpha + \right.\\&+(c_4+2c_5)(\partial_{\alpha\beta}w^0+\partial_\beta\varphi^0_\alpha+\partial_\alpha\varphi^0_\beta)\partial_\beta\eta_\alpha+\\&\left.+c_4\partial_\beta\varphi^0_\alpha\partial_\beta\eta_\alpha+\mu(\partial_\alpha w^0+\varphi^0_\alpha)\eta_\alpha\right]d\tilde{x} = 0,\end{aligned} \tag{4}$$

for all $\eta_i \in V(\omega) := \{\eta \in H^1(\omega,\mathbb{R}^2)\times H^2(\omega);\ \eta = \mathbf{0},\ \partial_\nu\eta_3 = 0 \text{ on } \gamma_0\} = H^1_0(\omega,\mathbb{R}^2)\times H^2_0(\omega)$, $q(\tilde{x}) := \int_{-h}^{h} f_3(\tilde{x},x_3)dx_3 + g_3(\tilde{x},\pm h)$, and

$$\begin{aligned}C_1 &:= c_3 - \frac{(c_1-2c_3)^2}{\tilde{c}},\\C_2 &:= c_1 + c_3 - \frac{(3c_1+c_2+2c_3)(c_1+2c_3)}{\tilde{c}},\\C_3 &:= 2c_1 + c_2 + c_3 - \frac{(3c_1+c_2+2c_3)^2}{\tilde{c}},\end{aligned}$$

By integrating by parts problem (4), we obtain the following differential system:

$$\begin{cases} h(C_1\Delta-\mu)\Delta w^0 + h(C_2\Delta-\mu)\mathrm{div}\boldsymbol{\varphi}^0 = q \ \text{ in } \omega,\\ (C_2\Delta-\mu)\nabla w^0 + (C_3\Delta-\mu)\boldsymbol{\varphi}^0 + C_4\nabla(\mathrm{div}\boldsymbol{\varphi}^0) = \mathbf{0},\\ w^0 = 0,\ \ \partial_\nu w^0 = 0,\ \ \boldsymbol{\varphi}^0 = \mathbf{0} \text{ on } \gamma_0,\end{cases}$$

where $\Delta\phi := \partial_{\alpha\alpha}\phi$ is the two-dimensional Laplacian operator applied to ϕ, $\mathrm{div}\phi := \partial_\alpha\phi_\alpha$ is the divergence operator applied to $\phi = (\phi_\alpha)$, $\nabla\phi := (\partial_\alpha\phi)$ is the two-dimensional gradient operator applied to ϕ, and

$$\begin{aligned}&\mathcal{C}_1 := c_4 + C_1, \quad \mathcal{C}_2 := c_4 + 2c_5 + C_2,\\&\mathcal{C}_3 := 2\left(c_4+c_5\right), \quad \mathcal{C}_4 := c_4 + 2c_5 + C_3.\end{aligned}$$

Remark. In several works (see, for instance, Aifantis (1999)), Aifantis has proposed a simplified strain gradient isotropic linearly elastic constitutive law, in which $c_1 = c_3 = c_5 = 0$, $c_2 = \ell^2\lambda$ and $c_4 = \ell^2\mu$, where ℓ is an internal length connected to the micro-structure. The simplified strain gradient constitutive law gets the following expression:

$$\begin{aligned}&\sigma^\varepsilon_{ij}(\mathbf{u}^\varepsilon) := \lambda^\varepsilon e^\varepsilon_{pp}(\mathbf{u}^\varepsilon)\delta_{ij} + 2\mu^\varepsilon e^\varepsilon_{ij}(\mathbf{u}^\varepsilon),\\&p^\varepsilon_{ijk}(\mathbf{u}^\varepsilon) := \ell^2\partial^\varepsilon_k(\lambda^\varepsilon e^\varepsilon_{pp}(\mathbf{u}^\varepsilon)\delta_{ij} + 2\mu^\varepsilon e^\varepsilon_{ij}(\mathbf{u}^\varepsilon)).\end{aligned}$$

In this particular case the limit problem takes the following form:

$$\begin{cases} h\mu(\ell^2\Delta - 1)(\Delta w^0 + \mathrm{div}\boldsymbol{\varphi}^0) = q & \text{in } \omega,\\ \mathcal{L}^2 D\Delta\mathrm{div}\boldsymbol{\varphi}^0 = -q & \text{in } \omega,\end{cases}$$

where $D := \frac{\mu(\lambda+\mu)h^3}{3(\lambda+2\mu)} = \frac{Eh^3}{12(1-\nu^2)}$ is the classical rigidity modulus of the plate and $\mathcal{L}^2 := 12(\ell/h)^2$.

The coefficient $\mathcal{L}^2$ usually appears in strain gradient plate and beam theories and it represents the ratio between the intrinsic length of the microstructure and the actual thickness (resp. diameter) of the plate (resp. beam). Its influence is high for small thicknesses, when the intrinsic length ℓ is comparable or bigger than the thickness of the plate. Besides, it has been shown in several works Lam et al. (2003), Lazopoulos (2009) and Yang et al. (2002) that, by comparing the deflections of a classical Kirchhoff-Love plate and the deflections of a strain gradient Kirchhoff-Love plate, for large values of $\mathcal{L}^2$, the bending stiffness of the plate increases drastically.

4 CONCLUSIONS

In the present work we derive a strain gradient Reissner-Mindlin plate model by means of an asymptotic analysis starting from the equations of strain gradient linearized elasticity. We concentrate our attention to the flexural behavior, by neglecting at this stage the membrane behaviour.

As it is mentioned in the Introduction to this paper, in order to obtain the Reissner-Mindlin kinematics for a plate through the asymptotic analysis or Γ-convergence, we need to generalize the initial classical elastic energy by adding some second gradient extra terms or by using the micropolar continuum model. In our work we give another proof of the fact that, in order to formally deduce the Reissner-Mindlin plate model, it is necessary to use a different continuum model, such as the second gradient continuum model.

From a mechanical point of view, the obtained strain gradient Reissner-Mindlin plate model can be used to study the mechanical behaviour of micro-plates and nano-plates, especially by considering the reduced Aifantis strain gradient elastic material. The new model contains a material internal length scale parameter ℓ to account the microstructural effect, unlike the classical Reissner-Mindlin plate model. The presence of this additional material constant enables this model to capture size effects.

As we already claimed in Sect. 2, in the asymptotic procedure, we assume that the thickness of the plate $h^\varepsilon = \varepsilon h$ is much smaller that the internal length scale parameter $\ell^\varepsilon = \ell$. As future developments, it would be interesting to study the asymptotic behavior of the plate by considering all the other situations, for instance, $\ell^\varepsilon \ll h^\varepsilon$ or $\ell^\varepsilon \sim h^\varepsilon$, which will lead to different limit models.

At last let us explicitly point out that all the obtained conclusions are true also when the plate is clamped only on a measurable subset $\gamma_0 \times [-\varepsilon h, \varepsilon h]$ of the lateral boundary Γ^ε with length $\gamma_0 > 0$, and $\gamma_1 \neq \emptyset$.

Inelastic buckling of annular plates in shear

J. Becque
The University of Sheffield, Sheffield, South Yorkshire, UK

ABSTRACT: This paper presents a solution to the problem of determining the buckling load of an annular plate made of an inelastic metal and subject to pure shear loading. The solution is new in that it is based on the principles of plastic flow theory while being unaffected by the so-called 'plastic buckling paradox'. New inelastic constitutive relationships are first derived linking normal stresses and normal strains at the point of buckling, which are then incorporated into the classical Kirchhoff theory. Finally, the new model is validated against previous experimental data pertaining to the buckling of aluminium, brass and stainless steel annular plates in shear.

1 INTRODUCTION

A state of pure shear in an annular plate (Fig. 1) may for instance result from performing an in-plane torsion test, which is an established way to determine the stress-strain response of metal plates. Buckling is thereby undesirable. The problem of purely elastic buckling of an annular plate in shear was first resolved by Dean (1924). In 1989, Ore and Durban published a milestone paper, in which they studied the inelastic equivalent of the problem, using both plastic flow theory (or 'incremental theory') and plastic deformation theory. The plastic flow formulation employed in their derivations was the well-established small strain J_2 model. When comparing the predictions of flow theory with those of deformation theory for a number of realistic material properties and geometries, it was observed that the predictions using flow theory exceeded the predictions of deformation theory by factors of up to 17. After carrying out a comparison with the experimental work by Bauer (1987, 1988), who conducted tests on clamped annular plates of various geometries and material properties, Ore and Durban concluded that the predictions of flow theory were unrealistically high, while deformation theory on the other hand agreed fairly well with the experiment. This conclusion highlighted the so-called 'plastic buckling paradox' (Hutchinson 1974).

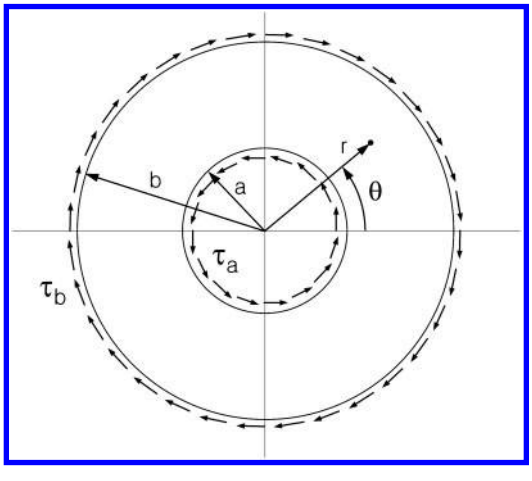

Figure 1. Annular plate in shear.

This paper revisits the problem of inelastic buckling of annular plates and proposes a model based on plastic flow theory. The plastic buckling paradox is thereby avoided by deriving the constitutive relations of an infinitesimal plate element while considering this plate element in its slightly deformed shape just past the point of local buckling. It is demonstrated that the theory leads to excellent predictions of Bauer's (1987, 1988) experimental results.

2 CONSTITUTIVE RELATIONSHIPS

Figure 2 depicts an infinitesimal element of infinitesimal thickness embedded within the plate and subject to an increment in shear stress $\dot{T}$. In this case, the plastic shear strain increment $\dot{\gamma}_p$ is linked to the shear stress increment $\dot{T}$ through the well-established equation of flow theory:

$$\dot{\gamma}_p = \frac{3}{E_p}\dot{T} = \left[\frac{3}{E_t} - \frac{3}{E_0}\right]\dot{T} \tag{1}$$

In Eq. (1), E_0 is the elastic (Young's) modulus of the material and E_t is the tangent modulus. E_t can be obtained from the stress-strain curve in uniaxial tension by determining the stiffness at an equivalent (normal) stress level $\sigma = \sqrt{3}\tau$.

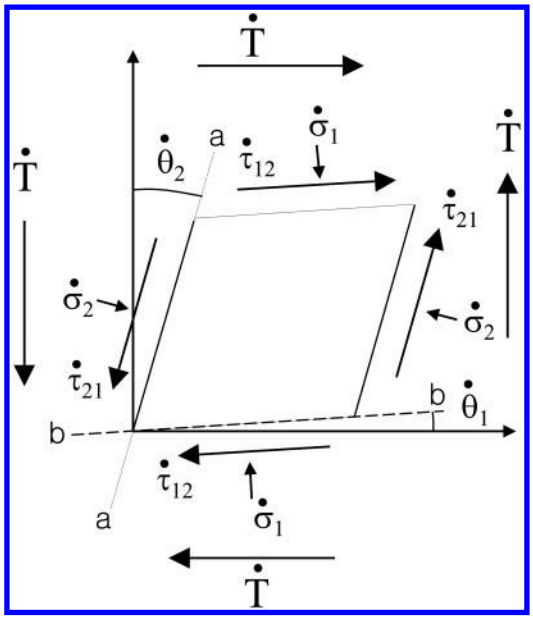

Figure 2. Infinitesimal plate element.

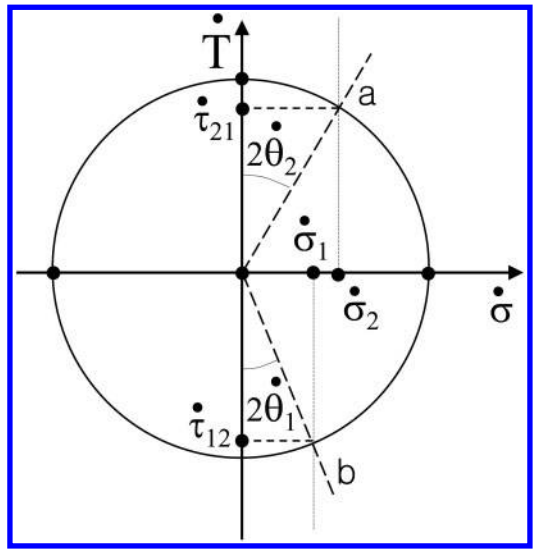

Figure 3. Mohr's circle of stress.

The above follows from the von Mises yield criterion and the concomitant definitions of equivalent stress σ_e and equivalent incremental plastic strain $\dot{\varepsilon}_{pe}$:

$$\sigma_e = \left(\sigma_x^2 + \sigma_y^2 - \sigma_x\sigma_y + 3\tau^2\right)^{1/2} \tag{2}$$

$$\dot{\varepsilon}_{pe} = \frac{2}{\sqrt{3}}\left(\dot{\varepsilon}_{px}^2 + \dot{\varepsilon}_{py}^2 + \dot{\varepsilon}_{px}\dot{\varepsilon}_{py} + \frac{1}{4}\dot{\gamma}_p\right)^{1/2} \tag{3}$$

With respect to the normal stresses, the governing opinion, as supported by, among others, Hutchinson (1974), Lubliner (1990), Bazant & Cedolin (1991) and Ore & Durban (1989), is that the normal stress and strain increments remain linked through the elastic modulus E_0 at the point of buckling:

$$\dot{\varepsilon}_1 = \frac{1}{E_0}\left(\dot{\sigma}_1 - \nu\dot{\sigma}_2\right) \tag{4}$$

$$\dot{\varepsilon}_2 = \frac{1}{E_0}\left(-\nu\dot{\sigma}_1 + \dot{\sigma}_2\right) \tag{5}$$

In other words, no plastic extension takes place. While this point of view is compatible with the Prandtl-Reuss equations (equivalent to the adoption of a flow rule associated with the von Mises surface), it leads to an overestimate of the axial stiffness of an infinitesimal plate element and is ultimately responsible for the immense mismatch between theory and experiment.

A counterargument to the above rationale can be constructed by considering the infinitesimal plate element in Fig. 2 at its transition from the initial unbuckled state into the shear buckled state. It is thereby reasonably assumed that the directions of the externally applied shear stresses remain unchanged, e.g. in Fig. 1 they remain tangential to the circumferential edges of the plate. Considering Mohr's circle of plane stress (Fig. 3), it is seen that along the rotating sides a-a and b-b of the elementary plate normal stresses $\dot{\sigma}_1$ and $\dot{\sigma}_2$ develop, which are given by:

$$\dot{\sigma}_1 = \dot{T}\sin\left(2\dot{\theta}_1\right) \approx 2\dot{T}\dot{\theta}_1 \tag{6}$$

$$\dot{\sigma}_2 = \dot{T}\sin\left(2\dot{\theta}_2\right) \approx 2\dot{T}\dot{\theta}_2 \tag{7}$$

On the other hand, since the principal directions of stress, and with them the principal directions of incremental plastic strain, remain firmly directed along the diagonals of the elementary plate during this shear stress increment, small plastic extensions necessarily have to take place along the inclined planes a-a and b-b. Their magnitude can be determined from Mohr's circle of the incremental plastic strains (Fig. 4), which in this case is a valid tool since the normal to the plate is a principal direction of plastic strain increment. It is seen that the plastic extension rates increase with the angles of rotation $\dot{\theta}_1$ and $\dot{\theta}_2$ from zero at the point of buckling to finite values at the end of the load increment. The incremental normal plastic strain $\dot{\varepsilon}_{p1}$ along b-b at the end of the load increment is thus given by:

$$\dot{\varepsilon}_{p1} = \int_0^{\dot{\theta}_1} \frac{1}{2}\left(\frac{\dot{\gamma}_p}{\dot{\theta}_1}\right)\sin(2\alpha)d\alpha \approx \frac{1}{2}\dot{\gamma}_p\dot{\theta}_1 \tag{8}$$

or, substituting Eqs. (1) and (6) into Eq. (8):

$$\dot{\varepsilon}_{p1} = \frac{3}{4E_p}\dot{\sigma}_1 \tag{9}$$

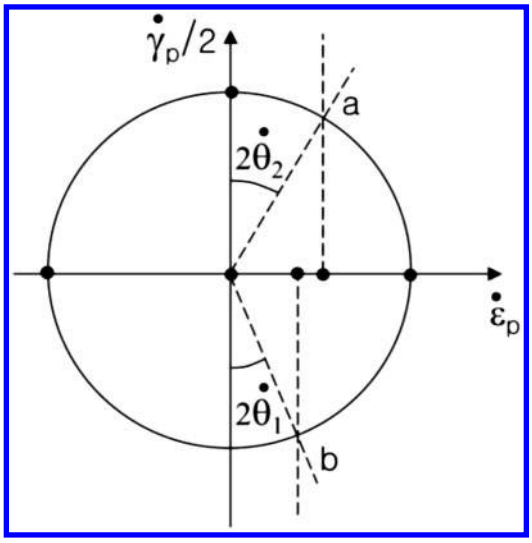

Figure 4. Mohr's circle of the incremental plastic strains.

The analogous equation for $\dot{\varepsilon}_{p2}$ is then:

$$\dot{\varepsilon}_{p2} = \frac{3}{4E_p}\dot{\sigma}_2 \tag{10}$$

Combining the incremental plastic strains given by Eqs. (1), (9) and (10) with Hooke's laws of the elastic strain increments yields the constitutive relations:

$$\dot{\varepsilon}_1 = \left[\frac{1}{4E_0} + \frac{3}{4E_t}\right]\dot{\sigma}_1 - \frac{\nu}{E_0}\dot{\sigma}_2 \tag{11}$$

$$\dot{\varepsilon}_2 = -\frac{\nu}{E_0}\dot{\sigma}_1 + \left[\frac{1}{4E_0} + \frac{3}{4E_t}\right]\dot{\sigma}_2 \tag{12}$$

$$\dot{\gamma} = \frac{(2\nu-1)E_t + 3E_0}{E_0 E_t}\dot{\tau} \tag{13}$$

3 DIFFERENTIAL EQUATIONS

The governing differential equations are derived by expressing the equilibrium of an infinitesimal plate element at the point of buckling. The very point of buckling may be seen as a limit state where, starting from the deformed plate element in Fig. 2, the angles $\dot{\theta}_1$ and $\dot{\theta}_2$ are reduced to zero while traveling back over the load history. The equilibrium equations then reduce back to the classical equations of St. Venant/Kirchoff theory, but combine with the constitutive equations (11–13), which are independent of $\dot{\theta}_1$ and $\dot{\theta}_2$ (within a small perturbation of the buckling point). For the purpose of studying an annular plate, the resulting equation is most conveniently expressed in polar coordinates r and θ (Fig. 1):

$$\begin{aligned}&\frac{1}{r}\frac{\partial^2}{\partial r^2}\left[r\left(E_{rr}\kappa_{rr} + E_{r\theta}\kappa_{\theta\theta}\right)\right] - \frac{1}{r}\frac{\partial}{\partial r}\left(E_{r\theta}\kappa_{rr} + E_{\theta\theta}\kappa_{\theta\theta}\right)\\ &+\frac{4}{r^2}\frac{\partial^2}{\partial r\partial\theta}\left(rG_{r\theta}\kappa_{r\theta}\right) + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}\left(E_{r\theta}\kappa_{rr} + E_{\theta\theta}\kappa_{\theta\theta}\right)\\ &-\frac{\lambda}{r^2}\kappa_{r\theta} = 0\end{aligned} \tag{14}$$

where the incremental curvature changes κ_{rr}, $\kappa_{r\theta}$ and $\kappa_{\theta\theta}$ are expressed in terms of the incremental plate deflections $\dot{w}$ as follows:

$$\kappa_{rr} = \frac{\partial^2\dot{w}}{\partial r^2} \tag{15}$$

$$\kappa_{r\theta} = \frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial\dot{w}}{\partial\theta}\right) \tag{16}$$

$$\kappa_{\theta\theta} = \frac{1}{r}\frac{\partial\dot{w}}{\partial r} + \frac{1}{r^2}\frac{\partial^2\dot{w}}{\partial\theta^2} \tag{17}$$

and:

$$E_{rr} = E_{\theta\theta} = 4E_0E_t\left(\frac{3E_0 + E_t}{9E_0^2 + 6E_0E_t + (1-16\nu^2)E_t^2}\right) \tag{18}$$

$$E_{r\theta} = \frac{16\nu E_0E_t^2}{9E_0^2 + 6E_0E_t + (1-16\nu^2)E_t^2} \tag{19}$$

$$G_{r\theta} = \frac{E_0E_t}{3E_0 + (2\nu-1)E_t} \tag{20}$$

Further to Eq. (14), λ is a load parameter which is proportional to the shear stresses in the plate:

$$\lambda = \tau_{r\theta}\frac{24r^2}{t^2} \tag{21}$$

where t is the plate thickness and the factor 24 has been introduced for convenience.

The solution method by Durban and Stavsky (1982) is followed where the incremental plate displacements $\dot{w}$ are represented as:

$$\dot{w} = \mathrm{Re}\left\{\phi(r)e^{im\theta}\right\} \tag{22}$$

where m is an integer and ϕ is a function which only depends on the radial coordinate r. Substitution of Eq. (22) into Eq. (14) yields the ordinary differential equation:

$$\begin{aligned}&E_{rr}\phi'''' + 2\left(E'_{rr} + \frac{E_{rr}}{r}\right)\phi''' + F_2\frac{\phi''}{r^2} + \left(F_1 - im\lambda\right)\frac{\phi'}{r^3}\\ &+\left(m^2F_0 + im\lambda\right)\frac{\phi}{r^4} = 0\end{aligned} \tag{23}$$

with:

$$F_0 = -r^2 E_{r\theta}'' + 2rE_{r\theta}' - 2E_{r\theta} + rE_{\theta\theta}' + (m^2 - 2)E_{\theta\theta} + 4rG_{r\theta}' - 4G_{r\theta} \quad (24)$$

$$F_1 = r^2 E_{r\theta}'' - 2m^2 rE_{r\theta}' + 2m^2 E_{r\theta} - rE_{\theta\theta}' + E_{\theta\theta} - 4m^2 rG_{r\theta}' + 4m^2 G_{r\theta} \quad (25)$$

$$F_2 = r^2 E_{rr}'' + 2rE_{rr}' + rE_{r\theta}' - 2m^2 E_{r\theta} - E_{\theta\theta} - 4m^2 rG_{r\theta} \quad (26)$$

The primes thereby indicate differentiation with respect to the radial coordinate r.

For many inelastic metals the stress-strain curve may be represented by the Ramberg-Osgood equation:

$$\varepsilon = \frac{\sigma}{E_0} + 0.002\left(\frac{\sigma}{\sigma_{0.2}}\right)^n \quad (27)$$

Where $\sigma_{0.2}$ is the 0.2% proof stress of the material and the exponent n is representative of the roundness of the stress-strain curve. By differentiating Eq. (27) and combining it with Eq. (21), the tangent modulus E_t can be expressed as an explicit function of the radial coordinate r:

$$E_t = E_0\left[1 + 0.002\frac{nE_0}{\sigma_{0.2}^n}\left(\frac{\sqrt{3}}{24}\lambda\right)^{n-1}\left(\frac{t}{r}\right)^{2(n-1)}\right]^{-1} \quad (28)$$

Through Eqs. (18–20), Eq. (28) allows the coefficients F_0, F_1 and F_2 (Eqs. 24–26) to be determined.

The boundary conditions to the problem are, along a clamped edge:

$$\dot{w} = 0, \qquad \frac{\partial \dot{w}}{\partial r} = 0 \quad (29)$$

or, along a simply supported edge:

$$\dot{w} = 0, \qquad \frac{\partial^2 \dot{w}}{\partial r^2} + \left(\frac{E_{r\theta}}{rE_{rr}}\right)\frac{\partial \dot{w}}{\partial r} = 0 \quad (30)$$

While a closed form solution of Eq. (23) is non-existent, the critical value of the load parameter λ_{cr}, associated with shear buckling of the annular plate can be determined by employing a finite differences scheme, as proposed by Ore and Durban (1989). For this purpose the radial interval between $r = a$ and $r = b$ (Fig. 1) is subdivided into N-1 equal intervals, bounded by N 'proper' nodes. A central differences scheme is here adopted, whereby two 'dummy' nodes are added outside the interval on both sides, in order to allow Eq. (23) to be expressed in its finite differences form at the boundary nodes of the interval. The values of the function ϕ at each node constitute $N + 4$ unknowns, while $N + 4$ linear equations are obtained by writing Eq. (23) in its finite differences form at each proper node and by adding two boundary conditions (Eqs. 29 or 30) at each end. In order to obtain a non-zero solution for ϕ and $\dot{w}$, the determinant Δ of the resulting system of equations needs to be zero. It is thereby noted that, while the coefficients in Eq. (23) are complex, the eigenvalues λ of the problem are real (Ore and Durban 1989). A numerical solution is obtained by calculating $\mathrm{Re}^2(\Delta) + \mathrm{Im}^2(\Delta)$ for increasing values of the load parameter λ until the smallest eigenvalue λ_{cr} is obtained. This procedure is carried out for a given plate geometry and given material properties, but needs to be repeated for a realistic range of m-values, where m indicates the number of circumferential waves of the buckling pattern. The smallest eigenvalue λ_{cr} considered over all m-values determines the critical shear buckling load.

4 EXPERIMENTAL VERIFICATION

The proposed theory was verified against torsion experiments on annular plates carried out by Bauer (1987, 1988). Plates were tested with inner and outer edges clamped. Three different metals were considered: aluminium (Al), stainless steel (ST) and brass (CuZn). The material properties are given as Ramberg-Osgood parameters (see Eq. 27) in Table 1.

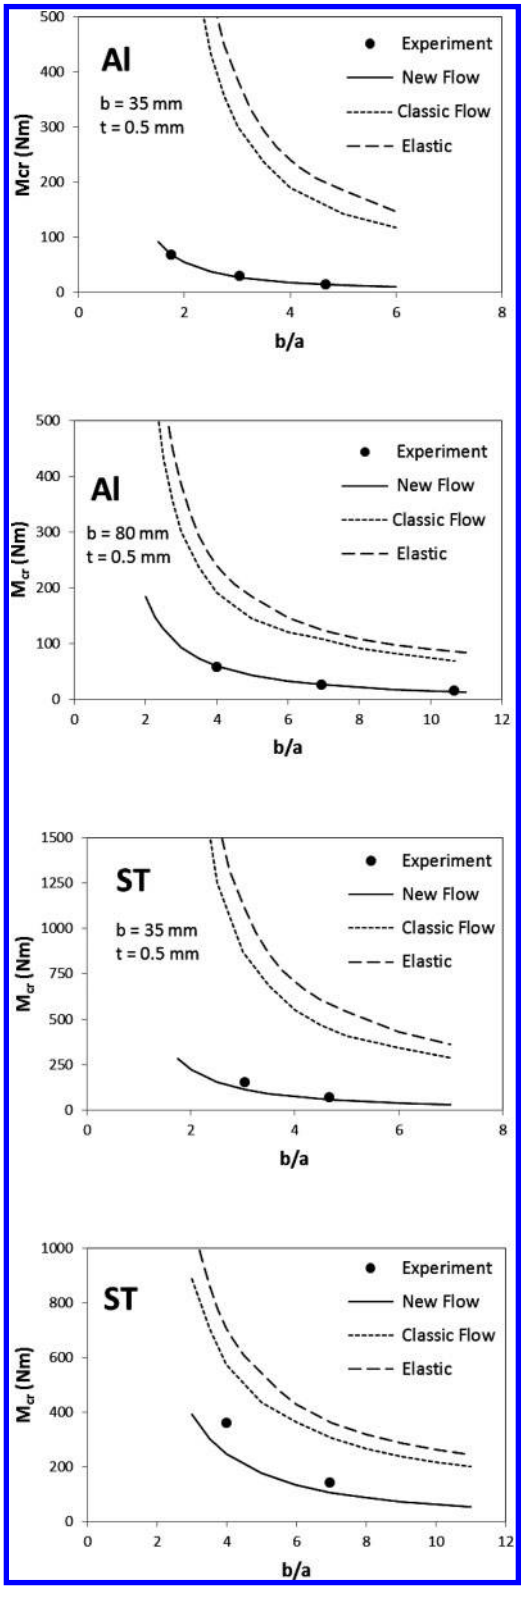

Figure 5. *continued*

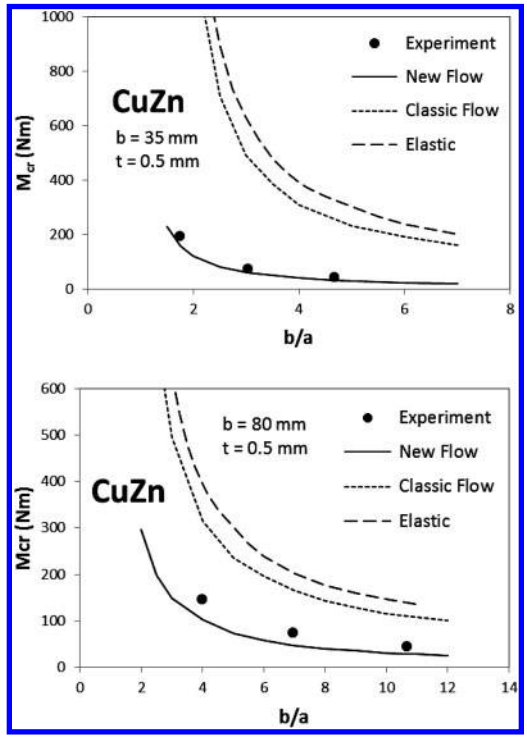

Figure 5. Comparison of theoretical and experimental results.

For each material, annular plates of widely varying geometries were tested. The onset of buckling was determined from the torsion-twist curve combined with visual observation. Table 2 makes a comparison between the experimentally observed critical (torsional) moment and the critical moment determined using the here proposed flow-based theory. Reasonably good agreement is obtained: the average ratio of the theoretical prediction to the experimental result is 0.86 with a standard deviation of 13.7%. In order to clarify and discuss the results further, a graphical representation is provided in Figure 5. First of all, a comparison between the experimental results and the elastic buckling curves clearly indicates that all plates buckle well into the inelastic range. Second, a very large discrepancy is noted between the experimental results and the predictions based on the classic interpretation of flow theory incorporating Eqs. (4–5) and detailed by Ore and Durban (1989) (labelled 'Classic Flow' in Fig. 5). On the other hand, the new approach laid out in this paper (labelled 'New Flow' in Fig. 5) matches the experiments well and yields results which are of the right order of magnitude.

5 CONCLUSIONS

A new model is proposed to describe the inelastic buckling of annular plates in shear. The model is

based on plastic flow theory ("incremental plastic theory"), but avoids the pitfalls of earlier theories by reinterpreting the plastic flow equations. In particular, incremental plastic extensions along the rotating sides of an infinitesimal plate element at the point of buckling are taken into account. The resulting plate equation, in general, requires a numerical solution. When verified against experimental data pertaining to aluminium, stainless steel and brass plates of various geometries, the proposed theory performs well, especially when compared to earlier flow-based attempts. An average ratio of the predicted buckling moment to the experimental buckling moment of 0.86 was obtained with a standard deviation of 0.137.

A novel analytical solution of orthotropic rectangular thick plate

Pan Baofeng & Liu heng
School of Civil and Hydraulic Engineering, Dalian University of Technology, Dalian, China.

ABSTRACT: Exact closed form solutions are presented for the thick plate with orthotropic properties. A novel analytical method for decoupling the governing equations of orthotropic thick plate is developed. By introducing two new functions the governing equations are converted into two independent equations. The uncoupling equations have been solved for the exact closed form solutions of orthotropic rectangular thick plate with simply supported four edges.

1 INTRODUCTION

The orthotropic plates are widely used in many fields of modern technology namely aerospace, naval, ocean and structural engineering. For the purpose of more accurate and reliable application, it is of much significance to investigate the characteristics of orthotropic plates. The present methods to solving the plate are divided into analytical approaches and numerical approaches. The Rayleigh-Ritz method is a widely agreed numerical method. Many research (Hearmon RFS 1959, Bhat RB. 1985, Dickinson SM & Di Blasio A. 1986) have extend the Rayleigh method to the solution of plates with different conditions and the obtained results are consistent with those of FME (Rossi RE & Bambill DV & Laura PAA. 1998). The analytical method of transforming a partial differential equation into an ordinary differential was also extended, shown in references (Jones R. & Milne BJ. 1976, Dalaei M. & Kerr AD. 1996, Bercin AN 1996, Sakata T. & Takahashi K. & Bhat RB. 1996). However the vibration model of orthotropic plates is more complicated than that of the isotropic plates. It is more difficult to solve the problem with the analytical method because of the increase of the number of governing equations and independent coordinates. In this paper, for decoupling multiple differential equations of high order, a novel substitution variable method is used. In section two, the novel substitution variable is determined according to the original equations, and transform the coupled equations into independent equations. In section three, using the method of separation of variables, two independent equations are solved respectively. And the result of a numerical example calculated using the novel method is shown in section four.

2 GOVERNING EQUATIONS AND DECOUPLE THE SYSTEM

Consider an orthotropic rectangular thick plate of length a,width b and uniform thickness h. The coordinate system $\{x, y, z\}$ of the rectangular plate is shown in Fig. 1.

The governing equations are given by

$$C_{11}\frac{\partial^2 w}{\partial x^2} + C_{22}\frac{\partial^2 w}{\partial y^2} - C_{11}\frac{\partial \beta_x}{\partial x} - C_{22}\frac{\partial \beta_y}{\partial y} + q = 0 \quad (1)$$

$$D_{22}\frac{\partial^2 \beta_y}{\partial y^2} + D_{66}\frac{\partial^2 \beta_y}{\partial x^2} + C_{22}\frac{\partial w}{\partial y} - C_{22}\beta_y + (D_{12} + D_{66})\frac{\partial^2 \beta_x}{\partial x \partial y} + m_y = 0 \quad (2)$$

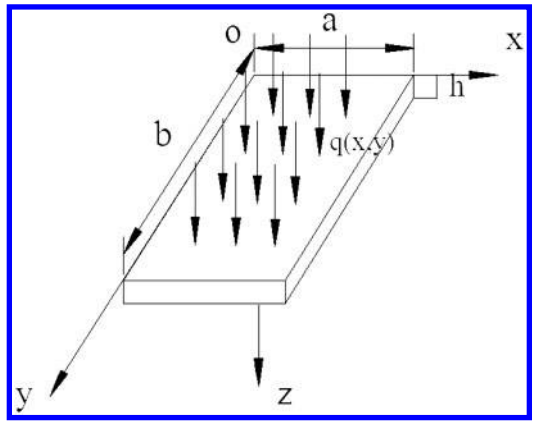

Figure 1. A rectangular plate and coordinates.

$$D_{11}\frac{\partial^2\beta_x}{\partial x^2}+D_{66}\frac{\partial^2\beta_x}{\partial y^2}+C_{11}\frac{\partial w}{\partial x}-C_{11}\beta_x+(D_{12}+D_{66})\frac{\partial^2\beta_y}{\partial x\partial y}+m_x=0 \quad (3)$$

where w is the transverse deflection of the middle surface, β_x and β_y are the rotations of a normal line due to plate bending, m_x m_y and q is the load distribution function, D_{ij} and C_{ij} are the bending stiffness and the share stiffness respectively. Defining some orthotropic stiffness parameters as:

$$\begin{aligned} D_{11} &= \frac{E_1h^3}{12(1-\upsilon_1\upsilon_2)}, & D_{22} &= \frac{E_2h^3}{12(1-\upsilon_1\upsilon_2)}, \\ D_{12} &= \frac{\upsilon_2E_1h^3}{12(1-\upsilon_1\upsilon_2)}, & D_{66} &= \frac{G_{12}h^3}{12}, \\ C_{11} &= hG_{23}, & C_{22} &= hG_{13} \end{aligned} \quad (4)$$

where E_i are the elastic modulus, G_{ij} are the share modulus, υ_{ij} are the Possion's ratios. The resultant bending moments M_x and M_y, the twisting moments M_{xy} can be obtained, namely

$$M_x=D_{11}\frac{\partial\beta_x}{\partial x}+D_{12}\frac{\partial\beta_y}{\partial y} \quad (5)$$

$$M_y=D_{12}\frac{\partial\beta_x}{\partial x}+D_{22}\frac{\partial\beta_y}{\partial y} \quad (6)$$

$$M_{xy}=D_{66}\left(\frac{\partial\beta_x}{\partial y}+\frac{\partial\beta_y}{\partial x}\right) \quad (7)$$

For decoulping the govering equations, it is assumed that

$$\beta_x=\frac{\partial F}{\partial x}+A\frac{\partial f}{\partial y} \quad (8)$$

$$\beta_y=\frac{\partial F}{\partial y}+B\frac{\partial f}{\partial x} \quad (9)$$

where A,B is undetermined coefficient. Substitution of Eq. (8) and Eq. (9) into Eq. (1) lead to the governing equation in terms of new variables as:

$$C_{11}\frac{\partial^2(w+F)}{\partial x^2}+C_{22}\frac{\partial^2(w+F)}{\partial y^2}-(C_{11}A+C_{22}B)\frac{\partial^2 f}{\partial x\partial y}-q=0 \quad (10)$$

For simplicity one can have $A=C_{22}$ and $B=-C_{11}$, then Eq. (10) has the form:

$$C_{11}\frac{\partial^2(w+F)}{\partial x^2}+C_{22}\frac{\partial^2(w+F)}{\partial y^2}-q=0 \quad (11)$$

Substitution of A and B into Eqs. (8) and (9) lead to

$$\beta_x=\frac{\partial F}{\partial x}+C_{22}\frac{\partial f}{\partial y} \quad (12)$$

$$\beta_y=\frac{\partial F}{\partial y}-C_{11}\frac{\partial f}{\partial x} \quad (13)$$

Substitution of Eq. (12) and Eq. (13) into Eq. (2) and Eq. (3) as followed:

$$\frac{\partial w}{\partial y}-\frac{\partial F}{\partial y}+\frac{D_{22}}{C_{22}}\frac{\partial^3F}{\partial y^3}+\frac{2D_{66}+D_{22}}{C_{22}}\frac{\partial^3F}{\partial x^2\partial y}=\frac{C_{12}D_{22}-C_{22}D_{12}-C_{22}D_{66}}{C_{22}}\frac{\partial^3f}{\partial x\partial y^2}+\frac{C_{11}D_{66}}{C_{22}}\frac{\partial^3f}{\partial x^3}-C_{11}\frac{\partial f}{\partial x}-m_y \quad (14)$$

$$\frac{\partial w}{\partial x}-\frac{\partial F}{\partial x}+\frac{D_{11}}{C_{11}}\frac{\partial^3F}{\partial x^3}+\frac{2D_{66}+D_{11}}{C_{11}}\frac{\partial^3F}{\partial y^2\partial x}=\frac{C_{12}D_{11}-C_{11}D_{12}-C_{11}D_{66}}{C_{11}}\frac{\partial^3f}{\partial y\partial x^2}+\frac{C_{22}D_{66}}{C_{11}}\frac{\partial^3f}{\partial y^3}-C_{22}\frac{\partial f}{\partial y}-m_x \quad (15)$$

then assume that

$$w=C_1F+C_2\frac{\partial^2F}{\partial x^2}+C_3\frac{\partial^2F}{\partial y^2} \quad (16)$$

where C_1,C_2 and C_3 are the undefined constants. Substitution into Eq. (14) and Eq. (15),

$$(C_1-1)\frac{\partial F}{\partial y}+(C_3+\frac{D_{22}}{C_{22}})\frac{\partial^3F}{\partial y^3}+(C_2+\frac{2D_{66}+D_{22}}{C_{22}})\frac{\partial^3F}{\partial x^2\partial y}=\frac{C_{12}D_{22}-C_{22}D_{12}-C_{22}D_{66}}{C_{22}}\frac{\partial^3f}{\partial x\partial y^2}+\frac{C_{11}D_{66}}{C_{22}}\frac{\partial^3f}{\partial x^3}-C_{11}\frac{\partial f}{\partial x}-m_y \quad (17)$$

$$(C_1-1)\frac{\partial F}{\partial x}+(C_2+\frac{D_{11}}{C_{11}})\frac{\partial^3F}{\partial x^3}+(C_3+\frac{2D_{66}+D_{11}}{C_{11}})\frac{\partial^3F}{\partial y^2\partial x}=\frac{C_{12}D_{11}-C_{11}D_{12}-C_{11}D_{66}}{C_{11}}\frac{\partial^3f}{\partial y\partial x^2}+\frac{C_{22}D_{66}}{C_{11}}\frac{\partial^3f}{\partial y^3}-C_{22}\frac{\partial f}{\partial y}-m_x \quad (18)$$

also for simplification it is requested that $C_1 = 1$, $C_2 = -D_{11}/C_{11}$ and $C_3 = -D_{22}/C_{22}$, so changing w into terms of F as followed:

$$w = F - \frac{D_{11}}{C_{11}}\frac{\partial^2 F}{\partial x^2} - \frac{D_{22}}{C_{22}}\frac{\partial^2 F}{\partial y^2} \tag{19}$$

subsititution Eq. (19) into Eqs. (11),(17) and (18) resulting as:

$$D_{11}\frac{\partial^4 F}{\partial x^4} + D_{22}\frac{\partial^4 F}{\partial y^4} + (\frac{C_{22}D_{11}}{C_{11}} + \frac{C_{11}D_{22}}{C_{22}}) \frac{\partial^4 F}{\partial x^2 \partial y^2} + q = 0 \tag{20}$$

$$\frac{C_{12}D_{22} - C_{22}D_{12} - C_{22}D_{66}}{C_{22}}\frac{\partial^3 f}{\partial x \partial y^2} + \frac{C_{11}D_{66}}{C_{22}}\frac{\partial^3 f}{\partial x^3} - C_{11}\frac{\partial f}{\partial x} - m_y = (\frac{2D_{66} + D_{22}}{C_{22}} - \frac{D_{11}}{C_{11}})\frac{\partial^3 F}{\partial x^2 \partial y} \tag{21}$$

$$\frac{C_{12}D_{11} - C_{11}D_{12} - C_{11}D_{66}}{C_{11}}\frac{\partial^3 f}{\partial y \partial x^2} + \frac{C_{22}D_{66}}{C_{11}}\frac{\partial^3 f}{\partial y^3} - C_{22}\frac{\partial f}{\partial y} - m_x = (\frac{2D_{66} + D_{11}}{C_{11}} - \frac{D_{22}}{C_{22}})\frac{\partial^3 F}{\partial y^2 \partial x} \tag{22}$$

Combination Eq. (21) and Eq. (22) getting the partial differential equations just including the new variable f as followed:

$$\alpha\frac{\partial^4 f}{\partial x \partial y^3} + \beta\frac{\partial^4 f}{\partial x^3 \partial y} + \gamma\frac{\partial^2 f}{\partial x \partial y} = -\Phi(m_x, m_y) \tag{23}$$

α, β, γ and $\Phi(m_x, m_y)$ defined as follow:

$$\alpha = (\frac{2D_{66} + D_{22}}{C_{22}} - \frac{D_{11}}{C_{11}})\frac{C_{22}D_{66}}{C_{11}} + (\frac{D_{22}}{C_{22}} - \frac{2D_{66} + D_{11}}{C_{11}})\frac{C_{12}D_{22} - C_{22}D_{12} - C_{22}D_{66}}{C_{22}} \tag{24}$$

$$\beta = \frac{C_{12}D_{11} - C_{11}D_{12} - C_{11}D_{66}}{C_{11}}(\frac{2D_{66} + D_{22}}{C_{22}} - \frac{D_{11}}{C_{11}}) - (\frac{2D_{66} + D_{11}}{C_{11}} - \frac{D_{22}}{C_{22}})\frac{C_{11}D_{66}}{C_{22}} \tag{25}$$

$$\gamma = (\frac{2D_{66} + D_{11}}{C_{11}} - \frac{D_{22}}{C_{22}})C_{11} - (\frac{2D_{66} + D_{22}}{C_{22}} - \frac{D_{11}}{C_{11}})C_{22} \tag{26}$$

$$\Phi(m_x, m_y) = \frac{\partial m_y}{\partial y}(\frac{2D_{66} + D_{11}}{C_{11}} - \frac{D_{22}}{C_{22}}) - \frac{\partial m_x}{\partial x}(\frac{2D_{66} + D_{22}}{C_{22}} - \frac{D_{11}}{C_{11}}) \tag{27}$$

In this section w, β_x, β_y are in terms of F, f and the system (1),(2),(3) is turned into two independent equations (20),(23). In what follows, two decoupled equations are solved respectively.

3 SOLUTION METHOD OF NEW EQUATIONS

In this section, take an orthotropic rectangular plate with four simple edges as an example. Solve (20) and (23) respectively. Lastly get the solution of the system though F and f. The boundary conditions of edges are:

$$x = \{^0_a\text{: } w = 0, M_x = 0, M_{xy} = 0 \tag{28}$$

$$y = \{^0_b\text{: } w = 0, M_y = 0, M_{xy} = 0 \tag{29}$$

substitution of (12),(13) and (19) into (28) and (29) leads to

$$(F - \frac{D_{11}}{C_{11}}\frac{\partial^2 F}{\partial x^2} - \frac{D_{22}}{C_{22}}\frac{\partial^2 F}{\partial y^2})|^{x=0}_{x=a} = 0 \tag{30}$$

$$[D_{11}\frac{\partial^2 F}{\partial x^2} + D_{22}\frac{\partial^2 F}{\partial y^2} + (D_{11}C_{22} - D_{22}C_{11})\frac{\partial^2 f}{\partial x \partial y}]|^{x=0}_{x=a} = 0 \tag{31}$$

$$(2\frac{\partial^2 F}{\partial x \partial y} + C_{22}\frac{\partial^2 f}{\partial y^2} - C_{11}\frac{\partial^2 f}{\partial x^2})|^{x=0}_{x=a} = 0 \tag{32}$$

$$(F - \frac{D_{11}}{C_{11}}\frac{\partial^2 F}{\partial x^2} - \frac{D_{22}}{C_{22}}\frac{\partial^2 F}{\partial y^2})|^{y=0}_{y=b} = 0 \tag{33}$$

$$[D_{22}\frac{\partial^2 F}{\partial y^2} + D_{11}\frac{\partial^2 F}{\partial x^2} + (D_{22}C_{11} - D_{11}C_{22})\frac{\partial^2 f}{\partial x \partial y}]|^{y=0}_{y=b} = 0 \tag{34}$$

$$(2\frac{\partial^2 F}{\partial x \partial y} + C_{22}\frac{\partial^2 f}{\partial y^2} - C_{11}\frac{\partial^2 f}{\partial x^2})|^{y=0}_{y=b} = 0 \tag{35}$$

then solve the Eq. (20) with the boundary condition (30) and (33). Use the separation of variables to obtain the general solutions for the system. It is assumed that F has the form as:

$$F(x, y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} X_m(x)Y_n(y) \tag{36}$$

In order to meeting the boundary condition Eqs. (30) and (33), $X_m(x)$ and $Y_n(y)$ are defined as followed:

$$X_m(x) = A_m \sin\frac{m\pi x}{a}, Y_n(y) = A_n \sin\frac{n\pi y}{b} \tag{37}$$

so Eq. (36) can be rewritten as:

$$F(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} A_{mn} \sin\frac{m\pi x}{a} \sin\frac{n\pi x}{b} \tag{38}$$

where $A_{mn} = A_n A_m$. Certainly Eq. (38) is also required to meet Eq. (20). In order for determing A_{mn}, the load function in Eq. (20) is expressed in double sine series form:

$$q(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} Q_{mn} \sin\frac{m\pi x}{a} \sin\frac{n\pi x}{b} \tag{39}$$

where

$$Q_{mn} = \frac{4}{ab}\int_0^a\int_0^b q(x,y) \sin\frac{m\pi x}{a} \sin\frac{n\pi x}{b} dxdy$$

substitution of Eq. (39) into (20) as:

$$\sum_{m=1}^{\infty}\sum_{n=1}^{\infty} A_{mn}[D_{11}(\frac{m\pi}{a})^4 + (\frac{C_{22}D_{11}}{C_{11}} + \frac{C_{11}D_{22}}{C_{22}}) (\frac{m\pi}{a})^2(\frac{n\pi}{ab})^2 + D_{22}(\frac{n\pi}{b})^4] \sin\frac{m\pi x}{a} \sin\frac{n\pi x}{b} = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \sin\frac{m\pi x}{a} \sin\frac{n\pi x}{b} Q_{mn} \tag{40}$$

According to the uniqueness theorem of Fourier expansion, obtain A_{mn} as:

$$A_{mn} = Q_{mn}[D_{11}(\frac{m\pi}{a})^4 + (\frac{C_{22}D_{11}}{C_{11}} + \frac{C_{11}D_{22}}{C_{22}}) (\frac{m\pi}{a})^2(\frac{n\pi}{ab})^2 + D_{22}(\frac{n\pi}{b})^4]^{-1} \tag{41}$$

substituting Eq. (41) into Eq. (38),

$$F(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \frac{4}{ab}\int_0^a\int_0^b q(x,y) \sin\frac{m\pi x}{a} \sin\frac{n\pi y}{b} dxdy[D_{11}(\frac{m\pi}{a})^4 + (\frac{C_{22}D_{11}}{C_{11}} + \frac{C_{11}D_{22}}{C_{22}}) (\frac{m\pi}{a})^2(\frac{n\pi}{ab})^2 + D_{22}(\frac{n\pi}{b})^4]^{-1} \sin\frac{m\pi x}{a} \sin\frac{n\pi y}{b} \tag{42}$$

What follow using the method of separating variables to solve Eq. (23) with boundary condition. The expression in the form of the separation of variables for $f(x,y)$ is:

$$f(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} X_m(x)Y_n(y) \tag{43}$$

also we can have:

$$\frac{\partial}{\partial x} f(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} X'_m(x)Y_n(y) \tag{44}$$

$$\frac{\partial^2}{\partial x^2} f(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} X''_m(x)Y_n(y) \tag{45}$$

$$\frac{\partial^2}{\partial x \partial y} f(x,y) = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} X'_m(x)Y'_n(y) \tag{46}$$

for simplification, only Eq. (46) will be used to solve the equation for f. Substitution of (42) and (46) into (31) and (34), getting the boundary function just about separations of f as followed:

$$x = \{^0_a : X'_m(x) = 0, \qquad y = \{^0_b : Y'_n(y) = 0 \tag{47}$$

in order to satisfy the condition Eq. (47), set separations of $X'_m(x)$ and $Y'_n(y)$ as:

$$X'_m(x) = B'_m \sin\frac{m\pi x}{a}, \qquad Y'_n(y) = B'_n \sin\frac{n\pi y}{b} \tag{48}$$

also we have:

$$X_m(x) = B_m \cos\frac{m\pi x}{a} + C_m$$

$$Y_n(y) = B_n \cos\frac{n\pi y}{b} + C_n$$

$$X''_m(x) = B''_m \cos\frac{m\pi x}{a} \qquad Y''_n(y) = B''_n \cos\frac{n\pi y}{b}$$

where B_m, B'_m, B''_m and B_n, B'_n, B''_n have the relationships as followed:

$$B_m = -(\frac{m\pi}{a})^{-1}B'_m = (\frac{m\pi}{a})^{-2}B''_m$$

$$B_n = -(\frac{n\pi}{b})^{-1}B'_n = (\frac{n\pi}{b})^{-2}B''_n$$

then substitute Eq. (42) and f into Eq. (32) and (35), and determine the constants in the equation about f,

$$2\sum_{m=0}^{\infty}\sum_{n=0}^{\infty} A_{mn}\frac{m\pi}{a}\frac{n\pi}{b} \cos\frac{n\pi}{b}y = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} B_{mn}[C_{22}(\frac{n\pi}{b})^2 - C_{11}(\frac{m\pi}{a})^2] \cos\frac{n\pi}{b}y - E_{mn}C_{22} (\frac{n\pi}{b})^2 \cos\frac{n\pi}{b}y + F_{mn}C_{11}(\frac{m\pi}{a})^2 \tag{49}$$

$$2\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}\cos m\pi\cos\frac{n\pi}{b}y=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\tag{50}$$

$$B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]\cos m\pi\cos\frac{n\pi}{b}y-$$

$$E_{mn}C_{22}(\frac{n\pi}{b})^2\cos\frac{n\pi}{b}y+F_{mn}C_{11}(\frac{m\pi}{a})^2\cos m\pi$$

$$2\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}cos\frac{m\pi}{a}x=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}B_{mn}[\tag{51}$$

$$C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]\cos\frac{m\pi}{a}x-E_{mn}C_{22}$$

$$(\frac{n\pi}{b})^2+F_{mn}C_{11}(\frac{m\pi}{a})^2\cos\frac{m\pi}{a}x$$

$$2\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}\cos\frac{m\pi}{a}x\cos n\pi=\sum_{m=0}^{\infty}\tag{52}$$

$$\sum_{n=0}^{\infty}B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]\cos\frac{m\pi}{a}x$$

$$\cos n\pi-E_{mn}C_{22}(\frac{n\pi}{b})^2\cos n\pi$$

$$+F_{mn}C_{11}(\frac{m\pi}{a})^2\cos\frac{m\pi}{a}x$$

where B_{mn} is equal to B_nB_m, and E_{mn}, F_{mn} are not usefull. So according to the uniqueness theorem of Fourier expansion, we have:

$$2A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}=B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]\tag{53}$$

$$-E_{mn}C_{22}(\frac{n\pi}{b})^2$$

$$2A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}\cos m\pi=B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}\tag{54}$$

$$(\frac{m\pi}{a})^2]\cos m\pi-E_{mn}C_{22}(\frac{n\pi}{b})^2$$

$$2A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}=B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]\tag{55}$$

$$+F_{mn}C_{11}(\frac{m\pi}{a})^2$$

$$2A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}cosn\pi=B_{mn}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\tag{56}$$

$$\frac{m\pi}{a})^2]\cos n\pi+F_{mn}C_{11}(\frac{m\pi}{a})^2$$

Solve Eqs. (53),(54),(55) and (56), we can obtain:

$$B_{mn}=2A_{mn}\frac{m\pi}{a}\frac{n\pi}{b}[C_{22}(\frac{n\pi}{b})^2-C_{11}(\frac{m\pi}{a})^2]^{-1}$$

$$E_{mn}=F_{mn}=0$$

So the expression in the form of double sine series for $f(x,y)$ is

$$f(x,y)=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{8mn\pi^2}{a^2b^2}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}\tag{57}$$

$$\sin\frac{n\pi y}{b}dxdy[D_{11}(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}+\frac{C_{11}D_{22}}{C_{22}})$$

$$(\frac{m\pi}{a})^2(\frac{n\pi}{b})^2+D_{22}(\frac{n\pi}{b})^4]^{-1}[C_{22}(\frac{n\pi}{b})^2-$$

$$C_{11}(\frac{m\pi}{a})^2]^{-1}\cos\frac{m\pi x}{a}\cos\frac{n\pi y}{b}$$

substitution Eq. (57) into Eq. (23), and define the relationship between m and n in Eq. (57), resulting as:

$$\alpha(\frac{m\pi}{a})^2+\beta(\frac{n\pi}{b})^2-\gamma=0\tag{58}$$

And substitution of Eqs. (42) and (57) into Eqs. (19) and (12) and (13), obtain the expression for w,β_x and β_y,

$$w(x,y)=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}(1+\frac{D_{11}}{C_{11}}(\frac{m\pi}{a})^2+\frac{D_{22}}{C_{22}}(\frac{n\pi}{b})^2)\tag{59}$$

$$\frac{4}{ab}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}dxdy[D_{11}$$

$$(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}+\frac{C_{11}D_{22}}{C_{22}})(\frac{m\pi}{a})^2(\frac{n\pi}{b})^2$$

$$+D_{22}(\frac{n\pi}{b})^4]^{-1}\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}$$

$$\beta_x(x,y)=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{4m\pi}{a^2b}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}\tag{60}$$

$$\sin\frac{n\pi y}{b}dxdy[D_{11}(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}$$

$$+\frac{C_{11}D_{22}}{C_{22}})(\frac{m\pi}{a})^2(\frac{n\pi}{ab})^2+D_{22}(\frac{n\pi}{b})^4]^{-1}$$

$$\cos\frac{m\pi x}{a}\sin\frac{n\pi y}{b}+\sum\sum_{\alpha(\frac{m\pi}{a})^2+\beta(\frac{n\pi}{b})^2-\gamma=0}$$

$$-\frac{8C_{22}mn^2\pi^3}{a^2b^3}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}$$

$$\sin\frac{n\pi y}{b}dxdy[D_{11}(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}+\frac{C_{11}D_{22}}{C_{22}})$$

$$(\frac{m\pi}{a})^2(\frac{n\pi}{b})^2+D_{22}(\frac{n\pi}{b})^4]^{-1}[C_{22}(\frac{n\pi}{b})^2-$$

$$C_{11}(\frac{m\pi}{a})^2]^{-1}\cos\frac{m\pi x}{a}\cos\frac{n\pi y}{b}$$

$$\beta_y(x,y)=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{4n\pi}{ab^2}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a} \quad (61)$$

$$\sin\frac{n\pi y}{b}dxdy[D_{11}(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}$$

$$+\frac{C_{11}D_{22}}{C_{22}})(\frac{m\pi}{a})^2(\frac{n\pi}{ab})^2+D_{22}(\frac{n\pi}{b})^4]^{-1}$$

$$\sin\frac{m\pi x}{a}\cos\frac{n\pi y}{b}+\sum\sum_{\alpha(\frac{m\pi}{a})^2+\beta(\frac{n\pi}{b})^2-\gamma=0}$$

$$\frac{8C_{11}m^2n\pi^3}{a^3b^2}\int_0^a\int_0^b q(x,y)\sin\frac{m\pi x}{a}$$

$$\sin\frac{n\pi y}{b}dxdy[D_{11}(\frac{m\pi}{a})^4+(\frac{C_{22}D_{11}}{C_{11}}+\frac{C_{11}D_{22}}{C_{22}})$$

$$(\frac{m\pi}{a})^2(\frac{n\pi}{b})^2+D_{22}(\frac{n\pi}{b})^4]^{-1}[C_{22}(\frac{n\pi}{b})^2-$$

$$C_{11}(\frac{m\pi}{a})^2]^{-1}\cos\frac{m\pi x}{a}\cos\frac{n\pi y}{b}$$

4 NUMERICAL EXAMPLE

In this section the exact solution of the *SSSS* rectangular plate is calculated by the method which is developed in this paper. The numerical example is considered, the data for the plate and load amplitude are $a=b=4\,m$, $h=0.8$, $E=343\,MPa$ and $\gamma=0.3$. The calculating result for deflection of the plate is shown in Fig. 2, where $q=2.0\times10^6\,N$. Then the exact value of maximal w is calculated shown in Table. 1, when x/a equals 0.5.

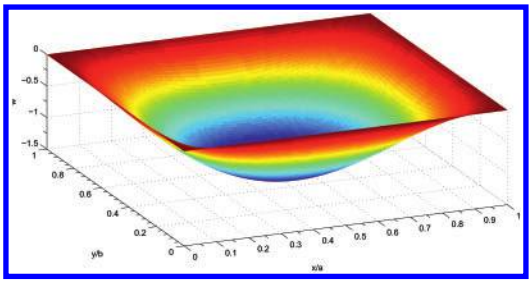

Figure 2. The result for deflection of the plate($a=b=4m$, $h=0.8$, $E=343\,MPa$, $\upsilon=0.3$ and $q=2.0E6N$).

Table 1. The exact value of maximal w for the rectangular plates with $\gamma=0.3$, $E=343\,MPa$, $y/b=0.5$

x/a	0.45	0.48	0.5	0.52	0.55
m,n = 10	−1.4492	−1.4629	−1.4655	−1.4626	−1.4492
m,n=15	−1.4490	−1.4625	−1.4651	−1.4625	−1.4490
m,n=20	−1.4490	−1.4626	−1.4652	−1.4626	−1.4490

5 CONCLUSIONS

The novel variables were introduced for simplifying the method to solving governing equations of orthotropic thick rectangular plate. The partial differential equations were decoupled into two independent ordinary differential equations. By the mean of the separation of variable exact closed form solutions for the deflection and rotation for the orthotropic rectangular plate were obtained. For this method, the accuracy of the numerical result and more cases for the orthotropic plates with different boundary conditions will be discussed to show its rationality in the future.

Wind loading on solar chimneys: from wind tunnel experiments to CFD simulation

F. Lupi & C. Borri
University of Florence, Florence, Italy

H.-J. Niemann
Ruhr-University Bochum, Bochum, Germany

ABSTRACT: The Solar Updraft Power Plant technology is a combined sun-wind energy solution for renewable energy harvesting. It is based on the natural updraft of warm air in a chimney and conversion into electric power by wind turbines at the chimney foot. The tower structure is basically a circular cylinder, which may turn into a hyperboloid at lower levels in order apply benefits of shape strengthening. The height of the tower is up to 1.5 km and it is usually designed as a thin reinforced concrete shell. A preliminary investigation of the shell response under an equivalent static wind load revealed the key role played by stiffening rings along the height. They allow a better distribution of internal forces under wind loading, reducing risk of buckling and peaks of tension at the windward side. An extensive wind tunnel investigation has been recently performed at WiSt laboratory at Ruhr-University Bochum (Germany) and at Criaciv laboratory at University of Florence (Italy). The tests highlighted a new phenomenon regarding cross-wind loads, induced by a bi-stable and asymmetric flow distribution. This is created by compartments between stiffening rings along the tower. A further insight into the flow structures is achieved by CFD simulations. Results of both experimental and numerical studies are addressed in the paper.

1 INTRODUCTION

The original idea of energy harvesting from sun and wind – by a combination of the greenhouse effect below a large collector roof and the natural updraft of the warm air in a tower – goes back to the early twentieth century (Cabanyes, 1903). The basic working principle was documented, some years later, in a publication by the German scientist Günther (Günther, 1931). The question, whether it is possible and convenient to use the updraft of air created by solar radiation input to generate electricity, was originally tested with a full-scale prototype ($h = 195$ m) by J. Schlaich and his team (Schlaich, 1995). Since then, several studies have been carried out regarding the feasibility of this new technology, namely Solar Updraft Power and, in its original name, Solar Chimney Power Plant (see, for example, SCPT 2010 and SUTPT 2012).

Basically, a Solar Chimney Power Plant consists of three elements: the collector area, the turbine(s) with coupled generator(s) as power conversion unit and the solar tower. Solar radiation heats the collector ground and consequently warms up the air inside the collector. The warm air rises up into the chimney of the plant. The driving force is the pressure difference between a column of cold air outside and a column of hot air inside the chimney. The stream of warm air turns the turbines at the chimney foot and in the power conversion unit the kinetic energy of the flow is then transformed into electric power. Figure 1 shows a recently built power plant of small size in Inner Mongolia (China). It is a 50 m tall reinforced concrete tower with a glass collector on an only one side. It is optimized for both sun and wind energy harvesting during the summer and the winter, respectively (Wei & Wu 2012).

Figure 1. Solar Heated Wind Updraft Tower in Wuhai Desert, Inner Mongolia (China).

In October 2010, the generating electricity system in Figure 1 was combined to the grid. However, the production of energy is proportional to the volume of the cylinder having the height of the tower and the diameter of the collector. For this reason, provided

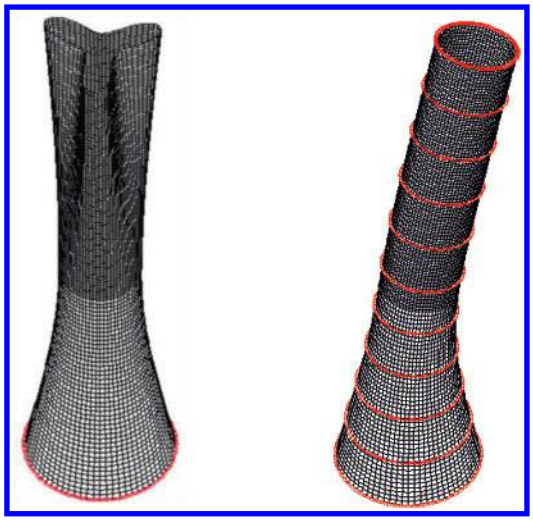

Figure 2. First natural vibration mode: without rings ($n_1 = 0.073$ Hz) and with 10 rings ($n_1 = 0.172$ Hz).

a sufficiently high solar radiation input (as it is, for example, in the great deserts), a very good efficiency of the power plant can be reached only with extra-large dimensions of the tower and/or the collector. A tower of 500 m in height can deliver about 50 MW of energy; values up to 200 MW can be achieved with structures of 1 km in height and 5 km in diameter of the collector.

2 PRELIMINARY STUDIES

Solar Towers are especially sensitive to wind, because they are ultra-high, slender and very thin shells. So, among all natural hazards, the wind action decides the structural feasibility of the tower. It comprises the mean wind load, averaged over ten minutes, the fluctuating wind load due to turbulence, the amount of resonance to turbulence, and the load induced cross-wind by vortex shedding.

A preliminary investigation on 1-km tower (predesigned by Krätzig et al. 2009) under an equivalent static wind load was performed in Lupi (2009) and discussed in Niemann et al. (2009) and Borri et al. (2010). The aims of the investigation were: 1) assess the feasibility of Solar Chimneys, with regard to the wind action, 2) find a strategy of optimization of the structure to minimize wind induced tensile stresses (reduction of steel reinforcement).

In accordance also with other authors (e.g. Krätzig et al. 2008/09/10 and Harte et al. 2007/10), it was proved that a key role in the structural design of the tower was played by stiffening rings, i.e. circular ring beams applied at the top and at various levels along the height, in order to stabilize the cross section and achieve a better distribution of internal forces. The stiffening rings guarantee a beam-like behavior at the first eigenmode (Figure 2).

One of the first issues which were studied in order to assess the feasibility of solar chimneys was the

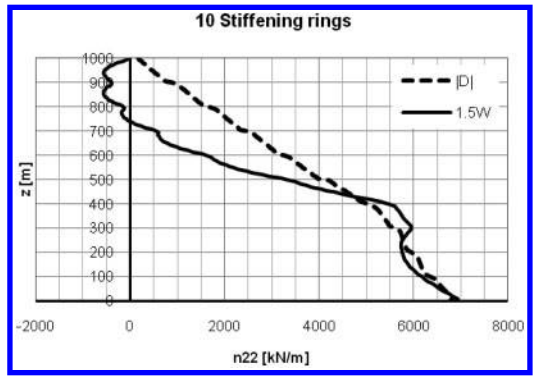

Figure 3. Meridional force n_{22} at stagnation (1-km tower with ten stiffening rings). D = self-weight induced stresses, W = wind induced stresses.

overturning of the tower by the wind action. The analysis was performed in Lupi (2009) in a combination at the ultimate limit states: D + 1.6 W, where the dead load (D) was not amplified because it is considered a favorable action, while the wind action (W) was amplified with a partial safety factor of 1.6. This value was suggested by the VGB guideline for cooling towers, in the version of 2005. In 2010, the revised version of the VGB allowed to use the factor 1.5 instead of 1.6, in line with the recommendations of the Eurocode. The results at stagnation, by using the amplification factor 1.5 for the wind action, are reported in Figure 3.

The investigation showed that the region of the tower which is more sensitive to the wind action is around 200–450 m in height, where the tensile stresses produced by the wind load at the windward side are not completely balanced by the self-weight.

Tensile stresses are caused by high peaks of tension in the shell. In the study it was noted that an increase of the stiffness of the rings beams improves the distribution of internal forces, with a consequent reduction of peaks of tension. The reason is due to the role played by the stiffening rings, which reduce the shell-like deformations of the cross section. Therefore, the distribution of internal forces in the cross section tends to be more similar to the one of a beam (linear distribution, crossing the x-axis at 90°). Since equilibrium is preserved at each level, a better distribution of internal forces, ideally tending to the one of a beam, implies reduction of peaks of tension.

In conclusion, this preliminary analysis of wind-induced global effects showed the importance of the stiffening rings in [1)] reducing the risk of overturning of the tower by the wind action, [2)] saving steel reinforcement due to the reduction of tension in the shell.

Further issues like the structural vulnerability to vortex shedding were also addressed in the feasibility analysis (Lupi 2011). In this regard, thanks to the beam-like vibration mode at a sufficiently high frequency (about 0.17 Hz for 1 km tall tower), which is ensured by the presence of the rings and the not too high aspect ratio, the critical velocity for onset of lock-in phenomena is very high (above 100 m/s).

All these promising results encouraged further investigation. In particular, the evaluation of local effects in the vicinity of the ring beams required a more sophisticated wind load model than the one suggested by the Codes, where the peak load is obtained by amplification of the mean load. Moreover, since the ring beams can be designed as circular ring beams which jut out of the structure, externally, their influence on the wind flow can have important effects. Therefore, in order to answer to these and other questions, wind tunnel tests are performed at WiSt (Ruhr-University Bochum, Germany) and at Criaciv (University of Florence, Italy). In addition to the cross-checked experimental investigation, numerical simulations have been performed on the basis of Criaciv' results by the TEE Group, Industrial Energy Department, University of Florence (Salvadori & Mattana 2013, unpublished).

3 WIND TUNNEL INVESTIGATION

The experimental investigation is performed in two wind tunnels, in order to cross-check results: the WiSt laboratory at Ruhr-University Bochum (Germany) and the Criaciv laboratory at University of Florence (Italy).

WiSt laboratory at Ruhr-University Bochum is an open circuit wind tunnel with a total length of about 17 m. The test section is 1.8 m in width and 1.6 m in height. The turbulent atmospheric boundary layer is created by three turbulent generators of Counihan type (Counihan 1969), a castellated barrier and a roughness field consisting of wooden cubes. The engine allows to attain a maximum wind speed of about 28–30 m/s. A Prandtl tube, placed at 1.3 m in height, allows to measure the dynamic pressure of the incoming flow. Temperature sensors acquire temperature during the measurements. The pressure sensors are four-active-element piezoresistive bridges. The A/D converter scans the pressures in a sample-and-hold modus, which produces simultaneous sampling of the measurements. A sampling frequency of 2 kHz is used for the measurements.

The Criaciv laboratory is an open-circuit wind tunnel located at Polo Universitario Città di Prato, which is a branch of the University of Florence. The total length is about 22 m, the tunnel has a slightly divergent shape from the inlet (in order to guarantee a constant pressure along the x-axis) and the test section is 2.4 m in width and 1.6 m in height. The atmospheric boundary layer profile which is used in these experiments is produced by three bigger turbulence generators of Counihan type and four smaller spires, followed by roughness panels with wooden cubes. The motor – with a nominal power of 160 kW – and the fan are placed at the end of the wind tunnel, followed by a T-shaped symmetric diffuser. The engine allows to attain a maximum wind speed of about 30 m/s. The pressures on the tower are measured with two different types of pressure scanners, at sampling frequency of either 250 or 500 Hz, depending on the scanner.

Figure 4. Wind tunnel model.

The model for wind tunnel tests (Figure 4) is a circular cylinder with a free-end and aspect ratio H/D ≈ 7. The cylinder is a rigid body of 1 m in height and 15 cm in diameter. In scale 1:1000, it represents a prototype of 1 km in height. Pressure taps are placed at several levels along the height and at an angular spacing of 20° in the circumferential direction. It is also possible to create an efflux inside the cylinder like in a chimney, but the most interesting results presented in the paper refer to the condition without efflux. Both external and internal pressures can be measured at each level.

The peculiarity of the model is the presence of ten circular rings along the height. They are equally spaced along the height. In the wind tunnel scale the rings are at a distance of 10 cm. The width (w) of the rings, in the wind tunnel scale is 7 mm ($w/D = 4.67*10^{-2}$). Such rings along the model reproduce the stiffening rings, previously introduced in the paper. The aerodynamic of the flow around the structure is the object of the investigation.

4 EXPERIMENTAL RESULTS

Due to the reduced scale of the model, in the wind tunnel the Reynolds number ($Re_{,WT}$) is around three orders of magnitude lower than in full-scale ($Re_{,FS}$).

$$Re_{WT} = \frac{UD}{\nu} = \frac{30*0.15}{1.5*10^{-5}} = 3*10^{5} \quad (1)$$

$$Re_{FS} = \frac{UD}{\nu} = \frac{60*150}{1.5*10^{-5}} = 6*10^{8} \quad (2)$$

Therefore, surface roughness (consisting of ribs) is applied on the model in order to attain a much higher effective Re. The concept of effective Re is described in ESDU 74030. A preliminary investigation on the circular cylinder (without rings) regarding the effect of surface roughness is performed at WiSt wind tunnel in turbulent boundary layer flow. The proper choice of surface roughness is decided with regard to a target surface pressure distribution, recommended by the VGB guideline (VGB 2010) for smooth cylinders in the transcritical range of Re.

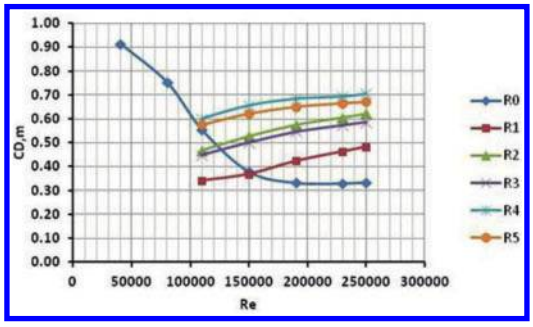

Figure 5. Mean drag coefficient versus Re. R0 = smooth cylinder, R1–R5 = rough cylinder, different distribution of ribs.

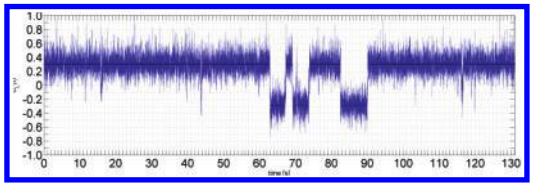

Figure 6. Time history of the lift coefficient at z/H = 0.95 (Re = 2.5*10^5, rough cylinder R1), result at WiSt wind tunnel.

Results are reported in Figure 5 in terms of mean drag coefficients. The blue curve (R0) in the graph refers to the smooth cylinder. The state of the flow ranges from the end of subcritcal to the first stage of supercritical regime. The latter is characterized by constant minimum drag, according to the classification proposed by Roshko (1961). All the other curves (named R1–R5) refer to the rough cylinder. Thanks to surface roughness and turbulence of the incoming flow, the range of Re tested in the experiments on the rough cylinder is beyond the critical Re. The target condition is well represented by the red curve (R1) at the highest Re, this is then adopted in the following analysis. Further details on Reynolds effects can be found in Lupi et al. (2012).

The tests performed on the tower with ten rings revealed a surprising effect due to the compartments created by the rings. It is a bistable flow condition, meaning that two stable states of the flow are clearly detectable in the time histories, as it is shown in Figure 6, which plots the lift coefficient at z/H = 0.95. The lift coefficient is obtained by integration of pressures in the across-wind direction.

Figure 6 proves that within each state of the bistable condition the mean lift is different from zero. Therefore, in terms of mean loads, the solar chimney exposed to wind should be designed for both mean drag and lift forces, i.e. mean forces in both the along-wind and the across-wind directions.

The existence of a not-zero mean lift force (i.e. a mean force in the across-wind direction) is due to a not symmetric mean pressure distribution. The result is rather astonishing, being the structure a circular cylinder. However, the compartments created by rings along

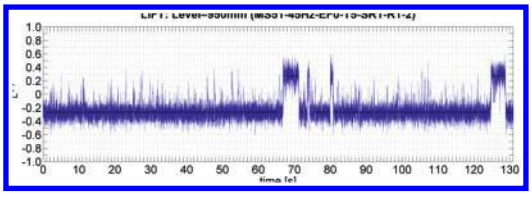

Figure 7. Time history of the lift coefficient at z/H = 0.95 (Re = 2.8*10^5, rough cylinder R1), result at Criaciv wind tunnel.

the height are responsible for a complicated flow structure, which results in not-symmetric mean pressure distribution alternated in neighboring compartments.

The cross-check of results on the same model in WiSt and Criaciv wind tunnels is decisive to assess the physical fundamentals of the phenomenon (Figure 7).

Therefore, the asymmetric mean pressure distribution, with higher suction on one side of the cylinder, must be considered an intrinsic characteristic of the observed phenomenon on the tower with rings, which is not induced by the conditions of the tests.

By the way, the bistable flow is not a completely new phenomenon in fluid dynamics. It is well known, for example, on smooth circular cylinders in smooth flow within the critical range of Re. In those conditions, transition from laminar to turbulent boundary layer occurs around the separation point and any disturbance in the flow may allow reattachment on an only one side of the cylinder. Thus, the asymmetry in the bistable flow condition is due to the formation of a laminar separation bubble on an only one side of the cylinder (Schewe, 1983). The same effect, with formation of a bubble in the wake of the cylinder, can be hypothesized also on the solar chimney. A separation bubble on an only one side of the structure produces the asymmetric load. However, it is absolutely not a laminar separation bubble in the classical sense, as described in literature on smooth circular cylinders. It cannot be, due to surface roughness applied on the cylinder surface (which promotes transition to turbulence very close to stagnation) and to turbulence of the incoming flow. Moreover, the Reynolds number of the experiment (Re = 2.5*10^5) is rather high and far beyond the critical value. In addition, in the range of Re which was possible to test in the experiments, there is not any significant dependence on Re which may suggest disappearance of the phenomenon.

This result presents several new and unknown issues regarding the flow around circular cylinders, which have also consequences for the structural design. A further proof, as well as the confirmation of formation of a separation bubble on one side of the cylinder, results from CFD simulations. It is shown in the next section.

5 CFD SIMULATIONS

CFD simulations have been performed on the basis of Criaciv' experiments by the TEE group, Industrial Energy Department (formerly known as Energy

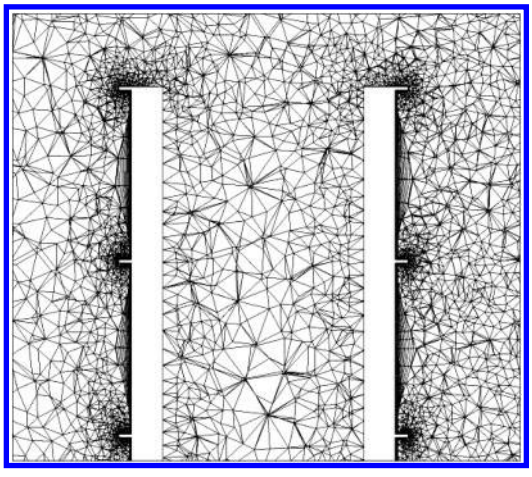

Figure 8. Detail of the mesh in the vicinity of the ring beams. Transversal cross-section.

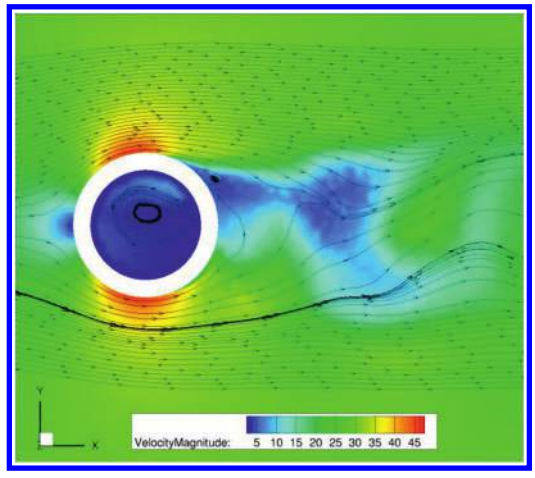

Figure 9. Horizontal cross-section, instantaneous flow velocity (magnitude, m/s) at $z/H = 0.75$.

Engineering Department "S. Stecco"), University of Florence (Salvadori & Mattana et al. 2013).

The URANS simulation is performed by using the software Ansys Fluent 14. The incompressible fluid is solved by applying Navier-Stokes equations. The time step is 0.001 s. The turbulence model is the Shear Stress Transport (SST) k-omega. This is suitable to describe separated flows on smooth surfaces and adverse pressure gradients.

In order to reproduce the conditions of CRIACIV experiments, the tunnel and also the diffusor downstream of the test section were modeled.

The boundary conditions at the inlet are the velocity profile, the turbulence intensity and the turbulent length scale. The velocity profile at the inlet is imposed like the one in Criaciv wind tunnel. The boundary conditions at the outlet are the pressure, the turbulence intensity and the turbulent length scale. No slip conditions are set to all the other surfaces.

A peculiar feature of the simulations is the high Re number ($Re = 2.8*10^7$), obtained by reducing the air viscosity of two order of magnitudes. In these transcritical conditions of Re, surface roughness on the cylinder is not necessary. Moreover, differently from wind tunnel experiments, the simulation benefits of ideal test conditions.

The research about the numerical simulation of the flow around the solar chimney is still on-going. Due to the stochastic occurrence of jumps in the time histories, a stochastic simulation like a LES should be more appropriate than a URANS. By the way, an important result is already achieved: the instantaneous flow picture in Figure 9 (horizontal cross-section at a representative level, $z/H = 0.75$), clearly confirms the asymmetry due to a separation bubble on one side of the cylinder. This is consistent with the expectations on the flow, deduced on the only basis of pressure measurements, as previously explained. The wake is not aligned on the rear of the cylinder, but it is shifted on one side. The result is rather relevant, because the numerical simulation benefits of ideal and symmetric test conditions, which could not be perfectly achieved in the wind tunnel. This confirms the physical fundamental of the phenomenon.

However, the period of time investigated in the numerical simulation (about 0.2 s) is presently too short for being representative and investigate bistable effects. Further studies are necessary.

6 CONCLUSIONS

The aerodynamic study of the flow around the solar chimney has shown several relevant features, induced by the stiffening rings along the height. The existence of a bistable not-symmetric flow around the cylindrical structure is confirmed in both experiments and simulations. Further studies are on-going, in order to investigate the three-dimensional features of the phenomenon and the wind-induced structural effects.

Stability and nonlinear behaviour of RC solar updraft towers

R. Harte
Department of Civil Engineering, University of Wuppertal, Germany,
Krätzig & Partner Civil Engineering Consultants, Bochum, Germany

ABSTRACT: Solar updraft towers will form the largest shell structures in technology. Because of their size they are extremely exposed to wind action. Many structural phenomena, like forced vibrations, static and dynamic instabilities, or damage-induced failure, will influence their safety and reliability. It makes sense to adopt the know-how from design and construction of natural draught cooling towers and transfer it to towers of solar updraft power plants. The present paper will report on typical structural design efforts to improve the load-bearing capacity of large-sized concrete shells, especially the shape optimization of the meridian, the structural safety including stability and vibrations, and nonlinear concepts to increase durability.

1 INTRODUCTION

More than 40 years of experience with natural draft cooling towers (NDCT) provide a profound insight into the response behavior of high-rise RC shell structures. Like the solar updraft tower a cooling tower shell is mainly loaded by its dead weight (*G*ravity load) G, by *W*ind action W and by ambient and service *T*emperature T. Further, in seismic active zones *E*arthquake excitations E, and in case of inhomogeneous soil conditions differential *S*ettlements S have to be considered (VGB 610 Ue 2010).

Numerical investigations have shown that the hyperbolic shape with continuous curvature is favoring the load-carrying characteristic of such shell structures. Figure 1 shows a rotational hyperboloid with its straight generators, which slope-angle β can be calculated according to (Flügge 1947). It is obvious from the sketches in Figure 1 that the shell with smaller angle β will be characterized by smaller tensile and compressive forces in the shell, thus minimizing the amount of reinforcement. This has been proved as well by numerous optimization analyses for natural draught cooling tower projects (Harte & Krätzig 2002; Krätzig et al. 2011; Noh et al. 2012).

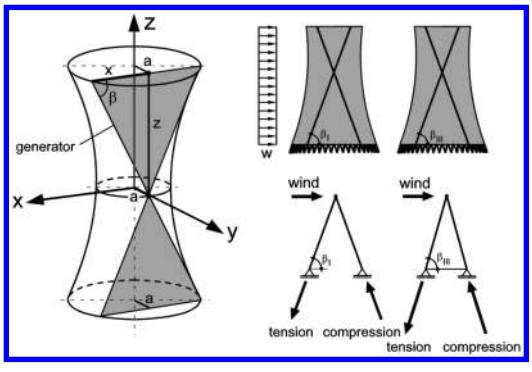

Figure 1. Principal load carrying behavior of hyperbolic shells.

From load-carrying viewpoint, solar updraft towers are extremely enlarged, over-scaled natural draught cooling tower shells, showing all problems known to cooling tower designers, as:

- high compressive stresses under *G*ravity load G, *W*ind action W and *T*emperature T,
- tendency to vertical outside cracking under G, W and T,
- high sensitivity to shell buckling instabilities under G, W and internal wind suction W_i,
- wind vibrations in the upper tower part, eventually leading to dynamic instabilities,
- a natural safety margin against seismic actions because of low 1st eigenfrequency,
- stress and thermal fatigue phenomena of the required high-performance concrete,
- durability problems to the end of life time.

Thus it makes sense to adopt the advantages of cooling tower design, i.e. the use of a hyperbolic instead of a pure cylindrical shape. Thanks to the double curvature, the structure applies the benefits of shape strengthening. Doubly curved thin shells with negative Gaussian curvature are able to resist loading acting perpendicularly to the shell surface mainly through in-plane extensional and shearing forces, the so-called membrane action. Plate and shell structures with Gaussian curvature 0 like slabs and cylinders might be dominated by bending action, characterized by transverse shear resultants, bending and twisting moments. It is well known from historical structures like pyramids and domes that structures with dominant membrane

behavior show a much better long-term stability and durability, sometimes over centuries. This principle must be adopted for cooling tower shells and even more for solar updraft towers, if the intended service life-time of more than 80 years shall be achieved.

2 STRUCTURAL BEHAVIOR

2.1 *The effect of stiffening rings*

Figure 2 shows the design study for a solar updraft tower with a total height of 500 m and diameters of 120 m at the throat and of 200 m at the base. The wall thickness increases from 0.25 m at the top to 0.60 m down to the foundation slab. The shell with shape-optimized meridian requires a classical upper edge ring and three intermediate stiffening rings.

Experienced designers of natural draught cooling towers would prefer to construct the shell without intermediate rings. In this case the wall-thickness has to be increased significantly required by globally extended instability modes and the concrete quality has to be increased to a high performance concrete of at least C 90/105.

Thus it seems to be advantageous to improve the stiffness by intermediate stiffeners. They serve three important purposes,

- to reduce the buckling lengths of the shell for sufficient safety against instability failure (Krätzig et al. 2009);
- to reduce the vibration wave length for balancing the eigenfrequencies of the shell (Borri et al. 2010; Goldack 2011);
- to constrain the meridional/shear forces in the shell due to wind towards a beam-like load-carrying behavior (Schlaich 1999; Krätzig et al. 2009; Borri et al. 2010).

The first and second purposes can be achieved with rather moderate sized cross-sections of all four stiffeners, attached on the shell outside, namely a hangover-width of 2.50 m and a thickness of 0.40 m.

The increase of the buckling safety can be observed from Figure 3. For the load combination (Gravity G + Wind W + Internal suction W_i), and for the tower design without any ring-stiffener one can clearly recognize, how the instability modes dominate the entire shell, whereas additional intermediate ring-stiffeners as arranged in Figure 2 will drive the buckling modes (as well as the vibration modes) to the lower shell region. The observable skew modal wave patterns which develop from bottom to top of the shell are a clear signal for the dominance of the (hyperbolic) shell geometry on the load response.

The third purpose requires stiffer rings in order to reduce the maximum wind tension towards the order of magnitude of the dead-load compression, an optimal design goal. These intermediate stiffening rings serve for a more cosine-like circumferential distribution of the meridional stress resultants under wind action W, as can be seen in Figure 4. With the above

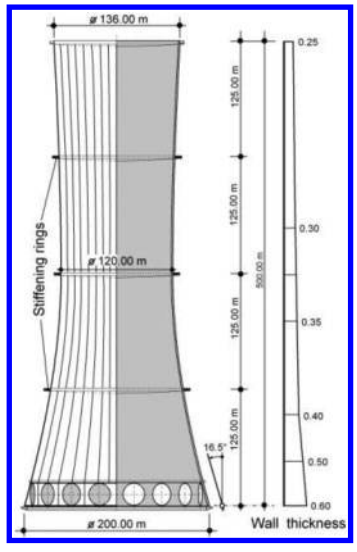

Figure 2. 500 m solar updraft tower prototype.

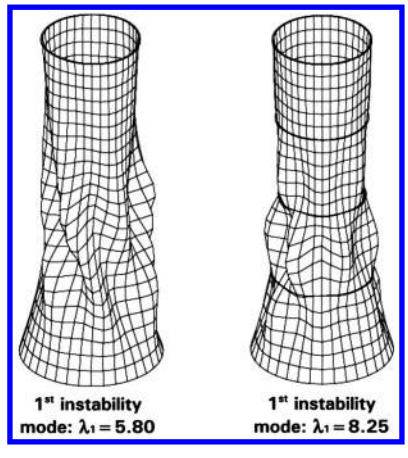

Figure 3. 500 m solar updraft tower – instability modes without and with 3 intermediate rings.

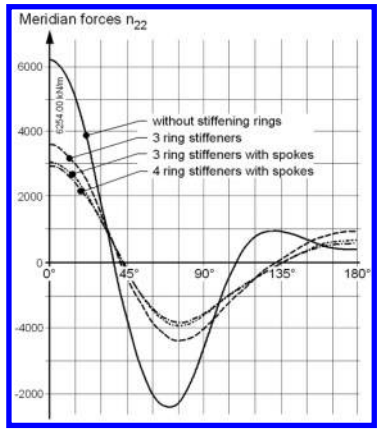

Figure 4. 500 m solar updraft tower – meridional stress resultants n_{22} due to wind action.

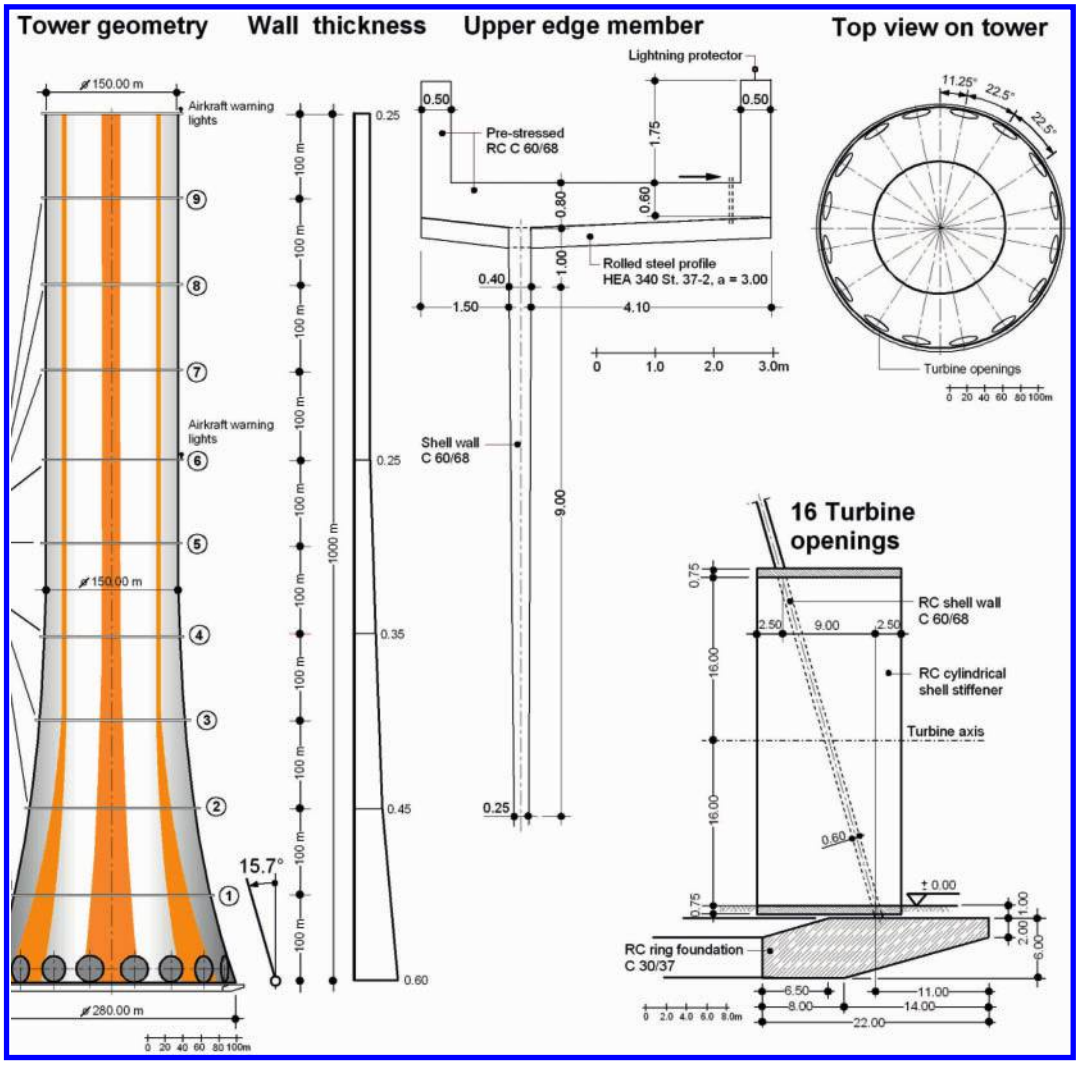

Figure 5. 1,000 m solar updraft tower pre-design by KRÄTZIG & PARTNER Civil Engineering Consultants (Harte et al. 2010).

given dimensions, the relevant tensile stress maxima can be reduced up to 2/3. Higher reductions require additional spoken wheels at the inner side of the rings, as recommended by (Schlaich et al. 2005).

2.2 *Extension to larger solar updraft towers*

The structural design of large solar updraft towers is an optimization process to compromise between several conflicting key points (Backström et al. 2008). The difficulties of the structural design of such large-sized shells are still enormous. The widening of the shell below the throat will be again shape-optimized for limitation of the shell bending and the in-plane shear.

Figure 5 presents a pre-design by KRÄTZIG & PARTNER Civil Engineering Consultants, a solar updraft power plant with a tower of 1,000 m of height. Together with a collector size of around 6,000 m of diameter this plant shall produce a peak power of 200 MW_p (equal to an annual work of ≈600 GWh/a) in regions with 2,240 MWh/a of solar irradiation. At the throat at 400 m height its shell diameter is 130 m wide, at the upper rim 145 m. Below 400 m the shell widens in a strength-optimized hyperbolic shape to a foot diameter of 260 m. The wall thickness of the shell of high-strength concrete C 70/85 varies from 0.25 m to 0.65 m. In addition to the usual upper edge ring, 9 intermediate and pre-stressed RC ring-stiffeners are fixed on the outer shell face.

16 turbo-generators are located directly on the foundation around the footing perimeter, to reduce air inflow losses and to avoid varying settlements between machinery and tower (Backström et al. 2008; Andres et al. 2010). The foundation itself is constructed as a closed ring of around 20 m of width, depending on the local soil conditions.

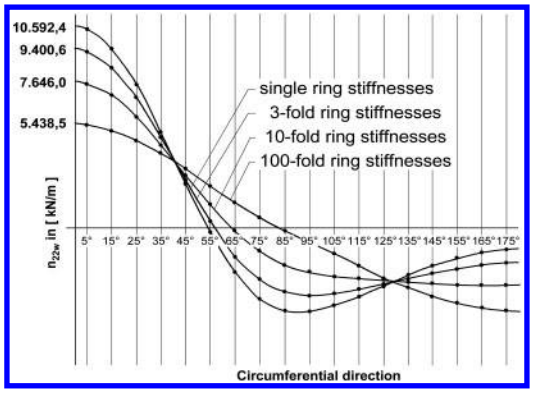

Figure 6. 1,000 m solar updraft tower at level 280 m – circumferential distribution of meridional stress resultants n_{22W} due to wind action for varying ring stiffnesses.

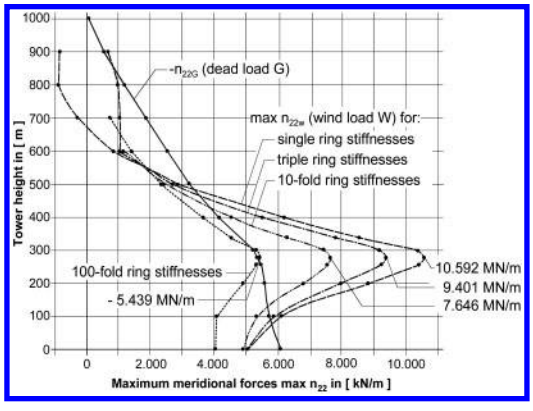

Figure 7. 1,000 m solar updraft tower – meridional stress resultants n_{22w} due to wind action versus tower height for varying ring stiffnesses.

The question is still relevant, whether a shell-like or a beam-like load-carrying characteristic will be better with respect to both structural stability and economic efficiency. The optimized shaping of the shell alone would never result in an economic tower design. In addition, the mentioned strong ring-stiffeners are required in order to constrain the meridional wind forces from shell-like distributions towards beam-like ones, and to guarantee a sufficient buckling safety.

In Figure 4 we already observed for the 500 m tower, how the wind force distributions approximate the cosine optimum, and how likewise the maximum tension stresses are reduced. Those are relevant for most of the required meridional reinforcement ratio in the cross-section.

Figure 6 elucidates the same fact again for the selected 1000 m solar updraft tower, plotting the towers response due to wind and depending on the varying stiffness of the 9 stiffening rings. The circumferential distributions of meridional wind forces at level 280 m are plotted, where the reference ring stiffness belongs to a rectangular cross-section of 0.40 m × 3.00 m, increasing from top to below over 3-fold, 10-fold finally to 100-fold values.

Figure 7 shows the maximum tensile forces from wind against tower height, again with increasing stiffness of the ring stiffeners. Compared to the compressive forces due to gravity (dead load) n_{22G} one can observe, how the tensile stresses are reduced by increasing the stiffness of the rings, likewise reducing the amount of reinforcement. But one should accentuate that any global optimization of a solar updraft tower comprises the global main dimensions, the meridional shape of the solar updraft tower as well as the stiffening rings.

The 9 intermediate ring-stiffeners constrain the structural response such that the internal lever arms are maximized, in order to keep both the tension (reinforcement) and compression (wall thickness) stresses small. Further results for the structural behavior of the stiffened 1,000 m tower shown in Figure 5 have been presented by (Borri et al. 2010).

Cost-optimized design of solar updraft towers requires thin shells because of the high costs for lifting concrete and reinforcement to great heights. But such saving will result in ring-stiffeners of increased stiffness, still an enormous construction challenge.

3 NONLINEAR DESIGN FOR DURABILITY

3.1 *Simulation method*

An economic load bearing behavior can only be achieved by use of nonlinear techniques, utilizing the increase of internal lever arms by consideration of horizontal cracking.

Up to now we have mainly treated linear elastic responses of solar updraft towers, including their instability resistance. But the constitutive behavior of RC will lead to non-linear responses (material nonlinearity), at least beyond certain wind-load intensities. Also aging of the material leads to non-linear structural response, an important aspect for the intended long life-duration of solar updraft towers of more than 80 years. In addition, in the beam-like tower structure second order effects might be activated during wind deformation (geometrical non-linearity), so any careful response study should comprise both kinds of non-linearity.

In contrast to classical linear elastic FE-technology, all applied 2D finite shell elements need to have at least a layered structure to treat material nonlinearities. This means, that each GAUSS-point of an element consists of a chain of integration sub-points, one in each layer. At these sub-points, on material point level, suitable 3D the constitutive relations of the material in question including deterioration effects have to numerically evaluated (Krätzig & Petryna 2001). The material point level, our lowest macroscopic simulation level, collects all constitutive information usually in a complete 3D environment, defined by the local base-vectors $\boldsymbol{a}_i$: $\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3$.

For our RC simulations these material properties are (Krätzig 1997):

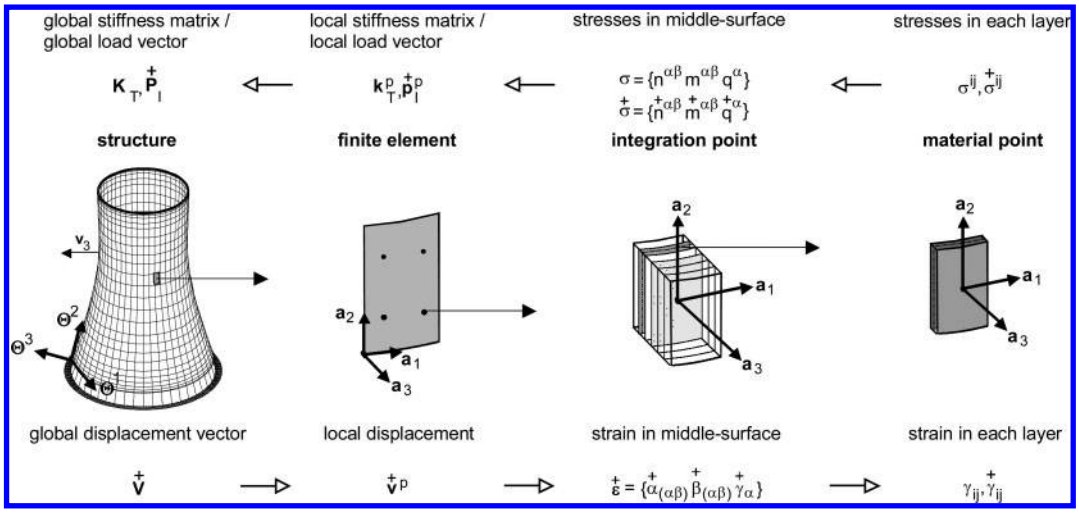

Figure 8. Layered finite shell element and multi-level simulation concept according to (Krätzig 1997; Andres & Harte 2006).

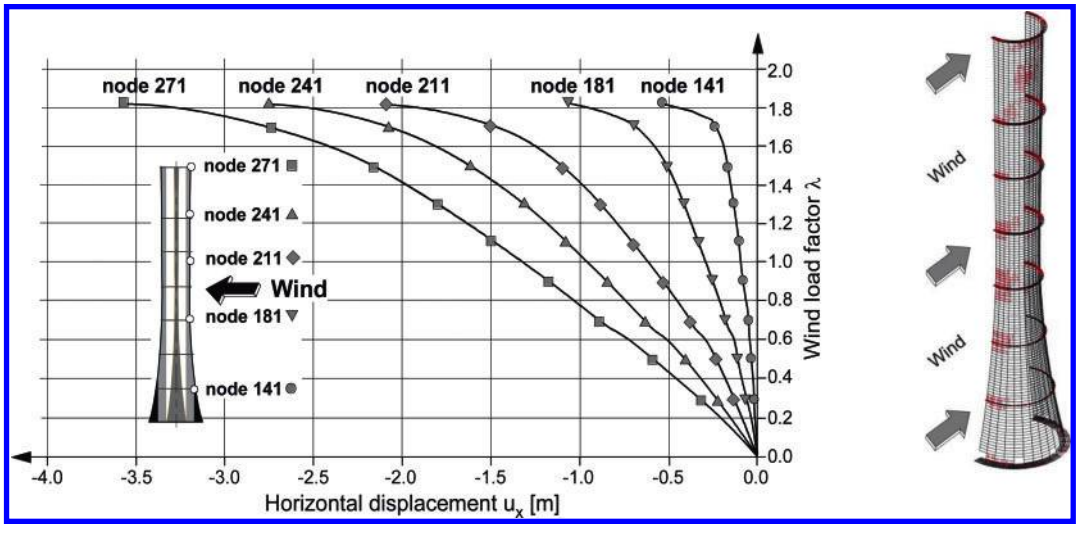

Figure 9. Non-linear displacements versus factor λ of load-combination $G + \lambda W$ for a 750 m solar updraft tower (left), and simulated crack pattern just before failure at load-level $G + 1.85W$ with max. crack-width $w = 1.8$ mm (right).

- nonlinear elastic-plastic $\sigma - \varepsilon$-behavior for concrete in compression including material micro-cracking, leading to stress release in the post-strength range,
- elastic-brittle behavior for concrete in tension with rather low tension strength leading to macroscopic crack-damage, modeled here in smeared crack manner,
- elastic-plastic material modeling for reinforcement steel,
- nonlinear inelastic bond behavior between steel and concrete, limited by inelastic slip damage.

Such nonlinear simulations are based on the tangential stiffness equation, which has to be solved incrementally with multiple iterations:

$$\boldsymbol{K}_T(\boldsymbol{V},\boldsymbol{d}) \cdot \overset{+}{\boldsymbol{V}} = \overset{+}{\boldsymbol{P}} = \boldsymbol{P} - \overset{+}{\boldsymbol{P}}_I(\boldsymbol{V},\boldsymbol{d}) \qquad (1)$$

Since $\boldsymbol{K}_T$ and $\overset{+}{P}_I$ depend on the current known deformation $\boldsymbol{V}$, the tangential stiffness equation is non-linear and thus requires iterative solution techniques for the incremental displacements $\overset{+}{V}$.

As shown in Figure 8, the final FE-analysis follows a multi-level iteration technique as described first in (Krätzig 1997). For each new load-step, the iteration starts with a new global vector of out-of-balance forces, transforming in each GAUSS-point of each element from increments of the global degrees of freedom to increments of the element degrees of freedom and finally to increments of the continuum strains at material point level. There the coded constitutive laws transform strain increments into stress

ones, after which the solution path returns back to the global structural level, to evaluate a new internal force vector $\overset{+}{P}_I$ for the next iteration step.

3.2 *Results of nonlinear simulation*

Non-linear results for another 750 m high prototype tower designed by KRÄTZIG & PARTNER (Krätzig et al. 2010) are shown in Figure 9. The nonlinear horizontal deflections of the shell at different nodes, or at different heights resp., are plotted versus the wind-load intensity factor λ, showing a max. top-deflection of approx. 3.6 m. The plot of crack evolution shows, where tensile stresses have exceeded the tensile strength of concrete and which max. crack-widths have to be expected.

Even with fast computers, such analyses require long computing time. But to study the crack evolution provides an important basis for the nonlinear improvement of the linear-elastic dimensioning of reinforcement. Thus such simulations will offer an economic, but still safe and reliable design tool for large-sized RC shells of solar updraft towers.

4 CONCLUSIONS

The beam-like load carrying characteristic has proved to be more safe and economic than the shell-like one. Thus additional stiffening rings will be inevitable. The aim of all detailed design considerations should be an operation-life of solar updraft towers of at least 80 years. Future research and development efforts have to be concentrated on the dynamic wind-structure-interaction and on a reliable prognosis of the non-linear material degradation and the resulting reduction of structural stability over life-time.

ABSTRACT: Renewable energy sources, including solar power, are becoming increasingly important in today's world. The Solar Thermal Chimney (STC) is a novel solar power technology which could provide a reliable large-scale power supply. However, as with all renewable energy technologies, ambient conditions (including insolation and ambient temperature) are important and thus some locations are better suited to solar power generation than others. A comprehensive STC model has been developed. It performs steady-state simulations incorporating all relevant heat transfer mechanisms, fluid shear stress and the air density lapse rate. The solar collector is simulated as a discretised, axisymmetric system composed of thermal components. This model is used, together with a simple cost model, to determine optimum system dimensions for a 100 MW STC plant at three selected sites: the Atacama Desert, Chile; Manzanares, Spain; and Arizona, USA. A tall chimney is necessary for large-scale power generation, and the significant technical challenges associated with constructing such tall, slender structures will be briefly touched upon.

1 INTRODUCTION

The solar thermal chimney – also known as a solar updraft tower or solar thermosyphon – is a large-scale solar power generation technology. It consists of a large solar collector – a transparent material supported above the ground covering a large area; a chimney located at the centre of the collector; and a turbine located at the base of the chimney. The sun heats the air beneath the collector via the greenhouse effect and the air flows through the collector and rises up the chimney under buoyancy. The turbine extracts power from the pressure difference generated by the airflow. A schematic diagram is shown in Figure 1.

The concept of extracting power from a buoyant updraft of air is not new. In 1926, Dubos proposed constructing a solar thermal chimney by affixing the chimney to a suitable mountainside and installing a solar collector at the base (Bernardes, 2010). The first large-scale research prototype of a solar thermal chimney was built in Manzanares, Spain, by German engineering consultancy Schlaich Bergermann und Partner. This solar thermal chimney had a chimney 194 m tall, a mean collector radius of 122 m and a nominal power output of 50 kW. It was built in 1981–82, and it was used for research programs before it was decommissioned in 1989 (Haaf, 1984; Haaf et al., 1983; Schlaich, 1995; Schlaich et al., 2005).

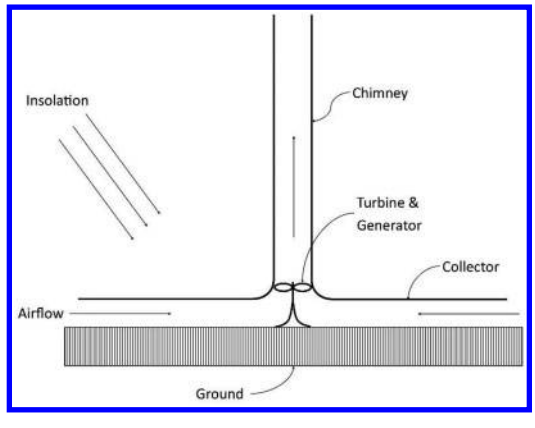

Figure 1. A schematic of the solar thermal chimney power plant.

Despite the absence of further physical prototypes, interest in solar thermal chimneys has increased and theoretical and computational modelling techniques are now well-established. Comprehensive models were developed by (Backström, 2003), (Bernardes et al., 2003) and (Pretorius et al., 2006). Studies of solar thermal chimneys using computational fluid dynamics have been produced by (Bernardes et al., 1999) and (Koonsrisuk et al., 2012). A comprehensive analysis

of system costs was produced by (Fluri et al., 2009). Cottam et al. have produced solar thermal chimney studies using a simple frictionless model with zero air density lapse rate to investigate solar thermal chimney performance for changing plant dimensions and environmental conditions (Cottam et al., 2012; Cottam et al., 2013). The model described in this paper was developed from Cottam et al.'s frictionless model.

Thermodynamic and physical models of the solar thermal chimney power plant are at an advanced stage and solar thermal chimneys can now be modelled with confidence. There are a few published models which evaluate the financial feasibility of solar thermal chimneys and projected costs vary. This paper proposes an optimisation routine which will form the foundation of an economic assessment of solar thermal chimney technology. This paper intends to evaluate the performance of solar thermal chimneys optimised for a mean power output of 100 MW at three different locations – Arizona, USA; Atacama Desert, Chile; and Manzanares, Spain.

2 COMPUTER MODELS AND METHODS

In order to assess energy-generating capacity of a solar thermal chimney power plant in different locations, two models have been developed in Matlab.

- Insolation model – predicts the annual insolation profile at a given location and altitude.
- Solar thermal chimney thermodynamical model – calculates all STC operating parameters for given environmental conditions and system size.

These models are integrated into an optimisation routine which will furnish three different configurations for an optimised STC plant, each capable of producing an annual mean power output of 100 MW. Due to differences in environmental conditions (ambient temperature and insolation), the optimised STC dimensions will be different for each location. The optimisation criteria is cost and hence a simple material cost model has been developed.

2.1 *Insolation model*

This model utilises trigonometry to calculate the profile of energy flux incident upon a particular location on the Earth's surface throughout the year. It calculates the air mass ratio to establish the attenuation of insolation through the atmosphere. It does not take into account cloud cover, and as such is seen as an over-estimate of the available solar energy. The insolation model reduces the required input variables to latitude ϕ and altitude Z_a. Note that latitudes south of the equator are denoted negative. The three locations are characterised as shown in Table 1.

2.2 *Solar thermal chimney simulation model*

The authors have developed a steady-state, incompressible flow model with axisymmetric collector flow, which calculates all STC operating parameters for given conditions and system size. It includes shear stress momentum losses in the collector and chimney and makes use of the Boussinesq approximation, which de-couples density from pressure and states that for small variations in fluid density, the density is a function of temperature only. This approximation simplifies the calculations and permits the model to use incompressible flow theory, despite the flow being driven by buoyancy.

Table 1. Characteristics of selected locations.

Location	Latitude (degrees)	Altitude (m)
Arizona, USA	32	1000
The Atacama Desert, Chile	−23	4000
Manzanares, Spain	39	500

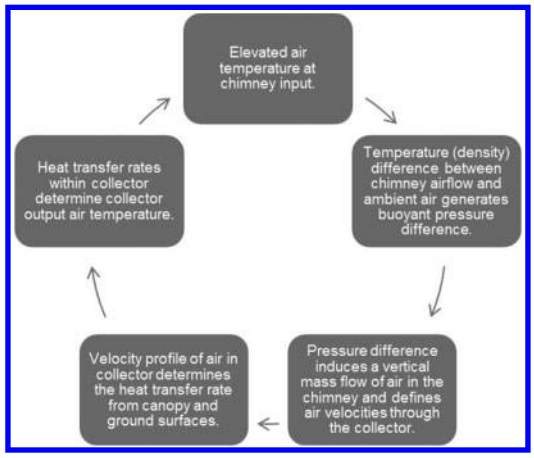

Figure 2. Implicit cyclical process for converging upon mass flow rate and collector outlet air temperature values.

This model is based largely upon the structure laid out in (Bernardes et al., 2003) with some modifications, and the heat transfer coefficient correlations are based on the relationships supplied in (Pretorius et al., 2006). An iterative algorithm is required to find the solution as the relationship of the collector output air temperature and system mass flow rate can only be expressed implicitly. Figure 2 shows the cyclical relationship which needs to be iterated in order to converge upon the solution.

The collector is modelled as a one-dimensional Boussinesq flow problem, whereby the flow from collector inlet to outlet is assumed to have radial symmetry about the chimney. The 1-D collector model is discretised and temperatures are calculated at each node for three thermal components:

- Collector canopy
- Collector air flow
- Collector ground surface

In Figure 3, energy inflows and outflows are identified for each component, where T = temperature;

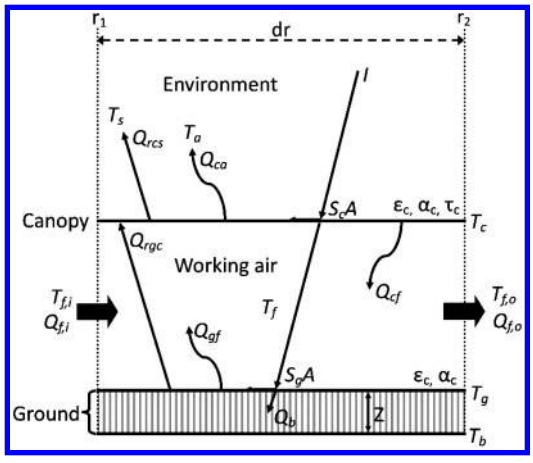

Figure 3. A discretised collector section with energy inflows and outflows.

Q = energy flux; ε = emissivity; α = absorptivity; τ = transmissivity; subscript s = sky; subscript a = ambient; subscript c = canopy; subscript f = working fluid; subscript g = ground surface; subscript b = ground at depth Z; subscript i = inlet; and subscript o = outlet. Using the First Law of thermodynamics, simultaneous energy equations are generated for each component at each node and solved via matrix methods.

The mass flow rate depends on the chimney's dimensions, the ambient temperature and the chimney inlet air condition (equal to the collector outlet air condition), and can be calculated as follows:

$$\dot{m} = \rho_{ch} A_{ch} \sqrt{\frac{2}{\rho_{ch}} \left(\int_{z_0}^{H_{ch}} (\rho_\infty - \rho_{ch}) g \, dz - \Delta p_f \right)} \tag{1}$$

where ρ_{ch} = air density within the chimney; A_{ch} = internal chimney flow area; ρ_∞ = ambient air density; g = acceleration due to gravity; z_0 = the height at which the buoyancy pressure difference is being evaluated; and H_{ch} = the total height of the chimney; and Δp_f = pressure difference due to friction. The integral term represents the pressure difference due to buoyancy. The air within the chimney is less dense than the ambient air due to the heat energy it received within the collector, and thus the collector outlet air temperature has an impact upon system mass flow rate. Solving the buoyancy difference integral requires knowledge of the rate of change of the ambient and chimney air densities with height z. The expansion of air with altitude is assumed to be isentropic and hence depends only on the air's initial condition (different for chimney air flow and ambient air) and its ratio of specific heats κ. The integrated buoyancy pressure difference equation at height z_{ch} up the chimney is presented in Equation 2. The variables α, β and γ are determined in Equations 3–5.

$$\begin{aligned} \int_{z_0}^{H_{ch}} (\rho_\infty - \rho_{ch}) g \, dz &= \frac{\alpha_\infty}{\beta_\infty(\gamma_\infty + 1)} \Big[(1 + \beta_\infty (H_{ch} - z_0))^{\gamma_\infty + 1} - (1 + \beta_\infty z_0)^{\gamma_\infty + 1} \Big] \\ &- \frac{\alpha_{ch}}{\beta_{ch}(\gamma_{ch} + 1)} \Big[(1 + \beta_{ch} (H_{ch} - z_0))^{\gamma_{ch} + 1} - (1 + \beta_{ch} z_0)^{\gamma_{ch} + 1} \Big] \end{aligned} \tag{2}$$

$$\alpha = g\rho(z_0) \tag{3}$$

$$\beta = \frac{g(\kappa - 1)}{\kappa R T(z_0)} \tag{4}$$

$$\gamma = \frac{1}{\kappa - 1} \tag{5}$$

where R = the specific gas constant for dry air. The subscripts ∞ and ch are applied to the appropriate terms of Equations 3–5, e.g. $\alpha_\infty = g\rho_\infty(z_0)$ and $\alpha_{ch} = g\rho_{ch}(z_0)$. The pressure loss due to friction is calculated using the standard theory for fluid pressure loss in a pipe, with the Darcy friction factor calculated by means of the Colebrook Equation for turbulent flow.

The turbine model remains simple, with a swept area equal to the flow area of the chimney and a constant efficiency and pressure drop ratio. Note that the solar thermal chimney utilises a Kaplan turbine extracting power from the pressure difference across it and not a wind turbine which extracts power from the kinetic energy of the flow. Equation 6 gives the power output from the turbine.

$$P = \eta_t x \Delta p_{ch} v_t A_t \tag{6}$$

where P = power output (W); η = efficiency; x = turbine pressure drop ratio; $\Delta p_{ch} = \Delta p_b - \Delta p_f$ = chimney pressure difference; v = air velocity; A = area; subscript t = turbine and subscript ch = chimney.

This model contains most of the features of those in (Bernardes et al., 2003) and (Pretorius et al., 2006). Bernardes et al. utilised a more comprehensive set of thermally-connected components to simulate the collector, including sealed water bags for heat storage, whilst Pretorius et al. included the pressure loss due to collector supports. This model includes a comprehensive simulation of pressure differences within the chimney (see Equations 1–5) and permits the simulation of solar thermal chimneys with sloping collector canopies.

This steady STC model calculates the power generated over time by calculating the monthly mean daily insolation profile using the insolation model and simulating the solar thermal chimney at half-hour intervals to produce a monthly-average daily power output profile for each STC.

2.3 *Optimisation of STC dimensions by cost*

A Matlab script optimises the STC dimensions by minimizing material cost. The associated cost model calculates prices for materials only and does not include labour, plant or financing costs. It is not intended as a full cost analysis, but rather as a metric for the optimisation procedure. All material costs are calculated assuming a 20% bulk-purchase discount. The prices per unit of material are given in Table 2.

Table 2. Material costs.

	Reinforced concrete (US$/m^3)	Transparent film (US$/m^2)	Steel C-section (US$/m)
Arizona	105.00	1.84	26.00
Atacama	85.10	1.49	21.00
Manzanares	86.80	1.52	21.40

Concrete cost based on UK direct quote.
Transparent film cost based on UK direct quote.
Steel C-section cost based on UK direct quote.
Adjustments for international price variations based on Faithful Gould Construction Parity Index (Faithful Gould, 2012).

Table 3. Optimised STC dimensions for 100 MW mean output power given location environmental conditions and local material costs.

Location	Mean insolation W/m^2	Collector radius m	Chimney height m	Energy generation MWh/a
Arizona	402	3952	1204	371.77
Atacama	427	3291	1060	265.73
Manzanares	369	3624	1151	278.31

The STC chimney height and collector radius are optimised against cost for a 100 MW power output. Collector height at input is fixed at 5 m. Collector height at output is set to $5\,\text{m} + 0.01 \times R_{coll}$. Chimney internal radius is set to $10\,\text{m} + 0.04 \times H_{ch}$. The STC's dimensions are optimised for a 100 MW power output under each location's annual mean insolation. The annual power and energy profiles from the optimised STCs were simulated and the annual energy yield from each STC design in each location was compared so that a conclusion can be reached regarding the best site for locating a solar thermal chimney and the most suitable system dimensions. The cost model utilised in the optimisation routine makes no claims to being suitable for evaluating the actual cost of constructing an STC of the optimised dimensions.

3 RESULTS & ANALYSIS

This exercise was undertaken to test the process for optimising solar thermal chimney dimensions considering both ambient conditions (insolation and ambient temperatures) and economic factors. As this was a preliminary investigation, the cost model used was greatly simplified, and considered only a cost per unit for the materials involved, which is sufficient for evaluating the optimisation procedure itself. Following this investigation, it can be concluded that the optimisation procedure performs well and that when coupled with a comprehensive cost model, it has the potential to become a powerful tool which delivers a full location-aware technical and economic analysis of an optimised

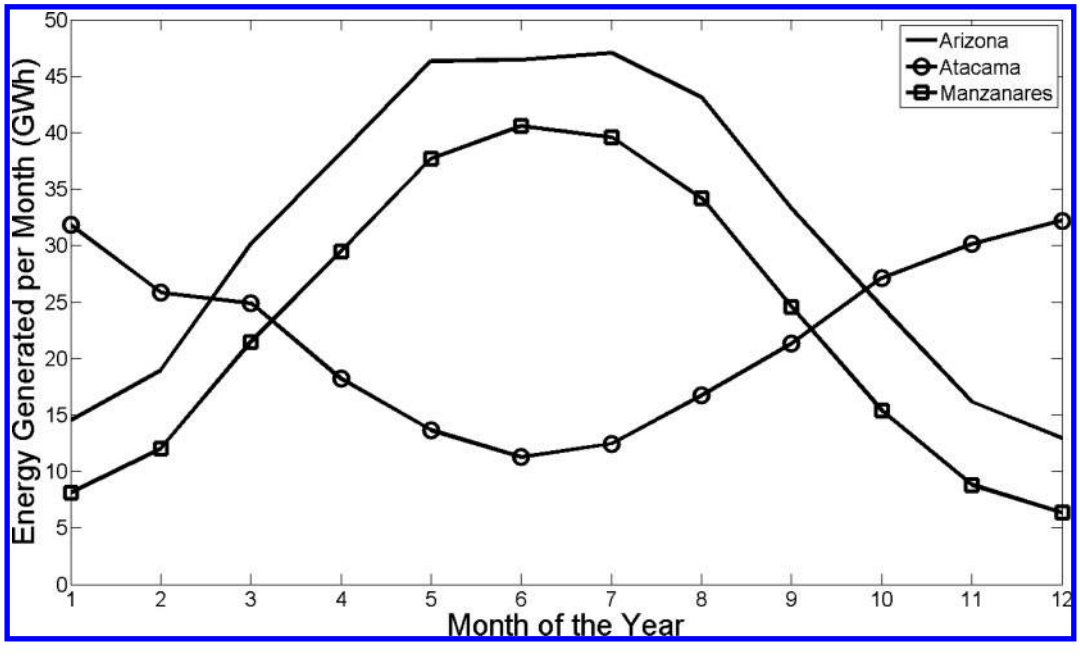

Figure 4. Monthly total energy profiles for an optimised STC rated at 100 MW in Arizona, the Atacama and Manzanares.

solar thermal chimney. In this investigation, the solar thermal chimneys were designed to deliver 100 MW at the mean insolation for each location. Table 3 gives the mean insolation, optimised collector radius and chimney height (from which other plant dimensions are calculated) and annual energy generated.

A solar thermal chimney rated to deliver 100 MW will deliver a different total of energy per year in different locations. Despite Arizona receiving a lower mean insolation than the Atacama Desert, an optimised 100 MW STC plant in Arizona will deliver 40% more energy throughout the year compared to a plant optimised to deliver the same rated power output in the Atacama. Table 3 gives the total energy generated per year for the optimised STC plant at each location, whilst the monthly total energy generation profile is shown in Figure 4.

Other factors also become important when choosing the appropriate renewable energy technology for a specific location. Solar power technologies have huge potential in areas of high solar gain, such as deserts. However, they are often criticised for the large quantities of water they consume for the regular cleaning of optical surfaces. Solar thermal chimney collectors need only be cleaned once every six months and in that time will only suffer a performance degradation of up to 12% (Haaf et al., 1983), significantly less than other solar technologies. This is particularly important given the shortage of water in the Atacama Desert.

This optimisation exercise has shown that solar thermal chimney power plants require particularly tall chimney structures in order to operate effectively (see Table 3). Furthermore, the walls of the chimney should be as thin as possible in order to reduce material usage, without endangering the structural stability of the chimney. Thin-walled structures are prone to buckling and ring stiffeners can be installed, with or without spokes, which will increase the lateral stiffness of the chimney and increase its resistance to buckling. Nevertheless, the construction of such a tall chimney still presents technical risks and uncertainties, not least concerning cost and seismic resilience. A radical reinvention of the status quo may merit investigation, particularly the concept of a fabric chimney held aloft by envelopes of lighter-than-air gas.

4 CONCLUSION

An insolation model and a solar thermal chimney model have been described. The insolation model calculates the solar flux incident upon any location after attenuation by the atmosphere, but assuming no cloud cover. The solar thermal chimney model is a 1-D incompressible Boussinesq radial-flow model using quasi-steady techniques to calculate power output profiles throughout the day and throughout the year. The impact of wall-fluid shear stress is included and particular attention is paid to the calculation of varying buoyancy pressure with altitude.

The two models were integrated in an optimisation routine with a simple material cost model to identify the location which would require the smallest material investment for a 100 MW solar thermal chimney power plant, based on the location's insolation and ambient temperature profiles and solar thermal chimney performance. The three locations studied were Manzanares in Spain, where Schlaich, Bergermann und Partner constructed a solar thermal chimney in 1982; the Atacama Desert in Chile, where there is a large unmet need for efficient and clean power generation for industrial mining and scientific consumers; and Arizona in the USA, where EnviroMission Ltd propose to construct two large-scale solar thermal chimneys. Of the three locations, Arizona in the USA delivered the greatest quantity of energy, yet the Atacama STC required the least material.

This investigation was undertaken primarily to test the optimisation procedure and integration of the insolation and STC models. A full economic analysis including life-cycle costs is required before firm conclusions can be drawn regarding Levelised Electricity Cost and profitability.

Solar energy systems under impact of aeolian sand and dust

C. Kalender-Wevers, U. Winkelmann & R. Höffer
Ruhr-Universität Bochum, Bochum, Germany

ABSTRACT: Renewable solar energy systems are situated and planned in areas, where a high solar radiation is available. Usually, these zones are desert regions and therefore a considerable amount of aeolian dust and sand transport can be expected during daily local wind and strong wind events (e.g. dust storms). The deposition and agglomeration of sand material can yield e.g. to shadowing of the solar input or to scratching of the structure surfaces materials. In this paper, the dust transport and the deposition are studied on two different solar energy systems, namely a Solar Updraft Power Plant (SUPP) and a Parabolic Trough Power Plant (PTPP). In case of the SUPP grains move over the collector surface and agglomerate at low-wind areas around and particularly behind the tower. Additionally construction parts of the glass panels may keep particles on the collector although a present sufficient threshold velocity is available. Because of the height of the collector rather fine sand/dust particles can be expected on the collector than larger sand grains. In contrast to this the troughs of the PTPP are closer to the soil bottom, so that they can collect large grains on its surfaces too. A physical wind tunnel study in combination with a numerical CFD-analysis for a single parabolic trough indicates for the deposition zones a high dependency on the orientation angle of the troughs. Both approaches are limited in terms of problem simplification and model characteristics, but give some reasonable and almost feasible results. Improvement of the models is still an ongoing work.

1 INTRODUCTION

Since last mid-century the impact of particle deposition on the output of solar energy systems were investigated. They are situated and planned in zones of the earth, where a high solar radiation is available to ensure an economical and effective energy production. Usually these areas are highly arid, semi-arid or sub-humid and belong to desert regions. The main conclusion from experiments and real measurements in past were the existent reduction of energy output due to deposition of material on the solar collectors (Mani & Pillai 2010). Since 1990 the accuracy and reliability of the performed experiments increases rapidly and the amount of considered parameters rises. But the complex interaction between different wind directions, local meteorological climate, particle type, inclination and material of the collectors and its positions within a group arrangement are still only partly investigated and understood.

Mekhilef et al. (2012) analysed the impact of dust accumulation, humidity level and the air velocity and conclude that this factors influence each other and should be considered together. El-Nashar (2009) describes in their study the effect of cleaning frequencies to the power production of a solar power plant for sea water distillation located close to Abu Dhabi. They found a high seasonal dependency of the transmittance of the collectors due to dust deposition. The lowest influence was found in January and the strongest influence was found in the summer months June, July and August, were frequently dust storms prevail. The transmittance of the class drops by monthly cleaning in that period around 10–18% and the power production decreases to 40% of the production of clean collectors. Simultaneously the development of dust risk maps for forecast the amount of expectable dust rates rises (Charabi & Gastli 2012).

These are some examples of actual research which indicates the importance of the local wind regarding the deposition of aeolian particles on solar collectors. The following chapters describe two approaches, namely physical wind tunnel and numerical CFD simulations, to model and analyse the sand and dust particle motion around two solar energy systems due to wind.

2 AEOLIAN SAND AND DUST

2.1 *Particle transport mechanism and modes*

Conventionally sand and dust are classified by their particle size, which mainly influences the wind induced motion (Tab. 1). The grains are entrained by the wind when the fluid drag and lift forces are higher than the inertial particle forces, which include vertical gravity and any cohesion between adjacent particles or surfaces (Pye & Tsoar 2009). When the wind shear force τ overcome a so called fluid threshold velocity

Table 1. Particle size and corresponding motion ranges (United nations Convention to Combat Desertification 2001).

Particle type	Particle size [mm]	Vertical height	Horizont. distance	Moving mode
Coarse sand	0.5–1.0	some cm	few m	creep
Medium sand	0.25–0.5	some 10 cm	some m	saltation
Fine sand	~0.1	some m	some km	short-term suspension
Dust	~0.01	some km	some 100 km	suspension
Fine dust	~0.001	10 km	some 1000 km	long-term suspension

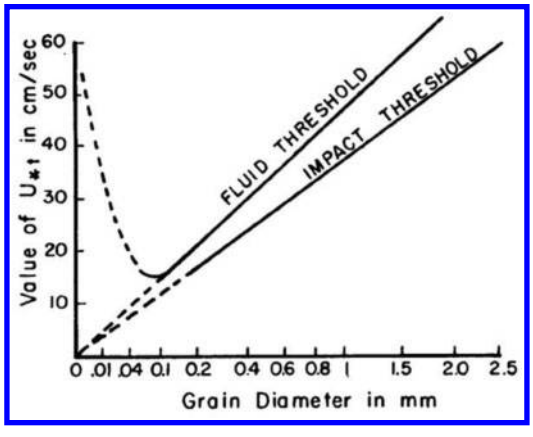

Figure 1. Required fluid threshold velocity (friction velocity) to move a particle from a sand bed (Bagnold 1954).

$u_* = (\tau/\rho_{air})^{0.5}$ corresponding to the grain diameter the particles are lifted and starts to move (Fig. 1).

Coarse sand particles creeps over the surface, medium grains starts to jump in a certain way (saltation) and fine grains are transported in suspension. The modes and trajectories are mainly influenced by the ratio between particle size, shape, settling velocity, and spin as well as wind shear stress and turbulence intensity. The larger grains settle down and deposit after a while according to their transport mode or re-enter into the air itself and inject new particles. This can results in a self-organised bed form like ripples or ridges by accumulate and sorting the jumping grains.

2.2 *The effect of local wind climate on the particle deposition*

Dust and particles, which are transported by wind, are natural and anthropogenic origin. Most solar energy systems are situated and planned in desert regions. Soil erosion due to wind occurs frequently and especially the appearance of dust/sand storms is high, e.g. Australia has about 15 dust storm days, Middle East 15–27 and North Africa around 22–27 (Pye 1987, p. 64). Dust/sand storms are defined to reduce the air visibility in eye level to less than 1000 m within 24 hours.

Beside strong wind events also the local daily wind transports fine sand and dust particles. Especially in regions, where less vegetation and urban structures slow down the wind velocity and cover the ground, the motion of dunes and soils material is well documented (Pye & Tsoar 2009). In addition daily wind can have a cleaning effect of already deposit particles. For Saudi Arabia the mean daily wind speed in 10 m height is 2–4 m/s (Rehman et al. 1994). After Figure 1 a minimum friction velocity of 0.15 m/s is necessary to move fine sand with 0.1 mm diameter. Using the logarithmic law (Eq. 1) for neutral turbulent boundary layer flow (Arya 1999) this results in a wind velocity in 10 height of 2.6 m/s, for slightly rough surface with a roughness length of $z_0 = 0.01$ m (VDI 3783-12 2000).

$$u_{10} = \frac{u^*}{\kappa} \ln\left(\frac{z+z_0}{z_0}\right) = \frac{0.15}{0.4} \ln\left(\frac{10+0.01}{0.01}\right) = 2.6\,\mathrm{m/s} \quad (1)$$

Very small dust particles can stick to a surface although the wind velocity might be high enough to move the grain. On one hand this can be caused by humidity or adhesive forces, which are very high between small particles and smooth surfaces (Goossens & van Kerschaever 1999). On the other hand the particles are so small that they are inside the laminar sublayer of the surface flow boundary layer and cannot be touched by higher velocities or turbulent eddies. Figure 1 shows this effect on the left hand side with the dashed line. The smaller the diameter the higher are the threshold velocities.

If once particles settled down they behave as obstacles for oncoming moving particles and the accumulation on the surface accelerate. On a smooth surface already settled dust particle were found to be in organised ripples systems, like described in the chapter before. Goossens & van Kerschaever (1999) found different dust coating schemes on a horizontal flat plate for different wind velocities (0.6–2.6 m/s) and show that the dust layer is less transparent during low wind velocity than during higher wind velocities, were particles starts to move over the plate. Nevertheless the older the dust-layer is the higher is the homogeneity of the particle distribution on the surface. In the end they conclude the drop of the solar cell performance due to dust deposition increase for higher wind velocities.

3 USED SIMULATION MODELS

3.1 *General simulation concept*

Two different model approaches are used in order to analyse dust and sand motion around the two solar energy systems: the physical boundary layer wind tunnel of the Ruhr-Universität Bochum and a Computational Fluid Dynamics (CFD-) simulation software. Because of the scaling requirements in the physical wind tunnel approach it is not possible to find a proper

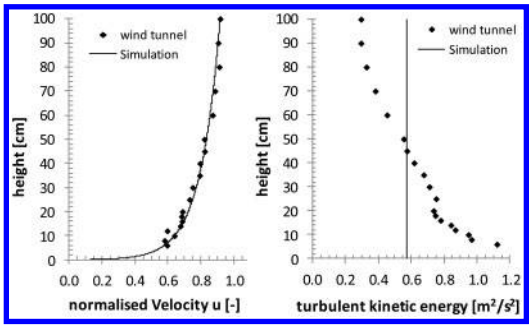

Figure 2. Boundary layer profiles in the physical wind tunnel and the used inlet conditions for the numerical simulations.

particle material for modelling suspension, deposition and saltation at the same time (Kind 1976). Therefore only velocity and pressure measurements were done and the discrete particles were considered just in the numerical approach.

In case of the PTPP physical and numerical simulations were performed and combined. The wind tunnel results are used to validate the calculated flow field as well as the pressure field. Then this validated model provides particle deposition zones. For the SUPP only numerical simulations were performed with different settings for the particle flow.

3.2 *Settings of the numerical model approach*

All numerical flow simulations are performed with a Finite-Volume Method as Reynolds-Averaged-Navier-Stokes (RANS) Simulations with the Standard k-ε turbulence model. For the approximation of the convective terms in the governing equations a second order scheme is used and the truncation error for the iterative solver is set for the maximum residuals of all equations to 10^{-6} within 1000 iteration steps. The inflow boundary conditions are modelled according to the method proposed by Richards & Norris (2011) in order to match the conditions to the performed physical wind tunnel simulations, shown in Figure 2.

Using the solved steady state flow field, discrete particles are moved with Euler-forward integration of the particle velocity in discrete points along paths through the domain (Lagrangian model). The particle velocity itself is calculated from an analytical solution of the particle momentum equation, which sums all forces acting on a spherical particle (ANSYS Inc. 2009). Equation 2 shows one of the most relevant force, the drag force, which is calculated using the Stokes-law. This includes the velocities of the fluid u_f and of the particle u_P as well as the particle diameter d_P, the dynamic fluid viscosity η and a correction factor C_{cor}, which depends on the Particle-Reynolds-Number (AEA Technology Engineering Software Ltd. 2002).

$$m_P \frac{du_P}{dt} = 3\pi\eta d_P C_{cor}(u_F - u_P) \tag{2}$$

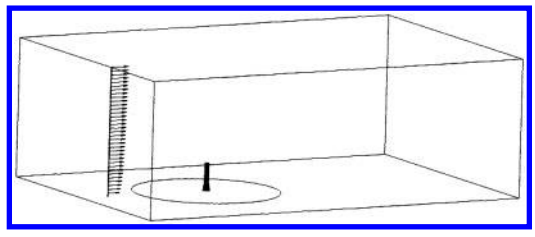

Figure 3. Numerical 3D domain of the SUPP.

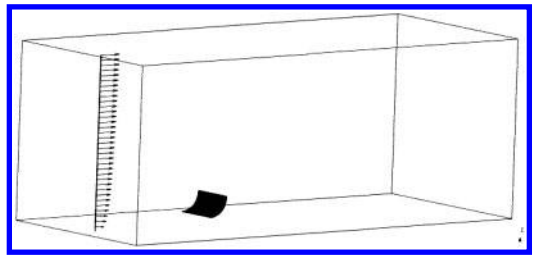

Figure 4. Numerical 3D domain of a single parabolic trough.

Additionally the stochastic "discrete droplet" model from Gosman & Ioannides (1993) is applied to calculate the turbulent diffusion of each particle due to turbulent eddies with a characteristic fluctuation velocity u_i', length ℓ_e and lifetime τ_e:

$$u_i' = \Gamma\left(\overline{u_i'^2}\right)^{1/2} = \Gamma(2k/3)^{1/2} \tag{3}$$

$$\ell_e = \left(C_\mu^{3/4} k^{3/2}\right)/\varepsilon \tag{4}$$

$$\tau_e = \ell_e/(2k/3)^{1/2} \tag{5}$$

The variable Γ denotes a normal distributed random number, k the local turbulent kinetic energy, its dissipation ε and C_μ a constant (ANSYS Inc. 2009). A certain number of idealised particles with a defined diameter distribution and density of Quartz are injected in different positions.

The geometries and meshes were generated regarding the used wind tunnel model and follow the recommendations of Franke et al. (2007). Figure 3 and Figure 4 show the domain size of each model. All meshes consist of block structured hexahedral elements and were successively refined in order to check the independency of the results regarding the mesh resolution and domain size.

3.3 *Settings of the boundary layer wind tunnel*

In the boundary layer wind tunnel the oncoming turbulent flow is generated using a Counihan-setup (Counihan 1969) and corresponds to an atmospheric wind over urban terrain with a real roughness length of $z_0 = 0.1$ m. The turntable has a diameter of 1.8 m and the height of the tunnel is 1.6 m. The measurement programme for the PTPP includes different

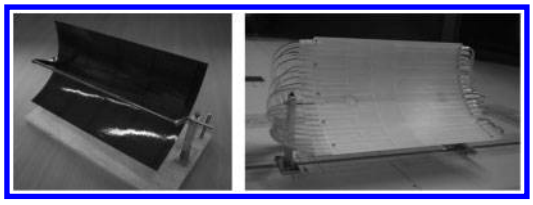

Figure 5. Left: Trough model for velocity measurements, right: trough model with pressure wholes on the surface.

wind velocities, yaw angles, orientation angles of the trough and group as well as single trough arrangements. For comparison reasons with the numerical results the single through with an approach flow with 0° is focused. Figure 5 shows the used models (scale 1:50), left for the velocity measurements with an x-hotwire anemometer and right for the surface pressure measurements.

4 AEOLIAN PARTICLES AROUND THE PTPP

4.1 *Flow field around the single trough*

The comparison of the velocity fields in front of the single parabolic trough is shown in Figure 6 exemplary for an orientation angel of 45°. The vectors are comparable in velocity magnitude, but close to the wall the wind direction of the numerical results (red) follow earlier the trough surface curve. Although the mesh consists of 2.7 Mio cells with refinement around the trough surface the mesh resolution might be not fine enough. For other orientation angles the most discrepancies can be found in the zones of recirculation. This is caused by the used turbulence model, which is not capable to predict and resolve separation eddies proper. The predicted surface pressure distribution is for the most areas partly overestimated compared to the measured pressure. This can be also explained by the used turbulence model, which was chosen due to its balance between numerical robustness and efficiency.

4.2 *Particle deposition zones on the trough*

Additional to the analysis of the flow and turbulence field around the single through, the surface inclination and the particle wall-shear zones, were particles hid the surface, from the numerical simulations were considered in order to define areas, were particle deposition on the trough can be expect. For different inclination angles the amount of particles which hits the surface are unlike.

In Figure 7 particle positions for different time steps are shown for the trough inclination of 90°. In the second time step the trough collects particles, which remains insides the vortex which occurs inside the trough.

If the wind approaches from the trough back-side almost, all particles flow overhead the tip and nearly no depositions occur. The trough-orientation follows the sun during the day and hence the directions of wind

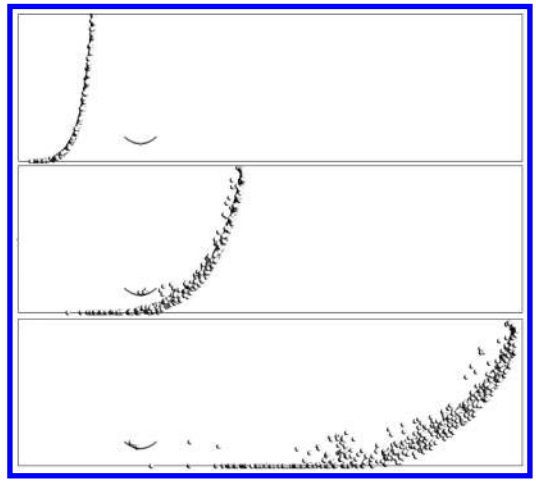

Figure 7. Particle positions in three different time steps; the particle size is scaled for visualisation purpose.

attack chances. In general, for the single through the most deposition of aeolian particles can be expect in the middle part of the surface. Close to the lateral edges the flow acceleration and the turbulence intensity prevent material settling. Usually a group arrangement of parabolic troughs builds a whole power plant with a complex flow field. Therefore the amount of settled material is most likely different for each trough in the whole arrangement.

5 PARTICLE DEPOSITION ON THE SUPP

5.1 *Simulation characteristics*

The dimensions of the SUPP are enormous with 750 m tower height and 2 km diameter of the solar collector, although this is the smallest concept of the

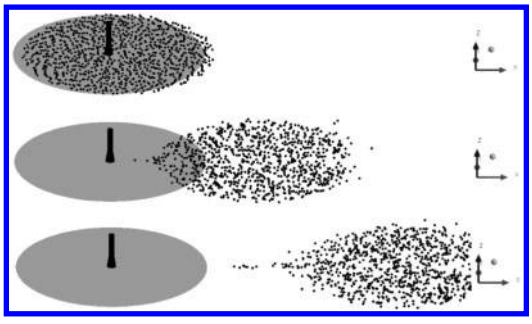

Figure 8. Particle positions on the collector surface for three different time steps; the wind comes from the left hand side.

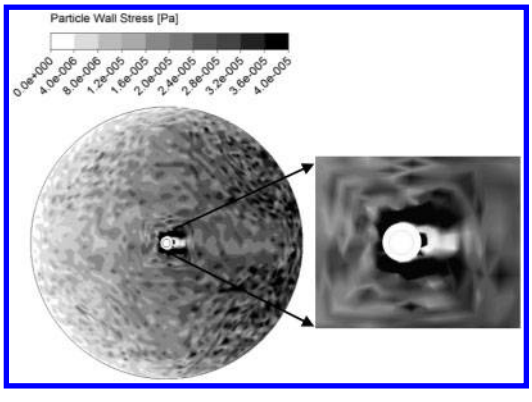

Figure 9. Mean particle wall shear stress on the collector surface, the wind comes from left the hand side.

actual designs (Harte et al. 2010). For applicability to the numerical model following simplifications and assumptions were made. The collector starts directly on the bottom, normally the height is 10 m over ground. The collector surface is almost smooth and has an ascending slope to the tower base, but the wind cannot blow under the collector or through the tower. For the inlet wind velocity a logarithmic profile is used (Fig. 3). The influence of the coriolis force, which rotates the wind angle of attack in the upper atmospheric boundary layer, is neglected.

Two scenarios are modelled: a) wind blow over an already with particles covered collector and b) wind driven particles approaching the clean collector. The interaction between the particles and the collector is modelled using a particle wall-interaction approach, which reduces the particles momentum.

5.2 *Wind over a particle-covered collector*

Figure 8 shows a first impression of particles on the collector surface which starts to move due to the wind. The particles have different diameter, which results in different particle velocities. It is not possible to model particle accumulation because of the nature of the Lagrangian particle model, but information about the particle wall shear on the collector surface can be obtained, see Figure 9. It can be seen that very close

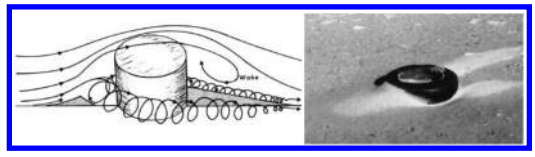

Figure 10. Flow characteristics around a cylinder (left) and resulting particle deposition (right) (Pye & Tsoar 2009).

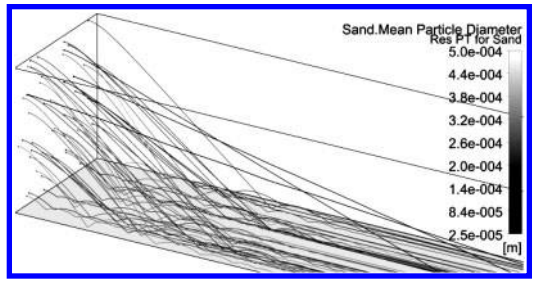

Figure 11. Particle tracks for different particle diameter.

to the tower base at the windward and lateral sides, the friction force is very high. This indicates a big amount of particles which were transported around the tower. Behind the tower, leeward, there is a white zone, were very low particle-wall interaction is found. There is a low wind recirculation behind the tower where particles settle down. Compared to Figure 10 the simulation show reasonable results, but it is obvious, that the quality of the mesh is still not high enough, because the contours in Figure 9 follow the mesh block structure (the results look slight like a cross with the tower in the centre).

5.3 *Wind driven particles approaching*

In order to identify proper boundary conditions and to save calculation time, the simulations are made without the solar tower in an empty box. Using different particle diameter the particle tracks follow the particle modes creep, saltation and suspension (Fig. 11). Still missing is the particle stop, by means of total deposition. Because of the collector height with 10 m rather fine sand and dust particles can be expect on the collector than larger sand grains (Höffer et al. 2010). Even strong winds are able to lift the coarser particles to heights about some meter, see Table 1. Because of the low velocities in the wind shadow of the tower tracked particles will settle down and accumulate. Construction parts of the collector panels can act like obstacles for the moving particles and collect them. This could yield to some local particle deposition zones, which need to be cleaned e.g. mechanically.

6 CONCLUSIONS

The impact of aeolian sand and dust particles on two solar energy systems is analysed. Two approaches were used to discover details of deposition zones on the surfaces. Numerical CFD simulations were performed for

a single parabolic through and for a simplified solar upwind power plant.

In case of the SUPP grains move over the collector surface and agglomerate at low-wind areas around and particularly behind the tower. Because of the height of the collector rather fine sand/dust particles can be expected on the collector than larger sand grains. In contrast to this the troughs of the PTPP are closer to the soil bottom, so that they can collect large grains on its surfaces too. A physical wind tunnel study in combination with a numerical CFD-analysis for a single parabolic trough indicates for the deposition zones a high dependency on the orientation angle of the troughs.

The local wind climate and the topography of the surrounding urban area play a major role for the determination of the expectedly amount of particles. To consider this before the construction can safe cleaning-costs, e.g. by choose a less dust-risky location or integrate additional windbreaks in order to reduce the amount wind transported particles.

Constructability-aspects for reinforced concrete solar updraft power plants chimneys: From construction technology and logistics to schedules and costs – data-requirements for economical evaluation

ABSTRACT: Up to today only a few small solar updraft power plant chimney towers have been built for evaluation reasons. In the last decades some companies tried to find investors for different mega projects with chimneys between 750 and 1,500 m and they are still doing so. But building chimneys of 500 m or more is not an everyday challenge for any construction industry in the world. Due to the needs of special climatic conditions and the availability of space for the horizontal collecting structure, solar power plants are discussed for areas far away from other industries, infrastructure and existing transportation systems, such as e.g. Western Australia, Namibia, Saudi Arabia and Arizona. But yet not one realization of these commercial intended projects has been started. This can have different reasons, e.g. economical or technological, but also commercial. The economic reasons can be divided into external factors such as the cost of construction and maintenance relative to the prices of generating power in other ways and internal factors such as perhaps the lack of plausible calculations about power output, depending on performance, efficiency and loss factors, or about energy and water needed for construction and maintenance relative to the energy generated by the plant. Technological reasons can be divided in perhaps unanswered questions about the natural hazard resistant tower design itself and those about the methods used to realize the construction work. Looking at commercial reasons, online discussions can be found, that today project development work seems to be more lucrative than project realization or that project development companies are waiting for additional subsidies. This paper gives some impressions about logistical and technological aspects of constructability of huge reinforced concrete chimneys, an important aspect, because besides all other named reasons it is crucial to know, if and how the chimney construction work as the center of the power generating project can be realized. And this knowledge also is the base for scheduling and cost calculation.

1 INTRODUCTION

1.1 *The idea of SUP*

The idea of solar updraft power (SUP) generation was first published by Cabanyes (1903). In the last decades the discussion about this "green" technology has become more popular and research started focusing these issues as could be seen in a new int. conference series (USA 2008, Germany 2010 (SCPT), China 2012 (SUTPT)). A good overview can be found under http://www.solar-tower.org.uk/.

1.2 *Review of SUPP project development*

Due to the needs of special climatic conditions and the availability of space for the horizontal collecting structure, in the last years SUP plants (SUPP) were discussed for areas with low population density, very high direct sunlight and good soil conditions for the substructure far away from other existing industries, transportation systems and infrastructure. Experts state, that only SUPP with huge chimneys (heights beginning with 0.5 km) would be commercial relevant, see e.g. Schlaich et al. 2005. Thereby SUPP-technology competes with other solar power plant technologies such as photovoltaic or concentrating solar thermal power plants (CSPP).

Yet only the construction of smaller, non-commercial research plants using subsides in

- Spain 1982 ($h_{tower} = 195$ m, A = 46 ha, <50 kW) &
- China 2010 ($h_{tower} = 53$ m, A = 6,17 m^2, ~200 kW)

are documented, whereby the 200 kW Chinese prototype in Inner Montgolia has to be seen as phase one of

three, where in ongoing phase three the SUPP shall reach 25.1 MW ($A = 2.51\,km^2$) (Chen et al. 2010). Some reports about other experimental prototypes e.g. in Botswana, Turkey, China and United Arab Emirates ($h_{tower} < 30\,m$) exist.

Today there are some discussions for SUPP with huge reinforced concrete (RC) chimneys initiated by commercial project development companies. Projects ideas are actual discussed for

- Namibia ($h_{tower} = 1.50\,km$, $A = 37\,km^2$, 400 MW),
- W. Australia ($h_{tower} = 1.00\,km$, A = ?, 200 MW),
- Saudi Arabia ($h_{tower} = 1.00\,km$, $A = 28\,km^2$, 200 MW),
- Arizona ($h_{tower} = 0.80\,km$, $A = 38\,km^2$, 200 MW),
- Spain ($h_{tower} = 0.75\,km$, A = ?, 40 MW),
- China Lan. ($h_{tower} = 0.25\,km$, $A = 1.3\,km^2$, 60 MW).

For Namibia the impact of the beginning of an investigation for a CSPP plant in 2012 on the 2008 proposal for a SUPP could not be estimated by the authors. The development of another project in Australia (New South Wales), that started 2001 ($h_{tower} = 1.0\,km$, $A = 38\,km^2$, ~200 MW), has been stopped.

The companies involved are looking for investors since several years, but there can be found some critical discussion about the commercial intention of these projects and about the assumptions used for calculating and promoting very low electricity producing costs and consequently high possible ROI. So is it e.g. possible to calculate construction costs of the SUPP today?

1.3 *Review of constructability quotations*

Schlaich 1995 states: *"… construction for a chimney about 1000 metres high … is possible without difficulty today. With the support of a German and an Indian contractor especially experienced in building cooling towers and chimneys, manufacturing and erection procedures were developed for various types in concrete … and their costs compared."* Stinnes, the initiator of the project development for Namibia, mentioned 2004: *"The structural risk* [of a tall chimney flue of 1.5 km] *is fully covered by professional insurances for design, based on the professional guarantees of Prof. Schlaich and Prof. Harte, and construction, based on the builders' insurances, so that there exists no risk for the prospective investors."* Harte et al. 2012 mention, that they think RC SUPP-chimneys (SUPPC) of max. 1.0 km can be seen as buildable today. Looking at chimney heights of 1.5 km Krätzig et al. 2013 speak of utopias.

2005 an engineering company involved in SUPP-development publicized: *"The respective structural approaches are well known and have been used in cooling towers. No special development is needed. … With the support of international contractors especially experienced in building cooling towers and towers, manufacturing and erection procedures were developed for various tower types in concrete and steel and their costs were compared. The type selected is dependent on the site. If sufficient concrete aggregate materials are available in the area and anticipated seismic acceleration is less than about one third of the earth's gravitational acceleration, then reinforced concrete tubes are the most suitable. Both conditions are fulfilled world-wide in most arid areas suitable for solar towers. Detailed statical/structural research showed that it is appropriate to stiffen the tower at several levels with cables arranged like spoked wheels within the tower, so that thinner walls can be used. This is maybe the only really new feature of solar towers compared to existing structures."* (Schlaich et al. 2005).

But is it really the same to build a 200 m cooling tower with flat surfaces and to build a 1.0 km SUPPC with overhanging stiffening-rings from a construction technology perspective? And can construction technology problems solved for high skyscrapers with floors usable as working platforms during the construction phase can be transferred to chimneys without any floors? And what about a detailed construction cost calculation reflecting these constructability aspects?

1.4 *Review of cost estimations*

Bergermann & Weinrebe 2010 point out, that the cost for the tower (without engineering and coordination) will be around 25% of the total investment costs for a SUPP and also, that *"tower costs may vary from one location to another due to availability of steel, cement or aggregates."* And so the big differences in published cost estimations are remarkable.

First cost estimations for a SUPP can be found in Schlaich 1995 for chimney height of 445, 750 and 950 m refering to German and Indian contractors with experiences in building cooling towers and chimneys. Stinnes 1997 published the results of cost estimations made by different local South African contractors for a 1.5 km RC chimney, which differ from each other with factor 3! These are followed e.g. by cost estimations for other chimney heights in Dos Santos Bernardes 2004, Schlaich et al. 2005 (some newer data can be found on their company webpage) and Fluri et al. 2009. Fluri et al. 2009 calculated costs for a 0.85 km and for a 1.0 km RC SUPPC. The newest estimations found by the authors are those in Krätzig 2012 for RC SUPPC with $h_{tower} = 0.5\,km$ and with $h_{tower} = 0.75\,km$. All these estimations are published without further breakdown of the amount and exempt from Fluri et al. 2009 nearly without giving information about the approaches. 2011 EnviroMission, one of the companies mentioned above, engaged the US contractor Hensel Phelpsw for delivering a schedule and cost estimations for the project in Arizona (EnviroMission 2011) – the results are unknown.

So yet no detailed calculations about the construction cost of RC SUPPC have been published, so that the above cost estimations could not be revised academically.

Some investigations about these differences in cost assumptions for SUPP can be found in Fluri et al. 2009. They divide the chimney cost in material cost, construction cost and transport cost. Their *"Results*

show, that previous models have underestimated the initial cost and levelised electricity cost of large-scale solar chimney power plants. … previous investigations were too optimistic … Solar Chimney power plant cost may be significantly reduced if construction materials are supplied by dedicated manufacturing facilities located on site. Additionally, these costs may be even lower when assuming the construction of multiple plants, but are unlikely to be as low as those assumed by Schlaich (2004) and Bernardes (2004)." Looking at too optimistic assumptions used for calculating levelized electricity costs, Krätzig is citated by Bonelle 2012 with the words that making such mistakes in assumptions *"illustrated the 'dangers of wishful thinking'."*

By saying *"Without humus no GreenTower"* or *"the greenhouse and humus transform the low profit updraught tower into high profit GreenTower"* Stinnes 2010 states his belief that using the space under the collector roof for agriculture is necessary to make SUPP investments commercial attractive.

At the same time different people are calling for subsidies, e.g. Bergermann & Weinrebe 2010.

1.5 *Review of construction time estimations*

Without any derivation several authors affirm, that the time needed for construction of a SUPP, including chimney, collector and aggregates etc., will be around two years (see e.g. Dos Santos Bernardes 2004 or Almasy 2011).

1.6 *Focus of the paper*

So even if companies looking for investors or for development or engineering contracts say that they were able to calculate the cost of construction already since 1995 and even if they claim in 2004 that they see no financial risks resulting from the construction of a 1.5 km high RC SUPPC, there are many reasons to do a little more research about these aspects also on academic level to find out more about the right methods and logistic concepts for doing the construction work, the time needed and the cost resulting from this work.

The intention of this paper is to identify some relevant aspects and give some estimation at the starting point of the academic research on constructability and logistic aspects for SUPPC in continuance to Helmus et al. 2010 end e.g. Strauß & Kreiner 2010.

This paper looks at some technological constructability aspects, because knowledge about the methods of construction are crucial for estimating construction costs, time needed for logistic and construction and so for economic and ecologic (e.g. energy input) valuation.

The authors will concentrate on SUPPC designs using RC structures as they seemed to be favored by the engineering companies dealing with design tasks of such chimneys (see e.g. Schlaich 1995), Schlaich et al. 2005 and Harte et al. 2012). Therefore the authors use the design concept delivered by Krätzig et al. 2009 as shown in figure 1.

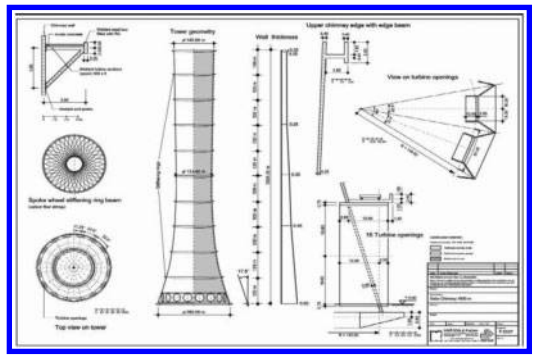

Figure 1. RC SUPPC design concept (Krätzig 2012).

2 CONSTRUCTION LOGISTIC AND CONSTRUCTABILITY ASPECTS

2.1 *Constructability aspects: Construction method*

Due to the lack of any experience building RC SUPPC is not an everyday challenge for any construction industry in the world. Various logistic and construction processes have to be evaluated, including availability of material, transport facilities, as well as building and construction technology aspects. This evaluation will lead to cost, time and resultant economic and ecological prognosis data.

Looking at constructability e.g. the following aspects have to be analyzed iteratively with the structural design of the chimney, so that loads resulting from the construction work can be considered in the static and dynamic analysis: concrete production, handling and placement method and equipment (self-climbing or crane-based), scaffold, temporary framework and formwork, vertical material transportation (cranes, elevators, pumps, helicopters, conveyor belts, winches) and additional construction safety constructions fixed at the chimney.

Helmus et al. 2010 conclude: *"Conventional concrete construction methods, with in-situ concrete and use of formwork, seem to be the only realistic and possible construction option … alternative techniques (e.g. prefabricated sections) aren't realizable."*

Some ideas can be found by analyzing technics used for high skyscraper building, pylons, water or cooling towers. The highest concrete chimney used for the cooling of conventional power plants has a height of 200 m (Niederaußem, 2000). The highest skyscraper (Burj Khalifa, Dubai, 2010) has a height of 828 m; there concrete was pumped over the first 606 m (Putzmeister 2007).

2.2 *Constructability aspects: Vertical transportation*

This assumption can also be recognized in Strauß & Kreiner 2010 or in Krätzig 2012. Latter gives an impression for some logistic aspects for equipment needed for the vertical transportation of personal and

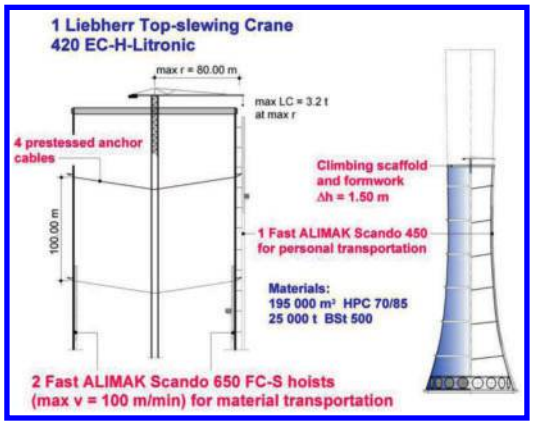

Figure 2. RC SUPPC construction concept (Krätzig 2012).

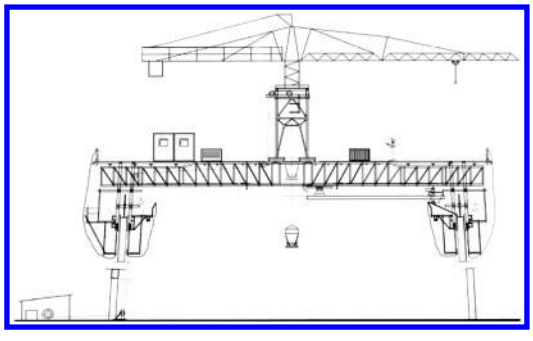

Figure 3. Concept for central crane with self-climbing working platform at the top combined with winch-systems (Gleitbau Salzburg GmbH).

material when building a 1.0 km RC SUPPC in Saudia Arabia, as shown in figure 2.

The shown Liebherr Top-slewing crane 420 EC-H has to be adapted for this purpose. Besides the tower height the length of the cable/winch system has to be considered. The max. length today is mentioned with 437 m and the max. winching speed for e.g. 5.2 to with 94 m/h (Liebherr 2012).

Another idea is to combine a central crane with a climbing platform on the top and a separate winching-system as shown in figure 3 (for smaller diameters) or the use of more than one crane (presentation to Helmus et al. 2010) is shown.

Strauß & Kreiner 2010 are thinking about *"high-speed elevators … to put huge concrete masses into position in time."* Looking at typical loads and elevating velocities, the following data could be found e.g. for the Alimak Scando 650 FC-S shown in figure 2: payload capacity 2,400–3,200 kg, speed 0–100 m/min, max. lifting height 400 m (Almiak 2012). Looking at e.g. 500 m height, once adapted for higher lifting processes, this elevator system can transport around 1 m^3 of concrete every ca. 15 minutes, assuming 2.5 min for loading, 5 min. for the way up, 2.5 min for casting and 5 min for the way back down. These are 4 m^3/h.

To make a comparison: the pumping system used for the Burj Khalifa was designed for 30 m^3/h

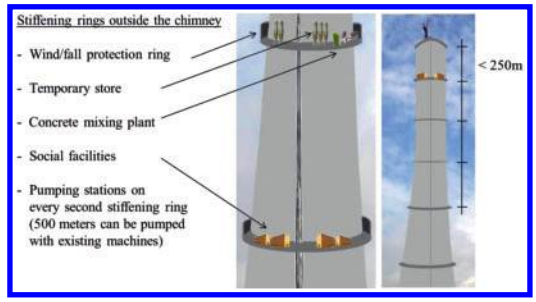

Figure 4. Working platforms at stiffening rings of a 1.5 km RC SUPPC (Presentation to Helmus et al. 2010).

(Putzmeister 2007) and Lohaus & Abebe 2010 are thinking about using two 100 mm pipes for pumping rates of 8 to 12 m^3/h for a RC SUPPC.

But this small diameter affords fine aggregate and so Lohaus & Abebe 2010 mention, that *"a new concrete concept has to be developed for the solar chimney in order to produce the type of concrete that complies with the stringent requirements of pumpability, workability and stability."*

In addition Lohaus & Abebe 2010 think about staged pumping, which requires working platforms at different levels.

So besides the working platforms which are usually combined with the self-climbing frame- and formwork at the climbing top of the chimney, there will probably be the need for additional working platforms. Perhaps the stiffening-rings of the prospected RC SUPPC-design can be used as the basis for additional platforms offering place for staged pumping, storage, for social rooms and for sanitary facilities. Or they can be even used for concrete mixing aggregates nearer to the place of concrete placement to reduce the distance for concrete pumping. The concept of several working platforms in vertical direction already has been showed related to Helmus et al. 2010 by figure 4 and is mentioned in Harte et al. 2012.

But before iteratively specifying the vertical transportation system, some more assumptions and estimates about the general resource requirement are affordable.

2.3 *Logistic aspects: Resource requirements*

Once the right place for an RC SUPP project is found, the key resources needed for construction are e.g. knowledge, skilled labor, concrete aggregate and admixtures as liquefier and retarder, cement, water, structural steel, special construction products, concrete mixing plants and pumps, climbing scaffold and formwork, cranes and elevators for personal and material transportation. Besides of these, a lot of other materials, equipment, building site facilities as well as energy and the right weather and environmental conditions for the particular work are needed.

As shown before, the construction site will probably be far away from other infrastructure, so that at least for the time of construction social and office facilities as

well as sleeping accommodations are needed. Helmus et al. 2010 assumed that for the construction work of a 1.5 km RC SUPPC a maximum of 230 employees is required doing three-shift operation.

Because as mentioned above, the only resources you can find near to the prospected sites are concrete aggregate and arid weather conditions, depending on the SUPP site chosen it would be necessary to build new roads, railway, water-pipelines, perhaps combined with seawater desalting plants, or groundwater supply wells, maybe harbors for the construction phase to bring in the required resources. So the construction logistic requirements are nearly the same as they can be found within mining projects in desert areas.

In figure 2 the amount of concrete for a 1.0 km chimney without foundation is given with 195,000 m^2 C70/85 and the amount of steel for reinforcement with 25,000 to. This is a factor of 128 kg/m^3 near to the factor of 120 kg/m^3 given by Fluri et al. 2009. The diameter of this chimney at the base is around 260 m (see figure 1). Lohaus & Abebe 2010 are calculating with 210,000 m^3, using C30/37 on the top and reaching stepwise C70/85 at the base.

They estimate around 100,000 m^3 of C25/30 or C30/37 for a ring foundation with an inner diameter of 260 m and an outer diameter of 300 m. Calculation with a steel requirement for reinforcement of 60 kg/m^3 concrete, as estimated by Fluri et al. 2009, leads to a steel requirement of 6,000 to for the foundation.

Calculating with 170 l of water per m^3 concrete, for 300,000 m^3 of concrete there is a need of 51,000 m^3 of water just for concrete production. More water is needed e.g. for the cleaning processes of aggregates. One special point is, that *"water is at least as valuable as energy in many sunny dessert countries"* (Bergermann & Weinrebe 2010). And influenced by the climatic conditions perhaps cooling of water to ice-water and flake ice will be necessary e.g. for mixing concrete, as shown by Lohaus & Abebe 2010 in their article about concrete technology aspects.

Most authors think, that climbing technology used for cooling towers can easily adapted for the RC SUPPC, but without giving answers they say, that some new developments are required for the overhanging stiffening rings.

So once the construction method is chosen, the scheduling of the project can be done iteratively with detailing construction as well as logistic tasks.

2.4 *Economic aspects: Construction time*

Lohaus & Abebe 2010 consider *"two [concrete] batching plants with a total capacity of … 2,000–2,400 m^3/day"* resulting in a minimum construction time of 50 days for the foundation, when other probably restrictive factors (e.g. capacity of pumps and trucks or other transportation systems) do not exist.

Once the construction of the chimney has started, concrete placement in sections of 1.5 m height is part of the concept shown by Krätzig 2010 (see also figure 2). Strauß & Kreiner 2010 mentioned vertical steps of 1.0 to 1.5 m as *"well established climbing technology for cooling towers"* have to be revised. Lohaus & Abebe 2010 mentioned, that using modern gliding formwork systems *"large capacity silos have been built at a concrete casting speed of 3–5 m/day"*. For RC SUPPC Lohaus & Abebe 2010 consider *"only a night-shift concrete casting of 10 hours"*, in which *"a 2 m high concrete section is assumed to be completed … The daily hours could be devoted to reinforcement installation and other related activities."*

Due to the extreme high and the long service lives of 100 to 120 years expected by Schlaich 1995, Krätzig et al. 2010 or Harte et al. 2012, Krätzig et al. 2010 postulate *"an execution quality far above the usual site level"*. So there can be doubt, if the construction velocity and technology used for cooling towers can be adapted without any change. Helmus et al. 2010 e.g. estimated three days for every 1.5 m-section in their presentation.

That means that once concrete placement for the chimney has started, a chimney of 1.0 km will consist of 1,000 m/1.5 m/section = 667 sections for casting. Calculating with 3 d/section will lead to 2,000 d and so 5.5 years assuming 7/7 d operation, calculating with 1 d/section to around 1.8 years – without foundation.

So the above mentioned estimation of a construction time of two years for the whole SUPP (incl. collector, chimney, turbines etc.) seems to be plausible only if an optimistic work cycle of 1 d per 1.5 m-section could be realized and all other work (collector, aggregates etc.) could be done parallel.

Further analysis and publishing scheduling assumptions should be done.

2.5 *Economic aspects: Construction costs*

One part of the input data for economic evaluation of an SUPP are the production costs for the chimney, that means costs for labor, material, transport, energy, machines, scaffold, framework, construction site installation etc. Some of them are depending on construction time. In 1.3 some not revisable estimates are mentioned.

E.g. Krätzig 2012 prospects that for a SUPP with a RC SUPPC ($h_{tower} = 0.75$ km, $A = 9.6\,km^2$) the production costs of the chimney will be 60.5 Mio.€ whereby the whole determined investment – neglecting costs for the land needed – will be 337.6 Mio.€. So the production costs for the chimney without the costs for engineering and testing are estimated to be nearly 18% of the whole investment. Having in mind the regular observable cost increases of mega projects, explained e.g. in Homola 1994 *("Dilemma of the first mentioned value")* or in Flyvbjerg 2009 *("Survival of the unfittest")* some more detailed cost analysis seems to be essential.

2.6 *Ecological aspects: Energy input*

It was stated, that the time needed for the energetic amortization of a SUPP construction project will be

around three years of operation. Following Almasy 2011, EnviroMission says *"the amount of carbon pollution created by the manufacture and shipment of the cement and other materials needed to build the facility* [1.0 km tower in Arizona] *will be offset after 2½ years of operation."* Detailed calculations confirming these statements couldn't be found by the authors.

3 SUMMARY

The paper shows, that even if the discussion about SUPP has taken place for decades, some basic aspects of constructability and construction logistic tasks, needed for calculating economic and ecological affects like construction time and cost, have not been subject of research in detail so far. The paper reviews some basic aspects of constructability and logistic questions with the intention to initiate further investigation needed for coming a step closer to the realization of SUPP with RC SUPPC.

SHM strategies, application and measurements on tripod offshore wind energy converters within the German offshore park Alpha Ventus

W. Rücker, S. Thöns, S. Said & W. Schmid
Federal Institute for Material research and testing, BAM Berlin, Germany

ABSTRACT: Prototypes of wind turbines of the megawatt class are to be built and tested until 2008 within a German offshore wind energy test field in the North Sea (ALPHA VENTUS). To ensure a high operational reliability of offshore wind turbines with economically acceptable repair and maintenance efforts, comprehensive diagnosis and supervision concepts are required. Automatic monitoring systems will be an essential part of such concepts. Because of the fact, that during operation there will be static and dynamic interaction between the components 'structure', 'machinery' and 'blades' it is necessary to develop the monitoring techniques in an overall concept. These monitoring systems are supposed to be applied for the design and testing as well as for the operation and maintenance phases. In the paper the developed approaches for the measurement of actions and the condition monitoring of all components of an offshore wind energy plant will be shown.

1 INTRODUCTION

The need to monitor offshore wind energy converters is a result of the completely new situation for civil engineers. Buildings and structures are usually unique but now a large number of the same structures with a complex design should be built in a relative short period in a harsh environment (offshore). To avoid downtimes of the facilities due to structural defects with extensive economical consequences as well as to initiate the maintenance based on the actual condition of the structure, a permanent monitoring system will be necessary to provide these data. For a condition analysis and a continuous monitoring system of (offshore) wind energy converters the following described problems are of primary interest.

2 OBJECTIVES

The loads acting on the facility from wind and waves in a stochastic manner will be simulated in a dynamic computation and provided for further system analyses. However, the statistical description of the wind and wave is to some extent arbitrary. Furthermore there is no certainty how well the loads (in reality and/or from numerical computation) correlate with the in situ loads of the components of the wind energy converter. This relation is of great importance in the design phase (assumption of safety factors) as well as for the monitoring (up to date assessment and condition prediction). To assess the condition of all components of an offshore wind energy converter also an accompanying monitoring system for the load is necessary. A particularly important aspect is the combination of loads from wind and waves. In terms of superposition of wind and wave loads there are assumptions or estimations for dimensioning the loading capacity and for the proof of operational stability (Germanischer Loyd, 2007). Currently there is no certainty for a complete combination of the loads including the interaction of dynamic loads of all components of an offshore wind energy converter.

The determination, assessment and monitoring of the stability (ultimate limit state) of the support structures of offshore wind energy converters are of central importance. For this purpose reliable indicators for the safety monitoring and defined thresholds need to be provided. Another key task in monitoring offshore wind energy converters is the development and supply of methods with which the occurring damages can be detected, localized and their evolution monitored.

3 MAIN TASKS

From the above described aims, the development and operation of continuous monitoring systems for offshore wind energy converters have the primary tasks as follows.

3.1 *Detection of the impact*

Generally not the acting loads of wind and wave on the structure should be measured. The aim is rather to determine the effect of the acting loads as generalized stress resultants at the tower head and the pile connections in the area of the foundation. These stress resultants are compared with the determined values of the design process. This results in an improved estimation for the load approaches and also a gain in safety,

if the measured stress resultants are less than the stress resultants of the design process.

3.2 *Condition monitoring and analyses*

The Condition monitoring of offshore wind energy converters is primarily the monitoring of parameters for the serviceability limit state. The main monitored parameters are.

Inclination: For a safe operating facility the inclination limit needs to be maintained. This limit is usually permanent at about 0.5 degree, including the inclination from the production and construction. Under a dynamic load the resulting inclinations are often greater.

Deformation: The elastic deformations of the tower and the rotor must be within specified limits. In particular, a safety distance needs to be maintained between the rotor and tower. The adverse combination of loads needs to be taken into account to compute the deformations. For concrete structures the deformation under operating loads must be limited in such a way that no damage occurs. For concrete a constant elastic modulus for tension and compression can be assumed to compute the deformations. The influence of shrinking, creep and temperature has also to be taken into account.

Remaining displacements: Remaining displacements in the support structure are an indicator for a change of the loading capacity (generally a decrease) and can also lead to additional loads in the support structure. The maintained allowable threshold values result from a numerical computation of the additional possibly stresses of the support structure including the tower.

Acceleration: For a safe operating facility the accelerations at the tower head, tower shank and tower base must be within specified limits. These limits are usually given by the machine manufacturer. Also, in the VDI guideline 3834 threshold values for the acceleration are given for all parts of the facility (VDI, 2009).

Natural frequencies: The first natural frequency of the whole system "nacelle-tower-foundation-soil" from currently designed facilities is in the area of the rotor speed. The blade-passing frequency (for three blades the triple rotor frequency) is usually above the first natural frequency. For a safe operation and to avoid early fatigue the natural frequencies must have a sufficient great distance to the operational frequencies.

3.3 *Stress monitoring*

Stress monitoring of offshore wind energy converters is primarily the monitoring of parameters for the ultimate limit state. The stress monitoring of a wind energy converter has the tasks as follows.

For concrete structures a limit of tension and/or compression has to be verified. Therefore, a limit of compression for concrete is given for specified load combinations. For steel structures plastic deformations have to be avoided for characteristic loads.

Due to the proof of operational stability each component or component section must have a sufficient resistance against the effect of cyclic-dynamic loads. The proof is usually based on the Wöhler or SN curve concepts which describe the tolerable number of load cycles depending on the type of connection and the geometry of the weld by arising stress amplitudes. The life-time relevant loads will be provided with a damage equivalent load spectrum and need to be adjusted with the respective sitespecific wave and wind loads. This concerns the frequency of occurrence as well as the distribution of direction of the wind and wave events. Regarding multi-megawatt wind energy converters, the life cycle loads are orders of magnitude beyond the number of load cycles and vibration amplitudes which are usually estimated for steel structures.

The detection of damage and the damage assessment are usually distinguished in four parts: detection, localization, quantification and prediction. Currently there exists no reliable method which would solve these tasks. The presently used and developed methods are based on a change of the dynamic behavior of the structure. A numerical model solves then the so-called inverse problem to identify the location and extent of the occurring damage. Therefore it is important to install the sensors at locations of the structure where appropriate and relevant information can be obtained. These monitoring points are determined in advance either by a numerical analysis or by a-priori knowledge. For example, the monitored accelerations of the pile head can give first indications of a change of stability of the tripod foundation. Another method, which is currently tested, is the so-called "Stochastic Subspace Damage Detection" method (SSDD) (Basseville & Abdelghani et al, 2000). This method does not depend on the model as far as the damage detection is concerned. However, this method requires an adequate numerical reference model to localize and quantify damages. In various projects the SSDD-method was tested and it gave sensitive indicators for the practice of damage detection (Rücker, 2007).

Basically, the permanently monitored strains can be unused to determine local damage indicators. They can be used as pre-indicators for the damage detection prediction.

4 MEASUREMENTS ON A PROTOTYPE

The previously mentioned methods are used as an example for a prototype off an offshore wind energy converter. The prototype is a Multiibrid M5000_2 wind energy converter (Fig. 1). The hub height of the facility is 102 m, the top of the tower is at 92 m and the diameter of the rotor blades is 112 m. The mass of the tripod foundation is 500 t, the mass of the tower 350 t, the mass of the rotor 108 t, including tithe hub, and the nacelle has a mass of 194 t neglecting the rotor and the hub. The rotational speed of the rotor varies in the operating range between 5.9 and 14.8 U/man ± 10%. The nominal power of the facility is 5 MW at a nominal rotational speed of the rotor of 14.8 U/min.

Figure 1. Prototype of Multibrid M5000_2 with measurement system.

Figure 1 shows the monitoring points of the sensors on the tower and the tripod. Totally 110 strain gauges, 114 acceleration sensors and 4 inclination sensors were installed in 6 monitoring levels. Additional sensors were installed on the nacelle to monitor r the machine as well as on the rotor blades to measure the accelerations and strains. The selection and number of monitoring points on the structure were made with the tested and still developing methods based on measured values to assess the damage and load identification. Furthermore, additional monitoring points were needed, that were associated with the problem of design verification. The technical equipment for a commercial structure monitoring system operating on an offshore structure and especially the required number of sensors are derived from the analysis of the structural condition assessment. The required number of sensors can be determined on the one hand from the identification of the sensitive structural components and on the other from tracing the measurements back to the damage mechanisms of the model (e.g. Thöns & Faber, et al. (2008). Therefore, a commercial monitoring system will have a significant lower number of monitoring points.

4.1 *Monitoring the loading side*

As described above, the aim in the present case is not to measure the acting loads of the structure. The aim is rather to determine the effect of the acting loads as generalized stress resultants on the tower top and the pile connections in the area of the foundation. The stress resultants N, My and Mz are determined here

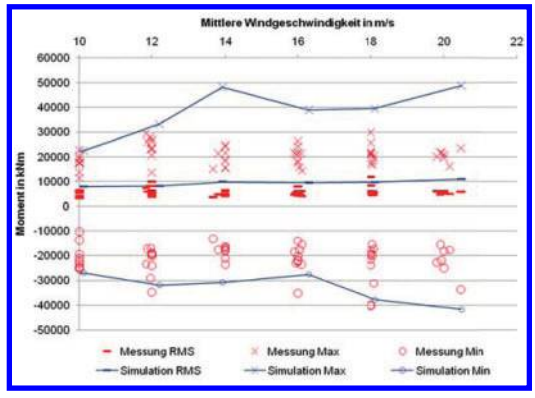

Figure 2. Comparison of measured (points) and calculated (solid line) stress resultants, exemplary for the bending moment on measurement system level 4.

Table 1. Comparison of natural frequencies determined by experiments and calculations.

Experiment	Calculation	Dev. [%]	Mode
0.4211	0.413	3.3	1.1 Bending
	0.417	2.1	1.2 Bending
	3.312	–	2.1 Bending
3.0–3.4	3.240/3.433	–	2.2 Bending

from normal stresses, which can be calculated directly from the strains. Figure 2 shows the comparison of the determined bending moment and the design bending moment on measurement system level 4 (see Figure 1). As can be seen, the design bending moment forms the envelope of the measured bending moments. The root-mean-square values (RMS value) of the monitored values are below the RMS value of the moment of the design computation with a few exceptions.

4.2 *Condition monitoring*

Tithe requirements of offshore wind turbine certification demands, inter alkali, a distance of ±5% between the natural frequencies of the structure f00,i and the excitations, i.e. operation frequencies (f_{1P}, f_{3P}, f_{6P}, …). This criterion ensures that no resonance occurs during operation. The calculated natural frequencies should thus be checked experimentally within the process of design verification before the structures are produced in a large number. Table 1 shows the results of the comparison of the first two natural frequencies of the M5000_2 on the basis of numerical and experimental modal analysis which provides information of the numerical model quality. For the numerical modal analysis monitoring data were collected over the time period of one year. A deviation of ±3% was found for the natural frequency belonging to the first bending mode.

All available acceleration measurements were analyzed for the precise identification of the behavior of

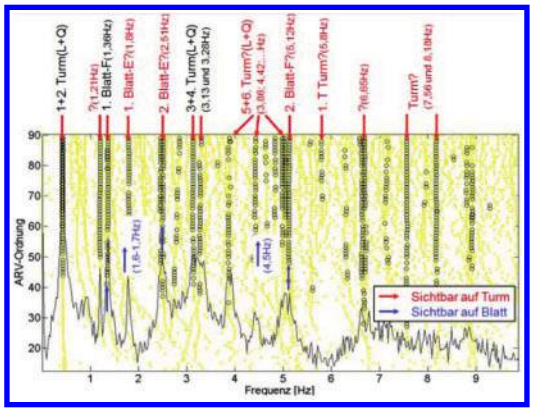

Figure 3. Frequency spectrum up to 10 Hz.

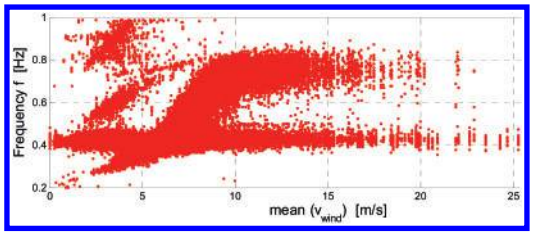

Figure 4. Measured frequencies in dependency of the mean wind speed.

the foundation, the tower and the rotor. The result is depicted in Figure 3. Up to 10 Hz more than 20 relevant frequencies have been identified which can be associated with lateral oscillations of the tower. In between there are several natural frequencies of the rotor blades. The damping is below 2% which can be concluded from the depicted spectrum.

The relevant frequencies up to 1 Hz in dependency of the wind speed are depicted in Figure 4. The first natural frequency of the tower (0.43 Hz; see the corresponding scatter band in Table 1) is passed by the excitation frequency of the rotor at about 7 m/s wind speed. The rotor frequency is constant at about 0.75 Hz for wind speeds higher than 10 m/s. Further, the triple rotor evolutions frequency can be also observed in Figure 4.

The measured inclinations of the tower at the bottom and at the top in dependency of the wind speed are shown in Figure 5. The bottom of the tower is the location for the measurement of the threshold inclination of 0.5 degrees which are defined in various guidelines. The operation mode (idle or operation) of the turbine must be considered when analyzing the inclinations. As a result, it can be seen that the inclinations in idle mode are relatively small. The inclinations increase slowly with increasing wind speed about 0.003 degrees/m/s. The maximum absolute inclinations are below 0.05 degrees. In operation mode a sudden increase of the inclinations for wind speeds higher than 5 m/s is observed. This sudden increase is correlated with passing the first natural frequency.

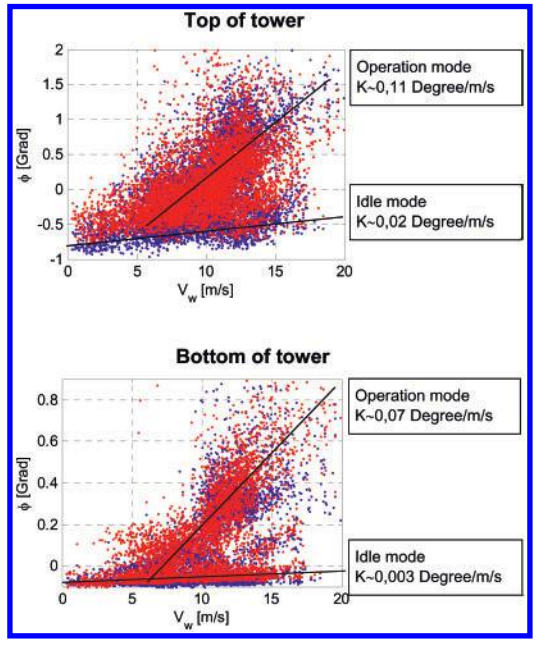

Figure 5. Correlation of inclinations with the wind speed at the bottom and at the top of the tower.

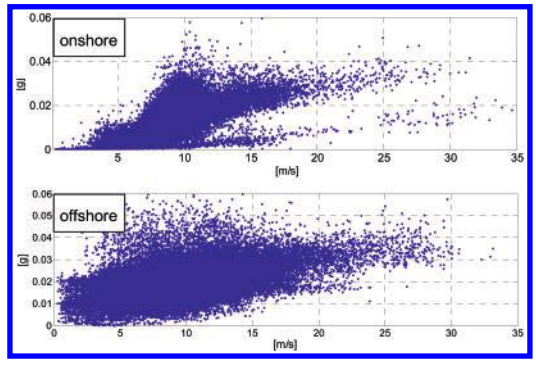

Figure 6. Correlation of accelerations with the mean wind speed on top of the tower onshore (top) and offshore (bottom).

The maximum absolute inclinations are 0.5 to 0.6 (dynamic) degrees for a wind speed of 15 m/s.

The maximum values of the accelerations at the top of the tower (onshore and offshore) in dependency of the wind speed are depicted in Figure 6. In principle the dependencies and the maximum values are very similar for onshore and offshore plants. As expected, the accelerations increase with increasing wind speeds also for onshore wind turbines. The maximum values of the accelerations at the top of the tower are about 0.4 to 0.5 m/s^2.

4.3 *Component loading monitoring*

The analyses for component loading monitoring comprise both, calculations and measurements. For the in situ measurements at the prototype of the M5000_2,

three hot spots were equipped with 24 strain gauges at each hot spot. The stress concentration factors (SCF) are calculated and compared to simulation data taking basis in a capture matrix data structure consisting of 10 min strain time series. For each of the time series 28,000 SCFs were calculated for which the mean values were consecutively determined. In this way the SCFs were analyzed for each of the four sensor chains above (HS A) and below (HS B) the weld for the hot spots 2, 3 and 4 (Figure 7).

The deviations of the mean values of the SCFs of the same hot spot are about 30%. A very good fit is found by comparing the mean values in Table 2 to calculated SCFs. A dependency of the SCFs on the wind speed is found in the lower frequency range of the M5000_2. Analyses show that in this power mode range, the dynamic hot spot strains are mostly influenced by the oscillation behavior in the area of the first natural frequency.

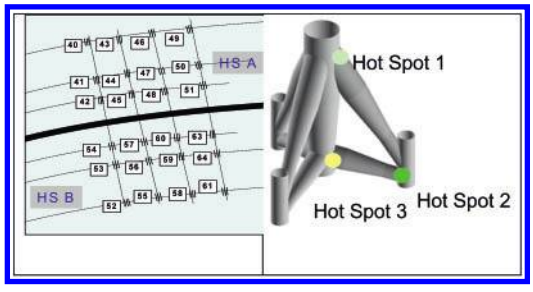

Figure 7. Sketch of strain gauge positions at hot spot (left) and location of measured hot spots on the tripod (right).

5 FURTHER DEVELOPMENTS

Deterministic behaviour has so far been assumed when performing condition assessments. In the future it is intended to utilize condition monitoring data as part

Table 2. Comparison of stress concentration factors determined by calculations and experiments.

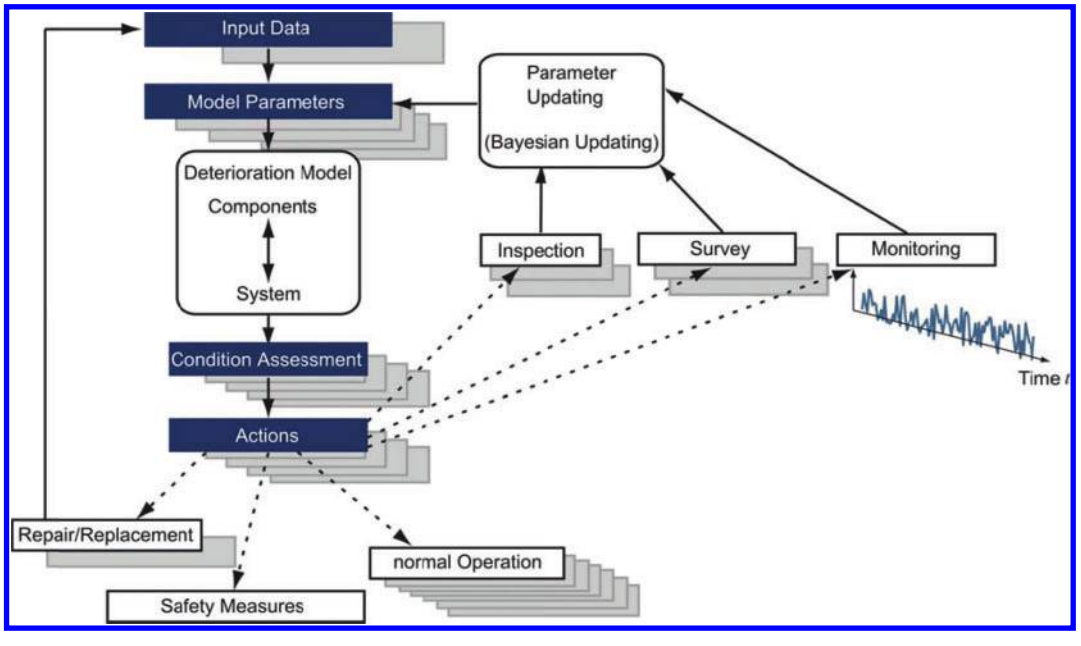

Figure 8. Concept for a reliability based condition assessment of bridges utilizing structural information (Fischer et al., 2012).

of probabilistic condition assessments. For this purpose it is necessary to develop probabilistic condition assessment models which can be updated when measurement data is available (see Figure 8 and Fischer & Schneider et al., 2012).

A probabilistic condition assessment model comprises a deterioration model of the structural components and a structural system model. These models are initialised with a-priori input data (geometry, material data, loads etc.). The models continuously provide information about the development of the reliability of the structure and its components over time.

Monitoring data and inspection results are utilized to update the parameters of the probabilistic condition assessment model using Bayesian updating. This approach makes it possible to consistently include all available information in a single model. The accuracy and information content of the collected measurement data and any other observations is explicitly taken into account when using this approach.

Through updating of the model parameters the condition assessment is also updated. This makes it possible to plan actions concerning the operation as well as monitoring activities and inspections – now conditional on the collected data. In this way the facility in combination with the monitoring system and inspections is an adaptive system which adapts to any changes. It is intended to integrate such conceptualised systems into condition monitoring systems.

6 SUMMARY

Continuous monitoring of the structural integrity as well as the serviceability of offshore wind energy converters becomes increasingly relevant due to the large number of such facilities. Implementing monitoring systems is already a requirement as part of the approval process of offshore wind energy converters. Additionally, operators utilise monitoring systems within the context of preventive maintenance planning.

The application of such conceptualised monitoring systems has been demonstrated for an existing offshore wind energy converter based on monitoring data gathered during an actual measurement campaign. The collected data allows an assessment of thee facility with respect to structural integrity, serviceability and durability. Finally, it was shown that it is possible to improve the assessment of the reliability of offshore wind energy converters based on measurement data from monitoring systems when using probabilistic methods.

ABSTRACT: The present work aims at comparing the dynamic response of a fixed-bottom offshore wind turbine subjected to the combined wind-waves action employing different nonlinear irregular wave kinematic models. To this purpose, linear, second-order and fully nonlinear models are implemented in the hydrodynamic module of a global hydro-aero-elastic solver. All the wave models are based on the potential flow assumption. The fully nonlinear wave kinematics is reproduced both on the full simulation time and, in order to save computational time, only on some space-time subdomains within a domain decomposition strategy. This approach permits achieving a much higher accuracy in the assessment of the hydrodynamic loads keeping the global computational effort similar to the one required by linear or weakly nonlinear models. The paper represents a preliminary investigation aimed at establishing to what extend the second-order wave model can efficiently capture the system response even when the system is exposed to moderate sea states. Moreover, a comparison between the four wave models seems to reveal that some resonant oscillations of the tower are triggered by nonlinear components higher than the 2nd-order. Hydrodynamic loads associated to the four wave models are coupled with aerodynamic loads acting on the rotor of a 5-MW wind turbine. Hydro-aero-elastic calculations are performed using the NREL open-source software FAST.

1 INTRODUCTION

The development of more accurate simulation tools capable of capturing the effects of complex environmental conditions on large multi-megawatt wind turbines are strongly required within reliability-based design framework. A novel numerical package capable of predicting the nonlinear loads acting on offshore wind turbines exposed to nonlinear sea states has been recently proposed in (Marino, Lugni, & Borri 2013, Marino, Borri, & Peil 2011, Marino, Borri, & Lugni 2011). The model reproduces the structural response by coupling a fully nonlinear wave kinematic solver, (Ogilvie 1967), (Longuett-Higgins & Cokelet 1976), (Faltinsen 1977), (Grilli, Skourup, & Svedsen 1989), (Grilli & Svendsen 1990), (Nakayama 1983) and (Nakayama 1990), with a hydro-aero-elastic simulator of the entire system (Jonkman & Buhl 2005). Due to the large number of simulations required to set up a suitable probabilistic model for the design loads extrapolation, the main goal of the proposed simulation scheme was the enhancement of the model accuracy without penalizing the computational time. The computational efficiency is guaranteed by a domain decomposition strategy such that the fully nonlinear numerical wave solver is invoked only on special subdomains where nonlinear waves are expected. Whereas, on the remaining parts of the space-time domain the linear wave theory is assumed.

In this paper an irregular second-order nonlinear wave model is added according to the model proposed in (Agarwal & Manuel 2011, Agarwal & Manuel 2009). The objective is the comparison of the system response subjected to hydrodynamic loads associated with four irregular wave kinematic models: linear, second order (2nd), fully nonlinear within the domain decomposition strategy (FNL w dd), fully nonlinear over the whole space-time domain (FNL w/o dd). Each hydrodynamic model acts in conjunction with aerodynamic loads generated by a hub-height turbulent wind. Aerodynamic forces are modeled by means of the Blade Element Momentum theory (Moriarty & Hansen 2005). Hydro-aero-elastic calculations are performed with FAST (Jonkman & Buhl 2005).

The paper is structured as follows: in Section 2 the Fully Nonlinear (FNL) wave model is recalled and emphasis is placed on the domain-decomposition strategy. In Section 3 the 2nd-order irregular wave model is described. Section 4 briefly describes the baseline wind turbine model. In Section 5 the effects of the four wave models on the system response are presented and discussed.

2 FULLY NONLINEAR IRREGULAR WAVES MODEL

2.1 *Domain decomposition strategy*

The environmental conditions defining the loading processes the wind turbine is exposed to are characterized by the mean wind speed U, significant wave height H_s and peak spectral period T_p. The JONSWAP wave spectrum is chosen and the 2D-linear theory is used to simulate an irregular sea (Faltinsen 1990) in a global space-time domain $\mathcal{D}(t) = [x_{\min}, x_{\max}] \times [0; T_{sim}]$, where $x_{\min}$ and $x_{\max}$ are the lower and upper spatial limits of the global domain and T_{sim} is the total simulation time.

A zero-crossing analysis of the free surface elevation at the wind turbine location permits detecting the times, t_{i_b}, when a wave steepness larger than a threshold value occurs

$$t_{i_b} = t_1^{up} + T_{i_b}/4 + \sum_{h=1}^{i_b-1} T_h \tag{1}$$

where T_{i_b} is the i_b-th period corresponding to a wave steepness exceeding the minimum threshold value $ka_{\min}$ (see Figure 1); $\bar{t}^{up}$ is the vector of the zero upcrossing time instants; $\bar{T}$ and $\bar{H}$ are the arrays containing the local wave periods and wave heights, respectively. Each of these time instants, along with the spatial location of the wind turbine, corresponds to a time-space subdomain

$$\Omega_{i_b} = [x_t - \delta_1 x_t, x_t + \delta_2 x_t] \times [t_{i_b} - \delta_1 t_{i_b}, t_{i_b} + \delta_2 t_{i_b}] \tag{2}$$

on which the FNL wave model is used in place of the linear solution. $\delta_1 x_t$, $\delta_2 x_t$ and $\delta_1 t_{i_b}$, $\delta_2 t_{i_b}$ are the spatial and temporal radii of the subdomain, respectively, and x_t denotes the location of the wind turbine.

2.2 *Fully nonlinear solver: mathematical and numerical formulation*

The 2D problem governing the nonlinear propagation of gravity waves is formulated within the potential-flow assumption. For an inviscid fluid in irrotational flow, the potential function $\Phi(t,p)$ describes the velocity field at time t in each point $p \in \Omega(t)$. For an incompressible fluid, Laplace's equation is valid in the whole domain

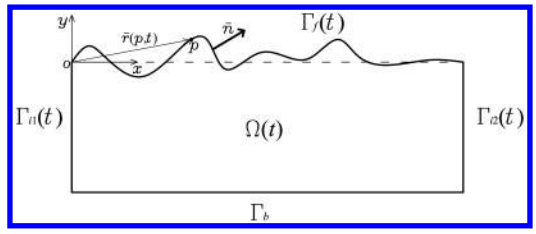

Figure 2. Two-dimensional domain of the time-depending Laplace equation.

$$\nabla^2 \Phi(t,p) = 0 \quad \forall p \in \Omega(t) \tag{3}$$

The 2D domain $\Omega(t)$ is bounded by four boundaries: inflow $\Gamma_{i1}(t)$, rigid bottom Γ_b, outflow $\Gamma_{i2}(t)$, and free-surface $\Gamma_f(t)$ (see Figure 2). On each of them, suitable boundary conditions have to be enforced. In particular, the impermeability condition $\nabla\Phi \cdot \bar{n} = 0$ is imposed on the rigid bottom, while the continuity with the linear wave kinematics has to be ensured on $\Gamma_{i1}(t)$ and $\Gamma_{i2}(t)$; finally, nonlinear kinematic and dynamic boundary conditions must be imposed on $\Gamma_f(t)$

$$\frac{\delta \bar{r}}{\delta t} = \nabla\Phi - (\nabla\Phi - \bar{v}), \quad \forall p \in \Gamma_f \tag{4}$$

$$\frac{\delta \Phi}{\delta t} = -\frac{p_a}{\rho_w} - g\eta - \left(\frac{1}{2}\nabla\Phi - \bar{v}\right)\cdot\nabla\Phi, \forall p \in \Gamma_f \tag{5}$$

where $\bar{r}$ is the position vector of the water particle p and $\eta(t)$ the free surface elevation. The operator $\delta(\cdot)/\delta t = \partial(\cdot)/\partial t + \bar{v} \cdot \nabla(\cdot)$. Depending on the values $\bar{v}(t,p)$ assumes, Eq.s (4) and (5) provide both the Eulerian and the Lagrangian description of the freesurface fluid particle, i.e.

$$\bar{v}(t,p) = \begin{cases} 0 & \text{Eulerian description} \\ \nabla\Phi(t,p) & \text{Lagrangian description} \end{cases}$$

The operator δ turns out to be either the material derivative or the partial time derivative when the Lagrangian or Eulerian description is respectively requested.

2.3 *On the transition between the linear and fully nonlinear models*

At the end sections of each spatial subdomain Ω_{i_b}, the linear wave theory is used to provide the boundary and initial conditions to the FNL solver. Coupling a linear solution with a fully nonlinear solver is formally incorrect causing numerical instabilities. The sources of inconsistency are: *a*) transition from linear to nonlinear (and vice-versa) solution; *b*) transition from Eulerian

to Lagrangian (and vice-versa) description of the free-surface evolution. Type *a*) inconsistency is faced with both a temporal ramp (for the Initial Value Problem, IVP) and damping functions at both ends of the spatial domain (for the BVP) (Dommermuth 2000, Cointe 1990). Type *b*) is addressed using ramp functions to smoothly switch in space and time $\bar{v}(t,p)$ from zero to $\nabla\Phi(t,p)$ and vice versa (see Eq.s (4) and (5)).

2.4 *The fully nonlinear solution*

The solution of the fully nonlinear time depending free-surface problem is based on a two-step Mixed Eulerian-Lagrangian (MEL) approach, which splits the problem into a kinetic and time evolution subparts.

In the Eulerian step, at a given time instant, the solution of the Boundary Value Problem (BVP) for the Laplace equation with mixed Dirichlet and Neumann boundary conditions is reformulated in an integral representation of the velocity potential (using Green's second identity). The boundary integral equation is discretized in space by means of quadratic isoparametric boundary elements (Brebbia & Dominguez 1998). We refer to (Marino, Lugni, & Borri 2013, Marino 2011) for additional details.

The Lagrangian step (time evolution) consists in the time integration of Eq.s (4) and (5) where the potential and the free-surface profile at the new time step $t+dt$ are provided. The fourth-order Runge-Kutta (RK4) algorithm is used for the time integration scheme.

3 SECOND ORDER NONLINEAR IRREGULAR WAVES

The second-order wave theory is implemented starting from the second order velocity potential. To solve Laplaces equation with nonlinear boundary conditions a perturbation approach is used (Sharma & Dean 1979). The free surface elevation $\eta(t)$ is described as a sum of a first-order term $\eta_1(t)$ and a second-order term $\eta_2(t)$. The first-order contribution comes from the sum of all the wave components used to discretize the wave spectrum

$$\eta_1(t) = \sum_{m=1}^{N} A_m cos(\omega_m t - \phi_m) \tag{6}$$

The second-order term is obtained as sum of differences and sums of frequencies as follows

$$\eta_2(t) = \eta_2^-(t) + \eta_2^+(t) \tag{7}$$

$$\eta_2^{\pm}(t) = \sum_{m=1}^{N}\sum_{n=1}^{N}[A_m A_n\{B_{mn}^{\pm} cos((\Psi_m \pm \Psi_n)\}] \tag{8}$$

In the equations above $\Psi_m = \omega_n t - \phi_m$, $\Psi_n = \omega_n t - \phi_n$. A_n, A_n, ω_n and ω_n are, respectively, the amplitude and the circular frequency of the m-th and n-th wave components. B_{mn}^- and B_{mn}^+ are the second order transfer functions (Sharma & Dean 1979).

Similarly, the second-order velocity potential is obtained as a sum of a first order and a second order term $\Phi(t) = \Phi_1(t) + \Phi_2(t)$. $\Phi_2(t)$ is defined by differences and sums of frequencies $\Phi_2 = \Phi_2^- + \Phi_2^+$, where

$$\Phi_2^{\pm} = \frac{1}{4}\sum_{m=1}^{N}\sum_{n=1}^{N}[\frac{A_m A_n g^2}{\omega_m \omega_n}\frac{cosh(k_{mn}^{\pm}(h+z))}{cosh(k_{mn}^{\pm}h)} \frac{D_{mn}^{\pm}}{(\omega_m \pm \omega_n)} sin(\psi_m \pm \psi_n) \tag{9}$$

In the above equation $k_{mn}^{\pm} = |k_m \pm k_n|$ and $D_{mn}^{\pm}$ are transfer functions (not reported here, see (Agarwal & Manuel 2011)). The horizontal particle velocity and the horizontal particle acceleration may be obtained with the second order velocity potential by taking the gradient of Φ.

3.1 *Numerical implementation*

The numerical implementation of the 2nd-order theory (as well as the first order theory) may be efficiently performed using the Inverse Fast Fourier Transform (IFFT). First-order terms, that involve single summations, require the definition of the first-order coefficients that, due to the limited space, are nor reported here, see (Agarwal & Manuel 2011).
