$$N_{CFLc} = \max\left[\frac{\Delta t}{\Delta x_i}\left(\left|U_i\right| + \sqrt{g h_{ci}}\right)\right] \le 1 \quad (1 \le i \le N) \quad (53)$$

Turbidity current thickness, h_c; depth-averaged velocity, U; and volumetric depth averaged concentration C are obtained from the resulting variables vector $\mathbf{U}_{ct}$ at instant $n+1$.

4.3 *Plunging*

Upstream boundary conditions for the turbidity current are given by the plunging phenomena. To determine the point where the current plunges over the delta, the formulation proposed by Toniolo (2003) is used.

Copyright © 2006 Taylor & Francis Group plc, London, UK

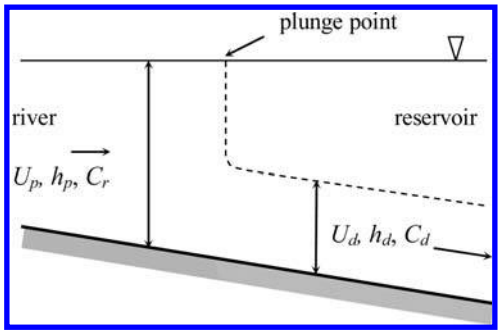

Figure 6. Definition sketch of plunging.

Accordingly to this, the relation between the current depth before and after plunging is determined from:

$$\frac{1}{\gamma_p^2}(1-\varphi)^3 - \frac{1}{\gamma_p^2}\frac{(1-\varphi)^3}{\varphi}(1+\gamma_p)^2 - (1-\varphi)^2 + 1 - \frac{\varphi^2}{1+\gamma_p} = 0 \quad (54)$$

where γ_p denotes the mixing coefficient and ϕ is defined as:

$$\varphi = \frac{h_d}{h_p} \quad (55)$$

Being h_p the depth of the turbidity current just at the plunge point and h_d the depth of the submerged turbidity current just after plunging (Fig. 6). The submerged turbidity current variables, which constitute the upstream boundary conditions for the current, are then obtained as follows: with the value of ϕ determined from Equation 54, and the value of the inflowing suspended sediment concentration at the river, *Cr*, the densimetric Froude number of plunge point, Fr_{dp} is obtained from:

$$Fr_{dp}^2 = \frac{1}{2\gamma_p^2}(1-\varphi)^3 \quad (56)$$

where Fr_{dp}^2 is defined as:

$$Fr_{dp}^2 = \frac{U_p^2}{RC_r g h_p} \quad (57)$$

U_p and h_p are determined from the section of the river where this densimetric Froude number occurs. h_d is obtained using h_p in Equation 55. The densimetric Froude number of the submerged turbidity current is computed from:

$$Fr_{dd}^2 = Fr_{dp}^2 \frac{(1+\gamma_p)^3}{\varphi^3} \quad (58)$$

where Fr_{dd}^2 is given by:

$$Fr_{dd}^2 = \frac{U_d^2}{RC_d g h_d} \quad (59)$$

where C_d is the volumetric concentration of the submerged turbidity current. This is determined from the following relation:

$$C_d = \frac{C_r}{1+\gamma_p} \quad (60)$$

Using Equations 58, 59 and 60, the depth-averaged velocity of the submerged current is obtained.

4.4 *Downstream boundary conditions*

In the suspended sediment mass conservation equation for turbidity current it is considered that particle velocity in the longitudinal direction is equal to flow velocity. Numerical simulations of the turbidity current have shown that a better treatment for downstream boundary condition is reached considering velocity at this location equal to average flow velocity, instead of zero velocity. Simulations have also shown that a downstream zero velocity condition does not allow concentration changes to travel along the turbidity current.

5 MODEL APPLICATION

The three models described in the previous sections were implemented together in a computational code written in Fortran90 language. The resulting software works using text data files as input and output. The input data for the model are: parameters such as number of nodes of the grid, simulation time, Courant numbers for flow and turbidity current, selected bedload relation, Manning coefficient, fall velocity, mixing coefficient and friction coefficient for turbidity current, etc; initial state for the discharge, water surface elevation and bed elevation; boundary conditions for discharge and volumetric concentration of suspended sediment in the river at upstream end, and water surface level at downstream end; grain-size distribution of the bed surface and cross-sectional properties such as basal width and side slopes.

The initial condition for turbidity current is determined internally in the model. In addition, it is considered that if the plunge point occurs before the delta toe, then the turbidity current flows without changing its hydraulic properties until that point. On the other hand, if the plunge point occurs beyond the delta toe, the inflowing suspended sediment concentration remains constant and equal to C_r until the plunge point.

To test the integrated model performance, it was applied using data from a real reservoir project called Puntilla del Viento placed at Aconcagua river in central Chile. Puntilla del Viento is a projected reservoir

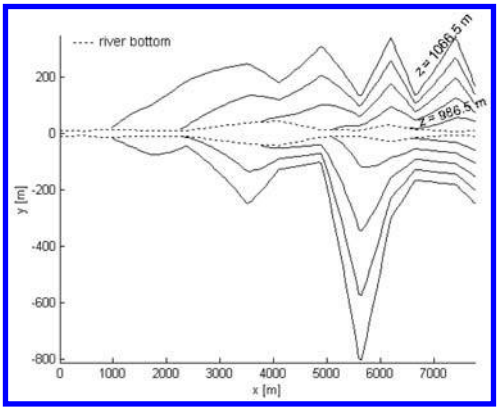

Figure 7. Isolevel curves for Puntilla del Viento reservoir referenced to sea level.

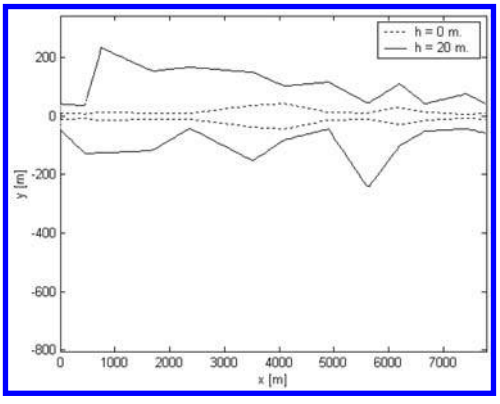

Figure 8. River bottom width and top width at a depth of 20 m.

that would be located at the upper reach of Aconcagua river. The river is born in the Cordillera de Los Andes and crosses the middle valleys of central Chile towards the Pacific Ocean. This example has been selected to test the model because it constitutes a challenge given the topographic configuration and the high slope of the river at the place of the project. The main objective of this application was to test the capabilities of the model when applied to a real engineering problem. The present application did not intend to solve an engineering project, where more reliable and accurate input data would be required. The geometry of the river and reservoir is described in Figures 7 and 8.

The downstream water depth was considered constant and equal to 100 m. The bottom of the reservoir at the dam is located at an elevation of 966.5 m referenced to sea level. The grain-size distribution used in the application was obtained in the lower reach of the Aconcagua River, being the only one available when the model was run (Fig. 9). This has to be kept in mind when analyzing the outcome of the model. The results

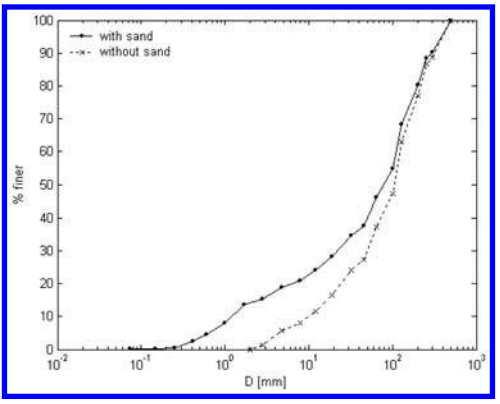

Figure 9. Grain-size distribution used for bed material.

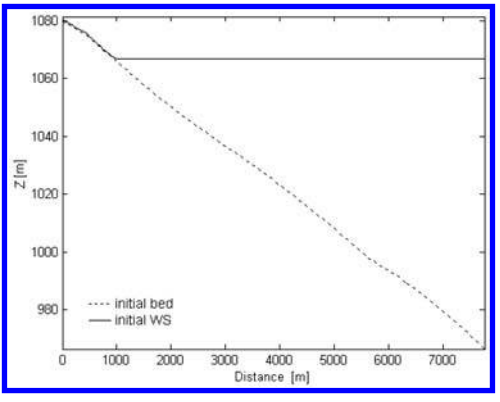

Figure 10. Initial condition for bed and water surface elevation.

obtained after using these data highlight the importance of the adequate representation of bed material. The initial conditions for bed and water surface elevation are shown in Figure 10, and the flow Froude number at that condition is shown in Figure 11. These conditions have been determined with an initial discharge of 22.5 m^3/s and a Manning coefficient of 0.03.

The mixing coefficient for plunging, γ_p, is taken to be equal to 0.6 and the friction coefficient for the turbidity current, c_f, equal to 0.01. Both values have been selected based on previous experimental work (Toniolo 2003, Kostic & Parker 2003a,b). Fall velocity for fine sediment particles was taken equal to 0.001 m/s, and the porosity of the deposit is taken to be 0.3 for both kind of sediments.

The simulation time is one year. The inflowing discharge was obtained from historical data collected between 27/08/91 and 27/08/92. Suspended sediment concentration in the river was related to discharge from samples taken in the river and is given by (Benitez 1997):

$$C_r = 4.741 \cdot 10^{-7} Q^{1.316} \quad (61)$$

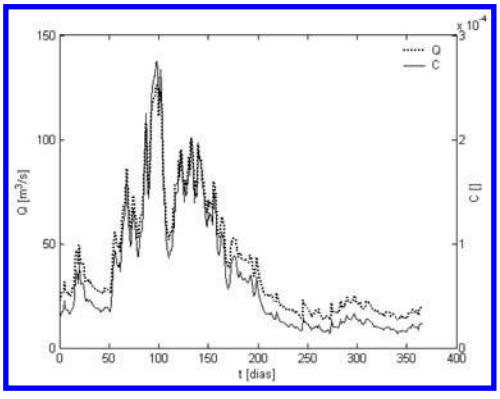

Figure 12. Discharge and suspended sediment concentration statistics used for upstream boundary condition.

where Q is in m^3/s. No attempt was made to discuss the accuracy of this equation. It was used only as an available relationship. It can be seen that according to Equation 61, the resulting concentrations are very small. In spite of that, a turbidity current will be modeled anyway, even when there is a high probability that this becomes dilute. The discharge data and corresponding suspended sediment concentration is presented in Figure 12.

The model was applied using the relations of Meyer-Peter & Müller and Wilcock & Crowe for bedload computation. In order to compare their results, a zoom of the delta deposit with bed profiles at the end of each month is presented in Figures 13 and 14, respectively. The comparison between final bed elevations using each relation is presented in Figures 15 and 16. Figure 16 shows that the turbidity current is strongly diluted. The almost null change in bed elevation of the zone near the dam indicates that turbidity current vanishes before it reaches the dam. However, its effect near the delta toe is still appreciable, rising the bed elevation.

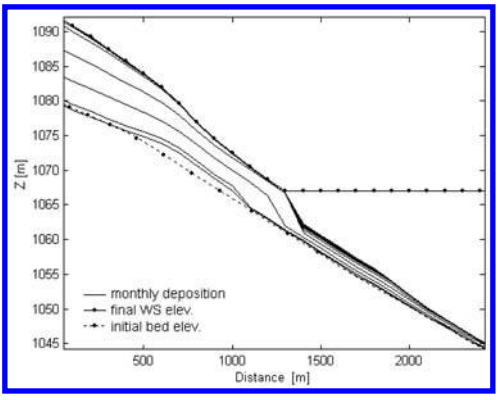

Figure 13. Evolution of sediment deposit obtained using the relation of Meyer-Peter & Müller. Zoom to the delta zone.

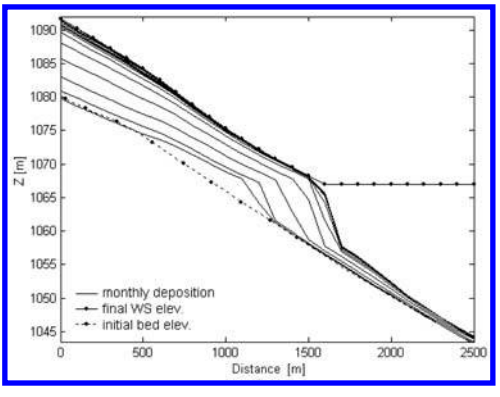

Figure 14. Evolution of sediment deposit obtained using the relation of Wilcock & Crowe. Zoom to the delta zone.

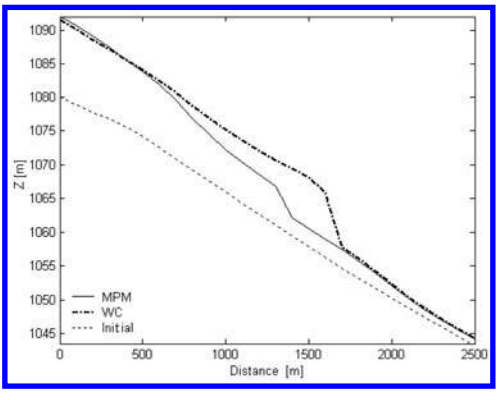

Figure 15. Comparison of the final bed elevations obtained from the application of Meyer-Peter & Müller and Wilcock & Crowe relations. Zoom to the delta zone.

The exaggerated rising of bed elevations at the upstream end obtained from the application of both bedload relations, is a consequence of using a grain-size distribution which is not representative of a steep

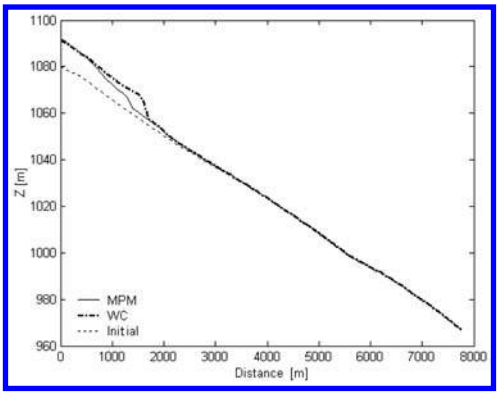

Figure 16. Final bed elevations obtained from the application of Meyer-Peter & Müller and Wilcock & Crowe relations.

slope mountain river. The geometric mean diameter of this distribution is about 39 mm which is a very small value for a river with such a high slope. Generally, the surface bed material at the upper reach of this kind of rivers is characterized by a large amount of boulders and coarse gravel particles.

The sand content of the grain-size distribution can also explain why the deposit determined using the relation of Wilcock & Crowe is larger than that obtained with the relation of Meyer-Peter and Müller. According to the former, during flows capable to mobilize the bed material, the sand content in the grain-size distribution acts to increase the transport of gravels. Furthermore, the relation of Wilcock and Crowe is not based on a critical condition for motion, in contrast to Meyer-Peter & Müller relation which can cease the transport for low flows.

6 CONCLUSIONS

A 1D reservoir sedimentation model that includes coarse and fine sediment transport and deposition has been developed. The model represents natural geometry using trapezoidal cross-sectional areas with variable properties in the longitudinal direction. A new approach to the interfacial entrainment velocity for turbidity currents has been proposed. The resulting equations give a complete representation of the suspended sediment fall velocity hydrodynamic effect. The resulting set of equations represents adequately both regimes of the turbidity current.

A finite volume numerical scheme developed for open-channel flows has been adapted to solve the turbidity current equations.

The model was tested using data from a real engineering project, showing the capability to deal with the characteristics of a steep mountain river, poorly sorted grain-size distribution of bed sediment and to incorporate deposition processes associated to turbidity currents. Future work should be oriented to incorporate in the model the change in time of surface bed grain-size distribution due to deposition. Extension of the model to represent natural cross- sectional geometry is almost direct.

Jets opposing flow on inclines

J. Bühler
Inst. of Environmental Engineering, ETH, Zurich, Switzerland

Ch. Oehy & A.J. Schleiss
Laboratory of Hydraulic Constructions, EPFL, Lausanne, Switzerland

ABSTRACT: Tracer-based scales for the depth and velocity of gravity currents, and a tentative extension of previous entrainment relations to coflowing ambients are proposed. These scales are consistent with the conventional ones used for open channel flows. They are used here to formulate conservation equations for flows on inclines, which are backed up by water jets directed upstream. The corresponding results for a single layer are compared with experiments carried out for this study.

1 INTRODUCTION

One well-known cause of reservoir siltation are sediment laden inflows which occur in the aftermath of intense rainstorms. After entering a reservoir, such flows tend to plunge to the bottom due to their excess density, and to follow the thalweg as turbidity currents. Most of the sediment is eventually deposited near the dam, and can impede the operation of the bottom outlets. A number of methods have been proposed for slowing down or blocking such turbidity currents along their path, and to let them deposit their load before reaching the dam. They include the installation of permeable screens, obstacles or bubble curtains (Oehy 2003, Oehy & Schleiss 2003, 2005). The concept examined in the present study is to use a number of water jets directed against the oncoming flow.

Water jets can also be used to induce a jump at the tail end of a spillway, or to prevent scour in a river (e.g. Wilson 1977). The corresponding momentum and continuity equations are, therefore, derived for both internal flows and flows in open channels. In contrast to previous studies on single layer flows, the present one is on jets entering obliquely from above, and the results are expressed by a single curve. In two-layer flows oscillations of large amplitude may occur when a jet hits a moving interface (Cotel et al. 1997). As the causes are not well understood yet, experiments for single layer flows were carried out as a first step. A few complementary experiments for turbidity currents were carried out by Oehy (2003), and showed that the sedimentation can be effectively enhanced by counterflowing jets.

In a first section, flow scales for the average depth, velocity and density of gravity currents are proposed, which are based on the density distribution instead of the velocity distribution, and a tentative entrainment relation for gravity currents in a coflowing ambient fluid is outlined. In a second section these flow scales are used to derive the conservation equations for internal and open channel flows backed up by jets. In the third section the result of this analysis is compared with experimental results for single layers, which were obtained in the laboratory of the Institute of Environmental Engineering (formerly IHW) in Zurich. Conclusions of the study are summarized at the end.

2 DEPTH AND VELOCITY SCALES FOR GRAVITY CURRENTS DERIVED FROM THE DENSITY DISTRIBUTION

An important difference between open channel flows and gravity currents on inclines is that the free water surface is much sharper than the upper interface of gravity driven underflows. The surface level of open channel flows is defined by the density jump, as well as by the lack of mixing between the two media, and the pressure distribution is close to hydrostatic in gradually varying flows. Deviations from the average velocity are taken into account by shape constants in the energy and momentum equations, respectively.

A quite different set of flow scales, the maximum velocity and velocity half width, has been used for free shear flows, possibly because early experiments were mainly carried out in wind tunnels on wakes and other nonbouoyant flows without a source of mass. In a related approach, Ellison & Turner (1959) (referred to as E & T) used integrals over the non-Gaussian velocity

Copyright © 2006 Taylor & Francis Group plc, London, UK

distribution in gravity currents to obtain a measure for their average depth H, and their streamwise excess velocity U relative to the ambient. In the frame of reference shown in Figure 1 they related these scales to flux integrals by setting

$$UH = \int (u^* - u_a)\, dy$$

$$U^2 H = \int (u^* - u_a)^2 dy$$

$$(U + u_a)\Delta H = g \int u^* \frac{\rho^* - \rho_a}{\rho_a} dy = B$$

Δ is the scale for the effective gravitational acceleration, B is the buoyancy flux, the star denotes mean local values, and the index a refers to the ambient (i.e. upper) layer.

The density distribution was related to these scales by shape constants S_1 and S_2 according to

$$S_1 \Delta H^2 = 2g \int \frac{\rho^* - \rho_a}{\rho_a}\, y\ dy$$

$$S_2 \Delta H = g \int \frac{\rho^* - \rho_a}{\rho_a}\ dy$$

In the spirit of a well-known approach by Morton, Taylor and Turner (1956) for steady free shear flows and thermals, the entrainment of fluid from the upper layer was specified by an entrainment function E as

$$\frac{d}{dx}\left[H(U + u_a)\right] = EU \qquad (1)$$

For gravity currents, E is a function of the Richardson number $Ri_E = \Delta H \cos\varphi / U^2$, where φ is the slope angle. The authors also carried out experiments on saline gravity currents without coflow ($u_a = 0$), and determined the entrainment function E for different slopes. The shape constants varied in the range from 0.2 to 0.3 for S_1, and 0.6 to 0.9 for S_2. From the velocity and relative excess density distribution they show for a slope of $\varphi = 14°$, it is possible to evaluate S_1 as 0.2 and S_2 as 0.64. An important result for $u_a = 0$ is that the excess velocity U and Ri become constant when the flow reaches an equilibrium state. An analogous transition occurs when free buoyant jets turn into plumes.

Princevac et al. (2005) determined profiles of mean velocity and potential temperature for katabatic winds in an ambient coflow. They used E to specify the excess volume flux according to

$$\frac{d}{dx}(HU) = EU \qquad (2)$$

and found that the entrainment in flows of such geophysical scales is substantially larger than in the earlier laboratory experiments.

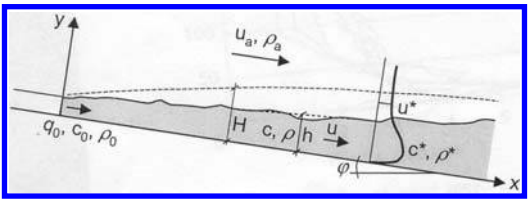

Figure 1. Velocity- and tracer-based flow depths H and h for a gravity current in deep water.

For E = 0 the conservation equations of E & T are consistent with the Bresse equations for open channel flows, except for the definition of the flow scales. Full consistency can be achieved by adopting the same approach for both flows, i.e. by deriving the depth and velocity scales of gravity currents from the density distribution as well. It should be noted that such mass-based flow scales have also been used for thermals, the extent of which was determined in laboratory experiments by adding dye to the flow (Scorer 1997). The momentum of clear ambient fluid, which is carried along with such clouds, is accounted for by an approximate shape factor, called added mass coefficient (Escudier & Maxworthy 1973). By relating the flow scales to the distribution of a dye, they can be used for nonbuoyant shear flows as well. Tracer-based flow scales are also consistent with recent work on entrainment, in which the interface of a jet is defined as the location of the front of a dye, which was added to the injected fluid (Westerweel et al. 2005).

A consistent set of scales for gravity currents containing a passive tracer of high Schmidt number is

$$ch^2 = 2\int c^* y\, dy$$

$$ch = \int c^*\, dy$$

$$cuh = c_0 q_0 \cong \int c^* u^*\, dy$$

Here, c^* is the local volumetric tracer concentration, u^* and u are flow velocities relative to the bed, and q_0 is the discharge from the source of the flow. The last statement implies that the turbulent transport of tracer is included. When the discharge and the concentration at the source are known, the flow scales can thus be determined without measuring velocities (Bühler et al. 1991). The concentration distribution, or at least the integral ch, can often be determined by flow visualization and other techniques, which do not interfere with the flow.

The shape constants are

$$(\gamma u - u_a)h = \int (u^* - u_a)\ dy$$

$$(\beta u^2 - u_a{}^2)h = \int (u^{*2} - u_a{}^2)\ dy$$

Alternatively one may determine a value of β_t, which includes the turbulent momentum flux. u_a is omitted in

Copyright © 2006 Taylor & Francis Group plc, London, UK

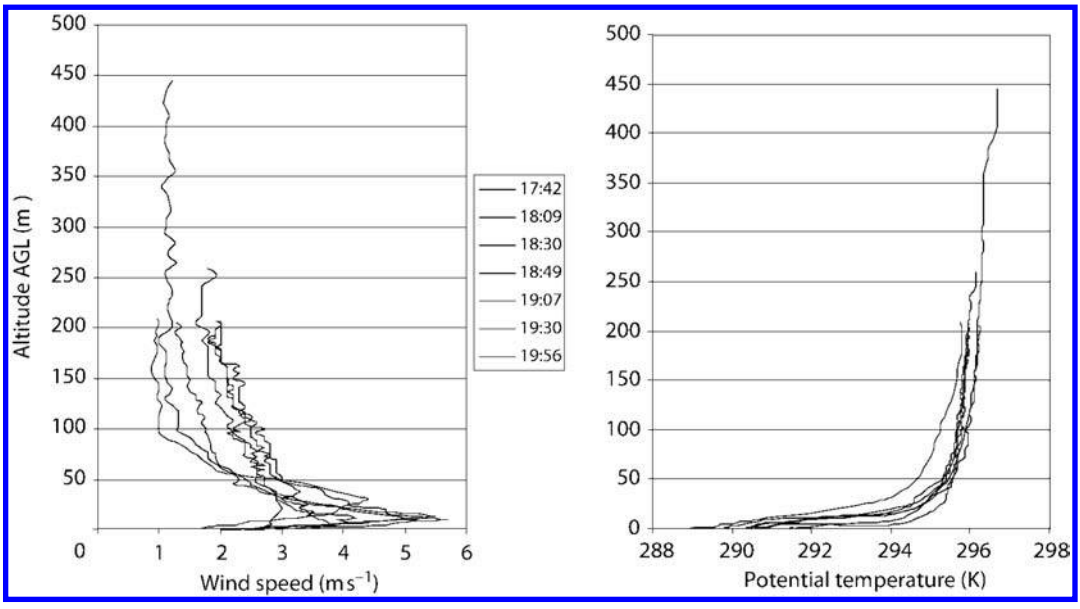

Figure 2. Distribution of wind speed and potential temperature in katabatic winds down a slope (from Princevac et al. 2005).

the case of open channel flows because the dynamics of the atmospheric layer is generally irrelevant, β is called momentum coefficient, and γ is not used as it is equal to one. The simplest equation of state relating the effective gravity g' to c in stratified flows is

$$g' = g\frac{c}{c_0}\frac{\rho_0 - \rho_a}{\rho_0} \tag{3}$$

In open channel flows $c = c^* = c_0$ and $g' = g$. A further advantage of tracer-based flow scales for experiments is that the ambient fluid can be kept uniform, which leads to a well-defined reference for the integrals over the density or tracer distribution, whereas the velocity induced in the ambient fluid by the entrainment can also have a streamwise component. Similar qualitative differences exist between profiles of the wind speed and potential temperature, which were determined by Princevac et al. (2005) in a katabatic downslope wind (Fig. 2). The coflow velocity u_a in the ambient is less well defined than the corresponding reference temperature in the upper layer. It should also be noted that the distributions of the potential temperature, which they obtained at different times, are less contorted and more consistent with each other than the corresponding velocity profiles, which have an inversion point and are strongly influenced by the no-slip condition at the bottom. Similar considerations apply to the velocity and excess density distributions shown by E & T for two distances from the source and a slope of 14°.

Reliable tracer-based width and velocity scales of gravity currents and free shear flows can thus be derived from the readily determinable concentration distribution of a scalar. As a consequence, it seems preferable to tie the more problematic measurements of the fluxes of volume and momentum to the tracer-based scales by means of shape constants instead of pursuing the inverse approach. Special considerations would be required for flows without a source of mass, as well as for two-phase flows like bubble plumes or particle swarms settling in a calm fluid (Bühler & Papantoniou 2001).

The depth-averaged equations of continuity, momentum and tracer conservation can be stated as

$$\frac{d}{dx}(hu) = E'(u - u_a) \tag{4}$$

$$\frac{d}{dx}(\beta h u^2 + \frac{1}{2}g' h^2 \cos\varphi) = u_a \frac{d}{dx}(\gamma h u) + g' h \sin\varphi - c_D u^2 \tag{5}$$

$$\frac{d}{dx}(g' h u) = 0 \tag{6}$$

E' is a function of the bulk Richardson number $Ri'_d = g' h \cos\varphi / (u - u_a)^2$, and c_D is a drag coefficient. By ignoring any variations of φ and the shape constants along x these relations reduce to

$$\frac{dh}{dx} = \frac{E'(1 - \frac{u_a}{u})(2\beta - \frac{1}{2}Ri' - \frac{\gamma}{\beta}\frac{u_a}{u}) - Ri' \tan\varphi + c_D}{(\beta - Ri')} \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$\frac{h}{3Ri'}\frac{dRi'}{dx} = \frac{E'(1-\frac{u_a}{u})(\beta+\frac{1}{2}Ri'-\gamma\frac{u_a}{u})-Ri'\tan\varphi+c_D}{(\beta-Ri')} \quad (8)$$

$Ri' = g'h\cos\varphi/u^2$ is the Richardson number related to the long-wave speed on the interface. The flow velocity is related to Ri' by $u = [B\cos\varphi/(Ri')]^{1/3}$. Ri' does not depend on u_a when the upper layer is deep, i.e. the flow is critical when $Ri' = \beta$, as it is for ambients which are at rest, and in open channel flows. To ensure this mutual consistency, the structure of Equation 4 was chosen in accordance with Equation 1. Special considerations would be required for arrested wedges, for which $u = 0$ by definition.

For $u_a = 0$ and $E' = 0$ the above equations reduce to those for open channel flows. For $u_a = 0$ they agree with the ones derived by E & T except for the definitions of the flow scales, which are related to the present ones by

$$g' = \Delta S_2^2/S_1 \qquad u = U/S_2$$
$$h = HS_1/S_2 \qquad E' = ES_1/S_2$$
$$\beta = S_2^3/S_1 \qquad \gamma = S_2^2/S_1$$
$$Ri' = Ri_d' = Ri_E S_2^3$$

The values of β and γ are 1.32 and 2.08, respectively, for the values of S_1 and S_2 obtained for the slope of 14°. Buhler & Schlaepfer (1986) compiled shape coefficients and related quantities for free shear flows, as well as for open channel and ducted flows (see also Chow 1959). The largest value is that of γ for gravity currents quoted above. The other values of β and γ were somewhat larger than one, except for plane plumes and axisymmetric jets, for which they are somewhat smaller. The momentum coefficient β for a gravity current is thus close to the corresponding value in an open channel or duct from which it may emerge. The width of jets and plumes determined from dye visualizations was also found to agree well with h. The depth h and velocity u of gravity currents in calm water can then be estimated on the basis of the information for β and γ provided here, and from the entrainment function E determined from laboratory and field experiments (Princevac et al. 2005).

Some doubts remain about the appropriate form of the entrainment relation for nonzero ambient flows. A further option would be to combine the approaches leading to Equations 1 and 2 by adding a term u_a dh/dx to the right side of Equation 4 for coflows ($u_a > 0$). According to the concept of jet diffusion proposed by Prandtl (1926), this quantity is proportional to $u_a(1-u_a/u)$ in terms of the present notation. His concept is generally used for jets in coflows and for wakes (Wright 1994, Davidson & Wang 2002), but it also works surprisingly well for free shear flows in calm water (Bühler & Papantoniou 2001). The parenthesis $(1-u_a/u)$ modifying E′ in Equations 7 and 8 could then tentatively be replaced by $\{1-(u_a/u)^2\}$, but further work is required to assess this parameterization. In the following sections we shall return to gravity currents in calm water, an approximation which is usually justified for hydropower reservoirs in river valleys.

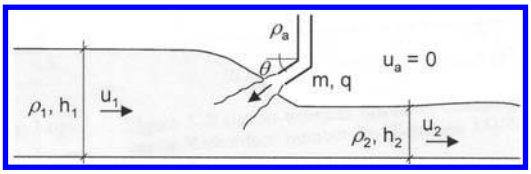

Figure 3. Jets opposing a flow.

3 BACKING UP FLOWS BY OPPOSING JETS

Oehy (2003) explored the possibility of slowing down turbidity currents in reservoirs by means of water jets directed against the flow. He carried out simulations and experiments which showed that this greatly enhances sedimentation and helps to keep bottom outlets from getting clogged. Similar arrangements have been proposed for open channel flows by inducing hydraulic jumps (Wilson 1977). In the following we shall assume that the slope and the sedimentation over the (short) test section can be neglected, that jets emerge from a number of equidistant nozzles arranged in the spanwise direction, and that they are inclined at an angle θ relative to the bed as shown in Figure 3. The jets are associated with a flow rate q, and a momentum flux m per unit width, regardless of the number of nozzles they emerge from. The jets are thus replaced by an equivalent line source (from a slot) for the purpose of the analysis. The upper layer is considered to be at rest ($u_a = 0$). The main difference between internal and free surface flows is that the former ones are diluted by the clear water of density ρ_a injected into them, but not the latter ones.

The conservation equations for the fluxes of volume, momentum and buoyancy are

$$\gamma h_1 u_1 + q = \gamma h_2 u_2 \quad (9)$$

$$\frac{1}{2}g'_1 h_1^2 + \beta u_1^2 h_1 - m\cos\theta = \frac{1}{2}g'_2 h_2^2 + \beta u_2^2 h_2 \quad (10)$$

and for internal flows

$$g'_1 h_1 u_1 = g'_2 h_2 u_2 = B \quad (11)$$

With $q_i = \gamma u_i h_i$ we can wite $q_1 + q = q_2$. For a convenient presentation in graphs we may redefine

Copyright © 2006 Taylor & Francis Group plc, London, UK

$Ri = Ri'/\beta$, such that $Ri = 1$ for critical flow. The flux $u_i^2 h_i$ can be expressed as $(B/\beta Ri_i)^{1/3} q_i/\gamma$, which leaves

$$\frac{1}{Ri_1^{1/3}}\left(1+\frac{1}{2}Ri_1\right) = \frac{q_2}{q_1}\frac{1}{Ri_2^{1/3}}\left(1+\frac{1}{2}Ri_2\right)+\frac{\gamma m\cos\theta}{q_1(\beta^2 B)^{1/3}} \quad (12)$$

For free surface flows $g' = g$, $\gamma = 1$, and $u_i^2 h_i$ can be expressed as $(gq_i/\beta Ri_i)^{1/3} q_i$, such that

$$\frac{1}{Ri_1^{1/3}}\left(1+\frac{1}{2}Ri_1\right) = \left(\frac{q_2}{q_1}\right)^{4/3}\frac{1}{Ri_2^{1/3}}\left(1+\frac{1}{2}Ri_2\right)+\frac{m\cos\theta}{(\beta^2 g q_1^4)^{1/3}} \quad (13)$$

Solutions can be obtained by substituting $Ri_1 = x^3$, and by denoting the RHS of Equation 12 or 13 by r, which leaves $x^3 - 2rx + 2 = 0$. A further substitution of $x = 2(2r/3)^{1/2}\cos\theta$ leads to solutions of the form $\cos(3\theta) = -(3/(2r))^{3/2}$, which can be used to draw the curve in Figure 4 for open channel flows. An analogous procedure can be used for cases where the downstream flow conditions and Ri_2 is known. From Equation 13 we obtain

$$\frac{1}{Ri_2^{1/3}}\left(1+\frac{1}{2}Ri_2\right) = \left(\frac{q_1}{q_2}\right)^{4/3}\frac{1}{Ri_1^{1/3}}\left(1+\frac{1}{2}Ri_1\right)-\frac{m\cos\theta}{(\beta^2 g q_2^4)^{1/3}} \quad (14)$$

This relation is shown in Figure 5.

Both relations can also be expressed in terms of the more generally used Froude Number $F^2 = 1/Ri$. For Equation 13 the result is

$$F_1^{2/3}\left(1+\frac{1}{2F_1^2}\right) = \left(\frac{q_2}{q_1}\right)^{4/3} F_2^{2/3}\left(1+\frac{1}{2F_2^2}\right)+\frac{m\cos\theta}{(\beta^2 g q_1^4)^{1/3}} \quad (15)$$

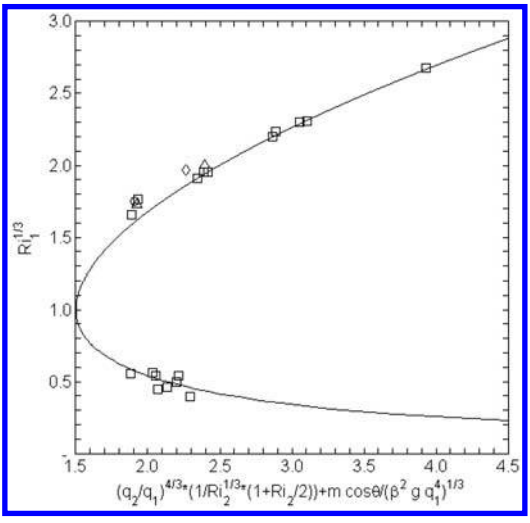

Figure 4. Relation between downstream conditions and upstream Richardson number Ri_1 (Equation 13). Eight 5 mm pipes (squares), four 7.5 mm pipes (circles), eight 10 mm pipes (diamonds), two 10 mm pipes (triangles).

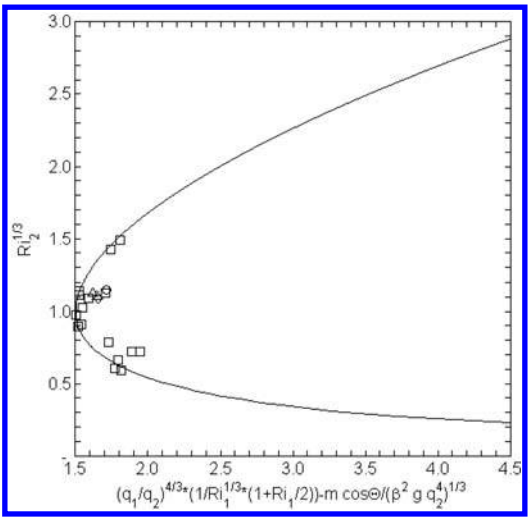

Figure 5. Relation between upstream conditions and downstream Richardson number Ri_2 (Equation 14). Symbols as in Figure 4.

4 EXPERIMENTS

The experiments on flows with a free surface were carried out in a glass-walled flume of 0.4 m width and 0.5 m depth (Fig. 6). A weir, which was located 3 m upstream from the injection pipes, allowed for the establishment of supercritical flows within the test section. The upstream and downstream depths were measured by point gages. In both cross-sections depth measurements made between, and at the spanwise locations of the injection pipes were averaged. The injection angle was $\theta = 15°$. Most of the experiments were performed with eight equidistant discharge pipes, with one-half that distance left free adjacent to the walls. These pipes had an inner diameter of 5 mm. A few other experiments were made with 7.5 and 10 mm pipes as marked in the Figures 4 and 5. For the present purpose β was chosen as 1.07 for both the pipe flow and open channel flow (Chow 1959). The depth h_1 ranged from 0.02 to 0.09 m, u_1 from 0.25 to 1.6 m/s,

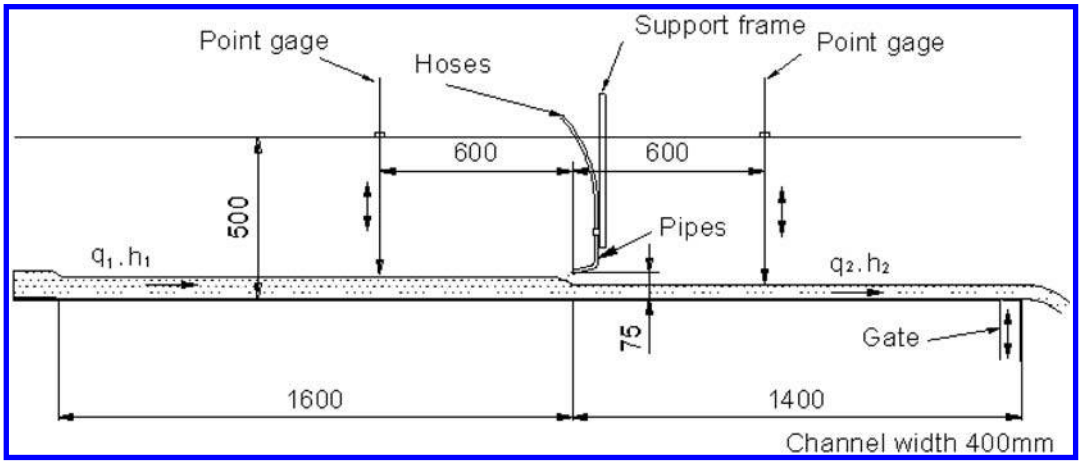

Figure 6. Experimental arrangement for jets opposing an open channel flow (measurements in mm).

and m from 0.9 to $19.6 \cdot 10^{-3}$ m^3/s^2. The agreement with the predictions is quite satisfactory, in particular there is no clear dependence on the number of pipes used within the range of observation.

5 CONCLUSION

Tracer-based depth and velocity scales for gravity currents and free shear flows provide a reliable alternative to scales derived from the velocity distribution. They also provide a good measure for the average flow velocity u and depth h of the layer when the ambient fluid is not at rest. The scales are used determine the depth to which flows on inclines can be backed up by jets directed upstream. Experiments were carried out for single layer flows, and the results agree well with these predictions.

ABSTRACT: Large shallow reservoirs of run-of-river power plants on rivers with high suspended sediments are endangered by significant sedimentation. In the framework of a research project, the influence of the geometry of the reservoir on sediment transport and deposition is studied by experimental and theoretical approaches. As a reference case, a rectangular basin geometry was analyzed in detail. The experimental tests have been conducted in a rectangular shallow basin with inner dimensions of 6 m length and 4 m width. Different test procedures were examined. The flow and sediment conditions used during the tests grantee fully developed turbulent flow. Bed level changes, surface, and 3D flow velocities were measured. The results help to understand the mechanism of the flow and the sediment exchange process. In spite of the symmetric setup and only clear water entering; an asymmetric flow pattern developed. But after changing the condition by adding suspended sediment to water in the mixing tank the flow pattern changed and bed forms emerged. They indicate that the flow pattern can easily switch to different directions, depending on the boundary and initial conditions. Moreover, bed forms affect the flow structure. It confirms the important role of boundary conditions in sedimentation and flow field patterns. Furthermore, these first results allow assessing the time evolution of deposition patterns.

1 INTRODUCTION

1.1 *Background*

Shallow flow models play an important role in hydraulic, environmental, river, and coastal engineering. It is thereby important to simulate hydrodynamic phenomena at different length scales that may co-exist in natural flow regimes, e.g. stagnation zones and eddies together with small-scale turbulence. Shallow turbulent flows are common for example in reservoirs, lakes, estuaries and seas. These flows are known to be predominantly two-dimensional, since the limited water depth prevents the development of large-scale three-dimensional structures.

The present study particularly focuses on shallow reservoirs with a prototype depth between 5.0 and 15.0 m and mainly governed by suspended sediments. The modeled bed material has been down scaled to obtain suspended sediment transport over a large part of flow depth. Recent laboratory experiments and numerical simulations for a wide flume (Sloff et al., 2004) showed that channel formation in shallow reservoirs is controlled by the flow pattern. It is highly dependent on the boundary conditions, the initial flow conditions and the geometry. Experimental investigation on the silting process in reservoirs and lakes was carried out systematically by (Mertens, 1985) in a square, shallow basin ($5.00 \times 5.00 \times 0.25$ m) with a horizontal bottom and an approaching channel 0.25 m wide.

The silting-up of reservoirs is a very complex process. Shear flow over a mobile bed induces sediment transport and the generation of bed forms. The interaction between the flow and the bed usually produces different types of regular patterns characterized by a wide range of sizes and shapes (dunes, ripples, anti-dunes, etc.). In turn both, sediment transport and bed forms, influence the flow. The importance of studying the presence and evolution of these regular patterns arises because those bed forms generated by the sediment transport can increase the resistance to flow. In particular, experimental results on the influence of suspended sediment on turbulence are still lacking.

1.2 *Aim of the study*

This study focuses on the sedimentation of shallow reservoirs by suspended sediments and the objective of the experiments is to gain insight into the physical

Copyright © 2006 Taylor & Francis Group plc, London, UK

process behind the sedimentation of shallow reservoirs governed by suspended sediment. Moreover, it is aiming at a better understanding of the mechanism governing the sediment exchange process between the jet entering the reservoir and the associated turbulence structures. Furthermore, we would like to examine different test procedures and find the optimal one to continue with future test configurations. These experiments are part of test series prepared to investigate the ideal reservoir geometry, minimizing the settlement of suspended sediments. The experiment described hereafter is expected to fill in part of our knowledge gap.

2 EXPERIMENTAL SETUP

2.1 *Similarity and dimensions*

Comprehensive information on similitude requirements for movable and fixed bed models can be found in Yalin, 1970 and Kobus, 1980. Scaled physical models are based on similarity theory, which uses a series of dimensionless parameters that fully or at least partially characterize the physics. The choice of a scaling factor $\lambda = L_p/L_m$, or length scale ratio, to be used in the experiments, is determined by the objectives of the research. According to the length of the tested section and the laboratory constraints, the model has been designed with horizontal and vertical scales of $\lambda_l = \lambda_h = 50$ (Kantoush et al., 2005). Application of the above similarity rules is shown in Table 1, with a comparison between the prototype and the model characteristic values.

The experiments were carried out in a specific test facility at the Laboratory of Hydraulic Constructions (LCH) of the Swiss Federal Institute of Technology (EPFL). The dimensions of the model were based on those of the Rhône River and the space available in the laboratory. A schematic view of the experimental setup is shown in Figure 1. The setup consists of an inlet rectangular channel 0.25 m wide and 1.0 m long made of PVC, a rectangular shallow basin with inner dimensions of 6.00 m length and 4.00 m width, an outlet rectangular channel 0.25 m wide and 1.0 m long, a flap gate 0.25 m wide and 0.30 m height at the end of the outlet (to control the water level), a drainage pipe 0.23 m diameter fixed after the flap gate, and stilling basin to collect the sediment and drainage the water in (see Figure 1).

The bottom and the walls of the basin consist of 8 mm thick PVC plates with 0.30 m height on the sides. Adjacent to the experimental reservoir, a mixing tank with a maximum capacity of 200 liters is used to prepare and store the sediment fluid mixture. A sediment supplier tank is mounted above the mixing tank. To control the sediment concentration, a small gate is installed at the down front of the sediment tank. Sediment supplier tank is attached to a vibrator, which has several speeds to increase or decrease the sediment concentrations. The mixing tank is equipped with a propeller type mixer to create a homogenous sediment concentration. After filling the experimental reservoir with water, the water-sediment mixture will flow by gravity into the rectangular basin through a flexible pipe with 0.10 m diameter. To ensure a uniform mixture in the mixing tank and reservoir basin, the density of the sediment mixture and the clear water were controlled before and during the experiments by means of a turbidity meter. On the basin side walls a movable aluminium frame is mounted with 4.0 m length, which carries the measurement instruments can move in three directions. The parameters that were measured during the experimental runs are shown at Table 2.

Table 1. Characteristic values of the prototype and the model (scale 1 : 50).

Item	Prototype	Model
Length, L[m]	300.0	6.0

2.2 *Experimental conditions*

To model suspended sediment currents in the laboratory model, walnut crushed shells with a median grain size $D_{50} = 50\,\mu m$, density 1500 kg/m^3 was used in all tests cases. These are non cohesive, light weight and homogeneous grain material. The sediments are added to the mixing tank during the tests. The hydraulic conditions were chosen to fulfill the sediment transport

requirements see Table 1. Furthermore, for all test cases, Froude number is small enough and Reynolds number is high enough to ensure subcritical fully developed turbulent flow.

2.3 *Measurements and data acquisition system*

Several parameters were measured during every test; namely: surface velocities, deposited sediment layer thickness, suspended sediment concentration at the outlet, 3D flow velocity, water level and water temperature. Table 2 provides an overview of the measurements and instrumentations used during the tests.

The velocities were measured by means of an Ultrasonic Doppler Velocity Profiler (Metflow SA, UVP-DUO), which allows an instantaneous measurement of the 1D velocity profile over the whole flow depth (Metflow, 2002). The measurement probes were mounted on a support in groups of three, allowing the measurement of the 3D flow field (Figure 2). To cover the whole cross section of the basin, 5 positions were chosen along the cross section; each position has four groups of three probes. All twelve probes were mounted on a frame which moves in the two horizontal directions. The probes were inclined at 20° to the vertical and had an emitting frequency of 2 MHz. The velocity measurements were taken at about 480 measurement points.

The bed level development was measured by means of Miniature echo sounder (UWS) see Table 3. The transmitted ultrasound impulse is reflected at any object serving as a target. This acoustic reflection

Specification
Lab device ULTRALAB UWS (see Fig. 3b)
Control keys and integrated 4 digit 12 mm LCD-Display
Dimensions: 330/115/260 mm, length/height/depth
Measuring rate: max. 10 Hz
Sensor (see Fig. 3a)
Dimensions: Diameter: 30 mm/
Length: 50 mm
Frequency: 1 MHz
Resolution: 1% of measuring range, max. 1 mm
Accuracy: 1% of measured value at constant circumstances

propagates in space and is received from the ultrasound sensor. In order to measure the effective distance between target and sensor the run-time must be determined which the sound needs from the sensor to the target and back to the sensor again. The measured run-time will be averaged. The distance to the target in meters can be calculated by the run-time and the sound velocity. The UWS was mounted on the movable frame (Figure 4) to scan the whole basin area (6 m * 4 m). The measured cross sections profiles were spaced at 0.05 m and some case 0.025 m was tested, starting from 0.10 m from the model's side wall, and ending at 0.10 m from the other wall, i.e. covering a total model width of 4.0 m with total 77 points. The measured longitudinal profiles were spaced at 0.20 and some case 0.1 was tested, starting from 0.05 m from the upstream sidewall, and ending at 0.10 m from the other downstream wall.

PIV offers a simple method of measurement in areas with complicated geometry and flow conditions. Surface flow measurements with PIV are described for e.g. in (Adrian, 1991). In hydraulic engineering, however, this technique has so far mainly been applied for surface velocity measurements of water and ice flow

in very uniform flow fields as well as in groyne field experiments (Ettema et al., 1997; Fujita et al., 1998; Uijttewaal et al., 2001; Weitbrecht et al., 2002).

The basic principal of PIV is simple: the flow is seeded with plastic particles (with average diameter 3.4 mm and specific weight 960.0 kg/m^3) which are then illuminated and their positions recorded at two successive instant (Figure 5) by video (SMX-155, monochrome, 1.3 megapixel, CMOS camera with USB2.0 interface and frame rate up to 33 FPS). The video of the whole 2D field is then divided into a number of interrogation areas and, in each area, the distance moved by the tracer particles from the time of the first image being recorded to the second is determined. Knowing the distance traveled and the time taken, the velocity of the flow in that area is therefore measured. This is done for every area, giving the 2D map of the instantaneous velocity field at the time of the recording. The camera fixed perpendicular on the basin covering the plane basin area (the whole width 4.0 m and 5.0 from the length, missing 0.5 m from upstream and downstream ends). The displacement of the plastic particle images over the time between the exposure of the first frame and the second analyzed by FlowManager software.

2.4 *Test procedure*

Two different experimental procedures were tested in order to find one approach for all test configurations. For this reason only experimental procedure for carrying out a standard continuously fed suspended sediment experiment will be described. The difference between the two procedures is as follows:

1. Discontinuous feeding: after 1hour of feeding sediment to the water mixture and doing the measurements (UVP, PIV& Pictures); close down-stream flap gate, open water bypass and stop sediment feeding. After suspended sediment deposits, start bed level profile measurements as explained before.
2. Continuous feeding: working the whole duration continuously feeding the mixture and doing the measurements.

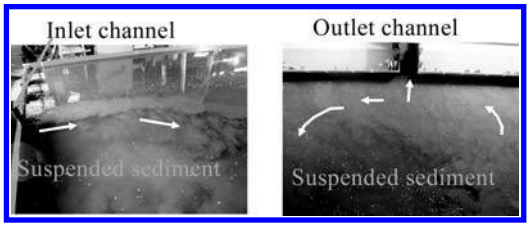

Figure 6. Left: mixture entering; Right: mixture exit.

Prior to each experiment, the mixing tank and the basin were cleaned. The pump was started and the electromagnetic flow meter and a valve were then used to adjust the desired inflow rate. The down-stream flap gate was regulated according to the ultra sound calibration curve to control the water level. Then the basin and mixing tank were filled with clear water. One hour after starting the pump and stabilizing the flow, the PIV measurements were performed for that initial case (only clear water entering the basin). Sediment was added to the sediment supplier tank and the sediment concentration which enters the mixing tank was checked. The mixer guaranteed a homogenous mixture in the tank. Figure 6 shows the homogenous suspended sediment mixture. The left panel shows the sediment entering from the upstream inlet channel to the basin whereas the right one shows the mixture arriving at the outlet in a completely mixed state and a certain concentration flowed from the outlet channel.

UVP probes were mounted to start 3D velocities measurements. The bed profile was measured for specific chosen cross sections every 20 minutes. PIV measurements were repeated during the test every 30 minutes and attention was paid to the transitional case during the test (decided according to the surface velocity observations). All the runs were repeatedly recorded with a digital video camera for selected durations in order to track the changes in flow patterns, and to determine the propagation of the suspended sediment concentration. The experiment was then run until equilibrium conditions were reached, defined as a minimal change in water surface and bed slope over the two consecutive measurements. Equilibrium was usually

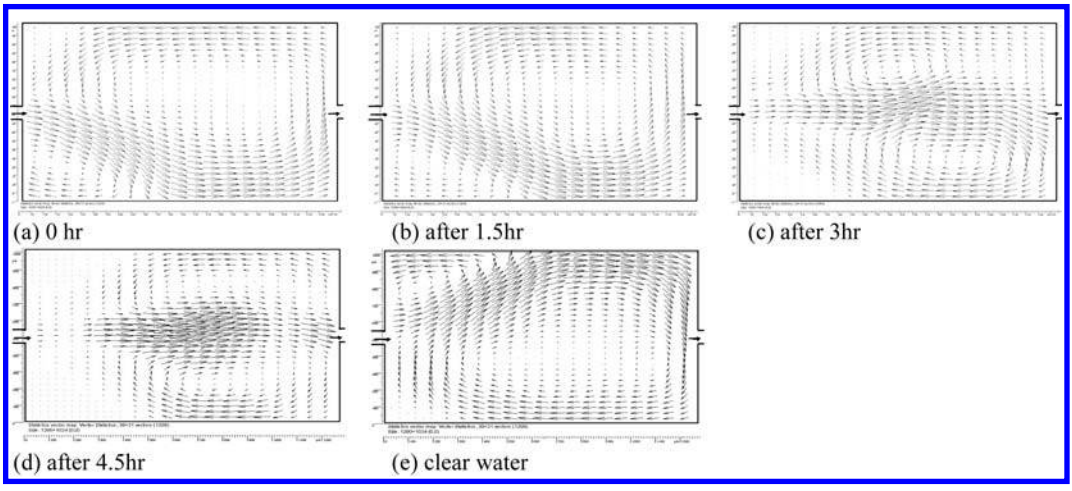

Figure 7. Flow pattern at different run times during test Series 1.

achieved within 4.5 hours after starting the experiments. The flap gate was then closed to permit for the suspended sediment to deposit and then measuring of deposit thickness was started using UWS as explained above. Finally the sediment at the outlet basin was collected, dried and weighted to calculate the trap efficiency coefficient and sediment volumes as well.

2.5 *Test series*

Three different test series have been carried out with the same boundary conditions and initial conditions as explained before but with different test procedure as following:

1. Series 1: The discontinuous feeding procedure has been used.
2. Series 2: Repeated test for Series A, with the purpose to check the reproducibility and the model sensitivity.
3. Series 3: The continuous feeding procedure has been used with the same condition as previous series.

3 RESULTS AND DISCUSSIONS

3.1 *Flow patterns*

Averaged flow fields have been obtained by using Particle Image Velocimetry (PIV) techniques and are depicted in Figures 7 to 9; each figure contains five flow patterns as following:

(a) Flow pattern for the initial state (no sediment neither in the basin nor in the mixing tank)
(b) Flow pattern after 1.5 hour of adding sediment concentration in the mixing tank.
(c) Flow pattern after 3 hours from the start with a constant sediment concentration
(d) Flow pattern after 4.5 hours from the beginning.
(e) Flow pattern using a clear water inflow after completely stopping the sediment supply.

Figures 7(a), 8(a) &9(a) show that the flow enters as a plane jet issuing from the narrow leading channel to the wide basin. After jet issuance, the main flow tends towards the right hand side, generating a large and stable main gyre rotating anticlockwise and two small 'triangular' gyres rotating clockwise in the two upstream corners of the basin. The jet appears to be attracted to one of the side-walls. Its preference for the right side is weak since a stable mirror image of the flow pattern can easily be established by slightly adapting the initial conditions. By following floating particles, it is noticed that in the first meter from the entrance the particle is straightly entering and, in the next two meters, it deflects to the right until it arrives at the stagnation points near the right wall at the middle (3 m from the entrance). The particles that do not leave the basin through the outlet channel circulate with the main gyre to arrive near the separation zone at the farthest left side wall. There, a small gyre has formed at the left corner of the basin with a triangular shape 1.2 m *1.2 m. The circulation pattern sustains itself because the inertia of the main gyre pushes the in-coming jet aside. A bottom that is initially smooth favors this inertia dominated pattern. By comparing the three figures similar gyre patterns are obtained even with different test procedures and different working days.

The water-sediment mixture flows from the narrow inlet channel to the much wider basin. At first, the inflow mixture behaves like a jet that remains quite separated from the clear water in the basin. After some distance, the shear between both bodies of water

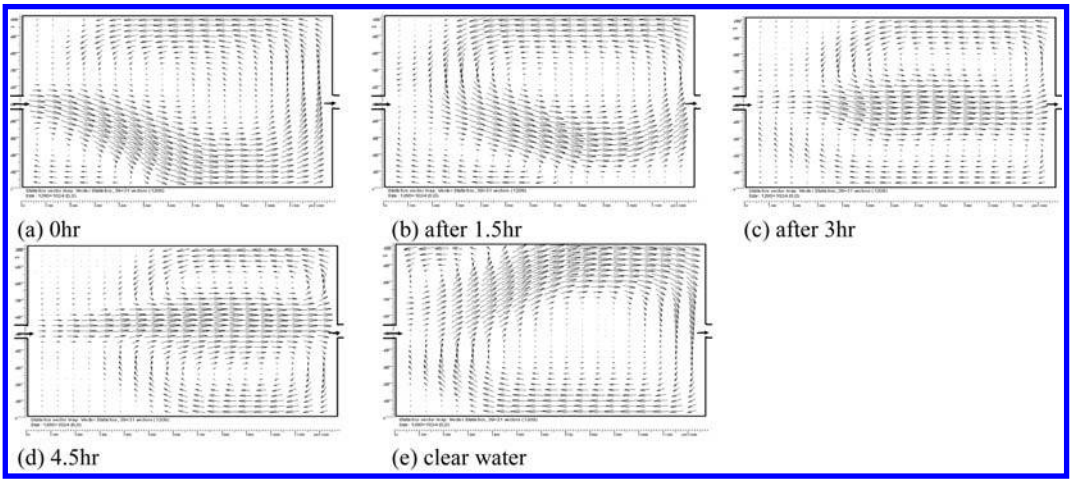

Figure 8. Flow pattern at different run times during test Series 2.

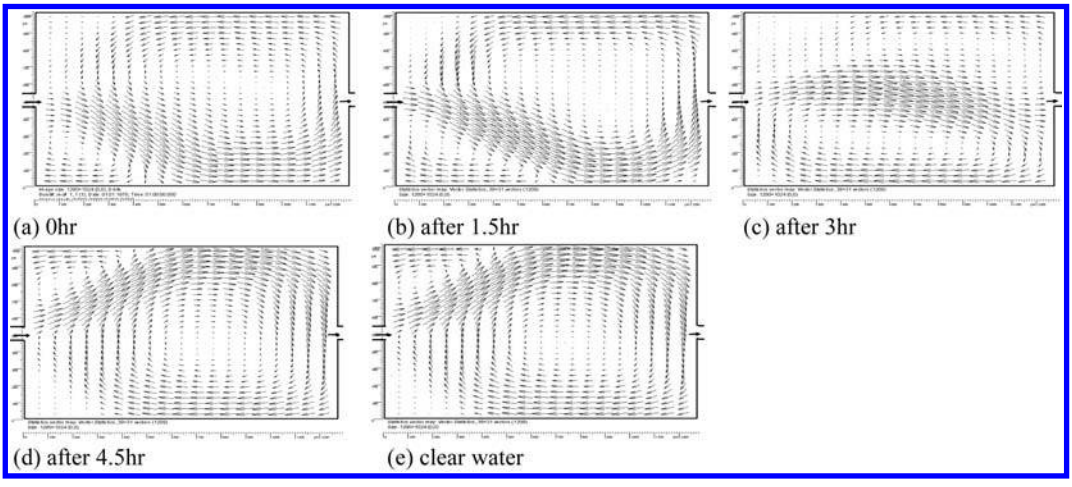

Figure 9. Flow pattern at different run times during test Series 3.

moving at a different speed causes mass and momentum exchange and thus eddies that are peeled off from the core of the jet. This peeling off occurs alternatively on both sides of the jet and generates eddies that increase with longitudinal distance. Furthermore, the jet starts to undulate with a wavelength and amplitude that increase with longitudinal distance. The behavior resembles to a continuously growing instability. This asymmetric and switching flow behavior continues until the downstream end of the reservoir, where the jet is forced to pass through the outlet channel.

During 1.5 hours of adding the sediment the observed flow pattern in Figures 7(b), 8(b) &9(b) did not differ much from what is previously explained for Series (a), except for the increase in size of the right corner gyre and a downstream shifted re-attachment point. Apparently this is due to the suspended sediment entrainment and the associated emergence of bed forms (see Fig. 10). It's clear that the flow structures in the different test series show a similar pattern in these figures.

Figures 7(c), 8(c) &9(c) present the flow patterns after 3 hours of adding sediment for the three test procedures. As a result of ripple formation and suspended sediment concentrations the flow field is completely changed. The gyres in the upstream corners are suppressed if not disappeared and a pattern has emerged that is rather symmetric with respect to the center line. It is also seen that the remaining two gyres interact with the jet which shows some tendency to meander. Since the exchange with the upstream corners of the basin is very small, it is expected that not much deposition

Copyright © 2006 Taylor & Francis Group plc, London, UK

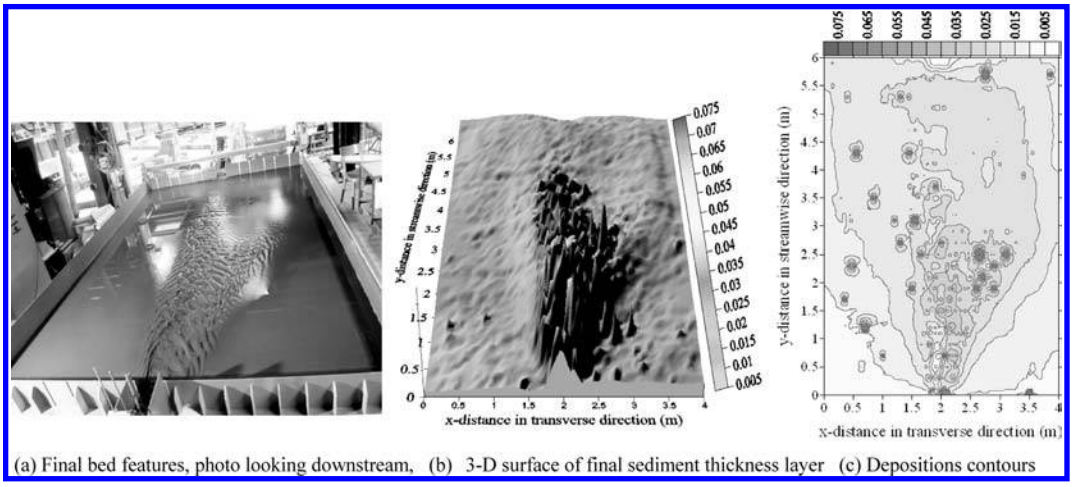

Figure 10. Morphological results after 4.5 hrs of sediment supply for Series 1.

takes place in those areas. Apparently the changes in the bed forms or effective roughness resulting from the sediment deposition are capable of completely changing the overall flow pattern. Through the same mechanism a further development can be expected. By comparing the three figures it can be concluded that similar flow patterns have developed but with small differences regarding the dimensions and strength of the circulation cells. In particular with the continuous feeding experiment (Fig. 9(c)), the asymmetry leading to the subsequent pattern can already be seen.

Figures 7(d), 8(d) &9(d) show the flow patterns that have developed after 4.5 hours of adding sediment for the different test procedures. Figures 7d &8d still show symmetric flow patterns with two gyres coupled to the jet flow. It is noticed that two very weak gyres that might have become laminar or stagnant have hardly any exchange with the main motion. In both figures the same test procedures were used which resulted in virtually identical flow patterns. Figure 9(d) presents the flow pattern of the continuous test procedure after 4.5 hours of adding sediment. It has a flow structure different from those in Figures 7(d) and 8(d). Due to the continuous feeding procedure already during the third hour the right side gyre starts to enlarge in size and develops into the one shown in Figure 9(d). This pattern appears to be rather stable. With the help of bed evolution measurements and final bed deformation pictures, it can be said that during the transition zone from the initial counterclockwise gyre to the final clockwise gyre the roughness of the bed showed strong local variations. It should be mentioned that all the flow patterns shown in the Figures (d) remained during the subsequent 2.5 hours of observation.

Figures 7(e), 8(e) & 9(e) present the flow patterns for the three test procedures After stopping the flow, clear water (without sediment) has been injected into the basin to investigate the further evolution of the bed at different time periods. The flow patterns in Figures 7(e) & 8(e) are similar and equal to the pattern of Figure 9(e). After restarting the flow it chooses the easiest path from the inflow to the outflow gate along the left side wall. The sedimentation from the previous period has apparently become too much of an obstacle to result again in a symmetric flow pattern. It shows at least that the symmetric flow pattern is not a very stable one and that in the long run it would have changed into one of the more stable asymmetric patterns anyhow.

3.2 *Morphological development*

This section presents a comparison of all test series for the time evolution of the bed. Figures 10 to 12 present a detailed comparison of final bed elevation, 3D for sediment thickness layer after 4.5 hour and the contours of deposition patterns. For all the tested scenarios, two typical features were observed. The first was development of sediment deposition with ripples formation concentrated on the right hand side and along the center line later on; the second was concentrated on both right and left sides and very low in the core of the basin. In the following sub sections the results will be described with further details.

Figure 10 presents the final bed elevations after 4.5 hours of testing of series 1. The mixture of water and sediment is advected and diffused throughout the basin following the general flow patterns described above. The footprint of the flow patterns was clearly visible in the morphology as shown in Figure 10(a). The resistance to flow is relatively small for the smooth and plane bed at the start. However, the flow resistance increases as ripples are being formed. The ripples play an important role in the interaction between the boundary layer flow structures and sediment transport.

Copyright © 2006 Taylor & Francis Group plc, London, UK

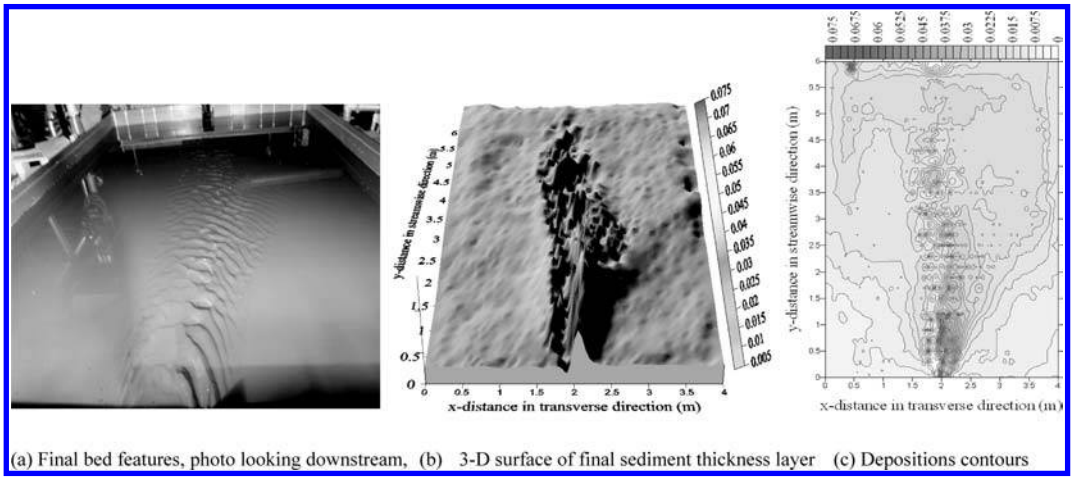

Figure 11. Morphological results after 4.5 hrs of sediment supply for Series 2.

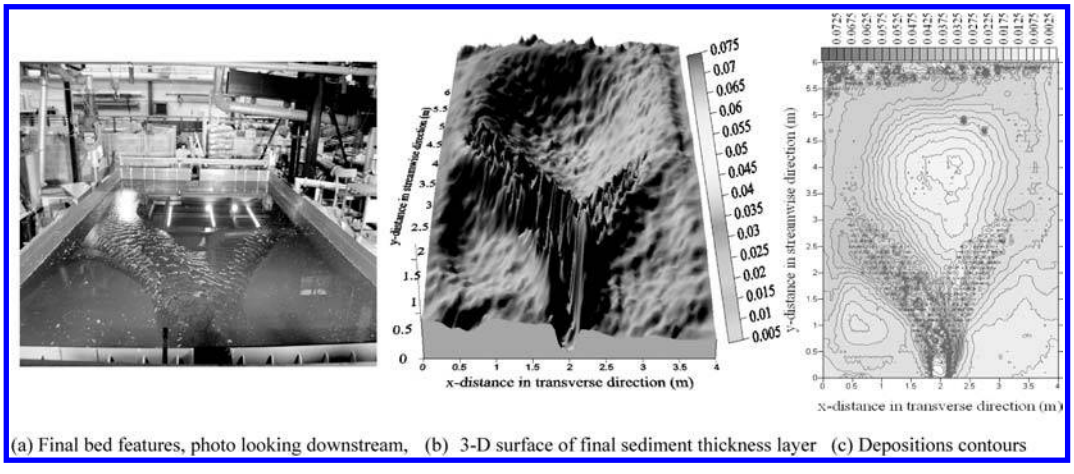

Figure 12. Morphological results after 4.5 hrs of sediment supply for Series 3.

Figure 10(b) shows the processed 3D surface bed elevation for the test series 1 after 4.5 hours. The asymmetric ripple patterns near the right side wall follow the same direction as the flow pattern shown in Figure 7. Ripples characteristics were measured manually before cleaning the basin. Moreover, several reference points were taken manually for calibration comparison with the UWS measurements. It was found that the UWS measures with a high accuracy of ± 1 mm and it's similar for the manual measurements. Nevertheless, some anomalous spikes are observed in Figure 10(b). Figure 10(c) presents the contours for the sediment thickness layer. It can be easily seen that most of the sediment depositions has take place around the centerline and the downstream part. It may be concluded that a stable morphology has been reached after 4.5 hours whereas possibly a longer run would needed to confirm the question of full morphological equilibrium in the basin.

The sediment concentration and sediment depositions are highest along the centerline of the basin and reduce towards the sides as shown in Figures 10 & 11. Figure 11 shows the evolution of the sediment depositions for the test series 2 (repeated test). The figure shows an almost similar sediment deposition pattern as was found for the series 1 presented in Figure 10.

There is a complex relation between flow patterns, sediment exchanges and sediment transport as well. Figure 12 shows the results for the series 3 obtained after 4.5 hours of test run. Figure 12(a) presents a picture of the final bed evolution. It is noticed that the sediment deposition takes place in accordance with the flow patterns of Figures 9(a)–(d). In the beginning it starts to form ripples near the right side wall

Copyright © 2006 Taylor & Francis Group plc, London, UK

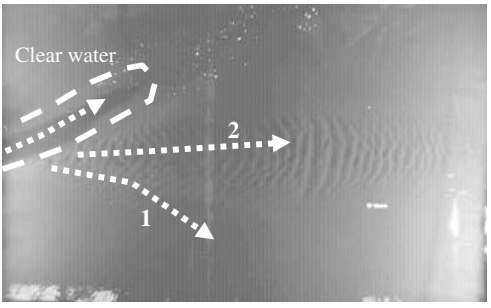

Figure 13. Plan view for the test series 2 with the clear water inflow without sediment.

leaving the area in the upstream corner void, which is associated with action of the small gyre.

From Figure 12(b) it is clearly seen that the deposition at both upstream corners is very small. Most of the sediment deposits right below the main streamlines connected to the inflow channel. After the flow pattern has changed to the clockwise gyre, a symmetric ripple pattern formed near the left side wall, similar to the one at the right side which formed in the beginning. After a certain period of testing, the deposition on the left side gradually increased generating a wider bed elevation underneath the jet centerline with a width of approximately three times the inlet channel. Similarly, in the first few hours of the experiment the elevated bed has reached the right side wall and followed the course of the streamlines down to the outlet channel. It is remarkable that in the downstream part of the basin the bed is elevated on a rather narrow ridge. Figure 12(c) shows the contours for the sediment layer thickness. Here the relatively steep gradients near the inlet channel and the first part of the jet are clearly visible. It is quite likely that on a much larger time scale the relatively quiet zone in the upstream corners and the central part of the main gyre will eventually be filled up with the finest sediment fraction.

The final bed morphology obtained from test series 2 was used as the initial topography for a clear water test. Here, clear water without sediment was introduced into the basin to investigate the further bed evolution under those circumstances. Figure 13 present the final bed deformation after 6 hours of clear water test. The most important change was found in the erosion of the bed near the entrance. No significant change has been observed anymore between the respective bed profiles after that period. Hence, for these flow and sediment conditions, the bed might be considered as stable.

4 CONCLUSIONS

The first results of ongoing research on the influence of the geometry of a shallow reservoir on suspended sediment transport and deposition have been presented. The mechanism of sediment transport and deposition in the basin differs according to the test procedure. In the discontinuous feeding procedure, the gradual changes during the transitional state are missing due to the effect of stopping and restarting the flow. For the continuous feeding procedure, it was easy to reach a stable flow and bed form in the basin after 4.5 hours. Whether this represents a long-term equilibrium morphology will be checked by subsequent tests. It was found that the flow and sediment patterns are quite sensitive to the boundary and initial conditions. Although it is clear that an asymmetric flow pattern is favored, a symmetric pattern can persist for quite a long time. The experiment also shows the mutual interaction between flow and bed forms and the substantial increase in complexity when sediment transport and morphodynamics play a role.

Regarding the continuation of this research project the major goal is to find out which reservoir geometry leads to minimum sediment deposition. This requires experiments of long duration combined with numerical modeling techniques that include the processes as observed in this study.

Effects of flushing of two reservoirs in Spain

R. Cobo Rayán
Centro de Estuduios Hidrográficos (CEDEX), Madrid, Spain

C. Mateos Iguacel
E.T.S. Ingenieros de Caminos, Canales y Puertos, Madrid, Spain

ABSTRACT: This paper is a summary of the main results of two flushing operations, one at the Barasona Dam (Huesca, Spain) and the other at the María Cristina Dam (Castellón, Spain). In the Barasona Reservoir the flushing was carried out using the bottom outlets in a short space of time during which a massive discharge of sediment took place. The effects of the full emptying were significant in terms of impacts on various physical and chemical variables, especially oxygen and ammonia. These changes were less intense downstream where the return to their former values was very fast due to the washing effects of natural floods. In María Cristina reservoir the flushing took place in a slower manner over several days without an appreciable quantity of sediment being mobilized.

1 INTRODUCTION

In Spain, the flushing of sediments from reservoirs has taken place since ancient times. In the East of Spain this activity has been especially important (Examples include: Puentes dam. Almansa, Tibi, Elche and Valdeinfierno dams). The procedure followed in the XVIIIth and XIXth Centuries was based on opening the bottom outlets at the same time as the first floods occurred. In this way the water removed part of deposited sediments.

Currently, this practice is less commonplace for environmental concerns and the fact that modern reservoirs are much bigger with a longer expected service life. Nevertheless, reservoir capacity recovery is a necessity that will become more and more important in the future.

In this paper two important recent cases will be discussed. The effects of the flushing operation made in the Barasona Reservoir were closely followed by multidisciplinary studies (Palau, 1988; Avendaño and Cobo, 1988) starting from the "LIVRE" French experience (Cardinal, 1989).

The flushing of María Cristina Reservoir had completely different characteristics: this flushing was accidental so only the end of the flushing operation could be observed.

2 CHARACTERISTICS OF THE RESERVOIRS

Barasona Reservoir which lies in the Esera river, in the Ebro Drainage Basin, came into operation in 1932. From that year until the end of 1993, approximately 18 hm3 of sediment were deposited in it. The height of sediment was 25 m adjoining the dam. Barasona is a gravity dam some 65 m in height and 80 m in crest

length. The reservoir capacity is 92 hm3, and is used for irrigating lands, water supply and hydroelectric power.The bottom outlets are located in two tunnels with three bottom gates for each one.

The Esera river downstream of the dam is 6 km long and its rocky bed lies within a narrow gorge.

The María Cristina reservoir lies on the River Rambla (Gully) de la Viuda in the Júcar Drainage Basin. It came into operation in 1920, and from that year until 2000, 9.6 hm3 of sediment were deposited in it (CEDEX, 1994). The height of sediment was 18 m next to the dam. It is a gravity dam of 59 m height and 318 m crest length. The reservoir has a capacity of 28 hm3. and is used for irrigation.

The Rambla de la Viuda flows through a wide and not very sharp valley.

3 FLUSHING OF MARIA CRISTINA RESERVOIR

The flushing of María Cristina Reservoir took place through an old discharge intake for irrigating land, following the rupture of a concrete plug.

The discharge intake had only a 1 m^2 of cross section, and, therefore, the resulting water flow was small. Full emptying lasted several days during which attempts were made to stop the discharge of water.

When the reservoir was completely empty, it could observe that the sediment had not been mobilized. Downstream of the dam no effects were observed on the river bed nor on the different biological communities.

4 FLUSHING OF BARASONA RESERVOIR

Flushing began on 12th October at 03:00 hours and finished at 20:00 hours. During this time the concentration of solids in suspension were less than 1 g/l. Immediately following the flushing, sediment began to slip through the bottom outlets, with a peak flowrate of 600 g/l.

Later, a fluvial flow began to erode the deposits of sediment giving rise to a concentration ranging from 80 to 100 g/l. The discharge varied from 180 m3/s at the beginning of flushing to 140 m3/s at the end. The fluvial flow dropped to 40 m3/s presenting a series

Figure 10. View of the upstream side of dam.OLS: original level of sediment.

of pulses due to the blocking and unblocking of the bottom outlets resulting from the eroded sediment.

The water temperature increased during the flushing, from 14°C (when flushing started) up to 16°C (when the superficial water came out). Following that there was an abrupt fall down to 12°C.

The turbulence taking place during the flushing operation caused oxygen levels to increase up to 10% of saturation. A few minutes after flushing finished the oxygen value went to zero (anoxia). The anoxia condition lasted one day. After that day it started to recover reaching 20% of saturation on the 3rd day and 70% on the 4th day.

The ammonia presented a first peak due to percolation water. After that it decreased during flushing until the moment of the exit of sediment. At that moment a concentration of 3.5 mg/l was reached.

Fish communities upstream of the dam were badly affected by the flushing, due to adults living in the reservoir. In the fisheries downstream the effect was less strong because fisheries were disturbed by the low flow regulation before flushing. (Morillo and García Jalón, 1998).

Aquatic birds showed intense changes in their use of space during the weeks following the flushing. Six months later, a considerable recovery was observed. (Rossel *et al,*1998).

The effect in the riparian vegetation were minimal. There were no significant changes in composition and structure of woody plants communities. (Alcázar and Ferrán, 1998).

After the flushing, upstream of the dam, a great quantity of sediment stored in the river bed was mobilized. This sediment occupied 2 km of channel with some 8 m average height.

5 CONCLUSIONS

The biggest effects, downstream of the dam, took place when the flushing happened quickly and the reservoir is completely empty.

If the flushing is interrupted before all the water is discharged, or flushing is carried out very slowly, the effects are almost null.

Time evolution of erosion depth and sediment motion for abutment scour in a pressure duct

A. Radice, S. Malavasi & F. Ballio
Politecnico di Milano, Dept. I.I.A.R., Milan, Italy

ABSTRACT: We present the results of abutment clear water scour experiments that were run in a pressurized rectangular duct. Simultaneous measurements of the scour depth and of sediment kinematics were made, in order to support analysis of the measured erosion trends via that of spatial and temporal distribution of sediment fluxes. The latter were measured by image processing from movies of the phenomenon in progress. Measured erosion trends were preliminarily compared to results of standard experiments with a free surface flow, founding that neither the time development of the maximum scour depth nor the scour hole shape were significantly affected by the flow pressurization. Features of sediment kinematics are dependent on the achieved scour levels, in that grain motion is rather regular in time during the first part of the scour process, and becomes more and more variable as a larger scour hole has been scoured. On the other hand, the initial stable sediment motion induces great erosion rates, while successive unsteadiness determines a lower effectiveness of sediment activity. The structure of the sediment pattern is also variable with time, showing an increasing weight of the vortical components of the flow field in determining local scour.

1 INTRODUCTION

Local scour at bridge structures has been extensively studied both experimentally and theoretically over the past fifty years, due to its economical and strategic fallouts.

A typical experimental approach to the phenomenon is the 'black box' analysis, where the dependence of a state variable (typically the maximum scour depth) on a set of bulk control parameters is investigated to tune prediction equations (see for example Coleman et al. 2003).

Experimental and numerical studies of the flow field around the obstacle have been made over the last thirty years in order to clarify the physics of the phenomenon, which cannot be investigated by black box experimentation (examples of such studies for bridge abutments are Kwan & Melville 1994, Barbhuiya & Dey 2003, Ouillon & Dartus 1997, Chrisohoides et al. 2003).

Sediment motion in local scour has not been quantitatively studied, despite some qualitative descriptions can be found in the literature. Analysis of grain kinematics represents the ideal complement to flow field study for a deeper phenomenological description of the process, since grain motion is the immediate consequence of the scouring flow field; furthermore, the composition of sediment fluxes determines the progression of local scour, that makes the analysis of sediment motion an important support to the interpretation of the large scale scour trends.

Eventually, availability of sediment motion data could significantly support calibration of water – sediment interaction equations, to be used in the numerical modelling of the temporal development of local scour. Such modelling has been made in the last years using the typical transport equation for one dimensional bed load on a plane bed (see for example Olsen & Kjellesvig 1998).

In this work we present results of abutment scour experiments where sediment kinematics was measured. The phenomenon in progress was filmed during the experimental tests; next, some image processing techniques recently set by the Authors were applied to the movies. In this way, complete non-intrusiveness of the measure was achieved. The experiments were run in a transparent pressurized rectangular duct, which allowed observing the scour process from the top without the need to locally inhibit the distortion effect of the free surface. Prior to grain motion analysis, similarity between the scour depth trends here obtained and those from earlier experiments with a free surface was verified.

2 EXPERIMENTAL CAMPAIGN

The experimental duct is 5.8 m long, with a rectangular transversal section having width and height equal

Copyright © 2006 Taylor & Francis Group plc, London, UK

to 40 and 16 cm, respectively. The whole duct is made of plexiglass to assure complete transparency of the walls. An upstream and a downstream tank complete the experimental installation; the hydraulic head in the duct is imposed by a Bazin weir posed in the outlet tank. Water entrance in the duct is guided by a streamlined inlet to avoid wake effects in the flow.

The test reach of the duct is deeper than the other parts; it was filled with PVC cylinders having median equivalent diameter $d_{50} = 3.6$ mm, a uniformity coefficient very close to 1 and specific gravity $\Delta = (\rho_s - \rho)/\rho = 0.43$, where ρ_s and ρ are the densities of sediments and water, respectively. In the upstream and downstream reaches, the same bed roughness is obtained by gluing the PVC grains to steel sheets posed onto the duct bottom; as a result, the effective duct height is $h = 15.5$ cm.

The abutment model is located at about 3.4 m from the duct inlet; it is a vertical plate made of transparent PVC, whose dimensions are 10 cm and 1 cm in the transversal and longitudinal directions, respectively.

Water discharge is measured by a magnetic flowmeter posed on the delivery pipe.

Test starting procedure was different from the standard ones for free surface channels. The granular bed was initially levelled, then the duct was filled with water at a very low rate prior to cover closure, to be able to correct any bed perturbation by the incoming flow. Once the water level reached some centimetres, steady conditions were imposed and the duct cover was closed. A two-component resin (DELO AUTOMIX 1895) was used to seal the cover; the use of such a material was preferred to traditional rubber washers, since it allowed a perfect sealing with a vanishing thickness. The resin needed about 24 hours to catalyze; as a result, the test could start only the next day from the duct closure. The water level was incremented until complete filling of the duct. Next, after eliminating the water bubbles accumulated in the upper part, water discharge was gradually increased to the test value; the transition lasted about 30 s.

The scour depth d at the abutment nose (see Fig. 1) was continuously measured by a laser distance sensor (Baumer Electric OADM 20I44/S14C) posed just over the duct ceil. During the test, the scouring process was filmed via a black and white CCD (SONY XC-8500 CE) capable of 50 fps with a resolution of 576×763 pixel. Duration of every movie was equal to 20 s. The digital images were used for two purposes: (i) to measure sediment kinematics by means of proper image processing described in the following; (ii) to measure the scour depth at the lateral wall. The transversal profile of the scour hole on the upstream face of the obstacle can be seen in the images; it is then possible to evaluate scour at the lateral wall by comparison with that at the abutment nose, whose value is known thanks to the laser measures.

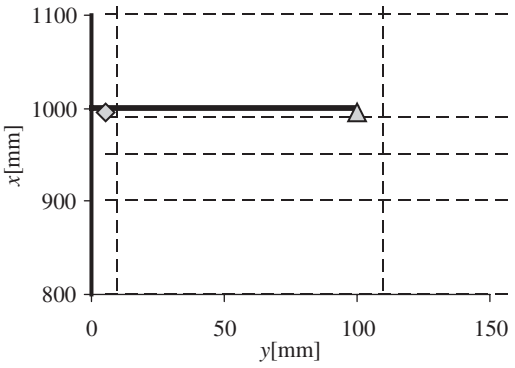

Figure 1. Planimetric definition sketch. Symbols: ▬ duct lateral wall and abutment; ▲ abutment nose measuring point; ♦ lateral wall measuring point; - - - surveyed sections of the scour hole. Flow is from bottom to top.

Profiles of transversal and longitudinal sections of the scour hole were surveyed one or two times during the tests, in order to measure also the scour hole shape. We surveyed transversal sections at $x = 700$, 800, 900, 950, 990 mm (sections upstream of the abutment); transversal sections at $x = 1100$, 1200, 1300, 1400, 1550 mm (downstream of the abutment); longitudinal sections at $y = 10$, 110, 200 mm. Some of the surveyed sections are presented in Figure 1.

We performed four experimental runs with the same water discharge ($Q = 18.5$ l/s), to verify repeatability of the experimental procedure. Water discharge was chosen as that inducing the incipient motion of the bed particles. Following Ballio & Orsi (2001), we defined the threshold conditions as those corresponding to a dimensionless longitudinal solid discharge per unit width equal to $\Phi = q_{sx}/(g \cdot \Delta \cdot d_{50}^3)^{0.5} = 5.7 \cdot 10^{-5}$, where q_{sx} is solid discharge per unit width and g is gravitational acceleration.

3 TEMPORAL AND SPATIAL DEVELOPMENT OF SCOUR DEPTH

Measured scour depth evolution upstream of the abutment is presented in Figure 2 with reference to run 2. Local scour begins at the abutment nose, where the largest scour values were measured during the first part of the process. The plot shows that time evolution of scour depth in this point can be well approximated by two straight lines in the semi-logarithmic plot: the first is steeper than the second, and the change in slope occurs after about 100 s of run. During the first 15–20 s, no scour occurs at the lateral wall; after activation, the scour development in this point can be approximated by a straight line, having a slope almost equal to that of the first line corresponding to the abutment

Copyright © 2006 Taylor & Francis Group plc, London, UK

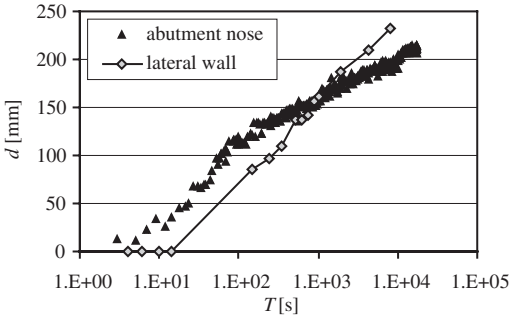

Figure 2. Temporal development of scour depth d upstream of the abutment for run 2. Refer to Fig. 1 for point position.

nose scour trend. After change in slope of the latter, the scour rate at the wall is larger than that at the nose; as a result, after about 900 s of run the scour depths at the nose and at the wall are equal. After this time, maximum scour depth is stably located at the lateral wall. Present result are consistent with earlier ones obtained for free surface experiments (Radice et al. 2002), demonstrating that the flow pressurization does not influence the qualitative features of the erosion process.

Scoured profiles of some transversal and longitudinal sections of the scour hole are presented in Figure 3 for run 2 and time $T = 9000$ s. For such experimental time, maximum scour depth location is stably at the lateral wall. The transversal sections upstream of the abutment have a more or less triangular shape, with a larger slope for the sections closer to the abutment (Fig. 3, a). The transversal sections downstream of the abutment present a sediment plume near the left wall. Sediments are conveyed downstream along two separate channels separated by a sediment ridge (particularly evident for the section at $x = 1400$ mm), whose formation is presumably due the structure of the wake generated by the obstacle. The longitudinal sections present the maximum scour depth in proximity of the abscissa of the abutment; the slope of the scoured profile is larger upstream than downstream, where the sediment are simply conveyed by the flow overpassing the obstacle. Figure 4 presents the three-dimensional reconstruction of the scour hole obtained from the sections of Figure 3, that synthesizes all the observations drawn before. The scour hole shape is consistent with that obtained during experiments with a free surface (Ballio & Orsi 2001); again, the pressurized flow did not affect the scouring process features.

The scour depth evolution at the abutment nose is presented for all the experimental runs in Figure 5. All the experimental curves are qualitatively similar, with some differences in the absolute scour values. For $T < 100$ s, differences are mainly due to the non perfect repeatability in the experimenter recognizing the ideal

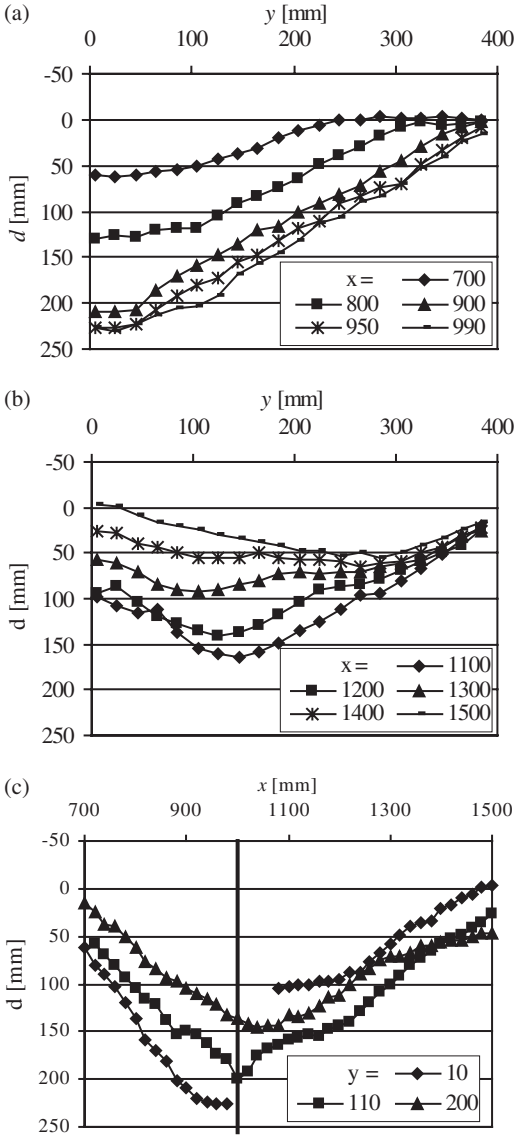

Figure 3. Surveyed section of the scour hole for run 2, time $T = 9000$ s. starting instant of the process within the transitional phase in which the water discharge is gradually set up to the final value; anyway, after less than two minutes the differences between the four scour trends become negligible, demonstrating that the starting procedure is acceptably repeatable. Then, the scour depth trends

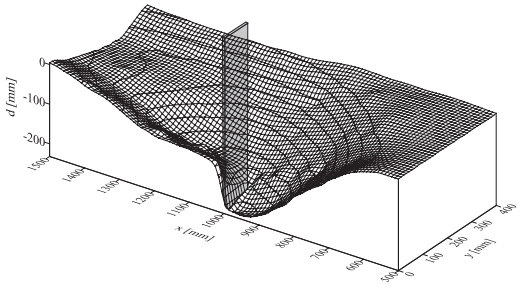

Figure 4. Three-dimensional representation of the scour hole for run 2, $T = 9000$ s.

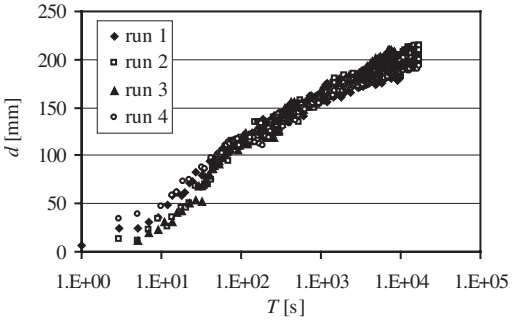

Figure 5. Temporal development of scour depth upstream of the abutment nose for all the experimental runs.

remain very close one to another until time $T = 1000$ s; after this time, the curves relative to the tests remain linear in the semi-logarithmic plot, but present different slopes; this can be due to instabilities either of the scour process for high experimental times or of the experimental installation itself. Anyway, for our test duration the difference between the final scour depth values is smaller than 10%.

4 IMAGE PROCESSING

Sediment motion can be quantified through independent measurement of concentration and velocity of the moving particles. In fact, the vector solid discharge per unit width (hereafter simply called solid discharge) can be calculated as $\boldsymbol{q_s} = C \cdot \boldsymbol{v_s} \cdot d_{50}$, where C is the aerial sediment concentration and $\boldsymbol{v_s}$ is sediment velocity.

Sediment concentration was measured via an image difference technique: consecutive frames in a movie were subtracted to highlight the occurred movements; the difference images were then thresholded and filtered to eliminate the noise and to obtain the definitive image of the displaced particles. After counting the number of displaced particles N, the corresponding concentration could be easily calculated as $C = (N \cdot W_g)/(\Delta x \cdot \Delta y \cdot d_{50})$, where W_g is the volume of a single particle, and Δx and Δy are the dimensions of the measuring cell. Sediment velocity was measured by applying a Particle Image Velocimetry algorithm to a couple of successive difference images. The measuring techniques are more thoroughly described in Malavasi et al. (2004) and in Radice et al. (2004).

Measures of both grain concentration and velocity require definition of spatial and temporal support scales, that have to satisfy opposite requirements. The spatial measuring scale has to be large enough in comparison to grain dimension, to allow for an eulerian continuous representation of movement; on the contrary, it has to be small enough to allow observing the spatial variability of grain motion. The temporal measuring scale has to be large enough to observe non vanishing grain movements between one instant and the next; on the contrary, a too long temporal scale compromises the measures due to dispersion of the grains. In this work, we used spatial measuring cells whose dimension was 2×2 cm^2, while the time sampling interval was the maximum allowed by the CCD, i.e. 0.02 s. Effect of variation of the support scales on the measure are described in Radice (2005).

5 SEDIMENT KINEMATICS

5.1 *Scour activation*

Time evolution of the magnitude of solid discharge is presented in Figure 6 for the start of run 2. Film capturing was started as soon as a non negligible number of moving grains was observed; this is also the condition we chose to identify the start of the process. The presented trends refer to locations in the proximity of the two points were scour depth was measured, i.e. the abutment nose and the lateral wall. Sediments start to move at the abutment nose, where a solid discharge of about 40 mm^2/s was measured since the beginning of the experiment (Fig. 6, a). In the earliest instants, no movement occurred in the proximity of the lateral wall, where the first appreciable motion could be seen after about ten seconds from what we considered the start of the process (Fig. 6, b). Sediment movement a little upstream of the abutment nose (Fig. 6, c) is weak (despite not null) in the first instants, suddenly growing after some seconds.

These observations indicate that at the very beginning of the process, only in the proximity of the obstacle nose the flow field is able to move many grains; given the obvious relation between the scour rate and the spatial distribution of solid discharge:

$$\dot{d} \cdot (1 - p) = \mathrm{div}(\boldsymbol{q}_s) \qquad (1)$$

where p is porosity, precedent observations are in agreement with scour starting at the abutment nose

Copyright © 2006 Taylor & Francis Group plc, London, UK

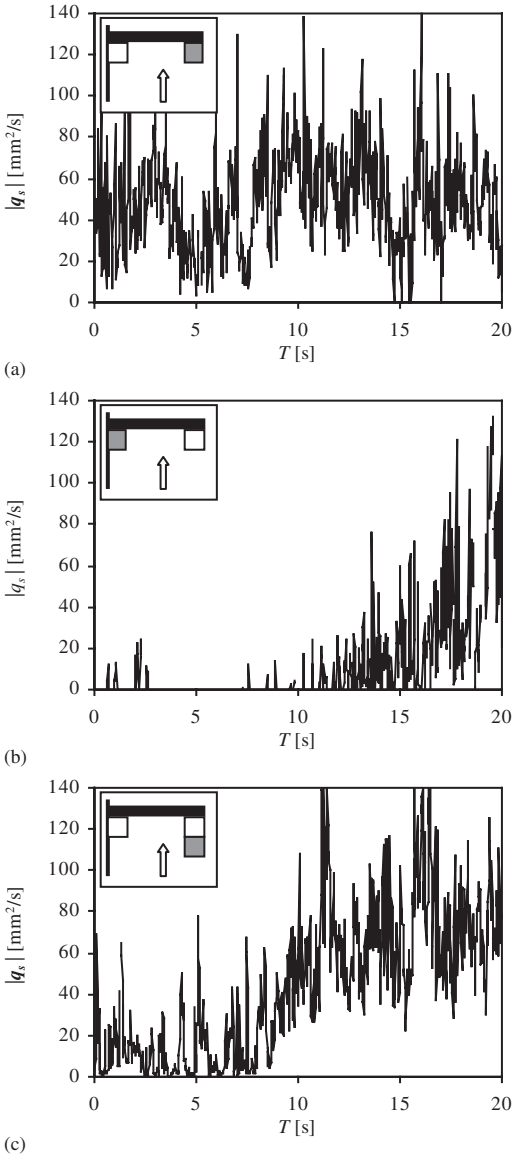

Figure 6. Temporal evolution of measured solid discharge at the start of run 2 upstream of abutment nose (a), in the proximity of the lateral wall (b), and 3 cm upstream of the abutment nose (c). The measuring position is indicated; dimension of measuring cells is $2 \times 2\,cm^2$.

(Fig. 2). From a phenomenological point of view, grain movement at the nose at the test start is very effective, since it is not a simple conveyance of sediments started elsewhere, but a real entrainment of grains from this region, which results in the great erosion rate at the start of the process (Fig. 2). After some moments, grains start to move also elsewhere; it is not clear if first movements are sediment sliding into the developing scour hole or sediment entrainment by the flow field, presumably a combination of both dynamics.

This result is a first index that the phenomenological features of the scouring process evolve during the experiment, since the position where for the developed stages there is the largest scouring activity (the corner region) is completely still in the initial condition of plane bed.

5.2 *Statistical analysis of solid discharge*

Average solid discharge fields around the obstacle are presented in Figure 7 with reference to run 2 and three experimental times, corresponding to the start of the experiment ($T = 0$–20 s), to a time at which scour depths at the nose and at the wall are almost equal ($T = 760$ s), and to the end of the experiment ($T = 17000$ s). The last plot was obtained averaging data from eight consecutive 20 s movies, while each of the former two was derived from a single movie of the same duration; possibility to accumulate movies for the largest experimental time is allowed by the logarithmic evolution of the scour process. The magnitude of average solid discharge was calculated as the composition of the average components along the coordinate axes:

$$q_{s(l)} = \sqrt{\left(\sum_{i=1}^{n} \frac{q_{sx,i}}{n}\right)^2 + \left(\sum_{i=1}^{n} \frac{q_{sy,i}}{n}\right)^2} \qquad (2)$$

where q_{sx} and q_{sy} are the instantaneous components of solid discharge along the coordinate axes and n is the number of measured solid discharge data.

It is evident the decreasing trend of solid discharge all around the abutment, that reflects a general diminishment of the erosive power of the flow field due to the progressively smaller blocking effect of the abutment as the scour hole is eroded.

Maximum solid discharge is located in the proximity of the abutment nose at the beginning of the experiment (Fig. 7, a); it decreases both upstream and towards the lateral wall. This result is the composition of two effects: first, in the nose region all the grains entrained elsewhere by the flow field are conveyed downstream; second, the low average values away from the nose are also determined by the initial stillness before scour activation (see Fig. 6, b and c), since all the zero values were non disregarded in computing the mean.

Streamlines obtained from the average solid discharge vector field are also plotted; for $y > 70$ mm, the sediments seem to be transported by the planimetric deviation of the flow field. Near the wall the streamlines are directed upstream, indicating the action of the principal vortex created by the downflow in front

Copyright © 2006 Taylor & Francis Group plc, London, UK

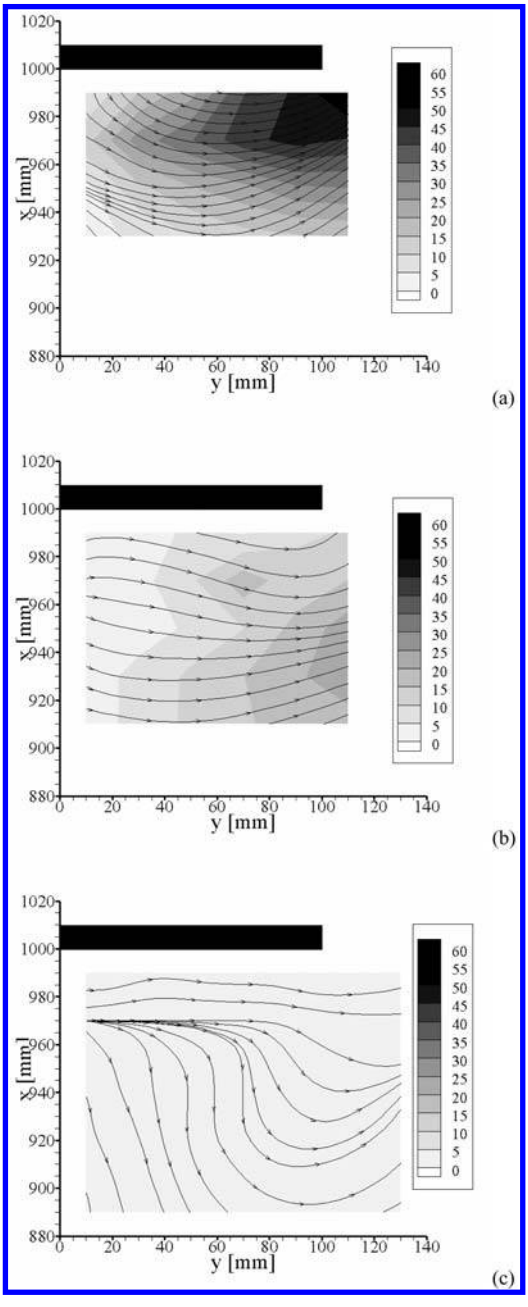

Figure 7. Spatial distribution of average solid discharge $q_{s(1)}$ given by (2) for run 2. Time $T = 10$ s (a), 760 s (b), 17000 s (c). Average streamlines are also indicated.

of the obstacle. In this phase, the vortex appears to be highly stretched by the outer flow field. The solid discharge magnitude increases along all the stream tubes, coherently with the general bed level decreasing.

The average solid discharge field is presented in Figure 7 (b) for an experimental time $T = 760$ s. Again, average solid discharge is minimum at the wall, increasing as the nose region is approached, due to the conveyance of all the sediments. Maximum solid discharge is not close to the abutment nose, but rather a little upstream of it ($x = 930$ mm), due to the presence of appreciable upstream movements also near the abutment nose. The scoured erosion hole determines a smaller concentration of flow at the nose, thus the principal vortex is less stretched than at the beginning of the test. Combination of these effects determines, on average, the existence of a sediment channel about 50–70 mm upstream of the nose.

Observation of the same plot for $T = 17000$ s (Figure 7, c) shows that the magnitude of average solid discharge is rather uniformly distributed in space in comparison to the precedent instants. The sediment pattern resulting from the average streamlines is completely different from what previously seen: upward direction indicates the global action of the principal vortex; all the streamlines come from a small location near the lateral wall ($x = 970$ mm, $y = 0$), showing that this point acts as a sediment source for all the others. This could be a reason for the maximum scour being located at the lateral wall.

Presented results are consistent with those obtained by the Authors in previous works (Malavasi et al. 2004, Radice et al. 2004) dealing with local scour in a free surface channel. Again, there is no substantial distortion imposed to the scour process by the flow pressurization.

Average streamlines are again presented in Figure 8, together with contour lines proportional to average magnitude of solid discharge; in this case, the latter was calculated as the average of the instantaneous magnitudes:

$$q_{s(2)} = \frac{1}{n}\sum_{i=1}^{n}\sqrt{q_{sx,i}^2 + q_{sy,i}^2} \qquad (3)$$

This gives a different information from that given by the magnitude of the average flux $q_{s(1)}$ given by (2): in fact, now we are observing the average intensity of sediment motion regardless of the direction, while the magnitude derived by the average components can be diminished by the presence of opposite direction vectors. The maps in Figure 8 present everywhere larger values than the corresponding ones of Figure 7, indicating that the presence of opposite direction movements is considerable. The increase in the magnitude of solid discharge is most evident in Figure 8 (c), where sensibly higher values are observed upstream of the abutment nose; it can be inferred that in this positions the presence of opposite direction movements is particularly frequent. Direct observation of the phenomenon in progress shows that the opposite events may correspond to grain entrainment by the principal

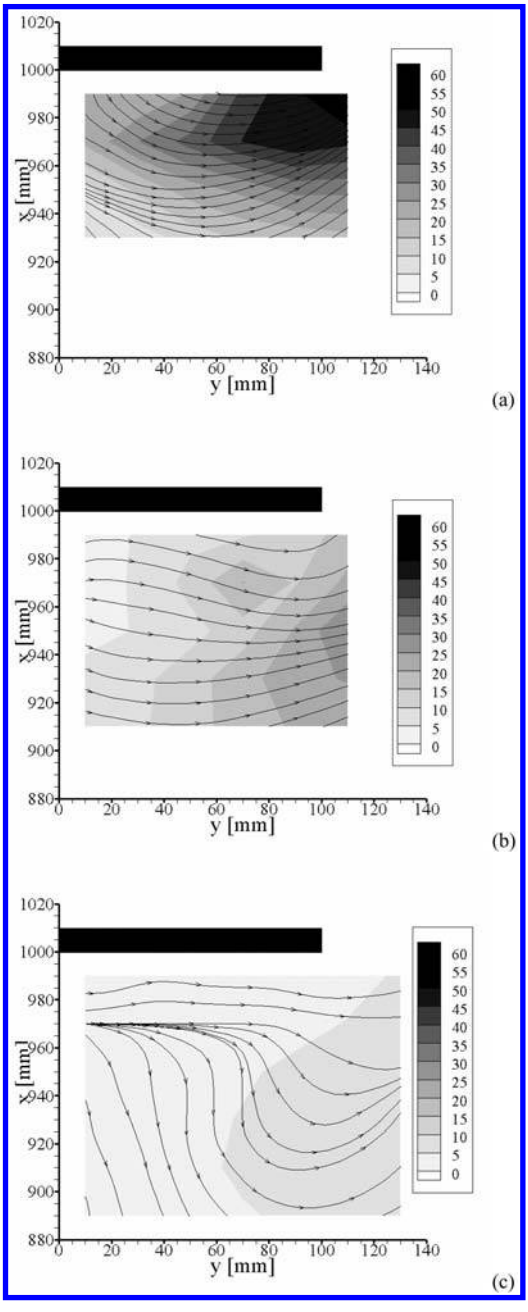

Figure 8. Spatial distribution of average solid discharge $q_{s(2)}$ given by (3) for run 2. Time $T = 10$ s (a), 760 s (b), 17000 s (c). Average streamlines are also indicated.

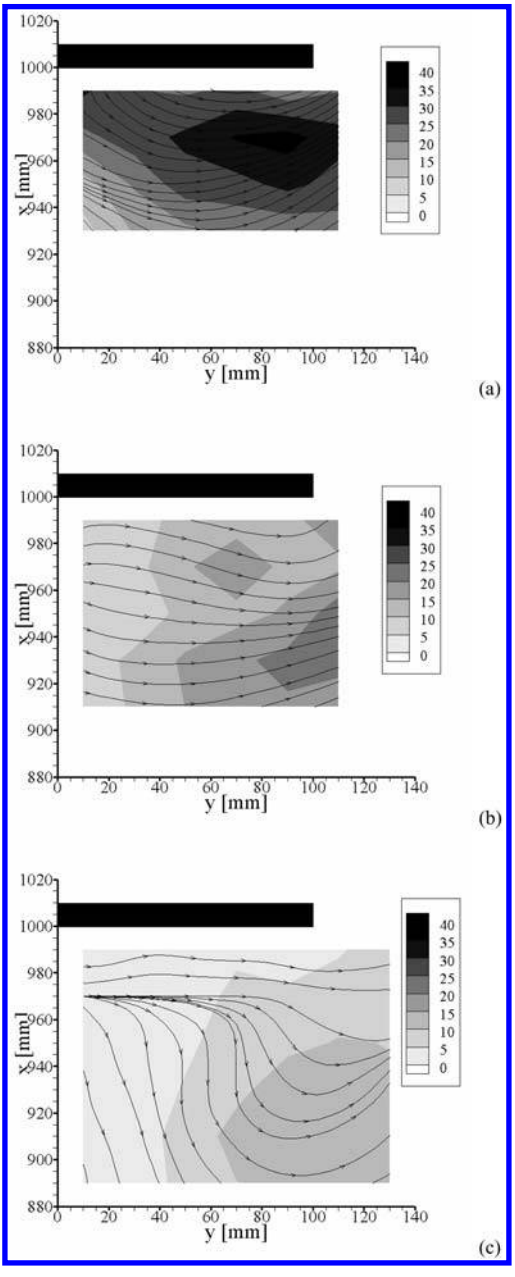

Figure 9. Standard deviation of average solid discharge around the abutment for run 2. Time $T = 10$ s (a), 760 s (b), 17000 s (c). Contour lines are proportional to $\sigma_{|qs|}$ [mm^2/s]. Average streamlines are also indicated.

vortex and to sediment sliding towards the bottom of the scour hole; it is evident that only the first type of movement are induced by the flow field, while the others are substantially related to endogenous instabilities of the scour hole. It is remarkable that if one wants to compare the statistics of grain motion and those of the scouring flow field, he should consider just the movements due to the flow field and not those due to sediment sliding.

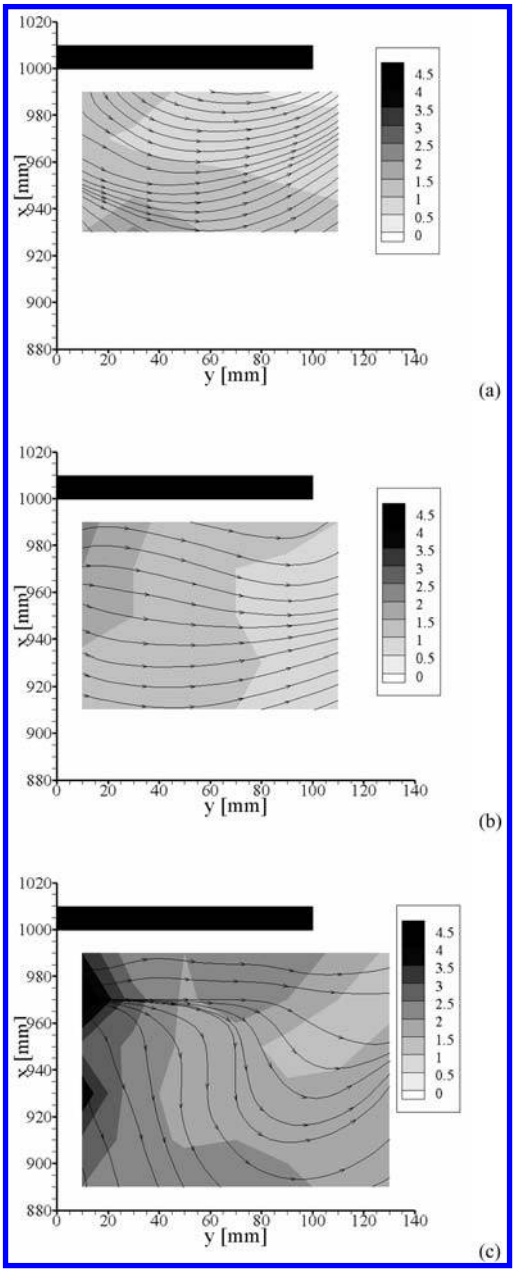

Figure 10. Variation coefficient of average solid discharge around the abutment for test 2. Time $T = 10$ s (a), 760 s (b), 17000 s (c). Contour lines are proportional to $CV_{|qs|}$. Average streamlines are also indicated.

Figure 9 presents spatial distributions of the standard deviation of solid discharge for the previously shown experimental times. Also the standard deviation of solid discharge decreases as scour proceeds. Furthermore, there is a general correspondence between positions of large solid discharge and those of large standard deviation (compare Figs. 8 and 9). The only exception is represented by time $T = 10$ s, where the position of maximum standard deviation is upstream than that of maximum average solid discharge. At the test beginning, grains are initially still, then solid discharge reaches large values after scour activation (Fig. 6, c). The presence of two distinct populations (zero and high values) determines the high standard deviation value.

Figure 10 presents the variation coefficient of the solid discharge (defined as the ratio between the standard deviation and the average value of Fig. 8). In this case, there is a correspondence between the positions of larger sediment activity and those of smaller variation coefficient. The largest values of CV were measured near the lateral wall for time $T = 17000$ s; again, it is possible such values be due to the very high number of zero values in the solid discharge for these locations. Finally, the variation coefficient increases as time proceeds, differently from both the average and the standard deviation, indicating that average values decrease at a higher rate than the standard deviation. As time proceeds, irregularity becomes higher and higher in respect to the sediment activity, indicating a growing role of the unsteady components of sediment motion.

6 CONCLUSIONS

Our works leads to the following major conclusions.

- The pressurized flow does not significantly alter the scour process features, in terms of both the temporal trend of the scour depth and the shape of the erosion hole. In particular, maximum scour is initially at the abutment nose; it successively migrates towards the channel wall.
- Sediment motion is initially mainly due to the planimetric deviation of the flow field; afterwards the action of the three dimensional principal vortex becomes more and more evident thanks to the formation of the scour hole, that reduces the blocking effect of the obstacle.
- Sediment motion analysis can support interpretation of the large scale erosion trends; with reference to the maximum scour displacement, we showed that no motion initially occurs in the corner region, while afterwards all the average sediment streamlines originate from this position.
- Average solid discharge decreases as time proceeds; a similar behaviour was obtained for the standard deviation but not for the variation coefficient, indicating a non similarity in the diminishment of intensity and irregularity of sediment motion.

Local scour at elliptical guide banks in plain rivers

B. Gjunsburgs, R.R. Neilands & E. Govsha
Civil Engineering Faculty, Riga Technical University, Riga, Latvia

ABSTRACT: The scour development in floods at abutments (Gjunsburgs & Neilands 2001, 2004, 2005, Gjunsburgs et al. 2004, 2005, 2006) and at elliptical guide banks is studied. The scour hole extents at abutments and guide banks are different. At the upstream head of the elliptical guide banks, a streamline concentration, a local increase in velocity, and the development of a scour hole were observed. The differential equation of equilibrium for the bed sediment movement under clear-water conditions is used, and a method for computing the scour development in floods at elliptical guide banks is elaborated. The method is confirmed by experimental data. The "ERoBo" computer program is elaborated and used in calculations. The scour hole parameters – depth, width, and volume – can be calculated by this method after one, two, or several floods both at the stage of designing the bridge crossings or in the maintenance period.

1 INTRODUCTION

Contraction of river flow by bridge crossings leads to changes in the flow pattern and to a scour at the bridge piers, abutments, and guide banks. The guide banks are constructed on plain rivers on the floodplains. Elliptical guide banks are used to guide the flow and sediments through a bridge opening, to reduce the flow separation at the alignment of the bridge, and to remove the scour hole from the abutment and embankment. The flow pattern and the scour hole dimensions at abutments and elliptical guide banks are different.

The concentration of streamlines, a local increase in velocity, and the development of a scour hole were observed at the upstream head of the elliptical guide banks.

During the past few decades, the equilibrium scour depth at bridge piers, abutments, and spur dikes were studied and fundamental books were published by Breuser & Raudkivi (1991), Hoffmans & Verheij (1997), Melville & Coleman (2000), and May et al. (2002). For determining the scour at the abutments, new approaches were elaborated by Kothyari & Ranga Raju (2001), Armitage & McGahey (2004), Yanmaz & Celebi (2004), Hager et al. (2002), and Gjunsburgs et al. (2001, 2004, 2005, 2006). The flow pattern and the scour process at abutments were studied in detail by Ahmed & Rajaratnam (2000) and Malavasi et al. (2004). However, the development of scour at the head of elliptical guide banks during floods has not yet been studied.

The differential equation of equilibrium for bed sediment movement in clear water is used, and a calculation method for the scour development at the head of elliptical guide banks during floods is elaborated and confirmed by experimental data.

According to the tests and the method suggested, the scour starts when the floodplain is flooded and usually stops at the flood peak. The scour development depends on the flow hydraulics, the river-bed parameters, and the flood duration. At the flood peak, a scour hole is usually formed. Although the scour process can be continued further, it stops, because the flood is time-restricted. The scour time is always less than the flood duration. At the next flood of the same probability, the scour process does not start when the floodplain is flooded, but at a later time step, closer to the flood peak. It happens because of the scour hole developed in the previous flood. The duration of the scour process at the second and forthcoming floods is less than at the previous floods.

The scour-hole parameters at elliptical guide banks can be calculated after one, two, or several floods, either during the maintenance of the bridge or at the design stage. The "ERoBo" computer program was elaborated and used in our calculations.

2 EXPERIMENTAL SETUP

The tests were carried out at the Transport Research Institute (Russia) in a flume 3.5 m wide and 21 m long.

Different forms of guide banks were studied by Latishenko (1960), and he recommended using elliptical guide banks as most acceptable in practice. The dimensions of the upper part of an elliptical guide

Copyright © 2006 Taylor & Francis Group plc, London, UK

bank, namely the turn and the length, were calculated according to the Latishenko (1960) method and were found to be dependent on the flow contraction and the main channel width. The length of the lower part of the guide bank was assumed to be half of the calculated upper part.

The tests were carried out under open flow conditions studying the flow distribution between the channel and the floodplain.

The rigid bed tests were performed for different flow contractions and Froude numbers in order to investigate the velocity and the water level changes in the vicinity of the embankment, along it, and near the modeled elliptical guide bank.

The aim of the sand bed tests was to study the scour process, the changes in the velocity in floods, the effect of different hydraulic parameters, the flow contraction rate, the grain size of the bed material, and the scour development in floods.

The openings of the bridge model were 50, 80, 120, and 200 cm. The flow contraction rate Q/Q_b (where Q is the flow discharge and Q_b is the discharge in the bridge opening under open-flow conditions) varied respectively from 1.56 to 5.69 for floodplain depth of 7 and 13 cm, and the Froude numbers varied from 0.078 to 0.134; the slope of the flume was 0.0012.

The sand bed tests were carried out under clear-water conditions. The sand was placed 1 m up and down the contraction of the flume. The mean grain size was 0.24 and 0.67 mm. The condition that $Fr_R = Fr_f$ was fulfilled, where Fr_R and Fr_f are the Froude numbers for the plain river and for the flume, respectively. The tests in the flume lasted for 7 hours, the length scale was 50 and the time scale was 7. With respect to the real conditions, the test time was equal to 2 days. This was the mean duration of time steps into which the flood hydrograph was divided.

The development of a scour was examined with different flow parameters in time intervals within one 7-h step and within two steps of the hydrograph, 7 hours each.

The tests were carried out with one floodplain model and one side contraction of the flow and with two identical or different floodplain models and two side contractions. The position of the main channel was varied for different tests.

3 METHOD

The differential equation for equilibrium bed sediment movement under clear water conditions at the head of elliptical guide bank has the form

$$\frac{dW}{dt} = Q_s \tag{1}$$

where W = scour hole volume; t = time; and Q_s = sediment discharge out of the scour hole.

In different tests, it was found that the shape of a scour hole is not changing and can be expressed as

$$W = \frac{1}{5}\pi m^2 h_s^3 \tag{2}$$

where m = scour hole steepness; h_s = scour depth.

The left-hand part of Eq. 1 can be written as

$$\frac{dW}{dt} = \frac{3}{5}\pi m^2 h_s^3 \frac{dh_s}{dt} = a h_s^2 \frac{dh_s}{dt} \tag{3}$$

where $a = 3/5\ \pi m^2$.

The sediment discharge was determined by the Levi (1969) formula

$$Q_s = ABV_l^4 \tag{4}$$

where $B = mh_s$ = width of the scour hole; V_l = local velocity at the head of the elliptical guide bank; and A = parameter in the Levi (1969) formula.

The sediment discharge upon development of the scour is given as

$$Q_s = Amh_s V_l^4 = b\frac{h_s}{1+\frac{h_s}{2h_f}} \tag{5}$$

where $b = AmV_l^4$.

Inserting Eqs. 3 and 5, Eq. 1 can be written as

$$ah_s^2 \frac{dh_s}{dt} = b\frac{h_s}{1+\frac{h_s}{2h_f}} \tag{6}$$

Separating and integrating the variables yield

$$t = D_i \int_{x_1}^{x_2} h_s \left(1+\frac{h_s}{2h_f}\right)^4 dh_s \tag{7}$$

An integration with the new variables, $x = 1 + h_s/2h_f$, $h_s = 2h_f(x-1)$, and $1\ dh_s = 2h_f dx$, yields

$$N_i = \frac{t_i}{4D_i h_f^2} + N_{i-1} \tag{8}$$

where $N = 1/6x_i^6 - 1/5x_i^5$; t_i = time interval.

Calculating the value of N_i, we find x_i and the scour depth at the end of time interval:

$$h_s = 2h_f(x-1)k_m k_s k_\alpha \tag{9}$$

where k_m = coefficient depending on the side-wall slope of the guide bank (Yaroslavcev 1956);

Copyright © 2006 Taylor & Francis Group plc, London, UK

k_s = coefficient depending on the guide bank shape; and k_α = coefficient depending on the angle of flow crossing (Richardson & Davis 1995).

Based on the method suggested, the "ERoBo" computer program was elaborated and used in our calculations. The "ERoBo" program allows us to compute and predict scour hole parameters – depth, width, and volume after multiple floods, e.g. after each flood in the course of 50–100 or more years, at the design stage of the bridge crossing lifetime. Considering the flood and river bed parameters, there is no restriction in time for computing the scour at the elliptical guide banks in plain rivers.

To determine the development of scour depth during the flood, the hydrograph was divided into time steps with duration of 1 or 2 days, and each time step was divided into time intervals up to several hours. In the laboratory tests, the time steps were divided into 20 time intervals. For each time step, the following parameters must be determined and entered in the "ERoBo" program: water depth in the floodplain, flow contraction rate, maximum backwater, grain size, thickness of the bed layer with d, and specific weight of the bed material. As a result, we have V_l, V_0, A, D, N_i, N_{i-1}, x, and h_s at the end of time intervals and finally at the end the time step. For the next time step, the flow parameters changed because of the flood and the scour developed during the previous time step. Thus, the depth, width, and volume of the scour hole can be computed after several floods both at the design stage and during the maintenance of bridge crossings.

4 RESULTS

According to the tests at the head of the elliptical guide banks, the concentration of streamlines, a sharp drop in water level, and a rapid increase in velocity were determined.

The local velocity at the head of the guide bank was studied in rigid bed tests, at different contraction rates, and for different flow Froude numbers. The local velocity was found from the formula

$$V_l = \varphi_{el}\sqrt{2g\Delta h} \tag{10}$$

where ϕ_{el} = the velocity coefficient for the elliptical guide banks; g = the gravitational acceleration; and Δh = the maximum backwater determined by the Rotenburg (1969) formula.

According to our tests, the velocity coefficient ϕ_{el} depends on the flow contraction. With increasing flow contraction, ϕ_{el} reduces, while with decreasing flow contraction, it increases. The local velocity and water level changes were measured in tests at the head of the elliptical guide banks. For the known V_l and Δh values, ϕ_{el} was found for each contraction rate of the flow. The coefficient ϕ_{el} as a function of the flow contraction is shown in Figure 1.

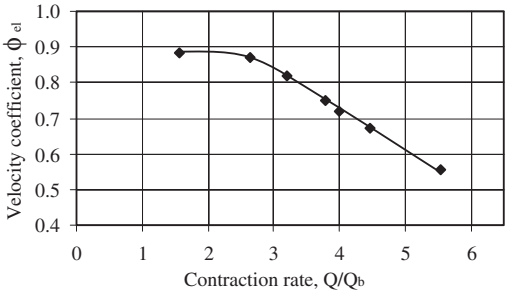

Figure 1. The velocity coefficient ϕ_{el} versus the flow contraction rate for elliptical guide banks (test data for ϕ_{el} with different flow contraction).

Table 1. Comparison between the experimental and calculated data for local velocities at the elliptical guide banks.

A comparison between the experimental and calculated data for local velocities at the elliptical guide banks is presented in Table 1.

Figure 2 shows a scheme of the bed level changes near the elliptical guide bank at the end of test EL9 for $Q/Q_b = 2.65$, $l_b = 120$ cm, $h_f = 7$ cm, and $d = 0.24$ mm. As follows from the test results, near the head of elliptical guide banks, a scour hole is developed. At the lower part of the elliptical guide banks, deposition of the sediments takes place, and the bed level increases.

Copyright © 2006 Taylor & Francis Group plc, London, UK

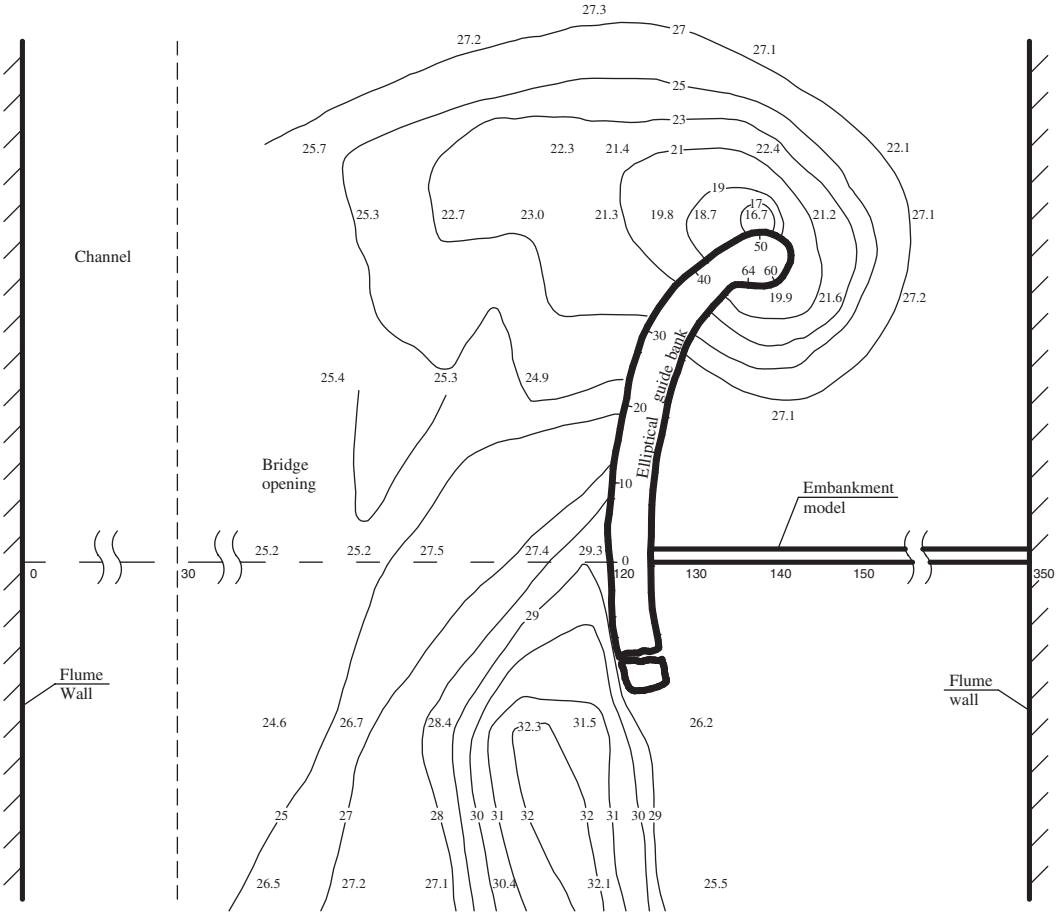

Figure 2. Scour scheme near the elliptical guide bank at the end of test EL9.

The changes in the bed level with time along the guide bank are presented in Figure 3.

Bed levels were measured by an electric pin-pointer along the guide bank length at points 0, 10, 20, 30, 40, 50, 60, and 64, as shown in Figures 2 and 3.

The shape of the scour hole was measured in tests with different Froude numbers, sand bed parameters, and contraction rate of the flow. According to the tests, the shape of the scour hole was not changing, remaining the same.

The volume of the scour hole near the elliptical guide bank can be found by Eq. 2. A comparison between the experimental and calculated volumes of the scour hole is given in Table 2.

In the case of elliptical guide banks, the distribution of velocities and scour in the contraction cross-section of the bridge crossing is more uniform. An example of scour at the contracted cross-section of the modelled bridge crossing with elliptical guide bank

* Time from start of the tests.

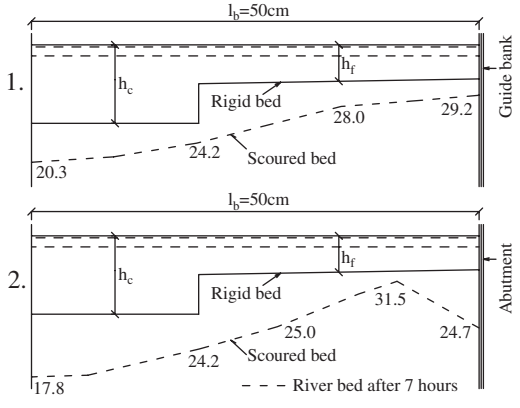

Figure 4. Scour in the contracted cross-section of the bridge-crossing model: with elliptical guide bank (1) and with abutment (2).

and abutment is given in Figure 4. The scour at the elliptical guide bank is smaller in magnitude and more uniform compared with an abutment.

The values of the scour depth development obtained in tests and calculated by the method presented under the steady and unsteady flow conditions are given in Figures 5 and 6. The scour depth development observed and calculated at the head of the elliptical guide banks in tests EL4 and ETL1 is similar – the rapid development at the beginning of the process is gradually reduced with time.

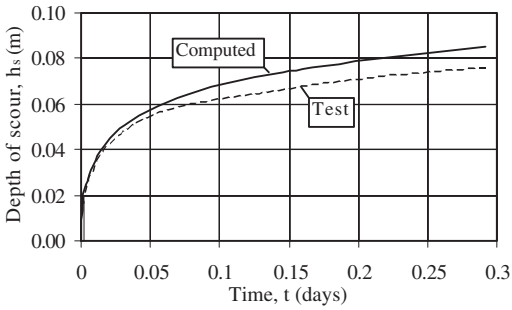

Figure 5. Scour development in time under steady flow conditions at the elliptical guide bank for test EL4.

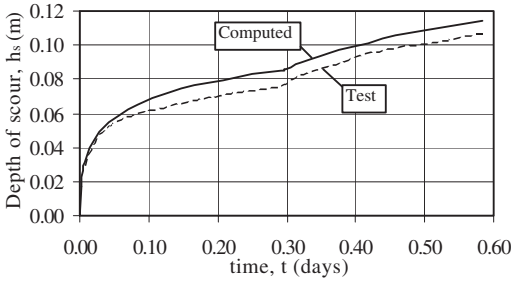

Figure 6. Scour development in time under unsteady flow conditions at the elliptical guide bank for test ETL1.

A comparison of the experimental and calculated scour depth is presented in Table 3.

The development of the scour depth, width, and volume after three floods of the same probability is shown in Figures 7, 8, and 9, respectively. The most rapid development of the scour hole was observed in the first flood. In the following floods, the scour started later and closer to the peak of the flood. The time of scour and the rate of scour hole development in time reduced with every subsequent flood.

5 CONCLUSIONS

The scour development in floods at elliptical guide banks is studied. The differential equation of the equilibrium bed sediment movement under clear-water conditions is used, and a method for computing the scour hole development with time at the head of the elliptical guide bank during floods is elaborated and

confirmed by experimental data. The "ERoBo" computer program has been worked out and used in our calculations.

The scour at the head of guide banks starts when the floodplain is flooded and usually stops at the flood peak. At the peak of the flood, the scour hole has already been formed. The scour time is always less

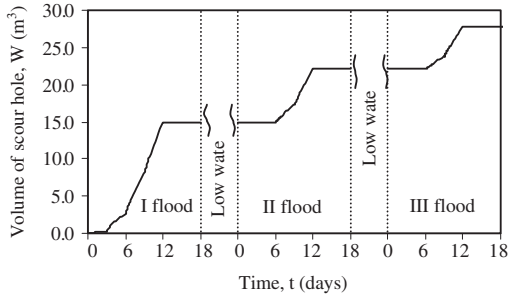

Figure 9. Scour hole volume development for three floods of the same probability at an elliptical guide bank.

than the flood duration, and it reduces with every subsequent flood of the same probability.

According to the method suggested, the depth, the width, and the volume of scour can be computed after several floods either at the stage of design or during the maintenance of the bridge crossing, which gives the possibility of predicting its stability.

ABSTRACT: The problem of assessing the equilibrium scour depth at bridge piers and abutments received great attention in the last two decades. Also the time evolution of scouring was investigated by many authors, and different predictive formulae were proposed in the literature. In this work, laboratory data by different authors are analysed so as to verify the onset of the equilibrium state. The data sets are also used to compare some empirical formulae on the time evolution of the scour depth at piers or abutments. Finally, the minimum test duration for calculating the equilibrium scour depth by extrapolation is investigated by applying the Bertoldi & Jones (1998) formula to the data sets.

1 INTRODUCTION

Local scouring at bridge piers and abutments is a problem of worldwide relevance in Fluvial Hydraulics. In fact, scouring is one of the main causes of damaging or failure of bridges (see e.g. Murillo 1987) and it has attracted significant research efforts.

Several scientific studies have dealt with the prediction of scour depth evolution over time, $d_s(t)$; many more tackle the issue of equilibrium scour depth, d_{se}; both piers and abutments have been studied (see Melville & Coleman 2000).

Empirical formulae proposed in the literature were obtained, mostly, by analysing data acquired in laboratory experiments; predictions of both $d_s(t)$ and d_{se} may differ considerably.

In addition, one important conceptual problem faced by researchers is the definition of the equilibrium condition, with direct implications on the choice of tests duration. Some procedures and criteria to evaluate the threshold duration (in the sense of time needed to reach the equilibrium state) have been suggested in the literature, but there is no universally accepted one.

In this work, the existence of the equilibrium state in experimental data sets generated by several authors will be assessed by adapting a procedure recently suggested by Grimaldi (2005). Then, the same data will be used to evaluate the performance of empirical formulae scrutinised in the literature about the prediction of time evolution as well as the equilibrium scour depth at piers or abutments. Finally, the minimum test duration needed for the prediction of equilibrium scour depth, through extrapolation, on the basis of short non-equilibrium experiments, will be addressed by applying the Bertoldi & Jones (1998) equation to the same data sets.

2 DATA SETS AND ONSET OF EQUILIBRIUM CONDITIONS

Grimaldi (2005) proposed the evaluation of the onset of equilibrium state through three different criteria: the first refers to the test duration, which can be calculated *a priori*; the second takes advantage of the pattern of time evolution of the scour depth; the third one relies on the increment of scour depth in the last 24 hours of a given test.

The test duration can be calculated *a priori*, as suggested, for instance, by Franzetti et al. (1994) or Melville & Chiew (1999) for piers and by Lauchlan et al. (2001) for abutments. The calculated duration can be used as a reference value, t_e, to design new tests or to verify the occurrence of the equilibrium state in past experiments.

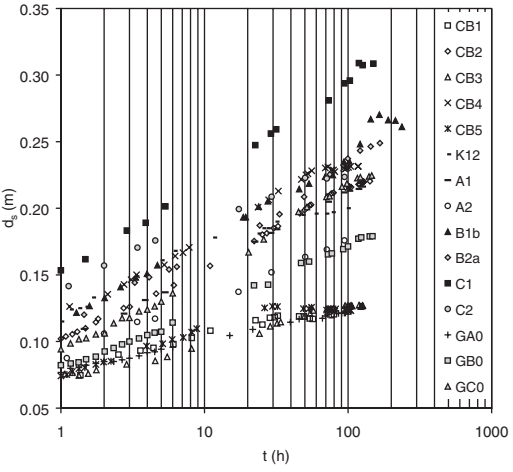

Figure 1. Time evolution of scour depth.

Cardoso & Bettess (1999) assumed that the equilibrium scour depth is reached when an almost horizontal trend is identified in a plot where the scour depth evolution in time is represented in a semi-logarithmic graph. In the present study, this condition will be assumed as mandatory.

If the variation of the scour depth in the last 24 hours of a given test, $\Delta d_{s,24}$, is less than a predefined appropriate threshold value, then the equilibrium state can be assumed as reached for practical purposes. Melville & Chiew (1999) suggested the following threshold value for piers: $\Delta d_{s,24} = 0.05 \cdot b$, where b is the pier width. Grimaldi (2005), having performed laboratory tests on local scouring at a circular pier, noted that the above threshold value did not satisfy the other two equilibrium criteria; therefore, he suggested a more restrictive criterion, namely $\Delta d_{s,24} = 0.05 \cdot b/3$.

In this work, 15 laboratory data sets of $d_s(t)$ were selected in the literature:

- 5 from Cardoso & Bettess (1999) (identified as CB1 to CB5), 1 from Kwan (1988) (K12) and 6 from Santos (1999) (A1, A2, B1b, B2a, C1 and C2) for scouring at vertical-wall abutments;
- 3 from Grimaldi (2005) (GA0, GB0 and GC0) for scouring at a circular pier.

Table 1 reports the characteristic values of these laboratory tests, namely, the water depth, h, the approach flow velocity, U, the critical velocity for the beginning of sediment motion, U_c, the median sediment size, d_{50}, the geometric standard deviation of the grain-size distribution, $\sigma_g = (d_{84}/d_{16})^{0.5}$, the length of the abutment or the pier width, respectively L or b, and the test duration, T. All the tests were performed with sand, for $0.93 \cdot U \le U_c \le 1.06 \cdot U$.

The reference test durations, t_e, were obtained by applying the criteria by Franzetti et al. (1994) for piers and by Lauchlan et al. (2001) for abutments. The former is expressed as: $t_e = 2 \cdot 10^6 \cdot b/U$; the latter as:

$$t_e = 1.1 \cdot 10^6 \frac{L}{U}\left(\frac{h}{L}\right)^{0.75U_c/U}\left(\frac{U}{U_c}\right)^3 \quad (1)$$

Results of these formulations are shown in Table 2. Tests CB4, K12, A2, B2a, C2, GA0, GB0 and GC0 lasted shorter than the calculated time to equilibrium or reference duration, since $T < t_e$. Nevertheless, it is to be noted that the duration of tests GA0 and GB0 is very close to the reference value (the difference $T - t_e$ is equal to 8 h and 1 h, respectively).

The time evolution of the scour depth can be observed in the semi-logarithmic graph of Figure 1. Tests A1, A2 and B2a do not present a clear slope change.

The increment of the scour depth in the last 24 hours of each test was obtained from the records as $\Delta d_{s,24,m}$, and computed according to Grimaldi (2005): $\Delta d_{s,24,c} = 0.05 \cdot b/3$ for piers and, analogously, $\Delta d_{s,24,c} = 0.05 \cdot 2 \cdot L/3$ for abutments, b being equivalent to $2 \cdot L$. Comparison shows that only test A2 does not satisfy the condition $\Delta d_{s,24,m} < \Delta d_{s,24,c}$ (Table 2).

Test A2 does not satisfy any criterion; for this reason it was considered not to have reached equilibrium. Since it was assumed that the criterion of slope change is mandatory, tests A1 and B2a were also considered not at equilibrium. Tests CB4, K12, C2, GA0, GB0 and GC0 were considered equilibrium tests, in spite of the fact that they do not satisfy the test duration criteria by Franzetti et al. (1994) or Lauchlan et al. (2001). All the remaining tests (CB1, CB2, CB3, CB5, B1b, C1) satisfy simultaneously the three criteria and they were equilibrium tests (see Tables 1 and 2).

Table 2. Results of the application of the equilibrium criteria.

Test	t_e (h)	$\Delta d_{s,24,m}$ (m)	$\Delta d_{s,24,c}$ (m)	Slope change	Equilibrium
CB1	72.314	0.0027	0.0049	Yes	Yes
CB2	130.804	0.0024	0.0049	Yes	Yes
CB3	85.899	0.0004	0.0090	Yes	Yes
CB4	158.579	0.0014	0.0090	Yes	Yes
CB5	90.441	0.0003	0.0133	Yes	Yes
K12	148.005	0.0040	0.0172	Yes	Yes
A1	79.603	0.0017	0.0060	No	No
A2	125.917	0.0069	0.0060	No	No
B1b	98.400	−0.0047	0.0133	Yes	Yes
B2a	188.306	0.0025	0.0133	No	No
C1	98.150	0.0012	0.0167	Yes	Yes
C2	167.617	0.0011	0.0167	Yes	Yes
GA0	104.167	0.0010	0.0013	Yes	Yes
GB0	148.810	0.0009	0.0015	Yes	Yes
GC0	198.413	0.0013	0.0020	Yes	Yes

In the next sections, all records will be used to evaluate the time evolution of scour depth; however, the last measurement, $d_s(T)$, of tests A1, A2 and B2a was not retained for the analysis on equilibrium scour since these tests were non-equilibrium tests.

3 EVALUATION OF TIME EVOLUTION AND EQUILIBRIUM SCOUR FORMULAE

Many formulae can be found in the literature for the assessment of the scour depth evolution over time at bridge piers or abutments. In this context, "scour depth" is to be understood as the depth of the deepest point in the scour hole at a given time instant.

Seven formulae were selected for evaluation by comparing their predictions with the experimental data of the tests described in section 2.

The formula of Shen et al. (1966) for piers reads as follows (see Cunha 1975):

$$\frac{d_s(t)}{h} = 2.5 Fr^{2/5} \left(\frac{b}{h}\right)^{3/5} \left(1 - e^{-m \cdot E}\right)^2 \tag{2}$$

$$m = 0.026 e^{2.932h} \tag{3}$$

$$E = \left(\frac{b}{h}\right)^{1/3} Fr^{1/3} \ln \frac{Ut}{h} \tag{4}$$

$$Fr = \frac{U}{\sqrt{gh}} \quad \text{(Froude number of the approach flow)} \tag{5}$$

The contribution of Franzetti et al. (1994) for circular pier scour on granular uniform sand, in the absence of secondary currents and contraction effects, can be written as:

$$\frac{d_s(t)}{b} = f_1(t) f_2\left(\frac{U}{U_c}\right) f_3\left(\frac{h}{b}\right) f_4\left(\frac{b}{d_{50}}\right) \tag{6}$$

$$f_1(t) = 1 - e^{-0.028\left(\frac{Ut}{b}\right)^{1/3}} \tag{7}$$

$$f_2\left(\frac{U}{U_c}\right) = 1 - 10\left(1 - \frac{U}{U_c}\right)^3 \quad for \quad \frac{U}{U_c} \le 1 \tag{8}$$

$$f_3\left(\frac{h}{b}\right) = 1 - e^{-1.3\left(\frac{h}{b}\right)^{1/3}} \quad for \quad \frac{h}{b} \ge 2 \tag{9}$$

$$f_4\left(\frac{b}{d_{50}}\right) = \begin{cases} 3.868\left(\frac{b}{d_{50}}\right)^{1.572} e^{-2.64\left(\frac{b}{d_{50}}\right)^{0.234}} & for\ b/d_{50} \le 50 \\ 2.48 & for\ b/d_{50} > 50 \end{cases} \tag{10}$$

The formula of Melville & Coleman (2000) for piers, valid for uniform sediments is:

$$d_s(t) = K_{hb} K_I K_d K_S K_\theta K_G K_t \tag{11}$$

$$K_{hb} = \begin{cases} 2.4b & for \quad b/h \le 0.7 \\ 2\sqrt{hb} & for \quad 0.7 < b/h < 5.0 \\ 4.5h & for \quad b/h > 5.0 \end{cases} \tag{12}$$

$$K_I = \begin{cases} \frac{U}{U_c} & for \quad \frac{U}{U_c} < 1 \\ 1 & for \quad \frac{U}{U_c} \ge 1 \end{cases} \tag{13}$$

$$K_d = \begin{cases} 0.57 \log\left(2.24 \frac{b}{d_{50}}\right) & for \quad \frac{b}{d_{50}} \le 25 \\ 1 & for \quad \frac{b}{d_{50}} > 25 \end{cases} \tag{14}$$

$$K_S = 1 \quad for\ circular\ pier \tag{15}$$

$$K_G = 1 \quad for\ channel\ with\ rectangular\ cross-section \tag{16}$$

$$K_t = \begin{cases} e^{-0.03\left|\frac{U_c}{U} \ln \frac{t}{t_e}\right|^{1.6}} & for \quad \frac{U}{U_c} \le 1 \\ 1 & for \quad \frac{U}{U_c} > 1 \end{cases} \tag{17}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$t_e(days)=\begin{cases}48.26\dfrac{b}{U}\left(\dfrac{U}{U_c}-0.4\right) & for\ \dfrac{h}{b}>6;\dfrac{U}{U_c}>0.4\\ 30.89\dfrac{b}{U}\left(\dfrac{U}{U_c}-0.4\right)\left(\dfrac{b}{h}\right)^{0.25} & for\ \dfrac{h}{b}\le 6;\dfrac{U}{U_c}>0.4\end{cases} \quad (18)$$

The formula of Oliveto & Hager (2002) applies to piers or abutments (replacing L by b) on rectangular straight channels, clear-water condition, $h/d_{50} > 5$ to 10, $B/b < 20$, d_{50} greater than about 0.8 mm, $F_t < 1.2$ in the approach flow and in the absence of bed-forms. It reads:

$$d_s(t)=0.068Nb^{2/3}h^{1/3}\sigma_g^{-1/2}Fr_d^{1.5}\log T \quad (19)$$

$$N=\begin{cases}1 & for\ pier\\ 1.5 & for\ abutment\end{cases} \quad (20)$$

$$Fr_d=\frac{U}{\sqrt{g\Delta d_{50}}}>Fr_{di}\ \text{(densimetric Froude number)} \quad (21)$$

$$Fr_{di}=\begin{cases}2.33D_*^{-0.25}\left(R/d_{50}\right)^{1/6} & for & D_*\le 10\\ 1.08D_*^{1/12}\left(R/d_{50}\right)^{1/6} & for & 10<D_*<150\\ 1.65\left(R/d_{50}\right)^{1/6} & for & D_*\ge 150\end{cases} \quad (22)$$

$$D_*=\left(g\Delta/\upsilon^2\right)^{1/3}d_{50}\ \text{(non-dimensional grain size)} \quad (23)$$

$$F_t=\begin{cases}\dfrac{U}{2.33D_*^{-0.25}\left(R/d_{50}\right)^{1/6}} & for & D_*\le 10\\ \dfrac{U}{1.08D_*^{1/12}\left(R/d_{50}\right)^{1/6}} & for & 10<D_*<150\\ \dfrac{U}{1.65\left(R/d_{50}\right)^{1/6}} & for & D_*\le 150\end{cases} \quad (24)$$

$$T=\sqrt{g\Delta d_{50}}\,b^{-2/3}h^{-1/3}t \quad (25)$$

In the equations above, $\Delta=(\rho_s-\rho)/\rho$ is the relative submerged density of sediments, ρ_s and ρ being the grain and water density respectively, R is the hydraulic radius and ν is the kinematic water viscosity.

The formula suggested by Cunha (1975) for abutment can be written as follows:

$$\frac{d_s(t)}{h}=189\left(\frac{L}{h}\right)^{0.69}\left(\frac{u_*}{\omega_s}\right)^{3.25}t^{0.16}\quad with\ t\ in\ minutes \quad (26)$$

u_* being the shear velocity and ω_s the fall velocity. These variables can be computed as follows:

$$u_*=\sqrt{gRS}\ \text{(shear velocity)} \quad (27)$$

$$S=\frac{(nU)^2}{R^{4/3}}\ \text{(energy slope; Manning's formula)} \quad (28)$$

$$n=\frac{d_{50}^{1/6}}{21.1}\left(\frac{s}{m^{1/3}}\right)\ with\ d_{50}\ in(m)\ \text{(Strickler's formula)} \quad (29)$$

$$\omega_s=F\sqrt{g\Delta d_{50}}\ \text{(Rubey 1933)} \quad (30)$$

$$F=\sqrt{\frac{2}{3}+\frac{36\nu^2}{g\Delta d_{50}^3}}-\sqrt{\frac{36\nu^2}{g\Delta d_{50}^3}} \quad (31)$$

The formula of Lauchlan et al. (2001) for abutments, on uniform sediments, under clear-water flow conditions, is given by:

$$d_s(t)=K_{hL}K_IK_dK_SK_\theta K_GK_t \quad (32)$$

$$K_{hL}=\begin{cases}2L & for & L/h<1\\ 2\sqrt{hL} & for & 1<L/h<25\\ 10h & for & L/h>25\end{cases} \quad (33)$$

$$K_d=\begin{cases}0.57\log\left(2.24\dfrac{b}{d_{50}}\right) & for & \dfrac{L}{d_{50}}\le 25\\ 1 & for & \dfrac{L}{d_{50}}>25\end{cases} \quad (34)$$

$$K_S=1\quad for\ vertical\ abutment\ walls \quad (35)$$

$$K_G=1\quad for\ channel\ with\ rectangular\ cross-section \quad (36)$$

$$K_t=e^{-0.09\left(\frac{U_c}{U}\right)^{-0.75}\left|ln\frac{t}{t_e}\right|^{1.4}} \quad (37)$$

K_I is evaluated from (13); t_e can be calculated from (1).

The above formulae were applied to the laboratory data (3 sets for piers and 12 for abutments, with a total number of measured scour depths equal to 122 and 353, respectively) in order to assess the scour depth at given time instants.

Figures 2 and 3 show typical comparisons between measured and computed $d_s(t)$, respectively, for circular piers (test GC0) and abutments (test CB5).

As shown in Figure 2, the scour depth for test GC0 was underestimated at all instants by the formula of Shen et al. (1966); on the contrary, it was always overestimated by the formulae of Melville & Coleman (2000) and Oliveto & Hager (2002). These conclusions were verified to be valid for the remaining tests too. The formula of Franzetti et al. (1994) produced very good estimates of $d_s(t)$; in the case of tests GA0 and GB0 the scour depths over time were overestimated of 24% and 11% respectively, whilst in the case of test GC0 predictions followed the measurements up to $t \approx 30$ h and, from there on, they became smaller, leading to a slight underestimation of the equilibrium scour depth, d_{se}.

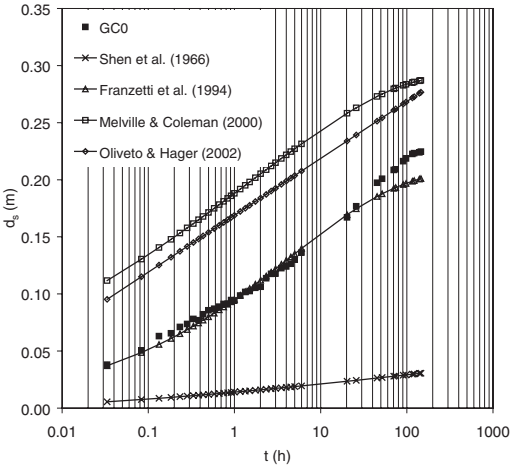

Figure 2. Comparison between computed and measured $d_s(t)$ at a circular pier (test GC0).

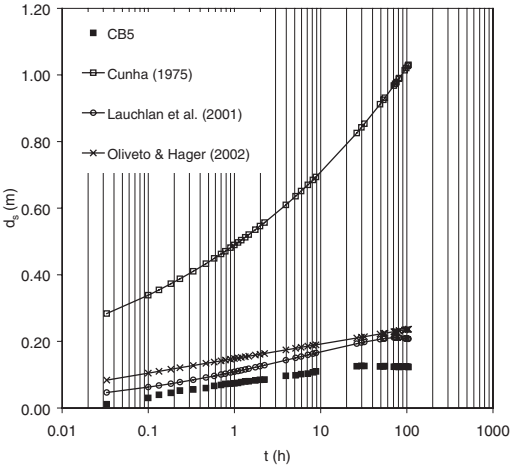

Figure 3. Comparison between computed and measured $d_s(t)$ at a rectangular abutment (test CB5).

Figure 3 shows that, for test CB5, the scour depth is overestimated by the three selected predictors of scour at abutments for all instants. It should be noted that the formula of Cunha (1975) leads to predictions from 5 to 6 times bigger than the observed values. Analogous conclusions can be drawn for tests CB3, CB4, K12, A2, B1b, B2a, C2. The best predictions are given by the Lauchlan et al. formula for tests CB1, CB2, A1 and C1 and by the Oliveto & Hager formula for test CB1. Measures of test CB2 were overestimated for $t < 22$ h and then underestimated by the Oliveto & Hager formula.

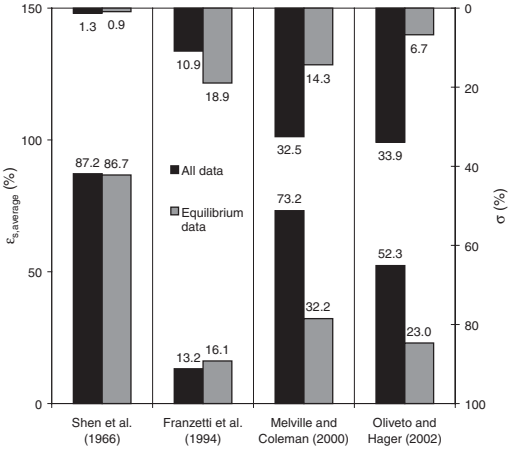

Figure 4. Relative errors and standard deviations of computed vs. measured $d_s(t)$ at circular piers.

The computed values, $d_{s,c}(t)$, were compared with the measured ones, $d_{s,m}(t)$; a percent relative error was calculated as follows for each instant:

$$\varepsilon_s(t)\,(\%) = \frac{\left|d_{s,c}(t) - d_{s,m}(t)\right|}{d_{s,m}(t)} \cdot 100 \qquad (38)$$

This parameter was also calculated for the equilibrium scour depths, i.e. for the particular cases of equilibrium time.

Figure 4 shows the average of ε_s values as well as the corresponding standard deviations, σ, associated with the predictions of each formula for piers. It also shows the same statistics for the equilibrium scour depths (see gray histograms).

Figure 5 replicates Figure 4 for abutments; only 9 equilibrium scour values were considered for abutments since tests A1, A2 and B2a were assumed out of equilibrium, according to section 2.

As it could be anticipated from the discussion of Figures 2 and 3, the best predictions were those given by the formula of Franzetti et al. (1994) for piers and the formula of Lauchlan et al. (2001) for abutments; they lead to average relative errors equal to 13.2% and to 32.2%, respectively; these statistics are quite similar to those associated with the equilibrium scour depth, where the same formulae lead to relative errors equal 16.1% and 32.2%.

The formulae of Melville & Coleman (2000) and Oliveto & Hager (2002) are better predictors of d_{se} than $d_s(t)$. Anyway, with respect to the Oliveto & Hager (2002) formula, it is to be underlined that condition (21) was never verified in the tests considered in the present work: in fact, the densimetric Froude numbers presented percent relative errors $(Fr_{di} - Fr_d)/Fr_d \cdot 100 = 7.3\%$ (tests A1 and C1) to

Copyright © 2006 Taylor & Francis Group plc, London, UK

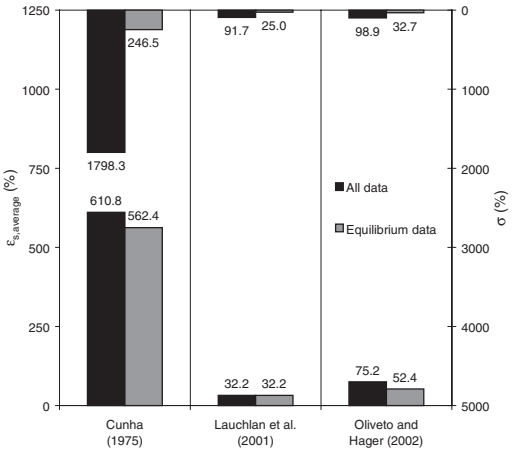

Figure 5. Relative errors and standard deviations of computed vs. measured $d_s(t)$ at abutments.

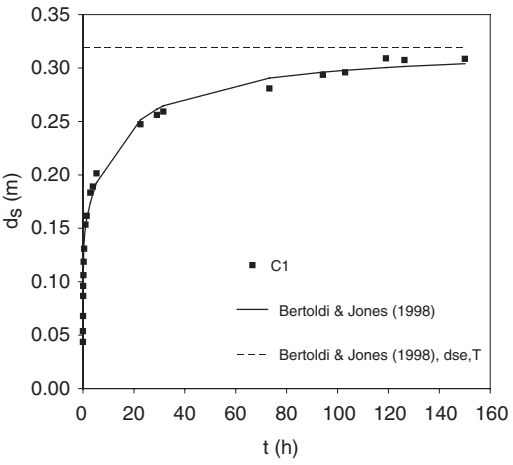

Figure 6. Time evolution of maximum scour depths. Comparison between measured (test C1) and computed (Bertoldi & Jones 1998) values.

30.7% (test CB4); in addition, the condition $B/b < 20$ was not respected either for test GB0 ($B/b = 22.2$).

The formula of Shen et al. (1966) leads to high average relative errors on both $d_s(t)$ and d_{se}, while σ values are the smallest, indicating that ε_s is almost constant at all the examined time instants.

On the contrary, the formula of Cunha (1975) produces very high average relative errors on both $d_s(t)$ and d_{se}, with very high σ values, i.e. the high predictions are equally affected by highly variable errors. In particular, the formula of Cunha (1975) depicts the highest relative errors for $t < 1$ h; in fact, considering only the data for $t > 1$ h, the average relative error reduces from 610.8% to 452.8%, and the standard deviation from 1798.3% to 203.8%. The formula is very sensitive to small variations of the shear velocity and the fall velocity; small errors in the evaluation of these variables may induce high deviations from reality. In addition, as shown in Figure 3, the predictions of $d_s(t)$ keep increasing with time, leading to unrealistic infinity scour depth for infinity time.

4 MINIMUM TEST DURATION

As mentioned before, many studies have been made on the influence of time on local scouring. Just to mention a few more of the most ancient, those of Laursen (1963), Breusers (1965), Rao & Sarma (1967), Sarma (1968) can be listed, together with those of Romita (1953), Shen et al. (1965) or Carstens (1966) for the particular case of bridge piers.

A high number of studies developed between the first and second half of the twentieth century were carried out by performing experiments with very short durations. Test durations of, e.g., Ishihara (1938–42) and Romita (1953) were, respectively, 20 and 30 minutes; equilibrium state was assumed as reached after 120 minutes by Dietz (1972) – see Breusers & Raudkivi (1991) – and Knight (1975); Basak et al. (1975) – see Breusers et al. (1977) – considered equilibrium after 400 minutes.

As shown in section 2 on the analysis of equilibrium, the test duration for equilibrium is of the order of days (Table 1). The increment of scour depth decreases with time, taking values of the order of d_{50} per day at high t values.

It would be interesting to reduce, in practice, the duration of laboratory tests. This would imply the definition of a minimum duration, T_{min}, allowing the determination of d_{se} by extrapolating measurements in the interval $0 < t < T_{min}$ to $t = t_e$. For this purpose, the following Bertoldi & Jones (1998) formula was considered:

$$d_s(t) = a\left(1 - \frac{1}{1+abt}\right) + c\left(1 - \frac{1}{1+cdt}\right) \qquad (39)$$

a, b, c and d being parameters, which can be obtained through regression analysis of $d_s(t)$ values versus t. When $t \to \infty$, Eq. (39) leads to $d_{se} = a + c$. This formulation assumes implicitly that $t_e \to \infty$.

The parameters of the Bertoldi & Jones (1998) formula were assessed for each test with the least squares regression applied to the $d_s(t)$ versus t data, for $0 < t \le t_i$, with t_i in the interval 1 day $\le t_i \le T$. Therefore, for each test, the equilibrium scour depth, $d_{se,i} = a_i + c_i$, was calculated for each t_i, i.e. limiting the data set at time t_i.

For example, Figure 6 shows the comparison among measured and computed $d_s(t)$ for test C1, and the

Copyright © 2006 Taylor & Francis Group plc, London, UK

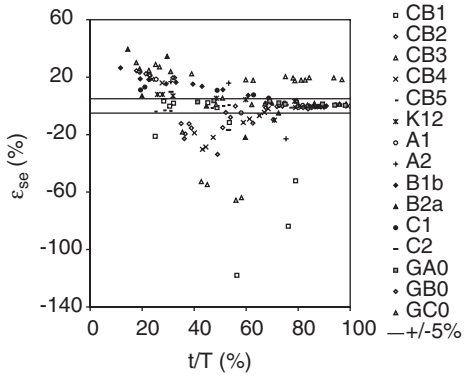

Figure 7. Percent relative errors vs. dimensionless time.

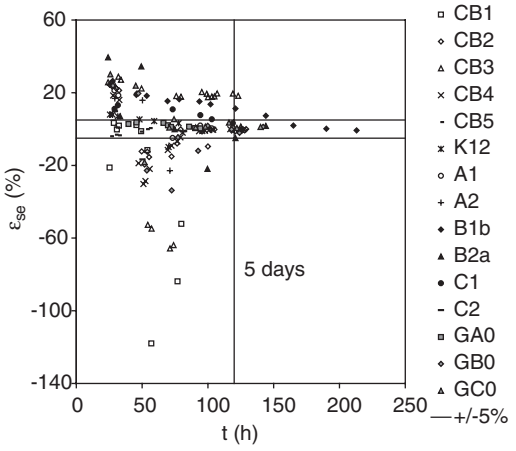

Figure 8. Percent relative errors vs. time.

equilibrium scour depth $d_{se,T} = a_T + c_T$, assessed with the Bertoldi & Jones (1998) formula by using the whole data set.

Assuming that $d_{se,T}$ is the best estimate of d_{se}, i.e. that $d_{se,T} \approx d_{se,\infty}$, the following percent relative error was computed:

$$\varepsilon_{se,i}\,(\%) = \frac{d_{se,T} - d_{se,i}}{d_{se,T}} \cdot 100 \qquad (40)$$

as to evaluate the precision of the d_{se} estimates for all $t_i < T$.

Figure 7 shows the percent relative errors versus dimensionless time, t/T. Each point in the graph represents the couple $(t_i/T, \varepsilon_{se,i})$. The band of ±5% relative error is also shown. The value of t/T after which $\varepsilon_{se,i}$ falls stably in the ±5% band is very different from one test to another. For example, test CB5 reached a maximum scour depth which differs of less than ±5% from $d_{se,T}$ after the 25% of its total duration; on the contrary, the 98% of the total duration of test CB3 was needed to obtain $-5\% < \varepsilon_{se,i} < 5\%$; for tests CB1 and A2, the minimum dimensionless time for estimating $d_{se,T}$ with ±5% relative error is equal to 100%.

Figure 8 shows the percent relative errors versus time. After some oscillations, the relative errors decrease with time. Apparently, within the experimental range covered in this study, test durations shorter than 5 days are not enough to guarantee a correct assessment of d_{se} through the Bertoldi & Jones formula, adjusted to measurements and extrapolated to $t \to \infty$. This conclusion is to be confirmed in future research works, since only 8 tests lasted more than 5 days and only 1 more than 7 days (see Table 1).

The above considerations show that it is not possible to establish the minimum test duration for a correct assessment of the equilibrium maximum scour depth on the basis of the considered data sets and the formula of Bertoldi & Jones (1998).

5 CONCLUSIONS

Fifteen laboratory data sets of scour depth evolution with time at piers and abutments were analysed to verify the onset of the equilibrium state. A multiple criterion was used, for which the test duration is compared with a reference value, the presence of the slope change in the time evolution of the scour depth is verified, and the variation of the scour depth in the last 24 hours of each test is compared with a threshold value. The application of the method to the data sets allowed to verify that three tests could not be considered at equilibrium.

Some formulae were selected in order to perform a comparison between their predictions and the experimental data of the considered laboratory tests. Results showed that the scour depth at piers was always underestimated by the Shen et al. (1966) formula and overestimated by the Melville & Coleman (2000) formula, while the formula of Franzetti et al. (1994) led to the best estimates. The Oliveto & Hager (2002) formula gave overestimations too, but it is to be noted that it was applied in cases in which some of its restrictions were not respected. The scour depth at abutments was generally overestimated by the selected formulae; the Lauchlan et al. (2001) formula gave the best predictions. Similar conclusions can be drawn for the equilibrium depths.

Finally, in order to reduce the duration of laboratory tests, the research of a minimum duration that could allow the calculation of the equilibrium value of scour depth through extrapolation was performed with the formula of Bertoldi & Jones (1998). Results showed that the percent relative error on the assessment of d_{se} presents strong oscillations over time; in some cases, these oscillations remain strong until close to the end of the records. Therefore, it was not possible by this way

Copyright © 2006 Taylor & Francis Group plc, London, UK

to establish the minimum test duration for a correct assessment of the equilibrium maximum scour depth.

Diversity of streambed features caused by open-slot groundsills

Chia-Chun Wu & Yuan-Chiao Lin
National Pingtung University of Science and Technology, Neipu, Pingtung, Taiwan

ABSTRACT: Groundsills and check dams are common practices implemented in mountain streams for grade control. However, both structures not only dissect the channel and create discontinuity in channel flow, but also destroy the diversity of streambed appearances. Therefore, the objective of this research is to experimentally access the feasibility of open-slot groundsills in creating streambed diversity. Groundsills with different numbers of open slots were tested in a laboratory flume. Shannon Diversity Index (SHI) was then used to express the diversity of streambed topographic features at different experiment settings including conventional groundsills as the control setting. Results of this study indicate that conventional groundsill has the lowest SHI value; whereas, groundsill with single slot opening has the highest. Groundsills with two and four open slots possess SHI values in between the preceding extremes. Even though single-slot groundsill produces the highest SHI value that representing the highest bed feature diversity, yet the concentrated scour development creates potential threat to the structure.

1 INTRODUCTION

A groundsill is a man-made structure running perpendicular to the flow. It is a common practice to install a series of groundsills in a channel to serve the purposes of grade control and flow training. However, the installation of groundsills alters both the flow fields and sediment transport in a channel reach, which results in a rather uniform appearance (Fig. 1) as compared to the riffle-pool setting in a natural environment.

Pool is a region of slow moving water with relative deep flow depth. Riffle, on the other hand, is a region of fast moving water with shallow flow depth. Riffle-pool structure not only provides great diversity on streambed bedforms, substrate materials, and local velocity distributions, but also provides shelters and feeding grounds for aquatic habits (Gordon et al. 1992).

Therefore, the objective of this research is to experimentally access the feasibility of open-slot groundsills in creating streambed diversity. The open-slot groundsill in this paper is referred to a conventional groundsill having a slot or few slots cutting on the apron.

Figure 1. Hydraulic environment created by a series of groundsills.

2 LITERATURE REVIEW

Research efforts have concentrated in the aspects of proper spacing interval between groundsills and scour at the toe of a groundsill. For instance, Dietz (1972) proposed an equation that described the equilibrium scour depth based on the velocity differences at the cross section. The equation was written as

$$\frac{y_m}{y_{m,e}} = \frac{\omega(U_0 - U_c)}{U_c} \tag{1}$$

where y_m = maximum scour depth (m); $y_{m,e}$ = equilibrium scour depth (m); U_c = critical velocity (m/s); U_0 = cross-section average velocity (m/s) = Q/A; Q = flow rate (m^3/s); A = cross-section area (m^2); $\omega = 1 + 3\gamma_0$; γ_0 = coefficient of turbulent intensity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Chang (1994) conducted flume study using three sets of uniform and two sets of non-uniform sands. By assuming streambed friction coefficient was the sum of friction coefficient induced by sand grain and that by groundsill, Chang proposed an equation for estimating the groundsill spacing interval:

$$\frac{L}{L_0} = 10^{9.8}\left(\frac{h}{R}\right)^{-3.46}\left(\frac{\nu}{UR}\right)^{-5.1}\left(\frac{gR}{U^2}\right)^{-3}\left(\frac{\tau_g}{\rho U^2}\right)^{-3.9} \quad (2)$$

where L = groundsill spacing interval (m); L_0 = total length of channel reach that having groundsills installed (m); h = height of the groundsill (m); R = hydraulic radius (m); ν = flow viscosity (m^2/s); U = average flow velocity (m/s); g = acceleration of gravity (m/s^2); τ_g = friction induced by groundsill (N/m^2); ρ = flow density (kg/m^3). However, Equation (2) did not demonstrate the effect of sediment sizes.

Based upon the concept of dynamic equilibrium, results from flume studies, and field survey, Hwang (1995) not only simplified Chang's groundsill spacing equation, but also restored the role that sediment sizes played in the phenomena. The simplified equation read as the following

$$L = 4.67\frac{D_{65}^{0.14}}{H^{0.73}S^{0.45}} \quad (3)$$

where L = groundsill spacing interval (m); D_{65} = representative sediment diameter (m); H = design flow depth (m); S = original channel gradient.

Aderibigde et al. (1998) found the correlation among Froude number, scour depth, and the length of the scour. Other factors that equally important were also identified. They were sediment mean diameter, channel gradient, and especially the variation in approaching flow depth. The reason was because the degree of variation in flow depth that approaching the transverse structure conducted the progression of scour. It was also found that the angle of approaching flow that plunging the channel bed directed the depth of the scour.

Wu (2000) conducted flume studies on the spacing interval for submerged groundsills. The study was carried out from the viewpoint of allowable scour depth under which the submerged groundsill remained durable. The equation was written as

$$L_I = 48.872\frac{h}{\tan^2\phi}\left[\frac{Q}{\sqrt{B\,y_n\left(S_g-1\right)g\,S\,D_{50}{}^3}}\right]^{-0.399} \quad (4)$$

where L_I = submerged groundsill spacing interval (m); h = height of the submerged groundsill (m); ϕ = angle of repose of the sediment that submerged in the flow; Q = designed peak discharge (m^3/s); S_g = specific gravity of the sediment; B = width of the channel between revetments (m); y_n = normal depth (m); g = acceleration of gravity (m/s^2); S = original channel gradient; D_{50} = sediment mean diameter (m).

Under the assumption of independence between groundsill spacing interval and scour development, Gaudio et al. (2000) conducted flume study on the mechanism of scour formation. By further ignoring the effect of turbulence velocity on scour development and assuming the constant sediment density, a simplified relation was obtained as the following

$$\frac{y_s}{H_s} = \phi\left[\frac{a_1}{H_s}, \frac{a_1}{\Delta D}\right] \quad (5)$$

where y_s = maximum scour depth (m); H_s = critical specific energy (m); a_1 = morphological jump (m); a_1/H_s = ratio of energy loss between different forms of hydraulic jump caused by groundsills; $a_1/\Delta D$ = relationship between forms of hydraulic jumps and representative sediment diameter; Δ = specific gravity of the sediment.

Lenzi et al. (2002) extended Gaudio et al. (2000) results to mountain streams, followed by flume studies. Their results indicated that densimetric Froude number calculated from D_{95} produced higher correlation. The resultant equation for the maximum scour depth (y_s) and maximum scour length (l_s); respectively, was written as

$$\frac{y_s}{H_s} = 0.435 + 1.452\left(\frac{a_1}{H_s}\right)^{0.862} + 0.059\left(\frac{a_1}{\Delta D_{95}}\right)^{1.491} \quad (6)$$

$$\frac{l_s}{H_s} = 4.479 + 0.023\left(\frac{a_1}{H_s}\right)^{-1.808} + 2.524\left(\frac{a_1}{\Delta D_{95}}\right)^{1.129} \quad (7)$$

Wu et al. (2002) re-analyzed Wu (2000) data and proposed an equation describing the geometric shape factor of the scour at the toe of the submerged groundsill. The equation was written as

$$\frac{d_{sc}}{L_{sc}} = 2.7046\left[\frac{1}{\left(S_g-1\right)D_{50}\,S\,L_I}\sqrt[3]{\frac{q^4}{g^2}}\right]^{-0.3384} \quad (8)$$

where d_{sc} = maximum scour depth (m); L_{sc} = projected length between the toe of a submerged groundsill and the location where maximum scour occurs (m); q = unit width flow discharge (m^3/m-s); S_g = specific gravity of the sediment; g = acceleration of gravity (m/s^2); S = original channel gradient; D_{50} = sediment mean diameter (m).

Wu et al. (2004) investigated the applicability of open-slot groundsill in the generation of meander in a trained channel through flume studies. Their study suggested that open-slot groundsills encourage the process of selective sediment transport along the thalweg. Scour adjacent to the open-slot was found to be limited to 2~4 times the width of the slot opening. A series of open-slot groundsills was possible to restore

Copyright © 2006 Taylor & Francis Group plc, London, UK

the meander in trained channel except for fine-bed-material channel. They also found that sediment sizes, design discharge, and channel slopes controlled the formation of meander; whereas, groundsill interval controlled the degree-of-freedom of the meandering.

3 EXPERIMENTAL APPARATUS AND MATERIAL

3.1 *Hydraulic flume, open-slot groundsill scaled models, and experiment setup*

The experiment was conducted in a semi-circulated flume located in Steepslope Hydraulics Laboratory at National Pingtung University of Science and Technology. The flume measured 4 m in length, 0.91 m in width, and 0.30 m in depth. A pair of revetments with the face slope of 1:0.3 (V:H) was furnished to imitate the revetments commonly adopted in Taiwan. The bottom width of the experimental channel therefore constrained by left and right revetments was 300 mm.

Groundsill models in the scale of 1:50 were cut from 15 mm-thick waterproof plywood into 300 mm by 315 mm plates. Open slots with constant depth of 15 mm but various lengths were then cut along one edge of the groundsill plates. By taking 150 mm as the total width of the openings ($\sum b$), four slot settings were designed for this study. They were 0, 1, 2, and 4; respectively.

The zero-slot setting represented a conventional groundsill without open slot. One-slot setting represented a single slot with width of 150 mm cut on an edge of a conventional groundsill. The slot was cut in such a manner so that it was centered on the edge of the groundsill. Two-slot setting represented a conventional groundsill with two slots evenly distributed and cut on the edge of the groundsill (Fig. 2). Similarly, four-slot setting represented a conventional groundsill with four slots evenly distributed and cut at the apron of the groundsill.

The process of slot cutting left blocks (white rectangular objects in Fig. 2) at the apron of the groundsill. These blocks created obstruction to the flow. To simplify the discussion, water blockage ratio (W_b) was therefore defined as the ratio between width of the block (T_b) and that of the open slot (b). The scaled open-slot groundsill models and the corresponding dimension as well as parameters were listed in Table 1.

Groundsill models were then installed into the flume and sealed with Silicone along the side and bottom edges of the sill to prevent flow from seepage. Groundsill models were placed 300 mm apart to finally form a train of groundsills. The top rims of groundsill blocks were set 15 mm above the sand-filled channel bed, which made the bottom rims of the open slots set flush with the sand-filled channel bed as shown in Figure 2. For the conventional groundsill, or zero-slot groundsill in this study, the apron of the structure was set 15 mm above sand-filled channel bed. After the seal was set, experiment sand was filled and carefully leveled.

Figure 2. Experiment setup for two-slot groundsills installed.

Table 1. Dimensions and parameters associated with open-slot groundsill models.

Slot setting	Block width (T_b) mm	Slot width (b) mm	Water blockage ratio (T_b/b)
0	300.0	0.0	1.00
1	75.0	150.0	0.50
2	50.0	75.0	0.66
4	30.0	37.5	0.80

Sand originated from river sediment with sizes ranged from 0.063 to 4.75 mm was sieved through U.S. standard sieves of #5, #10, #18, #35, #60, #120, and #230 into 8 size groups. They were then mixed to form three size groups with mean particle diameter (D_{50}) of 0.55, 0.85, and 1.45 mm that imitated 27.5, 42.5, 72.5 mm in prototype; respectively.

Flow was regulated using Omron E5AK-T PID controller and an automatic valve. The steady discharge entering the flume was constantly monitored through Siemens flow meter. Three steady flow rates were selected in this study. They were 0.001, 0.00068, and 0.00043 m^3/s for the models, and 17.67, 12.02, and 7.60 m^3/s for the prototypes, respectively.

The lower limit of the discharge was set at the rate so that not only the minimum level of transport beyond the incipient motion for the coarse sediment would be ensured, but also blocks of groundsills would not be submerged at all times. The upper limit of the flow rate was regulated to ensure the total submergence of the groundsills would occur in all cases. On the other hand, the mid flow rate was set between the two extremes, which could submerge the groundsills at low channel

gradient. Experiment parameters of this study were listed in Table 2.

3.2 *Flow- and channel-surface profile measurements*

The schematic drawing of the experiment setup was shown in Figure 3, in which measurement section was shown. Measurements conducted in this study included flow- and channel surface measurements. A digital point gauge with the accuracy of 0.1 mm was used for flow- and channel-surface profile measurements. Flow surface profile measurements did not engaged until one hour after the beginning of the experiment, and the measurements were taken as detail as possible to describe the flow surface profile.

Outlet of the flume was first blocked, followed by instant cut off of water supply and slow drain in the flume at the end of each run before the channel bed profile measurements started. Rill meter that often employed in soil erosion research was used with the assistance of a digital camera to capture the images of final channel bed profiles. Digital images were then manually digitized with respect to a reference point on the images to obtain channel bed profiles' elevations. Digital elevation model for each experimental run were finally constructed to data analysis.

4 RESULTS AND DISCUSSIONS

4.1 *Effect of water blockage ratio on flow concentration*

Blocks that created by cutting slots in a conventional groundsill created disturbance to the flow. The disturbance included flow concentration at the slot openings and backwater behind the blocks. Figure 4 demonstrated the effect of different water blockage to the flow that created by different slot settings. All pictures in Figure 4 were taken at the same flow rate, channel gradient, and bed material except the slot setting.

Photo of Figure 4A was taken when flow passed through a conventional groundsill with water blockage ratio of 1.00. Since conventional groundsill ran across the channel with fixed elevation uplift, therefore, the only way that flow could run over the groundsill was by overflowing. The elevation uplift at the cross section of the sill not only created backwater, but also generated elevation drop so that overflowing flow could plunge the streambed at the toe of the sill. The manner how overflowing flow plunged the streambed would be depended upon the flow depth downstream and the energy of the overflowing flow. It could change from plunged flow to pseudo-plunged flow, or into submerged hydraulic jump (Wu et al. 2002, Vischer & Hager 1998).

Photo of Figure 4B was taken when flow passed a four-slot groundsill with water blockage ratio of 0.80. Backwater effect was destroyed and flow became concentrated. Figure 4C was taken at two-slot groundsill with water blockage ratio of 0.66. Figure 4D was taken at one-slot groundsill with water blockage ratio of 0.50 where flow concentration became apparent and limited backwater occurred behind both wings of the groundsill. The effect of water blockage and that of flow concentration was clearly demonstrated as water blockage ratio decreased. Figure 4 also demonstrated how flow changed from uniform distributed plunged flow (Fig. 4A) to block-controlled pseudo-plunged flow (Fig. 4B), to slot-controlled pseudo-plunged flow (Fig. 4C), and to pseudo-submerged hydraulic jump (Fig. 4D).

Figure 6. Diverse streambed features created in one-slot sill setting.

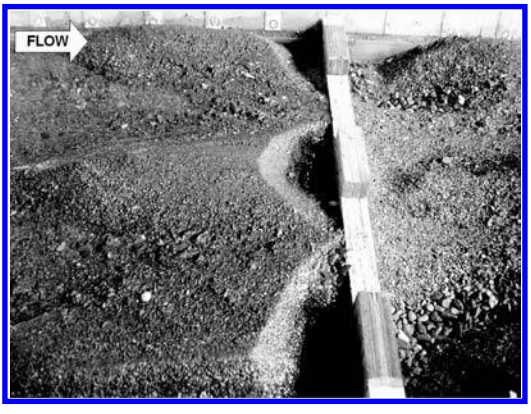

Figure 7. Diverse features caused by two-slot groundsill.

4.2 *Effect of water blockage ratio on streambed topographic feature*

Under the interaction of backwater and plunged flow, various topographic features thus developed at the streambed. For conventional groundsill setting, backwater effect could migrate upstream farther than other slot settings would ever be able to. This pool of relatively slow moving water reduced the flow velocity, which in turns reduced the transport capacity of the incoming flow that carried sediment freshly escaped from the scour hole. At the meantime, backwater also served as cushion at the toe of the sill to confine the scour produced by plunged flow.

The balance in energy between groundsills resulted a unique deposition like the sediment hump shown in Figure 5 near the downstream neighboring sill. This sediment hump was observed throughout the conventional groundsill settings regardless how flow changed from plunged flow at low flow rate, pseudo-plunged flow at mid flow rate, or submerged hydraulic jump at high flow rate (Wu et al. 2002).

Flow concentration reached to the maximum and backwater arrived at the minimum in one-slot groundsill setting as that shown in Figure 4D. The plunged flow dug into the streambed directly in the beginning of the process and gradually turned into submerged flow when scour hole at the toe of the sill become fully developed. Because backwater effect was confined at both wings of the one-slot groundsill, selective sediment transport was observed at the outskirt of the scour hole. Diverse streambed features were therefore cultivated as shown in Figure 6.

As the water blockage ratio increased due to the increase of open slots, flow became less concentrated and plunging effect at the streambed reduced as well. The block(s) that situated in the course of the flow stagnated the flow and caused backwater to occur as well as scour behind the block(s) by circulating flow.

Figure 7 illustrated the scour behind the blocks that sit at the central line of the channel as well as side corners at the wings. As far as the scour at the toe of the sill was concerned, it was caused by pseudo-plunged flow that overflowed the structure. On the other hand, scour behind the blocks and that behind the center block were mainly caused by circulating flow.

The diverse features caused by open-slot groundsills were not only controlled by the water blockage ratio that induced by openings, but also dictated by flow rates, sediment sizes, and channel gradients. Figures 8 and 9 illustrated the effect of flow rates and water blockage ratios imposed on the diversity of streambed features.

4.3 *Diversity of streambed features*

To quantify the channel bed feature changes at different slot settings, digitized channel bed elevation data that measured at the end of each run were used to build a digital elevation model. Elevations at the grid nodes were then categorized into discrete classes

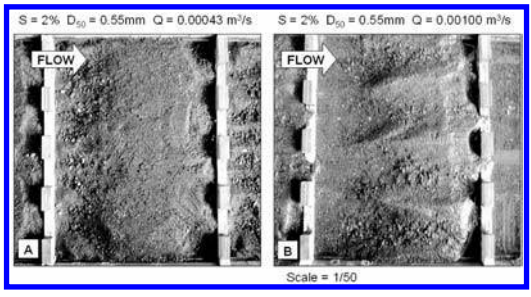

Figure 9. Effect of flow rate induced on the diversity of streambed features in four-slot groundsill setting.

using Sturges classification formula. Sturges formula provided a statistical-sound base that suggested the number of classes should be considered for the data population. The formula was written as

$$K = 1 + 3.3\,(\log n) \tag{9}$$

where K = number of classes, n = number of data points in the population.

Shannon diversity index was used to quantify the streambed elevation, and the formula read as

$$SDI = -\sum_{i=1}^{q}(P_i)\ln(P_i) = -\sum_{i=1}^{q}\left(\frac{m_i}{M}\right)\ln\left(\frac{m_i}{M}\right) \tag{10}$$

where SDI = Shannon diversity index; P_i = elevation richness in the ith elevation class; m_i = number of elevation points in the ith elevation class; M = total number of elevation points in data population; q = number of elevation classes suggested by Sturges formula.

When all nodal points possessed the same elevation, Equation (10) would return zero for SDI value. Table 3 summarized part of the research results obtained for $D_{50} = 0.85$ mm and $Q = 0.001$ m^3/s. Results included original channel slope (S), slot setting, maximum scour depth (d_{sc}); average scour depth ((d_{sc})$_{avg}$), and Shannon diversity index (SDI) for streambed features' elevations. Results from Table 3 were also plotted in Figure 10.

Table 3. Result summary for $D_{50} = 0.85$ mm and $Q = 0.001$ m^3/s runs*.

S (%)	Slot setting	d_{sc} (mm)	(d_{sc})$_{avg}$ (mm)	SDI
2	Conventional	15.0	10.1	0.59
	One-slot	30.1	15.0	1.04
	Two-slot	31.1	19.4	0.95

	Four-slot	35.8	23.6	1.50
6	Conventional	39.0	37.3	1.32
	One-slot	82.2	51.1	2.09
	Two-slot	70.0	40.5	1.82
	Four-slot	49.8	33.6	1.55

*Scale = 1/50.

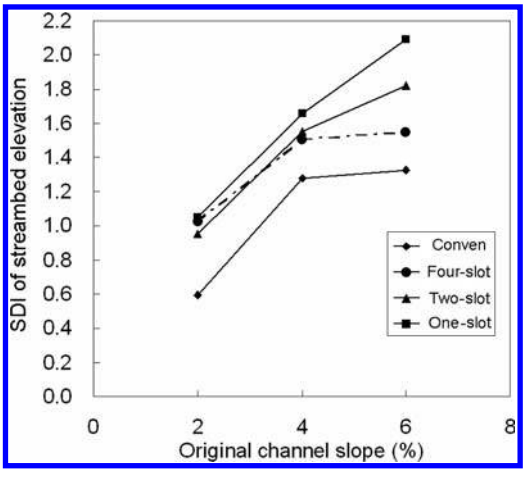

Figure 10. Relation between channel slope and SDI index for $D_{50} = 0.85$ mm and $Q = 0.001$ m^3/s runs.

Few observations could be drawn from Table 3 and Figure 10. One-slot groundsill produced highest SDI for all channel slopes; whereas, conventional groundsill produced the lowest SDI values. The reason was because one-slot groundsill concentrated inflow more effectively that created deeper and longer scour; whereas, conventional groundsill evenly distributed the inflow that equally divide the plunging force across the channel and created shortest and shallow scour.

Regardless the slot setting, all open-slot groundsill had lowest SDI values at 2% slope, and the SDI values increased as channel slope increased. The reason was because channel slope assisted flow to plunge farther and deeper into the channel bed. Hence, deeper and longer scours often occurred at steeper slopes.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Four-slot and conventional groundsills had similar trend in the *SDI* with respect to channel slope. However, *SDI* values at four-slot setting were always higher than that at conventional groundsill setting. In addition, four-slot groundsill generated the shallowest scour among all open-slot settings in this study.

Conventional groundsills produced the shallowest scour as well as the lowest *SDI* values among all groundsill settings. The common deposition hump as that shown in Figure 5 appeared to be the trademark of streambed features carved by flow overflowed the conventional groundsill. Even though the scour depth was the shallowest, conventional groundsill replaced the diversity of the streambed feature with a uniformly distributed scour trench and a regularly shaped hump.

On the other hand, scour trench running in the channel-wise direction resulted from the concentration of flow that enhanced by single slot opening with selective deposition at the outskirt of the trench made one-slot groundsill produced the highest *SDI* values among all groundsill settings. More diverse the streambed elevation appeared, higher the *SDI* values reached. However, the scour caused by one-slot groundsill may cut too deep that eventually put groundsill foundation in risk.

5 CONCLUSION

Results of this study indicate that having open-slot groundsills as grade control practices creates more diverse features on streambed as compared to conventional groundsills. The blocks resting between openings provide obstruction to the incoming flow that create circulating flow behind the blocks and make the streambed packed with patches of pools and sand dune ridges.

One-slot groundsill produces the highest Shannon diversity index values among all groundsill settings; which indicates that diversity in streambed feature's elevations is the richest at one-slot setting. However, deep scour at the toe of the groundsill that caused by the action of flow concentration may put groundsill foundation in risk; especially when the scour undercuts the streambed underneath the sill foundation.

Results from this study seem to suggest the existence of optimum opening setting between two- and four-slot or four-slot to conventional groundsills dependent upon how diverse the streambed features is about to create. Obviously, the interaction between groundsill interval and slot opening settings will make future study in the similar nature interesting and promising in the restoration of streambed diversity.

ACKNOWLEDGEMENT

Riprap design for spur protection

C. Gisonni
Department of Civil Engineering, Seconda Università di Napoli, Aversa, Italy

W.H. Hager
VAW, ETH-Zurich, Zurich, Switzerland

ABSTRACT: River training techniques are often based on spurs whose main purposes are to prevent bank erosion, besides an enhancement of ecological conditions in the proximity of river shores. Actually, no general design criteria are available, given the large variety of geometrical parameters which characterize a spur set. In addition, the duration and reliability of this river structure are strongly affected by local scour phenomena, whose mechanism is not yet completely understood. A detailed experimental campaign was conducted to investigate the effects of various parameters, namely the spur length, the spur spacing, the spur height, along with the main hydraulic and granulometric parameters on the failure condition for a riprap protection at spur heads. Following a data analysis, design equations were established to predict riprap failure. In particular, different failure modes may occur, according to riprap size and spur displacement.

1 INTRODUCTION

Spurs are considered as one of the oldest river training techniques to protect river banks from erosion and to concentrate flows to the river center; nowadays spurs are widely used because they preserve sustainable ecological conditions along river shores, compared to alternative bank protection techniques. Spurs may be submerged completely under flood conditions and are generally exposed from the water during the low flow season. In the latter case, they behave hydraulically similar to bridge abutments except for certain geometrical parameters.

Research on scour phenomena at spurs has not advanced significantly, compared to bridge scour; one reason is definitely the geometrical complexity of spurs that involves a larger set of design parameters as compared for example to bridge appurtenances (pier or abutment). During the past two decades, a huge set of experimental data was collected, mainly focusing on a description of the scour phenomenon around bridge piers or bridge abutments. In these cases, the scour process may be simply characterized by a limited amount of geometric, hydraulic and granulometric parameters involving:

- the pier diameter (or its geometric shape),
- the approach flow conditions as expressed with the average approach flow velocity V_o and the approach flow depth h_o,
- the fluid viscosity ν, the fluid density ρ and gravitational acceleration g, and
- the sediment properties as expressed with the average sediment size d_{50}, the sediment non-uniformity parameter $\sigma = (d_{84}/d_{16})^{1/2}$ and sediment density ρ_s.

The temporal advance of maximum scour around these elements was described with the densimetric Froude number of the approach flow $F_d = V_o/(g' d_{50})^{1/2}$ (Oliveto & Hager 2002) with the reduced gravitational acceleration defined as $g' = g[(\rho_s - \rho)/\rho]$.

Spurs involve a much more complex geometry as compared with bridge elements. In fact, spur arrangements may be characterized by the following geometrical parameters (Figure 1):

- spur orientation α_s relative to the river axis,
- spur length b as the spur projection perpendicular to river axis,
- spur spacing L_s,
- average spur height $s = (1/2)(s' + s'')$,
- spur permeability,
- and number M of spurs along the streambank.

Based on a literature review, most of the available experimental and theoretical researches refer to single spur, that behaves quite differently from the multiple spur arrangement; it may be stated that no definite design guidelines are presently available, therefore. Melville & Coleman (2000) presented a concise summary on the currently available information of spur hydraulics. The spur spacing ratio was recommended between 3 and 5 (Julien 2002, Kondap & Prayag 1989). Lagasse et al. (1995) provided some additional

Copyright © 2006 Taylor & Francis Group plc, London, UK

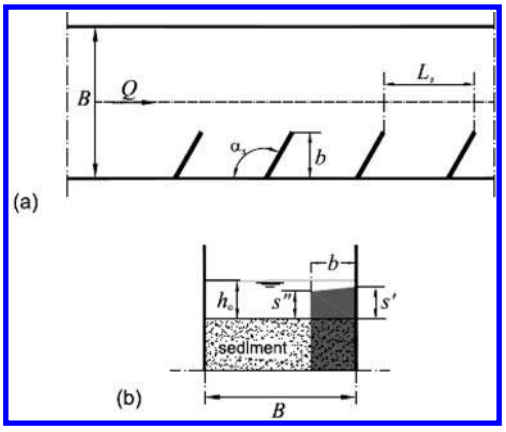

Figure 1. Definition sketch: (a) plan, (b) cross-sectional view.

information, such as the spur length should not be larger than 15% of the river width for impermeable spurs; spurs oriented perpendicular to the river axis are cost-effective because of their maximum projected length; the spur height should not exceed the bank height and a sloping spur towards the river axis was attributed advantageous. In addition these authors advised a riprap protection to the spur head and faces, among other items. The scour depth around a spur was estimated with an equation relating to low weir flow, without including some of the parameters previously mentioned. Lagasse et al. (1995) also stated that no generalized procedure for spur protection can be elaborated because each river reach is site-specific. According to Richardson et al. (1975) few other guidelines are given in the literature, and no definite design criteria are available, but only rules of thumb or special case studies are described.

The present paper reports of laboratory observations conducted at VAW, Swiss Federal Institute of Technology, Zurich, Switzerland. The purposes of the research program was (1) to focus on scour phenomena around spur dikes and corresponding countermeasures, and (2) to define the design criteria for practical applications. No systematic work on riprap protection of spurs has been done so far, even if spurs are used worldwide in river engineering. The knowledge of the failure conditions for spurs has to be considered crucial to the profession because of the costly structures and their effectiveness in terms of streambank protection and river ecology.

2 LABORATORY OBSERVATIONS

2.1 *Hydraulic model and preliminary experiments*

The experimental campaign on spurs was conducted in the VAW scour channel, whose width is $B = 1$ m, as described by Hager et al. (2002).

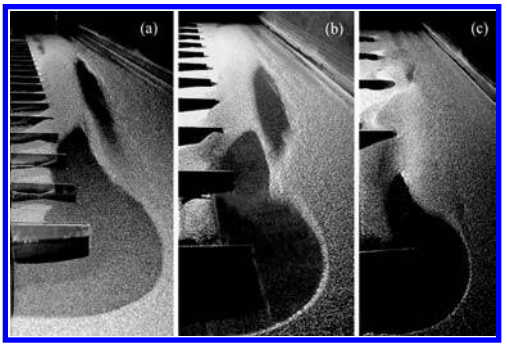

Figure 2. Scour patterns after 20 hours test duration for $F_d = 2.2$: effect of spur spacing for $\lambda = $ (a) 1, (b) 2 and (c) 4. View from upstream.

The experimental program was subdivided into two stages. Preliminary tests were performed to check the influence of different geometrical spur configurations on the scour performance (Gisonni et al. 2005).

Impermeable spurs 0.005 m thick were used. Experiments involved spur lengths of $b = 0.05$, 0.10, 0.15, 0.20, 0.35 and 0.50 m, and spur crest slopes from horizontal to 1:5. The approach flow depth h_o was always larger than 0.05 m to prevent scale effects. The average spur height s varied from 25% to 100% of the approach flow depth h_o, thus covering the range $0 < S \leq 1$ with $S = s/h_o$.

Given that the scour features around a spur head may be considered as a particular case of the scour process around bridge abutment (Oliveto & Hager 2005, Unger & Hager 2006), the hydraulic parameters were not systematically varied because their effect on the temporal scour advance and on the failure mechanism was considered known.

The mobile bed consisted of an almost uniform sand of size $d_{50} = 0.0011$ m ($\sigma = 1.18$); also, the hydraulic effect of the granulometry was not further investigated, because it was considered correctly contained in the failure formula of Unger & Hager (2006). The slope of the sediment bed was adjusted to 0.001 m/m to compensate for frictional effects.

Figure 2 shows upstream views along the spurs perpendicular to the left bank for $\alpha_s = 90°$, of which the relative height was $S = s/h_o = 0.75$. A densimetric Froude number of $F_d = 2.2$ was selected along with a relative spur width $\beta = b/B = 0.20$.

The figure refers to three spur spacings, namely $\lambda = L_s/b = 1$, 2 and 4, after 20 hours of test duration. The photographs were taken after the sediment bed had been drained with a water elevation slightly below the original bed elevation. The photographic light was positioned close to the sediment to increase the contrast between regions of sediment aggradation and scour.

Copyright © 2006 Taylor & Francis Group plc, London, UK

It was evidenced in these preliminary tests that the first spur of a spur arrangement in sand and gravel bed rivers is predominantly scoured. Consequently, a suitable spur protection appears to be essential to limit both the scour depth and the scour extension.

Following extensive experimentation the optimum spur arrangement in a straight river reach was identified for a certain granulometry and by restricting mainly to the clear-water flow regime, resulting in the subsequent recommendations:

1 spur length ratio $\beta = b/B$ up to 0.20;
2 spur spacing $\lambda = L_s/b$ varying between 2 and 4 to preserve a suitable flow recirculation within the spur fields and to guarantee the spur integrity;
3 relative spur height $S = s/h_o$ between 0.25 and 1, thus covering the complete spur overflow conditions up to the 'abutment' configuration;
4 spur alignment α_s equal to 90°, with possible angles between 60° and 120°,
5 spurs staggering, in terms of the average spur height, to reduce the severity of scour process. Accordingly, the crest of the first spur opposed to the flow should be set at a lower elevation as compared to the downstream spurs.

2.2 *Riprap experiments*

Spurs arranged according to the preceding recommendations resulted in an almost uniform distribution of the scour depth along the complete spur set, given that the first two spurs are protected with an adequate riprap to counter excessive scour.

The second part of the experimental program focused on selected ranges of the geometrical spur parameters:

1 spur length ratio $\beta = b/B$ up to 0.50, whereas the spur length b varied from 0 to 0.50 m, with $B = 1.0$ m as the channel width;
2 spur spacing $\lambda = L_s/b$ between 2 and 4;
3 relative spur height $S = s/h_o$ between 0.25 and 1;
4 spur alignment α_s equal to 90°, with selected runs for α_s equal to 60° and 120°;
5 average height of the first spur opposed to the approach flow was always set equal to $0.50s$, with s as the average height of the remaining spurs.

As previously stated, riprap protection was arranged for the first two spurs opposed to the approach flow. An almost uniform riprap was concentrically arranged around these spur heads; the riprap revetment is characterized by the riprap diameter d_R or the relative sediment ratio $\delta = d_R/d_{50}$, and the number of riprap rows n.

A single layer riprap, without any protection such as a filter or synthetic cloth, was carefully placed so that the revetment surface was flush with the surrounding bed sediment (Figure 3); as a consequence there was

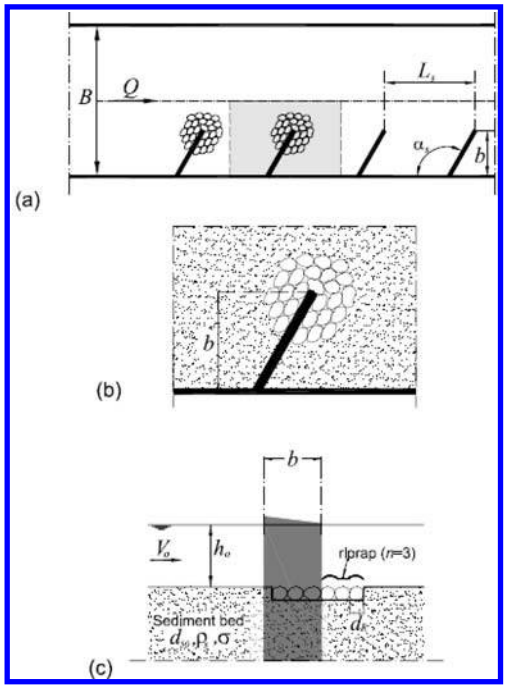

Figure 3. Riprap arrangement, definition sketch: (a) plan, (b) detailed plan view, (c) longitudinal section of one-layer riprap.

no riprap protrusion into the current, that may generate additional turbulence within the flow field.

Different diameters d_R of the riprap elements were considered, namely 5.3, 8.5, 12, 19, 30, and 50 mm; the ratio of riprap to bed sediment diameters δ ranged between 4.8 and 45.5, therefore. The number n of riprap rows concentrically placed around a spur head was 1, 3, 6 and 10. In total, more than one hundred experiments were completed, each running until the riprap failure condition was attained, as described in the following.

2.3 *Failure modes*

By definition, a riprap revetment was considered failed as soon as one of the riprap elements belonging to the inner row was dislodged (Figure 4). Therefore, failure had not yet attained when an outer riprap row was damaged.

Prior to the test beginning, the bed sediment was carefully positioned and the riprap elements were accurately inserted concentrically about the first two spur heads; a slight submergence of the test reach improved the accuracy of these preliminary steps, by reducing the disruption of the flat bed surface. When starting an experiment, the discharge was gradually increased and the sediment entrainment along the test reach was prevented by sufficient submergence. The

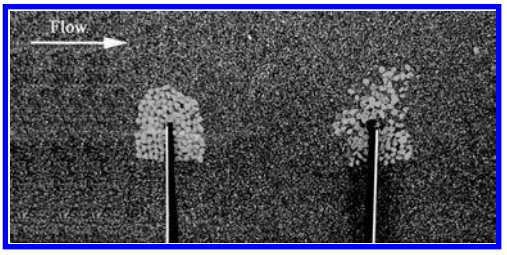

Figure 4. Riprap failure for $\delta = 8.5$, $n = 6$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 2$.

tailwater level was externally controlled with a flap gate of an accuracy of 0.5 mm; it was thus possible to lower the tailwater until a slight movement of the bed sediment around the riprap was observed. Then the discharge was increased to the test value and the flow depth was kept almost constant through adjustments with the flap gate, such that a certain value of $S = s/h_o$ was finally attained. Both the flow depth and the discharge were slowly varied to suppress inertial effects due to unsteady flow conditions. The failure (subscript f) discharge Q_f and the corresponding approach flow depth h_{of} were noted along with additional information on the failure details, the hydraulic grade line and the overall failure progress.

Figure 4 shows the riprap failure attained at the end of a test characterized by the following parameters: $\delta = 8.5$, $n = 6$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 2$. Note that the riprap of the first (half-height) spur remained intact whereas few riprap elements at the head of the second spur have slid away; the residual riprap elements in this specific experiment assured some protection against the scour advance around the river structure.

In general, as for the riprap failure at bridge piers, the scour hole close to the spur head increased massively once riprap failure had occurred. This circumstance is clearly shown in Figure 5, referring to a test with $\delta = 12$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 2$.

Figure 5(a) shows the riprap arrangement before the experiment was started; Figure 5(b) relates to the end of the run and shows that the riprap at the first (half-height) spur has remained almost intact except for a slight damage along the outer row, whereas riprap failure at the second spur has occurred. The scour pattern and the damages in the vicinity of the structure are also evident from a close illumination of the sediment bed.

When investigating riprap failure at circular bridge piers, Unger & Hager (2006) defined three distinct failures modes, namely:

– *Sliding* a mode occurring once the outer riprap rows are damaged due to the formation of a scour surface between the bed sediment and the riprap; any element from an inner riprap row may possibly fail by sliding into the scour surface.
– *Undermining* as the typical failure mode occurring for a riprap diameter much larger than the bed sediment. In this case, the critical riprap element is not moved horizontally, but sinks into the bed sediment. This condition is less severe than sliding, because a residual protection is guaranteed after failure has occurred.
– *Rolling* as a relatively seldom failure mode, if the sediment ratio δ is close to 1, so that the inner riprap members may roll away by jumping over the outer riprap rows due to the high velocity close to the element perimeter.

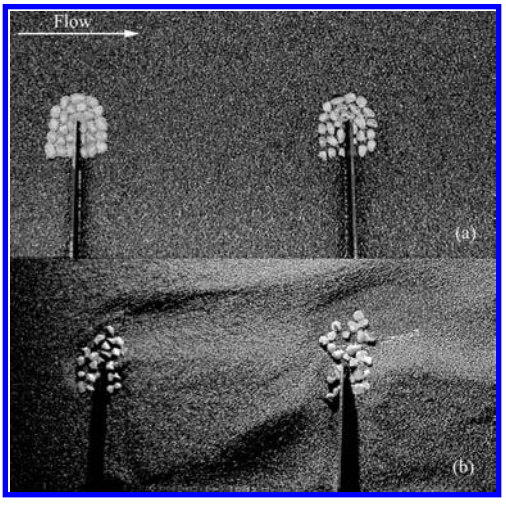

Figure 5. Experimental run for $\delta = 12$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 2$; (a) before and (b) after riprap failure.

These failure modes apply to both bridge piers and spurs, except for rolling. In addition, a novel failure mode was observed during the experimental campaign with spurs as described in the following.

Figure 6 shows a typical sequence of sliding riprap failure at the second spur for a test with $\delta = 12$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 3$; the riprap at the first half height spur was practically intact at the end of the run. Starting from the original arrangement (Figure 6a), the sliding mechanism was always associated with the displacement of the most peripheral riprap elements; similarly to bridge pier scour, the sediment entrainment normally started at an angle φ roughly equal to 130° measured from the channel axis, creating a scour hole around the riprap zone (Figure 6b). Consequently, outer riprap elements may move towards the river axis from a spur head.

Generally, the scour surface expanded and migrated upstream along the interface between the original bed and the riprap revetment stopping at an angle φ roughly

Copyright © 2006 Taylor & Francis Group plc, London, UK

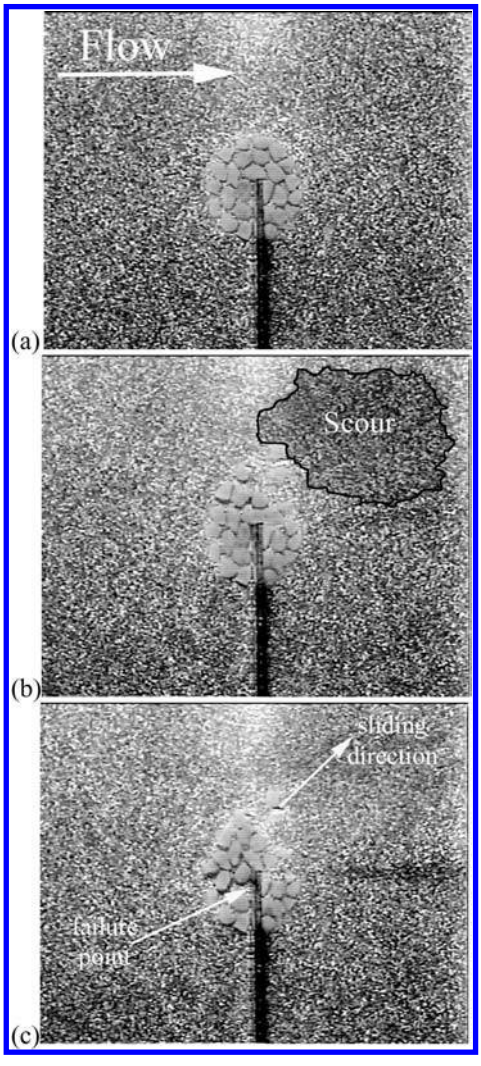

Figure 6. Sliding failure mechanism for $\delta = 12$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 3$: plan view of (a) original arrangement, (b) sediment entrainment in the tailwater spur zone, and (c) riprap failure after scour surface has migrated to the spur head zone.

equal to 75°. After the first riprap elements have been entrained, the contiguous stones may slide into the scour surface such that space is available for riprap elements of the next row. The failure process is normally completed when any of the riprap elements along the inner row becomes unstable, as shown in Figure 6c. Note that the upstream riprap zone was never significantly scoured at riprap failure during the sliding mode.

Whereas the sliding failure mode progresses from the riprap periphery towards the spur head, the undermining failure mode attacks directly the key riprap element at the spur head, thereby not seriously attacking the peripheral riprap members.

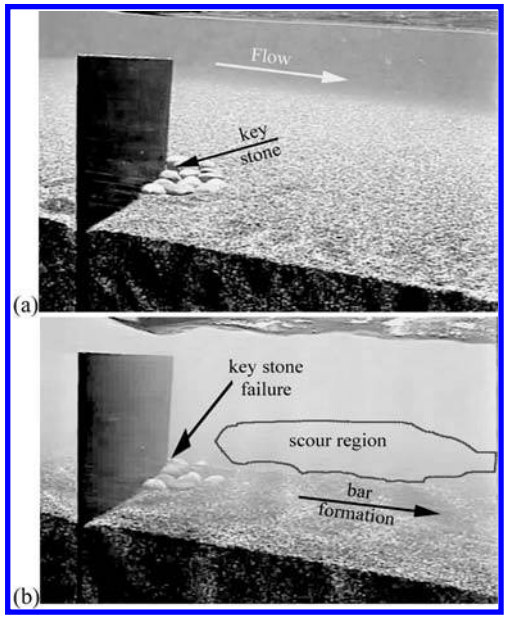

Figure 7. Undermining failure mechanism for $\delta = 19$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 3$: side views of (a) original arrangement and (b) riprap failure with typical scour pattern.

Undermining of riprap may hardly be recognized from a top look because the vertical riprap displacement during the failure process cannot be appreciated. This failure mode was considered less severe than sliding because the riprap elements adjacent to the key stone eventually slide into the cavity left by the undermined key element, thus protecting the spur head from a further scour advance. Once undermining has occurred, much less scour activity results in the following stage, until the interface scour has developed so strong that sliding is initiated and the integrity of the riprap protection is lost. The mechanism again is similar to observations conducted by Unger & Hager (2006) on bridge piers.

Figure 7 shows an example of the undermining mechanism at the second spur for a test with $\delta = 19$, $n = 3$, $\beta = 0.20$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 3$.

Figure 7a shows the original riprap arrangement, where the proper position of the key element is highlighted. When increasing the discharge, thereby keeping constant the approach flow depth, the sediment entrainment normally starts around the riprap periphery, similarly to the sliding failure mode.

Compared to Figure 6c, Figure 7b shows a larger interface scour with stronger sediment aggradation, forming a bar that eventually migrates downstream of

Figure 8. Final riprap arrangement after 'failure mode 3'.

the spur. In Figure 7b the key element is no more visible because it has sunk below the original bed elevation.

2.4 *Failure mode 3*

Riprap placed around a spur fails either by sliding or by undermining. For selected tests, still another sliding process was observed, defined as failure mode 3. For spurs of extremely small length b and small relative height S, the second spur was subjected with an almost plane jet originating from the overflow of spur 1. This jet impinged onto the second spur and caused downflow, similar to abutments or piers. Instead of generating an interface scour along the riprap periphery towards the channel axis, a downflow scour upstream of the second spur developed eventually so intense that the riprap element located upstream close to the river bank slid into the downflow scour hole.

Figure 8 shows a typical case of failure mode 3, recorded for a test with $\delta = 19$, $n = 3$, $\beta = 0.05$, $S = 0.75$, $\alpha_s = 90°$ and $\lambda = 3$. Note that the diameter of the riprap arrangement at the first spur was not uniform, because the effect of non-homogeneous riprap was verified for selected tests.

This phenomenon was particularly evident for a small spur length for which the relative spur spacing was smaller than $\lambda = 3$. Failure mode 3 occurred also for relatively small spur height S typically below 0.50. The combined spur parameter (βS) was identified as the main controlling parameter.

Experimental data indicated, however, that an additional effect originates from the relative spur length L_s/h_o. Combining the three parameters, the sliding parameter $\Lambda = [(b/B)(s/h_o)(L_s/h_o)]$ was found to describe the geometrical conditions leading to failure mode 3.

Experimental data show that failure modes 1 and 2 arise for $\Lambda > 0.35$, whereas failure mode 3 occurs for $\Lambda \leq 0.35$. Typically, minimum numbers adopted in river engineering practice are $b/B = 0.05$, $s/h_o = 0.50$ and $L_s/h_o = 20$ resulting in a minimum of $\Lambda = 0.50$. Failure mode 3 thus is hardly relevant in applications.

3 INCEPTION EQUATION

Sediment inception is evidently described by the Shields' diagram, indeed a widely used tool in river engineering during last decades. It is well known that the Shields' diagram cannot be used explicitly to evaluate the threshold condition for a uniform sediment to move along the bed. Many equations are currently available to represent the Shields' curve, accounting for different sediment transport regime.

Of particular interest is the fully turbulent regime for which Hager & Del Giudice (2001) found that the inception condition may be described by the following equation:

$$\mathrm{F}_{di} = \sigma^{-1/3} 1.65 (R_h/d_{50})^{1/6} \tag{1}$$

valid for $D_* = (\mathrm{g}'/\nu^2)^{1/3} d_{50}$ larger than 150, being F_{di} the inception densimetric particle Froude number defined as $\mathrm{F}_{di} = V_{oi}/(\mathrm{g}' d_{50})^{1/2}$, V_{oi} the inception velocity, R_h the hydraulic radius, g' the reduced gravitational acceleration, ν fluid viscosity and σ the sediment non-uniformity parameter.

Experimental evidences confirmed that the critical bed shear stress is reduced, e.g. the inception densimetric particle Froude number F_{di}, in the presence of obstacles due to the generation of 'extra turbulence' (Gisonni & Vacca 2005). Consequently the entrainment condition may be expressed through a reduced densimetric particle Froude number $\mathrm{F}_{d\beta}$:

$$\mathrm{F}_{d\beta} = \Phi_\beta F_{di} \tag{2}$$

being Φ_β a disturbance factor, smaller than 1, depending on the obstruction geometry. Hager & Oliveto (2002) found that for bridge hydraulics the disturbance factor may be estimated as:

$$\Phi_\beta = 1 - (2/3)\Sigma\beta^{5/4} \tag{3}$$

with the contraction ratio β equal to D/B where D is the pier diameter or the abutment width, and Σ a shape factor equal to 1 and 5/4 for bridge pier and abutment respectively.

In the present case, both the lateral spur extension as expressed with $\beta = b/B$ and the vertical spur height ratio $S = s/h_o$ are relevant. Given the conceptual approach according to which scour represents a hydrodynamic resistance problem, i.e. the resistance force being equal to a drag coefficient, times the approach flow velocity head times the surface of attack, the governing parameter describing the spur (subscript s) geometry may be identified as $\beta_s = (b/B)(s/h_o) = \beta S$.

The inception densimetric Froude number F_{ds} (subscript s for spurs) depends exclusively on the spur geometry by accounting for the disturbance factor Φ_s

Copyright © 2006 Taylor & Francis Group plc, London, UK

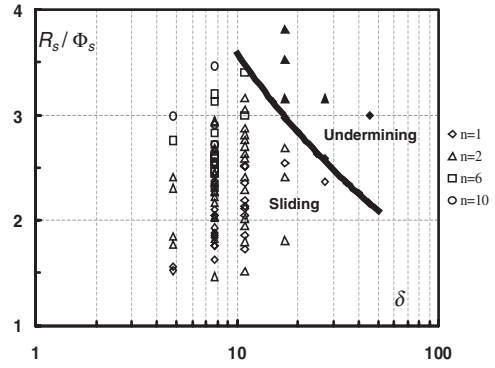

Figure 9. Distinction between Sliding (open symbols) and Undermining (full symbols) failure modes for different riprap row numbers n and relative diameters δ.

computed from equation (3) with Σ equal to 5/4, given that β_s is involved instead of β:

$$F_{ds} = \sigma^{-1/3} 1.65 (R_h/d_{50})^{1/6} \left[1 - (5/6)\beta_s^{5/16}\right], \quad (4)$$

valid for $\beta_s = \beta S$ values between 0.25 and 0.50.

4 PRELIMINARY RIPRAP DESIGN EQUATION

According to the preceding considerations on sediment entrainment at spurs, a similar approach was used to describe the riprap failure condition (subscript R) using the so called spur load factor R_s:

$$R_s = \frac{F_{dR}}{\sigma^{-1/3} 1.65 (R_h/d_{50})^{1/6} \Phi_R} = f(n, \delta, \lambda, \beta, S). \quad (5)$$

Equation (5) shows that the failure densimetric Froude number $F_{dR} = \sigma^{-1/3} V_{oR}/(g' d_{50})^{1/2}$, with V_{oR} as the cross-sectional velocity at riprap failure, depends on the relative riprap diameter δ, the number n of riprap rows, together with the geometrical parameters of spurs arrangement.

The failure disturbance factor Φ_R is similar to Φ_s for sediment inception and may consequently include the effect of β and S. Experiments showed that spur spacing λ has no significant effect on the factor Φ_R; within the experimental range $2 \le \lambda \le 4$, it is thus possible to consider $\Phi_R = \Phi_s = [1 - (5/6)\beta_s^{5/16}]$.

Figure 9 shows the relative hydraulic load factor R_s/Φ_s as a function of the relative riprap diameter δ. As intuitively considered, data referred to the Sliding failure mechanism are located on the lower left of the plot, whereas those with the Undermining failure mechanism are located on the upper right.

It is wise to remark that the Sliding mode is more dangerous than Undermining because riprap elements are 'lost' by Sliding, whilst Undermining reassures a significant residual protection also once failure has occurred. From the experimental data it was possible to locate the threshold line between these two failure modes with:

$$\frac{R_s}{\Phi_s} = 7.7\delta^{-1/3} \quad (6)$$

whose validity is obviously restricted to the experimental range $10 \le \delta \le 50$.

Unger & Hager (2006) expressed the failure condition for a concentric riprap layer of relative size δ with n riprap rows protecting circular piers by concentrating both parameter within the riprap number:

$$N = \delta^{0.20 n^{0.40}} \quad (7)$$

As shown by Gisonni & Hager (2006), the spur load factor R_s may also be considered as a function of the riprap number N, given that the disturbance factor Φ_s is properly assumed, as previously explained. The data may simply be plotted as $R_s(N)$, and the effect of various basic spur features analyzed in a two parameters' plot, as presented in the subsequent paragraphs. Note that equation (5) reduces to the entrainment condition of Hager & Oliveto (2002) for a circular pier or spur without riprap if $\delta = 1$, or $n = 0$, and further reduces to Shields' condition (1) for $\beta_s = 0$, i.e. $\Phi_R = 1$.

As already mentioned, the first spur of half spur height was always less attacked by scour than the second spur. Therefore, the following relates to riprap failure observations at the second spur.

4.1 *Effect of riprap gradation*

The effect of riprap gradation around a spur head was investigated with preliminary tests, in order to check whether a graded riprap assures a better protection compared to uniform riprap with the same average diameter. Three cases were closely considered for otherwise constant conditions, thereby using three riprap rows, namely: (i) uniform riprap, (ii) riprap with the largest element at the spur head and the smallest at the spur periphery, and (iii) inverse set-up with the smallest riprap element at the spur border.

Selected experimental runs were performed with $d_R = 5.3$, 8.5 and 12 mm, for spur length $b = 0.20$ m and various spur heights S. It was found that the hydraulic load factor was not significantly depending on the particular gradation considered; anyhow the performance of case (i) was slightly better than (ii), with case (iii) as the poorer choice. The failure process seemed to be quite abrupt in cases (ii) and (iii) as compared to case (i).

Accordingly, all tests were made with a uniform riprap consisting of diameter d_R and n rows around the spur heads of spurs 1 and 2, to protect the entire

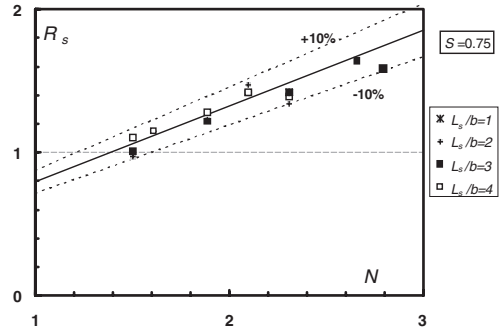

Figure 10. Effects of spur spacing $\lambda = L_s/b$ on the hydraulic load factor R_s as a function of riprap parameter N.

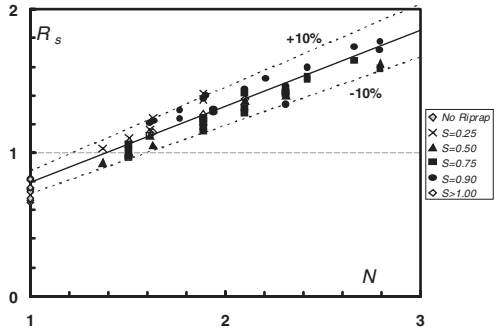

Figure 11. Effects of spur relative height $S = s/h_o$ on the hydraulic load factor R_s as a function of riprap parameter N.

spur set-up. Indeed an important simplification in terms of steering parameters of the phenomenon and, consequently, for design guidelines.

4.2 *Effect of transverse spur slope*

This parameter is hardly mentioned within design guideline, even if 1:10 transverse spur slope is mostly used. Nevertheless a number of experiments were performed with a relative spur height $S = 0.75$, $d_R = 8.5$ mm and $b = 0.20$ m, but different transverse slopes of the spur crest (ranging from horizontal to 1:5). The effect of this parameter was found to be extremely small and the maximum difference in terms of load factor R_s was confined within the $\pm 10\%$ limits. A similar result was obtained for other relative spur heights S, such that the transverse spur slope may be considered insignificant. Based on this conclusion, most part of the experimental set-up is characterized by 1:10 transverse spur slope.

4.3 *Effect of relative spur spacing*

Figure 10 shows the effect of relative spur spacing $\lambda = L_s/b$, for $b = 0.20$ m and $S = 0.75$, using riprap elements between 5.3 and 12 mm, and $1 \leq n \leq 10$.

The effect of the relative spur spacing on the hydraulic load factor was small, for λ between 1 and 4. It was observed, however, that the parameter λ mainly guides the internal flow pattern within the spur fields. Whereas mainly horizontal currents develop for larger λ values, typically above 2, vertical currents appear to form for 'small' relative spur spacing, with the main vortex axis perpendicular to the river bank.

This consideration supports technical recommendations proposing a relative spur spacing between 2 and 4, as mentioned in the introduction.

4.4 *Effect of spur length*

The effect of different spur lengths b was also analyzed, thereby considering riprap with $1 \leq n \leq 10$ and d_R from 8.5 to 19 mm. Many experimental runs were completed with $S = 0.75$ and different spur lengths, namely for $b = 0.10$ m, 0.20 m, 0.35 m and 0.50 m. Overall, the effect of the spur length b, e.g. the relative spur length β, appeared to be correctly contained in disturbance factor Φ_R, leading to maximum deviations of the hydraulic load factor R_s confined within $\pm 10\%$.

4.5 *Effect of spur angle*

The effect of spur angle was experimentally measured within the range $60° \leq \alpha_s \leq 120°$. Spur lengths $b = 0.20$ and 0.35 m were tested, again for a relative spur height $S = 0.75$, along with $d_R = 8.5$ and 12 mm and $1 \leq n \leq 10$. The data for $\alpha_s = 120°$ reveal a somewhat larger hydraulic load factor R_s than those for $\alpha_s = 60°$ and 90°, as was previously found by Oliveto & Hager (2005) for the scour depth at unprotected spurs. The effect of the spur angle α_s is correctly considered once the effective spur length b, e.g. perpendicular to the flow direction, is assumed when computing the disturbance factor Φ_R. Consequently, in straight river reaches as considered in the present research, no particular advantages were noted for spur angles different from $\alpha_s = 90°$.

4.6 *Effect of spur height*

The plot of figure 11 shows the effect of the relative spur height $S = s/h_o$ for $S = 0.25$, 0.50, 0.75, 0.90, and 1.00; hydraulic load factors were measured with spur lengths $b = 0.20$ m, 0.35 m and 0.50 m, riprap arrangements with diameter d_R ranging from 5 to 30 mm and riprap rows $1 \leq n \leq 10$.

It may be noted that the data are generally close to the trend line, even if the data for $S = 0.25$ are relatively high and those for $S = 0.75$ slightly low compared to the trend line, but always within the $\pm 10\%$ limits.

Beside riprap failure, Figure 11 includes also the data for inception at unprotected spurs, e.g. $\delta = N = 1$,

Copyright © 2006 Taylor & Francis Group plc, London, UK

based on selected experimental tests to evaluate sediment entrainment at the first two spurs without riprap placement. For $N = 1$ the hydraulic load factor R_s is observed to be significantly lower than unity and typically of the order 0.75 (±10%), confirming how spur arrangements without a riprap protection (of the first spurs) are not a safe design, as already remarked.

4.7 *Effect of riprap diameter*

The riprap diameter d_R was systematically varied between 5.3 mm and 50 mm and its effect was investigated thereby considering the remaining parameters $0.25 \leq S \leq 1.0$ and b from 0.10 to 0.50 m, along with $1 \leq n \leq 10$ and $2 \leq \lambda \leq 4$. All data demonstrated that the effect of riprap diameter d_R is properly represented by the riprap number N as defined by (7), with a good fitting to the trend line, as shown in Figures 10 and 11.

4.8 *Effect of riprap row number*

Similarly to d_R also the effect of riprap row number n is suitably contained within the riprap number N. For typical sediment size ratio $10 < \delta < 20$ the hydraulic load factor R_s is, respectively, increased by a factor of roughly 1.4 ($n = 3$), 1.7 ($n = 6$), and 2.2 ($n = 10$) as compared to $n = 1$. It is thus evident how an increasing value of n greatly improves the performance of a spur arrangement.

4.9 *Effect of densimetric Froude number*

For the whole set of experimental data the failure densimetric Froude number F_{df} was ranging between 1.4 and 3.4, i.e. from sediment entrainment at unprotected spurs until the transition between clear water and live-bed conditions. Figure 12 shows all the failure data plotted as the ratio of measured $R_{s,meas}$ and computed $R_{s,comp}$ hydraulic load factors versus the failure densimetric particle Froude number F_{df}.

It is evident that all the data, with few exceptions, are confined in the ±10% lines and that the approach is suitably representing the complex phenomenon of riprap failure. Therefore, the design equation for riprap failure can be expressed as:

$$R_s = 0.265(1 + 2N) \qquad \text{for } N_i \leq N \leq 2.8 \qquad (8)$$

with a correlation coefficient r^2 equal to 0.91. Here, N_i is the value of N for sediment entrainment of the order of $F_{di} = 1.5$.

Equation (8) along with figure 12 confirms that the original assumption is correct, according to which the hydraulic load factor correctly expresses the effect of the densimetric Froude number.

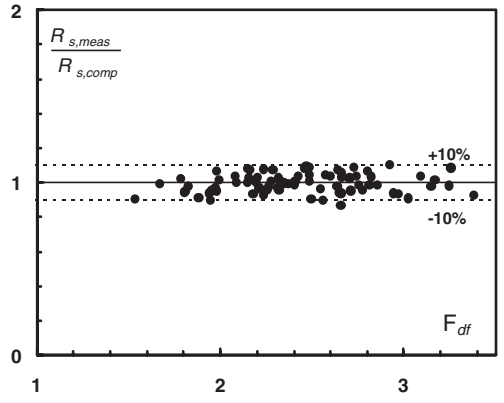

Figure 12. Measured $R_{s,meas}$ and computed $R_{s,comp}$ load factor ratio as a function of the failure densimetric Froude number F_{df}.

5 PRACTICAL ISSUES AND LIMITATIONS

The present research focused on the behavior of spurs arranged along a straight river reach, mainly investigating scour phenomena and the corresponding countermeasures. Given the large set of steering parameters, an experimental campaign was organized to analyze the main features of the spur failure process in the clear-water approach flow regime.

Following to previous experiments on bridge piers (Unger & Hager 2006), an approach based on a generalized Shields' equation was proposed. Experimental runs fall essentially in the rough turbulent regime although the dimensionless grain size is rather in the turbulent transition regime. The riprap failure design equation (8) thus accounts for the effects of hydraulics, granulometry and spur geometry. If both the riprap and the spurs extensions tend to zero, Shields' equation (1) is retained in its basic form.

The following main issues descend from the experiments: Spurs along straight river reaches are optimally arranged when the first spur has half height of all others. In any case the two first spurs must be carefully protected with a suitable riprap revetment to prevent the effects of severe scour action. The experimental set-up considered the simplest riprap configuration arranged in one layer flush with the original bed sediment without any filter. The purpose of this choice was to look for minimum performance in terms of protection, so that any other riprap arrangement is characterized by additional safety against failure. Furthermore, a feasible riprap model was conceived for a systematic experimentation.

Basically two distinct failure mechanisms were identified for riprap placed concentrically around the heads of the two first spurs. These include either Sliding into the interface scour hole that develops along the

Copyright © 2006 Taylor & Francis Group plc, London, UK

riprap periphery, or Undermining at the spur head. A criterion was established to predict the appropriate failure mode, as shown in Figure 9 and expressed with (6).

The average approach flow velocity V_{of} associated with riprap failure was expressed with (8) in which the hydraulic load factor R_s involves the hydraulics of the approach flow and the spur and riprap geometries, as defined with (5). The spur effect as expressed with Φ_s was correlated exclusively with the term βS representing the obstructed cross-sectional area by the spurs both in height and width.

A third riprap failure mechanism was detected for spur arrangements characterized by small length and height, for which an intense scour was noted within the first spur cell close to the river bank. This particular hydrodynamic effect may be described by combining the three governing length parameters to $\Lambda = [(b/B)(s/h_o)(L_s/h_o)]$. It was possible to recognize that failure mode 3 occurs for $\Lambda \leq 0.35$, whereas river applications generally result in a minimum of $\Lambda = 0.50$. Failure mode 3 thus hardly applies in applications, but may be of concern because of its comparatively small hydraulic load factor compared to Sliding and Undermining (Gisonni & Hager 2006).

The impact of the present results is significant in terms of contribution to the river engineering practice; the approach flow hydraulics and the spur arrangement are known for a hydraulic design procedure, and the spur riprap should be sized. However, for an existing spur and riprap arrangement, the existing structure should be checked against failure and the failure hydraulic load should be determined. Such technical issues may be tackled using the results of the present research, thereby also investigating the type of failure mode and the effect of certain parameters on the failure discharge. The proposed approach has inherent limitations due to the complexity of the investigated phenomena and the large number of steering parameters of the spur problem. This is the reason why future research needs to investigate several still open questions such as: (1) spur performance in river bends, (2) the effect of the live-bed regime and (3) the temporal scour advance at spurs once the riprap has failed. Nevertheless the present work may be considered an essential contribution to the study of spur hydraulics, from which the fundamental effects of the basic parameters on the riprap failure emerge, although several simplified conditions were considered.

6 CONCLUSIONS

This experimental study intended to identify the riprap failure conditions for a particular spur arrangement involving a first spur of half height as compared to the remainder, and riprap placed around the first two spurs.

Spur arrangements without a riprap protection at the front spurs are an unsafe design. Physical model tests allowed to evaluate the effects of various parameters on the spur performance and its riprap failure, by using the modified Shields' entrainment approach. The study involved the transverse spur slope, the relative spur height and length, the spur spacing and the effect of riprap diameter and riprap rows placed around a spur head. Finally a number of technical guidelines are proposed according to experimental evidences and the corresponding limitations.

Numerical simulation of flow and local scour around hydraulic structures

H. Zhang, H. Nakagawa, Y. Muto & Y. Baba
Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan

T. Ishigaki
Dept. of Civil & Environmental Engineering, Kansai University, Osaka, Japan

ABSTRACT: A numerical model is developed to simulate the flow and local scour around hydraulic structures. The model solves the 3D RANS equations for the flow with FVM formulation on an unstructured mesh. Arbitrary polyhedral mesh can be utilized to resolve complex geometries. Local scour due to bedload transport is simulated through the sediment continuity equation and empirical formulae for sediment transport rate. A bed slope factor is derived based on 3D force analyses to account for the local bed effect. Unrealistic bed slope possibly occurring in the computation is avoided by introducing a sediment slide process. The model verification is made by comparing the computed results with some existing experimental data obtained in different laboratory situations. It is shown that both the velocity field and the local scour profiles predicted by the current model are in reasonable agreement with those of the experiments.

1 INTRODUCTION

Researches on the flow and local scour around hydraulic structures (e.g. spur dykes, bridge piers and abutments) have a long history and are of continuous interest in the river engineering. Excessive scour holes have a potential to undermine the structure foundations in a river training project, in particular during flood events. This has resulted in a great number of failures and disasters. With the rapid expanding of the environmental concern, local flows and scour holes have also been found capable of forming satisfactory environment for the flora and fauna in river systems. For instance, Shields et al. (1995) documented significant increases in fish numbers, sizes, species and the area of aquatic habitat after the enlargement of local scour in a river restoration project. In-between the historically built groins along the Yodo River in West Japan, favorable environment for the growth and habitant of a variety of living things have also been observed. These have motivated construction of new groins in this basin (Kinki Regional Development Bureau, MLIT, Japan 2002). Although local scour phenomena are commonly encountered in river engineering practices, related researches are still far from enough and there remain a lot of challenges.

Essentially, local scour is the result of a dynamic feedback process involving the turbulent flow, sediment transport and bed evolution. The flow structure in the vicinity of a local scour hole is usually characterized by several vortex systems of different sizes, which initiate and control the local scour and provide the basic scour mechanism (e.g. Ali & Karim 2002 and Salaheldin et al. 2004). The predominant approaches in the state-of-the-art adopt empirical or semi-empirical formulae based on limited field data and experimental measurements. Despite the large number in amount, these formulae commonly select a number of variables from the approach flow depth, flow intensity, sediment size, the shape, size and alignment of local obstructions, etc. For example, the empirical formula proposed by Melville (1997) and its variants. This kind of methods has achieved a great development with the further understanding of the scour mechanism and more and more calibration data available. However, since these methods involve strong empiricism and introduce many uncertainties, they can provide very limited information and are usually problem-dependent. With the rapid development of both fluid dynamics and computer capabilities, 3D numerical modeling is increasing considered to be a more reliable solution. A well-established numerical model is able to resolve the evolution process of the 3D flow field and the 3D topography of scour holes, which are of significant meaning for engineering use. Previous researches have been carried out by several groups such as Michiue & Hinokidani (1992), Ushijima et al. (1992), Olsen & Melaaen (1993), Fukuoka et al. (1994), Ushijima (1996), Peng et al. (1998), Olsen & Kjellesvig (1998), Watanabe et al. 2001, Yen et al.

Copyright © 2006 Taylor & Francis Group plc, London, UK

(2001), Nagata et al. (2002), Bhuiyan et al. (2004) and Nagata et al. (2005). A brief overview of the recent studies has been reported by Zhang et al. (2005b) and Zhang (2005). It is found that most of the existing researches are based on structured mesh, which is only suitable for relatively simple geometries. However, study domains of engineering interests are generally complicated, especially in the case that the local scour is involved. In view of these arguments, this paper examines the 3D flow and local scour around hydraulic structures with numerical methods based on unstructured mesh. The flow velocity is simulated through solving the RANS (Reynolds-averaged Navier-Stokes) equations with the k-ε model for the turbulence closure. Local scour is assumed to generate due to bed load transport for the time being. The Ashida-Michiue formula (1972) is employed to evaluate the sediment transport rate. The bed evolution is obtained by solving the sediment continuity equation. A bed slope factor is derived to account for the effect of the local bed slope on the sediment transport. In order to guarantee that the local bed slope is not greater than the angle of sediment repose, a sediment slide algorithm is also proposed. Model verifications are performed under two experimental conditions. Both the velocity fields and the local scour profiles predicted by the current model are found to be in reasonable agreement with those of the experiments.

2 MODEL DESCRIPTION

The numerical model consists of a hydrodynamic module, a sediment transport module and a bed deformation module. The modules are linked together in a quasi-steady way on a moving unstructured mesh. The time scale of the bed evolution is assumed to be much larger than that of the flow field. Hence during the calculation of the bed deformation, the flow field and sediment transport conditions are assumed unchanged. These modules are described in the following contexts one after another.

2.1 *Hydrodynamic module*

The unsteady RANS equations written in the Cartesian coordinate system with the convention of Einstein summation are as follows.
Momentum equation:

$$\frac{\partial u_i}{\partial t}+u_j\frac{\partial u_i}{\partial x_j}=f_i-\frac{1}{\rho}\frac{\partial p}{\partial x_i}+\nu\frac{\partial^2 u_i}{\partial x_j\partial x_j}+\frac{1}{\rho}\frac{\partial \tau_{ij}}{\partial x_j} \quad (1)$$

Continuity equation:

$$\frac{\partial u_i}{\partial x_i}=0 \quad (2)$$

where u_i = averaged velocity component; x_i = Cartesian coordinate component; t = time; ρ = density of the fluid; f_i = body force; p = averaged pressure; ν = molecular kinematic viscosity of the fluid; τ_{ij} = Reynolds stress.

Due to the existence of the Reynolds stress terms, Equation 1 and Equation 2 are not a closed system. In the k-ε model, the Reynolds stresses are modeled from the information of the mean flow by introducing a concept of eddy viscosity and constructing two transport equations for the turbulence kinetic energy k and its dissipation rate ε.

In this study, the standard k-ε model is employed. Hence, the Reynolds stresses are estimated from the constitutive equation below.

$$\tau_{ij}=-\rho\overline{u_i'u_j'}=2\rho\nu_t S_{ij}-\frac{2}{3}\rho k\delta_{ij} \quad (3)$$

where u_i' = fluctuating velocity component; ν_t = eddy viscosity; S_{ij} = strain-rate tensor and δ_{ij} = Kronecker delta. The latter three parameters are expressed by

$$\nu_t=C_\mu\frac{k}{\varepsilon}\quad S_{ij}=\frac{1}{2}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)\quad \delta_{ij}=\begin{cases}1 & if\ \ i=j\\ 0 & if\ \ i\neq j\end{cases} \quad (4)$$

in which C_μ = coefficient, and is usually set to be a constant 0.09. k and ε are solved from their transport equations as follows, respectively.

$$\frac{\partial k}{\partial t}+u_j\frac{\partial k}{\partial x_j}=\frac{\partial}{\partial x_j}\left[\left(\nu+\frac{\nu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] \quad (5)$$

$$\frac{\partial \varepsilon}{\partial t}+u_j\frac{\partial \varepsilon}{\partial x_j}=\frac{\partial}{\partial x_j}\left[\left(\nu+\frac{\nu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right]+\left(C_{1\varepsilon}G-C_{2\varepsilon}\varepsilon\right)\frac{\varepsilon}{k} \quad (6)$$

in which G = rate of turbulence production, defined as

$$G=-\overline{u_i'u_j'}\frac{\partial u_i}{\partial x_j} \quad (7)$$

and the model constants generally take the universal values as follows.

$$\sigma_k=1.0\quad \sigma_\varepsilon=1.3\quad C_{1\varepsilon}=1.44\quad C_{2\varepsilon}=1.92 \quad (8)$$

2.2 *Sediment transport module*

2.2.1 *Sediment transport rate*

In the absence of suspended sediment, bed variation is due to the movement of bedload. If the shear stress acting on the particle is smaller than a critical value, there is no bed motion. Once the sediment is set in motion, the transport rate of bedload is commonly evaluated

Copyright © 2006 Taylor & Francis Group plc, London, UK

with empirical formulae. In this study, the Ashida-Michiue formula (1972) is employed, which is written as follows.

$$\frac{q_b}{\sqrt{(s-1)gd^3}} = 17\tau_{*e}^{3/2}\left(1-\sqrt{\frac{\tau_{*c}}{\tau_*}}\right)\left(1-\frac{\tau_{*c}}{\tau_*}\right) \quad (9)$$

where q_b = bedload transport rate per unit width; s = specific gravity of sediment; g = gravitational acceleration; d = sediment diameter; τ_{*e}, τ_{*c}, τ_* = dimensionless effective shear stress, critical shear stress and shear stress, respectively. The dimensionless shear stress is connected with the shear stress and the friction velocity via

$$\tau_* = \frac{\tau_b}{(s-1)\rho gd} = \frac{u_*^2}{(s-1)gd} \quad (10)$$

where τ_b = near-bed shear stress and u_* = friction velocity.

In the calculation of bedload transport in a channel with a relatively gentle slope, the critical shear stress can be obtained from the well-accepted Shield's diagram or other popular criteria such as the Iwagaki's relation (1956) and the particle gravity does not affect the sediment motion significantly. However, local bed slope usually becomes very steep in the situation where local scour occurs. According to van Rijn (1993), the bed slope may affect the sediment transport in three ways: (1) the near-bed velocity; (2) the threshold condition, i.e. the condition just sufficient to initiate sediment motion and (3) the transport rate once the sediment is in motion. Since a 3D turbulence model is employed, the first influence has been automatically included in the flow model. The latter two are discussed in the following context.

2.2.2 *Effect of the local bed slope*

The forces acting on a sediment particle resting on a sloping bed under the threshold condition are shown in Figure 1. In this figure, n stands for the normal direction of the local bed plane and α, β & γ are the corresponding direction angles (i.e. $n = \cos\alpha i + \cos\beta j + \cos\gamma k$). The forces include the submerged weight of the particle W and the hydrodynamic force F. The latter one is usually divided into a drag force F_D tangential to the riverbed plane and a lift force F_L normal to the riverbed plane in the analyses of sediment transport.

For reasons of simplicity, the lift force is not taken into account explicitly in the analyses. The effect of the lift force is assumed to be relatively small compared with the submerged particle weight and is accounted for through empirical coefficients in the expression of the drag force. Then it can be assumed that the hydrodynamic force F has a direction almost parallel to the riverbed plane. Hence, the resulted driving force F_r is written as

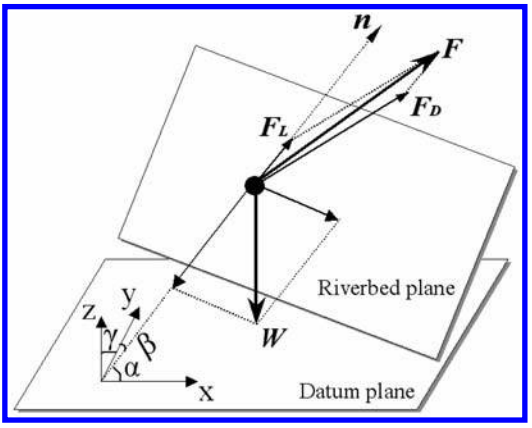

Figure 1. Definition sketch of forces on a sediment particle resting on a sloping bed under threshold condition.

$$\boldsymbol{F}_r = \left(W\cos\gamma\cos\alpha + f_x F\right)\boldsymbol{i} + \left(W\cos\gamma\cos\beta + f_y F\right)\boldsymbol{j} + \left(-W\sin^2\gamma + f_z F\right)\boldsymbol{k} \quad (11)$$

where f_x, f_y & f_z = direction cosines of the hydrodynamic force, i.e.

$$\boldsymbol{F} = F\left(f_x\boldsymbol{i} + f_y\boldsymbol{j} + f_z\boldsymbol{k}\right) \quad (12)$$

The resulted stabilizing force F_s is also easy obtained, which has the form as

$$F_s = W\cos\gamma\tan\varphi \quad (13)$$

where φ = angle of sediment repose.

Under the threshold condition, the resulted driving force equals the stabilizing force, i.e. $F_r = F_s$, one obtains

$$F^2 + 2lWF + \left(\sin^2\gamma - \cos^2\gamma\tan^2\varphi\right)W^2 = 0 \quad (14)$$

in which l is expressed by

$$l = f_x\cos\gamma\cos\alpha + f_y\cos\gamma\cos\beta - f_z\sin^2\gamma \quad (15)$$

The positive solution of Equation 14 is

$$F = \left(\sqrt{l^2 - \sin^2\gamma + \cos^2\gamma\tan^2\varphi} - l\right)W \quad (16)$$

On the other hand, the submerged particle weight W and the hydrodynamic force F including the effect

Copyright © 2006 Taylor & Francis Group plc, London, UK

of both the drag force and lift force are empirically expressed as follows.

$$W = c_1(s-1)\rho g d^3 \quad F = c_2 \tau_b d^2 \tag{17}$$

where c_1 = coefficient related to the shape of the particle; c_2 = coefficient depending on the local Reynolds number. Normalizing Equation 16 with expressions in Equation 17, one has the dimensionless critical shear stress τ_{*c} for a sloping bed as follow

$$\tau_{*c} = \frac{\tau_{bc}}{(s-1)\rho g d} = \frac{c_1}{c_2}\left(\sqrt{l^2 - \sin^2\gamma + \cos^2\gamma\tan^2\varphi} - l\right) \tag{18}$$

where τ_{bc} = critical near-bed shear stress.

In case of a horizontal bed $(\alpha, \beta, \gamma) = (90°, 90°, 0)$, Equation 18 becomes

$$\tau_{*c0} = \frac{c_1}{c_2}\tan\varphi \tag{19}$$

where τ_{*c0} = dimensionless critical shear stress for a horizontal bed. As has been mentioned before, this can be easily obtained from some well-tested criteria such as the Shields' diagram. If one compares Equation 18 with Equation 19, the difference between a sloping bed and a horizontal bed can be expressed by a bed slope factor K

$$K = \frac{\tau_{*c}}{\tau_{*c0}} = \frac{\sqrt{l^2 - \sin^2\gamma + \cos^2\gamma\tan^2\varphi} - l}{\tan\varphi} \tag{20}$$

If there is longitudinal bed slope (denoted as θ_l) only and the longitudinal velocity is predominant, i.e. $(\alpha, \beta, \gamma) = (90° - \theta_l, 90°, \theta_l)$ and $(f_x, f_y, f_z) = (\cos\theta_l, 0, -\sin\theta_l)$, one gets the following bed slope factor

$$K = \cos\theta_l\left(1 - \frac{\tan\theta_l}{\tan\varphi}\right) \tag{21}$$

If there is transverse bed slope (denoted as θ_t) only and still the longitudinal velocity is predominant, i.e. $(\alpha, \beta, \gamma) = (90°, 90° - \theta_t, \theta_t)$ and $(f_x, f_y, f_z) = (1, 0, 0)$, one goes to another bed slope factor

$$K = \cos\theta_t\sqrt{1 - \frac{\tan^2\theta_t}{\tan^2\varphi}} \tag{22}$$

Equation 21 and Equation 22 are commonly used bed slope factors in the literatures (e.g. van Rijn 1993 and Duan et al. 2000). However, these two factors are questionable when they are applied to the sediment transport around hydraulic structures where the magnitudes of the three velocity components are usually comparable. Comparing these two conventional bed slope factors with Equation 20, the new bed slope factor is more general while still maintains the simplicity for programming.

2.2.3 *Sediment slide process*

It is known that there is a critical value for the angle of the local bed slope during the development of the scour hole. This critical angle is generally assumed to be the angle of sediment repose for computational simplicity. In the calculation, the unrealistic steep slope larger than the angle of repose hence should be avoided. In this model, a simple algorithm considering the sediment slide process is introduced here.

A plane-view of the CV (Control volume) surface on the riverbed is shown in Figure 2 (left). At each time step, the program checks the nodes on the riverbed and the corresponding neighbors. If a slope steeper than the angle of repose has been detected connecting node $A(x_A, y_A, z_A)$ and node $B(x_B, y_B, z_B)$, the locations of node A and node B should be adjusted to nodes A' and B' as shown in Figure 2 (right). The change of the elevation is denoted as δz_A and δz_B, respectively. As the bed slope connecting nodes A' and B' equals the angle of repose, one has

$$(z_B - \delta z_B) - (z_A + \delta z_A) = \tan\varphi\sqrt{(x_B - x_A)^2 + (y_B - y_A)^2} \tag{23}$$

On the other hand, sediment conservation should be ensured during the adjustment, i.e.

$$\sum S_{A,neighbor}\delta z_A = \sum S_{B,neighbor}\delta z_B \tag{24}$$

where $S_{A,neighbor}$ = projected area of the mesh surrounding node A (i.e. mesh 1 to mesh 6 shown in Figure 2) and $S_{B,neighbor}$ = projected area of the mesh surrounding node B (i.e. mesh 1, mesh 2 and mesh 7 to mesh10 in Figure 2).

With Equation 23 and Equation 24, the new locations of node A and node B can be obtained. This process is repeated until the bed slopes connecting all the CV nodes and their corresponding neighbors are not more than the angle of sediment repose.

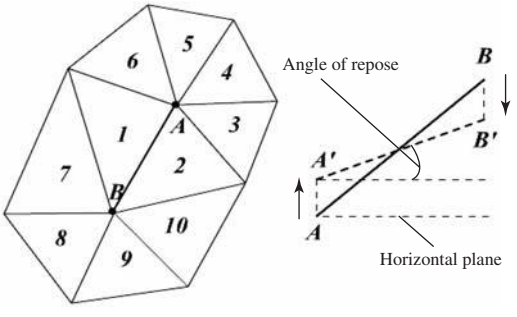

Figure 2. Definition sketch of sand slide process.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.3 *Bed deformation module*

If the bedload transport rate is known, the bed level is easy to calculate from the mass balance equation in the bedload layer, i.e.

$$\frac{\partial z_b}{\partial t}+\frac{1}{1-\lambda}\left(\frac{\partial q_{bx}}{\partial x}+\frac{\partial q_{by}}{\partial y}\right)=0 \tag{25}$$

where z_b = bed level; λ = sediment porosity; q_{bx}, q_{by} = bedload transport rate in x and y direction, respectively.

2.4 *Boundary conditions*

The boundary conditions include the inlet, the outlet, the impermeable wall, the free surface and the symmetrical plane.

The inlet boundary is usually taken as a Dirichlet boundary. All the quantities are known and prescribed there. At the outlet boundary, zero gradients are assumed along the normal direction. Near the impermeable wall, the flow velocity is assumed to be parallel to the wall. The standard wall function approach is used to link the turbulence domain with the near-wall area. For the time being, the free surface is considered as a rigid lid. As a result, the water level is unchangeable during the computation. In case of flow in a geometrically symmetrical domain, the symmetrical plane boundary is employed to save computer resources and computational time.

2.5 *Numerical scheme & solution procedure*

An FVM (finite volume method) based on a moving unstructured mesh is employed in the model formulation. The governing PDEs (partial differential equations) in the turbulence model are integrated over a number of polyhedral CVs covering the whole study domain in the FVM procedure. The final conservation equations have the following form considering the mesh movement.

$$\frac{\partial}{\partial t}\int_V dV+\int_S\left(u-u_m\right)\cdot ndS=0 \tag{26}$$

$$\frac{\partial}{\partial t}\int_V \phi dV+\int_S \phi\left(u-u_m\right)\cdot ndS=\int_S \Gamma\nabla\phi\cdot ndS+\int_V bdV \tag{27}$$

where V = volume of the CV; S = face of the CV with a unit normal vector n directing outwards; u_m = velocity of the CV face movement; ϕ = general conserved quantity representing either scalars or vector and tensor field components; Γ = diffusion coefficient and b = volumetric source of quantity ϕ.

Equation 26 expresses the mass conservation and Equation 27 stands for the conservation of other quantities such as the momentum. The equation system is mesh-independent and is valid for arbitrary polyhedral CVs. The conserved equations are discretized on a collocated unstructured mesh. For reasons of simplicity and stableness, the power law scheme has been adopted during the spatial discretization for the time being. The surface fluxes are calculated from the Rhie-Chow interpolation (1983) in order to avoid the checkerboard phenomenon. In the temporal integral, the second order implicit Crank-Nicolson scheme is employed. The widely used SIMPLE (semi-implicit method for pressure-linked equations) procedure is included for the coupling of the pressure and the velocity.

The final algebraic equation systems resulted from the discretization process are characterized by sparse and non-symmetrical coefficient matrices. They are solved with a preconditioned GMRES (generalized minimal residual method) incorporated with an ILUTP (incomplete LU factorization with threshold and pivoting) preconditioner proposed by Saad (2003). Before submitted to the solver, the relaxation method proposed by Patankar (1980) is implemented to increase the diagonal dominance of the coefficient matrices.

Based on the shear stress calculated from the turbulence model, the sediment transport rate is evaluated with the Ashida-Michiue formula. The bed deformation at one time step is then computed. If all the local bed slopes are not greater than the angle of sediment repose, a new mesh is generated and the calculation time is forward. This procedure is repeated until the prescribed time is covered or an equilibrium condition is reached.

3 MODEL VERIFICATION

The turbulence model and the proposed unstructured mesh methods have been verified to be capable of predicting some selected flows under fixed bed conditions with reasonable accuracy (Nakagawa et al. 2004 and Zhang 2005a). Hence, this paper examines the model performance under movable bed conditions only.

3.1 *Flow and local scour around a non-submerged cylindrical pier*

One of the most typical problems on local scour in the hydraulic engineering research is the flow passing a circular pier. In this verification case, the experiment carried out by Melville (1975) and Melville & Raudkivi (1977) is tested. The experiment was conducted in a glass-sided flume which was 19 m long, 456 mm wide and 440 mm deep. A cylindrical pier with a diameter of 50.8 mm was used as a bridge pier and installed in a movable bed section. The sediment in the experiment had a specific gravity of 2.65 and d_{50} = 0.385 mm. The experimental setup and the hydraulic conditions are shown in Figure 3 and Table 1, respectively.

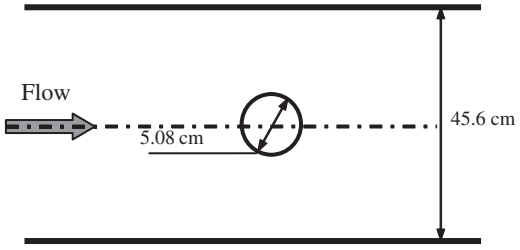

Figure 3. Experimental setup.

Table 1. Hydraulic conditions for the experiment (non-submerged cylindrical pier).

Parameters	Symbols	Values
Flow discharge	Q	17.121 l/s
Water depth	H	15 cm
Mean velocity	u	25.0 cm/s
Sediment diameter	d	0.0385 cm
Critical shear velocity	u_{*c}	1.4 cm/s
Shear velocity ratio	u_*/u_{*c}	0.86
Pier diameter	D	5.08 cm
Reynolds number	$Re.$	37,544
Froude number	$Fr.$	0.21

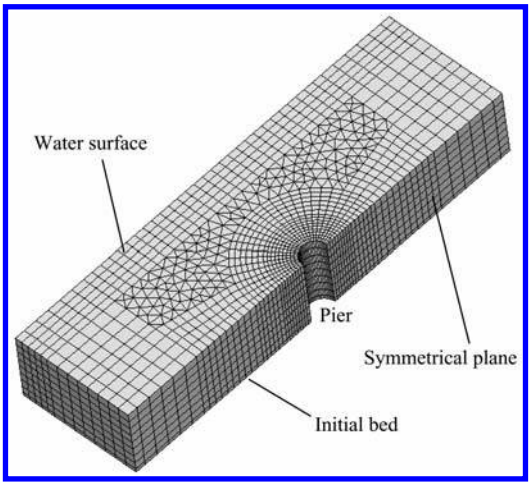

Figure 4. Unstructured mesh system around the pier at initial stage (half domain, not to scale).

Since the study domain is geometrically symmetrical, the calculation is based on half domain only. The mesh system around the pier at the initial stage is shown in Figure 4. It is a combination of both hexahedra and prisms. The inlet boundary is set at around 15D upstream from the pier and the outlet is about 20D downstream from the pier. A logarithmic velocity profile along the vertical direction is assumed at the inlet. The turbulence quantities k and ε are specified

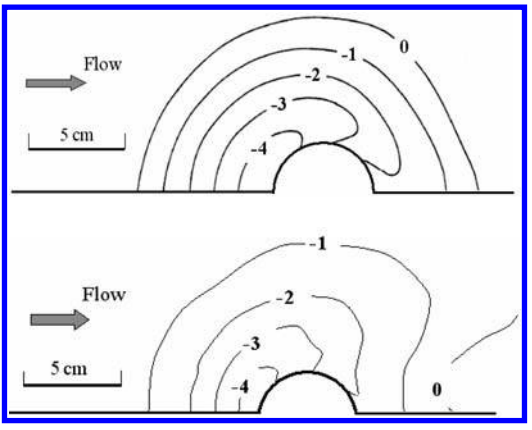

Figure 5. Bed contour after half an hour (Experiment: Top, Melville 1975; Computation: Bottom).

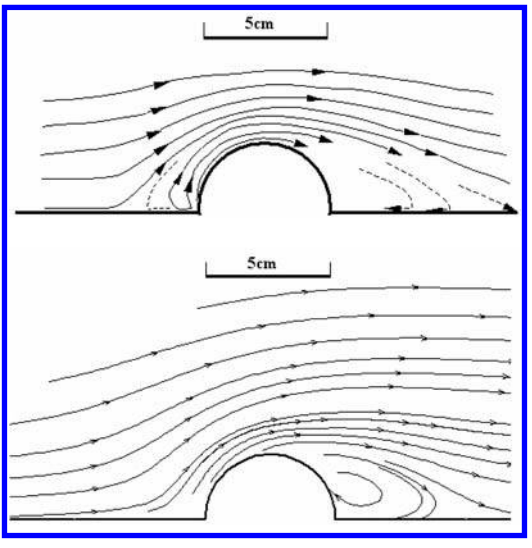

Figure 6. Streamlines at 2 mm from the bed at initial stage (Experiment: Top, Melville & Raudkivi 1977; Computation: Bottom).

corresponding to a turbulence intensity of 8% and taking the viscosity ratio as 10.0.

The bed deformation and corresponding flow field are investigated. The comparisons between the experimental measurements and computational results are shown from Figure 5 to Figure 7.

In Figure 5, the bed deformation around the pier after half an hour is shown. Basically, good agreement between the experimental measurement and computational result can be observed, in particular around the upstream side of the pier. Nevertheless, the computed scour hole appears not so smooth as that of the experiment. The slope is deeper near the pier and becomes

Copyright © 2006 Taylor & Francis Group plc, London, UK

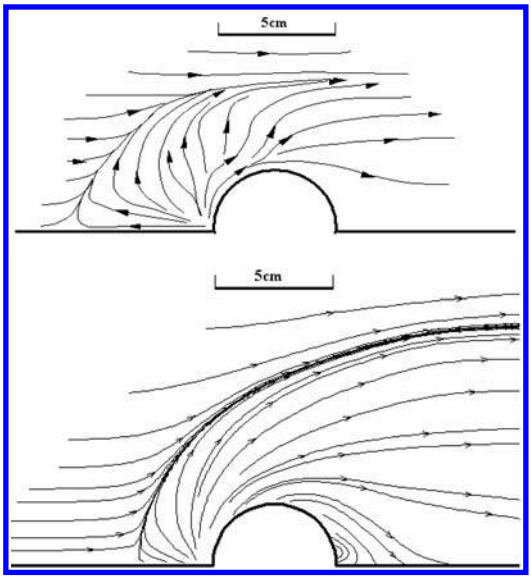

Figure 7. Streamlines at 2 mm from the bed after half an hour (Experiment: Top, Melville & Raudkivi 1977; Computation: Bottom).

milder in the area away from the pier. The zero line is even shifted outside of the plot range and very mild slope forms between line 0 and line −1. It is probably due to the sediment slide algorithm. With the current simple algorithm, the adjustment of the bed slope guarantees that the local bed slope is in the reasonable range. But the general scour geometry turns to be irregular at the same time. Hence a more effective solution is to include the sediment slide process before the bed deformation equation is solved. For instance, Sekine (2004) has considered this process as an additional sediment transport. The sediment slide algorithm is under improvement. In the downstream area, the computed scour hole does not extend as far as that of the experiment. An under-estimated shear stress distribution is responsible for this discrepancy. It will be discussed in the following context regarding the flow field.

The streamlines at 2 mm over the bed around the pier at the initial condition and after half an hour are shown in Figure 6 and Figure 7, respectively. From these two figures, the temporal variation of the flow field can be obtained. When the flow approaches the pier, a separation zone forms in the proximity of the pier. In this zone, the streamlines of the approach flow and some kind of spiraling flow meet together. As a result, a tracer placed upstream near the pier will be directed outward the pier and transported along the separation line after it joins the approach flow. With the development of the local scour and the spiraling flow, the separation zone becomes larger and larger. This phenomenon can be found in both the experiment and the computation. However, the scale of the spiraling flow and the separation area upstream of the pier seem to have been under-estimated by the computation. Figure 7 (Top) and Figure 5 (Top) indicate that the spiraling flow in the experiment almost occupies the whole area of the local scour hole after half an hour. But this kind of flow seems limited in the scour hole area where the bed deformation is more than 2 cm according to Figure 7 (Bottom) and Figure 5 (Bottom). One reason for this difference may be the slope difference between the upper part and the lower part of the scour hole. Moreover, the separation angle has been slightly over-estimated. It leads to a larger area of wake zone behind the pier where the shear stress is very small. In the wake zone, obvious circulating flow has been computed. This confirms the experimental plot (dashed lines) extended from the measured data (Melville & Raudkivi 1975).

3.2 *Flow and local scour around a submerged spur dyke*

Typical spur dykes in the river engineering usually suffer from the over-topping flow during the flood season. In order to understand the flow characteristics and local scour around submerged spur dykes, Ishigaki & Baba (2004) have carried out a series of experiments in the Ujigawa Hydraulics Laboratory, Kyoto University. In this verification, the model is tested under the same hydraulic conditions as one of their experimental cases.

The experimental flume was 10 m long, 1.0 m wide and 0.3 m deep, which was equipped with a discharge control system. A 1.8 m long movable bed was located in the middle part of the flume. It was filled with 0.2 m-thick sediment with a mean diameter of 0.026 cm. The spur dyke was set in the movable bed area and was perpendicular to the side of the flume. The experimental setup and the hydraulic conditions are shown in Figure 8 and Table 2, respectively. The details on the shape and size of the spur dyke are also depicted in Figure 8.

The bed evolution, flow velocity (in the longitudinal and vertical directions) and free surface level were investigated one hour after the experiment started. Before the measurement of the latter two, the bed was converted into a fixed bed with mortar. The measurement devices include a laser level meter, an electromagnetic velocimeter and an ultra-sonic level meter.

In order to diminish the boundary effect of the inlet and outlet, they are set to be far enough from the spur dyke. According to previous experiences and numerical experiments, the inlet is set at about $10H$ from the spur dyke and the outlet is around $20H$ from the spur dyke. A total number of 28,944 polyhedral CVs are employed in the calculation. The unstructured mesh consists of both hexahedra and prisms. The mesh system around the spur dyke is shown in Figure 9.

Copyright © 2006 Taylor & Francis Group plc, London, UK

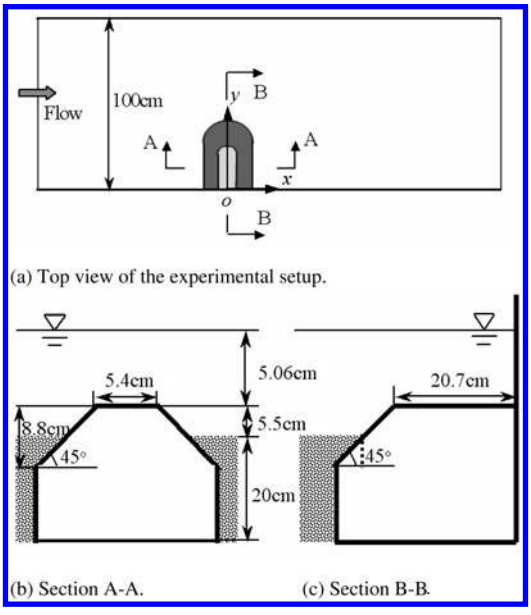

Figure 8. Experimental setup for the submerged spur dyke.

Table 2. Hydraulic conditions for the experiment (submerged spur dyke).

Parameters	Symbols	Values
Flow discharge	Q	21.12 l/s
Water depth	H	10.56 cm
Mean velocity	u	20.0 cm/s
Sediment diameter	d	0.026 cm
Critical shear velocity	u_{*c}	1.523 cm/s
Shear velocity ratio	u_*/u_{*c}	0.78
Spur dyke height	h	5.5 cm
Overtopping ratio	H/h	1.92
Reynolds number	$Re.$	21,120
Froude number	$Fr.$	0.20

Figure 10 shows the comparison of the resulted bed deformation after 1 hour. In Figure 11, the computed streamlines at 2 cm over the initial bed are shown. Figure 12 shows the velocity vector (u, w) 1 cm over the top of the spur dyke.

In both the experiment and the computation, the bed deformation is confined to the proximity of the spur dyke. In general, the scour-deposition pattern shows some simplicity. There are two big obvious scour holes downstream of the spur dyke. In the experiment, the scour hole depths are 2.78 cm and 2.05 cm, respectively. The corresponding results of the computation are 2.33 cm and 2.71 cm, respectively. The occurrence of two big holes can be interpreted as a result of both flow separation and downward overtopping flow. It has been well documented that the flow

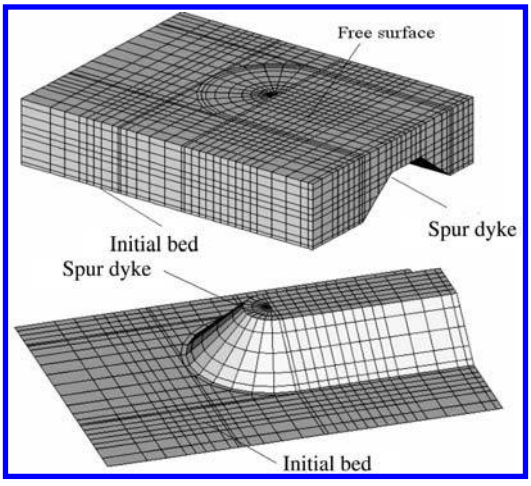

Figure 9. Unstructured mesh system around the spur dyke at initial stage (not to scale).

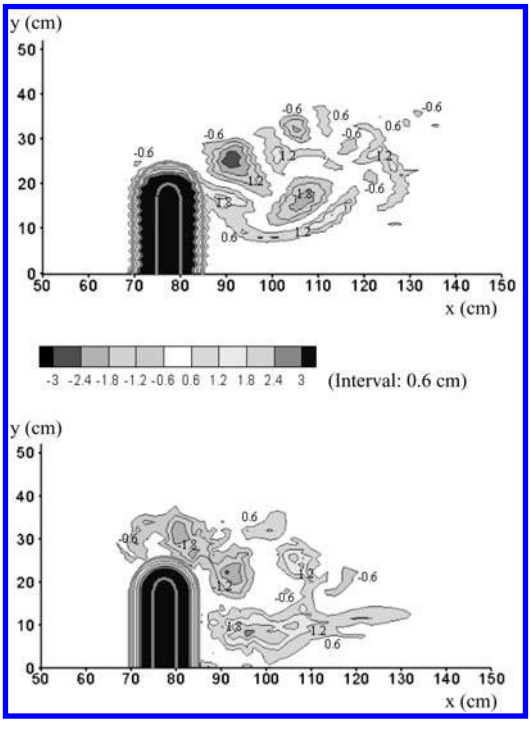

Figure 10. Bed deformation around the spur dyke after 1 hour (Experiment: Top; Computation: Bottom).

will separate when it approaches the head of the spur dyke. A horseshoe vortex forms there. This is the main reason for the scour hole near the head. The computed flow separation can be observed in Figure 11. Due to the overtopping ratio, the flow gets a strong downward

Copyright © 2006 Taylor & Francis Group plc, London, UK

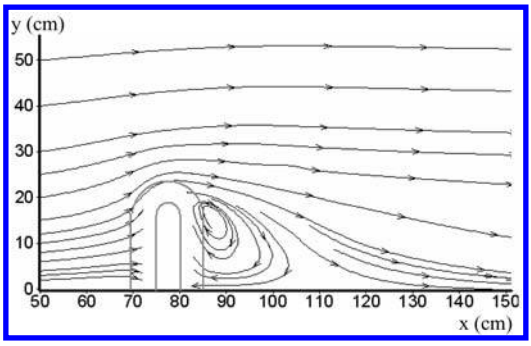

Figure 11. Computed streamlines at 2 cm over the initial bed after 1 hour.

component after it passes the top of the spur dyke. The downward flow intrudes into the wake area behind the spur dyke and leads to sediment erosion there. It also becomes an engine of local scouring. This flow has been observed in a cross-section by a submergible video camera in the experiment (Ishigaki & Baba 2004). However, there is no much evidence that the two big scour holes will maintain their individualities even in the equilibrium condition. Probably, the two scour holes gradually became a bigger one with the development of their scales if the experiment continued till the final equilibrium state.

The predicted local scour holes locate a little different from those of the experiment. The error may come from several sources. The foundation of the spur dyke extends to the movable bed with an angle of 45° (Figure 8c). Hence, the erodible depth in the extent of the spur dyke should be within the foundation limit. However, the foundation under the initial bed has been simplified to be vertical (dashed line in Figure 8c) in the current computation and there is no limit for sediment erosion. This difference will lead to different erosion pattern and velocity field in the extent of the spur dyke. Secondly, the Ashida-Michue formula is used to evaluate the sediment transport rate under equilibrium condition. However, the non-equilibrium transport of sediment load around hydraulic structures has been pointed out by many researchers, e.g. Fukuoka et al. (1994) and Nagata et al. (2005). Finally, the scour process is a dynamic feedback process. A small error in the velocity prediction due to the inherent deficiency of the turbulence model at initial stage will be probably magnified with the development of the local scour. On the other hand, the difference in the scour prediction may become larger with time due to the errors introduced by the flow simulation. This should be also considered as one of the reasons for the discrepancy in the detailed scour geometry as well as the velocity field in Figure 12.

In order to have more detailed information on the overtopping flow, the velocity components (u, w) in

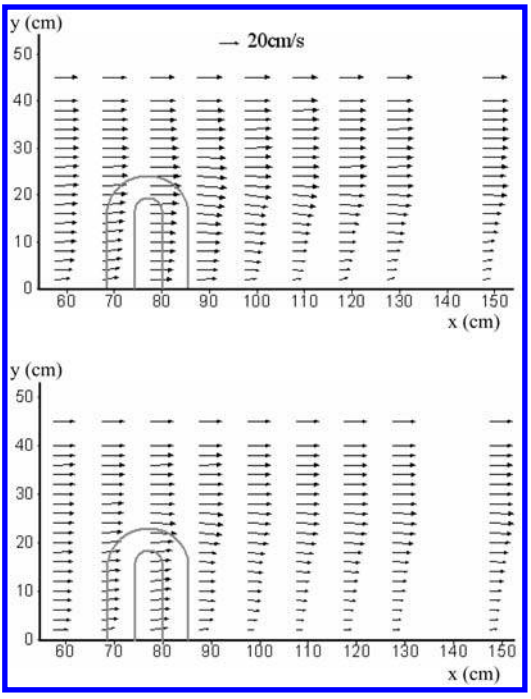

Figure 12. Velocity vectors (u, w) 1 cm over the top of the spur dyke after 1 hour (Experiment: Top; Computation: Bottom).

one layer over the spur dyke are plotted in Figure 12. For clarity, the computed results have been interpolated from the CV centers to the points where the measured data is available. The computational result is very encouraging and in good agreement with that of the experiment. The flow turns upward when it approaches the spur dyke and becomes downward after it leaves the spur dyke. The downward flow propagates for a distance in the wake region behind the spur dyke. As has been mentioned before, this downward flow attacks the riverbed and partially contributes to the development of local scour holes. This kind of flow generally does not appear in non-submerged cases.

Due to the local obstruction, velocity acceleration is observed in the proximity of the spur dyke. The maximum velocity is found to be over the head of the spur dyke where the lowest free surface level has been measured in the experiment.

4 CONCLUSIONS

This study gives a description and some applications of a 3D numerical model, through which the flow structure and the local scour around hydraulic structures can be simulated. The model solves the flow field by using a k-ε turbulence model incorporated with the

Copyright © 2006 Taylor & Francis Group plc, London, UK

wall function approach. In contrast to many existing methods, the current model is based on a moving unstructured mesh. It has significant meaning for engineering practices. Local scour due to bedload transport is simulated by solving the sediment continuity equation with the Ashida-Michiue formula to estimate the sediment transport rate. A bed slope factor is put forward to account for the effect of the local bed slope on the sediment transport. Moreover, a simple sediment slide algorithm is introduced to guarantee that the bed slope is not greater than the angle of sediment repose as well as to ensure that the sediment conservation law is maintained. The model applicability has been confirmed through reasonable predictions of the flow structure and local scour holes in two laboratory experiments.

Nevertheless, this study only constitutes the first step forward in the numerical investigation of the local flow and scour process with unstructured mesh methods. There remains much space for further improvements before it can be used in actual river conditions with sufficient confidence. Firstly, the variation of the free surface is an important phenomenon for flow passing a local obstruction. The rigid-lid assumption adopted in the current model does not allow the resolution of the free surface. It may cause significant error in the velocity and shear stress prediction when the surface variation is not negligible. Secondly, the evaluation of the bedload transport deserves much attention. Existing empirical formulae are generally used for equilibrium sediment transport condition. Since the non-equilibrium transport of sediment load around the hydraulic structures has been reported to be significant (e.g. Michiue & Hinokinadi 1992), the direct use of the existing formulae for equilibrium condition may probably lead to questionable result. Last but not least, the computational time is always an important factor to consider when a 3D model is planned for practical use. Although the authors did not quantitatively evaluate the model efficiency in terms of time consumption per step or per iteration, it has been found that the computational time on a PC (3.2 GHz Intel Pentium 4 CPU and 1G RAM) is at least decades times longer than that of the experiment. Solution methods such as the parallel computing and code optimization should also be paid much attention. These problems will be covered in the future research.

Dimensional analysis of bridge pier scour and the role of flow intensity

L. Teixeira & G. López
Fluid Mechanics and Environmental Engineering Institute, Universidad de la Republica, Montevideo, Uruguay

G. Simarro, E. Fernandez & M. Ortega-Sánchez
Civil Engineering Department, Universidad de Castilla La Mancha, Ciudad Real, Spain

ABSTRACT: A slightly different dimensional analysis is introduced to analyze the phenomena of local scour around circular bridge piers under clear water flow conditions. Assuming that the local scour process is not affected by the viscosity, in usual laboratory conditions (non cohesive sand below 6 mm and clear water), the flow intensity parameter defined as the ratio of the mean velocity on the critical velocity of the approaching flow is shown not to be a convenient parameter to be used. Therefore, the dimensionless expression considered does not include the flow intensity, but Froude-like numbers. The experimental results for uniform and non cohesive bed material by Melville & Chiew (1999), Ettema (1998) and Mia & Nago (2003) are used to validate the approach. Dimensionless groups such as particle Froude number, the dimensionless flow depth and the dimensionless grain size seem to properly describe the local scour problem.

1 INTRODUCTION

In the last 30 years there has been an intensive research activity in bridge hydraulics and local scour related problems (Melville 1997). Most of the works concentrate on studying the effects over the stability of structures (Melville & Coleman 2000). Other topics of interest are the understanding of the physics of the process and the time evolution of the scour (Oliveto & Hager 2002). A better understanding of the physical mechanisms of the local scour seems to be particularly important in order to find the appropriate dimensionless variables or parameters describing the phenomenon. Although there is a lot of work regarding this topic, there is not a uniform theory of the different parameters involved and their influence on the scouring process.

The flow intensity I (Melville 1997) is a dimensional group defined as the ratio of the approaching velocity (u) on the velocity for the initiation of motion (u_c). The flow intensity has a strong physical meaning, since $I < 1$ indicates clear water condition whereas $I > 1$ indicates live bed. Because of such physical meaning, it has been extensively used. However, there is also an increasingly important number of works which do not consider the flow intensity to describe the process. In this work, emphasis is remarked in the inconvenience of using this parameter.

This paper is structured as follows: in the first section, the flow intensity is shown not to be an adequate parameter to be used in usual laboratory conditions (clear water flow conditions and sediment size below 6 mm) if the local scour problem is supposed not to be affected by the viscosity (common assumption). Instead, a different dimensionless expression is proposed. In the following section, data of 97 experiments published by Melville & Chiew (1999), Ettema (1998) and Mia & Nago (2003) are used to analyze the influence of the different dimensionless groups (two experiments carried out by the authors are also used). Finally, the conclusions are exposed.

2 DIMENSIONAL ANALYSIS

Assuming that contraction effects are negligible (i.e., the cross section is very wide), it is usually considered that the equilibrium local scour depth d_{se} around a circular pier (the analysis is very similar for bridge abutments) depends on the water density ρ, the viscosity ν, the sediment density ρ_s, the sediment size d_{50} (assuming uniform sediment), the approaching flow velocity u, the depth h, the pier diameter d and the gravity g, i.e.

$$d_{se} = f(\rho, \nu, h, u, g, \rho_s, d_{50}, d) \tag{1}$$

A dimensional analysis of the above Expression 1 yields, for instance

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{g\Delta d_{50}^3}{\nu^2}, \frac{u}{\sqrt{g\Delta d_{50}}}\right), \tag{2}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where $\Delta = \rho_s/\rho - 1$ is the relative submerged density. Hereinafter, f stands a generic function.

2.1 *Critical velocity and flow intensity*

Firstly, attention is focused on the introduction of the flow intensity and its dependence on the viscosity. Flow intensity I is defined as the ratio of the approaching mean velocity u on the critical velocity u_c. Because the critical velocity is the mean velocity for the initiation of motion, using Shields analysis and resistance expressions, it can be readily shown that

$$u_c = \sqrt{g\Delta d_{50}\tau_{*c}}\,\phi\left(\frac{h}{d_{50}}, \mathrm{Re}_{*c}\right) \tag{3}$$

where $\tau_{*c} = f(\mathrm{Re}_{*c})$ is the Shields number (the critical dimensionless stress), ϕ stands for the resistance expression and Re_{*c} is the critical Reynolds number of grain

$$\mathrm{Re}_{*c} \equiv \sqrt{\frac{\tau_c}{\rho}}\frac{d_{50}}{\nu} \tag{4}$$

Because $\tau_{*c} = f(\mathrm{Re}_{*c})$ (van Rijn 1984), the above Equation 3 can be also expressed as

$$u_c = \sqrt{g\Delta d_{50}}\,\varphi\left(\frac{h}{d_{50}}, \mathrm{Re}_{*c}\right) \tag{5}$$

or

$$f\left(\frac{u_c}{\sqrt{g\Delta d_{50}}}, \frac{h}{d_{50}}, \mathrm{Re}_{*c}\right) = 0 \tag{6}$$

The dimensionless grain size d_* is defined as

$$d_* = \sqrt[3]{\frac{g\Delta d_{50}^3}{\nu^2}} \quad \left(= \mathrm{Re}_{*c}^2\,\tau_{*c}^{-1}\right) \tag{7}$$

So Shields diagram can alternatively be written as $\tau_{*c} = f(d_*)$ (van Rijn 1984). Moreover, the above Equation 6 can also be written (Simarro et al., in press) as

$$f\left(\frac{u_c}{\sqrt{g\Delta d_{50}}}, \frac{h}{d_{50}}, d_*\right) = 0 \tag{8}$$

showing how the critical velocity u_c depends on the viscosity through d_*. Only if $d_* \geq 150$ viscous effects can be disregarded (Simarro et al., in press) so that

$$f\left(\frac{u_c}{\sqrt{g\Delta d_{50}}}, \frac{h}{d_{50}}\right) = 0 \tag{9}$$

In usual laboratory conditions (clear water, $2\,\mathrm{mm} \geq d_{50}$, $\Delta \approx 1.65$), it is satisfied that $d_* < 150$, so that critical velocity u_c depends on viscosity.

Finally, taking into account Expressions 7 and 8,

$$\frac{g\Delta d_{50}^3}{\nu^2} = f\left(\frac{u_c}{\sqrt{g\Delta d_{50}}}, \frac{h}{d_{50}}\right), \tag{10}$$

so that Equation 2 can also be written as

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u_c}{\sqrt{g\Delta d_{50}}}, \frac{u}{\sqrt{g\Delta d_{50}}}\right), \tag{11}$$

or also

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u}{u_c}, \frac{u}{\sqrt{g\Delta d_{50}}}\right), \tag{12}$$

which is equivalent (i.e., contains the same information) to the above Equation 2 and introduces the flow intensity parameter.

Alternatively, Equation 12 is also

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u}{u_c}, \frac{u_c}{\sqrt{g\Delta d_{50}}}\right), \tag{13}$$

and, again through Equation 8,

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u}{u_c}, d_*\right), \tag{14}$$

equivalently.

2.2 *Viscous effects and flow intensity*

Due to the strength of the system of vortex around the pier, it is usually assumed that viscous effects are negligible in the local scour phenomena. This fact is to be used to reduce one of the dimensionless variables in the analysis.

Assuming that the viscous effects are negligible in the local scour phenomena, the viscosity ν is to be deleted from Expression (1). Thus, instead of Equation 2 we get

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u}{\sqrt{g\Delta d_{50}}}\right) \tag{15}$$

which has one parameter less in the right hand side, as anticipated.

Although viscous effects are negligible in the local scour process, the approaching flow is affected

Copyright © 2006 Taylor & Francis Group plc, London, UK

by viscous effects in usual laboratory conditions ($d_* < 150$). Therefore, Equation 8 holds (and not Equation 9).

Expression 8, which allowed the introduction of the flow intensity in Equation 2, is not that helpful if we consider Equation 15, since d_* is not present.

Thus, if the flow intensity is to be introduced, Expression 14 can be used, but not the frequently used expression (Melville 1997)

$$\frac{d_{se}}{d} = f\left(\frac{h}{d_{50}}, \Delta, \frac{d}{d_{50}}, \frac{u}{u_c}\right), \tag{16}$$

since d_* in Equation 14 stands for the viscous effects in the approaching flow (not negligible in general).

The problems related to the use of the above Expression 16 can be clearly exposed with a simple counter example. Let us imagine two experiments whose conditions are identical (velocity, water depth, …) except for the viscosity. The second experiment has a viscosity slightly different than the first one. In one hand, assuming that the viscosity does not affect the local scour, the equilibrium scour will be the same in both experiments. However, because critical velocity depends on the viscosity, flow intensities will be different. Thus, two experiments sharing all the dimensionless groups in the right hand side of Expression 16 except for the flow intensity will have the same scour, proving that in such conditions, flow intensity should not be used.

In summary, in usual laboratory experiments ($d_* < 150$ and clear water conditions) and assuming that the viscous effects are negligible in the local scour process, the flow intensity is not a convenient parameter to be used since it does not allow to take advantage of the fact that the viscous effects are negligible to reduce the number of dimensionless groups by one.

3 ANALYSIS OF EXPERIMENTAL DATA

Assuming that the viscous effects are negligible in the scour phenomena, Expression 15 has been proposed. Assuming that $\Delta = 1.65$ is constant, Equation 15 can be reduced to

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \frac{u}{\sqrt{g d_{50}}}\right) \tag{17}$$

after a simple manipulation (the substitution of h/d_{50} by h/d). If the viscosity is taken into account and $\Delta = 1.65$, from Expression 2 we can get

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \frac{ud}{\nu}, \frac{u}{\sqrt{g d_{50}}}\right), \tag{18}$$

which reduces to Expression 17 for the inviscid case. Experimental data are used to analyze above expressions. Note that in both Expressions 17 and 18, the particle Froude number $u/(gd_{50})^{0.5}$ can be replaced by the pier Froude number $u/(gd)^{0.5}$.

3.1 *Data from Melville & Chiew (1999) and Mia & Nago (2003)*

Melville & Chiew (1999) presented the results of 84 experiments carried out in different flumes and for cylindrical bridge piers, clear water flow conditions and uniform grain size. The data include the values of d, d_{se}, d_{50}, h, u, t_e (the equilibrium time, that required to reach the equilibrium stage) and flow intensity. The results by Mia & Nago (2003) for 22 experiments and 8 tests presented by Ettema (1998) have been also considered. Finally, two tests carried out by the authors at the University of Castilla La Mancha (López et al., in press) are used. The experiments were carried out at the Hydraulic Engineering Laboratory, University of Castilla – La Mancha (Spain), in a 37 m long and 0.75 m wide rectangular open channel flume with steel bottom and glass sidewalls. The downstream end of the channel is controlled by a tailgate to adjust the flow depth upwards. The channel had a working zone located 27 m downwards from the beginning. This zone is a recess of 3 m long and 0.3 m deep where a 0.09 m diameter cylindrical pier was placed. The whole channel was horizontally covered by a layer of 0.07 m height of sand. The median grain, the standard deviation and the density of the sediment are $d_{50} = 1.65$ mm, $\sigma_g = 1.32$ and $\rho_s = 2650$ kg/m^3, respectively. The scour depth and the water surface were measured using conventional point gauge, and clear-water flow conditions were imposed in all the experiments.

From the whole set of experiments, those corresponding to pier diameter below 4.7 cm were not included in the analysis, so that an overall of 97 tests remained to perform the analysis. The ranges of variation for the dimensional variables were

- $78 \geq d_{50}$ (mm) ≥ 0.26,
- $766 \geq d$ (mm) ≥ 47,
- $600 \geq h$ (mm) ≥ 20,
- $1.21 \geq u$ (m/s) ≥ 0.165.

Expression 18 can be written as,

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Re}_p, \mathrm{Fr}_s\right) \tag{19}$$

with $\mathrm{Fr}_s = u/(gd_{50})^{0.5}$ the particle Froude number and $\mathrm{Re}_p = ud/\nu$ is the Reynolds number corresponding to the pier. Ranges of variation of the dimensionless variables in the analyzed tests were

- $11.8 \geq h/d \geq 0.07$,
- $901 \geq d/d_{50} \geq 13$,
- $252{,}780 \geq \mathrm{Re}_p \geq 8700$,
- $6.73 \geq \mathrm{Fr}_s \geq 1.70$.

Copyright © 2006 Taylor & Francis Group plc, London, UK

For many of the experiments $d/d_{50} < 100$ so, according to Melville (1997), the influence of d/d_{50} is to be considered. On the other hand, h/d varies in the narrow range $2 < h/d < 4$ and, therefore, its influence will be difficult to assess.

As mentioned above, $\mathrm{Fr}_s = u/(gd_{50})^{0.5}$ can be replaced by $\mathrm{Fr}_p = u/(gd)^{0.5}$ in Expression 19, to get

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Re}_p, \mathrm{Fr}_p\right) \tag{20}$$

3.2 *The influence of the Reynolds pier number Re_p*

The influence of the pier Reynolds number Re_p shows the weight of the viscosity on the local scour phenomena.

The influence of the Reynolds number can not be established nor neglected from the present experimental data since there is a strong experimental correlation between the Reynolds and Froude numbers (not shown).

In general, it is difficult to isolate the effect of the viscosity in order to measure its relevance. It is usually assumed that viscous effects are negligible but, to the knowledge of the authors, explicit experimental evidences are still required.

It will be assumed, though, that viscous effects are negligible, so that Expressions 19 and 20 read

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Fr}_s\right) \tag{21}$$

and

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Fr}_p\right) \tag{22}$$

The above expressions are similar to that by Melville (1997) but introducing a Froude number instead of the flow intensity, for the reasons argued above.

3.3 *Expression for the local scour*

Figure 1 shows the dimensionless scour depth d_{se}/d against the pier Froude number classified in classes by d/d_{50} for a selection of 96 tests.

Figure 1 seems to confirm that d_{se}/d does not depend on the pier Reynolds number, since the correlation is quite good. Moreover, the scour seems not to depend either on h/d for the data analysed (recall the limitations of the data available, for which $2 < h/d < 4$ only).

Therefore, for the available data, Expressions 21 and 22 can be assumed to be of the form

$$\frac{d_{se}}{d} = f\left(\frac{d}{d_{50}}, \mathrm{Fr}_s\right) \tag{23}$$

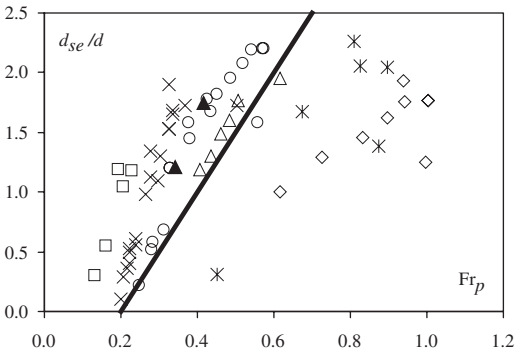

Figure 1. Analysis of $d_{se}/d = f(d/d_{50}, \mathrm{Fr}_p)$ (grouped in classes by d/d_{50}) for $d/d_{50} \approx 19$ (trapezes), $d/d_{50} \approx 27$ (asterisks), $d/d_{50} \approx 47$ (white triangles), $d/d_{50} \approx 53$ (circles), $d/d_{50} \approx 73$ (crosses) and $d/d_{50} \approx 222$ (squares). Black triangles correspond to experiments carried out at University of Castilla – La Mancha, being $d/d_{50} \approx 56$.

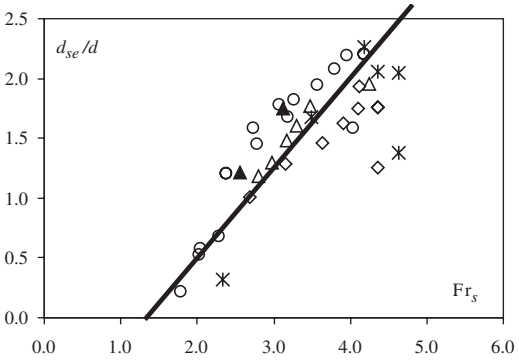

Figure 2. Analysis of $d_{se}/d = f(d/d_{50}, \mathrm{Fr}_s)$ (grouped in classes by d/d_{50}) for $d/d_{50} \approx 19$ (trapezes), $d/d_{50} \approx 27$ (asterisks), $d/d_{50} \approx 47$ (white triangles) and $d/d_{50} \approx 53$ (circles). Black triangles correspond to experiments carried out at University of Castilla – La Mancha, being $d/d_{50} \approx 56$.

and

$$\frac{d_{se}}{d} = f\left(\frac{d}{d_{50}}, \mathrm{Fr}_p\right) \tag{24}$$

Figure 1 shows the trends of the influence on d_{se}/d of both d/d_{50} and Fr_p, for the 62 tests where it was possible to group the results as a function of the parameter d/d_{50}. As it is well known, d_{se}/d increases with the parameter d/d_{50} for small values of d/d_{50} (i.e., $d/d_{50} < 70$). Furthermore, for $d/d_{50} > 70$ the data tend to collapse to

$$\frac{d_{se}}{d} = f\left(\mathrm{Fr}_p\right) \approx 5\mathrm{Fr}_p - 1 \tag{25}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 2 shows the results for $d/d_{50} < 70$ against Fr_s for the 37 tests were it was possible to plot the results as a function of d/d_{50}. The scatter that was present in Figure 1 for $d/d_{50} < 70$ is now basically collapsed, and

$$\frac{d_{se}}{d} = f(\mathrm{Fr}_s) \quad (\approx 0.75\mathrm{Fr}_s - 1) \tag{26}$$

works for $d/d_{50} < 70$ (Fig. 2).

4 CONCLUSIONS

Under usual laboratory conditions (small sediment size and clear water flow conditions) and assuming that the viscous effects are negligible in the local scour process, flow intensity is not an adequate parameter to be used.

Instead, assuming $\Delta = 1.65$ constant, an expression of the form

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Fr}_p \equiv \frac{u}{\sqrt{gd}}\right) \tag{27}$$

or

$$\frac{d_{se}}{d} = f\left(\frac{h}{d}, \frac{d}{d_{50}}, \mathrm{Fr}_s \equiv \frac{u}{\sqrt{gd_{50}}}\right) \tag{28}$$

is proposed, where the Froude numbers play a similar role of that usually assumed by the flow intensity.

The above expressions, which do not include the flow intensity, have shown to be able to explain the trends of the experimental data scrutinized from the literature.

For the experimental data available, the influence of h/d was scarce, in part due to the relatively small range of variation for h/d. The data showed that, for $d/d_{50} < 70$, $d_{se}/d = f(\mathrm{Fr}_s)$ while, for $d/d_{50} \lesssim 70$, $d_{se}/d = f(\mathrm{Fr}_p)$.

Maximum scour depth around spur dikes

M. Azarderakhsh & H. Norouzi
MSc Student of Tarbiat Modarres University, Tehran, Iran

M. Ghodsian
Professor of Department of Civil Engrg, Tarbiat Modarres University, Tehran, Iran

ABSTRACT: Realistic estimation of scour depth around spur dikes in alluvial rivers is important for safe and economic design of their foundations. Earlier research into the problem has mainly been of an experimental nature, with equations being derived for particular conditions. The available predictive equations for maximum scour depth, are applicable only to a limited range of situations.

There are many empirical equations for estimation of maximum scour depth; however they are derived for a special condition and each equation obtains different values for same case.

It seems necessary to evaluate these equations. We collected different data sets (contain 450 data set) from several researcher's experiments and used them to compare existent equation's ability of accuracy predict. The comparison shows that these equations can't predict scour depth accurately.

Also in this research we re-analysis the scour around a spur dike with dimensional analysis and obtain dimensionless maximum scour depth as a function of dimensionless parameters. Then we derive a new equation from this relation and a wide rang of data set. Finally the previous equations are compared with proposed equation.

1 INTRODUCTION

A spur dike may be defined as a structure extending outward from the bank of a stream for the purpose of deflecting the current away from the bank to protect it from erosion. In addition to bank protection, spur dikes have also been used to enhance aquatic habitat by creating stable pools in unstable streams (Klingeman et al.1984). Fish communities in warm water streams are quite sensitive to the availability of large stable pools (Schlosser 1987).

Spur dikes cause pools to be created and maintained, and have been found, in general, to be more beneficial to aquatic habitat resources than other types of bank protection (Knight and Cooper 1991; Shields et al. 1995a, 2000)(8). The magnitude of the benefit to the habitat in a disturbed stream is related to the scour depth.(Shields et al. 1995b) documented significant increases in fish numbers, size, biomass, and number of species in an incised stream following modification of spur dikes to enlarge scour holes and increase the percentage of pools in the reach. Designers of bank stabilization structures should, where possible, calculate maximum scour depth for determining of foundation elevation. Maximum depth of local scour in the vicinity of a spur dike is difficult to estimate accurately (5).

Although there are many experimental equations for maximum scour depth, they have been derived for a special condition and each equation obtains different values for one case (13).

The majority of previous research in this area has focused on predicting the maximum scour depth in vertical wall abutments and comparatively less studies have been done for prediction the scour depth around wing wall and spill through spur dikes e.g., Liu (1961), Wong (1982), Kwan (1988), Melville (1994, 1997). The effect of alignment of spur dike on the maximum depth of scour for abutments was summarized by (Melville and Coleman 2000). With a few exceptions Kwan 1984; Kandasamy 1985), maximum scour depth increased about 20% as the alignment angle increased from 30 to 150°.

In the present study, an extensive set of data (see tables 1 & 2) were used to evaluate the accuracy of available equations for estimation of maximum depth of scour. The correlation between maximum depth of scour and important parameters such as: angle of spur dike with respect to channel bank, densimetric fraud number; channel contracting relative; uniformity of bed materials and medium diameter of them; relative length of spur dike and type of spur dike were investigated.

Type of spur dike	Number of data
Vertical wall	353
Wing wall	62
Spill through	66

2 DATASET

The dataset used in this study consists of experimental data obtained by Tey (1982), Liu (1961), Gill (1972), Garde (1961), Kwan (1984, 1988), Wong (1982), Fathi (1993), Tehrani (1999), Nasrollahi (2001), Razmjoo (2002), Kandasamy (1985), Tison (1962), Counha (1975), Dongol (1994), Ladage (1998). Table (1) shows the range of the datasets that used. Totally 481 data were used. The dataset cover wide range of effective parameters (3), (4), (6), (7), (8), (9), (12).

The number of data for different types of spur dikes is given in table (2). The range of scour depth for each data set is given in table (3). As shown in this table, the scour depth in the collected dataset varies between 0.003 to 0.585 m.

These dataset were used in evaluating the existing scour depth equations. Most of the existing equations were collected and are shown in table (4) and they are collected from several researchers studies (2), (10), (11), (14), (15), (16).

3 EVALUATING THE EXISTING EQUATIONS

To evaluate the available empirical equations, maximum scour depth was calculated from relevant equation. The values of average percentage error E determined by comparing with measured values using:

$$E = \frac{100}{n}\sum_{1}^{n}\frac{ds_c - ds_o}{ds_o} \qquad (1)$$

Table 3. Researchers' data range of scour depth.

Researcher	Scour depth range (m)
Liu(1961)	0.064–0.585
Garde(1961)	0.003–0.18
Tison(1962)	0.068–0.082
Gill(1972)	0.032–0.19
Cunha(1972)	0.039–0.288
Wong(1982)	0.013–0.285
Tey(1984)	0.0785–0.365
Kwan(1984, 1988)	0.085–0.40

Razmjoo(2002)	0.325–0.43

in which *dsc* and *dso* are computed and measured values of scour depth respectively.

The values of E for different equations are shown in table 5. It can be seen from this table that equations of Lacy, Buy Ngok, Das and Ahmad have less errors than other equations and are suitable for predicting scour depth for spill through spur dikes and equations of Zaghloul, Mukhamedov, Neil, Papashvili are suitable for predicting Wing wall spur dikes because of less errors for this type of spur dike as compare with other equations. Moreover equations of Zaghloul, Lim, Neil, Garde, and Dietz are suitable for vertical wall spur dikes. The typical comparisons of computed and measured values of depth of scour for some of equations are shown in Figures 1 to 3.

4 DIMENSIONAL ANALYSIS

A schematic view of spur dike and some of important parameters being effective on scour depth are shown in Figure (4). Before determining the effective dimensionless parameters governing local scour around spur dikes the effective factors should be introduced. These effective parameters can be categorized as (1):

A-Flow condition parameters including: mean flow velocity (u), flow depth (y), fluid density (ρ), kinematic viscosity (υ), gravity acceleration (g).

B-Channel geometry parameter including: channel width (B).

C-Parameters depicting the geometry of spur dike including: length (l), width (w), angle of tip (β), side slope (m) and angle of spur dike with respect to channel bank (α).

D-Bed sediment material parameters including: fall velocity of sediment (ω), mean diameter of bed material (d_{50}), density of bed materials (ρ_s), standard deviation of bed materials (δ) which determined by

Table 4. Researchers' Equation for scour depth.

Researcher	Equation	Researcher	Equation
Inglis	$d_s + y = 2.32 \times \left(q^{2/3} / L \right)^{0.78}$	Das (1976)	$\frac{y + d_s}{y} = 0.56 \times 10^{(0.602n - 0.0294)} \times \left(\frac{y}{d_{50}} \right)^{0.29} \times Fr^{0.85}$
Ahmad	$\frac{y + d_s}{y} = k' \left(\frac{Fr}{1-n} \right)^{2/3}$	Neil (1980)	$d_s + y = 2.1 \approx 2.75 \times \left(\frac{2.59^2}{D^{0.318}} \right)^{0.333}$
Altunine , Buzunov	$\frac{y + d_s}{y} = k_\alpha k_m k_n$	Cunha (1976)	$\frac{d_s}{y} = 189 \left(\frac{L}{y} \right)^{0.69} \times \left(\frac{u_*}{w} \right)^{3.25} + 0.16$
Garde	$\frac{y + d_s}{y} = f_1(cd) \frac{Fr^{f_2(cd)}}{1-n}$	Buy Ngok (1981)	$\frac{y + d_s}{y} = \frac{1.09 \times \exp[-0.075(m-1)]}{(1-n)^{0.3}} * (\alpha/90)^{0.2} \left(\frac{h}{y} \right)^{0.41} f_1(c_d)(Fr)^{f_2(c_d)}$
Lacy	$Y + d_s = 0.47k \left(\frac{Q}{f} \right)^{0.33}$	Zaghloul (1983)	$\frac{d_s}{y} = \frac{2.62}{(180^0 - \alpha)^{0.043}} \times \frac{Fr^{2/3}}{1-n}$
Liu	$\frac{d_s}{y} = K_m \left(\frac{L}{y} \right)^{0.4} Fr^{0.33}$	Richardson et al (1991)	$\frac{d_s}{y} = 1.5 \left(\frac{L}{y} \right)^{0.48}$
Khosla (1963)	$\frac{y + d_s}{y} = \frac{0.9q^{2/3}}{yf^{1/3}}$	Lim et al (1992)	$\frac{d_s + y}{y} = 3.5(Fr)^{0.75} \cdot \left(\frac{d_{50}}{y} \right)^{0.25} \cdot \left(\frac{L}{y} \right)^{0.29}$
Laursen (1963)	$\frac{L}{y} = 2.75 \frac{d_s}{y} \left[\left(\frac{1}{11.5} \frac{d_s}{y} + 1 \right) \right]^{1.7} - 1$	Cardoso et al (1994)	
Maglakelidze(1968)	$\frac{d_s}{y} = 0.56 \left(\frac{\alpha}{90^0} \right)^{1/3} \frac{1 - 0.285m}{1 + 0.09C_b} \times \frac{(U/w)^{0.75}}{0.07 + y/L}$	Clear water	$\frac{d_s}{Y} = 38.3 * (L/Y)^{-0.56} * (Y/d50)^{0.23} \cdot Fr^{2.76}$
Dietz (1969)	$y + d_s = w \frac{q}{u_c}$	Live bed	$\frac{d_s}{Y} = 4.3 (L/Y)^{0.29} * (Y/d50)^{-0.21}$
Mukhamedov (1971)	$\frac{y + d_s}{y} = 15.1 \frac{\sin^{0.25}\alpha \times \cos^{0.5}\beta}{(1-n)\left(\frac{D_{85}}{D_{50}} \right)^{1/6}} \times \frac{Fr^{0.9}}{(1 + 0.09c_v)(1 + 1.08Fr^2)^{0.5}}$	Hoffmans (1995)	$d_s = y\left((1-n)^{-2/3} - 1 \right) + K_B \tanh\left(\frac{y}{L} \right)$
Gill (1972)	$\frac{d_s + y}{y} = 8.375 \times \frac{\left(\frac{D_{50}}{y} \right)^{0.25}}{(1-n)^{0.857}}$	Melville (1997)	$d_s = K_{yl} K_l K_s K_\theta K_G K_d$
Papashvili (1973)	$\frac{d_s}{y} = k_\alpha (1 - 0.285m) \times \frac{\left[\left[1 + k \left(\frac{L}{y} \right)^{1/3} Fr \right] \frac{u}{u_c} - 1 \right]}{\left[1 + 0.154 C_b \left(\frac{D_{50}}{D_{95}} \right)^{1/2} \right]^{1/2}}$	Nasrollahi (2001)	$\frac{d_s}{y} = 103.81 Fr^{1.5} (1-R)^2 \left(\frac{y}{L} \right)^{0.5} \left(\frac{d_{50}}{y} \right)^{0.25}$
		Razmjoo (2002)	$\frac{d_s}{L} = 0.221 \left(1 - R^2 \right)^2 \cdot Fr^{-1.0201}$

$\delta = \sqrt{d84/d16}$ (d84, d16 are the diameter that 84% and 16% of bed materials are less than).

Therefore one can write the following form function for the scour depth:

$$d_s = f(B, L, \rho, \rho_s, d_{50}, u, v, g, w, \beta, \alpha, m, \omega, y, \delta) \quad (2)$$

Using the dimensional analysis, dimensionless parameters for spur dike are obtained generally as:

$$ds/Y = f(L/Y, L/B, U/\sqrt{g.Y}, W/L, \rho/\rho_s, \alpha, \delta, Y/d50, m, \delta) \quad (3)$$

Parameters $y/d50$ and $F = u/\sqrt{g.Y}$ were combined to form the densimetric Froud number $Fd = u/\sqrt{g.d50}$.

The density of bed material is constant, so the relevant parameter ρ/ρ_s is neglected.

The parameter of side slope and width of spur dike can be eliminated with separating the type of spur dike.

Therefore the function form of equation (3) can be written as:

$$ds/y = f(Fd, L/y, L/B, \delta, \alpha, Type) \quad (4)$$

Here the effect of each dimensionless parameter on relative scour depth evaluated using the collected data set.

Effect of relative flow depth L/Y

The effect of this parameter on relative scour depth is shown in Figure (5). It is evident from this Figure that for the same bed material and densimetric Froud number and type of spur dike, the relative scour depth increases with increasing the L/y.

Effect of densimetric Froud number Fd

Another important factor having effect on relative scour depth is the densimetric Froud number. The effect of this factor on relative scour depth is shown on Figure (6). This Figure has been drawn for different L/B and L/y parameters. As shown in this Figure, the relative scour depth increases with increasing the flow intensity or Froud number.

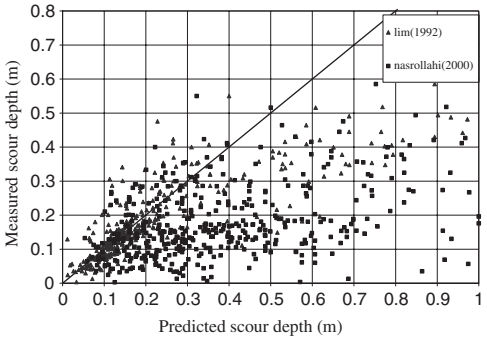

Figure 1. The best and worst equations for prediction of scour depth for vertical wall spur dikes.

Effect of relative length of spur dike L/B

To consider the effect of parameter L/B on relative scour depth the Figure (7) was drawn. All other parameters in this Figure are constant. As shown in this Figure, the L/B directly affects on scouring. It is clear that by increasing L/B the parameter ds/Y will increase.

Any increasing in length of spur dike causes increasing the maximum scour depth because it changes the direction of streamlines in tip of the spur dike and amplifies vortex.

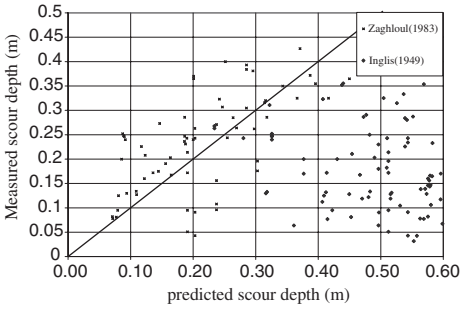

Figure 2. The best and worst equations for prediction of scour depth for Wing wall spur dikes.

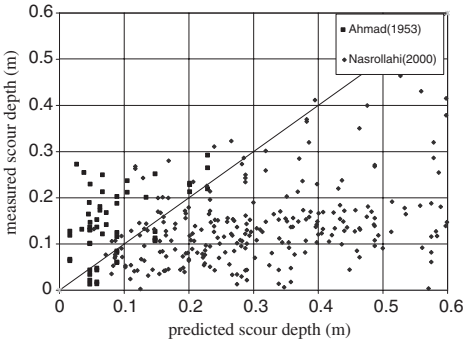

Figure 3. The best and worst equations for prediction of scour depth of spill through spur dikes.

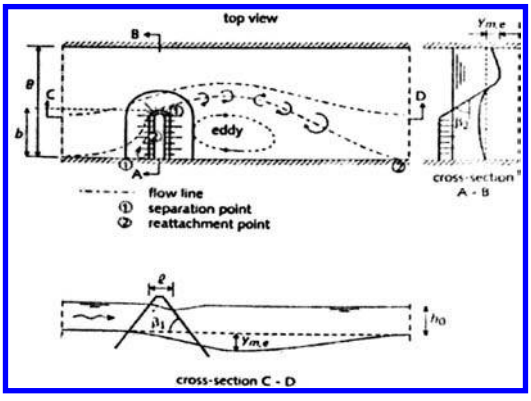

Figure 4. Typical spur dike and some parameters.

Effect of parameters α and δ

The effect of parameters α and δ on scour depth are shown in Figures (8) and (9) respectively. As seen from Figure (8), the relative scour depth increases with increasing the angle of spur dike. When α is less than 90 degree, the scour depth is less because of reducing the intensity of contact between flow and tip of spur dike.

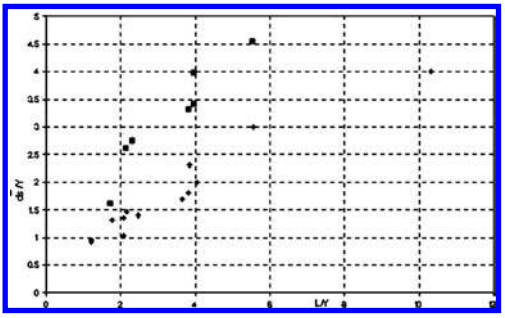

Figure 5. Effect of L/Y on ds/Y.

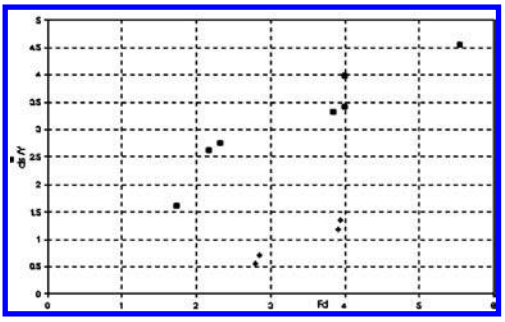

Figure 6. Effect of Fd on ds/Y.

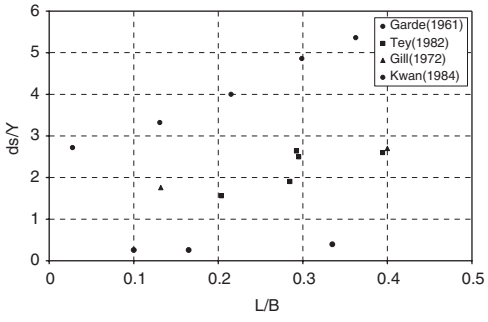

Figure 7. Effect of L/B on ds/Y.

The standard deviation of the bed materials (δ), as seen in Figure (9) affect on relative scour depth. When the ratio of δ increases the scour depth decreases.

Effect of type of spur dike

The effect of type of spur dike on scour depth is shown in Figure (10). As seen in this Figure the relative scour depth around vertical wall spur dike is more than that of the wing wall, and scour depth around wing wall spur dike is more than that of spill trough spur dike. Vertical wall inhibits more effect on flow pattern. It is clear that the scour depth will increase by increasing the intensity of stream flow around spur dike.

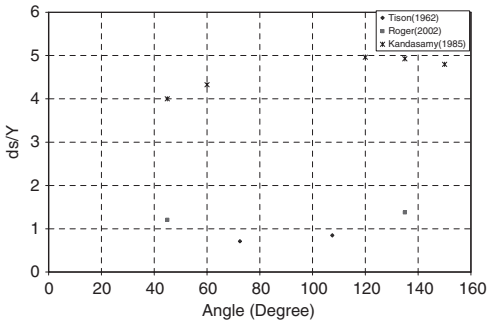

Figure 8. Effect of settlement angle on ds/Y.

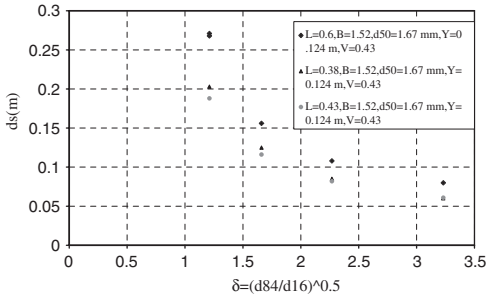

Figure 9. Effect of material homogeneity on ds/Y.

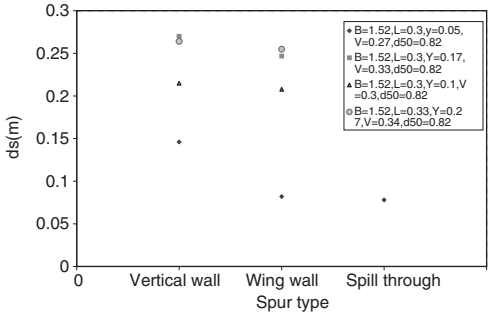

Figure 10. Effect of type pf spur dike on ds/Y.

5 THE PROPOSED EQUATION

The effect of important factors on scour depth around spur dike investigated using the dimensional analysis and data set. We used them to obtain the final function of scour depth. Several analyses were done to reach the final equation with minimum percentage of mean error:

$$ds/y = 0.25 * Fd^{0.614} * (L/y)^{0.3} * (L/B)^{-0.44} * f(\delta) * f(\alpha) * K_T \qquad (5)$$

in this equation, $f(\delta)$ and $f(\alpha)$ are functions of α and δ and are shown in Figures (8) and (9) respectively. The best regression for these functions is the one which has

Copyright © 2006 Taylor & Francis Group plc, London, UK

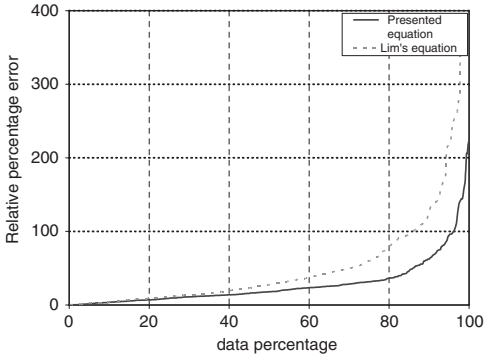

Figure 11. Error frequency of presented equation in comparison between the best earlier equation.

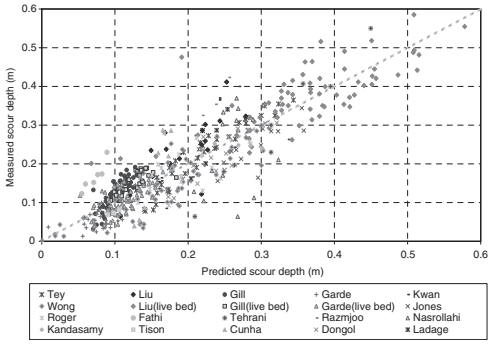

Figure 12. Comparison between predicted scour depth from the presented equation and measured values.

minimum mean error:

$$f(\alpha) = 0.586 + 0.0046 * \alpha \quad (6)$$

$$f(\delta) = 1.45 - 0.34 * \delta \quad (7)$$

the factor of K_t in equation (5) is related to type of spur dike and its value is equal to 1.23 for vertical wall, 1.04 for wing wall and 0.74 for spill through spur dike. This coefficient has been obtained from Figure (10).

The average percentage error of this equation is 29.32% for all the data set. This value is less than error due to other equations. The Figure (11) shows the error frequency for the presented equations. It is clear that 90% of data set have less than 60% error, while 80% of data have at least 36% of mean error and 50% of data have at least 18% of mean error. Also Figure (12) shows presented equation's ability of scour depth prediction.

6 CONCLUSIONS

The recent study was accomplished to evaluate the impression of effective parameters on maximum scour depth around spur dikes and present a new function. In this research, an equation for prediction of maximum scour depth was presented by using the dimensional analysis and the dataset collected from several experiments.

The important results of this study are summarized as:

1. The presented equation can predict the scour depth very well and its prediction error is less than earlier equations.
2. This equation has not the previous equations limitation; it can be used for 3 types of spur dikes considering, change in bed material distribution, angle of spur dike and other factors influencing the scouring.

Modelling the flow and morphology in groyne fields

Mohamed F.M. Yossef
WL | Delft Hydraulics, Delft, the Netherlands, Faculty of Civil Engineering and Geosciences, Delft University of Technology

Rebekka Rupprecht
University of Karlsruhe, Faculty of Civil Engineering and Geosciences, Delft University of Technology

ABSTRACT: Experiments have been conducted in a mobile-bed flume for a straight river with groynes on one side to study the morphological interaction between the groyne fields and the main channel. The flume had a geometrical scale of 1:100 based on typical dimensions of the River Waal. The bed material has been scaled to have bed load as well as suspended sediment transport. In this paper a numerical simulation of an emerged case of the laboratory experiment is presented. The sediment exchange between the main channel and the groyne field are of special interest. The simulation has been carried out using the DELFT3D-FLOW system coupled with Horizontal Large Eddy Simulation (HLES). For the morphological computations, the Online-sediment module was used; it calculates the sediment concentration, the sediment transport, and the bed level changes simultaneously with the flow. The model was calibrated against data from the experiment. The results of the hydrodynamic computations show the typical turbulent structures in emerged groyne fields, which have also been observed in previous experiments and described by several authors. With a sensitivity analysis, the influence of some input parameters on the computed flow field was studied. From this analysis, the effect of some physical parameters was investigated. The results of the morphological computation showed a qualitative accordance with the measured bed levels. In conclusion, we can state that Delft3D computes the morphological pattern in the vicinity of groynes qualitatively well.

1 INTRODUCTION

1.1 *Background*

Groyne fields are a central element in the river Waal and other Dutch branches of the river Rhine. They form a zone of sediment storage. Field measurements by ten Brinke et al. (2001) indicate that they have a significant contribution to the overall sediment balance of the river. Moreover, erosion of the groyne fields may affect the stability of the groynes. Additionally, they provide the sand for the natural formation of wind-blown dunes on the floodplains that are a valuable habitat for riverine flora and fauna.

To understand more the sediment exchange processes between the groyne field and the main channel, mobile-bed experiments have been carried out in the Laboratory of Fluid Mechanics at the Technical University of Delft (Yossef and De Vriend, 2004). In this paper we attempt to model these experiments using Delft3D system. A comparison of the measured and the computed results will be made and the capabilities of the numerical model to simulate the laboratory experiment will be evaluated.

1.2 *Objective*

The objective of the paper is to judge whether the current sediment transport model is capable of simulating the morphological interaction between the main channel and the groyne fields. The results of the morphological computations will be compared to the observations which have been made in the experiment. The results of the hydrodynamic computations need to be compared with the observed flow field as well. Furthermore, a sensitivity analysis will be made for both hydrodynamic and morphodynamic computations in order to study the influence of certain parameters on the result of the computation.

1.3 *Approach*

Numerical simulation has been carried out to model the laboratory experiments. In this paper, we will only present one case of emerged groynes.

The numerical simulations were carried out using the Delft3D system; in which, the flow model is based on the depth averaged shallow water equations. It is not our aim to describe the model equations in this paper;

Copyright © 2006 Taylor & Francis Group plc, London, UK

we will only describe the most relevant functionalities viz. HLES and Online-sediment.

Horizontal eddies are resolved using Horizontal Large Eddy Simulation (HLES), which uses a sub-grid-scale model to calculate the spatially and temporally varying horizontal eddy viscosity (Uittenbogaard and Van Vossen, 2003). With HLES it is possible to simulate the dynamics of the flow near groynes. The morphological simulation was performed, using the "Online-sediment" approach, which computes the sediment concentration, transport, and the bed level changes simultaneously with the flow and which has an immediate feedback to the hydrodynamics (Lesser *et al.*, 2004).

The simulations were done in two steps. Firstly, the hydrodynamic simulation was carried out to calibrate the model so as to reproduce the observed flow pattern. Then, after reaching a satisfactory hydrodynamic result, the morphological computations were performed. The results of the morphological computations are compared with the results of the experiment. The changes of the bed level, such as scour holes near the groyne tips and deposition in the groyne field, are of special interest. The conclusion will contain an evaluation of the model's capabilities to represent the hydrodynamic and morphodynamic situation in the laboratory experiment. Furthermore the model's applicability to other situations will be discussed.

2 LABORATORY EXPERIMENTS

2.1 *Dimensions*

Herein, we briefly present the laboratory experiments; for additional information about the experiments we refer to Yossef and De Vriend (2004). The experiments were carried out in a specially built facility in the Laboratory for Fluid Mechanics of Delft University of Technology. The dimensions of the model were based on those of the River Waal.

The model consisted of a schematised straight river reach, with a geometrically undistorted scale of 1:100 with respect to the Waal River. The working length of the model was 26.85 m, and the width 2 m. In the lateral direction, the model represents half of the river width. The model included nine identical groynes. The first groyne was placed at 4.0 m from the model entrance following three wooden pseudo groynes that were installed to let the inflow of water and sand adjust before reaching the first groyne. The groynes were equally spaced at $S = 2.0$ m, they had a crest length $L = 0.65$ m and a crest height $H_g = 0.25$ m, measured from the concrete bottom. The side slopes were 1 : 3 in all directions. The bed material was chosen such that to ensure both bed load and suspended load transport. As for the flow conditions, both emerged and submerged situations were investigated. Herein, we will consider only one case of emerged groynes.

2.2 *Flow pattern*

During the first few hours of the test, the observed flow pattern did not differ much from what was previously reported by e.g. Uijttewaal et al. (2001) and Yossef & Uijttewaal (2003). When the groynes are not submerged, the flow inside the groyne fields shows an unsteady circulation behaviour as shown in Figure 1 and characterised by a primary circulation cell that forms in the downstream part of the groyne field, a secondary circulation cell driven by the primary one with an opposite rotating direction and much smaller flow velocity, and a dynamic eddy that frequently sheds from the tip of the upstream groyne. This eddy migrates in downstream direction and merges with the primary one, which in return changes in size due to the interaction with the migrating eddy. After this eddy has disappeared, another eddy has room to form. The whole circulation is driven by the main stream via exchange of momentum through the interfacial mixing layer.

Along with the morphological development, the flow pattern changes. With the development of the scour hole, the intensity of the dynamic eddy decreases while stretching in the vertical direction following the newly formed scour hole. After the development of the deposition region, the interaction between the groyne fields and the main channel is hindered and the primary eddy gets slower, which ultimately leads to the disappearance of the secondary circulation cell.

2.3 *Morphological pattern*

In the emerged situation, the footprint of the flow pattern was clearly visible in the morphology. Both the scour hole and the deposition pattern follow the flow pattern, as shown in Figure 2.

The scour hole alignment follows the direction of the dynamic eddy. It is oblique to the flow direction and makes an angle of about 30° with the normal line (the imaginary line that connects the tips of the groynes).

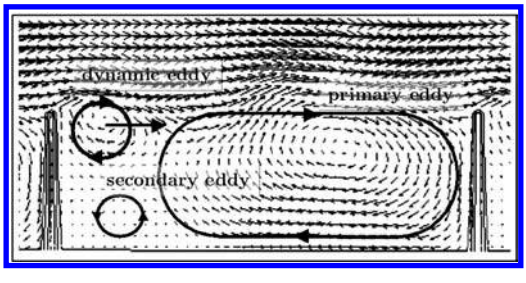

Figure 1. Flow pattern in a groyne field; emerged condition.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In a later stage, the scour causes a feedback to the flow by elongating the dynamic eddy in its direction.

The sediment deposition inside the groyne fields takes place through its downstream part (Figure 2). The sediment is transported from the main channel towards the groyne field following the direction of the primary circulation cell. Along with the drop of the velocity, the sediment settles. The asymmetry of the ripples near the wall deep inside the groyne field is opposite to the main flow direction, but complies with the flow direction inside the groyne fields. This indicates that the effect of the primary circulation cell is extending through the width of the groyne field. The area in the middle of the groyne field, which coincides with the centre of the circulation cell, is free from any bedforms. Figure 3 gives a perspective view of the results of the bed level readings after 40 hours. In this figure we can clearly distinguish the typical erosion deposition pattern of scour hole followed by deposition ridge that is associated with a series of groynes.

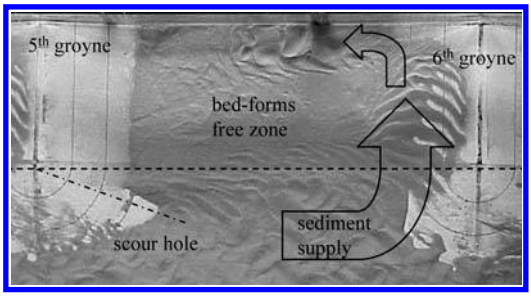

Figure 2. Morphological features for emerged groynes with indication to the sediment transport directions.

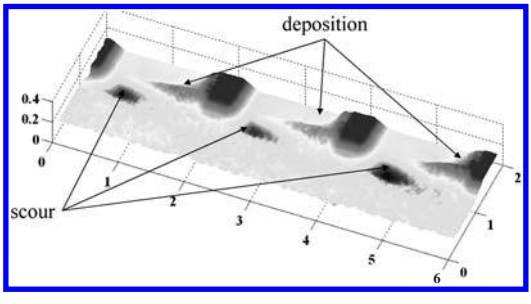

Figure 3. Perspective view of the results of the bed level readings after 40 hours (dimensions indicated on axis in metres).

3 NUMERICAL MODEL

3.1 *Model setup*

The modelled area is meant, as indicated earlier, to represent the laboratory experiments. Figure 4, shows an excerpt from the model grid indicating the test section. As the flume in the model experiment represented a straight river with groynes at a 90°-angle to the main flow, a rectangular grid could be used. Therefore the m and n-axes here correspond to the x and y-axes. When creating the grid attention was paid to guarantee that the crest and base of each groyne are situated at an intersection of grid lines. In order to avoid eroding the groynes, a fixed bed layer was defined at their locations. In order to resolve the high velocity gradient of the mixing layer the grid cells had to be smaller in the area where the dynamic eddy is expected.

The geometry of the flume was simplified by using less number of groynes. Instead of 11 groyne fields, only the three groyne fields of the test section and three adjacent groyne fields were modelled. The grid cell size varied at different locations on the grid with a minimum size of 3.5 cm. The number of grid cells 226×40, the computational time step was guaranteed to satisfy all Courant criteria. The upstream boundary condition was a constant discharge, and the downstream boundary is a constant water level, an overview of the model parameters is given in Table 1.

3.2 *Hydrodynamic results*

When examining the velocity vectors in the groyne field, the computation reproduced the large scale turbulent behaviour with the system of gyres described in Section 2.2. As seen in Figure 5 the presence of a primary gyre that occupies the downstream two thirds of the groyne field is clear. The dynamic eddy, which sheds from the tip of the upstream groyne and move into the groyne field merging with the primary gyre, is visible as well. However, the secondary gyre cannot be identified in the upper left corner; the velocity in that region is nearly zero.

Slope in loglog energy-spectrum α	5/3

Following the picture of the dynamic behaviour of the flow field given in Figure 5, we can identify a periodical behaviour. Using the time series of the velocity components (u, v) at a point near the tip of the groyne, it is possible to obtain the energy density spectrum. The energy spectrum gives the distribution of the turbulent energy over the different frequencies. The energy density spectra presented in Figure 6 shows a clear peak of energy at a frequency of 0.188 *Hz*, i.e. a wave period of 5.3 s; this value is comparable to the same periodicity of the eddy shedding of 5.0 s as observed in the experiment. This indicates that the model is capable of reproducing the dynamic behaviour of the flow near groynes. For additional information about the dynamics of the flow near groynes we refer to Yossef and Uijttewaal, (2003).

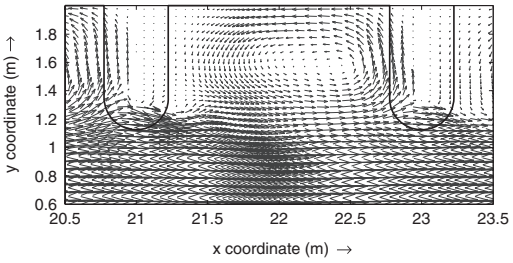

Figure 5. Snapshot of the calculated flow pattern in a groyne field (emerged groynes).

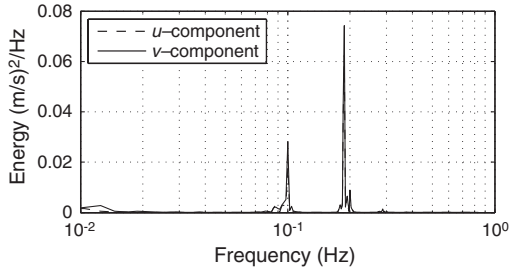

Figure 6. The energy density spectra at a point near the tip of the groyne.

3.3 *Morphodynamic results*

Generally speaking, the numerical simulation reproduced qualitatively well the same erosion and sedimentation pattern as observed in the laboratory experiment. In Figure 7 However, some differences between simulation and experiment are worth reporting.

Firstly, the main channel had a tendency of an over all erosion. The erosion rate in the middle of the main channel in the numerical simulation was larger than that in the experiment. While only little erosion of the bed in the main channel was observed in the experiment, the computed erosion in the main channel reached a maximum of 2.5 cm; note that near the side wall no erosion occurred. In the early stage (during the first 5 hours of morphological simulation) even some deposition was observed in the simulation; this was not observed in the flume experiment.

We must note here that this is attributed to the choice of a partial slip condition that reduces the velocity near the walls of the model. Accordingly, higher velocity is computed in the main channel. If a free slip condition was applied, similar to the glass wall of the experiment, this pattern would not have taken place. However, the partial slip condition and the wall roughness was an important calibration parameter to reproduce the system of eddies as indicated earlier.

Copyright © 2006 Taylor & Francis Group plc, London, UK

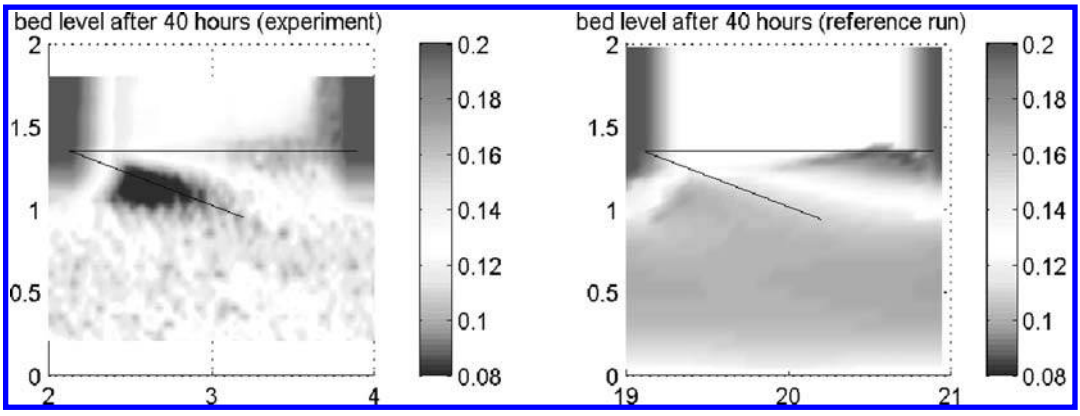

Figure 7. Comparison between the morphological pattern of the simulation and the experiment; bed levels after 40 hours.

Secondly, the scour hole at the groyne tip was less deep compared to the measured scour observed in the experiment, see Figure 7. After 40 hours the maximum computed depth of the scour hole was only 2.5 cm. This is smaller than the measured scour reach up to 6.5 cm. Moreover, the location of the scour hole is not exactly the same as in the experiment. The diagonal lines in Figure 7 indicate the direction of the movement of the dynamic eddy. It can be seen that the measured scour follows the direction of the dynamic eddy whereas in the simulation the scour hole is not located on this line.

Thirdly, the shape and volume of the deposition ridge in the groyne field differs from the measured one. While the deposition ridge in the experiment has a large width and a small height, the simulated deposition ridge has a much larger height and a smaller width (see Figure 7). From this shape it can be deduced that the suspended sediment, which is expected entering the groyne field, immediately settles as soon as the velocity decreases while entering the groyne field.

Finally, with respect to the volume of sand transported, and deposited, into a groyne field. We can observe that most of the computed sediment deposition takes place just across the normal line into the groyne field, approximately at $y = 1.35$ m. Little sediment is transported further into the groyne field. In the experiment the sediment is transported over a longer distance following the direction of the primary circulation cell. However, the total computed volume of deposited sediment in the groyne field amounts to 5.03×10^{-3} m^3, which is around 80% of the measured deposition volume. Even though the total volume of deposition is less than the volume from the experiment, the elevation of the computed deposition ridge is higher than that measured in the experiment.

4 DISCUSSION OF THE RESULTS

4.1 *Hydrodynamics*

When comparing the results of the hydrodynamic simulations with the computed flow pattern, we can confidently say that the numerical model represents the overall flow pattern observed in the experiment (e.g. discharge, water level and velocities) well. The large scale hydrodynamic behaviour was captured as well. Nevertheless, the full shape and distinction of the turbulent eddies and gyres in the groyne field cannot be directly compared with the experiment, since velocities were only measured at few locations in the experiment. The full two dimensional hydrodynamic picture was not recorded in the experiment, as the primary objective of the experiment was to study the morphodynamic behaviour. However, evidence of the presence of a dynamic eddy could be inferred from energy spectra of the velocity signals of the points in the mixing layer. Furthermore, both the primary gyre and an indication of the dynamic eddy were observed utilising dye tests.

In order to calibrate the model, the input parameters (e.g. the slip condition/wall roughness) were set, so that the appearance of the turbulent structures in the groyne field qualitatively matched the appearance of the turbulent structures in literature and in results from previous experiments, where these structures have been measured (e.g. Yossef and Uijttewaal, 2003). This resulted in reproducing the hydrodynamic picture as indicated in Section 2.2. These turbulent flow patterns, which contribute much to the mixing processed between the main channel and the groyne fields, were represented well in the hydrodynamic computation. Nevertheless, the transverse velocity of the water entering the groyne field was slightly under predicted.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The effect of the wall roughness was analysed by comparing a case with free slip condition with a case with a partial slip condition. The case with free slip yielded a large primary gyre and hardly any fluctuations near the groyne tip, instead of a smaller primary gyre and a clear dynamic eddy.

4.2 *Morphodynamics*

The morphodynamic computations gave good results concerning the general erosion/deposition pattern near the groyne tips and in the groyne fields. Even the effect of the side wall in the groyne field (small scour and deposition) is reproduced in the computation. This leads to the conclusion that the morphodynamic pattern is generally well reproduced. However, the model poorly reproduced the sediment transport into the groyne fields (cf. Yossef, and Klaassen, 2002). Furthermore, the depth of the scour hole was underestimated in all simulations.

In all morphodynamic computations that were carried out the scour hole was too shallow compared to the measured scour hole. It appeared from comparison between several simulations that the presence of the dynamic eddy did not influence the depth of the scour hole. In reality this is not true; the presence of the scour hole is strongly attributed to the presence of the dynamic eddy as seen in Figure 2. Apparently the simulated scour hole forms as a result of the narrowing of the flow, instead of the velocity fluctuations near the groyne tip. The under estimation of the scour depth can be explained by lacking important physics in the sediment transport model viz. the effect of horseshoe vortices.

The volume of sediment, which deposited on the upstream side near the groyne tip, was computed to be 80% of the volume computed from the measurements, and could be considered roughly in accordance with the experiment. However, the shape of the deposition ridge did not match with the observations from the experiment. The sediment didn't enter the groyne field before settling, but instead settled in front of the groyne field, as soon as the velocity decreased. This was a major problem with all simulations.

A similar observation was made near the wall of the main channel. At this location the velocity was lower than in the middle of the main channel, which leads to deposition in the early state of the simulation. This has not been observed in the experiment. The differences between the deposition patterns of experiment and simulation lead to the conclusion that the sediment is not kept in suspension long enough. On the other hand a decrease of the grain size or the settling velocity would result in stronger erosion in the main channel, which is not desired either. Apparently the morphological model doesn't include the relevant processes. The area near the groynes and along the normal line exhibits high turbulence intensity as well as high

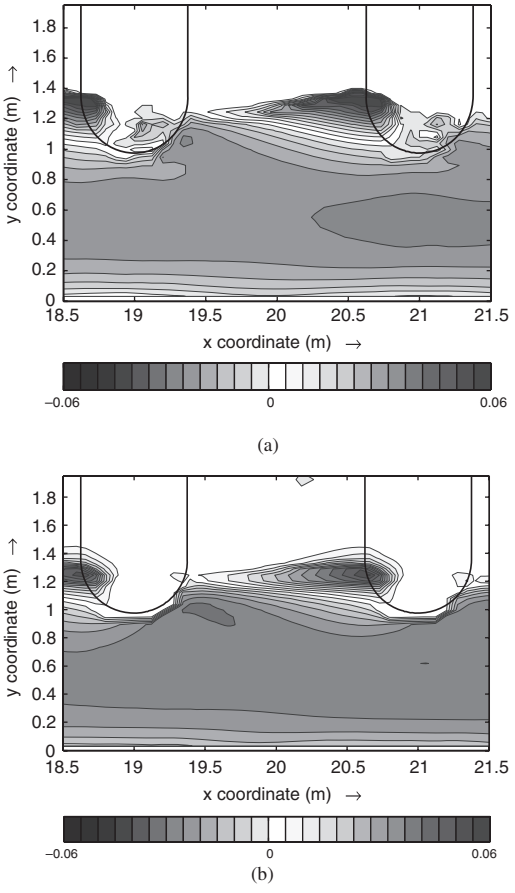

Figure 8. The effect of graded sediment on the morphological pattern; erosion deposition pattern (cm), for (a) single fraction representing D_{50} and (b) three fractions representing D_{10}, D_{50}, and D_{90}.

vorticity. Vortices shed from the tip of the upstream groyne and migrate in the downstream direction following the direction of the primary eddy. These vortices increase the sediment entrainment in their path (as observed from the mobile-bed experiments) causing higher sediment concentrations in the mixing layer that further extends following the path of the primary eddy. The applied/available sediment transport formula, however, ignores the increased turbulence level in the mixing layer, as well as the role of vortical motions that induce additional sediment entrainment in their path.

When using several sediment fractions (graded sediment) the resulting morphological pattern improves (see Figure 8). The depth of the scour hole was enhanced and the deposition ridge extended further into the groyne fields. We can then conclude that the use of graded instead of uniform sediment improves the results.

5 CONCLUSIONS AND RECOMMENDATIONS

From this study we can conclude that it is possible to reproduce morphological pattern associated with groynes in rivers, using a mathematical model that has the capacity to resolve large horizontal eddies. The first requirement to reproduce such a morphological pattern is a correct representation of time-dependent flow field. The flow field compares well to that measured in a laboratory experiment for the case of emerged groynes.

The bed morphology computed, is similar to what has been observed in the laboratory. The large eddies which form at the interface between the main channel and the groyne fields are an important mechanism underling the typical groynes-induced bed pattern.

Further improvements to the model are required in order to improve the results concerning the scour hole and the transport into the groyne fields. Yet, this study has demonstrated the important role that 2D models with HLES can play in improving our predictive capabilities.

The shortcoming of the numerical model in reproducing the morphodynamics of the groyne fields is primarily due to the lack of a transport model that accounts for the increased turbulence level in the mixing layer, as well as the role of vortical motions in picking up sediment and keeping it in suspension for extended distances. With the current performance of the hydrodynamic model, it is time to invest in improving our sediment transport modelling to include vortical motion and increased turbulence level.

On the positive side, it is envisioned that an application to the prototype scale would have better results due to the nature of the problem in hand. For example, the effect of the wall roughness would vanish in the prototype scale; the relative importance of eddiesinduced sediment entrainment would reduce significantly (cf. Ettema and Muste, 2004); and the velocity inside the groyne fields would take a much longer distance to drop below the critical velocity for initiation of motion thus keeping the sediment in suspension for a longer distance.

ACKNOWLEDGEMENTS

This study is carried out within the framework of DIOC Water, theme 1.3 (Intermediate-scale morphological developments in rivers due to human interventions) and Delft Cluster, theme 3 (Coasts and Rivers) under the supervision of Prof. Dr. Huib de Vriend who is deeply thanked for his guidance.

The authors would like to thank the staff members of the Laboratory for Fluid Mechanics of the Delft University of Technology for facilitating the experiment in all its stages, and to thank Ken Thiemann for conducting the experiments.

The authors would also like to thank Messrs. G.J. Klaassen and M. van der Wal, and Drs. E. Mosselman, C.J. Sloff, and W.S.J. Uijttewaal for their constructive comments and discussions during the different stages of the study.

Experimental study of the scour regimes downstream of an apron for intermediate tailwater depths

P. Espa
Università dell'Insubria, Dept. "Environment-Health-Safety", Varese, Italy

S. Sibilla
Università di Pavia, Dept. of Hydraulic & Environmental Engineering, Pavia, Italy

ABSTRACT: Local scour due to 2-D submerged horizontal jets is a well-known topic of hydraulic research. When the jet is directly injected on the erodible bed and the tailwater depth is either "deep" or "shallow", the equilibrium state characteristics of the scoured bed profile are mainly a function of the densimetric Froude number. If the submergence is between these two extremes, for fixed Froude number, three different scour regimes are possible, depending on the jet mainstream position. This paper integrates previous work by the Authors concerning the experimental description of the three mentioned regimes, in presence of a protection apron. The results of the investigation are also intended as a dataset to validate numerical models able to simulate the interaction between free-surface flows and non-cohesive granular beds.

1 INTRODUCTION

This paper describes the experimental investigation of the local scour of a non-cohesive sand bed, caused by a 2-D horizontal wall-jet issuing from a sluice and developing on a rigid apron.

Figure 1 shows a sketch of the laboratory channel, together with the *x*-*y* reference system and the symbols employed to indicate the main geometrical variables of the problem: l is the apron length, y_H the water level in the upstream tank, y_G the sluice gate opening, y_0 the height of the *vena-contracta* which develops downstream of the sluice, y_T the tailwater depth and y_W the height of the downstream weir. At any time, the maximum depth $h_{S,MAX}$ of the scour hole is located at a distance $x_{S,MAX}$ downstream of the of the apron; the peak of the dune developing downstream of the scour hole is instead located at $x_{D,MAX}$ and $y_{D,MAX}$. Finally, x_0 and x_F are the positions where the scour hole and the ridge end.

Any dimensional feature χ of the flow can be expressed as a function of nine parameters defining the flow and the bed (Ali & Lim, 1986):

$$\chi = \chi\left(u_0, g(\rho_S - \rho), \rho, \nu, y_0, y_T, l, d_G, t\right) \qquad (1)$$

where u_0 is the jet velocity at the contraction-section, ρ_S and ρ are the densities of sediments and water, ν is kinematic viscosity, d_G is a characteristic size of the grains, g is gravity acceleration and t is time. Assuming asymptotic steady-state conditions, the generic non-dimensional feature N_χ can be therefore written in terms of five non-dimensional parameters:

$$N_\chi = N_\chi\left(\frac{u_0}{\sqrt{g\, d_G \frac{(\rho_s - \rho)}{\rho}}}, \frac{u_0 y_0}{\nu}, \frac{y_T}{y_0}, \frac{l}{y_0}, \frac{d_G}{y_0}\right) \qquad (2)$$

where the terms in brackets are the densimetric Froude number F_0, the Reynolds number Re, the relative submergence, the relative length of the apron and the relative roughness, respectively.

Rajaratnam (1981) and Rajaratnam & Mac Dougall (1983) show that, when the protection apron is absent and the tailwater depth is either relatively deep ($y_T/y_0 \geq 10$) or very shallow ($y_T \approx y_0$), the asymptotic-state characteristics of the bed profile are essentially functions of F_0. They consider flows where Re is large enough and d_G/y_0 small enough to neglect their effects and find, in particular, that the maximum scour depth at equilibrium $h_{S,MAX,\infty}$, at a fixed F_0 value, is larger for deeply submerged cases (subscript ∞ refers here to asymptotic equilibrium).

Conditions of intermediate submergence (roughly $1 < y_T/y_0 < 10$) have been experimentally analyzed by Ali & Lim (1986), who show that the asymptotic scour depth at fixed F_0 depends on the tailwater depth.

Copyright © 2006 Taylor & Francis Group plc, London, UK

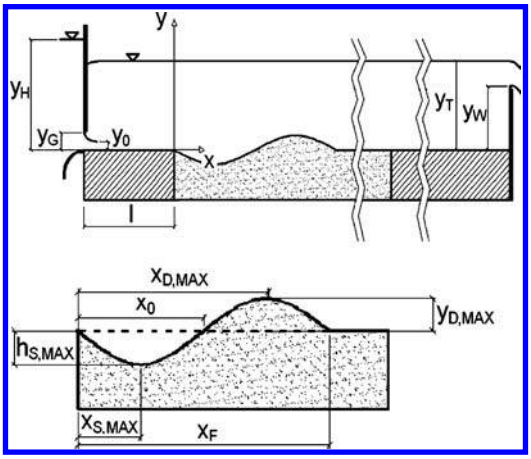

Figure 1. Sketch of the experimental channel with adopted symbols and reference system (x, y axes).

Moreover, they show that, beyond a critical tailwater depth, an increase or decrease in tailwater causes an increase in $h_{S,MAX,\infty}$.

Johnston & Halliwell (1987) propose that the development of the scour hole should be influenced by the different pattern of the jet mainstream, in accordance with their findings on 2-D jets in a rigid bed channel (Johnston & Halliwell, 1986), where, depending on the relative submergence, the jet shifts permanently either towards the bed or towards the free surface; furthermore, for some values of the tailwater depth, both the mentioned configurations may occur. Johnston (1990) confirms the above hypothesis, observing the periodical jet flicking between the free surface and the loose bed for particular values of the flow parameters.

Several works address the localized scour due to submerged 2-D wall jets downstream of protection aprons (Chatterjee & Ghosh, 1980; Nik Hassan & Narayanan, 1985; Chatterjee et al., 1994). Among them, only Espa & Sibilla (2005) report the existence of different patterns of scour hole-jet interaction, when the relative tailwater depth is varied.

2 EXPERIMENTAL SET-UP

The experiments have been performed in a horizontal glass-paneled channel 4.5 m long, 0.102 m wide and 0.44 m deep. A 0.2 m deep bed of non-cohesive sediments is placed between two steel boxes: the length of the upstream one (representing the rigid apron) has been varied during experiments ($l = 0.25$ and 0.5 m), while the downstream one (1.5 m long) has been kept fixed.

Figure 1 shows a sketch of the sharp-edged sluice gate which regulates the water inlet in the channel from an upstream constant-head tank. The reservoir is fed through a 100 mm diameter pipe, equipped with an electromagnetic flow-meter.

The lower and lateral sides of the tank outflow hole are equipped with circumference-arc steel profiles to prevent lateral and upward contraction of the *vena* entering the channel (Fig. 1). Therefore, the *vena contracta* height can be derived by the classical formula $y_0 = c_c y_G$, where c_c is a contraction coefficient. The water level in the channel is controlled downstream by a sharp edged (Bazin-type) weir. The main characteristics of the approximately uniform-sized sand here used are: $d_G = 1.6$ mm; $\rho_S = 2650$ Kg/m^3; porosity $n = 0.45$; angle of repose $\phi = 30°$; mean fall velocity $w_M = 0.13$ m/s.

Images of the bed profiles have been collected by a digital photo-camera. These photos have then been processed to measure the evolution of the bed shape.

A single component back-scattering Laser Doppler probe (TSI – LDP 100) equipped with a 250 mm focal length lens has been used to measure vertical plane profiles of the horizontal velocity component in the mid-channel plane; the 50 mW Laser-diode source generates red light at 694 nm wavelength. The particles dispersed in the water of the laboratory closed-circuit proved to be sufficient to collect a signal of good quality, and no further seeding has been used. The acquired signal has been processed by a completely PC-assisted processor (TSI – IFA 600) using a dedicated software package (TSI – Laservec 1.0). Each LDA measure includes no less than 5000 samples and lasts for at least 40 s (to stabilize the time averaged value of the signal); thus, at high sampling rate, the number of acquired samples exceeds (even by 5 times) the mentioned sample quantity. LDA measures have been carried out 8 hours after the beginning of the tests, assuming that the bed evolution was then slow enough and did not alter significantly the velocity field. These velocity measures may be therefore intended as the equilibrium state ones.

Less time consuming ADV measures have been performed by a system (Signal Processing DOP 1000) equipped with a 4 MHz ultrasound emitter/transducer, seeding the flow by fine clay particles. The pulse repetition frequency (PRF) has been varied between 3.125 and 5.95 kHz, depending on the maximum measurable depth needed; the vertical resolution varied between 1.4 and 2.1 mm. ADV profiles have been obtained by averaging no less than 6000 samples collected for at least 120 s.

3 ANALYZED CASES

The sluice opening y_G, the weir height y_W (and consequently y_T), the apron length l and the flow rate Q have been varied in the course of the investigation. Grain size d_G, sediment density and water viscosity

(assumed to be $\nu = 10^{-6}$ m^2/s) have instead been kept fixed in all the experiments.

Each reported test lasts for at least 8 hours. In general, no asymptotic equilibrium has been reached at the end of the tests: as noted by Nik Hassan & Narayanan (1985), asymptotic conditions need a very long time to be reached when the vertical scales of the bed profile (particularly the dune height) are, as in the present case, comparable to the submergence.

The main parameters of the tests are listed in Tables 1 and 2, ordered by run number. The average

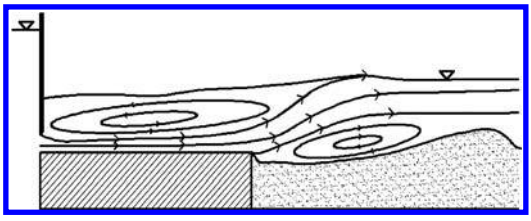

Figure 2. Sketch of the flow pattern for "surface jet" scour regime.

value of the water level just downstream of the sluice, where a submerged hydraulic jump takes place, is indicated by y_L. In tests where the difference $y_T - y_L$ is higher, owing to the free surface oscillations due to the submerged jump, y_T fluctuates and its value is here given as a time-averaged one.

The last column to the right in Table 2 indicates the scour regime which characterizes the test: "surface jet" (S), "bed jet" (B), slightly unstable "bed jet" (UB) and "bed-surface jet" flicking regime (F); the symbol – indicates that no grain motion takes place on the flume bottom. The contraction coefficient c_c (Tab. 2) has been estimated from the measured values of Q and $y_H - y_L$ by assuming energy conservation across the sluice. The values of y_0 and u_0 have been calculated accordingly. Some u_0 values have been checked against available LDA velocity measurements.

The d_G/y_0 ratio ranges from 0.03 to 0.06 in all the reported experiments. Each test is started from rest, the water depth in the tank and in the channel being equal to y_W. When the flow-rate Q is almost impulsively discharged in the tank, the water levels y_H and y_T approach quickly their steady-state values. The influence of the start-up phase on the scour development is therefore negligible.

Bed profile evolution and overall flow pattern in tests 13, 14, 15 are extensively discussed by Espa & Sibilla (2005) and will be recalled in the following.

4 STABLE REGIMES

4.1 *"Surface jet" scour regime*

In tests no. 10, 13 and 16, the jet mainstream directs towards the free-surface just downstream of the apron, as marked by the blowing up on the free-surface which is clearly visible during the experiments (Fig. 3). The flow pattern, deduced from wool-wire visualizations by Espa & Sibilla (2005), is sketched in Figure 2. It is characterized by two counter-rotating vortices: the submerged hydraulic jump and the separation vortex just downstream of the apron.

Regardless of the evolution of the bed (and therefore of the horizontal size of the two vortices, in particular the lower one) the described flow pattern remains the

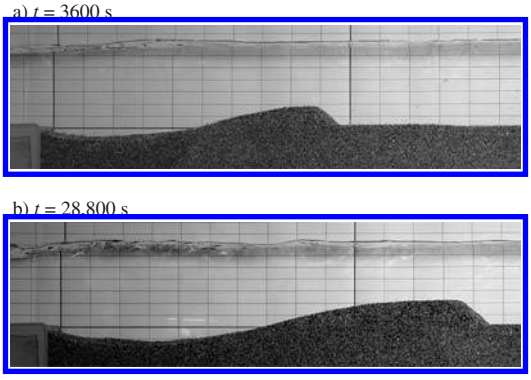

Figure 3. Bed profile after 1 hour (a) and 8 hours (b) for "surface jet" scour regime (run no. 13).

same during the whole run. The resulting "elongated" shape of the bed profile is characterized by relatively small vertical scales ($h_{S,MAX}$ and $y_{D,MAX}$) and relatively large horizontal scales ($x_{S,MAX}$, x_0, $x_{D,MAX}$, x_F). An example is given in Figure 3, where two subsequent images of the bed profile for run no. 13 are given (as in the following photographs, the vertical grid spacing behind the flow is 20 mm and the horizontal one is 50 mm).

The vertical profiles of time-averaged horizontal velocity u, measured by LDA, confirm the described flow pattern. For instance, Figure 4 shows the u profiles collected during run no. 13. Above the wall jet, the detected zone of backflow (Fig. 4a) highlights the presence of the submerged-jump roller, which extends for the whole apron length.

The u profile on the scour hole (Fig. 4b, $x = 150$ mm) displays near the bed a small backflow region, connected to the separation vortex downstream of the apron; the location of the maximum u value near the free surface confirms the behavior of the jet mainstream. Further downstream the velocity profile becomes more regular, almost linear, with maximum close to the free-surface (Fig. 4b, $x = 500$ mm).

4.2 *"Bed jet" scour regime*

In tests no. 2 and 15, the jet mainstream remains attached to the channel bed downstream of the apron and the free-surface appears only slightly perturbed. Runs 6, 11 and 18 show essentially the same behavior, although a displacement of the jet towards the free surface can be noticed for relatively short periods. The flow pattern (inferred from wool-wire flow visualizations by Espa & Sibilla, 2005) is sketched in Figure 5 and is again characterized by two counter-rotating vortices. The submerged jump roller extends now also above the sand bed, further downstream than in previous case. The vortex due to boundary-layer separation from the apron edge is considerably smaller

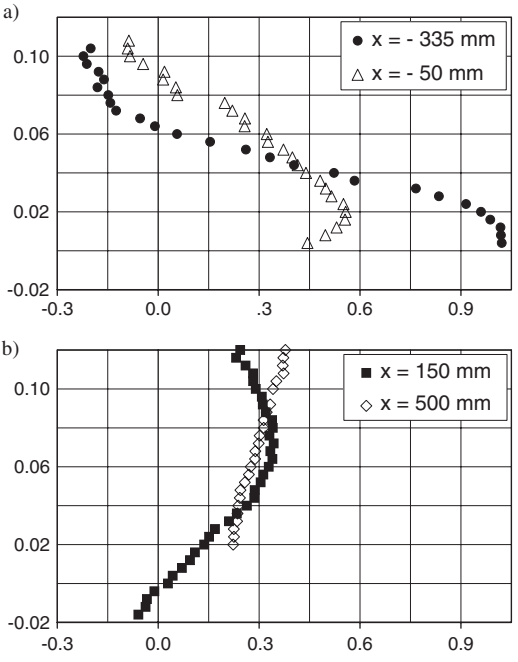

Figure 4. Vertical profiles of u (in m/s) vs y (in m) at different x positions for "surface jet" scour regime (run no. 13). Profiles at $x = -335$ mm and -50 mm (a) are located on the apron; profiles at $x = 150$ mm and 500 mm (b) are located on the scour hole and on the dune, respectively.

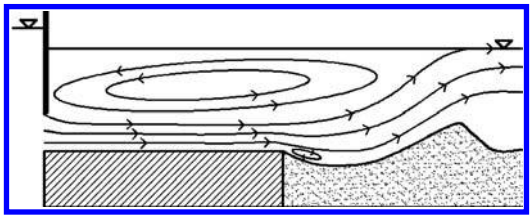

Figure 5. Sketch of the flow pattern for "bed jet" scour regime.

than in previous case; nevertheless, its presence is clearly highlighted by sand motion. When compared to the "surface jet" regime, the bed profile is characterized by larger vertical scales and smaller horizontal scales. Figure 6 displays for instance the bed profile shape at two different times for test no. 15.

The flow pattern has been confirmed even in the "bed jet" regime by measuring vertical profiles of time-averaged horizontal velocity u. Figure 7 shows velocity profiles measured during run no. 15. It must be noted that only ADV measurements could be obtained above the erodible bed, owing to a slight unsteadiness of the flow. However, the comparison between LDA and ADV measurements at $x = -50$ mm (Fig. 7a) shows the reliability of ADV measures.

Copyright © 2006 Taylor & Francis Group plc, London, UK

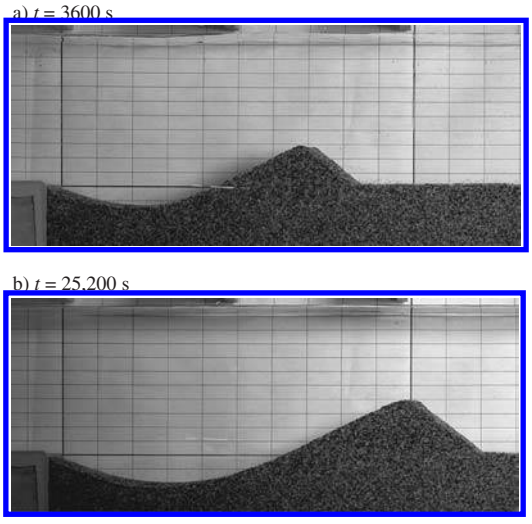

Figure 6. Bed profile after 1 hour (a) and 7 hours (b) for "bed jet" scour regime (run no. 15).

Velocity profiles shown in Figure 7b confirm that downstream of the apron the jet flows along the scour hole. Above the dune crest, the flow shows again an almost linear velocity profile, but its maximum value is now located close to the bed. Moreover, the backflow detected in the velocity profile measured at $x = 130$ mm shows that the submerged jump roller extends above the scour hole.

It should be underlined that in the discussed experiment the relatively small l/y_0 ratio ($\approx$9, Tab. 2) prevents the wall jet from becoming fully-developed at the end of the apron. Actually, the maximum jet velocity at the end of the apron (profile $x = -50$ mm, Fig. 7a) is still almost equal to the one measured just downstream of the sluice (profile $x = -335$ mm) and to the value $u_0 = 0.52$ m/s, which has been computed for run 15 by assuming energy conservation across the sluice (Tab. 2).

This behavior can be compared to the "surface jet" pattern described in Section 4.1. In run no. 13, the maximum velocity of the jet just downstream of the sluice (profile $x = -335$ mm, Fig. 4a) is slightly larger than 1 m/s and it agrees well with the energy-conservation estimate $u_0 = 1.12$ m/s (Tab. 2). When the jet approaches the loose bed (profile $x = -50$ mm, Fig. 4a), its maximum horizontal velocity is lower than 0.60 m/s, i.e. there is an almost 50% velocity decay along the apron. This decay appears to be much larger than the one expected for a simple 2-D wall jet: applying, for instance, a semi-empirical decay law for simple 2-D turbulent wall jets (Rajaratnam, 1976), the maximum velocity reduction at $l/y_0 = 19.1$ (i.e. the present normalized apron length, Tab. 2) should not be larger than 10%. This difference with the plane jet behavior is

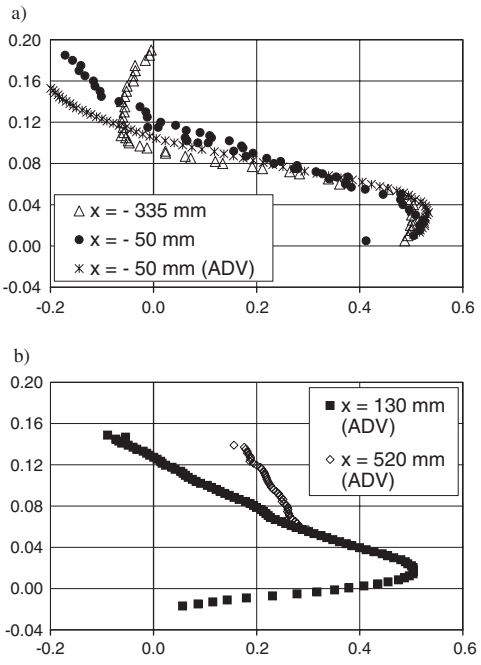

Figure 7. Vertical profiles of u (in m/s) vs y (in m) at different x positions for "bed jet" scour regime (run no. 15). Profiles at $x = -335$ mm and -50 mm (a) are located on the apron; profiles at $x = 130$ mm and 520 mm (down) are located on the scour hole and on the dune, respectively.

the obvious consequence of the reverse flow detected above the jet.

The analysis of these stable regime cases demonstrates that the definition of the proper velocity scale for the scouring jet is not immediate: the classical results concerning plane wall jets cannot be applied when the submergence is not very deep (i.e. when the effect of the submerged jump on the jet development is not negligible).

Most of all, it must be noted that scour profiles are substantially different (Figs. 3 and 6) even when the jet velocities are approximately equal at the end of the apron (as in the mentioned case of runs no. 13 and 15, where the maximum velocity of the jet leaving the apron is about 0.5 m/s). In particular, after comparable elapsed time, the maximum scour $h_{S,MAX}$ in run 15 ("bed jet" scour regime) is about twice as deep than in run 13 ("surface jet" scour regime).

5 "BED-SURFACE JET" SCOUR REGIME

Apart from the two stable regimes discussed in the previous section, an unsteady flow regime is also possible for intermediate tailwater depths. In this case, the jet flicks intermittently between its lower and the upper

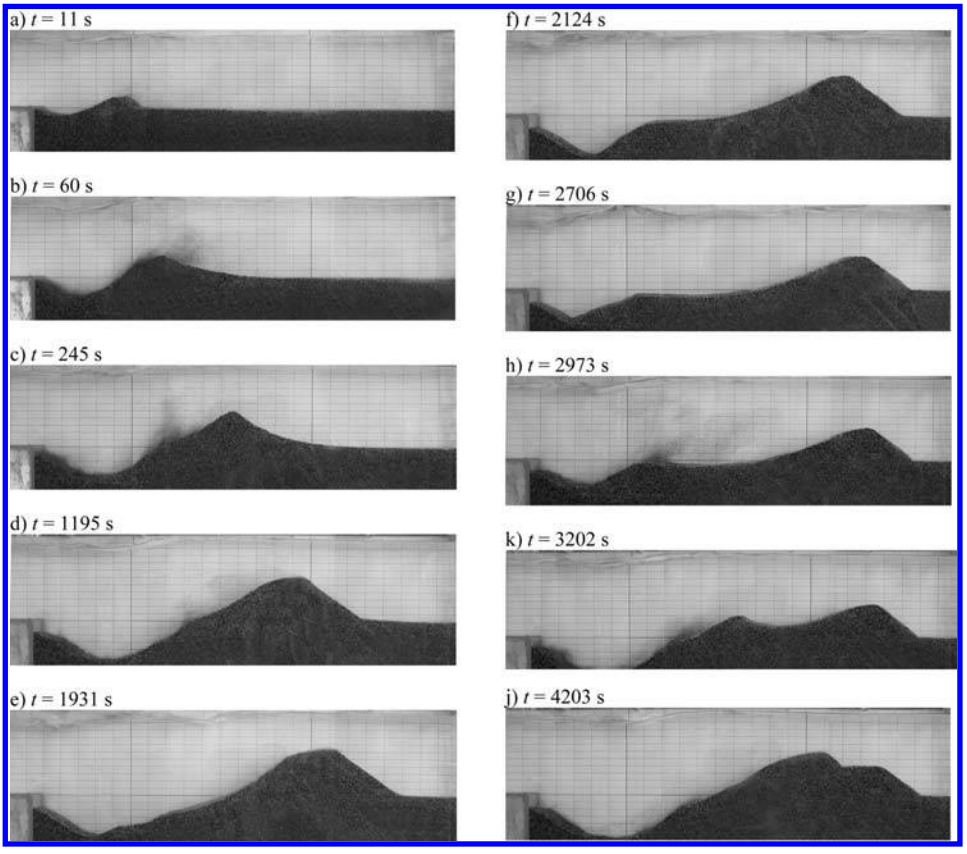

Figure 8. Sequence of run no. 8 showing the first complete cycle and the second "bed jet" phase. First "bed jet" phase is in frames a–d; first "surface jet" phase is in frames e–g; second "bed jet" phase is in frames h–j.

boundaries (the erodible bed and the free-surface, respectively).

At the beginning of each test characterized by this unsteady behavior (runs no. 1, 4, 5, 7, 8, 9, 14 and 17, Tab. 2), the jet remains attached to the bed generating the scour hole and the downstream dune. The strength of the scour process in this phase is evidenced by the frequent bursting of sand grains under the effect of the jet flow (Figs. 8a–d and 9a–b). During this initial phase, the flow pattern is similar to the one described in the "bed jet" regime (Fig. 5).

After a certain time has elapsed, the flow pattern suddenly shifts to the "surface jet" one (Fig. 2): the jet mainstream detaches from the bed and moves towards the free-surface. As a consequence, the upstream side of the dune (whose slope may exceed the repose angle under the effect of the incoming jet) collapses into the scour hole, which is partly filled up and assumes a typical cusp shape (Figs. 8f–g and 9c–d). At the same time, the free-surface hump moves backwards (Figs. 8d–e), marking the displacement of the region of impact between the jet and the free-surface (the submerged jump moves backwards too). The collapsing of the dune is determined not only by the abrupt interruption of the sustaining action of the jet flow, but also by the large recirculation established below the jet mainstream which flows along the free surface (Fig. 2). After maintaining for a certain amount of time the "surface jet" pattern, the jet suddenly shifts again towards the bed and a new cycle starts.

For a given run, the duration of each complete cycle and of each phase within a cycle ("bed jet" or "surface jet" phase) varies without regularity. The average cycle duration Δt together with the percentages of "bed jet" flow $\Delta t_B\%$ and of "surface jet" flow $\Delta t_S\%$ are given in Table 3 for each 8-hours run.

It has been observed that the duration of the "bed jet" phases is on average roughly constant during each test, while the duration of the "surface jet" phases tends to increase slightly with time; furthermore, the longer the jet is attached to the channel bed, the longer the following "surface jet" phase and vice-versa (nevertheless, exceptions to this intuitive rule have been noticed).

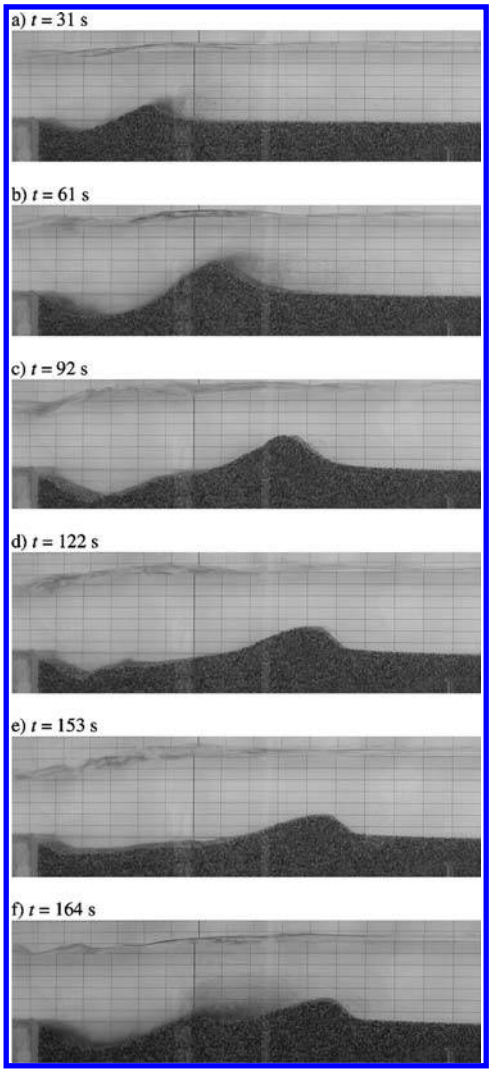

Figure 9. Sequence of run no. 7 showing the first complete cycle and the beginning of the second "bed jet" phase (f). First "bed jet" phase is in frames a-b; first "surface jet" phase is in frames c-e.

Comparisons of tests with approximately equal l/y_0 (as for example runs no. 1, 2, 4, 5, 7, 8, 12, 15, 18) suggest that, for fixed F_0, intermediate y_T/y_0 ratios lead to "bed-surface jet" flows. When the normalized tailwater depth is large, "bed jet" flows are expected while "surface jet" flows develop under low y_T/y_0. Moreover, the higher F_0, the larger the y_T/y_0 interval characterized by the jet flicking. Finally, again for fixed l/y_0 and F_0, the larger the normalized tailwater depth, the longer the average cycle period in "bed-surface jet" flows.

Table 3. Average temporal characteristics of jet cycles (deduced during 8-hours runs) for "bed-surface jet" regime tests.

No.	Δt [s]	Δt_B% [–]	Δt_S% [–]
1	1600	9	91
4	410	8	92
5	12,900	44	56
7	230	8	92
8	3700	47	53
9	4100	21	79
14	900	10	90
17	500	7	93

The jet cyclic behavior gives to the bed profile a less regular shape than that found in steady flow regimes. Two different dunes may be observed during the bed evolution: a main dune, at larger x, and a secondary dune, closer to the scour hole and generated by the "bed jet" flow. The main dune is still present at the end of the "surface jet" phase while the secondary one reaches its maximum height at the end of the "bed jet" phase, but collapses in the scour hole during the following "surface jet" phase. In a given run, the secondary dune at the end of each "bed jet" phase is in general systematically higher (or lower) than the primary one. However, in some cases the maximum height shifts from one dune to the other cycle by cycle. As shown in Figure 10a, after an intense "bed jet" phase, the secondary dune may even completely overlap the primary one.

The description of the time evolution of the bed-profile characteristics is therefore more complex than for stable cases. However, it can be noted that the maximum values of the scour depth $h_{S,MAX}$ and of the secondary dune height are still reached at the end of a "bed jet" phase and that the longer this phase the larger the mentioned geometric scales.

Espa & Sibilla (2005), analyzing run no. 14 and focusing only on cycles characterized by relatively long "bed jet" phases, report that scour hole profiles at the end of these "bed jet" phases are nearly equal; the Authors conclude that for this kind of regime scour depth and (secondary) dune height maximum values seem not to be reached asymptotically.

Analogous considerations can be repeated for other "bed-surface jet" cases, even when the average cycle duration is much larger (run no. 9, Figs. 11 and 12) or when it is shorter and the evolution of the primary dune resembles closely the one observed in the "surface jet" regime (run no. 7, Figs. 13 and 14).

Table 4 reports maximum scour depths $h_{S,MAX}$ measured for "bed-surface jet" regime tests as discussed above. Comparison is made with scour depths computed using the classical formulae by Schoklitsch (Equation 3) and Shalash (Equation 4), reported

in Breusers & Raudkivi (1991). With the adopted symbols, these formulae are respectively:

$$h_{S,MAX,\infty} = 0.378\, y_H^{0.5}\, q^{0.35} \quad (3)$$

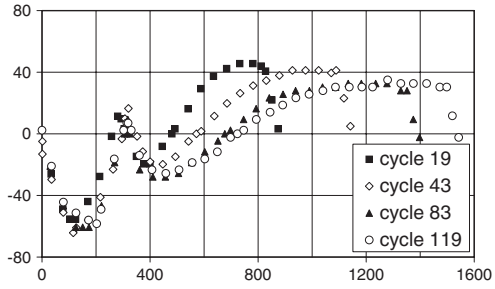

Figure 14. Dimensional bed profiles y vs x (in mm) after the "bed jet" phase for different cycles of run no. 7. Profiles are carried out processing frames a, c, d, h of Figure 13.

Table 4. Maximum scour depths for "bed-surface jet" tests.

No.	$h_{S,MAX}$ measured [mm]	$h_{S,MAX,\infty}$ equation 3 [mm]	$h_{S,MAX,\infty}$ equation 4 [mm]	$l/\Delta y$ [–]
1	38	35	–	15.6
4	54	46	–	6.0
5	113	56	–	4.5
7	65	58	61	3.2
8	131	67	41	2.6
9	91	59	–	11.9
14	45	55	–	9.3
17	45	67	–	5.5

$$h_{S,MAX,\infty} = 9.65\,\Delta y^{0.5}\, q^{0.6}\, d_G^{-0.4}\left(\frac{1.5\,\Delta y}{l}\right)^{0.6} - y_T \quad (4)$$

being $\Delta y = y_H - y_T$ and q the flow rate per unit width; all quantities are expressed in SI units, except d_G which should be in mm.

Equation 3 is based on model tests with short apron length ($l/\Delta y = 1.5$) but it gives acceptable estimates of the magnitude of observed scour depths. Nevertheless, contrary to expectations, the discrepancies between measured and calculated results do not decrease as $l/\Delta y$ approaches 1.5: for example in run no. 8 (whose $l/\Delta y$ ratio is the closest to 1.5 in Tab. 4) the measured scour depth is about twofold than the predicted one. On the other hand, Shalash formula (which explicitly takes into account the apron length) gives negative values (i.e. predicts no scour) for almost all the "bed-surface jet" regime tests of Table 4; moreover, it seems to give better results for smaller $l/\Delta y$ ratios (tests no. 7 and 8), again in disagreement with expectations.

Velocity profiles during both phases of the "bed-surface jet" cycle have been obtained for run no. 14 by averaging several ADV measurements during each phase. The different jet patterns above the scour hole are clearly visible in Figure 15 ($x = 205$ mm): during the "bed jet" phase (Fig. 15a) the velocity peak is closer to the bed and the scour process is consequently more intense; during the "surface jet" phase

Copyright © 2006 Taylor & Francis Group plc, London, UK

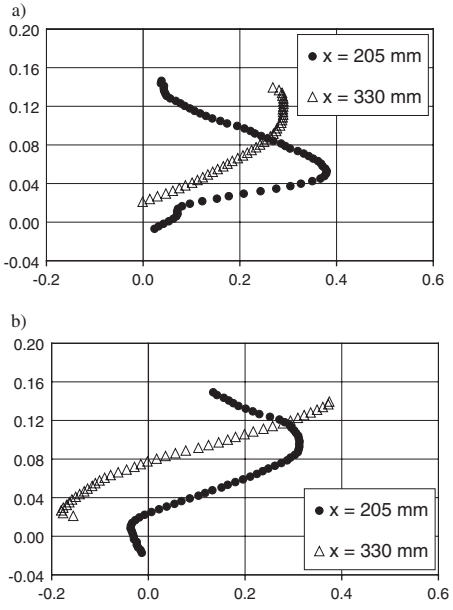

Figure 15. ADV vertical profiles of u (in m/s) vs y (in m) at different x positions, for "bed-surface jet" scour regime (run no. 14). Profile at $x = 205$ mm is located above the scour hole, profile at $x = 330$ mm is located approximately in the position of the secondary dune peak is found after the "bed jet" phase. (a) profiles collected during "bed jet" phase. (b) profiles collected during "surface jet" phase.

(Fig. 15b) the flow shifts towards the free surface and a re-circulation region appears close to the erodible bed. These differences extend downstream ($x = 330$ mm): in the "surface jet" phase (Fig. 15b), a large backflow region is present also above the dune, contributing, as previously observed, to the collapse of the secondary dune into the scour hole.

6 CONCLUSIONS

The scour of a non-cohesive bed downstream of an apron caused by a 2D horizontal jet flowing from a sluice gate has been studied experimentally on a laboratory channel. When the tailwater depth is just a few times the gate opening, but is high enough to guarantee a submerged hydraulic jump downstream of the gate, three distinct scour regimes can arise. In the "surface jet" regime, the jet tends to reach the free surface at the end of the apron and the scour hole and the dune develop mainly horizontally, following an elongated profile with low vertical dimensions. In the "bed jet" regime the jet adheres to the erodible bed and the resulting scour hole and dune are shorter, while their vertical dimensions are larger than in the previous case. An intermediate regime exists in which an unsteady cyclic flow onsets, the jet switching intermittently between the previous flow regimes: the resulting scour hole and dune shapes are also unsteady; in this case the maximum scour depth is not reached asymptotically but at the end of the more intense "bed jet" phases.

At least three non-dimensional parameters (when neglecting the effect of the Reynolds number and the grain size) are needed to predict the flow regime: the densimetric Froude number F_0, the normalized apron length l/y_0 and the normalized tailwater depth y_T/y_0. Comparisons of tests with approximately equal l/y_0 suggest that, for fixed F_0, intermediate y_T/y_0 ratios lead to "bed-surface jet" flows. When the normalized tailwater depth is large, "bed jet" flows are expected while "surface jet" patterns develop under low y_T/y_0. Moreover, the higher F_0, the larger the y_T/y_0 interval characterized by the jet flicking. Finally, again for fixed l/y_0 and F_0, the larger the normalized tailwater depth, the longer the average cycle period in flicking jet flows. Classical formulae by Schoklitsch and Shalash fail to reliably estimate maximum scour depth for "bed-surface jet" regime flows.

LDA and ADV velocity measurements, together with photographs and quantitative bed profiles evaluations, are provided for selected experiments: these data may be useful for the validation of numerical models able to simulate the interaction of free-surface flows with non-cohesive granular beds.

Scour protection downstream of block ramps

S. Pagliara & M. Palermo
University of Pisa, Department of Civil Engineering Via Gabba, Pisa, Italy

ABSTRACT: Block ramps or rock chutes are structures used in many river restoration projects. Generally, in such structures, a scour that must be controlled is present at the toe of the ramp. Aim of the paper is to analyse the scour that occurs downstream of the ramp and to indicate the protection works needed in order to avoid structural problems. Experimental tests have been carried out at the Hydraulic Lab. of the University of Pisa. Two different channels have been used for a total of about 300 tests. The ramp slope was varied between 1V:4H to 1V:12H while different materials have been used for both the ramp and the downstream base material. The protection has been realized by means of sills with different characteristics (i.e. continuous, permeable, or made by rocks). The advantages of a rock sill protection is evident in the sense of reducing the maximum scour depth.

1 INTRODUCTION

One of the problems in the design of transversal structures in natural rivers is the scour downstream of the toe of the structure. Pagliara & Hager (2004) analysed the scour downstream of a block ramp in absence of any type of protection work. They described the phenomenon and its scour mechanism. In their experiments, the bed and ramp materials were uniform. Two relationships were found both for the relative maximum scour depth Z_{max}, where $Z_{max} = z_{max}/h_1$, and for the relative medium cross-sectional scour depth Z_m, where $Z_m = z_m/h_1$. They found that:

$$Z_{\max} = E\ln(F_{d50}) + F \quad (1)$$

$$Z_{\mathrm{m}} = A\ln(F_{d50}) + B \quad (2)$$

where $A = 2.93i + 1.01$, $B = -0.83i - 0.62$, $E = 6.21i + 0.74$, $F = -2.18i - 0.24$, i is the ramp slope, $F_{d50} = V_1/(g'd_{50})^{1/2}$ the densimetric Froude number, $V_1 = Q/(bh_1)$ with b = channel width, V_1 = the average approach velocity, $g' = [(\rho_s - \rho)/\rho]g$ the reduced gravitational acceleration, ρ_s the sediment density; ρ as the water density, h_1 the approach flow depth at the ramp toe, Q the discharge, g gravitational acceleration, d the sediment size and the number indicates the percentage of the passage across a sediment net; z_{max} is the maximum measured scour depth and z_m the medium cross-sectional scour depth.

Successively, Pagliara (2006) analysed the same phenomenon using a non-uniform material for the downstream channel bed in order to put in evidence the effects of non-uniformity on the scour geometry. He found that:

$$Z_{\max} = Z_m(1 + 1.75F_{d50}^{-1.75}) \quad (3)$$

$$Z_m = 0.58F_{d50}^{1.8}\sigma^{-0.55}i^{0.75} \quad (4)$$

where $\sigma = (d_{84}/d_{16})^{1/2}$ is the geometric standard deviation (sediment non-uniformity parameter).

Aim of this paper is to investigate the effect of different types of protection works on the scour mechanism. Namely, as it was observed that the presence of different protection sills (i.e. continuous, permeable or made by rocks) had a great influence on the geometric scour parameters (length and depth), it seemed necessary to analyse the effects of different protection structure settlements on scour characteristics in order to compare and describe the final configuration. The qualitative description which is given in this paper could be a valid aid to understand the problems connected with the formation of a scour hole at the toe of a transversal structure. Moreover the aim of this paper is to give valuable suggestions for the choice of the protection structure typology and settlement in order to mitigate the scour depth and length in the case of uniform bed material.

2 EXPERIMENTAL SETUP

The experiments were conducted at the Hydraulic Laboratory of the University of Pisa, Pisa – Italy.

Two channels were used for experiments, channel 1-C and channel 1-D. The channel 1-D was rectangular,

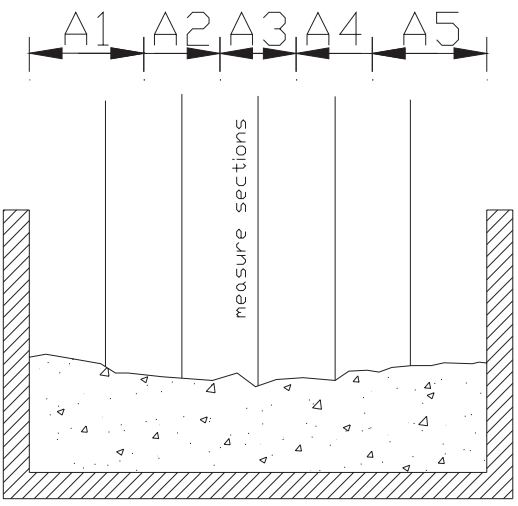

Figure 1. Measurement points in transversal cross-section.

Figure 2. Example of rock-made sill (view from downstream).

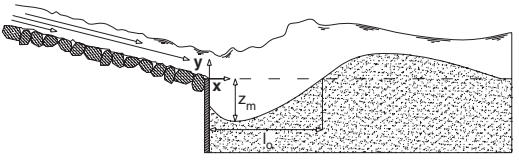

Figure 3. Reference test.

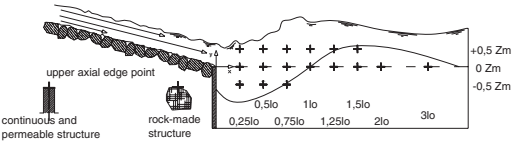

Figure 4. Selected control positions.

0.25 m wide, 3.5 m long and 0.30 m high and the channel 1-C was also rectangular, 0.35 m wide, 6.0 m long and 0.50 m high. Discharges up to 30 l/s were investigated. The ramp in the channels was made by inox steel sheets, on which two uniform granular materials were glued (material 1: $\sigma_1 = 1.17$, $d_{50} = 10.46$ mm; material 2: $\sigma_2 = 1.31$, $d_{50} = 4.00$ mm). The inox steel sheets had the same width of the channels and the length was varied from 0.40 to 1.0 m. The ramp was movable in order to change its slope in a range between 1V:4H and 1V:12H. Two granular uniform materials were put in the channel 1-C and in the channel 1-D, $s_{1\text{-}C} = 1.13$, $d_{50\text{-}C} = 10.60$ mm and $s_{1\text{-}D} = 1.18$, $d_{50\text{-}D} = 6.26$ mm, respectively, and they were graded in order to have an horizontal level downstream of the ramp before starting each experiment. The channelbed was measured both in transversal and in longitudinal direction before the beginning of each test. The distance of the longitudinal points of measurement varied from 5 to 15 cm, while, in the transversal direction, four points of measurement were selected for the narrower channel and five for the other one as shown in Figure 1. The protection works used were of three different types: continuous, permeable and rock-made sills respectively. Figure 2 shows an example of a rock-made sill.

Preliminary tests showed that after about 25 minutes scour progress vanished. For this reason a test duration of 25 minutes was chosen. At the end the measurements of previously selected points were taken after the bed material was completely dried. First of all, experiments were carried out without any type of protection work with the same methodology as mentioned above in order to have the average reference values of depth and length of the scour z_m and l_0, respectively, as shown in Figure 3.

3 DESCRIPTION OF EXPERIMENTAL DATA

Different "control positions" for the insertion of the protection works were fixed. Figure 4 shows the horizontal and vertical "control positions" which were selected for the experiments. The symbol "+" represents the position of the upper axial edge point of the structure, as shown in Figure 4. According to the reference frame, horizontal positions were selected at the distances of $0.25l_0$, $0.5l_0$, $0.75l_0$, $1.0l_0$, $1.25l_0$, $1.5l_0$, $2.0l_0$, and $3.0l_0$ from the toe of the ramp. The choice of the last two points ($2.0l_0$and $3.0l_0$) had the only aim to demonstrate that, if the protection work was put at a great distance from the toe of the ramp and its top was at $0.0z_m$, its effects on the scour process were negligible. Moreover, three vertical positions z_{op} were chosen for the top of the protection work, at $-0.5z_m$, $0.0z_m$ and $+0.5z_m$. A total of seventeen different positions was chosen as shown in Figure 4 with a "+" symbol. For each one of those seventeen different

selected positions, many experiments were conducted in order to understand and evaluate the influence of the parameters that affect the phenomenon. For this reason, three different ramp slopes, 1V:4H, 1V:8H and 1V:12H, two discharges and three different protection works were considered. These experimental tests confirmed that an opportune vertical and longitudinal settlement of a rock-made sill can minimize scour length and depth more efficaciously than other tested structures, as shown in Figures 5a, b, c and in

Figures 6a, b, c, in which a comparison of the effects of presence of different tested structures (located at $z_{op} = +0.5z_m$) is proposed. In these figures the ratios z_{ms}/z_m and l_s/l_0 are plotted against the dimensionless parameter λ. $\lambda = x_s/l_0$, where x_s is the longitudinal position of the protection work. z_{ms} is the medium cross-sectional scour depth and l_s is the scour length, both in presence of protection works.

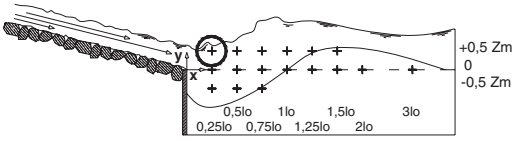

Figure 7. Protection work at $\lambda = 0.25$ and $z_{op} = +0.5z_m$.

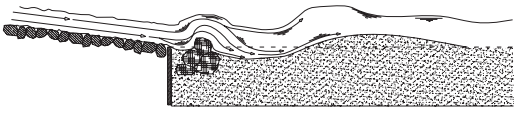

Figure 8. Rs1 scour profile.

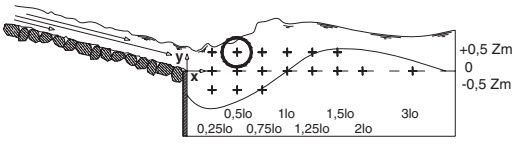

Figure 9. Protection work at $\lambda = 0.50$ and $z_{op} = +0.5z_m$.

Having proved that the rock-made sills performed better than the other structures in order to minimize the scour depth and length, several other experiments were conducted using rock-made sills as protection work. From these experiments four different scour typologies, called Rs1, Rs2, Rs3 and Rs4, were individuated.

Maintaining fixed the top of the protection work, it was possible to show the influence of the other parameters on the scour process. In other words, it was possible to evaluate the influence on the variation of depth, length and the geometrical form of the scour because of the variation of the longitudinal position of the protection work and of the ramp slope. Let us consider now the various typologies of scour that could be possible in the case in which the top of the protection work was set at $z_{op} = +0.5\, z_m$.

If the protection work is located at $\lambda = 0.25$ (Fig. 7), when the ramp slope was 1V:4H, there was a reduction of the scour depth ($z_{ms} < z_m$), and the length was almost the same of the reference prove ($l_0 \approx l_s$). If the ramp slope was 1V:8H or 1V:12H, for both we had $l_s > l_0$, but $z_{ms} < z_m$ and $z_{ms} \approx z_m$, respectively. The energy dissipation was essentially due to the impact of water on the protection work when the ramp slope was 1V:4H, while, in the other two cases, it was essentially due to the erosion downstream of the rock-made sill. In this case, the scour profile was indicated as Rs1, as shown in Figure 8.

If the protection work was put at $\lambda = 0.50$ (Fig. 9), two scour profiles were observed according to the different ramp slopes, Rs 3 and Rs 2 respectively.

When the ramp slope was 1V:4H, the value of the length of the scour was minimum ($l_s = l_{smin} < l_0$) but the depth was maximum ($z_{ms} = z_{msmax} > z_m$), because

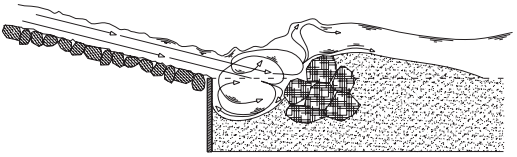

Figure 10. Rs3 scour profile.

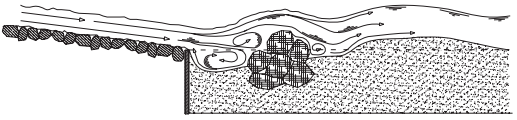

Figure 11. Rs2 scour profile.

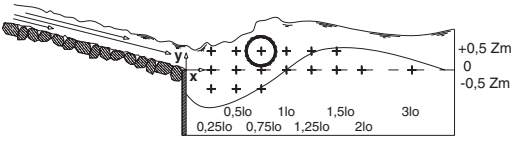

Figure 12. Protection work at $\lambda = 0.75$ and $z_{op} = +0.5z_m$.

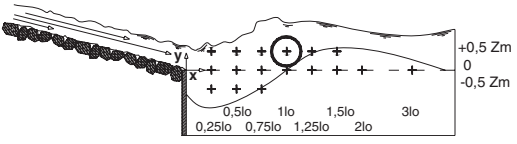

Figure 13. Protection work at $\lambda = 1.0$ and $z_{op} = +0.5z_m$.

of the great dissipation of energy upstream of the protection work. In this case, the scour profile was indicated as Rs 3, as shown in the Figure 10.

If the ramp slope was in the range 1V:12H – 1V:8H, the scour took place both downstream and upstream of the sill, the length of the scour increased, $l_s > l_0$, but there was a decrease in the depth, $z_{ms} < z_m$. In this case, the scour profile was indicated as Rs 2 as shown in the Figure 11.

If the protection work was located at $\lambda = 0.75$ (Fig. 12), the Rs3 scour profile was observed for all the tested ramp slopes.

The experiments showed that there was a scour upstream of the sill where part of the energy of the water was dissipated. For this longitudinal position, the length of the scour decreased, $l_s < l_0$ for all the three slopes, moreover, for ramp slopes 1V:8H and 1V:12H, it reaches its minimum. It was seen that $z_{ms} < z_m$ when the ramp slope was 1V:4H, and it became almost equal to z_m in the other two cases. The scour profile is shown in Figure 10.

If the protection work was located at $\lambda = 1.0$ (Fig. 13), when the ramp slope was 1V:4H, there was a reduction of the depth of the scour ($z_{ms} < z_m$) and of its length ($l_s < l_0$). The same scour profile shown in Figure 10 occurred (Rs3- type), but it was seen that a

Copyright © 2006 Taylor & Francis Group plc, London, UK

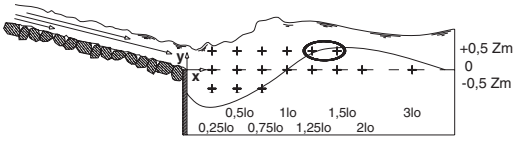

Figure 14. Protection work at $1.25 < \lambda < 1.5$ and $z_{op} = +0.5z_m$.

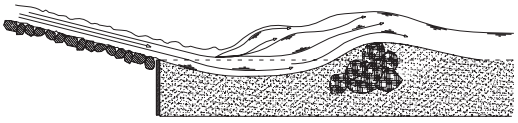

Figure 15. Rs 4 scour profile.

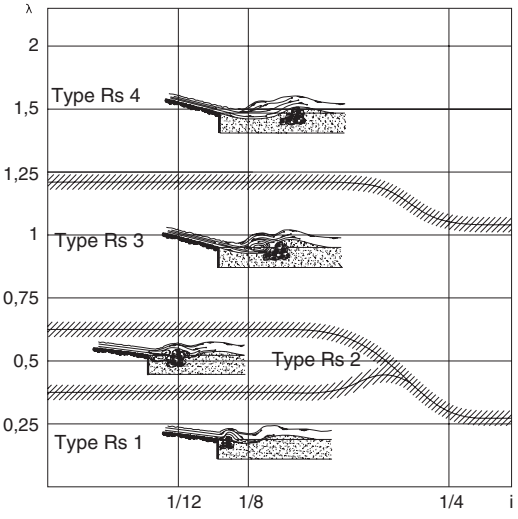

Figure 16. Scour profiles for $z_{op} = +0.5z_m$.

little increase of the longitudinal distance of the protection work caused a variation in the scour profile, which changed from Rs3 to Rs4 type. For ramp slopes 1V:8H and 1V:12H there was a reduction of the depth of the scour ($z_{ms} < z_m$) and of the length ($l_s < l_0$), and a Rs3 profile type occurred.

For the case of protection work located at $1.25 < \lambda < 1.5$ (Fig. 14), it was seen that another scour profile for all the three different ramp slopes occurred and it was called Rs 4 type.

It was observed that Rs4 scour profile (Fig. 15) was quite similar to the Rs3 type. The only difference was that the sill, in this case, was totally submerged by the dune downstream of the scour, while in Rs3 scour profile the sill was partially submerged. A decrease of the value of the scour depth and length, $z_{ms} < z_m$ and $l_s < l_0$, was observed.

Figure 16 shows a synthesis of all the geometric types mentioned above, when $z_{op} = +0.5z_m$.

Figure 17. Rs1 type scour profile.

Figure 18. Rs2 type scour profile.

Figure 19. Rs3 type scour profile.

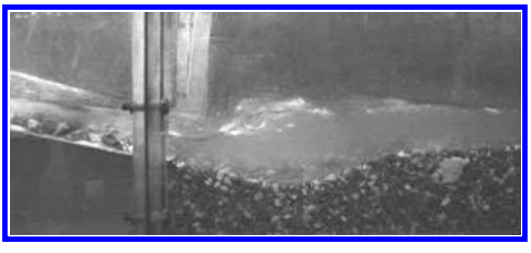

Figure 20. Rs4 type scour profile.

Figures 17–20 show the four scour typologies which were observed in the experiments.

The same methodology, as mentioned above, was followed for the other two positions of the top of the protection work, $z_{op} = 0.0z_m$ and $z_{op} = -0.5z_m$. It was seen that, also in these cases, the quantitative reduction of the scour depth and length due to the presence of a rock-made sill was similar to the examined case ($z_{op} = +0.5z_m$).

Copyright © 2006 Taylor & Francis Group plc, London, UK

4 CONCLUSIONS

The experiments show that opportune settlements of the protection work can reduce the scour depth and the scour length. It was seen that rock-made sills are more efficient than other types in order to reach these results. Particularly, it was seen that, when $z_{op} = +0.5z_m$, if we are interested in the minimization of the scour length two longitudinal positions of the sill have to be chosen: for ramp slope 1V:4H the best position is at $l = 0.5$ while, if the ramp slope is in the range 1V:12H-1V:8H, the best longitudinal position is at $l = 0.75$. Moreover, if we are interested in a reduction of both the scour depth and length, for all different ramp slopes, the longitudinal positions where the sill has to be located are in the range $0.75 < \lambda < 1.5$. The experiments also showed that, if the protection work is located at $l = 0.5$, when $z_{op} = +0.5z_m$ and the ramp slope is 1V:4H, there is an increase of the scour depth and in this position it reaches its maximum.

Temporal patterns of the maximum scour depth around a pier

G. Oliveto & A. Di Domenico
DIFA, University of Basilicata, Potenza (Italy)

ABSTRACT: In temporal and spatial development of scour processes around a cylindrical pier, the maximum scour depth does not occur at the same location over the time. It localizes at the pier sides firstly, then it tends to migrate towards the pier leading face at a rate mainly depending on the approach flow densimetric Froude number. Based on experiments carried out at University of Basilicata and experiments previously conducted at VAW-ETH, Zurich, this paper would like to provide mainly a relationship for the switch time T_{sw}, defined as the (dimensionless) time at which the maximum scour depth transfers from the pier sides to the axial pier front. The VAW data were globally processed to identify preventative outcomes. The data collected in the present study were devoted to the capture of T_{sw} and thus were used for a more detailed analysis. Findings, that appear wide-ranging, would provide useful tools for numerical modeling, field diagnostic and for proper analyses of literature data that are frequently based on observations at pier front only.

1 INTRODUCTION

Local scour is an important issue in bridge hydraulics. A great number of studies have been made in this research area, but several aspects are still unexplored or unclear.

With reference to a cylindrical pier it is well known that scour initiates at the sides of the cylinder, at an angle of approximately 70 degrees to the undisturbed flow direction, then advances to the leading face of the pier (Breusers & Raudkivi 1991, Hoffmans & Verheij 1997). Thus, the maximum scour depth at the upstream pier face occurs only at an advanced scour stage (Figure 1).

Moreover, for flow conditions with a densimetric Froude number F_d close to the entrainment condition at pier, this shift of maximum scour could even not occur because of the too small forces involved after the initial scour phase. The densimetric particle Froude number is defined as $F_d = V_o/(g'd_{50})^{1/2}$ with V_o the approach flow velocity and $g' = g(\rho_s - \rho)/\rho$ the modified gravitational acceleration with ρ and ρ_s the fluid and sediment densities, respectively.

According to Hager et al. (2002), one may refer to small, medium or fast scour progress, depending on F_d. Typically, for $F_{d\beta} < F_d < 2$, with $F_{d\beta}$ = densimetric Froude number for the entrainment of scour at pier, scour is weak with a tendency for slightly asymmetric scour on the two pier sides. Typical clear water scour may be expected for $2 < F_d < F_{di}$, with a significant effect of pier diameter on the scour extension. Here, F_{di} is the densimetric Froude number at the inception of sediment transport for the approach (undisturbed) bed. For $F_d > F_{di}$ scour does not really advance after a sufficient time because of an equilibrium between sediment transports into and out of the scour hole (Hoffmans & Verheij 1997).

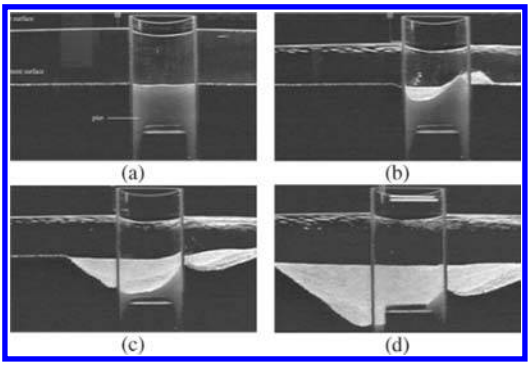

Figure 1. Experiment at VAW-ETH (Hager et al. 2002). Lateral view of scour advance for a half-cylinder. Flow is from left to right. (a) $t = 0$ (run starting); (b) $t = 5$ min; (c) $t = 3$ h; (d) $t = 21$ h with t = time.

Nevertheless, most of the proposed formulas on the scour at a pier are based on the growing of the scour depth axially at the pier front, and thus they could seriously underestimate local scour especially in the starting scour period.

Based on recent outcomes (Oliveto et al. 2005), experimental data previously collected at VAW-ETH (Oliveto & Hager 2002) and new selected tests carried

Copyright © 2006 Taylor & Francis Group plc, London, UK

out at University of Basilicata, this paper would like to set up general equations able to describe the temporal patterns of the maximum local scour around uniformly shaped circular piers.

The results may provide new insights in bridge analysis and design, and for a more intrinsic understanding of local scour processes.

2 EXPERIMENTS AT VAW-ETH

VAW-ETH initiated scour research in 1995 by focusing so-called building scour. The experiments were conducted in a rectangular channel 1.0 m wide and 13 m long with a working section of about 5 m.

Piers of diameters $D = 0.022$, 0.050, 0.064, 0.110, 0.257, 0.400, and 0.500 m were used.

Scour experiments were directed to survey both sediment and water surfaces. These characteristics were determined with conventional gauges. The sediment surface was observed with a shoe gauge, given its similarity with a shoe of 5 mm length to 2 mm width. Sediment surface readings were then much simpler than with a conventional point gauge with an accuracy of about 0.5 sediment diameter.

Sediment readings involved the original bed elevation, the upstream beginning of scour, the transverse extent of scour at the element upstream and downstream sides, the maximum scour depths at these two locations, the location of maximum aggradation downstream of the elements besides particular points for each test. Test readings were made in short intervals close to the beginning, and at longer intervals after the initial scour phase.

Three sediments of almost uniform average size of 0.55, 3.3 and 4.8 mm, and three mixtures, with $d_{50} = 5.3$, 1.2, 3.1 mm, and $\sigma = (d_{84}/d_{16})^{1/2} = 1.43$, 1.80 and 2.15, respectively, were used. The uniform sediment with $d_{50} = 3.3$ mm had a density of $\rho_s = 1.42$ t/m^3 to check for the density effect, whereas the remainder had $\rho_s = 2.65$ t/m^3. More details are given in Oliveto & Hager (2002).

3 NEW EXPERIMENTS

Selected experiments were conducted in a 1.0 m wide and 20 m long rectangular straight channel at the Hydraulic Engineering Laboratory, University of Basilicata, Italy.

The working section was about 10 m. The bed material was a nearly uniform sand with density $\rho_s = 2.65$ t/m^3, grain size $d_{50} = 1.4$ mm and sediment gradation $\sigma = (d_{84}/d_{16})^{1/2} = 1.35$. A pier of diameter $D = 0.12$ m was used. It was located at 5 m from the bed sediment beginning and at 9 m from the channel inlet to have good approach flow conditions and a fully developed turbulent flow at the scour element.

Table 1. Experiments at University of Basilicata: main test conditions and observed scour depths at the end of the run. F_t = threshold Froude number; F_d = densimetric Froude number; t_d = duration test; z = measured scour depth around the pier; subscripts s, f, d = side, front, and downstream, respectively.

Run	F_t –	F_d –	t_d (h)	z_s (cm)	z_f (cm)	z_d (cm)
1	0.73	2.46	1.9	1.10	1.28	0.57
2	0.86	2.84	1.9	1.27	1.47	0.78
3	0.76	2.55	2.2	1.21	1.33	0.70
4	0.82	2.93	1.8	1.37	1.53	0.86
5	0.52	1.82	7.9	0.65	0.71	0.15
6	0.42	1.45	52.5	0.28	0.26	−0.14

All the experiments were run under plane bed conditions, steady flow, and clear-water scour regime. Discharges Q were measured with an orifice plate of ±3% accuracy. Water surface was surveyed with a conventional point gauge, typically ±0.5 to 1 mm, whereas the bed morphology was surveyed with a shoe gauge having 4 mm by 2 mm wide horizontal plate at its base. Sediment readings involved: the scour depth at the pier sides, the scour depth at pier front, and the aggradation height or the scour depth at the rear of the pier. During each run the channel was carefully monitored to capture the time at which the maximum scour depth shifted from the pier sides to the pier front and that one marking the passage from aggradation to scouring phase just downstream of the pier. The main test conditions and the observed scour depths at the end of each run are given in Table 1.

The approach flow depth was controlled by an adjustable sharp-crested weir located at the channel downstream end. Once the bed was accurately leveled the experiment initiated submerging the working section by setting the sharp-crested weir up. This was lowered within 10 to 20 seconds to the pre-selected flow depth and the temporal start of the experiment was set at scour inception.

4 SWITCH TIME RELATIONSHIP

The approach by Oliveto & Hager (2002) for the temporal progress of scour at uniformly shaped piers was assumed as framework for this analysis. The dominant parameter governing scour processes is the densimetric particle Froude number F_d. The reference length, involving the approach flow depth h_o and the pier diameter D, is $z_R = (h_o D^2)^{1/3}$. Accordingly, the time scale is $t_R = z_R/[\sigma^{1/3}(g' d_{50})^{1/2}]$. Finally, the maximum scour depth z at a certain time t is given by

$$Z = z/z_R = 0.068\sigma^{-1/2} F_d^{1.5} \log T \qquad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

with $T = t/t_R$ the relative time. Equation (1) provides thus the temporal growing of the maximum scour depth around a pier independently of its location.

Figures 2a and 2b provide a set of plots for temporal trend of the scour depth at the pier side (Figure 2a) and at the pier front (Figure 2b), in the domain (ζ, log$T$) with $\zeta = Z\sigma^{0.5}/F_d^{1.5}$. Data refer to the VAW-ETH experiments. Equation (1) is plotted as a full straight line with the ±25% intervals added as dashed lines as in Oliveto & Hager (2002). In the domain (ζ, log$T$), the scour depth at the pier side follows a linear trend almost regularly, growing thus at a constant rate. The temporal scour evolution at the pier front appears clearly different. Scour typically starts at $T = 10^2$ at that location. The growing rate is particularly high for T from 10^2 to 10^4 and then decreases almost in conformity with Equation (1).

According to Oliveto et al. (2005), the switch time T_{sw} can be defined as the dimensionless time T at which the maximum scour depth migrates from the pier sides to the axial pier front.

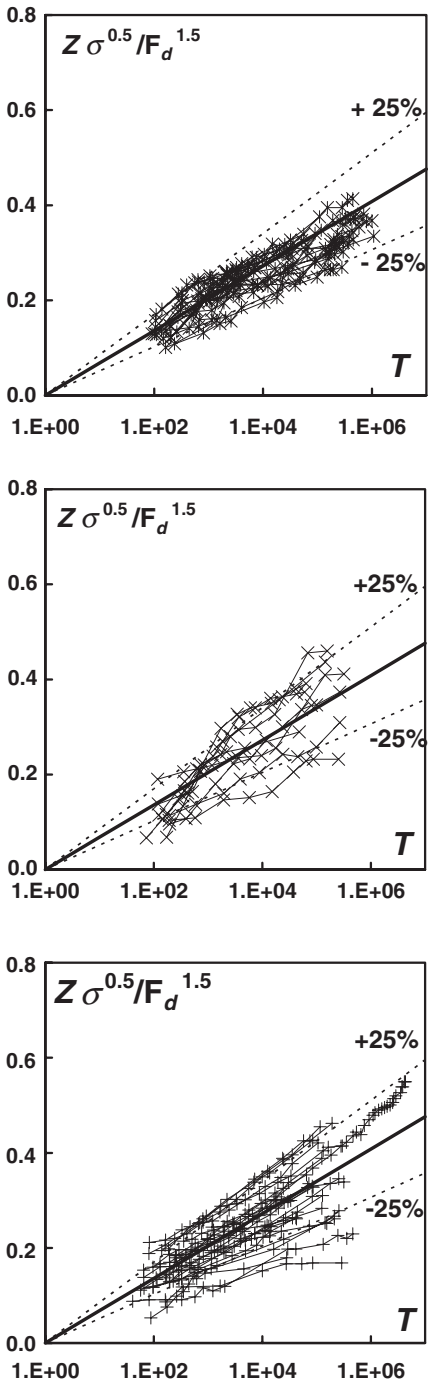
Thus, referring to the VAW-ETH experimental data, T_{sw} can be approximately determined by the intersection of the temporal trend of the scour depth at the pier front and Equation (1). The plots in Figures 2 reveal that such an intersection typically occurs for T from 10^2 to 10^4. In addition, the plot on the bottom of Figure 2b clearly shows that: for runs with F_t less then 0.5 (data embodied in region A) the above intersection does not occur and thus the maximum scour tends to persist at the pier side; for runs with $0.5 < F_t < 1$ (data embodied in region B) the switch time typically occur in the range 10^2 to 10^4; for runs with $F_t \geq 1$, but still close to 1 (data embodied in region C), T_{sw} tends to zero. Incidentally, F_t is the so called threshold Froude number given by V_o/V_t with V_t the cross sectional flow velocity at which bed sediment inception occurs. It was computed according to relationships suggested by Hager & Oliveto (2002).

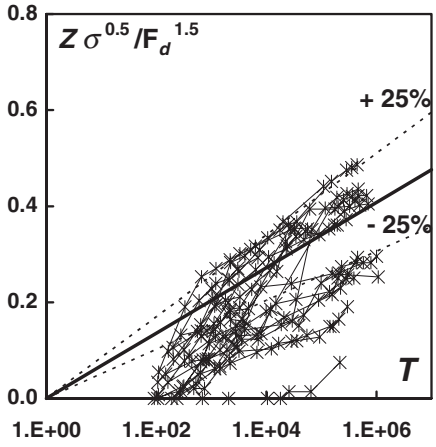
Thus, the VAW-ETH data reveal that T_{sw} should be a decreasing function of F_t tending to infinity as F_t tends to 0.5 and to 0 as F_t tends to 1.

To better define this relationship the data collected at University of Basilicata were processed and the plot in Figure 3 resulted.

Thus, in the domain (log T_{sw}, F_t) the experimental data appear to be adequately interpreted by a sigmoidal curve. In particular, for runs with F_t greater than 0.9, but close to 1, as it is usually done in the experimental practice, one can confidently assume that the maximum scour depth is always localized at the pier front.

The above results refer to runs in transitional regime (i.e. dimensionless grain size D_* from 20 to 150 with $D_* = (g'/\nu^2)^{1/3} d_{50}$). In effect, the same results would seem to apply to the runs in viscous regime also, although more experimental data would be needed.





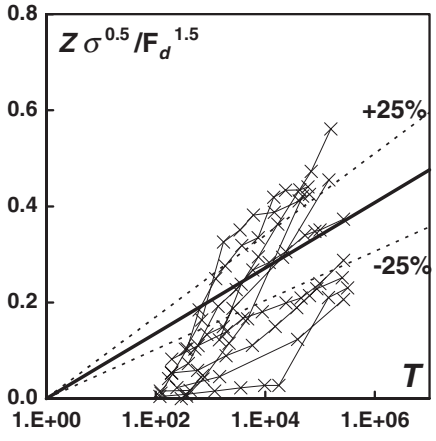


Figure 2a. $\zeta = Z\sigma^{0.5}/F_d^{1.5}$ as a function of the dimensionless time T at the pier side for runs in transitional regime. (∗) $d_{50} = 5.3$ mm; (×) $d_{50} = 4.8$ mm; (+) plastic with $d_{50} = 3.3$ mm.

Copyright © 2006 Taylor & Francis Group plc, London, UK

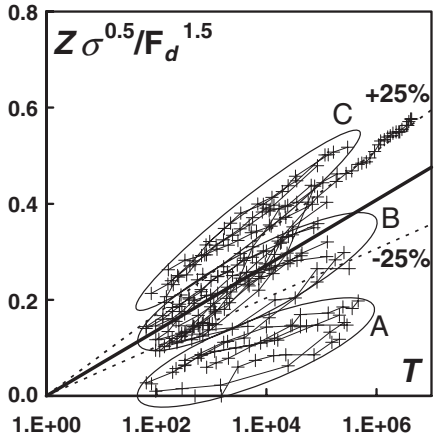

Figure 2b. $\zeta = Z\sigma^{1.5}/F_d^{1.5}$ as a function of the dimensionless time T at the pier front for runs in transitional regime. (∗) $d_{50} = 5.3$ mm; (×) $d_{50} = 4.8$ mm; (+) plastic with $d_{50} = 3.3$ mm.

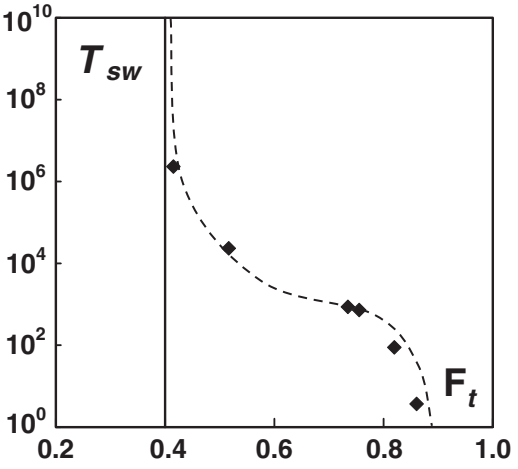

Figure 3. Switch time T_{sw} as a function of the threshold Froude number F_t. (- - - - -) sigmoidal fitting curve by eye.

The plots in Figure 4 represent the data for uniform sand ($d_{50} = 0.55$ mm, $\sigma = 1.37$). Due to viscous effects, Equation (1) should be corrected by a factor of 0.45 (Oliveto et al. 2005). Accordingly, it would seem that for F_t ranging between 0.6 to 0.9, the switch time still would occur in the range 10^2 to 10^4, whereas it would tend to infinity for F_t tending to 0.4.

An analysis on the scour depth at the rear of the pier was also performed for completeness. In particular, a trend similar to that of T_{sw} on F_t was observed for the switch time T'_{sw} marking the transition from the aggradation to the scouring phase. Figure 5 shows this trend which is overall confirmed by the VAW-ETH experimental data. The data collected in the present study confirmed also the appropriateness of the equation (5) given in Oliveto et al. (2005) for the temporal scour evolution at that location, on condition of F_t close to 1 (F_t from 0.8 to 1.0).

5 CONCLUSIONS

Selected experiments on the temporal evolution of clear water pier scour were carried out at the Hydraulic Engineering Laboratory, University of Basilicata, Italy.

The runs were devoted to the capture of the switch time at which the maximum scour depth migrates from the pier side to the pier front.

The experimental results, supported and integrated by some outcomes from several runs performed at VAW-ETH, have revealed that: (i) in the domain (ζ, log$T$) the scour depth grows differently in dependence of the location. At the pier side it exhibits a linear trend growing thus at a constant rate; at the pier front

Copyright © 2006 Taylor & Francis Group plc, London, UK

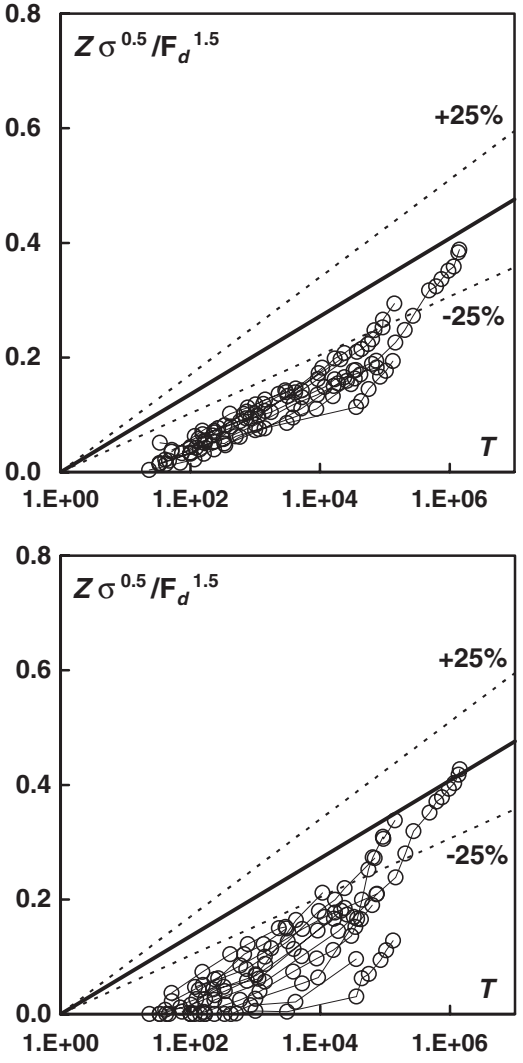

Figure 4. ζ as a function of the dimensionless time T at the pier side (top) and at the pier front (bottom) for runs in viscous regime.

its growing rate is particularly high firstly (for T from 10^2 to 10^4), then decreases by conforming to that of Equation (1); (ii) the switch time T_{sw} is a decreasing function of the threshold Froude number F_t tending to infinity as F_t tends to 0.4 and to 0 as F_t tends to 1. In particular, for runs with F_t close to 1 (F_t from 0.85 to 1.0), as it is usually done in the experimental practice, one can confidently assume that the maximum

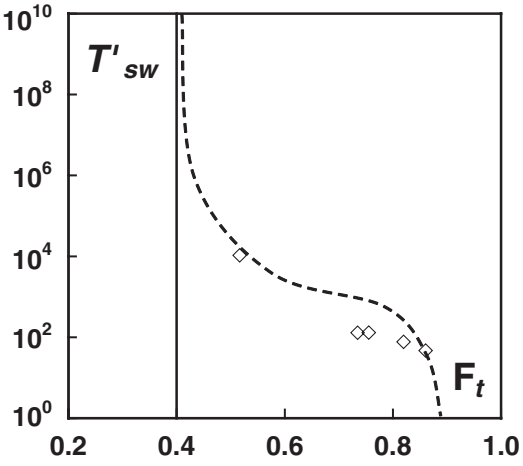

Figure 5. Switch time T'_{sw} at the rear of a cylindrical pier as a function of the threshold Froude number F_t. (- - - - -) sigmoidal fitting curve by eye.

scour depth is always localized at the pier front. These results are overall in agreement with those in Oliveto et al. (2005), but improved because based on runs specifically devoted to the capture of T_{sw}; (iii) a similar trend was observed for the switch time T'_{sw} marking the passage from aggradation to scouring phase downstream of a pier. For F_t close to 1, the temporal trend of the scour depth at this location is suitably interpreted by the equation (5) given in Oliveto et al. (2005).

Riverbed scour induced by a long constriction

G. Oliveto, B. Onorati & V. Comuniello
DIFA, University of Basilicata, Potenza (Italy)

ABSTRACT: This study is a part of a more comprehensive research and is focused on the bed scour that would occur when rivers are forced by manmade or natural contractions. To this purpose, some experiments, typically lasted for days, were carried out at University of Basilicata in a straight rectangular channel and under clear water scour regime. The bed material was uniform sand and three contraction models, with opening ratio (i.e. ratio between the widths of the contracted and uncontracted reaches) of 0.9, 0.8, and 0.7, were used. Starting from the monomial form of sediment transport formulas, a new relationship for the quasi-equilibrium scour depth is conjectured based on Froude's similarity and by relating the scour depth to the difference between the actual and the entrainment densimetric Froude numbers in the contracted zone. The proposed approach is validated by the data of the present study, and verified by available literature data.

1 INTRODUCTION

Flow constriction arises from a significant reduction of the width of a watercourse. When the flow is subcritical, the contraction of a river induces an increase in the velocity and in bed shear stresses, which may cause bed scour. Natural constraints as longitudinal bars, confluences and debris accumulations or hydraulic structures as bridge embankments, lateral banks and spur dikes are common examples of stream flow area reductions.

Figure 1 shows an extreme case of a short and abrupt contraction and the related damages caused by the construction of a diversion weir in an alluvial stream.

Most of the published works refers to the long contraction case (i.e. flow can be considered practically uniform in both the approach and restricted reach), which in general occurs when the length L of the constrained reach is one (Komura 1966) to two (Webby 1984) times the width b_1 of the undisturbed approach reach. Recent experimental investigations confirmed that $L/b_1 \geq 1$ is adequate for a contraction to be considered long (Dey & Raikar 2005).

Figure 1. High degree of contraction induced by the building of a diversion weir on the Sauro Creek, southern Italy. The photo on the right shows the flood damages during December 1990.

Straub (1934) was probably the first to introduce a simplified one-dimensional approach for long contractions. His work was based on the DuBoys' transport formula and Manning's equation applied to both the constrained and (unconstrained) approach reach. Afterwards, many equations have been suggested, most of which were derived using Straub's (1934) approach (e.g. Laursen 1960, Komura 1966, Gill 1981, Lim & Cheng 1998). A review of relevant literature is provided by Hager (1998) and Melville & Coleman (2000). Among the more recent papers are those of Briaud et al. (2005) and Dey & Raikar (2005). In particular, this latter work makes available the experimental data for more than 100 runs with uniform sediments under clear-water scour.

Despite the many studies on this topic, there is not a satisfactory concordance of results. Based on long-duration tests, Oliveto et al. (2005) demonstrated the inadequacy of the most common models for the estimation of the quasi-equilibrium scour depth in long contractions. The present paper aims to provide a contribute in this context. In particular, a new straightforward approach is proposed. It is validated by the data collected at University of Basilicata and verified by the data of other investigators.

2 EXPERIMENTAL INSTALLATION AND PROCEDURE

Experiments were conducted in a 1 m wide and 20 m long rectangular straight channel at the Hydraulic

Copyright © 2006 Taylor & Francis Group plc, London, UK

Engineering Laboratory, University of Basilicata, Italy. The working section was about 10 m. The bed material was a nearly uniform sand with density $\rho_s = 2.65$ t/m^3, grain size $d_{50} = 1.7$ mm and sediment gradation $\sigma = (d_{84}/d_{16})^{1/2} = 1.5$. The contracted reach was carried out by two polystyrene elements symmetrically attached to the side glass walls of the channel. This reach was made by three parts. The middle one was straight lined and 1 m long, whereas the entrance and outlet parts had a length of 0.5 m each and were carefully streamlined to minimize energy losses and local scour effects. The upstream end of the contraction model was located at 4 m from the bed sediment beginning and at 8 m from the channel inlet to have good approach flow conditions and a fully developed turbulent flow at the entrance of the contraction. Three contraction ratios $\beta = b_1/b_2$ of 1.11, 1.25, and 1.43 were used; where $b_1 =$ width of the (uncontracted) approach channel and $b_2 =$ width of the uniformly contracted reach. In addition, some experiments were performed with only one polystyrene element mounted at one side of the channel. In such case the constriction ratio was assumed equal to 1.18, by considering the side glass wall without contraction element as the centerline of a channel $2b_1$ wide.

All the experiments were run under plane bed conditions, steady flow, and clear-water scour regime. Discharges Q were measured with an orifice plate of $\pm 3\%$ accuracy. Water surface was surveyed with a conventional point gage, typically ± 0.5 to 1 mm, whereas the bed morphology was surveyed with a so called shoe gage having 4 mm by 2 mm wide horizontal plate at its base. The tests were of long duration, from 1 day up to 15 days, to ensure an adequate accuracy, especially for low degree of contraction, and to get conditions of quasi-equilibrium. Flow depths and bed levels, around and in the contracted zone, were normally recorded each day. The measurements during the test were taken along the channel centerline to minimize the flow disturbance. At the end, more than 500 bed level readings were typically recorded. The main experimental data are given in Oliveto et al. (2005).

The approach flow depth was controlled by an adjustable sharp-crested weir located at the channel downstream end. Once the bed was accurately leveled the experiment initiated submerging the working section by setting the sharp-crested weir up. This was lowered within 10 to 20 seconds to the pre-selected flow depth and the temporal start of the experiment was set at scour inception.

Photographs in Figure 2 refer to the run 18.11.04 with $\beta = 1.43$, discharge $Q = 40$ l/s, and approach flow depth $h_1 = 10.2$ cm. Figure 2a is an upstream view. The nearly streamlined shape of the entrance and outlet of the constriction model can be noted. As for all experiments, the flow was subcritical also in the contracted reach and only small cross waves were

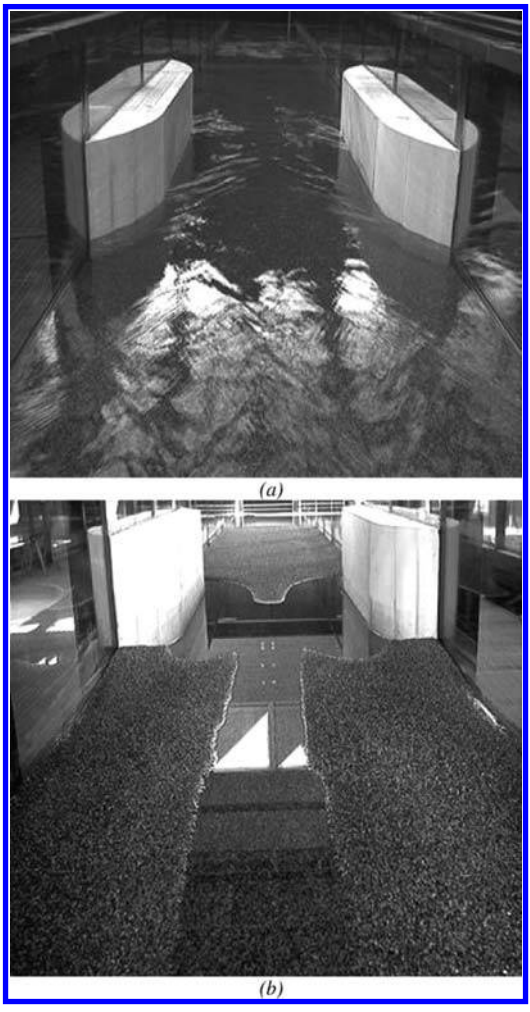

Figure 2. Run 18.11.04: (a) Flow conditions through the contracted reach. (b) Bed morphology at the end after practically water emptying.

observed. Moreover, the constriction reach induced only a small backwater effect so that the approach flow depth h_1 could be confidently measured 2 meters upstream from the model entrance.

Figure 2b is a downstream view at the end of the run and after water emptying. The bed configuration appears to be satisfactorily symmetric. Moreover, it can easily noted as the bed degradation tends to concentrate along the channel centerline and significantly extends downstream of the contracted zone. The deepest contraction scour depth was normally observed downstream of the middle of the model, even outside as for the run considered. There are also evident tracks of local scour in the vicinity and along the constriction elements. In general, local scour was

Copyright © 2006 Taylor & Francis Group plc, London, UK

not completely inhibited, although the elements were streamline shaped. Width constriction effects could be considered independent of local scour ones only when $\beta = 1.11$. Nevertheless, the two scour patterns were always distinguishable.

3 QUASI-EQUILIBRIUM SCOUR EQUATION

Sediment transport formulas for uniform sediment beds are typically given in monomial form as

$$\phi = \frac{q_b}{\sqrt{g' d_s^3}} \propto \theta^n \tag{1}$$

where q_b = volume of bed material in motion per unit width and time; $g' = g(\rho_s - \rho)/\rho$ with g as gravitational acceleration, ρ and ρ_s fluid and sediment densities; d_s = grain size; $\theta = v_*^2/(g' d_s)$ = the Shields' parameter with v_* shear velocity; n = exponent. According to Oliveto et al. (2005), one should expect that q_b and z_e are intimately connected so that Equation 1 could be rearranged as

$$\frac{z_e}{d_s} \propto \theta^n \tag{2}$$

with z_e = quasi-equilibrium scour depth. For nearly uniform sediment beds, Hager & Oliveto (2002) demonstrated that

$$\mathrm{F}_d \propto \left(\frac{R_h}{d_{50}}\right)^{1/6} \theta^{1/2} \tag{3}$$

with R_h = hydraulic radius; d_{50} = particle size for which 50% are finer by weight; F_d = densimetric Froude number. In particular, $\mathrm{F}_d = V/(g' d_{50})^{1/2}$ with V = cross-sectional velocity. Thus, assuming d_{50} as the characteristic grain size, Equations 2 and 3 yield

$$\frac{z_e}{d_{50}} \propto \left(\frac{R_h}{d_{50}}\right)^{-\frac{n}{3}} \mathrm{F}_d^{2n} \tag{4}$$

This latter equation was thus explored by considering the uniformly contracted reach (subscript 2). The densimetric Froude number $(\mathrm{F}_{d,2})_{t=0}$ at time $t = 0$ was considered (i.e. undisturbed bed). In particular, $(\mathrm{F}_{d,2})_{t=0}$ was computed by averaging the observed flow depths h_2 along the centerline. Note that in practical applications, h_2 could be confidently estimated according to Chow (1959). In the present study, the observed values of h_2 were satisfactorily estimated by applying the specific energy equation and by neglecting local energy losses. Equation 4 was validated with the experimental data and its adequacy is demonstrated by the plot in Figure 3.

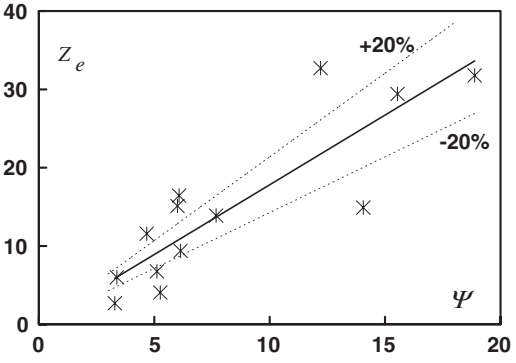

Figure 3. $Z_e = z_e/d_{50}$ as a function of the dimensionless combination $\Psi = \mathrm{F}_{d,2}^4 (R_{h,2}/d_{50})^{-2/3}$. (✳) Experimental data collected at University of Basilicata; (——) Regression line; (· · · · · ·) 20% error bands.

In particular, Equation 4 specializes as

$$\frac{z_e}{d_{50}} = \frac{7}{4}\left(\frac{R_{h,2}}{d_{50}}\right)^{-\frac{2}{3}} \mathrm{F}_{d,2}^4 = \frac{7}{4}\Psi \tag{5}$$

with $r^2 = 0.73$. Despite a certain deviation of the data from the regression line, it is significant that $n = 2$ can be deduced by comparing Equations 4 and 5. This value of n would corroborate the goodness of the above approach. In fact, it is close to the exponent 2.5 of the well known Engenlund-Hansen's sediment transport formula that is particularly indicated for sandy bed as that used in this experimental work. Moreover, from Equation 5, by approximating the hydraulic radius $R_{h,2}$ with h_2 (i.e. wide rivers) and by taking into account the definition of $\mathrm{F}_{d,2}$, one has $z_e \propto V_2^4/(d_{50}^{1/3} h_2^{2/3} g'^2)$. Thus, the cross-sectional velocity V_2 has the most significant effect on the scour process, followed by the effect of the flow depth h_2, whereas the effect of d_{50} is rather small.

More rigorously, Equation 4 should contain the difference between the actual, $\mathrm{F}_{d,2}$, and the entrainment, $\mathrm{F}_{di,2}$, densimetric particle Froude numbers in the contracted zone. $\mathrm{F}_{di,2}$ can be estimated according to the relationships given in Hager & Oliveto (2002). In particular, for transitional regime (i.e. $10 < D_* < 150$), as in the present study, $\mathrm{F}_{di,2}$ is given by

$$\mathrm{F}_{di,2} = 1.08 D_*^{1/12} \left(\frac{R_{h,2}}{d_{50}}\right)^{\frac{1}{6}} \tag{6}$$

where $D_* = (g'/\nu^2)^{1/3} d_{50}$ = dimensionless sediment size with ν = kinematic viscosity. Thus, Equation 4 can be generalized as

$$\frac{z_e}{d_{50}} \propto \left(\frac{R_h}{d_{50}}\right)^p (\mathrm{F}_d - \mathrm{F}_{di})^m \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

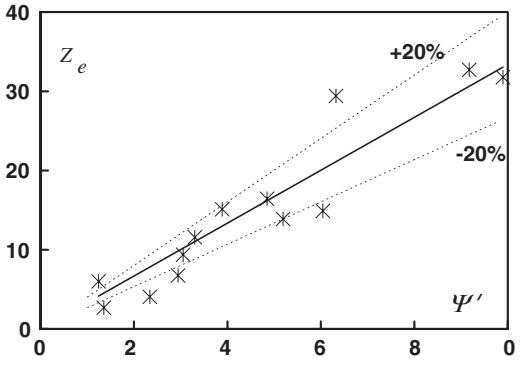

Figure 4. $Z_e = z_e/d_{50}$ as a function of the dimensionless combination $\Psi' = (R_{h,2}/d_{50})^{1/2}(F_{d,2} - F_{di,2})$. (⋇) Experimental data collected at University of Basilicata; (——) Regression line; (· · · · · ·) 20% error bands.

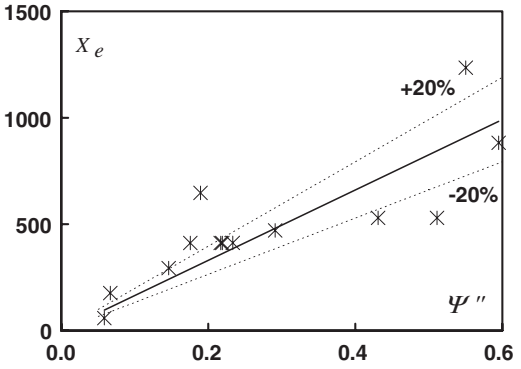

Figure 5. $X_e = x_e/d_{50}$ as a function of the dimensionless combination $\Psi'' = (R_{h,2}/d_{50})^{-1/4}(F_{d,2} - F_{di,2})$. (⋇) Experimental data collected at University of Basilicata; (——) Regression line; (· · · · · ·) 20% error bands.

with the exponent p not necessarily negative because of the dependence of F_{di} on R_h/d_{50}. Equation 7 was thus validated with the experimental data. A more straightforward relationship was found with even a significantly greater value of the coefficient of determination ($r^2 = 0.88$) and a larger amount of data within the 20% error bands. The fitting of the experimental data is shown in Figure 4.

In particular, Equation 7 specializes as

$$\frac{z_e}{d_{50}} = \frac{10}{3}\left(\frac{R_{h,2}}{d_{50}}\right)^{\frac{1}{2}}\left(F_{d,2} - F_{di,2}\right) = \frac{10}{3}\Psi' \qquad (8)$$

With respect to Equation 5, Equation 8 implies a little more uncertainty due to the estimation of F_{di}. But on the other hand, Equation 8 presents the evident advantage of being linear in F_d in contrast with Equation 5 in which F_d is to the power 4.

A similar approach was also applied for the location x_e of the quasi-equilibrium scour depth z_e. Specifically, x_e is the downstream distance from the beginning of the model constriction. The regression analysis revealed the following relationship

$$\frac{x_e}{d_{50}} = \frac{5}{3}10^3\left(\frac{R_{h,2}}{d_{50}}\right)^{-\frac{1}{4}}\left(F_{d,2} - F_{di,2}\right) = \frac{5}{3}10^3\Psi'' \qquad (9)$$

Figure 5 shows the fitting of the experimental data.

In Equation 9, the high value of the coefficient of proportionality is due to the different order of magnitude for x_e and d_{50} values. Although, the fitting was not particularly satisfactory ($r^2 = 0.64$), however the trend is evident. In particular, Equation 9 would imply a dependence of x_e on the flow velocity. This result does not completely match with the findings of Briaud et al. (2005) who found that, in cohesive soils, x_e is only a function of the contraction geometry (i.e. the ratio b_2/b_1 with b_2 as normalizing factor). Moreover, Equation 9 would also imply that x_e increases as d_{50} increases. This latter result, which is not immediately obvious, would need a more robust evidence.

To further validate the above approach, 156 experiments from literature were analyzed (Tab. 2 in Dey & Raikar 2005). Because such data are given in terms of approach flow conditions, Equation 7 was rearranged. In particular, it is reasonable to suppose $(F_{d,2} - F_{di,2}) \propto (b_1/b_2)^f F_{d,1}^m$ and $(R_{h,2}/d_{50}) \propto (R_{h,1}/d_{50})^p$, as corroborated by the experimental data of the present study. Thus, one can write

$$\frac{z_e}{d_{50}} \propto \left(\frac{R_{h,1}}{d_{50}}\right)^p F_{d,1}^m \left(\frac{b_1}{b_2}\right)^f \qquad (10)$$

The regression analysis (Fig. 6) yielded the following relationship

$$\frac{z_e}{d_{50}} = \left(\frac{b_1}{b_2} - 1\right)\left(\frac{R_{h,1}}{d_{50}}\right)^{\frac{3}{4}} F_{d,1} = \Phi \qquad (11)$$

with $r^2 = 0.92$. The computed value of the coefficient of proportionality was 0.93, however for simplicity and conservatively it was approximated to 1.

Equation 11 appears to be satisfactorily straightforward and its adequacy wide ranging. The data analyzed refer in fact to experiments with $d_{50} = 0.81$, 1.70, 1.86, 2.54, 4.10, 5.53, 7.15, 10.25, and 14.25 mm and $\beta = 1.11$, 1.18, 1.25, 1.43, 1.52, 1.54, 1.67, 2.00, 2.50, 3.03, and 4.00.

4 CONCLUSIONS

Selected experiments on the riverbed morphological changes induced by long constrictions were carried out at the Hydraulic Engineering Laboratory, University of Basilicata, Italy.

The runs lasted typically 3 days up to 15 days to obtain quasi-equilibrium conditions and to acquire a suitable measurement accuracy especially at low degree of contraction.

Empirical evidences revealed that (i) the bed degradation tends to concentrate along the channel centerline; (ii) the deepest contraction scour depth localized typically downstream of the middle of the constriction model and even outside; (iii) an equilibrium stage was never observed even for the run of duration 15 days.

Starting from sediment transport formulas, a novel scour equation was conjectured in the light of the densimetric Froude number. (i) The approach was validated by the data collected in the present study. By regression analysis, Equation 8 was found in which the quasi-equilibrium scour depth z_e is linearly related to the difference between the actual and the entrainment densimetric particle Froude number in the contracted zone; (ii) by using the same normalizing factors a new relationship (Eq. 9) was also found for the location x_e of the quasi-equilibrium scour depth z_e; interestingly from Equation 9 would seem that x_e increases as d_{50} increases. This result would need to be corroborated by other assessments; (iii) the novel approach was also rearranged in terms of approach flow conditions. Thus, it was validated by the data from this study and from literature. 156 experiments were analyzed (d_{50} from 0.81 to 14.25 mm and $\beta = b_1/b_2$ from 1.11 to 4.00, with b_1 = width of the approach channel and b_2 = width of the uniformly contracted reach). The regression analysis yielded Equation 11 with a significantly high value of the coefficient of determination ($r^2 = 0.93$). This equation appears to be adequately straightforward and wide ranging; finally, (iv) the dependence from the densimetric Froude number, coming out of Equation 3 suggested by Hager & Oliveto (2002) on the basis of several experiments including also runs with sediment density ρ_s significantly different from 2.65 t/m^3, would confer to the proposed approach more generality than that provided by the (simple) Froude number. This, in a similar way to the recent equation proposed by Oliveto & Hager (2002) for pier and abutment scour. Nevertheless, such a dependence needs to be supported by selected experiments that have been planned to be conducted.

ABSTRACT: Extensive studies on the temporal evolution of scour have been made recently at Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie (VAW), ETH Zürich, Switzerland, and models for scour estimation were presented. The VAW scour model is further investigated in the present study and possibilities for its refinement are identified. It is conceptualized that expression for temporal evolution of scour at bridge elements that is based on Froude's similarity should more logically relate scour depth to the difference between actual densimetric particle Froude number and entrainment densimetric particle Froude number. The analysis of VAW data set on pier and abutment scour validates this concept. Also contrary to the previous assumption of a logarithmic increase in scour depth with time, the characteristics of 'end scour' is noticed to have been exhibited by a few of the VAW scour data on mixtures.

1 INTRODUCTION

In the present age of fast communication, bridges occupy a place of pride in the society as they facilitate rapid movement of material and personnel safely and quickly across the rivers and other drainages. The disruption of traffic due to failure of a bridge therefore results in a disaster. Several bridges failed in the past in many countries and majority of these resulted from the hydraulic conditions and primarily the scour of the foundation material by flow around the bridge elements like piers or abutments.

The process of scour around bridge elements involves the complexities of both the three dimensional flow pattern and the sediment transport. The estimation of the scour characteristics at bridge elements continues to be a major concern for the hydraulic engineers. The underestimation of the scour depth results in a foundation that is exposed to the flow and endangers the structural safety whereas an overestimation of the scour depth results in an uneconomical design.

Figure 1 shows a definition sketch of scour at bridge elements (Oliveto & Hager 2002). Modeling of the temporal scour evolution rather than the equilibrium scour has been emphasized in the more recent literature (Oliveto & Hager 2002, 2005, Chang et al. 2004, Sheppard et al. 2004, Mia & Nago 2003, Kothyari & Ranga Raju 2001, Ahmad & Rajaratnam 2000, Melville & Coleman 2000, Melville & Chiew 1999, Cardoso & Bettess 1999). Kothyari et al. (1992 a, b) were however, among the first investigators who showed that temporal development of scour rather than the equilibrium scour of a peak flood should form the basis of design.

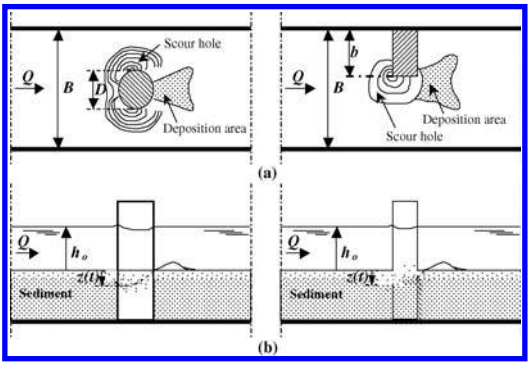

Figure 1. Definition sketch for bridge scour, (a) plan, (b) section for circular pier (left) and abutment (right).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Based on the analysis of a large data set on the temporal evolution of scour collected during long observational periods at Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie (VAW), a logarithmic increase in scour depth with time was noticed by Oliveto & Hager (2002). In the present study however, the features were noticed in the data on scour evolution that are related to the characteristics of the sediment which lead to an 'end scour' condition in steady flows.

From the analogy between hydraulic resistance and scour, Oliveto & Hager (2002, 2005) proposed plausible relationships for the computation of the maximum scour depth z as function of time t. It was observed that the dominant parameter controlling the scour process is the densimetric particle Froude number $\mathsf{F}_d = V_o/(g' d_{50})^{1/2}$; with V_o = velocity of the approach flow; $g' = [(\rho_s - \rho)/\rho]g$ the relative gravitational acceleration; ρ_s sediment density; ρ fluid density; and d_{50} = median grain size. By combining F_d with the parameters for reference length z_R and reference time t_R, the Froude similitude based scour relation was proposed as

$$Z = z/z_R = 0.068 N \sigma^{-1/2} \mathsf{F}_d^{1.5} \log T \quad \text{for } \mathsf{F}_d > \mathsf{F}_{d\beta} \qquad (1)$$

where $\mathsf{F}_{d\beta}$ is the densimetric particle Froude number for the entrainment of scour at the bridge element; the reference length is $z_R = (h_o D^2)^{1/3}$ for the cylindrical pier and $z_R = (h_o b^2)^{1/3}$ for the rectangular abutment with D as the pier diameter, b the abutment width and h_o the approach flow depth. Equation 1 is also applicable to other flow obstructing elements like sloping abutments and submerged spur dikes. The shape factors are $N = 1$ for circular shaped cylindrical pier and $N = 1.25$ for the vertical as well as the sloping abutments, respectively; $\sigma = (d_{84}/d_{16})^{1/2}$ = sediment uniformity parameter; and $T = t/t_R$ = relative time with $t_R = z_R/[\sigma^{1/3}(g' d_{50})^{1/2}]$. Hager & Oliveto (2002) proposed relationships for $\mathsf{F}_{d\beta}$ with regard to bridge pier and rectangular abutments as

$$\mathsf{F}_{d\beta} = \Phi_\beta \mathsf{F}_{di} \qquad (2)$$

where F_{di} is the densimetric particle Froude number for inception (subscript i) of motion in the approach flow and Φ_β represents the ratio between $\mathsf{F}_{d\beta}$ and F_{di}. The following relationships for F_{di} were proposed, based on Shields' diagram:

$$\mathsf{F}_{di} = 2.33 D_*^{-0.25} (R_h/d_{50})^{1/6} \qquad (3)$$

for viscous regime with $D_* \leq 10$,

$$\mathsf{F}_{di} = 1.08 D_*^{1/2} (R_h/d_{50})^{1/6} \qquad (4)$$

for transition regime with $10 < D_* < 150$,

$$\mathsf{F}_{di} = 1.65 (R_h/d_{50})^{1/6} \qquad (5)$$

for rough regime with $D_* \geq 150$, and

$$\Phi_\beta = 1 - (2/3)\Sigma\beta^{\Sigma/4} \qquad (6)$$

where $\beta = D/B$ or b/B for pier and abutment, respectively; with B = channel width, shape effect parameter $\sum = 1$ for piers and $\sum = 5/4$ for abutments.

Oliveto & Hager (2002) considered that $\mathsf{F}_d >> \mathsf{F}_{d\beta}$ for application of Equations 1, 2. However, from a similitude with the sediment transport theory it is logic that a scour equation should contain the term denoting a difference between the actual densimetric Froude number F_d and the entrainment densimetric particle Froude number $\mathsf{F}_{d\beta}$ in presence of an element. The VAW data on pier and abutment scour were therefore, reanalyzed in the present study with this objective. The Equations 1, 2 are not applicable to scour conditions subjected to viscous effects, the VAW data on uniform sand therefore, are excluded from the present work. In addition, the limitations listed by Oliveto & Hager (2002, 2005) for Equation 1 also apply to the present work.

2 CONCEPTUAL APPROACH FOR MODEL OF SCOUR ADVANCE

The sediment transport rate relates strongly to the difference of the total shear stress exerted by the flow and the critical shear stress for the inception of the transport (Meyer-Peter & Müller 1948). Accordingly, it is logic to relate the scour depth to the difference of the actual densimetric particle Froude number and the entrainment densimetric particle Froude number, *i.e.* $Z \approx (\mathsf{F}_d - \mathsf{F}_{d\beta})^\gamma \times f(T)$, where $f(T)$ increases with time and represents the temporal advance function on the right side of Equations 1, 2 and γ is an exponent. Results are obtained concerning the applicability of the proposed concept using all the experimental runs of Oliveto & Hager (2002) on pier and abutment scour. Typical of these results only, however, are illustrated below to avoid overlapping or congested plots and thus to provide a clear representation.

2.1 *VAW Pier Data*

Figures 2a,b depict the variation of $f(Z)$ with log T for piers in uniform sediments (VAW gravel and plastic, respectively) for several experimental runs that corresponded to different values of $(\mathsf{F}_d - \mathsf{F}_{d\beta})$. Here $f(Z) = z/(0.068 N \sigma^{-0.5} z_R)$. Similar plots for sediment mixtures (VAW mix1, mix2 and mix 3, respectively) are shown in Figures 2c-e. The systematical variation in the slope S of the trend lines of $f(Z)$ *versus* (log$T$) relation for different values of $(\mathsf{F}_d - \mathsf{F}_{d\beta})$ as depicted by the runs given in Figure 2 and other such plots,

Copyright © 2006 Taylor & Francis Group plc, London, UK

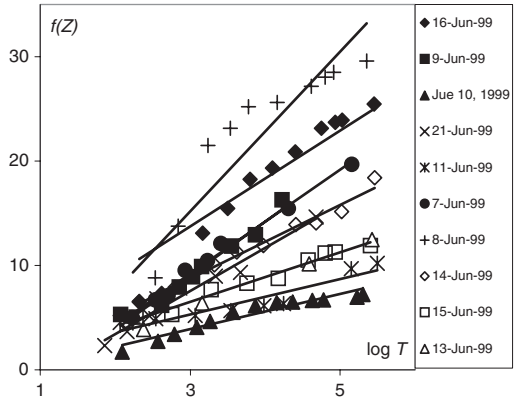

Figure 2a. Variation of $f(Z)$ with log$T$ for VAW data on pier scour (gravel).

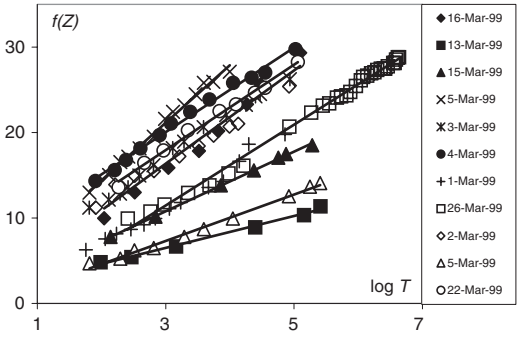

Figure 2b. Variation of $f(Z)$ with log$T$ for VAW data on pier scour (plastic).

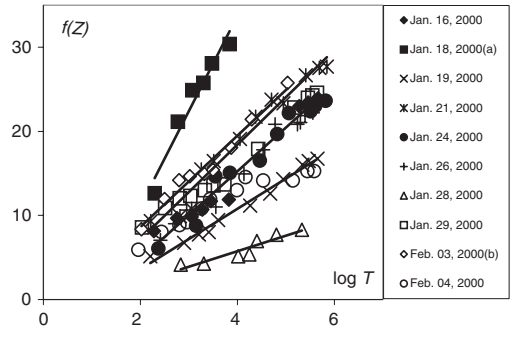

Figure 2c. Variation of $f(Z)$ with log$T$ for VAW data on pier scour (mix1).

not shown here because of space limitations, confirmed the present concept. Value of the coefficient of determination R^2 for the straight line fits to different experimental runs shown in Figure 2 was always more than 0.81 indicating a strong dependence of $f(Z)$

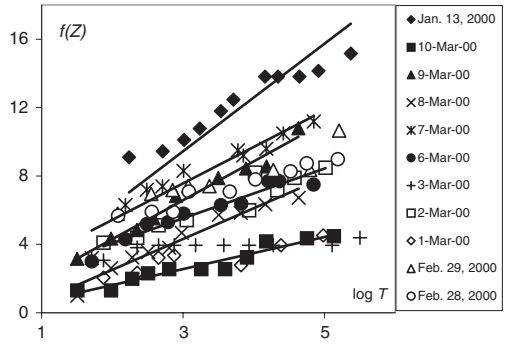

Figure 2d. Variation of $f(Z)$ with log$T$ for VAW data on pier scour (mix2).

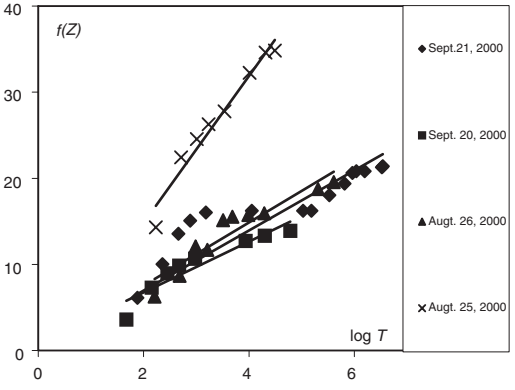

Figure 2e. Variation of $f(Z)$ with log$T$ for VAW data on pier scour (mix3).

on log$T$. The slope S of the $f(Z)$ versus log$T$ relation was determined for the complete VAW data set on pier scour. Results from the analysis on variation in the values of S are presented subsequently.

2.2 *VAW Abutment Data*

Figures 3a,b illustrate the variation of $f(Z)$ with log$T$ for abutments in uniform sediments (*i.e.* VAW gravel and plastic, respectively) and these plots for sediment mixtures (VAW mix1, mix2, and mix3, respectively) are shown in Figures 3c-e. The systematical variation in the values of S with the corresponding values of $(F_d - F_{d\beta})$ for abutment data as depicted for the runs of Figure 3 and other such plots, not shown here, also confirmed the present concept. The R^2 values of straight line fit to different experimental runs shown in Figure 3 was always more than 0.78 indicating a strong dependence of $f(Z)$ on log$T$ for abutment data also. The slope S of the $f(Z)$ versus log$T$ relation was also determined for the complete VAW data set on abutment

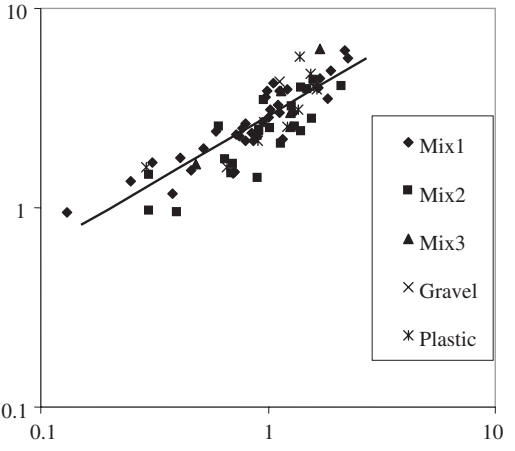
scour and results from the analysis on variation in thus obtained values of S are presented below.



3 TEMPORAL EVOLUTION OF MAXIMUM SCOUR DEPTH

Except for certain conditions (to be described later) the scour process always involves the function $f(T) = \log T$.The variation of S with log$T$ is depicted in Figures 4a,b, respectively, for the pier and the abutment tests suggesting that S is strongly correlated with $(F_d - F_{d\beta})$. Thus from Figure 4 it follows that other conditions remaining the same, the variation of Z is strongly influenced by the variation in $(F_d - F_{d\beta})$. Similar plots between S and corresponding F_d values contained relatively larger scatter than that is seen in Figures 4a,b. Thus, an expression for Z in terms of $(F_d - F_{d\beta})$ should produce a novel relation for scour evolution and giving more realistic estimates of the scour depth than presently available. In contrast to Equation 1 the shape factor N should be unity in such

novel expression for Z as the relation for $F_{d\beta}$ would account for the shape effects. The accuracy of such a relation for temporal evolution of scour shall be significantly influenced by the method used for the computation of $F_{d\beta}$. Therefore, further investigations are being made by the authors currently for deriving newer relationship for $F_{d\beta}$ and Z that should be applicable to common geometries of the bridge elements.

4 CONDITION FOR END SCOUR

Based on the analysis of a large data set on the temporal evolution of scour collected during long observational periods at VAW, a logarithmic increase in scour depth with time was recommended by Oliveto & Hager (2002). A close scrutiny of the VAW data on scour in sediment mixtures (Figs 5, 6) indicated that Z can become constant beyond certain values of $\log T$ in sediment mixtures. The likelihood of the existence of 'end scour' condition at a bridge element is thus controlled mainly by the bed material characteristics. It is easy to visualize that the logarithmic scour progress would tend to end in sediment mixtures that are likely to form a stable armour layer over the scoured surface due to partial removal of the fines by the flow from the parent bed material around the obstruction. The condition that a stable armour layer develops, or not, and the activity of scour therefore has a definite end, would therefore, be governed by the degree of heterogeneity in the bed material, the flow and the element shape and dimensions, respectively. The criterion for deciding that the 'end scour' condition shall develop in a certain run is also important in design of rip rap protection at bridge elements and therefore needs further investigations.

5 CONCLUSIONS

The VAW studies on temporal evolution of scour of bridge piers and abutments are revisited. Based on

Copyright © 2006 Taylor & Francis Group plc, London, UK

analysis of data on pier and abutment scour it has been proposed that a logical relation for Z based on Froude's similarity should relate scour depth to the difference $(F_d - F_{d\beta})$ rather than F_d only. Contrary to the previous assumption of a logarithmic increase in scour depth with time, a few of the scour data on mixtures are noticed to exhibit the characteristics of 'end scour'. The 'end scour' condition is likely to occur in situations when a stable armour layer can form over the scour hole. The results of present research thus provide basis for developing new expression for scour depth evolution and are important in the design of measures for protection against scour at flow obstructing elements.

ABSTRACT: Groynes are structures built in the rivers to protect the banks from flow erosion and also to divert or guide the flow itself. One of the main problems in the design of these structures is to establish the maximum depth of local scour, which occurs near the groyne's tip, in order to avoid the undermining of its foundation. The local scour is the main cause of damage or collapse in these or analogous structures, like bridge abutments. In the paper, the results of experimental and numerical investigations of 3D turbulent flow around a groyne in presence of local scour are reported. From this analysis a design criterion to predict the local scour via computational fluid dynamics is derived, by comparing the computed shear stress at the scour hole boundary and the particle critical shear stress.

1 INTRODUCTION

Damage to structures due to local scour is a frequently recurring event, particularly affecting structures such as groynes, bridge abutments and piers in alluvial rivers. Thus, some local scour monitoring projects are brought about both in USA and Europe. Research on this topic can lead to significant reductions in damages cost and increase in transport safety. In the last years many experimental studies have been carried out to define the evolution of the scour depth in time and its maximum depth. From the analysis of scour data, several formulations have been proposed to predict scour around these structures (e.g. Dey & Barbhuiya 2005, Kothyari & Ranga Raju 2001, Lim 1997, Melville 1992, Melville 1995, Melville 1997). The proposed formulations are characterized by a different choice in the relevant parameters used, so that the results are hardly comparable, and lead to different evaluations of the maximum scour depth, when applied to practical cases. This evidence emphasizes the necessity to improve the knowledge on the nature and structure of the turbulent flow near groynes, in order to improve the erosion prediction methods.

To this purpose, the 3D turbulent flow around a spur dike in the flat fixed bed case was analyzed experimentally by Rajaratnam & Nwachukwhu (1983b) and Barbhuiya & Dey (2004) and via 3D turbulence numerical models by Tingsanchali & Maheswaram (1990), Mayerle et al. (1995), Ouillon & Dartus (1997), Chrisohoides et al. (2003).

It must be observed that the presence of a scour hole substantially modifies the flow field with respect to the fixed flat bed condition, so that the use of parameters derived from flat bed analysis to predict the maximum scour depth is questionable (Armenio et al. 1998).

Only Kwan & Melville (1994) achieved an experimental analysis of the flow field around a spur dike in presence of a scour hole, using the hydrogen bubble technique, thus defining qualitatively and quantitatively the velocity field. They pointed out a primary vortex (which is analogous to the horseshoe vortex at bridge piers) as the main cause of scour at bridge abutments.

Fiorotto & Cividin (1996), using 3D turbulence models, analyzed the flow field around a groyne in two cases, i.e. in presence and absence of the local scour. They showed a substantial change in the flow field between the case of a non-erodible flat bed and the case of an erodible bed associated with local scour. Experimental runs and numerical simulations confirmed the experimental observations of Kwan & Melville (1994) with reference to the horseshoe vortex but highlighted a change in shape of the downstream recirculation zone that tends to produce also a secondary vortex in form of a frustum of cone with the vertex in the deepest point of the scour. This vortex produces important vertical velocity components (by disequilibrium between the centrifugal forces and pressure gradients inside the hole), which are absent in the case of a flat bed.

The capacity of this vertical velocity component to lift sediments from the deeper zone of the scour is particularly evident during the later phases of the scouring process, when the horseshoe effects on the scour are weakened.

Copyright © 2006 Taylor & Francis Group plc, London, UK

A first objective of the present study is to check the capability of the standard k-ε model to simulate a so complex flow, particularly inside the scour hole. This is done by comparison between the velocity measurements taken using an acoustic 3D Doppler velocimeter in an artificial laboratory flume, in presence of local scour, and the numerical results obtained by the code FLUENT.

Salaheldin et al. (2004), in the case of circular piers, and Fiorotto & Cividin (1996) for an abutment, by comparing the results obtained from the standard k-ε turbulence model with the ones computed using theoretically more accurate closure schemes, showed that the velocity fields have practically the same order of accuracy Salaheldin et al. (2004), comparing the results of the standard k-ε model with experimental data, inferred that it can be used to calculate the flow field around the pier.

A second objective is to highlight, from the numerical results, the most important coherent structures around the groynes that are responsible of the scour and to compute the velocity components close to the alluvial bed and the shear stress at the bottom.

The knowledge of the flow field can bring to an estimate of the equilibrium condition for sand particles on the scour boundary, thus allowing to define a design criterion to predict the maximum scour depth via computational fluid dynamics, which constitutes the third objective of this work.

This task requires to define the limiting stability conditions at the scour bottom. The study of the incipient motion of the sediments along the scour hole boundary is hence required, which must take into account the local slope of the bed. To this purpose, two methods are here used: the first was proposed by Brooks (1963) and modified by Lim (1985); the second, called simple rotation model, is due to Baker (1980). The first method was employed by Ali & Karim (2002) in an analogous study involving numerical simulation around bridge piers and it is based on a correction of the Shields shear stress critical value computed on a flat plane to take into account the local slope of the bed.

The second method presents the condition of incipient motion for particles with diameter d in terms of rotational force balance assuming the flow velocity acting at d/2 above the bed, taking into account the particle packing and geometry effects.

Notwithstanding the complexity of the phenomena, where the intermittent nature of near-bed turbulence, bed packing density etc, play an important role in the initiation of sediment motion (Papanicolau et al. 2002), an engineering criterion to predict the maximum depth of local scour is derived by seeking a bed configuration such that the computed shear stress at the scour hole boundary and the particle critical shear stress are comparable.

2 EXPERIMENTAL AND NUMERICAL METHODS

The laboratory experiment was conducted in a laboratory flume 7 m long and 1 m wide. A perspex rectangular groyne with length 20 cm and thickness 1 cm was placed in the channel, perpendicularly to the flume side wall, at a distance of 3.5 m from the flume inlet. The sand bed material was characterized by a median size d50 = 0.27 mm and geometric standard deviation $\sigma g = 1.3$. A geometric standard deviation less or equal to 1.3 implies that the sediments can be considered as uniform (Breusers & Raudkivi 1991).

The approach flow was set close to the threshold conditions for bed movement, with mean velocity and flow depth in the approach reach equal to v = 0.19 m/s and y = 20 cm respectively. The equilibrium scour hole was obtained with a run test 72 h long, a very larger time as compared to simulations reported in literature. The scour hole depth and the bed elevations were measured with 0.1 mm in accuracy at the nodes of a regular square grid at 2 cm intervals.

The measurement of the instantaneous flow velocity components was performed using a laboratory acoustic Doppler velocimeter (ADV) by Nortek. To avoid noise in measures, the flume bed was fixed by application of a synthetic cement which formed a solid crust, after the scour hole had developed completely.

The sampling volume distance from the probe tip is equal to 10 cm, which reduces the intrusiveness effects of the instrument. The sampling frequency was set to 25 Hz with an uncertainty in the velocity measurements less than 1%. The sampling time was chosen equal to 600 s to satisfy the ergodicity condition, with reference to the velocity mean and variance (Bendant & Piersol 1971). The velocity field was sampled in 1500 points with a total acquisition time of 250 hours. Measurements were taken at nodal points in an ideal regular grid, which is shown in Figure 1. The vertical spacing of nodes was set to 2 cm above the original bed level and 1 cm below into the scour. Therefore the interval among measurement points is reduced near the groyne's tip and into the scour hole where larger gradients in the velocity field are expected (Fig. 1). A set of measures was made at 1.5 m upstream of the groyne in order to define the upstream boundary conditions needed in the numerical simulations.

The accuracy of the data collected by ADV was checked via the WindADV computer program developed by the Bureau of Reclamations, Water Resources Research Laboratory (Wahl 2000) in order to detect anomalies, spikes and ambiguities caused by aliasing of the Doppler signal (e.g. Goring & Nikora, 2002). Moreover all the signals were filtered via the Phase-Space Threshold Despiking algorithm (Wahl 2003, Goring & Nikora 2003) and the difference in variance with the non filtered signal was calculated; the

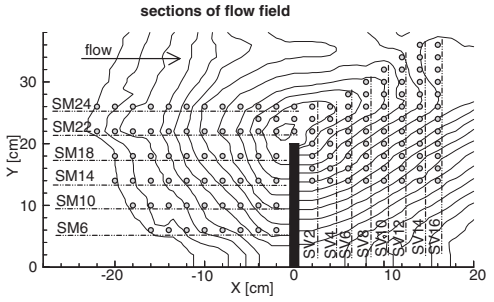

Figure 1. Scour contour lines around a groyne, with the measurement grid. The difference in elevation between the contour lines is equal to 1.0 cm.

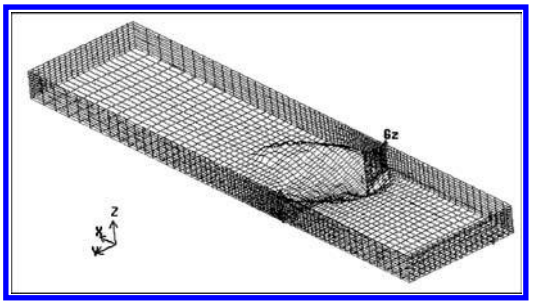

Figure 2. Computational grid.

maximum difference was less than 3% assuring the goodness of the measurements.

The numerical analysis where performed using the FLUENT package which solves the three-dimensional Reynolds-averaged Navier Stokes equations for incompressible flow via the standard k-ε turbulence model.

The computational domain (Fig. 2) was set with a length in the mean flow direction equal to 22.5 L, (L being the transverse length of the groyne) and a width of 1 m, the same of the laboratory flume. The groyne was placed at 7.5 L downstream the inlet boundary and 15 L upstream of the outlet boundary. This distance is larger than the length of the recirculation zone downstream the groyne, estimated in 7 L according to the experimental analysis of Adami (1979). In this context the flow field behavior is independent from the outlet boundary conditions; for this reason they were not imposed. The bed elevations, as measured in the flume at 2 cm regular spaced points, were interpolated to obtain a continuous bed surface needed to build the finite elements mesh. A mesh with 454000 hexahedrical elements refined near the groyne and inside the scour hole, where larger gradients of the velocity and pressure fields are expected, was chosen after several trial runs, with different mesh density, in order to guarantee a grid independent solution.

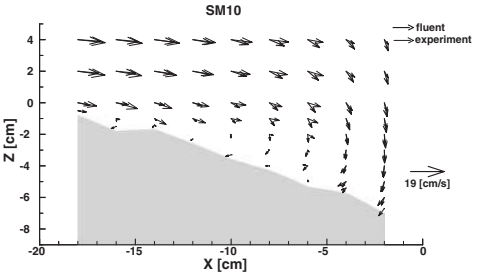

Figure 3. Comparison between numerical and experimental mean velocity components in section m10 (Fig. 1).

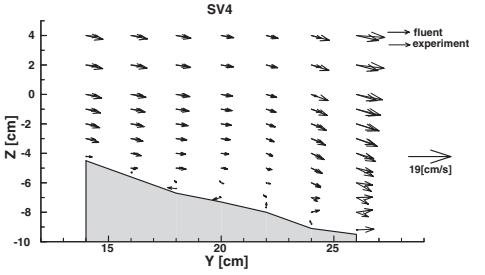

Figure 4. Comparison between numerical and experimental mean velocity components in section v4 (Fig. 1).

The inlet boundary conditions were imposed according to the distribution of velocity and turbulent kinetic energy as measured in the laboratory flume, while along the lateral side wall and groyne wall, in perspex, the smooth wall conditions were imposed. At the bed surface the rough wall conditions were imposed on the bed roughness, which was evaluated using a procedure given by FLUENT. The free surface was modeled via symmetry condition.

3 COMPARISON BETWEEN NUMERICAL RESULTS AND EXPERIMENTAL DATA

Comparisons between measures and numerical results were made along the 14 cross sections indicated in Figure 1, in order to check the goodness of the numerical results. The comparison between experimental measurements and numerical results, in a zone where high gradients in the velocity field are expected, can be affected by difficulties to obtain accurate ADV instantaneous velocity measurements near the bottom, by limits of the closure scheme in turbulence models (Rodi 1993), by approximations in the bed shape and inlet boundary conditions. Nevertheless, the results of the numerical simulations match quite fairly the measurements as put in evidence in Figure 3 and Figure 4.

In the upstream zones (Fig. 3) the presence of a horseshoe vortex is recognized, rotating clockwise

Copyright © 2006 Taylor & Francis Group plc, London, UK

along the axis of the vortex towards the flume centerline, with the groyne on the right bank. This vortex is confined mostly within the scour hole beneath the original bed level in agreement with the experimental evidences of Melville (1992).

Figure 4 shows the mean velocity behavior at cross-sections downstream the groyne, transversal to the mean flow direction. From these graphs, a good agreement between the computational results and measures is pointed out as well. The presence of a vortex system located behind the abutment, inside the recirculation zone transversally to the mean flow direction is observed; near the bottom the flow is directed toward the channel right side wall, congruently with the observed sand grains deposition process. From these measurement points it is very difficult to have an idea of the complex structure of the flow downstream the groyne.

A more evident appraisal of the flow pattern can be derived by plotting the computed pathlines, which is consistent, considering the fair agreement between the experimental measures and the computational results,with reference to the mean flow field. In this framework an analysis in term of mean shear stress on the boundary of scour hole, compared with critical shear stress of the sediment particles, could be useful to define a practical criterion in the design of these structures. This is the goal of the next section.

4 PREDICTION OF SCOUR MAXIMUM DEPTH AND PROFILE

The prediction of incipient motion of the sediment is an important first step for analyzing sediment transport and scour in clear water conditions. The approaches for the practical prediction of the incipient motion are substantially based on two different methods (Marsh et al. 2004): the first method is based on the Shields critical shear stress concept, the second, called simple rotation method, on the equilibrium of moments and forces which drive and resist particle motion.

The critical shear stress concept does not account explicitly for grain stability to predict incipient motion, but it was introduced as a nondimensional framework to analyze experimental evidences. The well-known Shields curve is essentially an empirical result where a threshold limit was drawn within scattered experimental data to separate fixed and moving bed states. The Shields curve is related to channels with a flat bed: to use it in the case of the scour hole, it is necessary to take into account the local slope of the river bed. It is manifest that the critical stress required for moving a grain upslope is larger than that required to move it downslope. This is because in the former case gravity counteracts the impelling stress, whereas in the latter case it acts to enhance it.

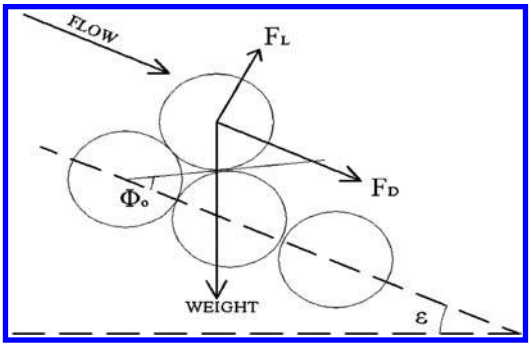

Figure 5. Simple rotation model scheme.

The correction employed by Ali & Karim (2002) to analyze the scour around bridge piers derived by Brooks (1963), is:

$$\frac{\tau_{sc}}{\tau_c} = -A \pm \sqrt{A^2 + B} \tag{1}$$

where: τ_c = critical shear stress on a flat bed according Shields criteria, τ_{sc} = the corrected Shields critical shear stress taken into account the local slope of the river bed, $A = (\sin\phi \cdot \sin\beta)/\tan\vartheta$ and $B = 1 - (\sin^2\phi/\sin^2\vartheta)$ are two parameters where: ϕ = slope angle of bed profile (positive downward slope), β = angle between flow direction and slope direction measured in the plane of the slope while ϑ = static rest angle of sediments.

The second method, based on solving the dynamic equilibrium of a particle, is due to Baker (1980); the incipient motion is presented in terms of the critical velocity V_{c-bed} acting at a height d/2 above the bed, when the particle configuration at the bottom is accounted for via the particle packing angle parameter ϕ_0. With reference to the Figure 5 the formula is given by:

$$V_{c-bed}^2 = \frac{4}{3} \cdot \frac{\sin(\phi_0 - \varepsilon) \cdot (\rho_s - \rho_f) \cdot gd}{\rho_f \cdot (C_L \cdot \sin\phi_0 + C_D \cdot \cos\phi_0)} \tag{2}$$

where: ϕ_0 = particle packing angle, equal to 60°, ε = local bed slope, C_L = uplift coefficient and C_D = drag coefficient equal to 0.3 and 0.6 respectively.

The critical shear stress, according to the simple rotation model, is defined from (2) via the wall function for hydraulically rough conditions with reference to the mean sand diameter at the bottom:

$$\tau_{srm} = \left(\frac{\sqrt{V_{c-bed}^2}}{6.77} \right)^2 \cdot \rho$$

where ρ is the fluid density.

Copyright © 2006 Taylor & Francis Group plc, London, UK

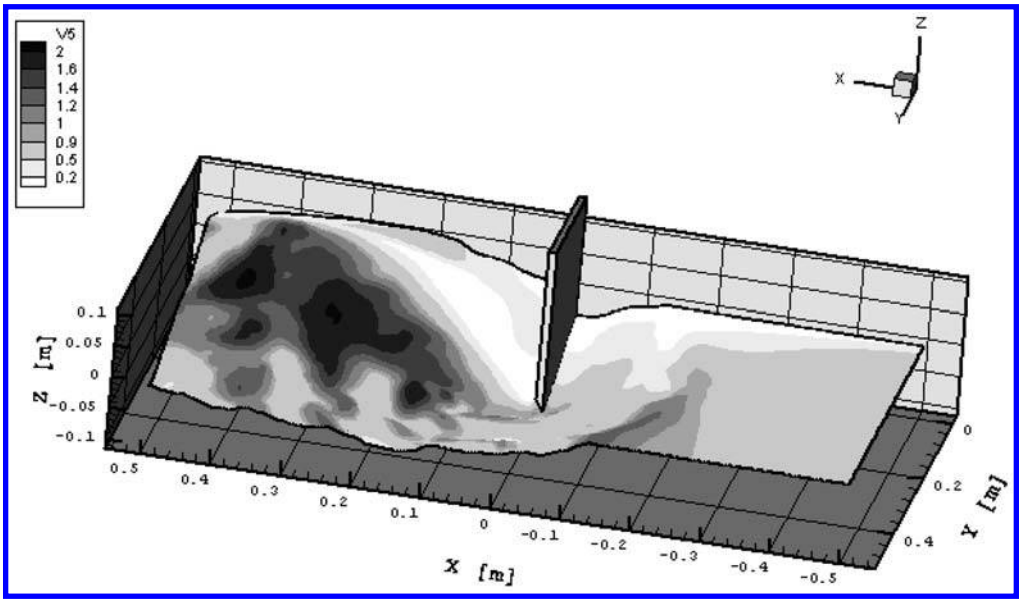

Figure 6. Behavior of the ratio between bottom shear stress and critical shear stress computed by shields criterion.

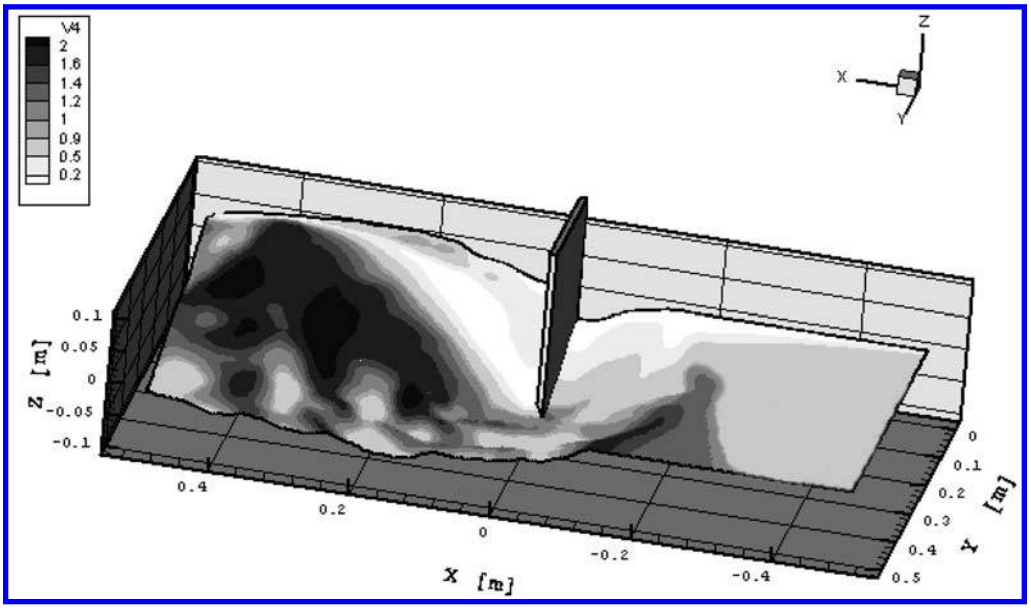

Figure 7. Behavior of the ratio between the bottom shear stress and critical shear stress computed by the simple rotation method.

The following law of the wall, modified for roughness, was used to calculate the bottom shear stress τ (FLUENT 2001):

$$\frac{u_p}{u^*} = \frac{1}{k}\ln\left(E\frac{\rho C_\mu^{1/4} k_p^{1/2} z_p}{\mu}\right) - \Delta B$$

where u_p = mean flow velocity at point p; k = von Karman's constant (k = 0.418); u^* = shear velocity related to the bottom shear stress $\tau = \rho u^{*2}$; ρ is the fluid density; C_μ = constant having a value of 0.09; k_p = turbulent kinetic energy at point p; E = constant having a value of 9.79. The parameter ΔBrepresents

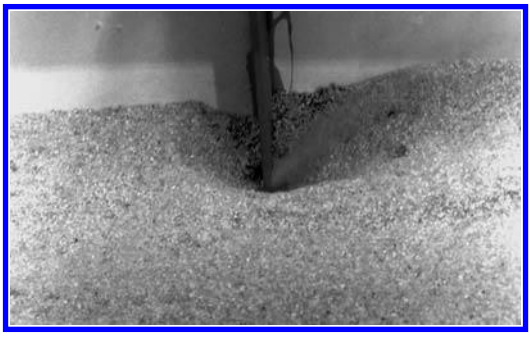

Figure 8. Sediment transport burst plume.

Figure 9. Deposition of painted grains injected into the bottom of the scour.

the roughness function that depends on the nondimensional roughness height $K_s^+ = \rho K_s u^*/\mu$; where K_s is the physical roughness height taken equal to the mean sediment size of the bottom. The formula proposed by Cebeci & Bradshaw (1977) is used by the FLUENT code to compute the ΔB parameter.

By the comparison of the results, as illustrated in the two figures, one can note a good accord between the two solutions, as calculated with the two different approaches in computing the critical shear stress. For practical purposes, either of the two schemes can be used indifferently.

From a theoretical point of view, according to this simplified criterion, a ratio higher than unity indicates instability of the sediment. It is possible to observe a bed shear stress larger than the critical one near the groyne's tip and, downstream, in a zone where the sediments uplift from the scour have been accumulated.

In the upstream zone, where the horseshoe vortex occurs, the bed shear stress is lesser than the critical one. This result seems to prove the experimental evidences that highlight the role of the horseshoe vortex during the initial scour phases as the main responsible of the scouring process while, in later phases, a vertical axis vortex, evidenced in Figure 8 (Fiorotto & Cividin 1996) by a sediment transport burst plume, seems to be the only coherent structure able to uplift and drag particles from the deepest part of the hole.

As further evidence, Figure 9 (Fiorotto & Cividin 1996) shows the zone of deposition of painted grains injected into the bottom of the scour in the final phase of scour hole development, which is incompatible with the action of the horseshoe vortex.

In Figure 10 the computed trajectories of tracer injected in the deeper zone of the scour hole is shown; this trajectory is concordant with the experimental flow visualization of the recirculation behind the groyne (Figs. 11,12 – Fiorotto & Cividin 1996). Particularly, Figure 11 shows a stagnation zone behind the groyne's wall for tracers injected near the groyne's tip. In Figure 12 wool's threads evidence the upward velocity component behind the groyne.

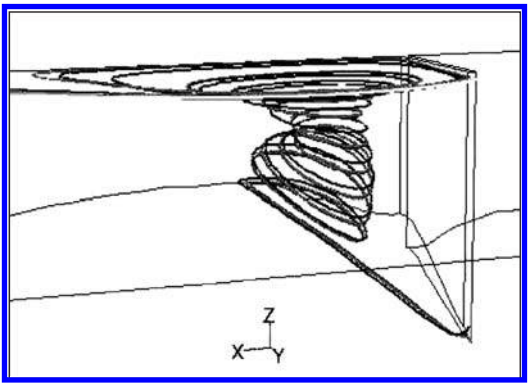

Figure 10. Computed trajectories of tracer.

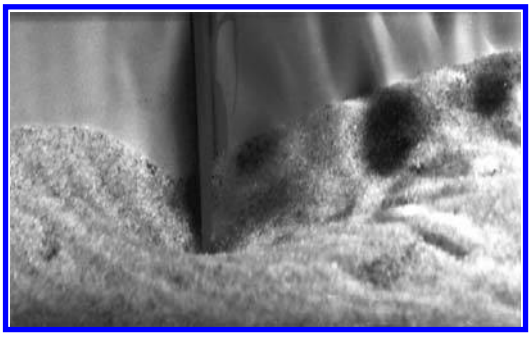

Figure 11. Tracer injected near the groyne's tip.

Both measurements and numerical simulations characterize the recirculation vortex as a frustum of cone with the vertex in the deepestpoint of the scour. The vertical velocity components are generated by disequilibrium between the centrifugal forces and pressure gradients inside the hole. This unbalance can generate a radial flux towards the vortex axis; by continuity, a vertical flux is generated inside the recirculation zone.

Figure 12. Visualization of downstream flow by wool's thread.

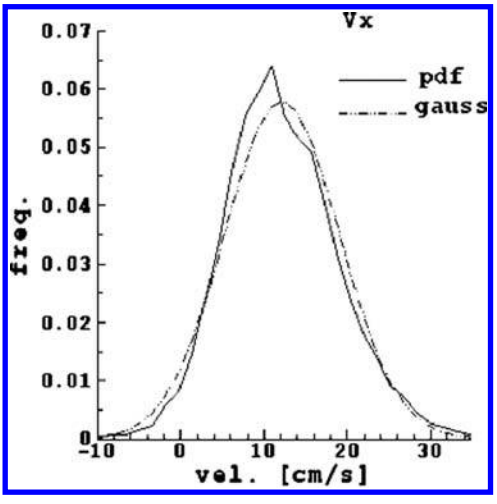

Figure 13. Pdf of vx velocity component.

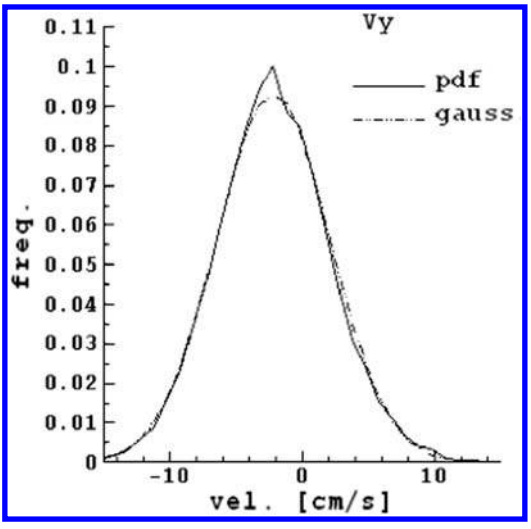

Figure 14. Pdf of vy velocity component.

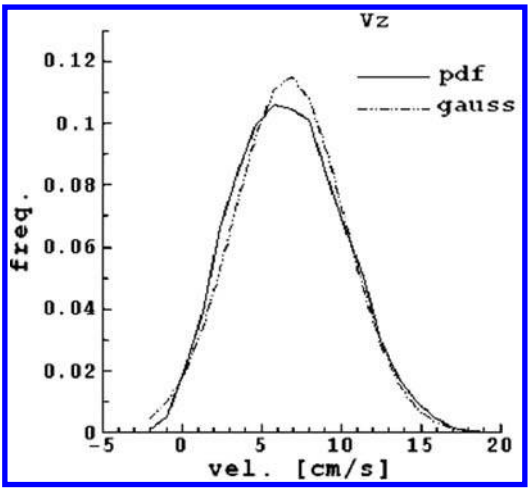

Figure 15. Pdf of vz velocity component.

This flow is able to uplift sand grains from the deepest zone of the scour and deposit them near the channel wall, behind the groyne, in a zone incompatible with the horseshoe vortex trajectory. This fact is particularly evident during the later phases of the scouring process when the horseshoe vortex effects on the scour are weakened, as shown experimentally in Fiorotto (1993).

Detachment of grains from the hole bottom is observed as an intermittent phenomenon, related to the turbulence characteristics of the flow. This vortex structure could prove to be of some importance in determining the maximum scour when very long scouring duration is considered.

In Figures 13–16 the pdfs of the 3D fluctuating velocity components are reported, along the mean flow direction, transversally and in the vertical direction, as measured close to the groyne's tip in the deepest zone of the scour. From the figures one can note the high three-dimensionality of the strong turbulent characteristics of flow, with velocity fluctuations larger than the undisturbed mean velocity. This fact gives reason of the intermittence of the grains detachment in the deeper zone of the scour.

Besides, starting from the deepest zone of the scour, one can note a zone where the shear stress is larger than the critical one, directed bankward behind the groyne. Along this zone the particles, uplifted by the vertical vortex, can travel downstream (Fig. 9).

These numerical results give also a reason of the experimental evidence related to the time evolution and shape of the scour hole as measured by Rajaratnam & Nwachukwu (1983a). Figure 16, showing in the later phases of the scouring, a deepening effect located

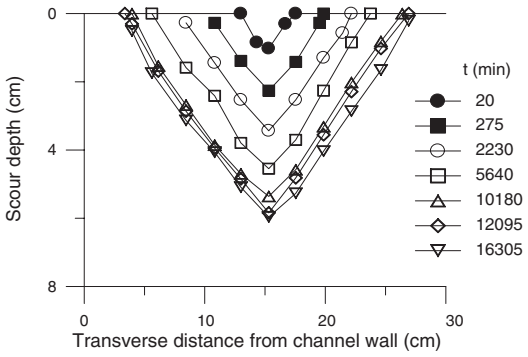

Figure 16. Scour depth versus time along a section transversal to the mean flow direction just upstream of the groyne. Redrawn from Rajaratman and Nwachukwu 1983a.

principally in the deepest zone of the scour hole close to the groyne's tip.

Figures 6,7 suggest a design criterion for defining the maximum depth of scour hole at bridge abutments and groynes in clear water conditions, solving the Reynolds-averaged Navier Stokes equations; this is established by the correspondence between the bed shear stress and the critical shear stress of the sand particles along the scour boundary.

In order to predict the maximum scour depth, further research is needed, aimed to define a realistic shape of the scour, which is required to perform numerical computations. To this purpose, some suggestions are given by Dey & Barbhuiya (2005) that found an average upstream slope of scour hole larger than 10–15% than the rest angle of bed sediments and by Rajaratnam & Nwachukwu (1983a) that detected some similarities in scour profiles by comparison of experimental outcomes in terms of scour hole geometry.

As soon as a sound tool is defined to better predict the scour shape, the stable configuration of the scour hole in clear water conditions could be obtained via an iterative procedure, by varying the scour hole depth and shape properly, until a limit equilibrium condition is reached.

It is obvious that, if this approach is to be applied in real life cases, a suitable safety coefficient in the computation of the maximum scour depth must be used in order to account for the theoretical limits and for the approximations in the sediment incipient motion formulas, in sediment size representation, in the turbulence model, in the approaching flow characterization and in the bed river roughness and shape description.

5 CONCLUSIONS

In this work the k-ε turbulence model was used to predict the main characteristics of the flow field around a groyne. Results, when compared to direct measurements in a laboratory flume, proved satisfactory. Particularly it was possible to highlight the coherent structures mainly responsible of the scour process: the horseshoe vortex located in the upstream zone and a vortex system located behind the abutment, inside the recirculation zone transversally to the mean flow direction, starting from the groyne's tip. These results allow to argue that the primary horseshoe vortex is not the only cause of the scour process. In fact the secondary vortex takes importance in advanced phases of the scouring process and it could be the cause of the deepening effect located principally in the deepest zone of the scour hole close to the groyne's tip observed in these phases (Fig. 16).

Based on k-ε turbulence model, calculation of sediment stability, especially inside the scour hole, highlighted the presence of instable bed particles near the groyne's tip, while in the upstream zone, where the horseshoe vortex is located, the bed particles were stable. This allowed confirming a decreased effect of the primary vortex in the later phases of the scouring process.

In perspective, it is felt that computational fluid dynamics could be applied as a tool to predict maximum scour depth. Once defined a tentative initial scour shape, erosion and aggradation computations could bring to a new scour hole shape up to a stable limit equilibrium condition.

The methodology and the experimental evidences here exposed could help to clear some incongruence in the experimental formulas as pointed out by Richardson (1998) with reference to the I-70 bridge over the Missouri River near Rocheport, where the computed clear water abutment scour using the Lim's formula (Lim 1997) exceeds 100 m while the actual abutment scour at this site is approximately 19 m. In this context, applying the computational fluid dynamics, taking into account the scouring process, could be a suitable alternative to the traditional methods.

Sediment supply effect on local scouring at bed sills in high gradient streams

M. Tregnaghi & A. Marion
Dept. of Hydraulic, Maritime, Environmental and Geotechnical Engineering, University of Padua, Italy

F. Comiti
Dept. of Land and Agroforest Environment, University of Padua, Italy

ABSTRACT: This paper presents the results of an experimental study about the pattern of local scouring generated downstream bed sills commonly used in mountain rivers to limit bed degradation. The effect of sediment supply on the scour depth at the toe of bed sills displaced along a staircase-like sequence is evaluated for the first time. The experiments simulated conditions of steady upstream sediment supply which had the same grain size composition as the deposit placed on the bed of the flume. Results of forty-eight new tests are presented. The geometry of three scour holes developed under conditions of steady flow discharge and steady upstream sediment supply are examined for each test, giving a total of 144 scour holes. Three sediment feed rates were examined. Twelve tests were performed with clear water conditions. The collected data were examined using non-dimensional groups developed by the authors in previous no-feed studies. It is shown that the imposed sediment transport, appearing as a new independent variable, does not require the introduction of new non-dimensional parameters in existing prediction formula calibrated with clear water conditions data. The effects of sediment feed are shown to be incorporated in the existing non-dimensional parameters. The new data set was used to re-calibrate existing scour depth formula. Closer inspection of the data indicates a possible two-stage behaviour, dependent on the range of the ratio between the morphological jump created at a scour hole and the flow specific energy.

1 INTRODUCTION

1.1 *Morphological control structures*

The processes which transport both coarse and fine sediment in high-gradient mountain streams are very effective in defining their morphologic characteristics.

Steep mountain catchments feed a two-phase mixture composed of water and sediment into river channels. River cross-sections are not fixed, and their morphology reflects the pattern of erosion or deposit occurred along the stream. During storm events mountain streams are often subject to channel incision. One method to stabilise them is to use a sequence of transverse grade-control structures.

Traditionally, the principle governing the prevention of channel erosion through bed sills or check-dams is to reduce the mean longitudinal bed slope, S_0, to a lower value S_{eq}, defined as the slope established when dynamic equilibrium between bed scouring and aggradation is achieved.

The equilibrium configuration is reached with reduced delivery of sediment to the downstream reaches of the stream. Excessive sediment release in the steeper reaches can lead to sudden deposition in downstream reaches which may cause flooding of populated areas.

The insertion of sequences of bed sills in a riverbed changes the flow characteristics in proximity of the works themselves, potentially causing the phenomenon of local scouring. The scour develops immediately downstream the bed sills and it arises in addition to the jump produced by the decrease of bed slope.

The overall eroded sediment volume is much less than the volume necessary to erode the whole reach down to the equilibrium slope, but in this way the steps formed downstream of the structure induce the water to plunge over the sill, and, unless the toe of the structure is protected, the plunging jet erodes the bed locally generating a scour hole. Designers must take into account this problem in order to avoid structural failure due to toe scouring, by building foundations with adequate depth. Quantitative predictive formulae of the scour dimensions are therefore required.

1.2 *Local scouring*

Prediction formulae for scour depth, all based on experimental tests on scale models, have been developed by several authors (Rajaratnam 1981, Mason and Arumugam 1985, Whittaker 1987, Chatterjee et al. 1994, D'Agostino 1994, Habib et al. 1994, Marion et al. 1998, Gaudio et al. 2000, Gaudio & Marion 2003, Lenzi et al. 2002, 2003a, b, Marion et al. 2004). These approaches have all been based on the empirical curve fitting of experimental data.

Gaudio et al. (2000) were the first to apply Dimensional Analysis to this problem, in order to define appropriate dimensionless groups before some existing data for gently sloping channels was used to develop empirically fitted relationship. They found predictive formulae for clear-water and long-term scour hole depth. This work was subsequently extended to steep channels by Lenzi et al. (2002) to provide a more generalised relationship:

$$\frac{y_s}{H_s} = 0.44 + 1.45\left(\frac{a_1}{H_s}\right)^{0.86} + 0.06\left(\frac{a_1}{\Delta D_{95}}\right)^{1.49} \quad (1)$$

calibrated in the ranges $0.16 \leq a_1/\Delta D_{95} \leq 1.15$ and $0.22 \leq a_1/H_s \leq 1.87$; where y_s is the maximum scour depth; H_s is the specific critical energy available at each sill; D_{95} is the grain size for which 95% of the sediment by weight is finer; Δ is the sediment relative submerged density; and a_1 is the "morphological jump", i.e. the sill step produced by bed degradation in absence of local scouring.

Marion et al. (2004) found that the dimensionless parameter a_1/H_s is sufficient to describe equilibrium scour depth at high slopes, in the case of non-interfering scours and in uniformly sized sediment. Other parameters were subsequently added to take into account the geometric interference (Comiti et al. 2001, Lenzi et al. 2002), which is the reduction in scouring caused by the closeness of sills, and the effect of sediment composition. The final relationship is:

$$\frac{y_s}{H_s} = 2.7\left(\frac{a_1}{H_s}\right)^{0.43} SI^{-0.19}\left(1 - e^{-0.14\frac{L}{H_s}}\right) \quad (2)$$

which is valid in the range $0.22 < a_1/H_s < 1.87$ and $SI = 1.48 - 5.93$, where L is the sill spacing and SI is a grading parameter called the sorting index (equal to σ_g for log-normal distributions), defined by:

$$SI = \frac{1}{2}\left(\frac{D_{84}}{D_{50}} + \frac{D_{50}}{D_{16}}\right) \quad (3)$$

As recent studies indicate (Lenzi et al. 2003a, b, Marion et al. 2004), normalized maximum scour depth, for long-term and clear-water conditions with non-interfering scours and uniform sediment, can be expressed as function of only one non-dimensional group given by the ratio between the morphological jump:

$$a_1 = (S_0 - S_{eq})L \quad (4)$$

where S_0 and S_{eq} are, respectively, the initial and equilibrium bed slopes and L is the sill spacing, and the specific critical energy available at the sill:

$$H_s = \frac{3}{2}\sqrt[3]{\frac{Q^2}{B^2 g}} \quad (5)$$

where Q is the water discharge, B the channel width and g is gravity. However no local-scouring observations were made in conditions of upstream sediment feed which is common in real mountain rivers.

Experiments aimed to study the influence of upstream sediment transport have been carried out in order to complete the observation of local-scouring mechanisms under all probable conditions.

2 EXPERIMENTS

2.1 *Experimental Set-up*

In these tests a glass sided tilting flume 10 m-long, 0.5 m-wide, 0.5 m-deep was used. The bed of the flume was covered with a 330 mm-deep sediment layer and the gravel was well mixed before starting each test. The sediments used in the tests were graded river gravels, with the following characteristics $d_{30} = 7.3$ mm, $d_{50} = 8.7$ mm, $d_{90} = 13.4$ mm, and uniformity coefficient $C_u = 1.96$. Rectangular wooden plates, 500 mm-wide and 10 mm-thick were used to simulate the presence of morphologic control transverse structures.

During the test bed profile was subject to net degradation under erosive flow action and sediments were transported downstream. At the downstream end of the flume the water flowed over a tail gate into a tank. This was used as a storage basin for the sediment exiting the flume. A schematic diagram for the experimental set-up is shown in Figure 1.

The flow was recirculated: water without sediment passed into a sump and a submerged pump raised the water from the sump to the inlet of the flume. The inlet had a "honeycomb" flow straightener to reduce secondary currents and to create uniform flow in a short reach. The flow discharge was measured using an electromagnetic flow meter, positioned on the inlet pipe; the measurements showed oscillations of flow discharge around a mean of about half litre per second.

Sediment was weighed and placed on a 40 cm-wide and 180 cm-long conveyor belt on the upstream end of the flume. Maximum sediment charge was 60 kg/m, while conveyor velocity ranged between 1.28

Max	7.4	26.0	35.5	2.0

* Data not present in these tests.

and 6.23 m/h. This allowed controlling sediment feed rates to be fed into the flume.

Measurements of the water and bed profiles were made with a point gauge mounted on a gantry which was manually moved on rails placed on top of the sidewalls of the flume.

2.2 *New sediment feed tests*

Tests were performed at different initial bed slopes, S_0, between 4.2% and 7.4% with steady flow discharges, Q, between 18 l/s and 26 l/s and with steady input sediment rates, Q_s, between 0.0 g/s and 35.5 g/s (see Table 1).

Before each test series (i.e. tests distinguished by the same initial slope S_0), the flume was tilted to the desired slope. Reaches between sills were filled with gravel and the bed was reconstructed so that sills would be fully inserted into the gravel. At the beginning of each test the sediment was carefully mixed over the whole depth, to avoid preferential sorting and compaction of the gravel at different depths which may have biased scouring measurements.

The pump was started and the water was pumped into the flume with low discharge (4–5 l/s) slowly increasing the flow depth to avoid sediment transport before the designed flow discharge value was attained. Once the whole mass of sediment was saturated, the discharge was raised to the desired value. At the same time, the conveyor belt, previously prepared with an assigned charge of gravel, was turned on. Tests lasted 5 to 6 hours, assuring constant water flow discharge and upstream sediment feed. This duration was found to be long enough to reach final equilibrium conditions, as the scour development always took place within the first two hours. During the last two hours of each test, the three scour holes were measured every ten minutes, recording the maximum scour depth with the respect to the line between the top of sills.

Measurements were made through the glass of the lateral walls and the scour depths of both left and right sides of the flume were recorded. It was necessary to make measurements in this way because observations during preliminary tests showed clearly that there was a temporal oscillation of scour depth around an average value, after the equilibrium configuration has been reached.

This phenomenon was present only during tests with constant sediment transport, it was absent during clear water tests. In addition the input sediment transport caused a lack of two-dimensionality of the scour shape, therefore it was required to hypothesize a linear variation of the depth and to estimate the scour depth as average between the two measured values. A temporal average was used to estimate the equilibrium scour depth.

In the last half an hour of the test, measurements of the water profiles were made at 5 cm intervals along the flume centreline. After the pump is turned off and the flume carefully drained measurements of the bed profiles were made at 5 cm intervals too.

3 RESULTS AND DISCUSSION

The collected data were examined using non-dimensional groups developed by the authors in previous no-feed studies. The most important result of this study is shown in Figure 2. It shows the maximum scour depth normalized to the critical flow energy, y_s/H_s, plotted against the drop ratio a_1/H_s, dividing data in series classified according to the value of the imposed sediment feed.

Trends are roughly estimated as straight lines, which correspond to different values of sediment discharge. These lines appear to collapse along a unique line. This denotes clearly that sediment transport is not influencing the depth of the local scouring in a direct way and suggests that any effect of sediment transport is accounted for in the value of the morphological jump, a_1. The only effect of the introduction of sediment from upstream is to increase the equilibrium bed slope and, as consequence, to reduce the value

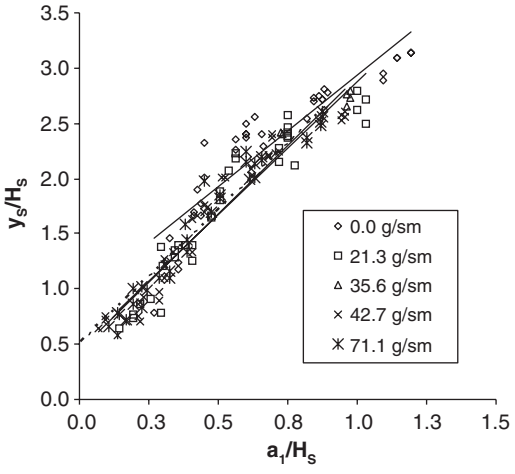

Figure 2. Experimental data divided into series according to upstream sediment feed rate.

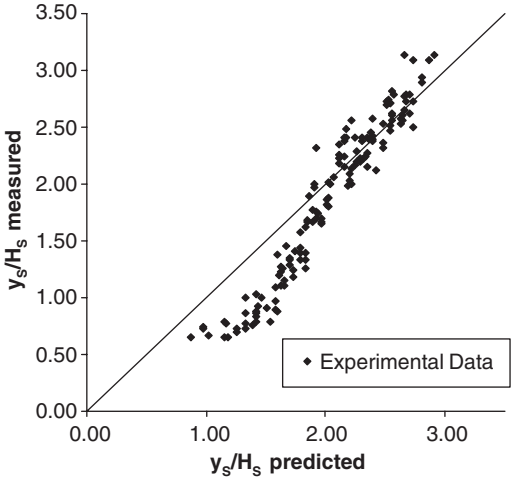

Figure 3. Comparison of measured and predicted maximum scour depths with eq. (2).

of a_1. This experimental evidence justifies the proposed simplification of the problem, since it allows all measurements to be considered in the same way, without distinguishing between clear water and sediment feed conditions. The aim is now to recalibrate the existing scour depth formula using the new scour depth data obtained in both clear water and upstream sediment feed conditions. Figures 3 and 4 show the prediction of the existing formulae of Marion et al. (2004) and Lenzi et al. (2002) with respect to the new experimental measurements. In general the calibrated Equation 2 provides better prediction, even if

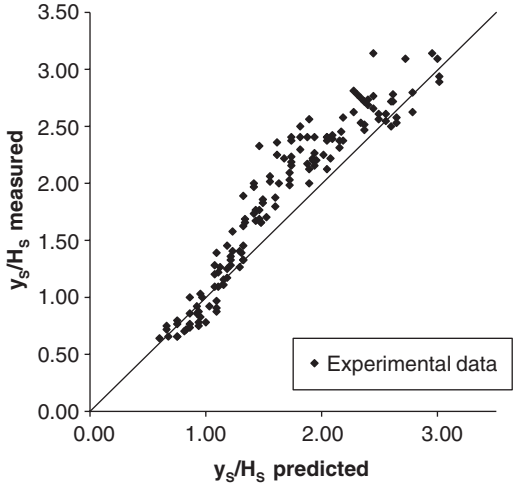

Figure 4. Comparison of measured and predicted maximum scour depths with eq. (1).

it overestimates normalized scour depth for low values of ratio y_s/H_s. Anyway it is noted that validity range of Equation 2 is slightly shifted with the respect to the range in which experimental data fall, which is $0.07 < a_1/H_s < 1.19$. It means that the relationship is more effective for values of the morphological jump, a_1, large with respect to the specific energy of the flow, H_s, which is a common situation for high gradient stream.

Equation 1, obtained by Lenzi et al. (2002) with both high and low bed slopes, slightly underestimates the extent of the measured maximum scour depth over the data interval. It is plausible that the term $a_1/\Delta D_{95}$ can be completely neglected also in the cases of low gradient. This formula shows a better correlation for low values of the ratio y_s/H_s.

Figure 5 contains all data obtained from the current experimental tests, and shows the maximum scour depth normalized to the critical flow energy, y_s/H_s, plotted against the drop ratio, a_1/H_s.

A satisfying correlation over all the full experimental range is attained with a non-linear regression, which gives a curve following a power law similar to Equation 2. The final relationship is:

$$\frac{y_s}{H_s} = 3.0\left(\frac{a_1}{H_s}\right)^{0.6} \tag{6}$$

which is valid for $0.07 < a_1/H_s < 1.19$, with a correlation coefficient $R^2 = 0.93$.

This relation has the same form as the relationship stated in Marion et al. (2004), which is shown in the same graph, and the multiplicative and exponent coefficients are similar (equal respectively to 2.7 and 0.43 in eqn. 2).

Copyright © 2006 Taylor & Francis Group plc, London, UK

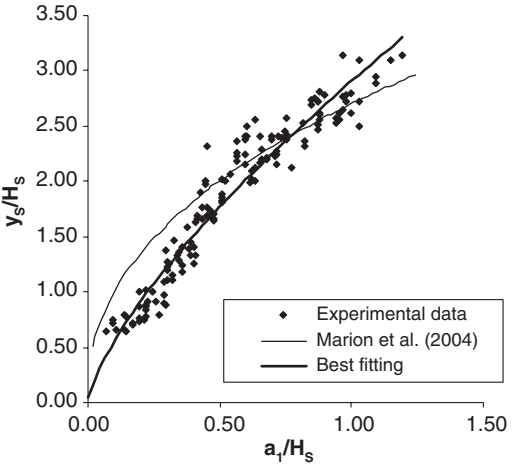

Figure 5. Best-fitting of experimental data; comparison between eq. (2) and eq. (5).

Closer examination seems to show that it is quite difficult to approximate all data with a unique curve. The expression obtained by Marion et al. (2004) is very effective for $a_1/H_s > 0.6$, where non-dimensional maximum scour depth increases approximately with the square root of the normalized morphological jump. Unlike, in the interval $0.0 < a_1/H_s < 0.6$ the trend seems to follow an almost linear law, therefore with an exponent very close to that present in the formula obtained by of Lenzi et al. (2002), equal to 0.86.

This suggests that there may be two types of physical modes of scour hole formation that are not apparent from the initial non-dimensional analysis of the data and that probably depend on the jet inclination and efficiency. Jet inclination plays an important role in entraining sediment particles and sweeping them out of the scour hole, being the more tilted the jet the higher the erosion intensity.

Therefore, with the growth of the morphological jump, maximum scour depth rises not only because of a bigger availability of potential energy (i.e. the morphological jump, a_1), but also because of the more vertical jet. This mechanism becomes weaker in the case of elevated drop heights, because of the pool tailgate depth, so the jet efficiency is not increasing further.

Although jet inclination was not included in the non dimensional analysis it can be stated that it was partially accounted for in the ratio between the morphological jump, a_1, and the critical specific flow energy, H_s.

Furthermore it is noted that, for the lower values of x-axis, more exactly for $a_1/H_s < 0.2$, the non-dimensional ratio between maximum scour depth and specific critical flow energy appears to be attaining a stable value of 0.5 to 0.6 rather than declining steadily towards zero.

4 CONCLUSIONS

Experimental data are presented on local scouring downstream of bed sills placed in high gradient gravel bed streams. The aim was comparing data trends relevant to both clear water and constant sediment feed conditions.

As expected, experiments showed that local scour depth decreased with the increasing of the sediment discharge, once all other factors are fixed. Plotting data normalized accordingly to non-dimensional analysis proposed by previous studies showed that data obtained from clear water tests and sediment feed tests had the same trend. This was justified as sediment discharge, q_s, only implied an increase of the equilibrium bed slope and a consequent decrease of the morphological jump, a_1, which was already accounted for in the analysis. No other effect seems to be produced by the upstream sediment transport rate on the development of the local scouring phenomenon. This allows all data to be analysed using the non-dimensional groups developed with no sediment feed conditions.

Existing non-dimensional relationships to predict scour depth which had originally been developed in experimental tests in clear water conditions were compared with the new data. A good correspondence was observed.

For ratios a_1/H_s greater than 0.6, Equation 2 from Marion et al. (2004), obtained with uniform grain sized sediment, corresponds well with new data. In the range where a_1/H_s is less than 0.6 the relation overestimates normalized scour depth; with regard to this it has been noticed that the interval of validity of the formula is shifted towards the right with the respect to the range, which data fall in. For lower values of the ratio a_1/H_s, Equation 1, obtained by Lenzi et al. (2002) on both high and low gradient streams data, seem to fit better.

In general it can be said that both formulas are valid, if applied on appropriate intervals, but Equation 2 has the great usefulness for evaluating the maximum scour depth, using the only parameter a_1/H_s. Probably this ratio is enough to describe the phenomenon also in the case of low gradient bed slope. A correction of the exponent to the value 0.6 instead of 0.43 improves the prediction performance of this formula for low values of a_1/H_s.

The value $a_1/H_s = 0.6$ describes a point at which the physical mechanisms of erosion that cause the scour depths appear to change and this is reflected in the performance of the two formulae.

Riprap protection of vertical-wall bridge abutments

C.M.S. Fael

ABSTRACT: This study addresses the use of riprap as a countermeasure against scouring near vertical-wall bridge abutments under clear water flow conditions. It deals with the diameter of riprap, D_{r50}, the layout of mattresses and their layer thickness, t. It aims to confirm existing criteria and to define appropriate formulations, whenever pertinent. Experiments were performed on a rectangular sand-bed open-channel, by imposing different abutment lengths and by choosing three riprap stone sizes. It became obvious that i) the stone size and mattress extent depend on the ratio between the abutment length and the flow depth and that ii) winnowing can be avoided when the layer acts as a granular filter or the layer thickness exceeds $3D_{r50}$.

1 INTRODUCTION

Scour around bridge abutments is widely recognized as one of the major causes of collapse of bridges. However, due to the complexity of the local scour phenomenon, there is a significant lack of guidelines for the design of countermeasures to mitigate scour. Research efforts are still needed in order to establish sounder guidelines.

Two groups of countermeasures are referred to in the literature. The first group includes armoring countermeasures, where riprap mattresses are the most common; the second group includes flow-altering devices which are not in the scope of this paper.

The riprap matting around abutments is the most widespread countermeasure. It creates a physical barrier intended to resist to the eroding capacity of the flow. However, studies concerning this countermeasure are comparatively rare and the existing guidelines are based on limited evidence. In practice, engineers frequently assume, for instance, that mats should cover the predictable scour area of the unprotected riverbed around the obstacle, ignoring that protection itself is a factor influencing scour. Other key aspects of mattress design are also poorly known or controversial.

Scarcity of information justifies this new investigation effort aiming to confirm existing criteria and to define more appropriate formulations, whenever pertinent. Vertical-wall abutments were chosen for this study since they assumedly induce the most severe conditions concerning design criteria.

The study has adopted an experimental approach. Tests were carried out under clear-water flow conditions, i.e. conditions, in which the mean velocity of the undisturbed approach flow is below or at the threshold velocity for the beginning of motion.

2 LITERATURE REVIEW

Bridge engineers frequently face the need to address the specification of riprap mats for bridge abutments, including the median stone size, layer thickness and mattress plan layout. The correct consideration of these design variables implies the understanding of riprap failure mechanisms.

According to Eve & Melville (2000), the failure mechanisms of riprap are essentially the same for bridge abutments as for piers. For clear water conditions, Parola (1993), Chiew (1995) and Lauchlan (1999) identified three failure mechanisms: shear failure, winnowing failure and edge failure.

Shear failure is clearly linked with the riprap stone size; winnowing depends on the thickness of mats and on the gradation coefficient of the riprap stones; edge failure and plan dimensions of mattresses are also inter-related.

Copyright © 2006 Taylor & Francis Group plc, London, UK

For specifically evaluating the riprap stone size, several authors have suggested empirical formulas. For non-vertical-wall abutments, Simons & Lewis (1971), Croad (1989) and Richardson & Davis (1995) can be quoted. Furthermore, for vertical-wall abutments, the studies of Pagán-Ortiz' (1991), Atayee's et al. (1993), Austroad's (1994) and Richardson & Davis' (1995) studies can be mentioned.

Most of the formulas found in the literature can be arranged as follows:

$$\frac{D_{r50}}{d} = \frac{C}{s_r - 1} F_r^n \quad (1)$$

where D_{r50} = median riprap stone diameter; d = flow depth; s_r = specific gravity of blocks; F_r = flow Froude number; C and n = coefficients.

Regarding thickness, t, of the riprap layer, the Ministry of Works and Development (1979) recommended the value $t = 2D_{r50}$, on top of a suitably graded filter or filter cloth. Later on, Lagasse et al. (1997) improved this criterion recommending that the riprap thickness should be at least $1.5D_{r50}$ or D_{r100}. They also recommended that the riprap thickness should be increased by at least 50% when placed under water, to allow for any uncertainties associated with the placement.

Concerning the layout of riprap mats, Richardson & Davis (1995) and Austroads (1994) recommended the use of riprap around the abutments, down to the expected scour depth. An alternative is to lay an equivalent blanket of riprap, known as a launching apron, on the existing bed.

Based on the studies carried out by Pagán-Ortiz (1991) and Atayee et al. (1993), Richardson et al. (1993) and Richardson & Davis (1995) suggested that, for abutments extending partly into the floodplain, the apron riprap should extend twice the flow depth in flood plain, i.e. $w = 2d_f$ (see Figure 1).

Eve & Melville (2000) have proposed Equation 2,

$$\left(\frac{w}{d}\right) = \left(0.5 - 1.82\frac{D_{r50}}{d}\right)\left(\frac{B}{B-L}\right) \quad (2)$$

which gives the required apron length, w, for a given riprap stone size, as soon as $0.1 < D_{r50}/d < 0.2$. In Equation 2, B = channel width; L = abutment length.

As mentioned before, it is frequently assumed that mats must cover the predictable scour area at the riverbed level of unprotected abutments. Melville & Coleman (2000) suggest $w = \mathrm{H/V} d_{se} \approx 1.5 d_{se}$, where H/V is the horizontal-to-vertical ratio of a spill-through abutment and d_{se} is the equilibrium scour depth of the supposedly unprotected bed.

Below, the mentioned recommendations are evaluated against new laboratory evidence and some alternative guidelines are also presented.

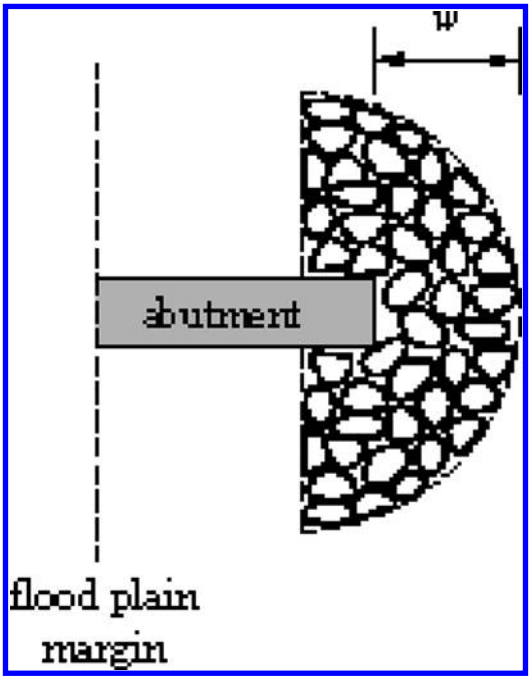

Figure 1. Riprap layout at bridge abutments according to Richardon & Davis (1995).

3 EXPERIMENTS

Experiments were carried out in a 28.0 m long, 4.0 m wide and 1.0 m high concrete flume. The right lateral wall of the flume is made of glass panels, which make it possible to observe the flow in the reach where countermeasures were tested. This reach includes a 3.0 m long, 4.0 m wide and 0.6 m deep recess box, starting at 13.9 m from the flume entrance.

Vertical wall abutments were placed on the bottom of the recess, at its mid cross-section (at 15.4 m from the flume entrance), protruding at right angle from the glass wall. The recess was practically filled with natural quartz sand, of which the median diameter is $D_{50} = 1.28$ mm and the gradation coefficient is $\sigma = 1/2(D_{84.1}/D_{50} + D_{50}/D_{15.9}) = 1.46$ (*cf.* Table 1). Three different types of riprap stones (see Figure 2 and Table 1) were placed around the abutments, on top or embedded in the quartz sand. In Table 1, subscript r, standing for riprap, was not used since the characteristic diameters of sand are also included.

The abutments were simulated by 140 mm wide, vertical wall, parallelepiped perspex boxes. The top of the perspex boxes was kept open, allowing the handling of a video camera to record images of the experiments from inside. Abutment lengths equal to 0.28 m, 0.51 m, 0.72 m, 0.93 m and 1.13 m were used. This way, L/d varied between 2.33 and 9.42.

Riprap #3	13.43	15.69	18.66	1.18	2.65

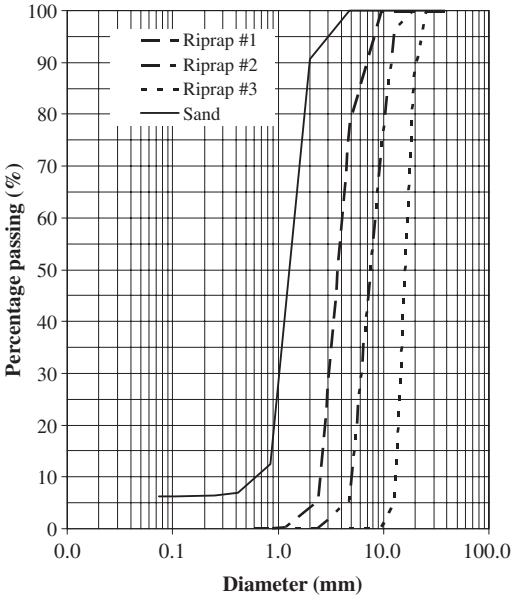

Figure 2. Sand and riprap grading curves.

The study was done for a reasonably high and practically constant flow depth ($d \approx 0.12$ m).

During the experiments, the water is pumped from a reservoir and the discharge can vary continuously from 0.0 m^3/s up to 0.18 m^3/s. Just upstream the flume entrance, a diffuser pipe has been installed to ensure the "uniform" flow distribution along the flume width. At the downstream end of the flume, a hand-operated tailgate makes it possible to regulate the water level. The water falls from the tailgate into the mentioned reservoir, closing the water circuit. The flume is equipped with a moving carriage used to install measuring equipment.

Four sets of experiments were carried out. The first is a set of preliminary tests intended to determine the critical flow velocity, U_c, for the beginning of motion of the quartz sand and the three riprap stone sizes.

The second set of tests aimed at evaluating the critical flow velocity for scour inception, i.e. the approach flow velocity above which scour develops close to the abutment. Fifteen short duration tests were carried out. For each type of riprap, the quartz sand in the recess box was entirely covered with a filter cloth and one upper layer of riprap. The thickness of this layer, levelled with the concrete flume bottom, was $3D_{r50}$. Tests started with a very low flow velocity. Velocity was successively increased while the flow depth was maintained constant by handling the downstream tailgate. The procedure was repeated until the first riprap stones began to move close to the abutment.

The third set of tests was designed so as to further address the thickness of the mattresses. Eight tests were performed without filter cloth, for riprap #2 and riprap #3. Tests were conducted for the two extreme lengths of the abutment, i.e. for $L/d = 2.33$ and $L/d = 9.42$. As for the second set of tests, the sand recess box was covered by a riprap layer levelled with the adjacent concrete flume bottom. Two riprap layer thicknesses, t, were tested per setup, i.e. per combination of L/d and type riprap stones: $t = D_{r50}$ and $t = 2D_{r50}$ or $t = 2D_{r50}$ and $t = 3\ D_{r50}$. Approach flow velocities were kept equal to 90% of the corresponding critical values of scour inception, as defined in the second set of tests. A rule was fixed to the transparent wall of the abutment and scouring was monitored with the video camera placed inside the abutment until equilibrium could be practically guaranteed.

The last set of the experiments was intended to evaluate the minimum plan dimensions of mats. In this case, the recess box was filled with sand. Mattresses, made of riprap #3 and set on filter cloth were embedded in the sand, being leveled with it, around the abutment noses. Tests were accomplished for $L/d = 9.42$, 7.75, 6.00 and 4.25, on filter cloth, for $U \approx U_{cs}$, U_{cs} being the critical approach velocity for the beginning of sand motion. The layer thickness was, in all cases, $t = 2D_{r50} \approx 31$ mm.

4 DISCUSSION

4.1 *Beginning of motion in the approach flow*

The beginning of sediment motion is difficult to identify in the laboratory, because this is not a neat, unambiguous phenomenon. It rather depicts a random character, of which the visual evaluation is somewhat subjective. Therefore, two values of U_c – critical velocity for the beginning of motion – were retained: a lower limit, where motion is about to but still does not exist, and an upper one, corresponding to a very weak sediment motion (incipient motion). Table 2 presents the observed values of U_c, together with the results of Neil (1967) and Garde (1970) equations, as well as the results of Shields diagram.

Apart from the intrinsic value of the measured values of U_c for the subsequent discussion, the following result can be drawn: within the experimental range of

Austroads (1994)	1.03	2.00
Richardson & Davis (1995)	1.02	2.00

this study, Garde (1970) and Neil (1967) equations lead to better predictions than the Shields diagram.

4.2 *Size of riprap stones, D_{r50}*

As for the beginning of motion (see §4.1), the determination of critical flow velocity for scour inception is subjective; it also led to the definition of intervals. The values reported below correspond to the centre of such intervals.

The results of the fifteen tests carried out to evaluate the critical flow velocity for scour inception were used to check the applicability of Equation (1). Values of C and n understandably differ with the bibliographic source. Some authors use the undisturbed approach flow depth, d, and Froude number, F_r whereas others suggest the corresponding values at the contracted cross-section.

Pagán-Ortiz' (1991), Atayee's et al. (1993), Austroads's (1994) and Richardson & Davis's (1995) contributions were chosen for the analysis. Their values of C and n are summarized in Table 3.

Figure 3 compares the fifteen pairs of D_{r50}/d *versus* F_r issued from the experiments with the results obtained via Austroads (1994) equation, where d and F_r are defined for the undisturbed approach flow corresponding to scour inception close to the abutments. The same applies to Figure 4 regarding the Pagán-Ortiz' (1991), Atayee's et al. (1993) and Richardson & Davis' (1995) contribution, but here d and F_r are defined at the contracted cross-section.

From Figures 3 and 4 there can be concluded that none of the equations adequately fits the experimental

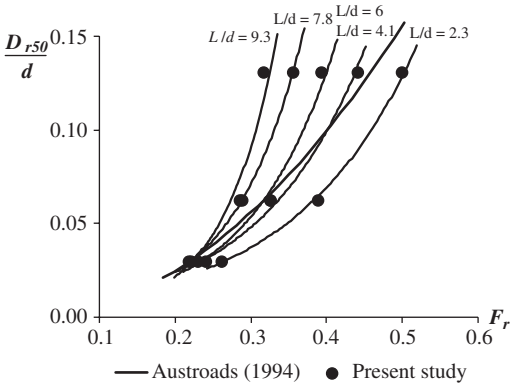

Figure 3. Variation of D_{r50}/d with the Froude number of the approach flow.

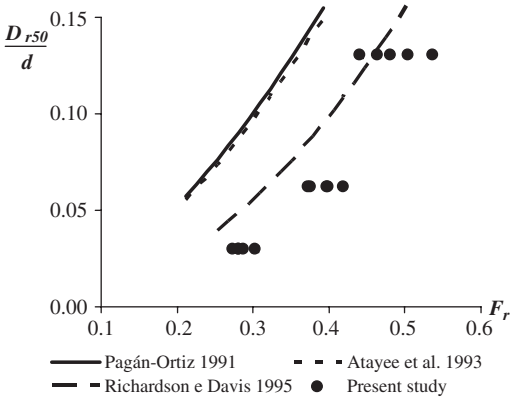

Figure 4. Variation of D_{r50}/d with the Froude number of the contracted cross-section.

data. Nonetheless, Austroads' (1994) and Richardson & Davies' (1995) contributions produce results in the range of the observed values. It is clear that D_{r50} depends both on the Froude number and on L/d. Again, it should be noted that D_{r50} refers to the minimum stone size assumed to resist to scouring in the neighbourhood of the abutment. In this sense, it can be considered as a critical diameter. The inability for the tested equations to predict the critical value of D_{r50} derives from the fact that coefficients C and n might not take into account the effect of L/d.

An alternative approach to access D_{r50} is to define the critical value, I_c, of the approach flow intensity, $I = U/U_c$, below which scour does not show up, for a given value of L/d.

When no obstacle exists in the flow, it is clear that the beginning of motion can be predicted through formulations like those used in §4.1.

It is also consensual that the presence of obstacles increases, in their vicinity, the susceptibility for the

Copyright © 2006 Taylor & Francis Group plc, London, UK

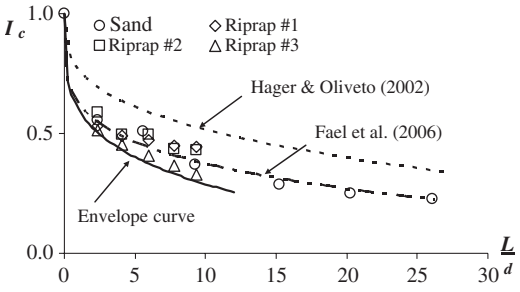

Figure 5. Variation of I_c with L/d for sand and for riprap stones.

motion of particles. In practice, this means that, even for flow intensities less than 1, scour may occur close to obstacles. Some controversy exists on the lower value of I, i.e. I_c, below which no scour exists. Some authors have adopted Chabert & Engeldinger's (1956) result for piers: no scour would occur as long as $I < I_c = 0.5$. Cardoso et al. (2002) corroborated this conclusion for comparatively short abutments ($L/d < 7$). On the contrary, Melville (1992) and Melville (1997) implicitly suggested $I_c = 0$. Hager & Oliveto (2002) have proposed an equation to calculate I_c as a function of the flow contraction, L/B, where B = channel width. According to these authors,

$$I_c = 1 - \frac{5}{6}\left(\frac{L}{B}\right)^{5/16} \quad (3)$$

For wide open channels where scour is not influenced by flow contraction, Fael et al. (2006) suggested one equation that can be rewritten as

$$I_c = 1 - \frac{3}{8}\left(\frac{L}{d}\right)^{2/9} \quad (4)$$

It should be emphasized that Equations 3 and 4 were established for sand bed material. *A priori*, they may or may not directly apply to the design of riprap stones.

Figure 5 compares the results of these equations with the "measured" values of I_c. It is clear that I_c depends on L/d. As L/d increases, there is an increasing susceptibility for scour inception. It seems that Fael et al. (2006) equation performs the best. Still, it should be noted that the observed values of I_c might be smaller than those issued from this equation, particularly for the coarser riprap. For $L/d = 9.42$, I_c may be as low as 0.31. In practice, it is clear that the widespread Hanco (1971) value – $I_c = 0.5$ – leads to unstable riprap stones, as soon as $L/d > 3 \sim 4$.

Figure 5 presents important information towards the design of stones for riprap mattress at abutments. Since the Fael et al. (2006) equation may over predict I_c, a lower envelop curve

$$I_c = 1 - \frac{2}{5}\left(\frac{L}{d}\right)^{1/4} \quad (5)$$

is also included. This equation is suggested for practical engineering applications. Let us assume a 20 m long vertical wall abutment inserted in a 4 m deep flow, of which the approach velocity is 2 ms^{-1}. According to Equation 5, $I_c = 0.39$. This means that the riprap stones around the abutment must be designed as if they were to remain stable for a fictitious flow velocity $U = I_c^{-1} \times 2\,\text{ms}^{-1} = 5.2\,\text{ms}^{-1}$ in the bottom of the approach channel. From Neil (1967) and Garde (1970) equations, the stone size of stable riprap, D_{r50}, would then be about 0.4 m.

Table 4. Scour depth due to winnowing *versus* riprap layer thickness.

4.3 *Riprap layer thickness, t*

The main objective of this section is to assess the minimum mattress thickness, t, needed to avoid failure due to winnowing of the underlying sediment particles through the voids of the riprap stones. No comment can be made on the thickness, t, of mattresses laying on filter cloth, because no experiments were carried out for this setup.

Since experiments were run for approach flow intensities below I_c of scour inception, shear failure was neither expected nor observed; as the entire recess box was covered with riprap, edge failure was not possible. Thus, only failure due to winnowing was expectable.

Table 4 summarizes the results of the third set of experiments described in §3. In the same table, N = number of equivalent layers, such that $t = ND_{r50}$, T = test duration. The most relevant result for the analysis is the equilibrium scour depth, d_{se}, generated by winnowing, as measured at the end of each experiment.

Copyright © 2006 Taylor & Francis Group plc, London, UK

According to Table 4, scour is practically nonexistent for riprap #2 regardless of the layer thickness. The exception is test 1 ($L/d = 9.23$; $N = 1$), where a 1.5 cm deep scour hole was observed at the end of a 5-days run. The reason for this excellent behavior of riprap #2 is, probably, its acting as a filter. In fact, it fulfils Terzaghi-Vicksburg criterion: $D_{r15} < 5D_{85}$; $5D_{15} < D_{r15} < 20D_{15}$; $D_{r50} < 25D_{50}$. It should be noted that the subscript r applies to riprap while the absence of this subscript is valid for the underlying sand. The existence of scour for test 1 may be explained by the phenomenon of winnowing through the practically unavoidable spaces between the vertical surface of the abutment and the surrounding riprap stones.

Table 4 also shows that, on the contrary, scour is possible for riprap #3. This is compatible with Terzaghi-Vicksburg criterion since the condition $D_{r15} < 5D_{85}$ is not verified. It should be noted that the deepest scour depth was observed at the shorter abutment ($L/d = 2.33$) for $N = 2$. It would certainly be deeper for a hypothetical test carried out for $N = 1$. The occurrence of the deepest scour hole for the shortest abutment is somewhat surprising since the wake vortices at the edge of longer abutments are expectably stronger and should render winnowing stronger too. Since this is not confirmed, further experiments are needed with the simultaneous measurement of the flow field to obtain an insight into the physics of phenomena.

From Table 4, it seems that scouring is negligible in the absence of filters of any kind as soon as $N \geq 3$. However, this result should be confirmed too, since, according to Parker et al. (1998), p. 242, winnowing can act down to depths of about $12D_{r50}$ around cylindrical piers.

4.4 *Mattress plan dimensions*

Experiments on edge failure and minimum mattress plan dimensions were carried out for 31 mm thick layers ($\approx 2D_{r50}$) of riprap #3, laying on filter cloth, so as to avoid winnowing failure. Since the approach flow velocity was approximately equal to the threshold velocity for the beginning of motion of the surrounding sand, shear failure was avoided too.

At the beginning of the fourth set of experiments, it was assumed that a reasonable layout for the mattresses would correspond to the configuration of scour holes previously observed by Fael et al. 2006 at the undisturbed sand-bed level of similar unprotected abutments. For this reason, w (see Figure 6) was predicted as $w = d_{se}/tg\theta$, where d_{se} = calculated equilibrium scour depth for unprotected bed; θ = angle of repose of sand. In this way, w was set equal to 0.75 m for test 1 (see Table 5).

Experience has shown that values of w of this order of magnitude do not lead to mattresses that completely avoid scouring at their edges, particularly downstream. It was also observed that increasing the dimension of mattresses does not lead, necessarily, to completely inhibit scour but, simply, to further deviate the scour hole from the abutment. Besides, riprap stones tend to roll into the scour hole that appears close to the mattress. Thus, a decision was made to reassess edge failure, assuming it to occur only when riprap stones are removed from the immediate vicinity of the abutment toe, by rolling into the scour hole.

For $L = 0.70$ m, tested mattresses evolved from a comparatively large mattress (test 1) to the one that strictly fulfilled the reassessed failure criterion (test 2).

Table 5 summarizes the results of ten experiments. It includes the values of L as well as those of w = characteristic length of the tested mattress; T = test duration; d_{se} = equilibrium depth of the observed scour hole; d_x and d_y = distances of the scour hole deepest point to the upstream vertical edge of the abutment; and α = angle defining the position of the deepest point (see Figure 6). It also indicates the results of edge failure assessment.

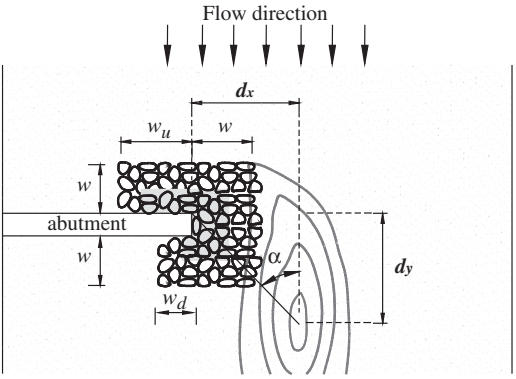

Figure 6. Characteristic dimensions of riprap mattresses; position of the deepest point of scour, defined by d_x, d_y and α.

Table 5. Plan dimensions of tested mattresses and results of the tests on the layout of riprap mattresses.

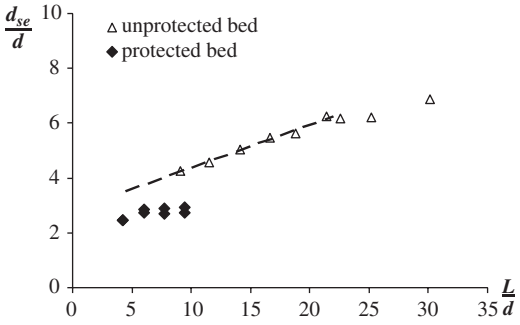

Figure 7. Effect of mattresses on equilibrium scour depth.

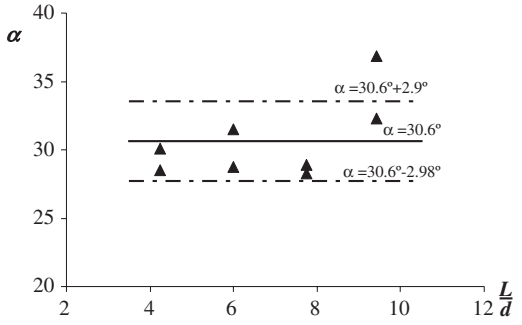

Figure 8. Variation of α with L/d.

It should be noted that the dimensions of the filter cloths used in these tests were set equal to 75% of the dimensions of the riprap layers, according to Melville & Coleman (2000).

Since scour is assumed as inevitable, a decision was made to evaluate the maximum observed scour depth by comparing the values issued from the protected-bed tests with those of similar tests carried out for unprotected bed by Fael et al. (2006). A comparison is presented in Figure 7, in which the dashed line is just intended to produce a comparison framework. In this figure, tests 1 and 4 were not included because they do not correspond to conditions close to the threshold of edge failure.

It seems that the riprap protection reduces the equilibrium depth of the associated scour hole. However, the reduction is not very significant, particularly for short abutments.

For practical engineering applications it may be important to address the position of the deepest point of the scour hole. Consequently, a decision was made to characterize α, d_x and d_y.

Figure 8 presents the variation of α with L/d. As for Figure 7, it does not include the results of tests 1 and 4 but their inclusion would not change the conclusions.

The figure does not make it possible to identify any trend of α with respect to L/d. It seems that $\alpha = 30.6° \pm 2.9°$ (average $\pm$ standard deviation), independently of L/d.

Figure 9 shows the variations of d_x/d and d_y/d with L/d. There is a small increasing trend of both d_x and d_y with L, but, for the reported experimental range, it may be assumed that $d_x \approx 4.5d$ and $d_y \approx 7.5d$ (in coherence with α).

The most important results reported in Table 5 refer to the values of w corresponding to the threshold of edge failure.

From Figure 10, it can be concluded that w increases with L/d. The influence of d/D_{r50} cannot be addressed since it was kept practically constant and equal to $120/15.69 \approx 7.65$, which indicates the need to vary

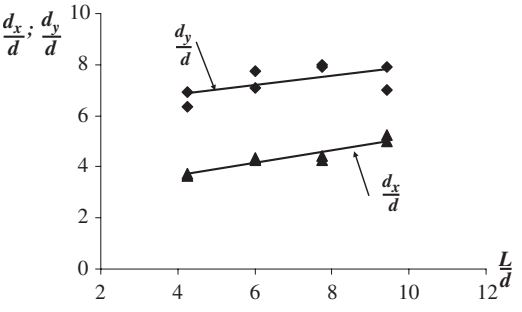

Figure 9. Variation of d_x/d *and* d_y/d with L/d.

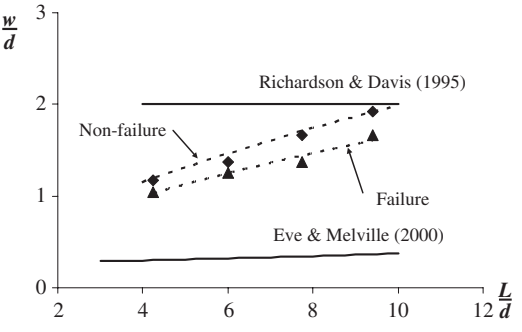

Figure 10. Variation of w/d with L/d.

d/D_{r50} in future research studies. It is also clear that Richardson & Davis's (1995) proposal – see Figure 1 – leads to safe predictions of w, within the experimental range of this study. Again, Figure 10 suggests the need to extend research for values of $L/d > 10$.

Eve & Melville (2000) Equation (2) seems to underestimate w. This may derive from the fact that the work of these authors applies to spill-through abutments, where the strength of the vortex system is presumably weaker than for the vertical-wall. This implies a reduced scour potential in the former and,

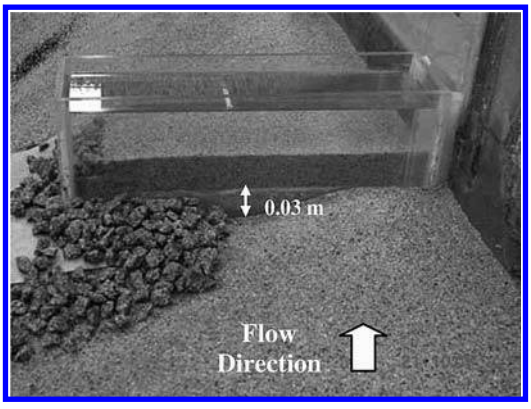

Figure 11. Scour hole immediately upstream of the abutment.

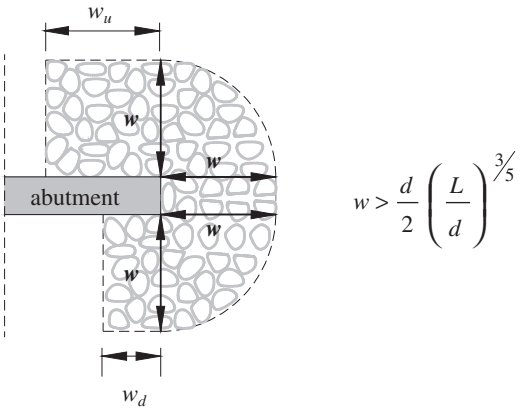

Figure 12. Layout of riprap mattresses for vertical-wall abutments.

therefore, weaker conditions for edge failure and smaller required apron length. Since the values of L/B varied, in this study, between 0.13 and 0.28 – with no visible contraction effect – while Eve & Melville's (2000) ones varied between 0.41 and 0.49, there may be different effects of contraction as a source for the discrepancies depicted in Figure 10.

According to Figure 10, there can also be concluded that edge failure can be avoided as soon as:

$$\frac{w}{d} > \frac{1}{2}\left(\frac{L}{d}\right)^{3/5} \quad (6)$$

under the conditions of $d/D_{r50} \approx 7.5$ and existence of filter cloth underneath riprap stones.

Preliminary experiments were also carried out on the specification of w_u and w_d (see Figure 6). It seems that w_u may be bigger than w itself, particularly for short abutments. This is illustrated in Figure 11 regarding test 10, where scour was observed at the toe of the abutment by the end of the run, although $w_u = 0.19$ m, while $w = 0.14$ m. It seems also clear that w_d can be very small or even null. The criterion $w_d = 3D_{r50}$ was observed to avoid edge failure along the mattress boundary facing the channel wall.

From the experiments reported in this section, it seems that the adequate layout of riprap mattresses for vertical-wall abutments would be as sketched in Figure 12. However, this proposal has to be regarded with caution since it only applies to $d/D_{r50} \approx 7.5$, in the range of L/d values between 4.25 and 9.42. Little evidence was produced on the values of w_u and w_d.

5 CONCLUSIONS

The use of riprap protection of vertical-wall abutments under clear-water flow conditions was addressed in this study. Abutments protruded at right angle from the wall of a rectangular, sand-bed channel. For the experimental range of this study ($4.25 \leq L/d \leq 9.42$), the following conclusions can be drawn:

i) Regarding the design of stable riprap stone sizes, it is clear that characteristic diameters depend on the Froude number as well as on L/d. The influence of L/d is not taken into consideration by several formulations selected in the literature.
ii) The concept of critical flow intensity, I_c, for scour inception applies to the design stone sizes. Equation 5 is suggested, which, leads to increasing stone sizes as L/d increases.
iii) Scour due to winnowing did not develop when the riprap layer acted as a granular filter. Scour seems negligible when, in the absence of filters of any kind, the riprap thickness is such that $N \geq 3$.
iv) For reasonable mattress extensions, scouring at its boundaries seems unavoidable, inducing the rolling of riprap stones into the scour hole.
v) Scour holes develop downstream the abutment; their depth seems to be mitigated as compared with unprotected bed. The deepest scour hole occurs at $d_y \approx 7.5d$ for $\theta \approx 30°$ (see Figure 6).
vi) Assuming edge failure to occur when stones are removed from the toe of the abutment, the lateral extent, w, of mattresses resisting to edge failure increases with L/d, according to Equation 6 for the range of L/d values mentioned above, $d/D_{r50} \approx 7.5$ and riprap layers placed on filter cloth. Richardson & Davis' (1995) proposal seems to predict safe w values.

The study reported in this paper encourages the adoption of the layout presented in Figure 12 but further research is needed so as to extend the conclusions and proposals, for different abutment shapes, to a wider range of L/d values as well as to different

values of d/D_{r50} and D_{r50}/D_{50}, where D_{50} stands for the under laying sand.

Geometrical effects in non-continuous riprap stability

Gustavo A. Mazza de Almeida & Juan P. Martín-Vide
Department of Hydraulic Engineering, Technical University of Catalonia (UPC), Barcelona, Spain

ABSTRACT: An experimental investigation was performed to determine the influence of geometrical characteristics (length and protrusion) on shear failure conditions of non-continuous riprap protections. Incipient motion of particles was used as failure criterion and the reference transport method was used to establish flow conditions for the threshold of motion. Altogether 201 experiments were conducted in a 30-m long, 0.75-m wide tilting flume with a fixed bed. Riprap materials were represented by four groups of uniform crushed rock with a median particle size $D_{50} = 0.85$, 1.25, 1.57 and 1.75 cm and the same shape. Flow conditions ranged from Froude numbers between 0.3 and 1 and relative depths Y/D_{50} between 9.4 and 19.4. In each test riprap transport rates were measured at different time intervals using a sediment trap placed immediately downstream from the test reach so that time dependence could be described well. A statistical method was developed to convert riprap transport rates into a fractional number of entrainments using standard video-imaging techniques. First results reveal that incipient motion conditions are strongly influenced by both protrusion and length of bed protection, indicating that stability significantly increases with increasing protection length and decreases with increasing protrusion.

1 INTRODUCTION

Rock riprap is widely used as a countermeasure against river scouring. As a consequence, during the last decades considerable effort has been devoted to develop new methodologies for determining its size, gradation, layer thickness and filter characteristics (Stevens et al. 1976; Maynord et al. 1987; Escarameia and May 1995; Pilarczyk 1998). Most of these design techniques consider the most general case of a continuous revetment or some very specific protections such as those used for bridge piers. On the other hand there seem to be an increasing tendency of using riprap in other river engineering works. Among these applications we give emphasis to those non-continuous cross sectional protections such as bed sills (fig. 1) or pipeline revetments. This type of protections are commonly built partially buried, allowing for a certain degree of protrusion.

Flow field surrounding these structures is extremely dependent on its particular geometry (length and protrusion) and, consequently, failure conditions may differ strongly from those observed for continuous protections. The purpose of this article is to investigate the influence of geometrical variables on shear failure of non-continuous riprap protections by comparing its critical conditions with those observed for continuous riprap protections.

Incipient motion of particles was used as failure criterion and the reference transport method was used to establish flow conditions for the threshold of motion. Although there are several good studies on incipient motion of gravel bed and continuous riprap protections, some authors (Buffington and Montgomery 1997) have highlighted a considerable scatter in τ_c^* values. This scatter may be explained by differences in experimental conditions and methodologies assumed

Figure 1. Riprap bed sill under construction. Besòs river close to Barcelona (Martín-Vide, 2002).

by each author. To avoid errors related to the comparison of failure conditions of non-continuous protections with those "universal" values found in the bibliography (e.g. Shields entrainment function), a group of experiments were conducted to estimate failure conditions of a continuous riprap bed with the same conditions (flume, rock characteristics, relative depth, etc) and criteria used for the other experiments.

2 EXPERIMENTAL SETUP

An experimental program was conducted in a 30-m long 0.75-m wide glass-sided tilting flume to determine failure conditions of non-continuous riprap protections. Test reach consisted in a 3-m long recess located 9 m upstream from the channel outlet. Water was pumped by a set of three pumps, each of them able to produce a flow up to 90 ls^{-1}. The slope of the flume can be set up to 0.04. An adjustable gate at the downstream end of the flume was used to control flow depth in each experiment. Both the gate and the channel slope were adjusted to ensure uniform flow in the test reach before each run. All tests used the same flow depth $Y = 16.5$ cm. An area with dissipation screens was installed at the channel entrance to prevent large-scale disturbances. Coarse natural gravel was used to roughen the upstream part of the channel, needed to achieve uniform flow.

Flow discharges were measured by a V-shape sharp crested weir installed upstream of the channel. Velocity measurements were conducted using a 3D acoustic Doppler velocimeter (ADV:SonTek). The sampling frequency of the ADV was set 25 Hz and the duration of the measurements at each point was 80 s. A point gauge with precision of 0.1 mm was used for measuring water level. The movements of the ADV and the point gauge in both longitudinal and vertical directions were controlled by a mechanism with an accuracy of 0.01 mm. The particles displaced from the protection were computed by weight and number using a replaceable sediment trap located downstream of the test reach. The trap is 75-cm wide and 5-cm high and is placed on the bottom of the flume.

Riprap materials were represented by four types of uniformly distributed sharped edge particles with quite similar shape factors. Rock characteristics are shown in table 1, where λ is the porosity of the material, γ_s and γ_w are respectively the rock and water specific weight and σ is the rock standard deviation

$$\sigma = \sqrt{\frac{D_{84}}{D_{16}}} \tag{1}$$

Experiments may be divided in two categories: continuous (C) and non-continuous (NC) protections. For continuous bed experiments all the bottom of the 3-m test reach was covered by a layer of rock with thickness $T = 2D_{50}$. To avoid problems related with internal boundary layer development due to the transition from the roughened reach (upstream) to the test reach, the first 1 m of bed was made rigid by gluing the rocks. Furthermore, this transition also prevents the sudden change of bed level at the upstream boundary of the movable bed. Figure 3 shows the schematic diagram of the flume and experimental setup of continuous protection experiments. The 200-cm movable bed was considered large enough to behave the same way as an infinite protection.

Non-continuous tests were prepared dumping rock material inside a slot at the bottom of the channel. The slot have the same width of the flume, a depth (below the flume bottom) $T = 2D_{50}$ and variable length l (figs. 2 and 4). Particles were laid in the slot allowing different values of protrusion p. The level of topmost particles and the bottom level were measured at several points prior to each test using the point gauge, so that protrusion values were computed as the difference between their mean values. The placement was also controlled by the total weight of the rocks in the slot.

Table 1. Rock characteristics.

Rock type	D_{16} (cm)	D_{30} (cm)	D_{50} (cm)	D_{84} (cm)	σ	$\frac{\gamma_s - \gamma_w}{\gamma_w}$	λ
I	0.66	0.74	0.85	1.10	1.29	1.89	0.48
II	1.10	1.15	1.25	1.48	1.16	1.82	0.47

3 EXPERIMENTAL PROGRAM

In C experiments four series of tests were conducted to determine incipient motion conditions of the four rock types presented in table 1 (series 1 to 4 in table 2). Each series consisted in a number of tests with different discharges, providing sufficient information so that the relationship between shear stress and transport rate of riprap particles could be well described.

NC experiments aimed at verifying the influence of protection length and protrusion on incipient motion conditions. In series 5 to 8 the four rock types were tested with a fixed value of relative length $l/D_{50} = 4$ and an initial value of relative protrusion $p/D_{50} = 0.95$. Each of series 6, 9, 10, 11 and 12 had the same characteristics (width, D_{50}, p, Y) but protections with varying lengths. Series 6, 13 and 14 used the same variables (width, D_{50}, l, Y) but two different initial values of protrusion.

As shown in table 2, although in some series the relationship between shear stress and transport rates was established through many tests, most of the series counted with 8 tests.

The first step prior to each test was to adjust both the flume slope and the tailgate position to produce, for a given water discharge, the water depth $Y = 16.5$ cm. The preparation of the bed for continuous experiments consisted in mixing the material so that it represented the condition of dumped riprap. Then it was leveled with a leveling bar. Non-continuous protections preparation consisted in placing the material inside the slot and carefully measuring its protrusion with the point gauge, as mentioned before. After the bed was prepared the channel was slowly filled with water.

Table 2. Experimental program. C:continuous; NC: non-continuous.

Series	Prot. type	N. of tests	l (cm)	D_{50} (cm)	p (cm)	Q ls^{-1}
1	C	14	200	0.85	0	90–120
2	C	41	200	1.25	0	90–132.5
3	C	8	200	1.57	0	95–135
4	C	8	200	1.75	0	124–155
5	NC	45	3.4	0.85	0.81	60–95
6	NC	8	5.0	1.25	1.19	80–132.5
7	NC	8	6.3	1.57	1.49	95–130
8	NC	8	7.0	1.75	1.66	95–130
9	NC	8	10	1.25	1.19	95–130
10	NC	8	20	1.25	1.19	95–130
11	NC	8	35	1.25	1.19	95–130
12	NC	8	50	1.25	1.19	95–130
13	NC	8	5	1.25	0.35	95–130
14	NC	21	5	1.25	0.76	80–130

Obstacles were introduced downstream the test reach to increase the water level and ensure no bed motion. After steady flow conditions had been reached the obstacles were removed, the 16.5-cm water depth was achieved, and time began to be computed. Transport rates of riprap particles were measured by removing the sediment trap and extracting the trapped solid material.

Time dependence of transport rates may introduce important errors in incipient motion determination and must be taken into account. Measurements of transport rates were made at different time intervals. First measurement was taken at $t = 40\,s$ and time intervals gradually increased until $\Delta t = 5\,min$ at $t = 10\,min$. After $t = 10\,min$ all measurements were taken at $\Delta t = 5\,min$ intervals. Almost all experiments had a total duration of 1 hour.

This experimental procedure was repeated for different water discharges in the ranges shown in table 2, changing the flume slope to obtain the same flow depth ($Y = 16.5$ cm).

4 BASIS FOR ANALYSIS

4.1 *Reference transport method*

As mentioned before, reference transport method is used in this paper to estimate critical shear stresses for initiation of motion. The method consists in applying different shear stresses to a bed and measuring the corresponding bed load transport rates. Then, from a fitted relation between shear stress and transport rates, the threshold value of bed shear stress may be determined both by extrapolating to zero transport or by an arbitrary definition of a small but finite constant transport rate (Wilcock 1988; Parker et al. 1982; Fenton and

Copyright © 2006 Taylor & Francis Group plc, London, UK

Abbott 1977; Shvidchenko and Pender 2000). As suggested by Fenton and Abbott (1977), "this procedure is appropriate to a physical situation in which quantities vary randomly in time and space, for by collecting a large number of individual grains removed from the bed over a long period, the statistical population is large enough that the values obtained for transport rates, and subsequently threshold stress, may be considered reliable". Several reference transport parameters have been proposed to represent the level of transport activity. Most of them represent bed mobility in some dimensionless form of unit transport rates (Parker et al. 1982; Einstein 1950). Due to the stochastic nature of both fluctuating forces associated with turbulent flow and particle position distribution the probabilistic approach is certainly the most appropriate.

Shvidchenko and Pender (2000) in their study on the influence of relative depth on incipient motion conditions have linked incipient motion to the probability of sediment entrainment through the intensity of sediment motion:

$$I = \frac{m}{N\Delta t} \tag{2}$$

in which I is the intensity of sediment motion and m is the number of particle displacements observed during the time interval Δt on an area that contains N surface particles. As stated by Einstein (1942) (extracted from Shvidchenko and Pender (2000)) I can obviously be regarded as the probability that a particle be detached from the bed in a given unit time interval.

In this study the intensity of sediment motion (eq. 2) is used as a measurement of bed activity. This approach requires measurements of the number of entrainments per unit bed area instead of the cross section solid discharge measured in the experiments using the sediment trap. Yalin (1972) (extracted from Shvidchenko 2000) proposed the relationship between unit weight solid transport discharge q_s and the number of particle entrainments per unit area:

$$q_s = \frac{m}{A\Delta t} G L_m \tag{3}$$

where G is the mean particle weight, A is the bed area in which m entrainments are observed and L_m may be regarded as a characteristic or "mean" value of particle displacement after dislodgement. This relationship may be considered valid for all those cases in which the maximum particle displacement is smaller than the bed length. In the present study non-continuous riprap protections with small length do not fulfil this condition. In other words, two protections having the same relative number of displacements (e.g. I values) but different lengths will obviously generate different q_s values. As a result, the relationship between I and q_s must be based on particle displacement statistics rather than on its mean values.

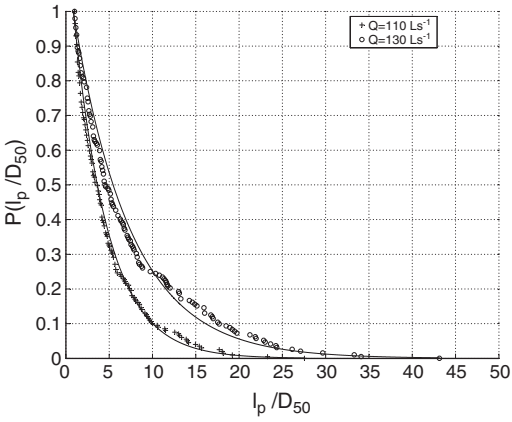

Figure 5. Particle displacement distribution tests using rock type II. Observed data (from video) in dots and eq. 5 in continuous line.

4.2 *Conversion of transport rates into intensity of sediment movement*

In this study particle displacement distribution is estimated by using standard image processing techniques. Nine tests were conducted using rock types II, III and IV (table 1) for flows ranging from $\tau^* = 0.022$ up to $\tau^* = 0.059$, where τ^* is the dimensionless shear stress, defined as

$$\tau^* = \frac{\tau_o}{(\gamma_s - \gamma_w) D_{50}} \tag{4}$$

and τ_o is the mean bed shear stress.

For each test a number of displacements ranging from 100 to 200 was recorded. Only particle displacements with length greater than $1D_{50}$ were considered. Data was fitted using an exponential probability distribution

$$P\left(\frac{l_p}{D_{50}}\right) = e^{-\alpha\left(\frac{l_p}{D_{50}} - 1\right)} \tag{5}$$

where $P(\frac{l_p}{D_{50}})$ is the probability that dimensionless particle displacement $\frac{l_p}{D_{50}}$ be greater than a fixed value, and l_p the absolute value of particle displacement. Figure 5 shows two distributions and the corresponding fitted curves.

Linear regression was then used to estimate a relation between α and τ^*, resulting:

$$P\left(\frac{l_p}{D_{50}}\right) = e^{(3.04\tau^* - 0.29)\left(\frac{l_p}{D_{50}} - 1\right)} \tag{6}$$

The relation between the number of particles collected in the sediment trap N_t and a relative measure of entrainments

Copyright © 2006 Taylor & Francis Group plc, London, UK

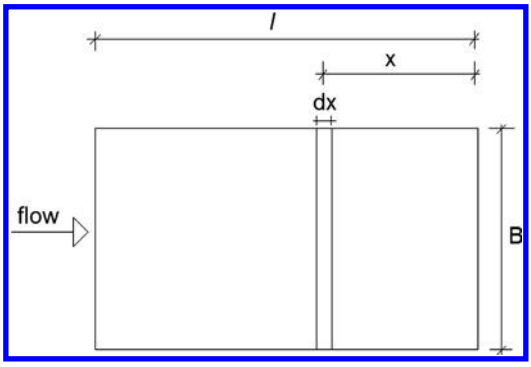

Figure 6. Diagram showing variables used in eq. 8.

$$m' = \frac{m}{A} \tag{7}$$

may now be derived as

$$N_t = Bm'\left(D_{50} + \int_{D_{50}}^{l} P(x)dx\right) \tag{8}$$

where B is the channel width, x is the longitudinal coordinate, starting at the downstream boundary of the protection and l is the total length of the protection (fig. 6). The first term in the right-hand side of equation (8) is due to the assumption that the most downstream particle will always reach the trap after dislodgement. The integral means the fraction of dislodged particles that will leave the protection and then will be collected in the trap. This fraction may be regarded as the probability that the length of the particle motion l_p be greater than its x coordinate.

Substituting (6) into (8) and solving the integral:

$$m' = \frac{N_t}{BD_{50}\left(1 + \frac{e^{(3.04\tau^* - 0.29)\left(\frac{l}{D_{50}} - 1\right)} - 1}{3.04\tau^* - 0.29}\right)} \tag{9}$$

Defining N' as the particle surface density:

$$N' = \frac{N}{A} \tag{10}$$

$$\frac{m}{N} = \frac{m'}{N'} \tag{11}$$

Substituting (11) into (9):

$$\frac{m}{N} = \frac{N_t}{N'BD_{50}\left(1 + \frac{e^{(3.04\tau^* - 0.29)\left(\frac{l}{D_{50}} - 1\right)} - 1}{3.04\tau^* - 0.29}\right)} \tag{12}$$

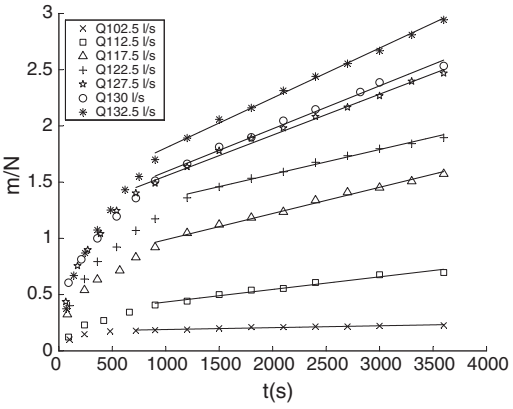

Figure 7. Time evolution of accumulated m/N values. Series 2.

Defining ϕ as

$$\psi = BD_{50}\left(1 + \frac{e^{(3.04\tau^* - 0.29)\left(\frac{l}{D_{50}} - 1\right)} - 1}{3.04\tau^* - 0.29}\right) \tag{13}$$

it results:

$$\frac{m}{N} = \frac{N_t}{\psi N'} \tag{14}$$

The values of N' were determined for each rock types by counting the number of surface particles contained in an area of known dimensions. Equation (14) provides the relation to convert measured N_t into relative number of entrainments in the riprap blanket.

4.3 *Time dependence*

As observed by other investigators (Shvidchenko and Pender 2000; Froehlich and Benson 1996) transport rates in experiments with a bed composed of dumped stones is not a constant but varies with time. The initial stages present a higher transport that asymptotically decreases to a steady value. Figure 7 shows the time evolution for series 2. The transport rates shown in this figure have been already converted to m/N values, where m represents the accumulated number of movements computed since the start of the experiment (since $t = 0$). This is the typical behavior observed in continuous bed experiments and corresponds to the process of reorganization of bed structure toward the more stable condition of "water worked" bed. The steady values of I reached after this reorganization will be used in this study for determining incipient motion. These values correspond to the slopes of the fitted lines in figure 7.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Transport rates in the case of non-continuous riprap protections also present higher values of I at the first stages of the experiments but gradually converges to a zero transport. This phenomenon may be explained by the dependence of transport rates on protrusion values, which vary significantly during the tests. Some authors have observed decreasing values of τ_c^* as particle protrusion increases (Fenton and Abbott 1977; James 1989; Coleman et al. 2003). During non-continuous experiments the erosion process reduces protrusion of the protection gradually increasing its stability. This behavior may be modeled by establishing a relation between the protrusion and the erosion rate. Herein we have assumed the potential relation:

$$\frac{dp}{dt} = -K(p - p_e)^a \tag{15}$$

where K and a are constants and p_e is the equilibrium protrusion, defined as the value of p for $t \to \infty$.

Integrating (15) and rearranging constants the expression describing the time evolution of protrusion may be written as:

$$p = K_2 (at - t + C_2)^{\frac{1}{1-a}} + p_e \tag{16}$$

The eroded thickness may be written as a function of the number of riprap particles dragged by flow:

$$e = \frac{N_t G}{\gamma_s (1 - \lambda) lB} \tag{17}$$

where γ_s is the particle specific weight and λ is the porosity of the material. The product $\gamma_s(1 - \lambda)$ will be called γ_b.

Therefore, protrusion may also be expressed as a function of the eroded thickness $e(t)$:

$$p(t) = p_o - e(t) \tag{18}$$

where p_o is the initial protrusion (at $t = 0$).

Substituting (16) and (17) into (18):

$$N_t = \left[-K_2(at - t + C_2)^{\frac{1}{1-a}} + p_o - p_e\right]\left(\frac{\gamma_b lB}{G}\right) \tag{19}$$

From (19) and (14):

$$\frac{m}{N} = \left[-K_2 (at - t + C_2)^{\frac{1}{1-a}} + p_o - p_e\right]\left(\frac{\gamma_b lB}{\psi G N'}\right) \tag{20}$$

Equation (20) was best fitted for all non-continuous tests (series 5 to 14). Figure 9 shows an example of fitting equation (20) with the experimental data from one of the tests of series 5.

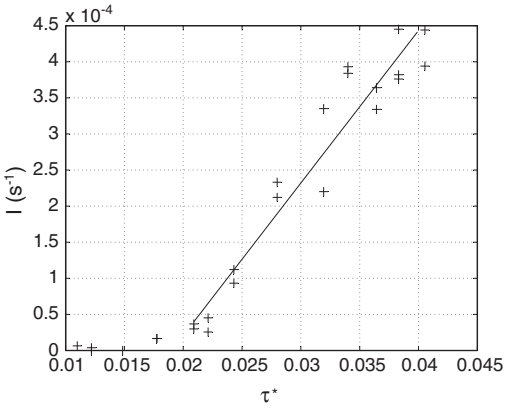

Figure 8. Estimation of critical shear stress. Series 2.

4.4 *Incipient motion estimation*

Following the criterion used by Shvidchenko and Pender (2000) critical shear stresses were determined as the bed shear stresses that produced an intensity of sediment motion $I = 10^{-4} s^{-1}$.

For continuous bed experiments I values were taken as those corresponding to the "water worked" situation by fitting straight lines of accumulated $\frac{m}{N}$ as a function of t once a constant transport rate was reached. Figure 7 shows the temporal evolution of accumulated $\frac{m}{N}$ and the fitted lines.

I values were then plotted against dimensionless bed shear stresses τ^* and a linear relation was fitted.

Bed shear stresses were calculated by

$$\tau = \rho v^* \tag{21}$$

where v^* is the shear velocity estimated for each test by fitting the logarithmic velocity profile

$$\frac{V}{v^*} = \frac{1}{K} ln\left(\frac{y}{y_o}\right) \tag{22}$$

A sensitivity analysis was carried out to determine the influence of datum level, deviations from logarithmic profiles in the outer flow region and the choice of using fitted or fixed values for y_o on shear velocities results. Results showed the best correlations when using data including part of outer flow layer and fitting both v^* and y_o.

Figure 8 shows the results for series 2.

In non-continuous experiments velocity profiles were measured at a point located 8 cm upstream from the protection where velocities may be assumed not disturbed by its presence. As a result, τ values may be considered representative of "mean" bed stresses (τ_o) rather than "local" stresses above the protection (τ_p). Although local stresses are the most suitable for

Copyright © 2006 Taylor & Francis Group plc, London, UK

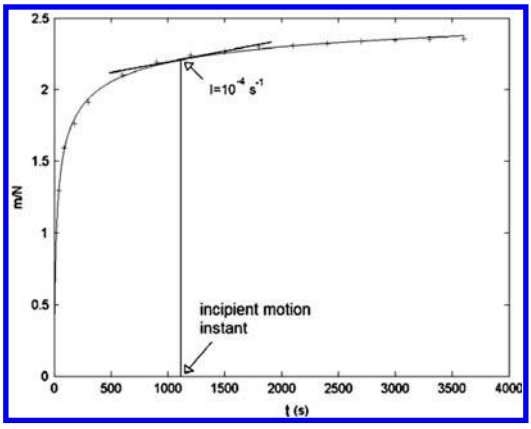

Figure 9. Determination of incipient motion instant. Series 5, $Q = 95\, ls^{-1}$.

describing the transport phenomenon in the protection, τ_o seem to be the most suitable variable for engineering applications.

For non-continuous protections, for a given value of τ_o, the intensity of sediment motion gradually decreases with time as the protection is being eroded. As a result, each value of $I(t)$ may be associated with a specific value of protection protrusion $p(t)$. The time derivative of (20) gives the function $I(t)$ and the time instant corresponding to incipient motion may be found by:

$$\frac{d\left(\frac{m}{N}\right)}{dt} = I(t) = 10^{-4} \tag{23}$$

Figure 9 illustrates the instant corresponding to $I = 10^{-4} s^{-1}$. The protrusion corresponding to the incipient motion (p_c) is finally calculated using (16).

5 RESULTS

Figure 10 illustrates the relation between the critical protrusion p_c, made dimensionless with D_{50}, and τ^* for series 5, 6, 7 and 8. These series have the same value of $l/D_{50} = 4$ and $p_o/D_{50} = 0.95$ but each of them corresponds to one of the four rock types presented in table 1.

Results show that dimensionless shear stresses values for "complete stability" ($p_c = p_o = 0.95 D_{50}$) are about 10% of Shields critical stresses found in the bibliography. For increasing τ^* values there is a linear reduction of critical protrusion values. For $\tau^* \simeq 0.016$ the critical protrusion is $p_c \simeq 0$. In other words the bed sill is "swept" to the general bed level.

The influence of the relative length on incipient motion conditions is shown in figure 11. This figure shows data of series with different relative lengths but

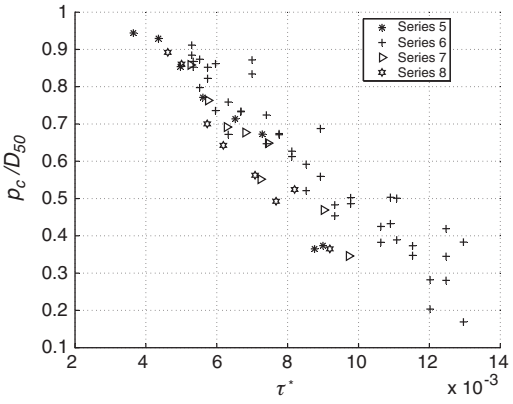

Figure 10. Critical protrusion for series 5, 6, 7 and 8.

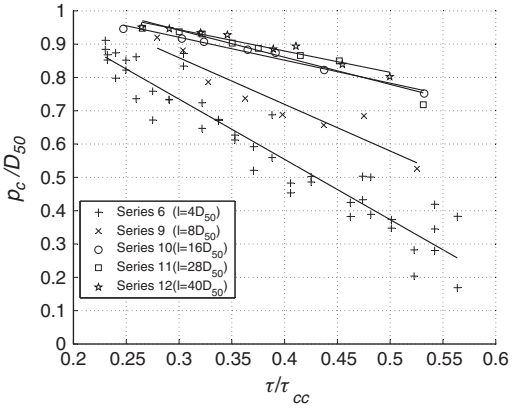

Figure 11. Analysis of the influence of relative length on critical protrusion values.

the same values of both p_o and D_{50}. Values of p_c/D_{50} are plotted against shear stresses, made dimensionless with critical shear stresses found for continuous protection tests (τ_{cc}). Fitted linear relationships corresponding to each series are also plotted. Data from series 6 is used both in figure 10 for protrusion effect and in figure 11 for length effect.

From figure 11 we observe that as the relative length increases, stability is significantly enhanced. For a fixed value of critical relative protrusion, say $p_c/D_{50} = 0.8$, shear stresses for a relative length $l/D_{50} = 16$ is almost twice the corresponding value for $l/D_{50} = 4$. For relative lengths greater than $l/D_{50} = 16$ this variable seems to have no influence on incipient motion conditions. The last observation confirms the intuitive idea that as the protection becomes longer it tends to behave as a continuous protection.

Fitted lines for series 10, 11 and 12 all have approximately the same slope, which is milder than those

Copyright © 2006 Taylor & Francis Group plc, London, UK

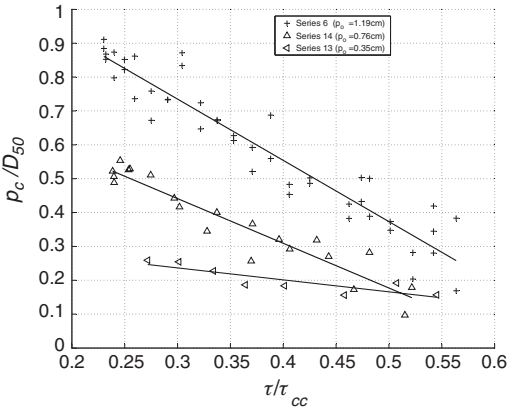

Figure 12. Analysis of the influence of initial values of relative protrusion on incipient motion conditions.

corresponding to series 6 and 9. This demonstrates that critical protrusion of a larger protection is less sensitive to shear stresses. Another feature in figure 11 is the fact that all the fitted lines intersect $p_c = p_o = 0.95D_{50}$ for τ/τ_{cc} around 0.2 (i.e. 20% of critical shear stress for a continuous revetment).

The influence of initial protrusion is analyzed in figure 12. This figure presents three series of experiments with different values of initial protrusion p_o but with the same values of l and D_{50}. Figure 12 demonstrates that designing protections with protrusion values corresponding to the "stable zone" of figure 11 does not ensure that no motion will occur. Even for very low initial protrusions some displacements were recorded. In other words, the equilibrium of a higher bed sill after 1 hour of flow does not imply that a bed sill with this initial height is stable under the same flow. For practical purposes, the idea of a sacrifice thickness to take this into account is recommended.

6 CONCLUSIONS

An experimental investigation on the effect of geometrical variables on shear failure of riprap protections has been presented.

Complete stability (no motion) of a non-continuous riprap protection requires shear stresses values about 10% of Shields critical values usually found in bibliography and approximately 20% of critical values determined in this paper for a continuous riprap bed.

Increasing the length of the protection significantly increases its stability. On the other hand for relative lengths greater than $l = 16D_{50}$ it appears that this variable has no effect on incipient motion conditions.

Although all tests with non-continuous protections reached a stable protrusion for a given shear stress, this value does not assure that no motion will occur. Particle losses were recorded even for initial protrusion values much lower than those corresponding to p_c in tests with higher p_o using the same shear stresses.

ABSTRACT: An integrated hydrodynamic-sedimentologic-morphological model is proposed to deal with the morphological evolution of channel cross-sections in practical situations. While based on a physically sound formulation, efficiency is attained by considering only the relevant physical mechanisms, in view of the geometric scales of the water course, and the time scale of the observer. Its performance is assessed through specific validation tests for the different mechanisms. A numerical experiment is undertaken.

1 INTRODUCTION

Water courses that develop on alluvial material show a changing morphology, determined by the variable water current action. Variations are observed in both the channel depth (bottom evolution) and width (bank evolution). Water acts on the channel boundaries by exerting a shear stress, which depends on the flow velocity. In curved channels, in addition to the longitudinal velocity component, a transversal component also exists, constituting the so called secondary currents.

To numerically simulate these processes, it is necessary to formulate an integrated hydrodynamic-sedimentologic-morphological model. This formulation is conditioned by the geometric scales of the water course, and the time scale of the observer. In this paper, such a model is presented, valid for practical values of those scales.

2 MODEL FORMULATION

2.1 *Hydrodynamic model*

For an open-channel flow problem, we can distinguish locally three 'natural' spatial coordinates: one along the flow direction (longitudinal), a second one in the horizontal plane and across the flow direction (lateral), and a third one in the vertical direction (assuming a mild channel slope). We will consider that, as usual, the characteristic scales are very different in those three spatial directions, allowing for some simplifications. In the first place, it will be assumed that the longitudinal scale of interest (the scale of the observer) is much larger than the transversal dimensions of the cross section, i.e.,

$$L_{ox} \gg \hat{B}, \hat{h} \tag{1}$$

where $\hat{B}$ is a scale for the channel width, $\hat{h}$ a scale for the water depth, and L_{ox} is the longitudinal spatial scale of the observer, which is calculated as (Menéndez 2003) $L_{ox} \equiv \hat{U}\hat{T}$, with $\hat{U}$ being a scale for the longitudinal flow velocity, and $\hat{T}$ the observer time scale. Condition (1) means that the problem can be treated with the 1D approximation (Menéndez 2003), i.e., that the longitudinal variation of the cross-sectional mean flow velocity can be calculated independently of the transversal variation of the flow velocity, using a 1D Longitudinal Model as the well known Saint Venant Equations (Jain 2001).

In the second place, the cross section will be considered as shallow:

$$\hat{B} \gg \hat{h} \tag{2}$$

As a consequence of condition (2), the lateral distribution of flow velocity, if needed, can be determined independently of the vertical distribution.

In the third place, it will be assumed that the lateral spatial scale of the observer L_{oy}, which is calculated as (Menéndez 2003) $L_{oy} \equiv (\hat{\varepsilon_y}\hat{T})^{1/2}$, with $\hat{\varepsilon_y}$ being a scale

Copyright © 2006 Taylor & Francis Group plc, London, UK

for the lateral diffusivity, is at most of the same order of the lateral dimension of the cross section, i.e.,

$$L_{oy} \tilde{<} \hat{B} \tag{3}$$

As a consequence of (3), it is pertinent to calculate the lateral distribution of the longitudinal flow velocity (Menéndez 2003), which may be obtained from a 1D Lateral Model, such as the Lateral Distribution Method (LDM) proposed by Wark et al. (1990):

$$ghI_x - \frac{B_g f}{8} U^2 + h \frac{\partial}{\partial y}\left[\varepsilon_y \frac{\partial U}{\partial y} \right] = 0 \tag{4}$$

where y is the lateral coordinate measured from the right bankline, $h(y)$ the local flow depth, $U(y)$ the vertically averaged local longitudinal flow velocity, I_x the longitudinal flow slope (obtained from the 1D Longitudinal Model), and f the Darcy-Weisbach friction factor; B_g is a geometrical factor and ε_y the lateral eddy viscosity; they are given by

$$B_g = \sqrt{1 + \tan^2\alpha + \tan^2\omega}\,, \quad \varepsilon_y = \chi U_* h \tag{5}$$

where α is the angle of the longitudinal channel slope, ω the angle of the lateral channel slope (Figure 1), χ the dimensionless lateral eddy viscosity coefficient (taken as 0.25), and $U_* = \sqrt{\tau_b}$ the shear velocity, with τ_b being the kinematic bottom shear stress, which is parameterized as

$$\tau_b = \frac{1}{8} f B_g U^2 \tag{6}$$

As boundary conditions for eq. (4), the free-slip condition may be imposed:

$$\left.\frac{dU}{dy}\right|_{\text{bankline}} = 0 \tag{7}$$

which physically means that the wall boundary layers by the banklines are not solved.

For the present applications, the non linear ordinary differential equation (4) is solved numerically. It is discretized using a centered finite difference scheme. The resultant non linear algebraic system is solved by means of the Newton-Raphson method.

As a consequence of curvature, in addition to the longitudinal flow velocity there are transversal components, which constitute the secondary flow. In particular, the lateral velocity component at the bottom, $u_r(y)$, is of relevance for bed load transport. It has been determined from the parametric vertical velocity profile model of Kikkawa et al. (1976), which assumes

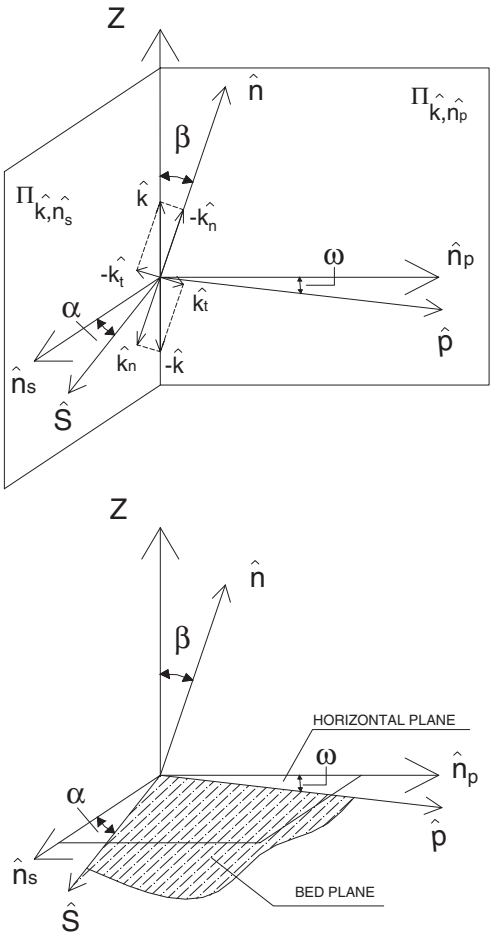

Figure 1. Geometrical parameters.

that the radius of curvature of the channel is much larger than its width. The expression is the following:

$$u_r = \frac{U^2}{\bar{U}} \frac{h}{r} \frac{1}{\kappa} \left(4.167 - 2.640 \frac{1}{\kappa} \frac{\bar{U}_*}{\bar{U}} \right) \tag{8}$$

where $\bar{U}$ and $\bar{U}_*$ are the transversally-averaged longitudinal flow velocity and shear velocity, respectively, $r = r(y)$ the radius of curvature, and κ von Karman constant (≈ 0.4).

At the banklines it must hold the impenetrability condition

$$u_{rb}\big|_{\text{bankline}} = 0 \tag{9}$$

The transition between the parametric model value, given by eq. (8), and the bankline value, eq. (9), is

Copyright © 2006 Taylor & Francis Group plc, London, UK

taken into account by means of a modulating function, or mask, $M(y)$, with the following form:

$$M(y)=\begin{cases}1-\left(\dfrac{\delta-y}{y}\right)^{1/2} & \text{if } 0\le y\le\delta\\ 1 & \text{if } \delta\le y\le B-\delta\\ 1-\left(\dfrac{\delta+y-B}{\delta}\right)^{1/2} & \text{if } B-\delta\le y\le B\end{cases} \tag{10}$$

where B is the channel top width, and δ the bank boundary layer thickness, which is proposed to scale with the near-bank depth h_b, i.e.

$$\frac{\delta}{h_b}=\kappa_b=const. \tag{11}$$

where the value of κ_b is to be determined from experimentation. Hence, the lateral bottom flow velocity component is given by

$$u_{rb}(y)=M(y)u_r(y)\big|_{\text{model}} \tag{12}$$

2.2 *Sediment transport model*

Kovacs & Parker (1994) model, based on force balances, is used. In the first place, the forces acting on a sediment particle are considered: the drag force due to the moving fluid, which is the driving mechanism; the component of the immersed weight of the particle tangential to the plane of the bed, that also constitutes a driving force; and the dynamic Coulomb resistive force, which represents the momentum loss due to collisions. The following equation follows:

$$\left|\vec{u}_\Delta^*\right|\vec{u}_\Delta^*=a\tau_{C0}^*\left(\left|\vec{k}_n\right|\hat{t}_{v_p}-\frac{\vec{k}_t}{\mu_C}\right) \tag{13}$$

where $\vec{u}_\Delta=\vec{u}_b-\vec{v}_p$, with $\vec{u}_b$ and $\vec{v}_p$ being the bottom fluid velocity and the particle velocity, respectively, $a\equiv(\vec{u}_b/U_*)^2$, τ_{C0}^* is the dimensionless shear stress (or Shields parameter) for initiation of motion on a flat bottom, $\hat{t}_{v_p}\equiv\vec{v}_p/|\vec{v}_p|$ the versor in the direction of the particle velocity, μ_C the dynamic Coulomb friction factor, and $\vec{k}_n$ and $\vec{k}_t$ the components of the vertical versor, pointing downwards, along the normal and transversal directions to the bottom, respectively. The fluid velocity can be expressed as

$$u_b=\varepsilon U\,\hat{s}\;+\;u_r\sqrt{1+\cos^2\alpha\tan^2\omega}\;\hat{p}' \tag{14}$$

where $\hat{s}$ is the versor in the longitudinal direction of motion, $\hat{p}'$ the versor on the plane tangent to the bottom and normal to $\hat{s}$, and ε the relation between the longitudinal component of the bottom velocity and the mean transversal velocity U.

To solve eq. (13) for the sediment particle velocity, it is proposed to split it into components, by multiplying it alternatively by versors $\hat{s}$ and $\hat{p}'$, obtaining

$$\begin{aligned}\left|\vec{u}_\Delta^*\right|\left(u_{bs}^*-v_p^*\cos\psi\right)-a\tau_{C0}^*\left(\left|\cos\beta\right|\cos\psi-\frac{\sin\alpha}{\mu_C}\right)=0\\ \left|\vec{u}_\Delta^*\right|\left(u_{bp}^*-v_p^*\sin\psi\right)-a\tau_{C0}^*\left(\left|\cos\beta\right|\sin\psi-\frac{1}{\mu_C}\frac{\sin\omega\cos^2\alpha}{\sqrt{\sin^2\omega\cos^2\alpha+\cos^2\omega}}\right)=0\end{aligned} \tag{15}$$

where

$$\left|\vec{u}_\Delta^*\right|=\left(u_{bs}^{*2}+u_{bp}^{*2}+v_p^{*2}-2u_b^*v_p^*\cos\psi-2u_{bp}^*v_p^*\sin\psi\right)^{1/2}, \tag{16}$$

$v_p=|\vec{v}_p|$, ψ is the angle between the velocity vector and the s direction, and the asterisc indicates dimensionless velocities, with the scale $\sigma\equiv\sqrt{Rgd}$, being R the relative grain density, which diameter is d. System (15) is solved by means of Newton-Raphson method, to obtain the two unknowns v_p^*, and ψ.

The dimensionless vectorial volume bedload sediment transport rate per unit normal width (made dimensionless with the scale $d\sigma$) is calculated as

$$\vec{q}_b^*=\xi^*\vec{v}_p^* \tag{17}$$

where ξ^* is the dimensionless volume of particles participating in bedload transport. To obtain this volume, Kovacs & Parker (1994) perform a momentum balance for the bed layer. The generalization of their formulation to include curvature effects leads to

$$\xi^*=\frac{\tau_b^*-\tau_C^*}{\left(\mu_C\left|\vec{k}_n\right|\hat{t}_{v_p}-\vec{k}_t\right).\hat{s}'} \tag{18}$$

where $\hat{s}'=\cos\alpha_s\,\hat{s}+\sin\alpha_s\,\hat{p}'$,

$$\tau_b^*=\frac{\varepsilon^2U^2}{aRgd\cos\alpha_s} \tag{19}$$

is the bottom shear stress, and τ_C^* is the dimensionless critical shear stress for initiation of motion. This is obtained by specializing (13) for critical conditions. Taking into account curvature effects, and squaring it, we obtain

$$\left(\frac{\tau_{Cs}^*}{\tau_{C0}^*}\right)^2+\frac{2}{\mu_C}\frac{\vec{s}_p.\vec{k}_t}{s_p^2}\frac{\tau_{Cs}^*}{\tau_{C0}^*}+\frac{1}{\mu_C^2}\frac{k_t^2}{s_p^2}-\cos^2\beta=0 \tag{20}$$

where $\vec{s}_p\equiv\sqrt{1+\tan^2\alpha_s}(\hat{s}+\tan\alpha_s\hat{p}')$, which physically meaningful solution is

$$\frac{\tau_{Cs}^*}{\tau_{C0}^*}=-\frac{1}{\mu_C}\frac{\vec{s}_p.\vec{k}_t}{s_p^2}+\sqrt{\cos^2\beta+\frac{1}{\mu_C^2}\left[\left(\frac{\vec{s}_p.\vec{k}_t}{s_p^2}\right)^2-\frac{k_t^2}{s_p^2}\right]} \tag{21}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.3 *Morphologic model*

The channel bottom evolution is calculated through Exner equation, which arises from the sediment mass conservation condition (Raudkivi 1990):

$$\frac{\partial z_0}{\partial t}+\frac{1}{1-\lambda}\left[\frac{1}{r}\frac{\partial}{\partial y}\left(rq_{by}\right)+\frac{\partial q_{bx}}{\partial x}\right]=0 \qquad (22)$$

where z_0 is the bed elevation, t the time coordinates, λ the porosity of the bottom sediment, q_{bx} and q_{by} the total stream-wise (longitudinal) and lateral volumetric sediment load per unit width, respectively, and where no suspended sediment load is considered.

For the present applications, uniform longitudinal conditions are assumed, i.e., $\partial/\partial x = 0$. Hence, eq. (22) was discretized by means of a simple explicit centered finite-difference scheme:

$$\frac{\left[z_0\right]_j^{n+1}-\left[z_0\right]_j^n}{\Delta t}+\frac{\left[r\right]_{j+1/2}^n\left(\left[q_{by}\right]_{j+1}^n-\left[q_{by}\right]_j^n\right)-\left[r\right]_{j-1/2}^n\left(\left[q_{by}\right]_j^n-\left[q_{by}\right]_{j-1}^n\right)}{(1-\lambda)\left[r\right]_j^n\Delta y^2}=0 \qquad (23)$$

where n is the time coordinate index, and j the spatial coordinate index.

Non-cohesive bank erosion is taken into account through the following algorithm, which assumes that the water level is equal to the streambank level (bankfull conditions):

a) After each calculation step, the bank slope at the two border nodes of the calculation domain (in the following, bank-nodes), are determined.
b) If the slope is lower than the critical value, given by the condition $\tan\omega_C = \mu_C$, no action is taken.
c) On the contrary, if the slope is equal or higher than the critical value, a local "slide" process is considered: the bank-node height is lowered so as the slope becomes critical, and a new node (with the streambank level) is added to the calculation domain (towards the exterior of the channel) to represent the new bank location (i.e., it becomes the bank-node for the next time step). To account for mass conservation, the slide volume is next distributed among nodes adjacent to the bank.

If a cohesive stratum exists on top of the non-cohesive bank, the retreat of the latter produces undermining of the former, leading eventually to cantilever type failure. A geotechnical stability analysis is performed which, following Darby & Thorne (1996), includes the effects of positive pore water pressure in the saturated portion, negative pore water pressure in the unsaturated portion, and hydrostatic confining pressure due to the water level in the river, considering a relatively general bank profile geometry. A planar failure type is supposed, common for streambanks destabilized by severe bed degradation (Darby et al. 2000), with the failure plane passing through the top point of the non-cohesive portion of the bank. All possibilities, regarding the relative elevations of water surface, phreatic surface, and tension crack depth are considered, as pointed out by Darby & Thorne (1996), but properly adapted to deal with this specific failure type, as schematized in Figure 2. A search is performed, sweeping the possible fail angle range. Once the safety factor falls below one, the angle corresponding to the minimum cohesion is selected as the fail angle.

The computational treatment of the cohesive stratum is very simple: two nodes (per bank) are used to define it, as shown in Figure 3 as open circles (a third node will be used in the future to indicate the tension crack depth). When a failure is assumed, the bottom node is moved to coincide with the extreme node of the non-cohesive base (black circle), while the top node is located so as to define the failure angle.

The coarse fraction of the failure material is considered to fall at the bank toe, and distribute laterally according to its angle of repose (Figure 4), as proposed by Darby et al. (2002), while the fine fraction is supposed to incorporate to the wash load, and hence ignored. An ad-hoc algorithm was devised to perform the coarse failure material distribution. This material is then treated as non-cohesive material of a mean grain diameter different from that associated to the bottom sediment.

3 VALIDATION

3.1 *Validation strategy*

In order to validate the proposed integrated model, the effects of the main erosion mechanisms are tested separately, comparing the model predictions with existing experimental data and/or previous calculation results. In the first place, a straight channel with non-cohesive banks is considered, so as to check that the methodology can successfully deal with the original problem of Kovaks & Parker (1994). In the second place, a curved, fixed banks channel is taken, where the incorporated secondary flow effects are validated. For both cases, uniform longitudinal conditions are assumed, i.e., $\partial/\partial x = 0$. The time evolution of the channel cross section is analyzed. In the third place, the cohesive stratum failure algorithm is tested. The validation of the procedure for the treatment of the failure material is still under way.

3.2 *Straight channel with non-cohesive banks*

The experiments performed by Ikeda (Kovacs & Parker 1994) are chosen as the first validation test. The channel is straight, prismatic, and symmetric, with a 0.220 m base width, and a longitudinal slope of 0.00215. The initial channel cross section is

Copyright © 2006 Taylor & Francis Group plc, London, UK

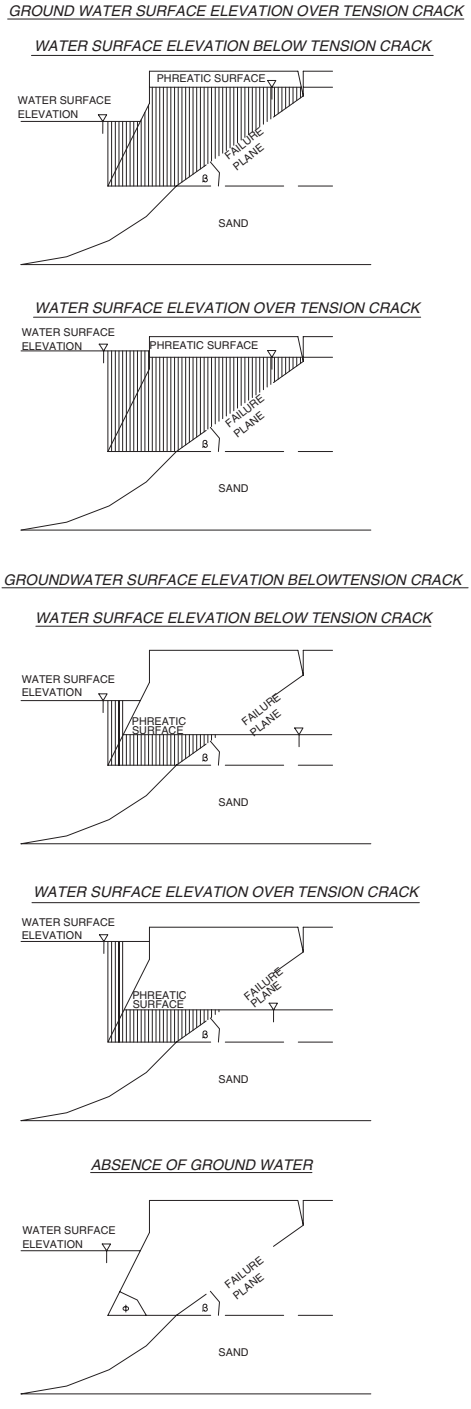

Figure 2. Bank failure cases.

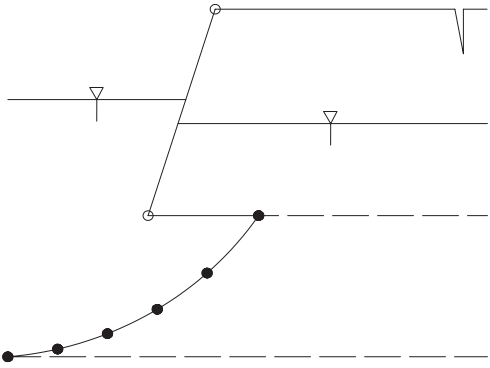

Figure 3. Cohesive-bank nodes (open circles).

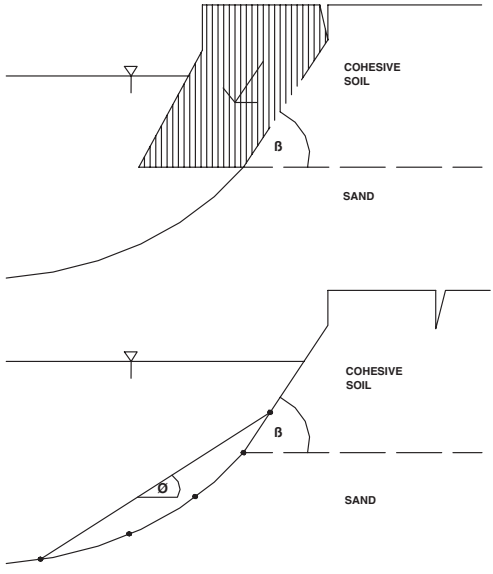

Figure 4. Distribution of failure material.

trapezoidal, with bottom and banks made of sand, with mean diameter $d_{50} = 1.3$ mm. The initial depth was 0.061 m The model parameters were fixed at the values used by Kovacs & Parker (1994). The initial lateral model domain was discretized into 100 intervals, resulting a spatial step $\Delta y = 0.00438$ m. The temporal step was chosen as $\Delta t = 1$ second, which produces a bed elevation change no larger than 1 mm per time step, thus providing enough accuracy to the solution, while preserving numerical stability.

Figure 5 presents the comparison for the (right half-) channel cross section evolution between the present numerical results and the ones obtained by Kovacs & Parker (1994), identified as K&P in the figure. The latter authors used a 2D transversal hydrodynamic model,

Copyright © 2006 Taylor & Francis Group plc, London, UK

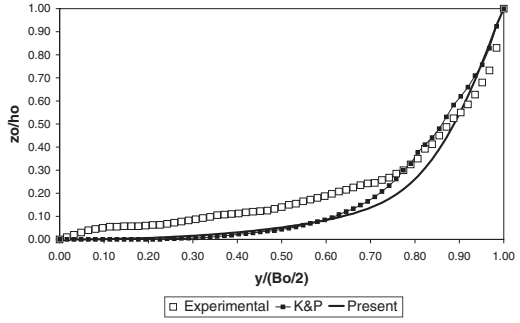

Figure 5. Comparison between K&P and present model results, for the cross section evolution.

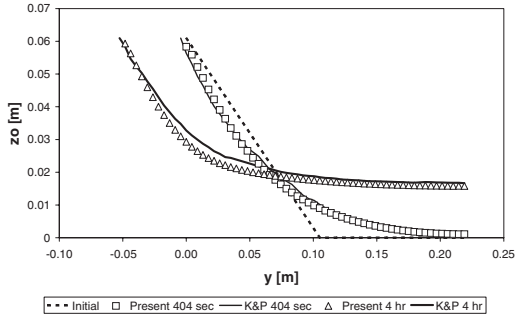

Figure 6. Comparison among K&P, present model results, and experimental results, for the cross section form after 12 hours.

i.e., they did not decouple the vertical and lateral directions of motion, and took into account the vertical velocity component, which lead to a more complex calculation procedure. Additionally, they pushed the validity of their bed load transport model beyond the water surface, to account for sediment delivery from the dry bank. The very satisfactory agreement between the two solutions observed in Figure 5 indicates that the present simpler, but physically sound, approach is good enough to capture all the relevant phenomena.

In Figure 6 the normalized (left half-) channel profile (B_o is the initial bottom width, and h_o the initial centerline depth) according to both models and Ikedas's experimental results, are presented. It is observed that K&P model seems to capture more accurately the bank slope, which could be due to their more elaborated hydrodynamic and bank erosion model. The deviations of the model results from experimental data in the bottom zone are thought to be due to the presence of bottom forms, not included in the present theory.

Similar comparisons are presented in Figure 7 for the time evolution of the top width W and centerline depth h, relative to their initial values (W_o is the

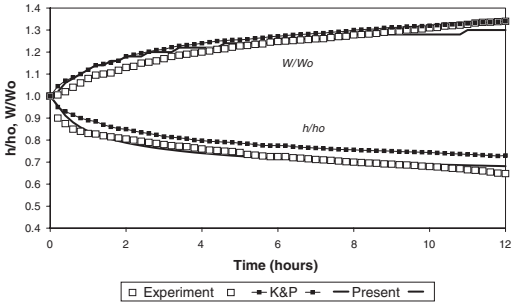

Figure 7. Comparison among K&P, present model results, and experimental results, for the top width and depth evolution.

initial top width). In the case of the top width, it is observed that the present approach, which gives stair-like responses due to the impulsive nature of the bank erosion algorithm, follows the trend of K&P results, with both of them overestimating the experimental rate of increase at the initial stages, but improving the agreement as time flows. Regarding the centerline depth evolution, the present model provides a better overall agreement with experimental results.

3.3 *Curved channel with fixed banks*

The second validation test refers to the experiments performed by Kikkawa et al. (1976). The experimental apparatus was a curved open channel, with vertical rigid walls, bed width $B_o = 1$ m, longitudinal bottom slope $I_x = 0.002$, initial uniform depth $h_o = 0.063$ m, sand bed with $d_{50} = 0.9$ mm, and curvature radius varying from 4 m at the inner bank to 5 m. at the outer one. The flow discharge was 30 l/s.

The channel width was represented with 100 intervals, which gives a spatial step $\Delta y = 0.01$ m. A temporal step $\Delta t = 1$ second was taken, which produces a bed elevation change no larger than 1 mm per time step, keeping the numerical solution accurate enough.

Taking as bank- depth h_b the one corresponding to the node adjacent to the bank-node, the best results were obtained for $\kappa_b = 420$.

Figure 8 shows the comparison between model predictions and experimental data, using Kikkawa et al. (1976) lateral velocity model, which in the following will be called, for simplicity, Kikkawa model. The agreement is considered as satisfactory, in view that the model represents the correct evolution trend and gives the right magnitude of the bottom height change. The most significant qualitative and quantitative departures occur close to the left bank ($y/W_o \approx 1$).

3.4 *Failure of cohesive stratum*

The third validation test consisted in comparing the failure angle of the cohesive stratum as predicted by the

present model and Darby et al. (2000) model (the computer program was kindly made available to the authors by request), for the particular case of the failure plane passing through the toe of the stratum (the only matching situation between the two models). The stratum height was taken as 5.86 m, with an initially practically vertical bank slope (89°), in order to guarantee unstable conditions, and a tension crack depth of 2 m. The soil parameters were selected as follows: cohesion = 14.9 kN/m^2, friction angle = 29°, and specific weight = 20.9 kN/m^3. For two phreatic surface depths (relative to the streambank level), different water surface depths were used. Table 1 shows the comparisons between the results obtained from both models. It is observed that the fail angles provided by the two models are very similar, so the present formulation is considered as validated, taking into account that some truncation errors occur during the angle searching.

4 NUMERICAL EXPERIMENT

A numerical experiment was performed for an initially very unstable straight channel, with a trapezoidal form 22 m wide, 9 m deep, and 20° bank slopes. The non-cohesive base stratum has $d_{50} = 0.130$ mm and a friction angle of 20°, while the cohesive stratum (at

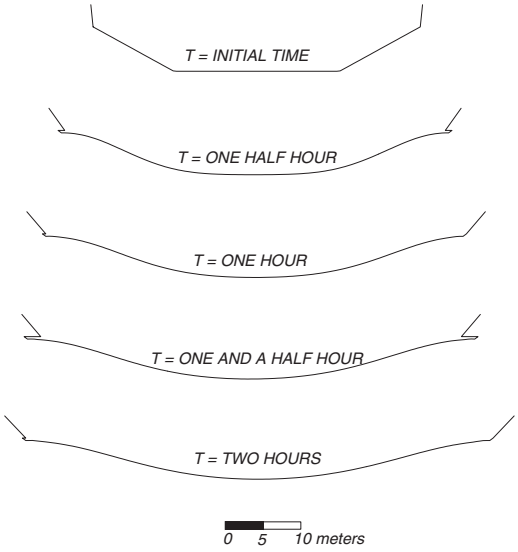

Figure 9. Cross-sectional (undistorted) form for different instants of time.

both banks) is 3 m thick, with cohesion 20 kN/m^2. The spatial step is 0.43 m, while the time step amounts to 1 second.

The channel cross-sectional form evolves very fast during a single day, increasing its width about three times, and reducing its depth to about half the initial value. Figure 9 shows the cross-section form for different instants of time. It is observed how the widening process proceeds through undermining and failure of the cohesive strata, while the non-cohesive base flattens, with its bottom level growing. The failure material is not considered. The small asymmetry observed between the two banks is due to round-off errors, which sometimes trigger bank failure with a difference of one computational time step.

As an illustration, Figure 10 presents a detail of the undermining process, till failure, for the right bank.

5 CONCLUSIONS

The integrated hydrodynamic-sedimentologic-morphological model proposed in the present paper constitutes an efficient tool to deal with the morphological evolution of channel cross-sections in most practical situations, i.e., while based on a physically sound formulation, it preserves simplicity by considering only the relevant physical mechanisms. The treatment of the non-cohesive bank base and the cohesive bank upper stratum has been validated separately, thus expecting

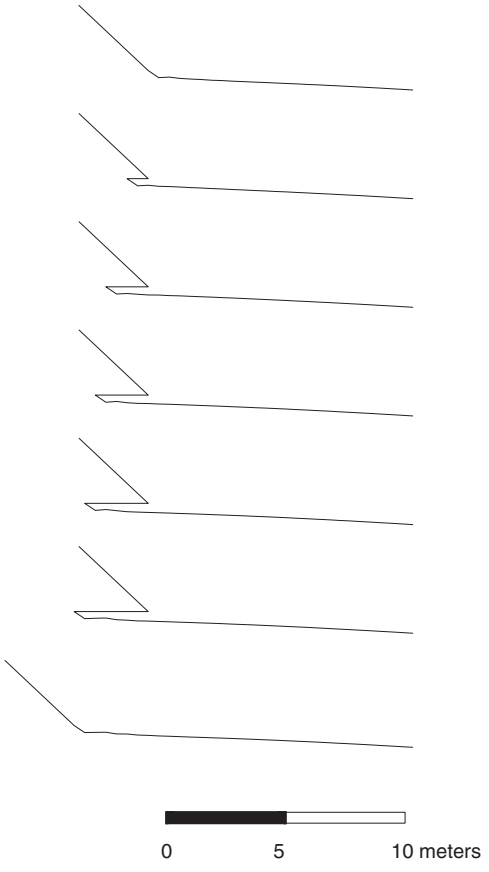

Figure 10. Undermining process for the right bank. Cross section each half hour, since 16.5 hours after start.

that their combined action performs well. Work is still under way to incorporate the failure material.

Bend scour reduction and flow pattern modification by an outer bank footing

M. Roca & J.P. Martín-Vide
Department of Hydraulic Engineering, Technical University of Catalonia (UPC), Barcelona, Spain

K. Blanckaert
ICARE-ENAC, Ecole Polytechnique Fédérale, Lausanne, Switzerland

ABSTRACT: This paper investigates in an experimental flume the efficiency of scour reduction and bank protection near the outer bank in open-channel bends by means of a horizontal foundation, called footing, protruding into the flow. Comparison of experiments with and without footing under similar hydraulic conditions convincingly demonstrates the efficiency of this bank protection technique: a maximum scour reduction of more than 40% was obtained with an optimal choice of the footing width and elevation. The scour reduction by the footing is attributed to two phenomena: (i) the development of a transversal bed slope is attenuated; (ii) the outward velocity redistribution by the secondary flow is attenuated.

1 INTRODUCTION

Embankments are designed to confine the flood flows. Therefore, bank scour and failure can lead to devastating inundations that endanger property and cause important damage, especially in urbanized areas. The protection of river banks against erosion is essential but very costly.

The interaction between the main downstream flow component, the secondary flow and the bed topography leads to an increased erosive attack on the outer bank in open channel bends. Secondary flow induced by streamline curvature, also called helical flow or spiral flow, is a characteristic feature of flow in open-channel bends (Rozovskii 1957, Engelund 1974, Struiksma et al. 1985, Blanckaert & de Vriend 2004). By advecting momentum, it redistributes the downstream velocity and causes it to increase/decrease in the outer/inner part of the cross-section (Blanckaert & Graf 2004), hence also an increased/decreased erosive capacity of the flow. Moreover, the secondary flow transports sediment from the outer to the inner part of the cross-section and thereby creates the typical bar-pool bed topography in alluvial bends (Whiting & Dietrich 1993, Odgaard 1982, Yalin & Ferreira 2001).

Thus, outer banks in river bends need to have a more resistant scour protection and a deeper foundation than straight river banks. Several techniques are reported in literature to reduce the attack and the scour on the outer bank. Groynes direct the flow towards the center of the channel and promote sedimentation near the bank (Przedwojski et al. 1995). Submerged vanes counteract the secondary flow and reduce bend scour but create obstacles in the river (Odgaard & Mosconi 1987). Macro-roughness elements at vertical outer banks frain the flow velocity adjacent to the bank and reduce bend scour (Hersberger 2002).

This paper considers rigid horizontal footings as a part of vertical outer banks, and aims at optimizing the footing width, b and depth, z_f (Fig. 1). This type of protection is especially relevant in urban environments

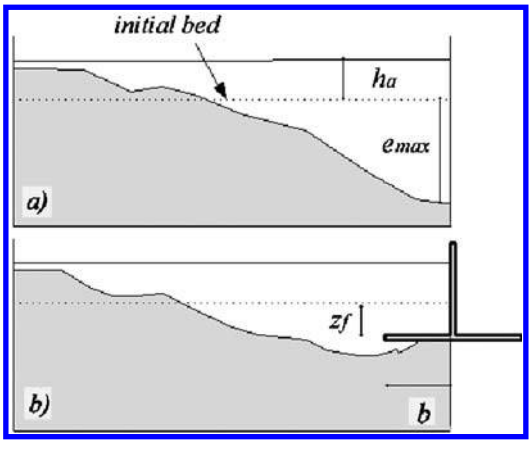

Figure 1. (a) Typical bed topography in a cross section of a river bend; (b) Reduction of bed scour by an optimally designed bank footing.

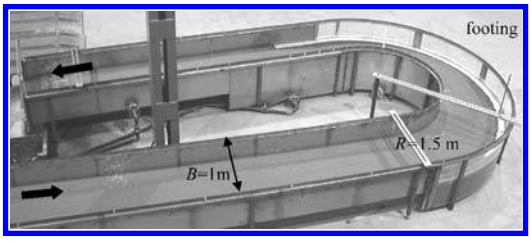

Figure 2. Laboratory flume with the footing on the outer bank (at the University of Castilla-La Mancha).

where vertical banks are imposed by space limitations or preferred by their visual aspect.

Figure 1 illustrates the principles underlying the optimal design of the bank footing. Figure 1a shows the typical bed topography in the cross section of a river bend without outer bank protection. An outer bank foundation below the maximum scour depth, e_{max}, is unconditionally stable, but over conservative. An optimal choice of the footing width and elevation can lead to a reduction of the maximum scour depth (Fig. 1b), and thus a more economical bank protection. Moreover, the flow depth is more homogeneous over the width of the river.

The aim of this paper is to investigate changes of bed topography due to the presence of the bank footing and the mechanisms underlying the protective effect of the outer bank footing, by comparing the patterns of downstream flow, secondary flow, turbulence and bed topography. More details and extended data are reported in Roca (2003) and Roca et al. (in prep.).

2 THE EXPERIMENTS

The experiments were carried out in a single bend laboratory flume of constant width, $B = 1$ m, consisting of a straight 9 m long inflow reach followed by a 186° bend with constant radius of curvature, $R = 1.5$ m, and a straight 5 m long tailwater reach (Fig. 2). The bed was composed of a quasi-uniform natural sand with a mean diameter of $D_{50} = 1.65$ mm and a geometric standard deviation, $(D_{84}/D_{16})^{1/2}$, equal to 1.26.

The A1 reference experiment was carried out without footing. Subsequently, experiments were carried out with different footing configurations (z_f, b) but under similar hydraulic conditions. The footing on the outer bank was made of 1 cm thick PVC plate rigidly fixed to the bank. The footing was installed in the bend reach and extended over a length of $0.75B$ in the straight tailwater reach.

The hydraulic conditions are the same for all the experiments: $Q = 0.042$ m^3/s, $h_a = 0.098$ m and $U_f = 0.39$ m/s. A horizontal flat bed and a free fall tailwater are the initial conditions in all experiments. For a constant discharge, the bed topography will deform due to bend effects, but ultimately reach equilibrium allowing the univocal definition of the maximum scour depth, e_{max}, in the river bend. All experiments were continued until the equilibrium scour depth was attained.

Water discharge was measured by a thin-plate V-notch weir upstream of the flume.

Bed and water surface elevations were measured with point gauges installed on a carriage on top of the flume walls, which were accurately levelled to be used as a datum. Additional staff gauges were used at the outer bank to track the bed and water surface. Bed elevation under the footing was measured after carefully removing the PVC plate.

Velocities were measured in detail in tests A1 and B4 with an acoustic Doppler velocimeter (ADV) developed by Nortek. Data of the 3D flow structure was collected at several verticals (located every 10 cm across the channel width) of different cross-sections (each 10° or 20° from $\theta = 20°$ to 100°). Vertical distance between points from the same profile was about 1 to 3 cm, depending on the local water depth. The sampling rate was 25 Hz and 4500 data were collected for each point.

The adopted ADV configuration does not allow measuring inside a flow region of 5 cm near the water surface. The computation of depth-averaged velocities requires extrapolations inside this region. The increased uncertainty in the depth-averaged velocities due to these extrapolations does not alter the conclusion of this research.

3 BED TOPOGRAPHY

The influence of the footing design on bend scour is investigated by varying the footing's vertical depth, z_f, and width, b. An outer bank foundation below the maximum scour depth without bank protection, $e_{max,A1}$, is unconditionally stable but over conservative. Vertical depths tested range between the position of the initial flat bed ($z_f/e_{max,A1} = 0$) and the ultimate maximum scour depth without bank protection ($z_f/e_{max,A1} = 1$). Increasing its width should improve the effectiveness of the footing, but also its construction cost. Footing widths investigated were of the order of the approach flow depth, h_a. The footing configurations investigated are summarized in Table 1.

The bed topography in the experiments with outer bank footing is characterized by the same main features as in the experiment without, as illustrated in Figure 3. A typical bar-pool topography with two scour holes develops around the bend due to the same physical mechanisms and the transversal bed slope shows an oscillating behavior.

However, these main features are affected by the outer-bank footing. The outer bank footing

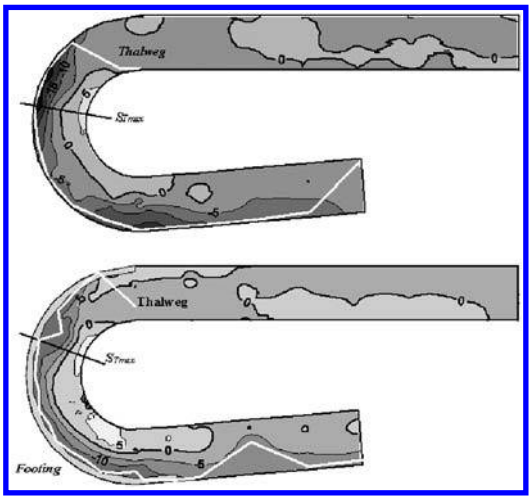

Figure 3. Bed topography in the A1 experiment without footing (upper) and the B4 test with footing (lower). Bed elevations are in cm above the flume averaged initial bed level.

significantly reduces the bend scour. The maximum scour depth in the bend is significantly reduced by up to more than 40% (Table 1). The maximum transversal bed slope is reduced and its oscillation around the bend is attenuated for footings with optimal width and depth parameters, as in tests B4 and B7 (Fig. 4).

The thalweg is not found at the outer bank, but is shifted to the edge of the outer bank footing (Fig. 3). Even though the flow erosive attack on the bed increases in outward direction, the footing protects the underlying bed, even in cases where underscour develops. This protective effect increases from the footing's tip towards the outer bank.

The scour holes are slightly shifted in upstream direction (see θ_{max} in Table 1). This behaviour could tentatively be attributed to a reduction in width of the mobile bed zone. The total eroded volume around the

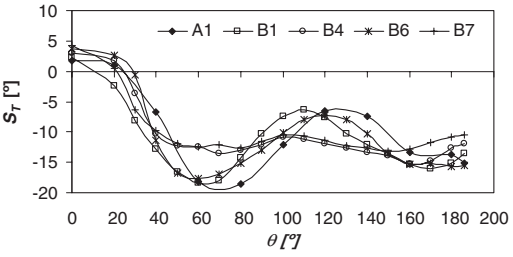

Figure 4. Evolution of transversal bed slope, $S_T(°)$ in four experiments with footing compared with A1 experiment without.

bend, V_o, is slightly increased. This means that the outer bank footing does not minimize the total scour but merely redistributes and uniformizes it around the bend (Table 1).

Wider footings yield a larger reduction in bend scour, as illustrated by experiments B1, B4 and B7. With the footing placed at one third of the maximum scour depth, $z_f/e_{max,A1} = 0.33$, the scour reduction increases from 13% for a footing width of $b/h_a = 0.7$, to 28% for $b/h_a = 1.1$, and reaches a maximum of 42% for $b/h_a = 1.5$.

Experiments B3 to B6 investigate the influence of the footing elevation for a constant footing width of $b/h_a = 1.1$. Elevations of $z_f/e_{max,A1} = 0.17$, 0.33, 0.50 and 0.67 are investigated. The maximum scour reduction in this series of experiments is obtained for $z_f/e_{max,A1} = 0.33$. Placing the footing at a lower level reduces its efficiency, which should vanish for $z_f/e_{max,A1} = 1$.

Obviously, the footing's width and elevation interact. The optimal vertical elevation of the footing will depend on its width.

When the footing is not wide enough or is placed at a higher level scour can develop below it, which can endanger the footing's structural stability.

The following paragraphs compare the distributions of downstream flow, secondary flow and turbulence in the A1 reference experiment without footing and the B4 experiment with successful footing design.

4 DOWNSTREAM FLOW

The depth-averaged downstream velocity, U, and the downstream unit discharge, $q = Uh$, are the main flow parameters, since they determine the sediment transport that shapes the bed topography.

The depth-averaged velocities are computed by adopting linear extrapolations in the flow region near the water surface where no velocity measurements could be carried out. The uncertainty in the depth-averaged values is less than 2% when comparing different possible and reasonable extrapolations.

Copyright © 2006 Taylor & Francis Group plc, London, UK

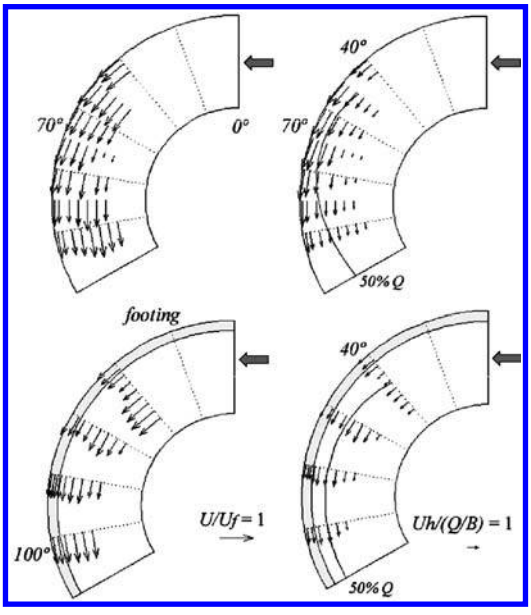

Figure 5. Depth averaged downstream velocity, U (left); Downstream unit discharge, $Uh/(Q/B)$ and streamtubes containing 50% of the discharge (right) in the A1 experiment without footing (top) and the B4 experiment with footing (bottom).

In the A1 experiment without footing, the downstream velocity U is quite uniform from the bend inlet, but at section at 60° and more clearly at 70° the maximum values are found near the outer bank (Fig. 5). Downstream of the section at 80° maximum values are found in the middle of the cross-section.

The pattern of unit discharge, $q = Uh$, is modulated by the water depth. Without footing it is more non-uniform than the velocity pattern, with greater values near the outer bank. It reaches a maximum in the cross-section at 70° where the transversal bed slope is maximum.

The presence of the footing clearly modifies this pattern. In the B4 experiment, the cores of maximum velocity and maximum unit discharge are found nearer the centerline of the flume in all the cross-sections; they do not reach the outer bank as in the experiment without footing. Between the core of highest velocities and the outer bank, the depth-averaged downstream velocity first reaches a minimum value (see $\theta = 40°$) and then again somewhat increases.

The distribution around the bend of the downstream velocity (Fig. 6) clearly deviates from typical straight-flow distributions that monotonously increase from the bed towards the water surface.

In the A1 experiment without footing, the downstream velocity starts increasing near the outer bank and close to the bed in the cross-section at 60°. Further downstream in the bend, in the cross-section at 100°, the maximum velocities are found close to the bed and they decrease towards the water surface. This pattern is explained by the influence of the secondary flow. The high velocities near the bed enhance the erosive attack on the toe of the bank and are an important cause of bank failure.

In the B4 experiment with footing, the 3D flow patterns also illustrate the shifting of core of highest velocities towards the edge of the footing. The core of highest velocities remains further away from the bed than in the A1 experiment. The area of lower velocities that occurs between the core of highest velocities and the outer bank gets weaker along the bend and shifts towards the water surface.

5 SECONDARY FLOW

The redistribution of the downstream velocity may be attributed to advective momentum transport by the cross-stream motion and to the non-uniformity of the bed topography, which is also indirectly caused by the cross-stream motion (Blanckaert & Graf 2004).

Cross- stream motion (v, w) is defined as the projection of the velocity vector in the cross-section. The transversal velocity, v, can be decomposed into a translatory part, V, called cross-flow, and a circulatory part, v^*, called the transversal component of the secondary flow or the 'identifiable downstream vortices' (Bradshaw 1987). Depth-averaged values of $v*$ are zero by definition.

The circulatory part of the cross-stream motion, (v^*, w), can also be represented by the downstream component of the vorticity vector, defined as:

$$\omega_s = \frac{\partial v}{\partial z} - \frac{\partial w}{\partial n} = \frac{\partial v^*}{\partial z} - \frac{\partial w}{\partial n} \qquad (1)$$

which has the advantage of being a scalar quantity.

The patterns of the normalized downstream vorticity, $\omega_s H/U_f$ in the experiments with and without footing are shown in Figure 7. These patterns are obtained by first extrapolating the measured (v,w) patterns by Krigging and subsequently evaluating the derivatives in Equation 1 by means of two-point central finite-differences scheme. Note that the cross-flow, V, does not contribute to ω_s, which is not affected by the extrapolations outside the measuring grid near the water surface.

In the A1 experiment without footing, a vorticity cell develops in the cross-section at 60° over the deepest part of the cross-section. This cell weakens downstream and almost disappears at $\theta = 100°$. This characteristic feature of flow in open-channel bends is often called secondary flow, spiral flow or helical flow, and has been abundantly investigated (Rozovskii 1957, Struiksma et al. 1985, Blanckaert & de Vriend 2004). It appears due to the interaction between the

Copyright © 2006 Taylor & Francis Group plc, London, UK

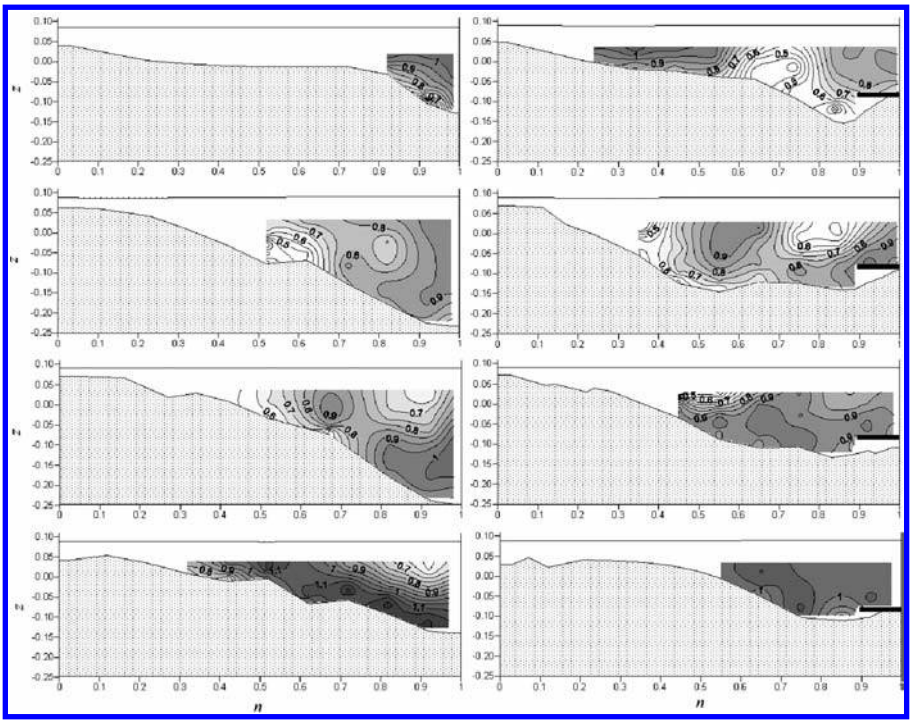

Figure 6. Isolines of normalized downstream velocity u/U_f in cross-sections at 40°, 60°, 80° and 100° in the bend (from top to bottom) in the A1 experiment (left) and the B4 with bank protection (right).

centrifugal force and the pressure gradient induced by the tilting (superelevation) of the water surface.

In B4 experiment with footing, maximum values of vorticity are lower than in the A1 experiment, but the downstream distribution is more uniform. The core of the cells is located close to the edge of the footing near the location of the core of minimum downstream velocity (Fig. 6). It seems to gradually shift towards the outer bank around the bend. A second and stronger cell of downstream vorticity is observed near the centreline in the cross-section at 60° in both experiments.

6 TURBULENCE

Turbulence plays an important role in the formation of the pattern of downstream vorticity cells in open-channel bends (Blanckaert & de Vriend, 2004). In spite of its relevance, little is known about the turbulence characteristics in open-channel bends.

In straight uniform flow, the vertical distribution of the turbulent kinetic energy, $k = 1/2\ (u'^2 + v'^2 + w'^2)$, is well approximated by an exponential profile (Nezu & Nakagawa 1993). The observed patterns in the curved-flow experiments are fundamentally different (Fig. 8).

The profiles do not monotonically decrease from the bed towards the surface, but the core of highest values is found in the middle or even in the upper part of the water column. The distributions of k and of the mean flow kinetic energy, $K/(1/2U_f^2) \approx (u/U_f)^2$ (Fig. 6) exhibit opposite patterns in the water column as well as over the width. The core of minimum k-values nearly coincides with that of maximum u-values, and positive/negative gradients of k correspond to negative/positive gradients of u. Similar behavior has been observed and explained by Blanckaert & de Vriend (2005). The zones of high k are located near the eye of the downstream vorticity cell (Fig. 7). These maximum values in the cross-section are larger than in straight uniform flow, indicating that the turbulent kinetic energy content of the investigated flow is increased by the curvature and/or the bed topography. The turbulent activity seems to decay in the second part of the bend, which resembles the evolution of the strength of the downstream vorticity cells.

7 CONCLUSIONS

One of the most important variables in bank protection design is the depth of foundation.

The present experimental results convincingly show that a well-designed horizontal bank foundation that protrudes into the flow (called footing) can

Copyright © 2006 Taylor & Francis Group plc, London, UK

significantly reduce bend scour, allowing for reduced construction costs of bank protections.

Widening the footing reduces scour depth and risk of underscour, but increases construction cost. Lowering the footing also limits the risk of underscour, but reduces its protective efficiency. A maximum scour reduction by more than 40% was obtained in the reported experiments with footing parameters of $b/h_a \approx 1.5$ and $z_f/e_{max,A21} \approx 0.33$.

The presence of the outer bank footing modifies the mechanisms of bend scour. It reduces the flow depth in the outer-half of the cross-section; hence, the outward increase of the downstream velocity is also reduced. Vorticity cells are clearly observed from cross-sections at 40° to 100°, but their shape and intensity are modified comparing with the experiment without footing.

The outer bank footing increases the turbulence activity in its neighborhood. This leads to an increase in the erosive capacity of the near bank flow, which is however outweighed by its reduction thanks to the more favorable distribution of the main downstream velocity component.

This paper presents a preliminary study to show the benefits of an optimal footing design on the bend scour reduction. More research is needed before defining generally valid design rules that avoid underscour.

NOTATION

B = flume width [m]
b = width of wall footing [m]
D_{50} = mean diameter of sand bed [m]
e_{max} = maximum erosion [m]
H = averaged water flow depth along the flume [m]
h = local water flow depth [m]
h_a = approach water depth [m]
n = transverse reference axis; 0 at the inner bank and 1 at the outer one
K = mean flow kinetic energy per unit mass [m^2/s]
k = turbulent kinetic energy per unit mass, $1/2(\overline{u'^2} + \overline{v'^2} + \overline{w'^2})$ [m^2/s], where u', v' and w' are the velocity fluctuations

Self widening by lateral erosion in gravel bed rivers

P. Requena, R.B. Weichert & H.-E. Minor
Laboratory of Hydraulics, Hydrology and Glaciology (VAW), ETH Zurich, Zurich, Switzerland

ABSTRACT: River widening is an effective measure to reduce the flood hazard and to improve the ecologic situation by restoration of the original morphologic dynamics. The widened river reach can be achieved due to lateral erosion after removing existing bank protection works. In order to understand the morphological dynamics of the lateral erosion process and to describe and quantify the influence of relevant parameters, as e.g. discharge, bed slope, sediment supply and grain size distribution, physical model investigations are carried out at the VAW. In the present paper, the experimental set-up and the procedure of this study are described. A method for analyzing the spatial and temporal evolution of the lateral erosion is presented and finally, observations and preliminary results from the first experiments are discussed. The developed method allowed the quantification of erosion rates with high precision. First results show that the lateral erosion does not progress continuously, but has a pulsating behavior.

1 INTRODUCTION

River correction works carried out in the 19th century in Switzerland to prevent flooding as well as malaria and to fulfill an increasing land demand for industry and agriculture, resulted in monotonous river landscapes with confined narrow channels. The objective at that time was to increase the sediment transport capacity of the rivers to initiate bed erosion and consequently to increase the discharge capacity of the rivers. However, today excessive bed erosion leads to a number of negative consequences, such as undermining of the river bank foundations, lowering of the groundwater level and reduction of the typical river habitat (fauna and flora). Furthermore, recent flood events have shown the limits of conventional river training. It has been realised that rivers in Switzerland need to be given more space. This can be achieved by re-widening of selected river reaches.

Since 1990, various river reaches in Switzerland have been widened. Today, a meandering, partly braided river with pool-riffle systems and variable velocities has developed in these reaches (Fig. 1). In the widened river reach the riverbed erosion has been stopped and flood protection has also been improved. As a result of the varying river morphology the ecological value has increased and the typical river habitat has reappeared. The experiences of the last 15 years have proved that river widening is an effective river renaturation measure, which at the same time satisfies the requirements of flood protection and ecology.

A number of research projects focusing on river widening were carried out at the VAW. These studies investigated the effect of river widening on bed morphology and sediment transport in gravel bed rivers as well as the morphological dynamic of the widening process (Zarn 1993, 1997, Hunzinger & Zarn 1997, Hunzinger 1998, Marti 2002, Requena et al. 2005). The widening of a river reach can be achieved by excavating the floodplains along the reach in question, or naturally by lateral erosion after the bank protection works have been removed. However, lateral erosion is not allowed to progress unchecked because urban areas and infrastructures are often situated close to the rivers. An area must therefore be defined within which the river is allowed to erode its banks and consequently to develop dynamically (Fig. 2). In this context, an understanding of the lateral erosion process is of considerable interest. The present paper focuses on this process.

2 LITERATURE REVIEW

The lateral erosion process in sand and gravel bed meandering rivers was investigated using field or laboratory data by many authors (e.g. Hooke 1980, Ikeda et al. 1981, Parker 1983, Nanson & Hickin 1986, Odgaard 1987, 1989, Osman & Thorne 1988, Thorne & Osman 1988). Within these studies, the main influencing parameters were identified and investigated. This intensive research focused on meandering

channels, but few investigations considered so far the lateral erosion process in gravel bed rivers with the tendency to develop braided morphologies. Most of the research works about braided rivers focused on the development of braided structures starting from a straight channel. The main topics of these investigations were the mechanisms of braiding (Ashmore 1982, 1991), the bed load transport and its spatial and temporal fluctuations (e.g. Ashmore 1988, Hoey & Sutherland 1991, Warburton & Davies 1994), the relationship between bed load transport, braiding intensity and channel width (Ashmore 2001) or the sorting process of the bed material in gravel bed streams (Ashworth & Ferguson 1989, Ashworth et al. 1992). Warburton (1996) considered the bank erosion rate by investigating the interrelation between sediment transport, braiding morphology and braided channel width. Schmautz (2004) developed a method to estimate the maximum expected river width during the widening process. In general, the lateral erosion process in gravel bed rivers has not yet been examined in detail and its spatial and temporal evolution have not been quantified.

3 GOAL OF THE PRESENT STUDY

In order to understand the morphological dynamics of the lateral erosion process, physical model investigations have been carried out at the VAW. The aim of this research project is to describe and quantify the influence of the relevant parameters, such as discharge, bed slope, sediment supply, grain size distribution and initial river width, on the lateral erosion process. These results should enable the interrelation between lateral erosion rate, sediment transport, braiding morphology and braiding width to be determined. In the present paper, the experimental setup, the procedure and the methods for data analysis of this study are described. Finally, observations and preliminary results from the first experiments are presented.

4 FLUME EXPERIMENTS

4.1 *Experimental setup*

The experiments presented here were performed in a concrete flume that was 28.5 m long and 3.2 m wide (Fig. 3). The slope of the flume could be varied between 0.8% and 2.2%. Water discharge and the sediment supply were remotely controlled by a computer. Flow rates were measured by an electromagnetic flow meter. Dry sediment was introduced at the head of the flume by a sediment feeder. The sediment output at the downstream end of the flume was collected and continuously weighed. A sediment

mixture, which is typical for Alpine gravel bed rivers, was used in this study. This mixture was widely graded with $D_{50} = 3.2$ mm, $D_{90} = 9.4$ mm and $\sigma = D_{84}/D_{16})^{0.5} = 3.3$. Grain Reynolds numbers obtained for the investigated discharges were higher than 100 and therefore fully turbulent conditions were guaranteed. The topography and the water level were surveyed by laser and ultrasonic sensors installed on a xyz-positioning system, which automatically scanned the bed surface in a predetermined regular, dense grid. Seven digital cameras were installed above the flume (Fig. 3) to monitor the morphological dynamic of the braiding process over the full duration of the experiment (1 photo per min).

Furthermore, the time-lapse photos were used to quantify the lateral erosion process. A method, developed to analyze and quantify the spatial and temporal evolution of the lateral erosion, will be described in detail in Section 5.

4.2 *Experimental procedure*

In the present project several experiments were planed to quantify the influence of discharge, bed slope, sediment supply and initial river width on the lateral erosion rate. With each experiment different combinations of one initial width (to be varied between 40 and 80 cm), one discharge (to be varied between 10 and 40 l/s) and one sediment supply rate (to be varied between 0 and 80 g/s) are investigated. All the chosen discharge values were higher than the critical flow discharge at which, sediment transport begins.

Sediment supply rates were calculated for the given combination of discharge and width according to the bed load transport formula of Hunziker (1995). These values represent the transport capacity for the given hydraulic conditions. In order to investigate the influence of low bed load rates on the lateral erosion process, experiments with the sediment rate matching 50% and 0% of the transport capacity for the specific hydraulic conditions will also be performed.

Until now, three experiments have been conducted. The experiments were interrupted after a certain time to refill the sediment feeder, to empty the sediment basket and to survey the bed topography in a dry state. Each experiment was divided into two phases: the equilibrium phase and the widening phase.

4.2.1 *Equilibrium phase*

In this phase the channel alignment was determined by fixed sidewalls over the whole length and lateral erosion was not yet allowed (Fig. 4a). Starting from a straight, narrow channel an equilibrium state had to be reached for the specific combination of discharge, width and bed load rate. The state of equilibrium was reached by steady-state conditions when the sediment output approximately equaled the sediment input, so that the mean bed slope remained constant during the considered time interval.

The reason for carrying out this phase was to start the widening phase of all the experiments under the same initial conditions, namely with the equilibrium channel bed slope. Furthermore, this procedure guaranteed that before the process of lateral erosion started, the channel bed resembled conditions, which corresponded to existing configurations in nature (e.g. bed material sorting process). The equilibrium bed slope could be predetermined for the given discharge, channel width and bed load rate by means of one of the available sediment transport formulas. By building an initial channel bed slope which approximately matched the expected equilibrium bed slope, the duration of this phase could be reduced considerably. In the experiments, the initially built channel bed slope was

Copyright © 2006 Taylor & Francis Group plc, London, UK

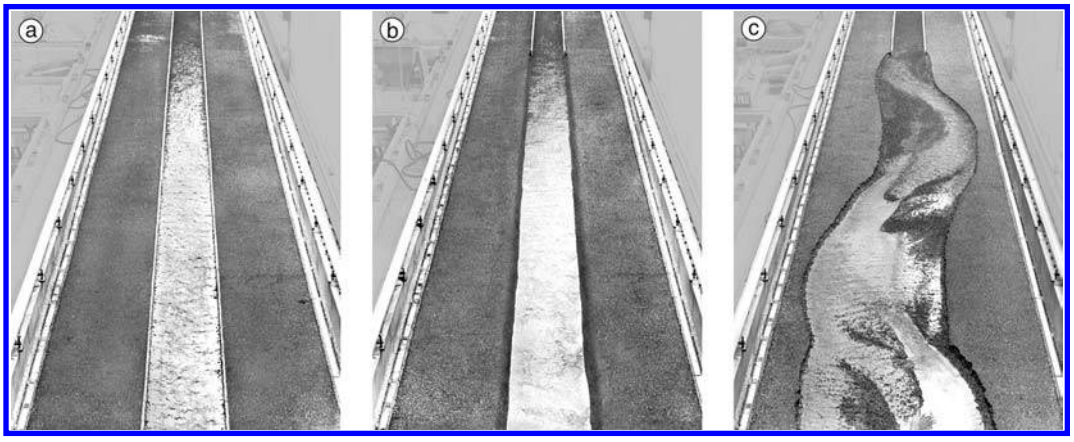

Figure 4. Experimental procedure: a) Equilibrium phase with fixed sidewalls over the whole length. In this phase lateral erosion was not allowed; b) Removed sidewalls at the beginning of the widening phase. At the head of the flume the sidewalls stayed fixed over a 7 m long section; c) Widening phase with lateral erosion.

first determined by the formula of Hunziker (1995), a slightly modified form of the Meyer-Peter & Müller's (1948) formula:

$$\phi = 5(\theta' - 0.05)^{1.5} \quad \text{where} \tag{1}$$

$$\phi = \frac{g_b}{\rho_s}\left[\left(\frac{\rho_s}{\rho} - 1\right) \cdot g D_m^{\,3}\right]^{-0.5} \tag{2}$$

$$\theta' = \frac{v_*^{\,2}}{\left(\frac{\rho_s}{\rho} - 1\right) \cdot g D_m} \tag{3}$$

In the above relations $\phi =$ dimensionless bedload transport rate per unit channel width (Einstein number), $\theta' =$ dimensionless boundary shear stress (Shield number) and $g_b =$ bedload transport rate per unit channel width.

4.2.2 *Widening phase*

For this phase the sidewalls were removed (Fig. 4b). In the three experiments conducted so far, the discharge and the sediment rate was the same as for the first phase (sediment supply matched 100% of the transport capacity). In further experiments the sediment supply will be reduced in the widening phase to 50% or 0% of the transport capacity in order to model states with low or no bed load respectively. During this second phase the channel width began to increase by means of lateral erosion (Fig. 4c) and consequently to develop new dynamic morphologies. This phase finished when the maximal braiding width was attained or until the channel reached the sidewall of the flume.

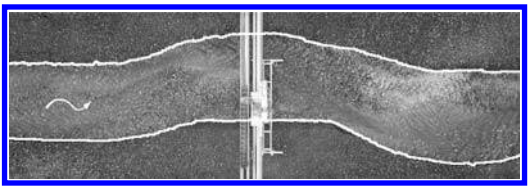

Figure 5. Eroded bank lines, detected from the digital photos. In this figure a 10 m long section of the flume is shown.

5 EVALUATION OF THE LATERAL EROSION

In this project, a method to analyze the spatial and temporal evolution of the lateral erosion was developed. The digital cameras installed above the flume (Fig. 4) automatically took vertical photos at one minute intervals. All the cameras were positioned at the same level and synchronized. Each camera covered a part of the flume and they simultaneously took the photos in the defined time step. Assembling the photos resulted in one picture of the entire flume. Based on an edge detection algorithm, a program was developed to analyze the photos and to identify the position of the laterally eroded banks automatically (Fig. 5). These lines are detected by identifying the different contrast values of the wetted and the dry bed zone respectively. The accuracy of the results was improved by increasing the contrast of the photos before detailed analysis. With this method, the position of the left and right eroded bank is known for any time during the experiment. This allows analysis of the spatial and temporal evolution of the lateral erosion with a high time resolution.

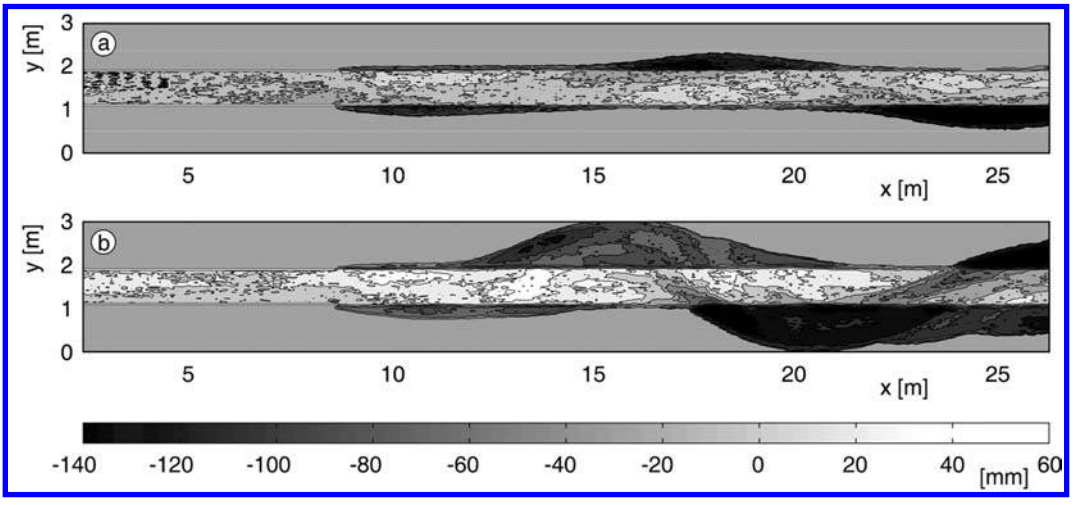

Figure 6. Difference of the bed level elevation heights for two topographies measured in the widening phase, a) after 7 hours and b) after 30 hours, compared to the topography measured at the end of the equilibrium phase. The showed plots correspond to topography measurements of the first experiment (discharge = 25 l/s and sediment rate = 30 g/s).

6 PRELIMINARY RESULTS

As the experimental investigation is in its initial stage, only some observations and preliminary results from the first three experiments are presented in this paper.

6.1 *Equilibrium state*

In the first phase an equilibrium state was reached according to the experimental procedure (see Section 4.2). In the three experiments this state was reached after approximately 30 h. The equilibrium bed slopes at the end of this phase, obtained from the measurements of the bed topography, closely matched the bed slopes calculated using Hunziker's formula (1), as described in Section 4.2.1.

Applying the formula of Meyer-Peter and Müller (1948), the computed bed slope values were approximately 20% lower than the measured ones. In terms of sediment transport, this difference means an overprediction of the bed load rates when this formula is used. This is in line with the specifications that can be found in the literature (e.g. Hunziker & Jäggi 2002, Parker et al. 1982, Wong & Parker 2005).

6.2 *Initiation of channel widening*

The observed mechanism to initiation of channel widening and consequently channel braiding within the three experiments was very similar. After removing the sidewalls, the channel width slightly increased. From the beginning, it was observed that the bed load transport occurred in pulses. Due to the initial width increase sediment material was deposited and after 4 to 6 hours the development of alternating bars could be observed. These bars grew rapidly so that after 7 to 9 hours from the beginning of the experiment a meandering thalweg was established and the flow began to erode the banks on the opposite side of the bars (Fig. 6a). The sinuosity of the meandering channel then increased continuously due to the lateral erosion. The bank erosion migrated in an upstream direction (compare Figs. 6a and 6b). The material from the eroded banks was deposited directly downstream, forming a middle bar. The flow began to bifurcate due to these bars, so that the braiding process started. The maximum braiding width could not be reached in these experiments because the channel first touched the side wall of the flume. The spatial and temporal fluctuations of the bed load transport, observed from the beginning of the experiments, are known to be a typical feature of the braided stream dynamic (Ashmore 2001) and they were observed and investigated by many authors (e.g. Hoey & Sutherland 1991, Warburton & Davies 1994, Ashmore 1988, Cudden & Hoey 2003).

6.3 *Mean bed level*

When designing the widening of a river reach, it is very important to quantify the effects that influence the adaptation of the river bed level upstream and downstream of the widened section. This influence was investigated in detail by Hunzinger & Zarn (1997) and Hunzinger (1998) for rivers which are in a state of equilibrium regarding the sediment transport conditions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The three experiments evaluated so far were carried out with a bed load rate that matched 100% of the transport capacity (equilibrium state). Within the three experiments, typical effects of river widening were observed. Figure 7 shows a longitudinal profile of the mean bed level in one of the experiments. From this longitudinal profile the bed slope was estimated by linear regression.

As can be seen in Figure 7, the channel bed gradient became steeper in the widened river section.This led to a parallel elevation of the bed level upstream of the widened reach. The observed processes correspond to the investigations by Hunzinger (1998) for rivers that are in a state of equilibrium. However, by some evaluated widening projects in Alpine eroding rivers, which are not in a state of equilibrium, this bed elevation upstream of the widened section was not observed; instead, the river bed was eroded further (Requena et al. 2005). In the present study, the experiments carried out with low bed load rates will allow to quantify the effects of widening on the mean bed level for rivers that are in an eroding state.

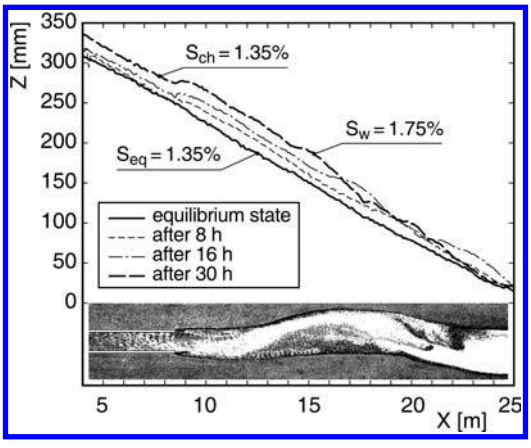

Figure 7. Longitudinal profile of the mean bed level for the first experiment (discharge = 25 l/s and sediment rate = 30 g/s). The bed slopes were estimated by linear regression of the longitudinal section. In the figure S_{eq} = equilibrium bed slope at the beginning of the widening phase, S_{ch} = bed slope after 30 hours for the channel reach and S_w = bed slope after 30 hours for the widened reach.

6.4 *Lateral erosion*

From the analysis of the experiments carried out so far, some qualitative tendencies of the lateral erosion process can be concluded.

6.4.1 *Spatial evolution*

As described in Section 5, a program was developed for analyzing the photos and detecting the positions of the eroded banks. Knowing the position of the left and right eroded banks at an interval of one minute allows a highly precise analysis of the progress of the lateral erosion. Figure 8 shows the result of this analysis for a time interval of 800 minutes. It illustrates the successively detected positions of the eroded banks for a 10 m long section of the flume. It can be seen that the eroded bank line moves upstream, namely against the flow direction. This development was observed in all experiments and contrasts with the downstream meander migration observed in field and laboratory investigations by many authors (e.g. Odgaard 1987, 1989, Nanson & Hickin 1986).

6.4.2 *Temporal evolution*

An important parameter to quantify the widening process is the lateral erosion rate, defined as the velocity

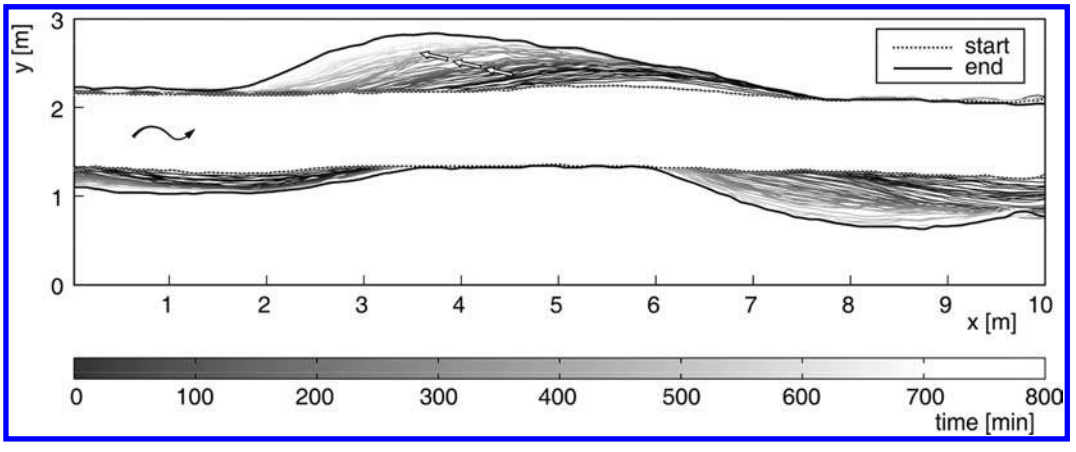

Figure 8. Successively detected positions of the eroded banks for a time interval of 800 minutes. Each line in the figure corresponds to a detected position.

Copyright © 2006 Taylor & Francis Group plc, London, UK

of bank erosion at a considered time increment and measured perpendicular to the initial bank line of the straight channel. The high density of the detected eroded bank lines (Fig. 8) allows the erosion rate to be estimated with precision. Figure 9 shows a 3D plot of the spatial and temporal evolution of the erosion of the left bank for one experiment. The grey shading illustrates the absolute values of the erosion rates estimated for the 800 minutes measured and for a 10 m long section of the flume. In Figure 9, the lightest grey zones correspond to high values of erosion rate.

For this experiment, the maximal value of erosion rate was 0.27 cm/min, occurring after 520 minutes at the position X = 4.2 m (Figure 9). Observing the time-dependent evolution of the high values of erosion rate (lightest grey zones in Figure 9), a pulsating mode of the erosion rate can be found. This confirms the observation that the erosion of the banks does not occur continuously, but has a pulsating behavior. As described in Section 6.2 it was also observed that the bed load transport occurred in a pulsating mode. Following this, the correspondence of these two observations suggests a correlation between the bed load transport and the lateral erosion rate.

Another interesting observation was made by considering only the maximum values of erosion rate of the left bank plotted in Figure 9 for the 800 minutes measured. These maximum values were plotted in Figure 10. The same values for the right bank were added to this figure. Figure 10 illustrates then for the 800 considered minutes the absolute maximum value of erosion rate found at any position of the banks (along the considered 10 m long section). From this plot it can be seen that during the experiment the absolute maximum value of erosion rate did not occur at the same time at both banks. When one of the banks was eroded intensively, the lateral erosion at the other bank was not prominent at any position x [m] of the channel.

Similarly to Figure 9, the pulsing progression of the erosion rate can also be observed in Figure 10.

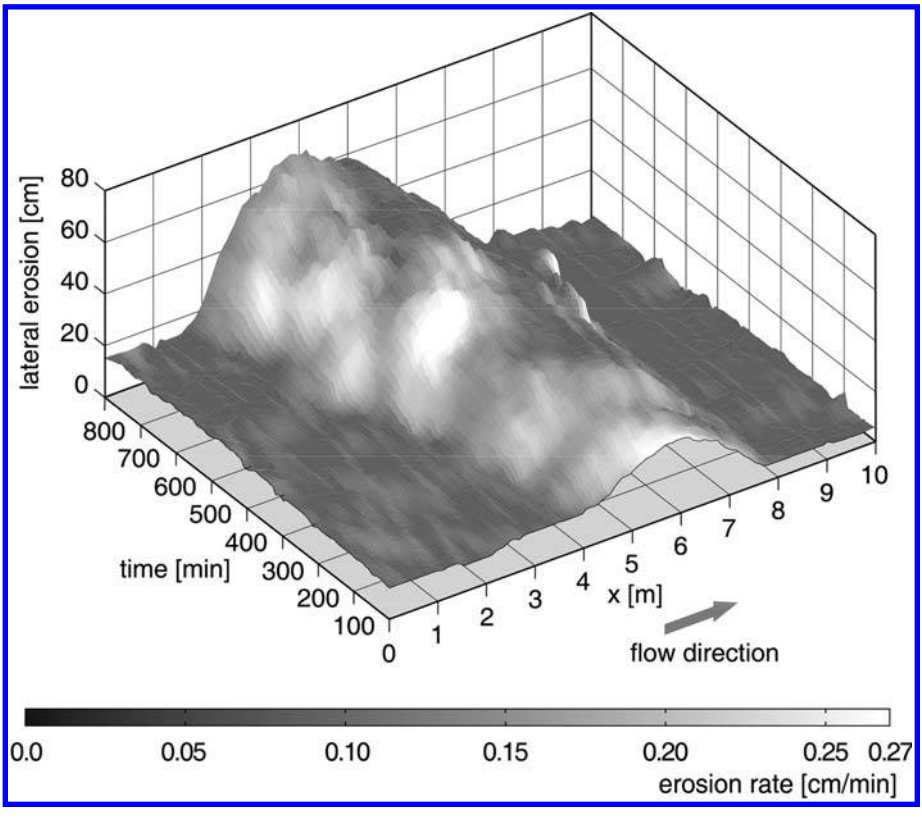

Figure 9. 3D plot of the spatial and temporal evolution of the lateral erosion of the left bank for a time interval of 800 minutes. The grey shading indicates erosion rates deducted from the same data set.

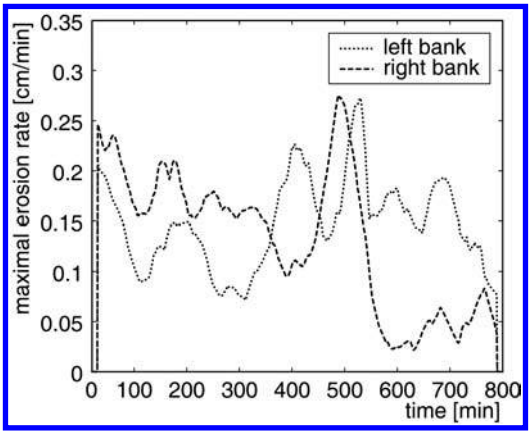

Figure 10. Temporal evolution of the maximal erosion rate for a time interval of 800 minutes for one experiment. Note that the banks within the time are changing their alignment due to lateral erosion and that the location of the maximum erosion rate consequently is changing with the time.

7 CONCLUSIONS

Physical model investigations are carried out in order to describe and quantify the lateral erosion process by channel widening. The observed mechanism for the development from an initially straight channel toward a widened channel with a poorly braided pattern was similar in the three evaluated experiments. In a first step alternating bars developed. These features were responsible for an initial erosion of the bank and the formation of a meandering channel. Thereafter, the eroded material deposited directly downstream, forming a central bar. The flow began to bifurcate due to these bars, so that the braiding process started.

Based on an edge detection algorithm, a program was developed to analyze the lateral erosion process. This program automatically analyzes the digital photos and detects the eroded banks. As the cameras take a photo per minute, the position of the left and right bank lines is known at any time of the experiment (Fig. 8). This allows a detailed analysis of the development of the lateral erosion. Through analysis of the spatial evolution of the lateral erosion it was found that the eroded banks moved upstream, namely against the flow direction.

As could be shown, the erosion rate of the banks can also be estimated with high precision due to the presented method in Section 5. The erosion rate, which is an important parameter to quantify the widening process, is defined as the velocity of bank erosion at a considered time increment and measured perpendicular to the initial bank line. Initial results in the experiments show that the erosion of the banks occurred in pulses. This pulsing behavior of the erosion rate is presumed to be related to the pulsating mode of the bed load transport, which was also observed in the experiments. Furthermore, it could be demonstrated that the location of the maximum erosion rate was changing with the time and the maximum erosion rates did not occur at the same time at both banks.

In addition to the observations and to the topography measurements, the presented method to identify the eroded bank lines constitutes the basis for analyzing the lateral erosion rates. This will allow to describe and to quantify the influence of the investigated parameters (discharge, bed slope, sediment supply and initial river width, on the lateral erosion process. Furthermore these results allow analyzing the interrelation between lateral erosion rates, sediment transport and braiding morphology after widening initiation.

NOTATIONS

D_{16}	particle size for which 16% of the sediment is finer by weight
D_{50}	particle size for which 90% of the sediment is finer by weight

DPIV study of the turbulent boundary layer over V-shaped cavities

A. Amador
Escola Superior de Tecnologia do Barreiro/IPS, Barreiro, Portugal

M. Sánchez-Juny & J. Dolz
Universitat Politècnica de Catalunya, Barcelona, Spain

ABSTRACT: In the present work the digital particle image velocimetry technique (DPIV) is used to study the turbulent boundary layer over a surface made up of V-shaped cavities placed transversely to the flow direction. The integral measures of the boundary layer like the displacement and momentum thickness are estimated from the mean velocity field. The wall shear-stress is higher than the corresponding smooth surface values. From the fluctuating velocity field it is observed maximum turbulence levels in the region just above the cavities. Study of coherent turbulent structures suggests the presence of strong outflows of fluid from the cavities as well as inflows into the cavities. It is conjectured that the mass transfer/exchange between cavities and main stream, play an important role in the high levels of turbulent energy observed.

1 INTRODUCTION

The present study on wall turbulence concerns open-channel flows over V-shaped cavities.

The equations of motion indicate that energy is removed from the mean flow and transferred into the turbulent motion by the action of the Reynolds shear stresses. The turbulence energy production and resulting turbulence characteristics depends on the nature of the surface (Djenidi et al, 1999). For turbulent flow over smooth surfaces the periodic bursting process is the predominant mode of turbulence production (Tantirige et al, 1994). Over rough surfaces, coherent structures are more intense than for a smooth wall layer. Antonia (1994) based on measurements over three different types of surfaces (d-type roughness, V-grooves and k-type roughness), indicated that Reynolds stresses are increased relative to smooth wall. It was also mentioned different changes to the turbulence structure as a result of the different types of surface. Experimental studies of side-cavity open channel flows by Nezu and Omnitsuka (2002 a,b), reported that coherent eddies are generated in the roughness element and contribute significantly to momentum and mass transfer between cavity and main channel.

Most experimental studies of turbulent boundary layers over rough surfaces (Perry et al., 1969; Wood and Antonia, 1975; Antonia, 1994; Tantirige et al., 1994; Djenidi et al., 1999; Kameda et al., 2004) employed as measurements tools flow visualizations, hot wire anemometry and laser Doppler velocimetry. Kameda et al. (2004) attributed the few quantitative studies of the roughness sub-layer, to the difficulty of measurement, which is complicated by the presence of reverse flow and intense turbulence. Sousa and Pereira (2002) demonstrated the advantages of using digital particle image velocimetry (DPIV) for identification of large scale vortical structures embedded in the flow.

The aim of the present work is to better understand the effect of V-shaped cavities have on the physical processes responsible for enhancement of turbulence production. The flow over a steeply sloping wall made up of two-dimensional V-shaped cavities placed transversely to the flow direction is measured using a DPIV system. The effects of the rough wall on the mean and fluctuating velocity field are investigated and discussed. The behaviour of the separated free shear layer formed behind the roughness elements is studied and the wall shear stress is determined. An effort is made to identify coherent structures that may contribute to turbulence production.

2 EXPERIMENTAL SET-UP

The experiments were performed in a large-scale water channel assembled at *A Coruna* University. The experimental facility and measurement technique are described in the following.

The free-surface water channel is 0.50 m wide, 2.0 m high and the bottom inclination is 51.3°. The rough wall is composed of transverse V-shaped

Copyright © 2006 Taylor & Francis Group plc, London, UK

cavities. The height of the roughness elements is 0.031 m (k_s) and the width is 0.064 m (L_{cav}), which corresponds to a roughness pitch ratio (p) of 2.1 ($p = L_{cav}/k_s$). The tested unit water discharge (q) was 0.11 m^2/s that corresponds to a Reynolds number ($Re = q/\nu$) of 1.1×10^5. The electromagnetic flowmeter installed in the supply conduit of the model had an accuracy of $\pm 2\%$.

The DPIV system is composed of a double-pulsed Nd-Yag laser, with 400 mJ of energy per pulse, a 1280×1024 pixel resolution, high sensitive peltier cooled, CCD camera. A Nikkor 50 mm 2.8, together with a narrow bandwidth filter that passes the 532 nm light from the Nd-Yag laser, is mounted on the CCD camera. An electronic sequencer synchronizes the camera and laser pulses.

The water was seeded with 70μm ceramic micro spheres. The images cover two steps. Bigger measurement areas imply unacceptable perspective errors (Fig. 1). The camera captured double frame, double exposure particle images. The separation time was adjusted at 200–250μs between two laser pulses in order to give a maximum particle image displacement of eight pixels.

Both image frames are subdivided into small interrogation areas that are partially overlapping. Interrogation areas at identical positions in the images frames are correlated by means of Fast Fourier Transformation. From the two dimensional cross-correlation function, the position of the highest peak representing the mean displacement of the particle images is estimated. In order to obtain high-accuracy estimators of the particle displacements, the correlation peak position is calculated at sub-pixel level by the three point Gaussian interpolation scheme. The accuracy of the resulting DPIV estimators is about 0.1 pixel, which in the present study corresponds to an accuracy regarding the measured velocities of 50–62.5 mm/s.

Zero offsetting is applied in order to optimize the signal and to minimize biasing effects in the PIV estimators (Westerweel et al., 1997). The interrogation of the images initiates with large dimensions of the interrogation areas that are reduced in size after each interrogation. In this way, high dynamic velocity ranges can be combined with a high spatial resolution. In this study adaptive interrogation area sizes have been used from 128×128 pixels to 32×32 pixels, with an overlapping of 50% (i.e. 16 pixels). Some data sets are checked on peak-locking effects by examining the statistics of the DPIV estimators at sub-pixel level. All data are validated on outliers by the median test (Keane and Adrian, 1990; Westerweel, 1994). Detected outliers are substituted by the local mean value of its neighbouring estimators.

The study region comprises seven V-shaped cavities. The distance from the channel crest to their leading edges (X) is respectively of 0.343 m (cavity E35), 0.407 m (cavity E34), 0.471 m (cavity E33), 0.535 m (cavity E32), 0.599 m (cavity E31), 0.663 m (cavity E30) and 0.727 m (cavity E29).

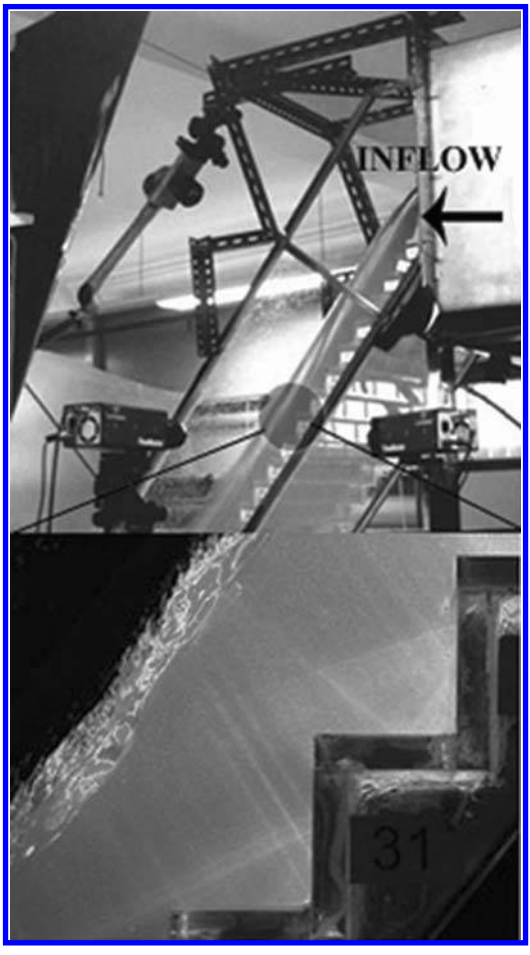

Figure 1. Experimental facility, $q = 0.11$ m^2/s; Image captured by CCD camera for cavities E34 ($X/k_s = 13.04$) and E33 ($X/k_s = 15.09$).

3 MEAN VELOCITY FIELD

The mean velocity field over the seven V-shaped cavities was obtained from 500 instantaneous velocity fields. The velocity vector spacing is 2.0 mm (i.e. 16 pixels) and kriging interpolation was chosen as a gridding method.

From the mean velocity contour map, shown in Figure 2, it can be observed that the flow is accelerating and developing in the downstream direction. The flow over the rough wall consists of a turbulent boundary layer next to the pseudo-bottom (imaginary

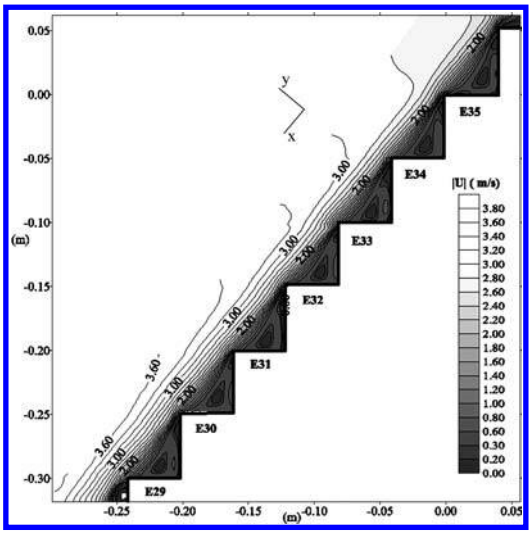

Figure 2. Contour map of mean absolute velocity (*|U|*).

line joining the leading and trailing edges of a cavity) and a frictionless fluid flow region above. Near the free surface the velocity varies from 2.8 to 3.7 m/s, corresponding to the potential flow velocity.

A well defined recirculation zone occupies part of the cavities. The quasi-steady rollers are maintained through the transmission of shear stress from the overlying flow. Considering the reverse flow a solid body rotation, for an equivalent circumference trajectory of 2 cm, the angular velocity and frequency of rotation were estimated to be approximately 40–50 rads^{-1} and 6–8 Hz in the cavities studied.

3.1 *Turbulent boundary layer*

The boundary layer thickness in the study region was evaluated. The boundary layer thickness (δ) is defined as the perpendicular distance from the pseudo-bottom to where the velocity is 99% of its maximum value (U_0).

The boundary thickness was obtained from the forty velocity profiles obtained over cavities E34, E33, E31 and E29 (Fig. 3). This is a difficult quantity to estimate, since it depends on measurements of small velocity differences and of the irregular behaviour of the outer edge of the boundary layer. The development of the boundary layer may be expressed by (U.S. Bureau of Reclamation, 1977):

$$\frac{\delta}{X} = a \cdot \left(\frac{X}{k_s}\right)^b \qquad (1)$$

where X is the streamwise distance from the start of the growth of the boundary layer assumed to be the channel crest; k_s is the roughness height, and "a" and "b" are constants which according with the experimental results are equal to: a=0.112 and $b = 0.309$.

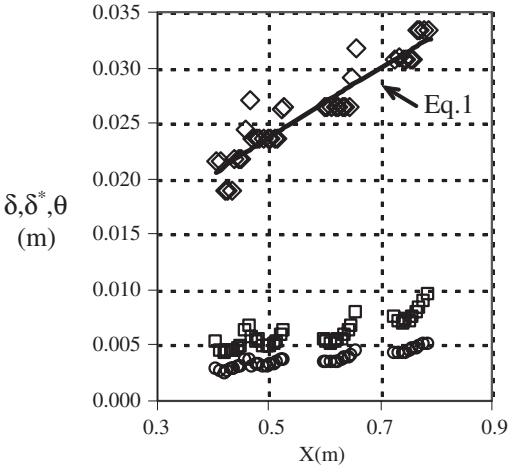

Figure 3. Evolution of the $\delta(\Diamond)$, $\delta^*(\square)$, $\theta(\bigcirc)$.

In Figure 3 is also shown other integral measures of the boundary layer obtained from the velocity profiles, as the displacement thickness (δ_*):

$$\delta^* = \int_0^\delta \left(1 - \frac{U(y)}{U_0}\right) \cdot dy \qquad (2)$$

and the momentum thickness (θ):

$$\theta = \int_0^\delta \frac{U(y)}{U_0}\left(1 - \frac{U(y)}{U_0}\right) \cdot dy \qquad (3)$$

where $U(y)$ is the streamwise mean velocity at y transverse coordinate and U_0 is the freestream velocity.

The use of the von Karman integral momentum equation (Pope, 2000) allows the estimation of the flow resistance coefficient (c_f) in the developing flow region:

$$c_f \equiv \frac{\tau_w}{\frac{1}{2}\rho U_0^2} = 2\frac{d\theta}{dx} + \frac{(4\theta + 2\delta^*)}{U_0}\frac{dU_0}{dx} \qquad (4)$$

where τ_w is the wall shear stress.

It was considered that the momentum thickness (θ) increased linearly in the flow direction (x) in accordance with Djenidi et al. (1999) that studied a similar surface. The data analysis gave a $d\theta/dx = 0.0052$. The term dU_0/dx is deduced from the Bernoulli equation. In Figure 4 is plotted the flow resistance calculations for four V-shaped cavities. The c_f seem to present a linear growth at each half end of the cavity and a global constant mean value of 0.031 for all cavities.

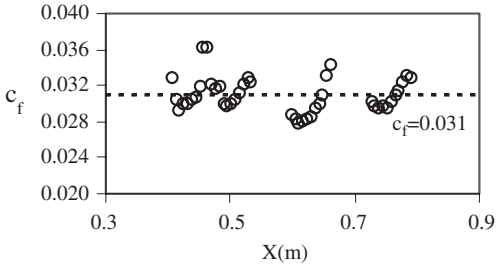

Figure 4. Flow resistance coefficient (c_f) along the study region.

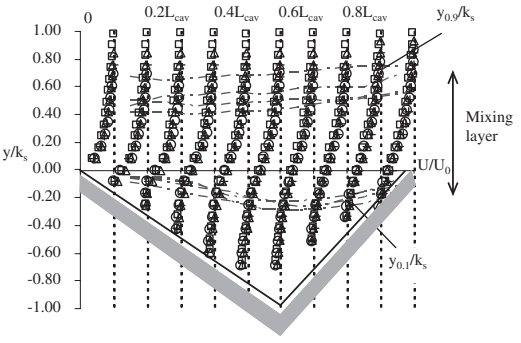

Figure 5. Mean velocity profiles (U/U_0) and variation of y_α along the V-shaped cavities: E29, $X/k_s = 23.29$ (□); E31, $X/k_s = 19.19$ (Δ); E33, $X/k_s = 15.09$ (+); E29, $X/k_s = 13.04$ (◯).

3.2 *Velocity distribution*

The mean velocity distribution can be divided in two zones: above the boundary layer, where the mean velocity can be considered constant and equal to the ideal-fluid flow velocity (U_0) and the boundary layer where the mean velocity gradient is relevant. In Figure 5 mean velocity profiles normal to the pseudo-bottom and taken at different positions along the cavities E34, E33, E31 and E29 are shown. At the cavity edges, the velocity distribution in the boundary layer can be approximated by a power law (Chanson, 2001), with an exponent determined for the four cavities edges equal to 3.0, This is in close agreement with the value of 3.3 obtained by Matos (1999) using a flushed Pitot tube in a similar model. In smooth walls with identical slopes, the value of $N = 6.0$ from the analysis of Cain (1978) and Chanson (1989), is usually suggested for the developing boundary layer upstream of the inception point. comparison shows that the mean velocity profile rises much more steeply from the reference level ($y = 0$) in smooth walls than in rough walls and then is flatter away from the "bottom".

Between the step edges ($0 < x < L_{cav}$), the velocity profiles suggest a local developing mixing layer that forms at the leading edge. Defining the characteristic width (b) of the mixing layer as (Pope, 2000):

$$b(x) = y_{0.9}(x) - y_{0.1}(x) \tag{5}$$

where y_α is the coordinate y where $U = \alpha U_0$.

In Figure 5 it is shown the spreading of the mixing layer by plotting the evolution of $y_{0.9}/k_s$ and $y_{0.1}/k_s$ along the cavities E34, E33, E31 and E29.

It seems that the mixing layer spreads linearly with a maximum of b at $x/L_{cav} = 0.7$. The displacement of $y_{0.1}$ to the interior of the cavity is much more noticeable than the variation of $y_{0.9}$ to the free surface. This is a typical characteristic of a mixing layer that spreads preferentially into the low speed stream (Pope, 2000). The maximum reverse flow velocities found in the recirculation zone are $0.15U_0$ and are located near the cavity boundaries.

3.3 *Mean velocity gradient tensor*

The 2D DPIV data provides two velocity components. This data can be differentiated in two directions and thus some terms of the mean velocity gradient tensor or deformation tensor can be estimated with PIV. Therefore the spanwise vorticity (ω_z) and in-plane shear strain (ε_{xy}) can be determined as follows:

$$\omega_z = \frac{dV}{dx} - \frac{dU}{dy} \tag{6}$$

$$\varepsilon_{xy} = \frac{dU}{dy} + \frac{dV}{dx} \tag{7}$$

The second order central-difference scheme was employed for estimation of the spatial derivatives, this scheme is implemented for data spaced at uniform ΔX, according:

$$\left(\frac{d\phi}{dx}\right)_i = \frac{\phi_{i+1} - \phi_{i-1}}{2\Delta X} \qquad O\left(\Delta X^2\right) \tag{8}$$

The shear strain contour map (Fig. 6) shows maximum levels just behind the upstream corner, where the separation of the shear layer begins. The peaks of shear strain develop in the flow direction, highlighting the pseudo-bottom as the most active zone in terms of shear stress. A gradual decrease of the shear strain is observed towards de free surface, where the flow can be considered irrotational.

Assuming the turbulent-viscosity hypothesis valid, as the production/generation of turbulent kinetic energy (P) is defined by (Pope, 2000):

$$P = -\overline{u'v'} \cdot \varepsilon_{xy} = \nu_t \cdot \varepsilon_{xy} \cdot \varepsilon_{xy} \tag{9}$$

where $\overline{u' \cdot v'}$ is the mean Reynold shear stress and ν_t is the turbulent viscosity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

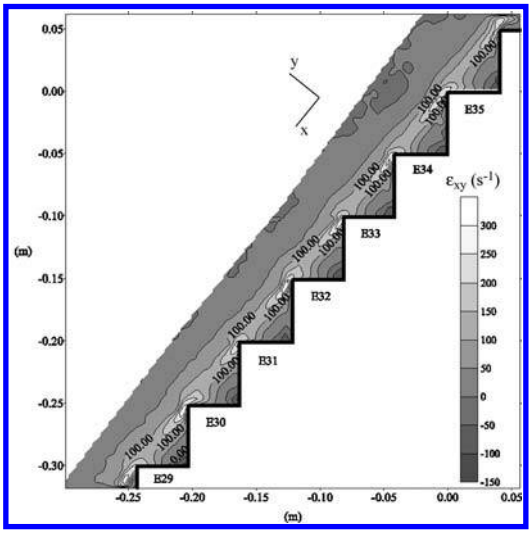

Figure 6. Contour map of mean shear strain (ε_{xy}).

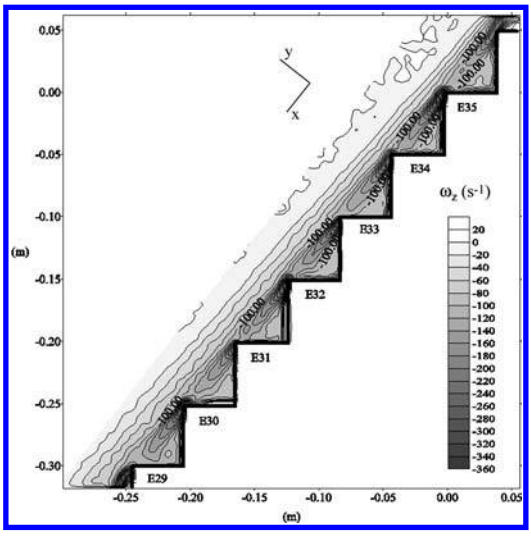

Figure 7. Contour map of mean spanwise vorticity (ω_z).

The production (P) is proportional to the mean shear strain rate. It is possible then to identify the zone just behind the leading edge as a region of formation and growth of large-scale turbulent structures, associated with local pressure reduction in the vicinity of the vortex cores.

The vorticity contour map (Fig. 7) presents a similar pattern with the shear strain map; the negative vorticity is due to counter clockwise rotation. Very high levels of vorticity are generated immediately downstream of the corner and occur over a relatively small characteristic thickness. This is most likely linked to the rapid onset of small-scale vortical structures, which appear immediately downstream the leading corner of the cavity. The dominant vorticity levels extend along the separated shear layer between the leading (upstream) and trailing (downstream) corners. Within the cavity, the flow pattern exhibit a large-scale recirculation flow, the vorticity results from agglomeration of the small scale concentrations.

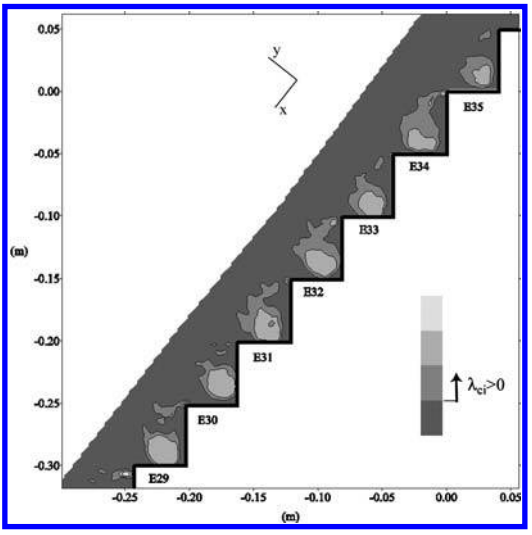

Figure 8. Contour map of swirling strength.

The vorticity level inside the cavity varies between 80 and 100 s^{-1}, which is in close agreement with the angular velocities estimated from the mean velocity field for the large recirculation zone, following the Stokes theorem equation.

The vorticity not only identifies vortex cores but also any shearing motion present in the flow. Adrian et al. (2000) proposed vortex identification based on the swirling strength. This method does not reveal regions which contain significant vorticity but do not have any local swirling motion (i.e. shear layers). It is based on the analysis of the mean, local velocity gradient tensor and its corresponding eigenvalues. The local 2D velocity gradient tensor will either have two real eigenvalues (λ_r) or a pair of complex conjugate eigenvalues ($\lambda_{cr} \pm \lambda_{ci}$). The vortices are identified by plotting iso-regions of $\lambda_{ci} > 0$ (Adrian et al. 2000). Iso-regions of swirling strength are shown in Figure 8. Swirling strength is noted just behind the leading edge and inside the cavity due to the presence of the recirculation vortex. This quantity proved to be more useful than vorticity as a means of identifying eddies.

4 TURBULENCE CHARACTERISTICS

The 500 velocity fields measured allow studying the mean velocity field and the fluctuating velocity field.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The turbulent kinetic energy was chosen to represent the turbulent flow field. As the spanwise velocity component is not available, it is estimated from the other two components. The turbulent kinetic energy (k) is then expressed by (Sousa and Pereira, 2002):

$$k = \frac{3}{4} \cdot \left(\overline{u'^2} + \overline{v'^2} \right) \tag{10}$$

where $u' = u - U$ is the velocity fluctuation in the streamwise direction, $v' = v - V$ the velocity fluctuation in the transverse direction.

Figure 9 confirms that the maximum turbulent kinetic energy is located in the region near the pseudo-bottom. In the shear strain field (Fig. 6) the region of production of turbulent kinetic energy was identified: the mean velocity gradient removes kinetic energy from the mean flow and transfers it to the fluctuating velocity field. Also it can be observed the turbulent kinetic energy levels increasing in the downstream direction with more and more important values appearing in the overlying flow closer to the free surface.

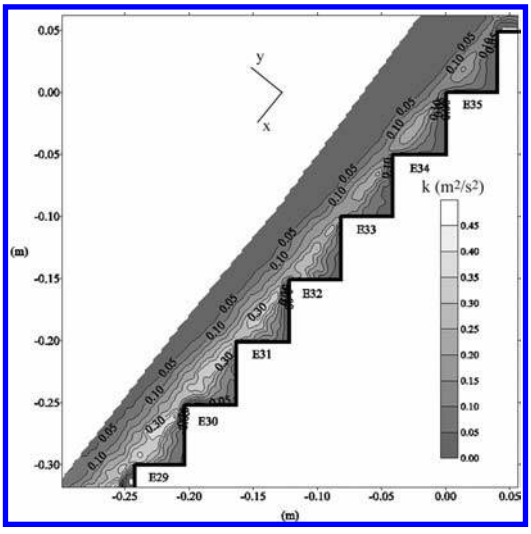

Figure 9. Contour map of turbulent kinetic energy (k).

4.1 *Turbulence intensity distribution*

As for the mean velocity, ten equally spaced turbulence intensity profiles were obtained over the cavities E34, E33, E31 and E29.

The turbulence intensity in the flow direction (T_u) is defined as:

$$T_u(y) = \frac{\sigma_u(y)}{U(y)} \tag{11}$$

where $\sigma_u\,(y)$ is the root mean square of the streamwise component of turbulent velocity and $U(y)$ is the mean streamwise velocity at y coordinate.

A gradual reduction of the turbulence intensity towards the edge of the boundary layer (δ) can be observed in Figure 10. In the transition between the boundary layer and the irrotational flow region were measured turbulence intensity (T_u) levels of 0.04. Near the pseudo-bottom ($y/\delta \approx 0$) the turbulence intensity ranges from 0.40 to 0.65.

The degree of turbulence intensity is much higher than the maximum levels reported for a turbulent boundary layer over a smooth open channel, $T_u = 0.2$ (Nezu y Nakagawa, 1993).

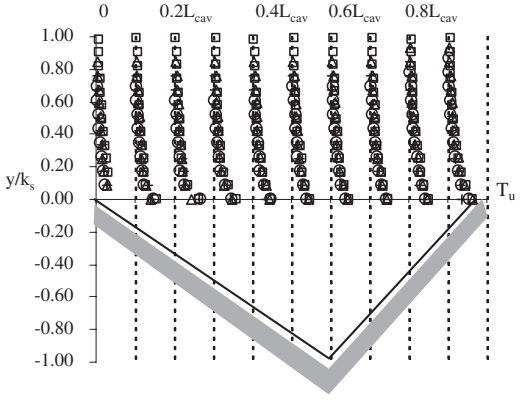

Figure 10. Turbulence intensity (T_u) profiles normal to the pseudo-bottom, along the V-shaped cavities. Symbols as in Figure 5.

4.2 *Quadrant Analysis*

The u'v' quadrant splitting scheme is one of the existent eduction techniques to study turbulent structures (Willmarth and Lu, 1972). This technique is based on the joint distribution of the velocity fluctuations on both longitudinal ($u' = u - U$) and vertical ($v' = v - V$) components. Four quadrants are defined in the $u'v'$ plane (Fig. 11): quadrant I ($u' > 0$ and $v' > 0$); quadrant II ($u' < 0$ and $v' > 0$); quadrant III ($u' < 0$ and $v' < 0$) and quadrant IV ($u' > 0$ and $v' < 0$).

Each quadrant represents an event; quadrant II is associated with "ejection" that can be schematically characterized by an upward movement ($v' > 0$) of a low-speed fluid ($u' < 0$), in quadrant IV are the sweeps that are downward movements ($v' < 0$) of high speed ($u' > 0$) fluid. Events in these regions correspond to the production of turbulent energy (see Equation 8) (Pope, 2000). Quadrants I and III are outward and inward interactions respectively.

Copyright © 2006 Taylor & Francis Group plc, London, UK

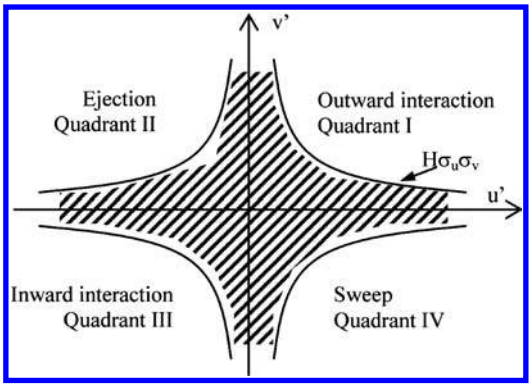

Figure 11. Definition sketch of the $u'v'$ plane (after Nezu and Nakagawa, 1993).

In Figure 11 the cross-hatched zone is bounded by the curves:

$$|u'\cdot v'| = H\cdot\sigma_u\cdot\sigma_v \tag{12}$$

where σ_u and σ_v are the root mean square values of the u and v velocity components. Only the region out of the cross-hatched zone is considered contributing to the events. The threshold values defined by H, allow distinguishing high-magnitude events (H high) and most frequent events (H equal to zero).

The quadrant contributions in each velocity field can be evaluated by the following discriminating function (Cellino and Lemmin, 2004):

$$I_H^i(x,y,n) = \begin{cases} 1, & [u'(x,y,n), v'(x,y,n)] \in Q^i \wedge |u'\cdot v'| > H\cdot\sigma_u\cdot\sigma_v \\ 0, & otherwise \end{cases} \tag{13}$$

The occurrence probability ($f_H^i = x$) of each quadrant (Q^i), over the 500 (N) instantaneous velocity fields can be determined by:

$$f_{H=x}^i = \frac{\sum_{n=1}^{N} I_{H=x}^i(x,y,n)}{N} \tag{14}$$

In this study two threshold values were adopted: $H = 0$, where all events within a quadrant are considered; and $H = 2$ where only the strongest events are considered, the value 2 has been used in other quadrant analysis studies (Bélanger and Roy, 1998).

Figures 12 and 13 shows that the events associated to quadrant II and IV are the most frequent or have the highest probability in the flow field. For $H = 0$ (Fig 12) ejections (Q^2) have the highest probability of occurrence over the region near the pseudo-bottom and inside the cavity, while the sweeps (Q^4) are the most frequent in the upper region of the overlying flow.

For the high-magnitude events, $H = 2$, occurs precisely the inverse. In the zone near the pseudo-bottom

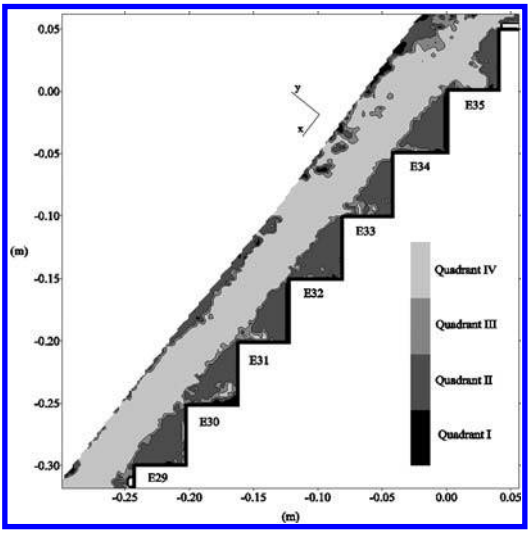

Figure 12. Contour map of the dominant quadrant in terms of occurrence probability for $H = 0$.

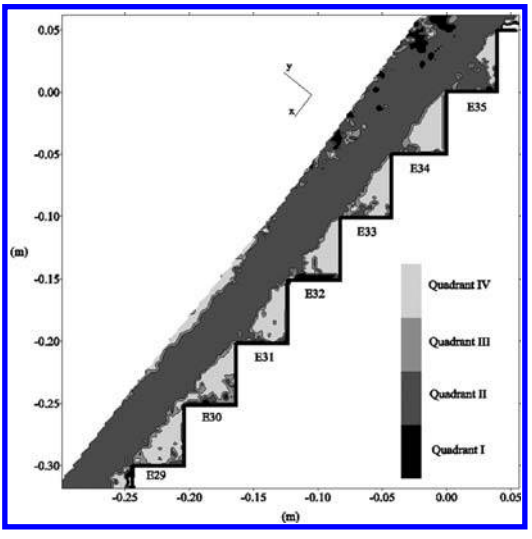

Figure 13. Contour map of the dominant quadrant in terms of occurrence probability for $H = 2$.

and inside the cavity, the highest probabilities of occurrence are for the sweeps and in the upper region of the coherent steam that skims over the cavities the dominant event is the ejection (Fig 13).

The previous considerations seem to corroborate the flow visualizations over transverse square cavities made by Djenidi et al. (1999). The visualizations indicated random occurrence of three types of events: outflows from the cavities into the overlying flow; inflows into the cavities; and, periods where the overlying flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

skims over the cavities with no significant exchange of fluid. The highest occurrence probability of high magnitude ejections in the overlying flow (Fig. 13) corroborates the existence of important outflows from the cavities. Continuity demands that an outflow which occurs at a spanwise location must be balanced, at the same time, by one or more inflows at other spanwise positions into thecavity, and that would explain why sweeps are dominant inside the cavity.

Djenidi et al. (1999) also observed that outflows occur sequentially in the downstream direction: an outflow from one cavity is followed by another in the adjacent downstream cavity.

These sequences of outflows indicate that the initiating mechanism for the outflows may be triggered by the overlying flow rather than have its origin within the cavity (Townes and Sabersky, 1966; Djenidi, 1999). The passage of quasi-streamwise vortices near the pseudo-bottom could pump fluid out of the cavities as these turbulent structures have associated pressure minimum at its core.

The outflows of strong magnitudes from the cavities into the overlying flow could play an important role in the increased turbulent intensities measured over surfaces composed of V-shaped cavities in comparison with smooth surfaces.

5 CONCLUSIONS

The experimental study presented herein investigated the developing turbulent boundary layer over a steeply sloping surface made up of V-shaped cavities. The main conclusions are summarized below:

(1) In the region upstream the inception point of air entrainment the flow is accelerating and the turbulent boundary layer is developing and growing in the downstream direction. The recirculation inside the cavity can be approximated to a solid body rotation. The velocities measured confirm the hypothesis of irrotational flow in the region closer to the free surface;
(2) The boundary layer thickness, δ depends on the distance from the channel crest and roughness height and can be predicted by Equation 1;
(3) The Von Karman integral momentum equation was applied to estimate the flow resistance coefficient (c_f). The mean value obtained was 0.031;
(4) The shear strain (Fig. 6) and vorticity (Fig. 7) contour maps agree in showing maximum levels just behind the leading edges, where the separation of the shear layer begins. These regions can be associated with the formation and growth of large scale turbulent structures which are convected in the downstream direction. The swirling strength proved to be an appropriate quantity to identify existent eddies in the mean velocity field (Fig. 8);
(5) The measured turbulence intensities (T_u) between 0.40 and 0.65 near the pseudo-bottom are much higher than the corresponding smooth surfaces values;
(6) A quadrant analysis was performed to study turbulent structures. It shows that "ejections" are the most frequent events in the region near the pseudo-bottom and "sweeps" dominate the upper region of the skimming flow, Figure 12. When considering only high magnitude events ($H = 2$), the opposite situation occurs. The "sweeps" are dominant near the pseudo-bottom and inside the cavity and the "ejections" are more frequent in the upper region of the overlying flow, Figure 13. This analysis seems to corroborate the flow visualizations of Djenidi et al. (1999). Along the span of the cavities, the outflows alternate with inflows of appreciable magnitude and contribute in producing and maintaining turbulence intensities and Reynolds shear stresses by exchanging momentum between the cavities and overlying layers. The fluid trapped within the cavities functions as a natural reservoir of low-momentum that facilitates the exchange of momentum between cavities and the overlying stream. It is conjectured that these would help maintaining a higher turbulent energy of the flow over a rough wall in comparison with a smooth wall.

Time variation of three-dimensional scour geometry

Oscar Link & Ulrich Zanke
Institut für Wasserbau und Wasserwirtschaft, Technische Universität Darmstadt, Germany

ABSTRACT: An experimental investigation on time variation of three-dimensional scour geometry at a circular pier in sand is presented. Experiments were conducted in a relative large laboratory flume that has length, width and depth of 26, 2 and 1 m respectively. During experiments high-resolution scour geometry measurements has been carried out applying a non-intrusive measurement method in which a laser distance sensor placed inside the plexiglas pier is used. Radial and vertical position of the sensor was controlled by precision step-motors. Data were aquired with a frequency of 70 Hz. Whole topography was measured within two minutes. From the experimental results an accurate characterization of scour-hole geometry is presented, quantitatively defining the different scour phases, namely initial, development, stabilisation and equilibrium phase. The data are useful for testing results of numerical simulations.

1 INTRODUCTION

Pier scour is a topic of continuous interest in civil engineering. State-of-the-Art reviews have been given by Breusers et al. (1977), Hoffmans & Verheij (1999) and Melville & Coleman (2000). Mostly, past experimental investigations focused on measurement of time-dependent and equilibrium scour depth at the pier nose.

Regarding geometry of scour-hole, slopes of symmetry axis of a scour-hole has been studied by Dargahi (1987). Equilibrium scour-hole geometry has been presented by Melville (1975), Olsen & Melaeen (1993) and Yanmaz & Altinbilek (1991). Link & Zanke (2004) presented an experimental curve relating scour-hole volume with scour depth at the pier front. Nevertheless, a systematic study on time-dependent scour-geometry remains undetected. The possible reason is partly attributed to the difficulties araising in the necessary measurement technique, which should include a non-intrusive sensor that rapidly moves to get the scour hole geometry especially during scour initial phase. Information on time-dependent scour-hole geometry is crucial for validation of three-dimensional numerical models. Scour hole geometry has been assumed as a frust of an inverted cone in simulations by Richardson & Pachang (1998).

In this article we present an experimental setup for the non-intrusive high-resolution measurement of the complete scour-hole in time. The measuring system was used to investigate the time-dependent characteristics of scour-hole geometry in a well graded sand at a single cylindrical pier.

The results describe scour mechanism quantitatively well, allowing definition of threshold values for the scour phases: initial, development, stabilisation and equilibrium phase, first proposed by Zanke (1978a,b) for two-dimensional scour and generalised for the three-dimensional case by Hoffmans & Verheij (1997).

The structure of the paper is organized as follows: In the second part we present the experimental setup and measurement technique. In the third part we present laboratory measurements. In the fourth part threshold values for the scour phases are defined.

2 EXPERIMENTAL SETUP AND MEASURING TECHNIQUE

2.1 *Experimental facilities*

Experiments were conducted in a rectangular flume with glass side-walls, 26 m long, 2 m wide and 1 m deep, at the Institute for Hydraulic and Water Resources Engineering, Darmstadt University of Technology, Germany. A 20 cm diameter plexiglas cylindrical pier was mounted in the middle of a working section with movable bed. This is located 16 m downstream of the flume entrance, having a length of 4 m, width of 2 m and depth of 0.5 m. A false bottom made of concrete plates was installed outside the working section in order to avoid filling the whole flume with sand. The plates rested on bricks, 0.5 m over the original flume bottom. The sides of the working section

Copyright © 2006 Taylor & Francis Group plc, London, UK

were coated with absorbing material in order to avoid secondary flows.

2.2 *Sediment material*

The bed material was a mixture of sand with grain sizes ranging between 0.06 and 2.00 mm and having a representative particle diameter $d_{50} = 0.25$ mm. The geometric standard deviation $\sigma_g = (d_{84.1}/d_{15.9})^{0.5}$ of the particle size distribution was 1.37. Figure 1 shows the sieve curve of the employed sediment material.

The critical velocity for the initiation of motion of isolated sediment particles, in the following called critical velocity, u_{cr} was equal to 0.26 m/s. The natural repose angle of sediment particles ϕ was 30°.

The sand was filled in the working section up to 5 cm over the false bottom level having 10 m upstream and 2 m downstream of the pier also covered with a 5 cm thick sediment layer.

2.3 *Measurement method*

The flow discharge, controlled by an inlet valve, was measured using a magnetic inductive sensor attached at the flume inlet. The flow depth, adjusted by a tailgate, was recorded by an acoustic sensor with an accuracy of ±0.5 mm. Initially, the flume was slowly filled with water. The flow discharge was increased and once the predetermined stable flow condition attained the measurement was taken.

A laser distance sensor located in the plexiglas pier (see Fig. 2) was used to measure the scour-hole radius with an accuracy of ±0.4 mm. The sensor was driven by high-precision step-motors in the vertical and radial directions with an accuracy of ±0.1 mm and ±0.5° respectively.

Vertical profiles containing about 20–30 points were taken in 24 different directions around the pier by turning the distance sensor in steps of 15 degrees around its vertical axis. Figure 3 shows a schematic diagram with the pier and measurement directions.

In order to compute maximum scour depth at each profile, vertical steps were adjusted according to the actual radius measured by the laser. In that way, when the sensor approached the scour-hole bottom, the vertical step was continuously reduced to a minimum value of 0.4 mm.

Point-data were aquired with a frequency of 70 Hz allowing a fast measurement of the complete scour-hole. A measurement of the whole scour-hole topography took about 30 seconds at the beginning of the experiments and about 2 minutes at the end of them.

Experiments with different section-average flow velocities, u_∞ have been carried out. Experimental runs were taken until maximum scour depth increased at a rate of about one representative particle diameter d_{50} per hour. Scour was studied under both, clear-water and live-bed conditions.

3 RESULTS

3.1 *Maximum scour depth in azimuthal planes*

Results correspond to a 20 hours duration scour experiment under the clear-water condition, with $u_m = 0.95u_{cr}$. After about 16 hours, the sediment transport rate in the scour hole was considered negligible. For the plots in Figure 7, 120 hours scouring has been analysed.

Dimensionless scour depth is defined as the maximum actual scour depth in a given plane at a certain time normalized by the maximum reached scour depth i.e. maximum scour depth at the front of the pier at the end of the experiment. Dimensionless time is the actual time normalized with the experiment duration.

Figure 4 shows dimensionless scour depth on dimensionless time in azimuthal planes with $\theta = 0°$, $60°$ and $105°$ for the first 20% of the maximum dimensionless time.

As scour initiates at the sides of the pier, at azimuthal planes with $\theta = 65°–75°$, curves present an offset in time within the first 2% of maximum dimensionless time. During this lapse, scour progresses faster downstream than upstream (compare slope of curves corresponding with $\theta = 60°$ and $\theta = 105°$).

At the pier nose ($\theta = 0°$) scour begins after a very short time of about 2% of experiment duration.

As it is well known, about 70–80% of scour develop in the first 10–20% of the maximum dimensionless time. Remarkably, the experimental curves show that the maximum depth of scour-hole is observed at the pier nose first after about 70% of scour has developed.

After about 20% of maximum dimensionless time maximum scour-hole depth is observed at the pier front (between $\theta = -30°$ and $+30°$).

Figure 5 shows dimensionless scour depth (at $\theta = 0°, 30°, 60°, 90°, 120°$ and $150°$) on dimensionless time after maximum scour depth reaches the azimuthal plane $\theta = 0°$. Scour progresses with the same velocity in all planes i.e. curves in Figure 5 are nearly parallel until time reaches about 50–60% of maximum dimensionless time.

After about 60% of maximum dimensionless time, scour progresses slower, with different velocity at the different azimuthal planes, i.e. curves of scour-depth on time change from a parallel to a slightly divergent development.

Figure 6 shows dimensionless scour depth on dimensionless time at azimuthal planes with $\theta = 0°$, $30°$ and $60°$.

3.2 *Scour volume*

Figure 7 show the scour-hole volume on maximum scour depth during 120 hours experimentation. The plotted curve confirms the tendency indicated in Figure 6. When scour reaches about 80% of maximum

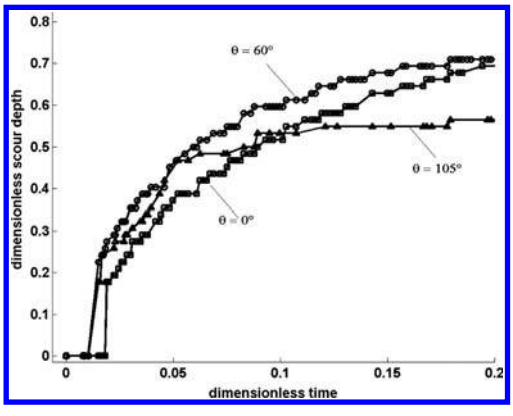

Figure 4. Dimensionless scour depth on dimensionless time in azimuthal planes with $\theta = 0°$, $60°$ and $105°$.

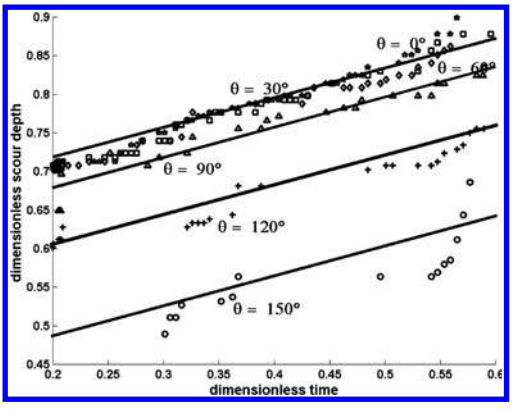

Figure 5. Dimensionless scour depth on dimensionless time in azimuthal planes with $\theta = 0°, 30°, 60°, 90°, 120°$ and $150°$.

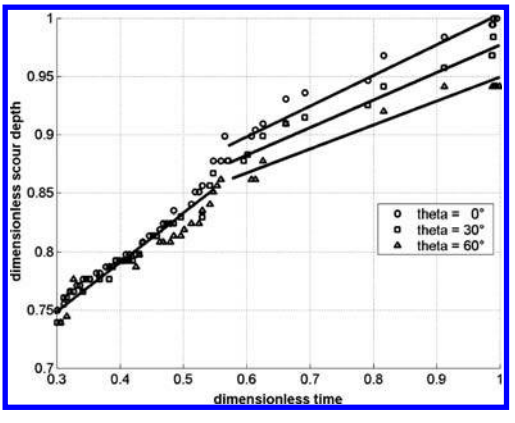

Figure 6. Dimensionless scour depth on dimensionless time in azimuthal planes with $\theta = 0°$ (circles), $30°$ (squares) and $60°$ (triangles).

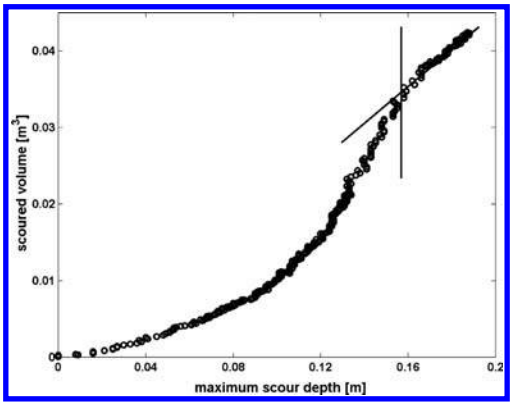

Figure 7. Scour-hole volume on maximum scour depth.

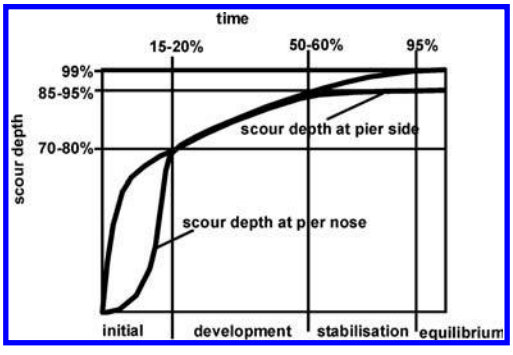

Figure 8. On definition of scour phases: initial, development, stabilisation and equilibrium.

depth, a new inflection point in volume on maximum scour depth is observed. Erosion intensity at the scour-hole decays to a small constant rate which growth nearly linear with maximum scour depth signalising a tendency to stabilisation.

4 DISCUSION

The presented high resolved measurements of scour-hole geometry in space and time suggest a threshold criteria to define scour phases. The presented measurements correspond to clear-water scour experiments with $u_m = 0.95\ u_{cr}$.

Schematically, scour phases can be defined as shown in Figure 8, extending the concepts suggested by Zanke (1978a,b) and adopted by Hoffmanns & Verheij (1997).

During initial phase, a given design scour depth, i.e. 70–80% of equilibrium scour depth is first achieved at the sides of the pier. Bridge scour monitoring should take this characteristic of scour-geometry into account, placing scour measurement devices at the pier sides rather than at the pier nose.

The validity of the proposed threshold values for experiments with lower and higher approach velocities is discussed by Link et al. (2006). Further research with different approaching flow depth and sediment materials is under development to investigate the influence of hydraulic and sedimentologic parameters on scour phases.

5 CONCLUSIONS

An experimental investigation on time variation of three-dimensional scour-hole geometry at a circular pier in sand has been presented.

Time-dependent scour-hole geometry has been measured by a new high-resolution non-intrusive method.

Experimental results provide information for a quantitative definition of the different scour phases, namely initial, development, stabilisation and equilibrium phase.

The presented data can be used in improving bridge scour monitoring and testing results of numerical simulations.

Discharge measurement using Large Scale PIV under varied flow conditions – Recent results, accuracy and perspectives

A. Hauet, J.D. Creutin & P. Belleudy
Laboratoire d'Etude des Transferts en Hydrologie et Environnement, Grenoble, France

M. Muste & W. Krajewski
IIHR-Hydroscience & Engineering, The University of Iowa, Iowa City, USA

ABSTRACT: For 10 years now, Large Scale Particle Image Velocimetry (LSPIV), an image-based method, has been increasingly used for non contact rivers survey. LSPIV is a statistical identification of displacement flow from images on natural scale of rivers. This includes measurements of surface velocity distribution and discharges for very different sizes of rivers with sections as small as few meters and as large as hundreds of meters, without and with seeding of the flow, and with different sensing systems. This presentation is a review of a number of experiments, using the LSPIV method, conducted those last 10 years under varied flow conditions, i.e. from low flow to high flow. The authors present results of those experiments and highlight the advantages and weaknesses of the LSPIV measurements. The authors also present recent collaborative work between IIHR-Hydroscience & Engineering, Iowa City, USA and the Laboratoire d'étude des Transferts en Hydrologie et Environnement (LTHE), Grenoble, France. Those include measurements (i) from a mobile LSPIV platform, i.e. a truck-based system and (ii) from a permanent location at the Iowa River, where continuous real-time estimations of the discharge are performed. The authors present results of those experiments and highlight the advantages and weaknesses of the LSPIV measurements in field conditions.

1 INTRODUCTION

In the last decade, image-based methods have been increasingly used for non-contact measurements in rivers. The Large Scale Particle Image Velocimetry (LSPIV) used for this purpose is an extension of the conventional Particle Image Velocimetry and mainly consists in the statistical identification of the displacement of tracers floating at the surface of natural rivers.

The LSPIV measurements involve four steps: (i) recording of images, (ii) geometric transformation and image reconstruction, (iii) processing of the images by the way of statistical correlation to obtain a surface velocity field, and (iv) post-processing and quality check of the obtained velocity field. That measurement conveniently provides surface velocity distribution in straight channels as well as in more complex structures such as recirculation at junction between channels Lecoz (2005) or flow around hydraulic structures Dermisis & Papanicolaou (2005) or Fujita et al. (1998). By adding a fifth step, the free surface velocity associated with river bathymetry and hydraulic hypothesis leads to the discharge estimation.

This study is focused on the discharge estimation with LSPIV. We identify main problems of the actual hydraulic and hydrometry and explain, by the way of a review of selected papers, the contributions but also the limitations of LSPIV in the resolution of those problems. Recent results concerning a Mobile LSPIV unit and a continuous real-time LSPIV station are discussed.

2 LSPIV: AN INTERESTING TOOL FOR SOLVING MAJOR PROBLEMS OF HYDROMETRY

2.1 *Low flows*

Low flow measurements are very important for the study of physical and biological processes in coastal wetlands, marshlands, small channels or streams during drought conditions. Low flow discharges estimates are usually obtained by combining continuous water stage measurements at streamgages with rating curves. However, the uncertainty of the rating curves for low flow can be very important, especially for the small

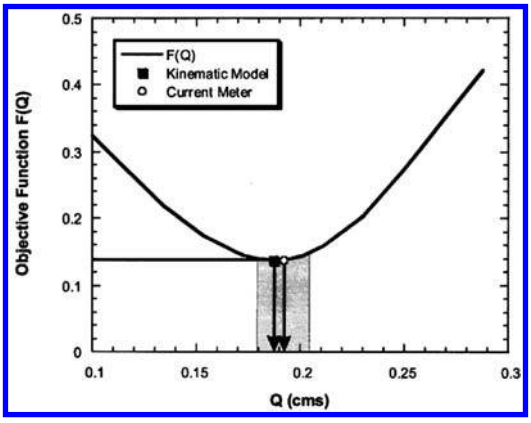

Figure 1. Mean-squared difference F(Q) between the PIV surface velocity estimates and the simulated velocities by the kinematic model as a function of discharge. The final estimate (corresponding to the minimum) is 0.187 cms. The current meter measurement (also shown) is 0.192 cms. The shaded area defines the range within one standard error of the current meter measurement. From Bradley et al. (2002).

streams Pelletier (1988). This has several causes. First of all, direct measurements of low flows with traditional equipment, such as current meter or ADCP, are in limited number, because (i) of the low return period of such events and (ii) of the difficulty of making such measurements with immersed material in very small water depth layer. The narrow channel width and shallow water depth usually make it impractical to follow recommended current meter guideline Buchanan & Somers (1969) regarding the minimum number of vertical profiles for the cross-section, and minimum number of depth velocity measurements at each profile. For ADCP, the blanking distance and the side lobe interference Simpson (2001) make the measurement impossible for shallow water. Furthermore, the modifications in the streamgage cross-section bathymetry, in alluvial channels, during floods have significant impact on low flow ratings.

LSPIV seems to be very well adapted for measurements in low flow conditions. Bradley et al. (2002) proved that, in a 5.7 m wide and 0.2 m deep channel at Clear Creek (Iowa), image velocimetry combined to a kinematic flow analysis allows a very good estimation of the discharge (0.187 $m^3\,s^{-1}$ for LSPIV, 0.192($\pm$6.4%) $m^3\,s^{-1}$ with current meter, see Figure 1).

At the same time, the USGS gage located approximately 15 m downstream of the experimental site, gave an estimate via the rating curve of 0.085 $m^3\,s^{-1}$, that is of the current meter measurement. Bradley et al. (2002) concluded that the large observed difference illustrate the significant errors that can results for low flow estimates based on traditional stage-discharge rating curve. The major limitation concerning LSPIV measurements in field conditions highlighted by the authors is the need for tracers at the free surface during low flow. Bradley et al. (2002) artificially seeded the surface of the river with fallen leaves, which limits the benefit of the "noncontact" aspect of the method.

Meselhe et al. (2004) studied the efficiency of LSPIV for low velocity measurement by the way of laboratory experiment. The velocity tested ranged from 0.013 to 0.044 $m\,s^{-1}$, which correspond to discharges from 0.002 to 0.0038 $m^3\,s^{-1}$ in a 1.524 m wide rectangular channel. By selecting appropriate seeding density and flow field sampling frequency, Meselhe et al. (2004) found that the LSPIV surface velocity have an average error of $\pm$5%, which proves the efficiency of the technique for low velocity measurement.

2.2 *Floods*

Accurate knowledge of the flow during a flood is crucial for hydrologist, fluvial geomorpholmogist, and river ecologist. Current meter and acoustic gauging methods require boat, cable cars or bridges, or wading into the stream in order to measure discharge for the cross-section. This procedure is time consuming and labor intensive. As noted by Creutin et al. (2003), gauging with this traditional equipment is difficult during periods of high flows for at least two reasons: (i) high flow velocities and floating debris endanger the operators and the equipment, and (ii) the river level and discharge can significantly change during the measurement, compromising the quality of the discharge estimate. As a result, 80% of the French rivers are not gauged for discharges with return periods superior greater than 10 years. An alternative is the use of aerial photographs, but they are associated with several deficiencies Fujita et al. (1997). LSPIV is an indirect (i.e. without contact with the water) method which can be applied by any flow condition, from a flood protected area. During floods, velocity measurements can be made from naturally occurring tracers, including foam, boil and ripple structures, and debris.

In an application to the Yodo River (Japan), Fujita et al. (1998) used LSPIV for monitoring a flood plain of a 100 m wide stream. The velocity measured reached 4 $m\,s^{-1}$. The authors observed a good representation of the velocity distribution of the flood plain, and the measurement of the discharge was in very good agreement (within 3%) with an estimation of discharge from a gauging station, where the stagedischarge curve was known, at the same location.

Because of it's fastness, LSIPV measurement seems to be also particularly adapted for the monitoring of flash floods. The imagery technique is ideally suited for making repeated measurement at low cost, so that it allows measuring not only the peak of the flood but all the dynamic of the periods of increasing and decreasing of the flow.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The main problems that come up against the application of LSPIV for floods monitoring are: (i) the very important size of the area of interest to be recorded, which means a low resolution of the images. Flood plains are usually areas of several hectares. The tracers need to be larger than the resolution of one pixel to be followed. (ii) the deficiency of illumination and seeding. Floods happen most of time during rain periods, i.e. with cloudy weather and so poor illumination. Moreover, rain can destroy tracers such as bubbles or foam, or created patterns at the surface of the water that created errors in the PIV surface velocity computation.

2.3 *Rating curve improvement*

Most of time, the stream-flow records do not come from direct measurements of the discharge but are computed from continuous water stage measurements (pneumatic level indicator, float gauge . . .). The water stage is linked with the discharge using a rating curve that is unique for each stream gauging location. As the bed and the banks of a river are not static, the rating curve could change in time. A major task is then establishing and updating the stage-discharge relation. For the USGS Hirsch & Costa (2004), a good updating means direct discharge measurements 8 times a year for each gauging station. As explained in section 2.2, traditional gauging are time consuming and labor intensive. Following the USGS guideline, it needs at least 2 hours and 2 operators to estimate a discharge at a cross-section using current meter. Finally, the budget allowed for the updating of the rating curve is considerable. It represents 12K$ per year per gauging station for the USGS. 50% of this cost is dedicated to the maintenance of the infrastructure and 50% is dedicated to the operators. As a consequence, the majority of the rating curves are based on few measurements, and the uncertainty is high.

Creutin et al. (2003) demonstrate the capability of LSPIV for repeated measurements at the same location. In a time period of only 20 days, 10 LSPIV measurements were realized on the Iowa River, in Iowa City (USA). The experimental area was situated close to a USGS gauging station. Naturally occurred foam was used as tracer of the flow. Discharge for the experiment ranged from 50 to 300 $m^3\,s^{-1}$, which covers a large portion of the existing rating curve. As illustrated in Figure 2, Creutin et al. (2003) showed that the LSPIV measurements were very consistent with the 215 current meter measurements made by the USGS at the same site since 1984.

The authors suggested that image-based approach may be a reliable way to establishing and updating a stage-discharge relationship at a site at very low cost. They identify limitations including the need of recognizable tracer particles or flow patterns to detect motion, problem associated with shadows and reflections on the water surface, as well as the problem of the need for survey information on the channel cross-section.

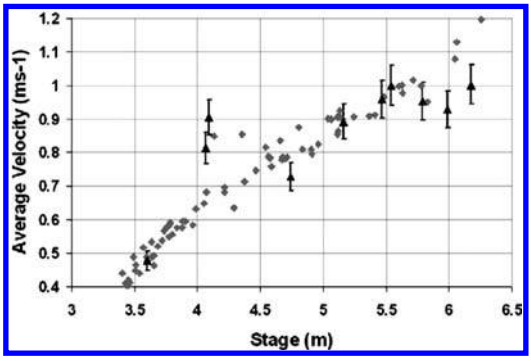

Figure 2. Display of the average velocity of the flow as a function of the river stage for both the USGS gauging (gray squares) and the PIV measurements (black triangles). The error bars on the PIV measurements indicate the sensitivity due to the correction coefficient applied to derive the mean vertical velocity from the surface velocity. From Creutin et al. (2003).

3 IIHR – LTHE COLLABORATIVE WORK

3.1 *Mobile LSPIV for monitoring of ungauged sites*

As Moss (2003) noted, "the problem of estimation of hydrological variables at ungauged sites is perhaps among the oldest challenges for the hydrological practitioner". This problem is especially strong in developing countries, where a decline of measuring networks and poor quality of available data is observed Smakhtin (2004). Some statistical physically based methods have been developed to estimate discharge at ungauged basins, but those formulas are not easy to apply, need a measuring network in the region of the studied basin, and cannot access to very small time step. With traditional equipment, the cross-section of the stream to be gauged needs to be geographically ideally situated, i.e. close to a road, on flat banks.

The Mobile LSPIV (MLSPIV) unit, a truck-based system that essentially comprises an image device (video or camera) set on a telescopic mast (Fig. 3), is in development at IIHR in order to deal with that problem.

In that unit, camera positioning and control and the image processing are conducted remotely from a laptop. The MLSPIV is equipped with a mast, a power generator, uninterrupted power supply (UPS) and two batteries. The light weight aluminium hydraulic operated mast allows setting the camera from 5 m to 14 m above the ground level to accommodate imaging of

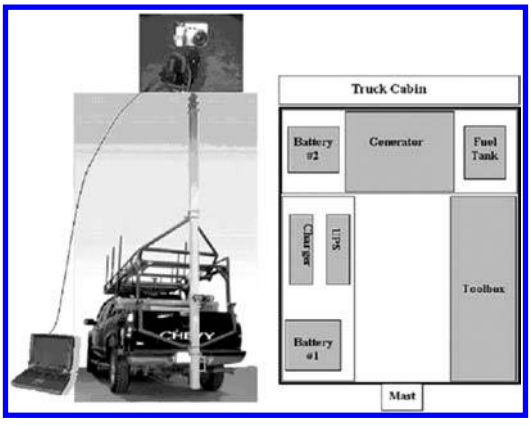

Figure 3. MLSPIV and equipment.

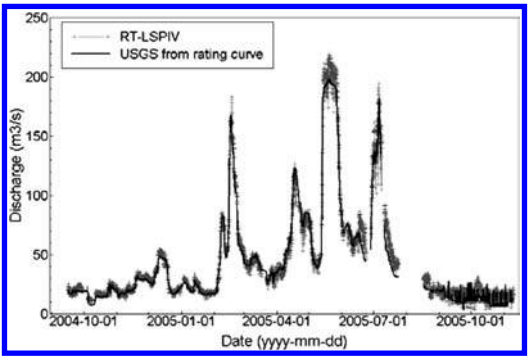

Figure 4. Sample time series of discharge estimates made by USGS, and using the RT-LSPIV.

various stream widths. Three guy lines secure the mast after positioning against wind and accidental oscillations. The assembly for capturing images is composed of a pan-tilt unit, which allows the positioning of the image device with a resolution of 0.0514 degree. The image device is used to record successive images with a pre-selected time delay and resolution. An in-house developed software allows the computation of the surface velocities, and of the discharge (if the bathymetry of a cross-section is known) in "real-time", i.e. with a computational time of around 1 minute.

A case study of the MLSPIV was realized by Kim et al. (2005) at Clear Creek near Coralville (USA). The stream was about 20 m wide and 0.5 m deep at that location. Two measurements of discharges were conducted using digital and video camera, during normal flow condition, and compared to estimations, via a rating curve, of a USGS gauging station located 25 m upstream from the studied cross-section and recorded stage every 30 minutes. The MLSPIV gave good agreements with the USGS estimations, as the error, defined as $100^* (Q_{MLSPIV} - Q_{USGS})/Q_USGS$ was −2.53% for the digital camera, and 4.46% for the video camera.

The MLSPIV has capabilities to measure discharges and free-surface velocity distribution in stream during normal and extreme flow conditions during daylight, and in situations where the interior of the flow is, for one reason or an other (low flows, flows over rock beds and submerged control structures), inaccessible or difficult to reach. At that time, experiments using MLSPIV have only been conducted on small to medium river sizes. The capability of theMLSPIV to estimate discharge, with good accuracy, in very large rivers needs to be assessed with more experiments. The system can not only provide a cost-effective means to measure discharge at ungauged sites, but can improve rating curves at existing gauging sites during extreme flow conditions.

3.2 *Real-Time, continuous LSPIV*

Previous studies of image-based approaches for river discharge estimation (see the previous sections) have demonstrated the accuracy of LSPIV for brief measurements (recordings of 10 minutes or less) and under good to ideal illumination conditions. Hauet et al. (2005) examined the feasibility of a continuous, real-time, image-based, non-contact approach for estimating discharge in rivers, called Real-Time LSPIV (RT-LSPIV). The continuous operation of RTLSPIV throughout the year implies that estimates can be evaluated over a large range of discharge, and under varied natural weather conditions (illumination, wind, rain). Continuous real-time operation also imposes computational requirements for data transmission, computer memory, and processing time.

The experimental site for the prototype system is the same than in the experiment of Creutin et al. (2003) (see section 2.3). A web cam autonomously records an image pair of the river every 2 minutes, and the discharge estimation is computed in real-time. Weather data are recorded at the same time step from a NOAA station. A data base is updated with the new images, discharge estimation, stage measurement and weather data every 2 minutes. The results are posted in real-time at the IIHR website, along with real-time estimates from the USGS (based on rating curves). From the experience over the first 14 months of operation, the authors found that, most of time, the realtime PIV discharge and cross-sectional average velocity estimates were consistent with those based on USGS current meter measurement at this site since 1984, and with other image-based measurement made by Creutin et al. (2003), as demonstrated by the discharge chronology in Figure 4.

Several challenges with the field PIV technique for continuous real-time discharge estimation was identified by the authors. The most significant challenges are illumination of the river surface, seeding conditions,

Copyright © 2006 Taylor & Francis Group plc, London, UK

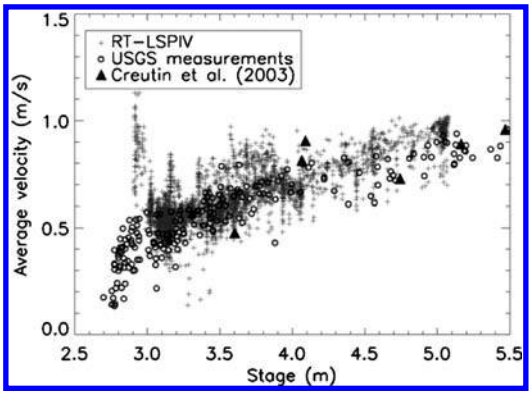

Figure 5. Average flow velocity (discharge divided by the crosssectional area) from USGS measurements, (Creutin et al. 2003), and RT-LSPIV.

wind effect and rainfall effect. Discharge estimates during those conditions are highly variable and have systematic errors. In consequence, as illustrated in Figure 5, the RT-LSPIV measurements are consistent with the USGS measurements, but have more dispersion.

The long-range vision for the Iowa River demonstration site is as a test-bed for research on imagebased discharge measurement techniques. Its location at a USGS gauge site facilitates comparisons with direct measurements. In addition, raw images, USGS data and weather data are archived continuously, which will provide extensive data for retrospective testing, comparison, and validation of image processing and discharge estimation algorithms.

4 CONCLUSIONS

In that study, we present a review of papers dealing with the application of LSPIV, an image-based method, in the discharge monitoring of streams. Recent works, resulting from a collaboration between IIHR-Hydroscience & Engineering, Iowa, USA, and the Laboratoire d'étude des Transferts en Hydrologie et Environnement, Grenoble, France, and new results are presented. The limitations of LSPIV identified in the reviewed papers and in the works in progress include problems of:

- Illumination: general illumination intensity and local illumination nonuniformity (light reflections and shadows)
- Seeding: density, size, brightness and contrast, wind effect
- Recording: image resolution, time between images, sampling time, camera movement during recording
- Geometrical transformation
- PIV processing

Despite all the challenges, there are many aspects of PIV discharge measurement that make it attractive for river monitoring. The capabilities of LSPIV for measurement of extreme events, floods or low flows, and its interest in the establishment and the updating of rating curve at very low cost are exposed in that paper. The equipment used is simple, light-weight, and inexpensive, and can be mounted well above the river surface, protected from floods. Rather than estimating discharge from measured stage using an empirical rating curve, the discharge is estimated from measured surface velocities every few minutes. Whereas a rating curve must be extrapolated beyond the range of direct measurement, in principle, the image-based approach is valid for any river stage (from very low to high flows). Indeed, one can see that PIV measurement could provide a means to construct a rating curve quickly and efficiently. Although individual PIV discharge measurements have greater uncertainty than direct measurements, in a very short time, one can obtain many more PIV discharge measurements, spanning a range wide range of flow conditions, using a continuously operating system.

Discharge measurements in a small ungauged river: Comparison between conventional current-meter and tracer dilution methods

A. Bolognesi, G. Gottardi & M. Maglionico
DISTART – Università di Bologna, Viale Risorgimento 2, Bologna, Italy

ABSTRACT: The majority of small rivers and channels that flow across the Emilia-Romagna region (Northern Italy) are monitored by an extensive network of level meters. Unfortunately a stage-discharge relationship is available only for the main among them. The purpose of this study is to determine the reliability and accuracy of discharge measurements carried out by tracer dilution method. Experimental investigations have been carried out on a small river nearby Bologna (Italy), performing slug injections of a conservative tracer (NaCl) and recording electrical conductivity in a downstream section, while at the same time, conventional current meter measurements have been taken in a section placed between the injection point and the conductivity meters. Data obtained from both the methods have been compared each other, giving also main relevance to the uncertainty analysis. Monte Carlo Simulations were performed to integrate single uncertainties coming from different potential sources of error, either experimental or analytical.

1 INTRODUCTION

The determination of discharge value is certainly one of the most relevant aspects within the study of open channel flows and related processes. Reliable knowledge of flow data is a fundamental issue in many branches such as water quality monitoring, water resource management, as well as hydraulic devices design and control. The most common approach to measure discharge is the so called conventional current-meter method. The method is based on determining the mean streamflow velocity and flow cross sectional area; the product of these variables determines the stream discharge. Applicability of velocity measurements using a current meter appears rather hard in small streams (Hudson & Fraser, 2002), like the steep ones, such as mountain streams or in general the ones where small water depths and velocities, approach the unreliability ranges of the method. These characteristics are common in a large part of the small rivers flowing across the main plain of Northern Italy, most of which passing through urban or densely populated areas. In those streams and channels, whose catchments rarely exceed a few hundred km^2, and where the outlets of waste water treatment plant are often the only source of flow, low water depth conditions almost always occur during dry weather period.

In order to test the reliability of a suitable discharge measuring strategy for those streams, a comparison between traditional current-meter measures and salt dilution method has been carried out in a small river near Bologna, Italy.

The characteristics of the investigated reach, are within the range of applicability for both the methods. Stream width and water depth (further details in the following paragraph) are big enough to take several current meter measures, as well as small enough to justify the use of salt dilution method.

2 THE EXPERIMENTAL SITE

The Navile channel is an ancient artificial channel dug in the 12th century, in which typical features of a small natural river have developed during the years. The Canale Navile has its origin inside the urban area of Bologna city, receiving water from both natural and artificial sources. One of the most relevant among those sources, comes from the waste water treatment plant of Bologna (650000 E.I.), whose outflow gives, in particular during the summer months, a great part of the total conveyed flow. Consequently during dry weather periods, the Navile discharge rarely exceed 2 m^3/s, while during heavy stormwater events reaches up to sensibly higher values.

The reach chosen for the experimental comparison flows across the village of Bentivoglio, almost 15 km north of Bologna. Located in a flat territory, which means negligible bed slope values, the reach is placed downstream a sluice gate, whose opening has been kept constant during the entire measuring campaign, in order to achieve steady state conditions. The aerial photo in Figure 1 shows the Navile channel at Bentivoglio, evidencing with “Section B” the

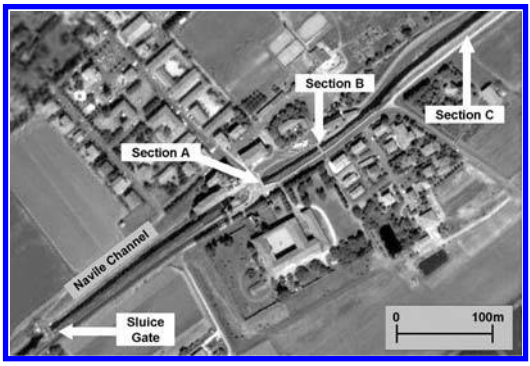

Figure 1. Aerial view of the Navile reach involved in the experimental activity.

bridge where velocity measures have been taken with a current meter, while in "Section A" and "Section C", respectively the salt solution injection point, and the section where conductivity has been measured for the tracer dilution method. Distance between section A and C, which is indeed the investigated reach, is about 300 metres.

The channel path is almost completely straight, its free surface width ranges from 6 to 10 metres and its depth from 0.5 to 1 meter.

In order to improve the measurement conditions, maintenance works have been executed on the river bed and embankments. In fact the effect of unexpected irregularities in such a small channel could deeply affect the final results.

3 THE CURRENT METER METHOD

Streamflow discharge is defined as the volume of water flowing past a fixed point in a fixed unit of time. If the water velocity distribution over a cross section normal to the direction of flow and the area A of that fluid section are known, then the discharge Q is given by:

$$Q = \iint_A \boldsymbol{v} \cdot \boldsymbol{n}\, dA = \iint_A v(x,y)dx\, dy \qquad (1)$$

where: v = velocity vector, n = the unit vector normal to the cross section in the considered point; $v(x,y)$ = the velocity field as a function of width x, and depth y.

In practice, theoretical integral is approximated by the sum:

$$Q = \sum_{i=1}^{m} b_i d_i \overline{v_i} \qquad (2)$$

where: b_i = the width oh the i_{th} vertical sub-section; d_i = the depth of the i_{th} vertical sub-section; m = the number of vertical sub-sections in which the entire cross section is divided.

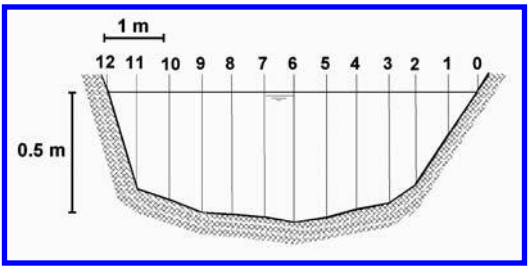

Figure 2. Cross section where current meter measurements have been taken. In evidence the 11 vertical sub-sections.

In order to obtain a mean velocity for the considered cross section, several velocity measures have to be taken at different points.

A current meter is an instrument that measures the velocity of flowing water. Traditional mechanical current meters are based on the principle that the velocity of water is proportional to the angular velocity of the meter's rotating propeller. A relationship exists therefore between stream velocity and the number of spins during a certain lapse of time.

Current meters are classified according to their rotors. Vertical-axis rotors normally operate in lower velocities than horizontal axis meters, while the last ones disturb less flow because of the axial symmetry with the flow direction. Their propeller is therefore less likely to be obstructed by debris or leaves.

Both natural water bodies and artificial channel show the presence of turbulent flow and local eddying. This results in velocity pulsations at a point, which have been proved to be higher for lower velocities (Rantz et al., 1982). Therefore, in order to obtain a better representation of the average velocity at a point, current meter observations should cover a longer period, especially when low velocities are being measured.

3.1 *Experimental activity*

A pedestrian bridge (section B in Figure 1) has been chosen as the gauging section (Figure 2), allowing easy installing and management of the current meter but also satisfying the method requirements. In fact no piers occupy the wetted section and the river bed has no evident irregularities, therefore streamlines flow quite uniform, parallel to each other and normal to the bridge.

Velocity measurements have been taken with a SEBA horizontal axis current meter, having a propeller diameter of 125 mm and weight of 50 kg.

The chosen section, which has a free surface width of 6.25 m and a maximum depth of 0.55 m, has been divided into 11 verticals, almost equally spaced by

Copyright © 2006 Taylor & Francis Group plc, London, UK

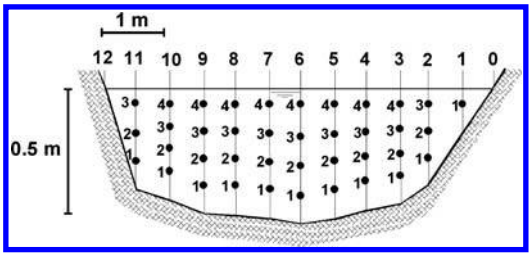

Figure 3. Gauging cross section with all the 39 measuring points.

0.52 m. Along each one of the verticals, up to 4 measuring points have been defined at different depths (Figure 3), for a total amount of 39 points within the section.

For each of those points 6 or 7 readings have been recorded, in order to assess velocity fluctuations due to turbulence and also to avoid accidental bad measures, allowing about 30 seconds for each reading to stabilise. Each point took therefore at least 3 minutes. Even though the regularity of the cross section as well as the stream velocities, probably did not require such a large number of points and so many repeated measures for each point, it has to be pointed out that this somehow redundant procedure has been carried out for research purpose and therefore not accomplishing the traditional cost and time saving procedures, but literally fulfilling the ISO EN 748:2000 requirements.

3.2 *Data processing and results*

Different readings at each measuring points allow a statistical analysis for the mean velocity variable, according to the "Student" small-sample theory.

Considering "N" samples extracted from a quasi-normal population having mean μ, it is possible to obtain:

$$t = \frac{\overline{X} - \mu}{\hat{s}/\sqrt{N}} \tag{3}$$

where: $\overline{X}$ = the sampled mean; $\hat{s}$ = the standard deviation; t = the Student distribution, having N − 1 degrees of freedom.

Starting from observed data, it is then possible to obtain a probability density estimate for each of the 39 measuring points (Figures 4, 5), built through Monte Carlo random sampling from the distribution (3) and then, sampling once again from those probability estimates, it is possible to generate *n* vectors, each one containing 39 velocity values.

Consequently, each vector represent one of the potential velocity fields over the gauging section, which can be now integrated according to different methodologies reported in the ISO EN 748-2000, ISO

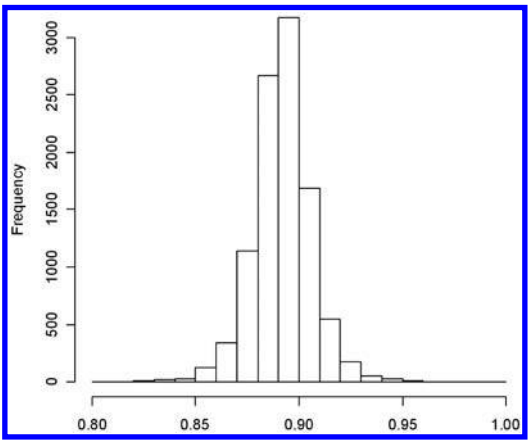

Figure 4. Frequency histogram of the velocity value at point no. 1 on vertical line no. 3, for n = 10000 generations.

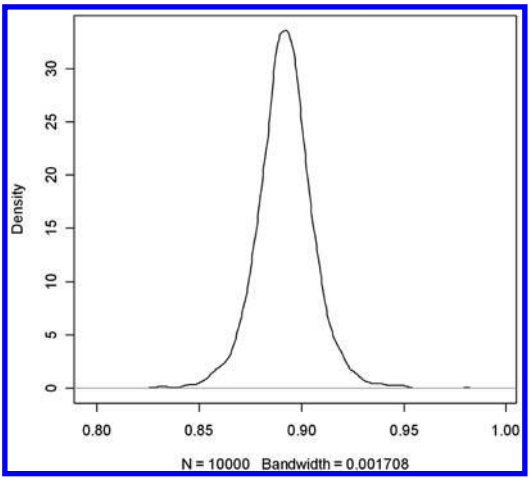

Figure 5. Probability density distribution derived from the frequency histogram of Figure 4.

1088-1985, ISO/TR 7178-1983, in order to obtain N values of discharge (i.e. a mean value and its confidence intervals) for each single integration method (Figure 6).

The computation of the discharge basically consists in the approximation of (1), hence the application of (2). The first common step is to calculate the discharge per unit width, which is based on the construction of the usually parabolic velocity profile along a single vertical (Figure 7) and of its integration over the total depth H:

$$q = \int_0^H v\,dh \tag{4}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

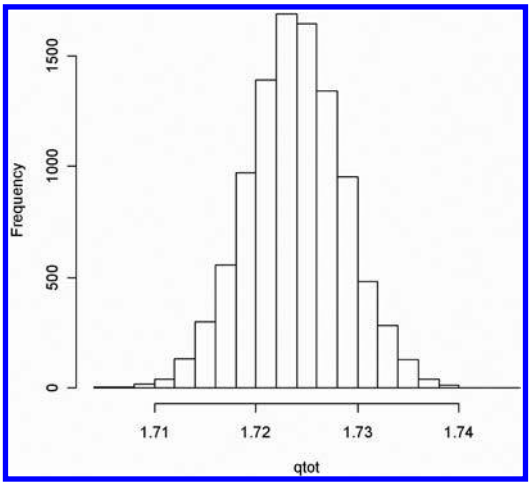

Figure 6. Frequency histogram of the discharge value simulated with n = 10000 generations (Method 1).

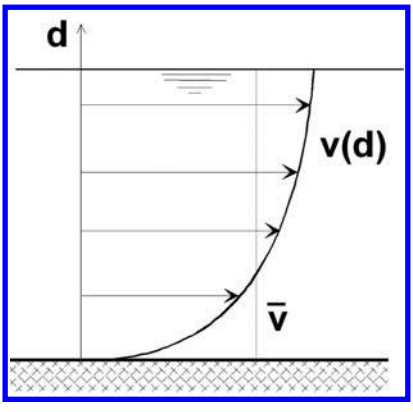

Figure 7. Vertical velocity profile and its mean value $\bar{v}$.

Integral (7) is then approximated by:

$$q = \sum_{i=1}^{n} \frac{(v_i + v_{i+1}) \cdot (d_{i+1} - d_i)}{2} \quad (5)$$

Assuming that bed velocity is null and surface velocity equal to the one measured 6 cm under the free surface.

Total flow is then calculated by integration of unit width discharge over the cross section extent (Figure 8), whose approximated solution, according to (2), is based on the "Mid-section method". From now on this method will be called "Method 1".

$$Q = \sum_{i=1}^{m} q_i \frac{b_i + b_{i+1}}{2} = \sum_{i=1}^{m} \bar{v}_i d_i \frac{b_i + b_{i+1}}{2} \quad (6)$$

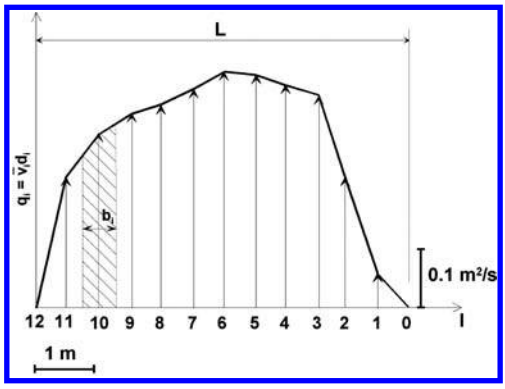

Figure 8. Unit width discharge distribution over the cross section.

As previously mentioned, discharge value has been calculated through other methods, based on different numerical simplification of (1) and on different hypotheses about the vertical velocity profile.

In "Method 2", usually called "Mean-section method" (Young, 1950), the cross-section is regarded as being made up of a number of segment, each bounded by two adjacent verticals.

If $\bar{v}_i$ and $\bar{v}_{i+1}$ are the mean velocities at the i and $i+1$ verticals respectively, if d_i and d_{i+1} are the total depths measured at vertical i and $i+1$ respectively, and if b is the horizontal width between the said verticals, the discharge q of a segment is taken to be:

$$q_{\bar{i}} = \frac{(\bar{v}_i + \bar{v}_{i+1})}{2} \cdot \frac{(d_i + d_{i+1})}{2} \quad (7)$$

This is repeated for each segment and the total discharge is obtained by the sum of single contribution:

$$Q = \sum_{i=1}^{n} q_{\bar{i}} \quad (8)$$

"Method 3" is formally equivalent to "Method 1", except for the assumption made on the vertical velocity profile. In fact bed velocity is not supposed to be null, but equal to the 70% of the value measured at 12 cm above the bed itself. (Figure 9).

This hypothesis, which is not uncommon in such measurement conditions, considerably affects the mean vertical velocity value.

"Method 4" prescribes that once unit width discharges have been obtained by Method 1, total discharge is then computed by the "truncated pyramids" schematization, where the width discharges q_i and q_{i+1} represent the base surfaces and the distance b_i between them is the height. Partial flow referred to the i_{th} segment is then given by the pyramid volume:

$$Q_i = \frac{(q_i + q_{i+1}) + \sqrt{q_i \cdot q_{i+1}}}{3} \cdot b_i \quad (9)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

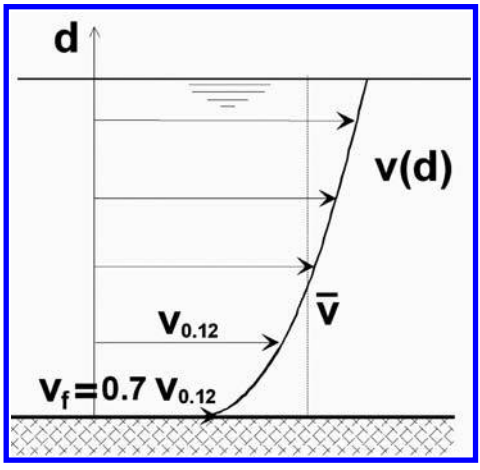

Figure 9. Vertical velocity profile and its mean value $\bar{v}$, assuming that bed velocity $v_f = 0.7v_{0.12}$.

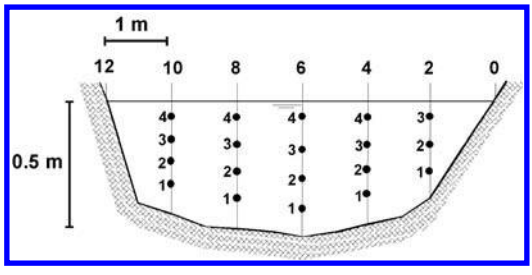

Figure 10. Reduced number of measurement points within the cross section, according to method 5.

and finally total flow comes from:

$$Q = \sum_{i=1}^{n} Q_i \tag{10}$$

"Method 5" considers instead just 6 out of the 11 measured verticals, therefore average spaced by 0.89 m (Figure 10), satisfying therefore the time saving indications, according to which a measure must be a compromise result between accuracy and time availability. In addition to this, it must be noticed that the longer the measurements take, the higher is the probability of discharge variation during the measure.

All the previous introduced methods can be combined in different ways producing therefore a wide range of possible results, here synthesized in Table 1. The same table also presents a sensitivity analysis to the number of random generations produced during Monte Carlo simulations (n = 100, n = 10000), which has been performed for every reported method.

Table 1 and Figure 6 before, clearly show how the variability of the resulting mean discharge values do not depend on the uncertainty of the single velocity values. In fact firstly there is no significant difference between the results obtained after 100 and 10000 generations, secondly the variance of the results distribution appears almost negligible if compared to the mean value (Figure 6).

Table 1. Final results of mean discharge values obtained by Monte Carlo generations, for the different methods applied.

	Discharge Q [m^3/s]	
Method	N = 100	N = 10000
1	1.723959	1.723866
2	1.678593	1.678471
3	1.888714	1.888575
4	1.704999	1.704891
5	1.603540	1.603076
1 + 3 + 5	1.749866	1.749206
2 + 3	1.839684	1.839512
2 + 5	1.463283	1.462853
2 + 3 + 5	1.595128	1.594514
3 + 4	1.854000	1.853837
3 + 4 + 5	1.645516	1.644884
4 + 5	1.509198	1.508755

The lowest value is obtained with Method 5, while the highest belongs to Method 3, not casually the ones having the most simplifying assumptions. Method 2 shows a light underestimation if compared to similar Methods 1 and 4.

In synthesis, the mean value calculated from all the mean discharges reported in Table 1 is $Q = 1.688$, which is almost identical to the median value (less influenced by the outliers) of $Q = 1.691\ m^3/s$. According to this, Method 2 seems to be the closest to the general mean value, ranging within a 95% confidence interval from 1.677 to 1.679 m^3/s, showing therefore once again the non influence of the random generations.

4 THE SALT DILUTION METHOD

The basic principle of salt dilution methods (Moore, 2004), with particular reference to the one involving slug injection (Hudson & Fraser, 2005) is to add a known mass of a conservative non cohesive solute (i.e. sodium chloride) in an upstream river section, which causes a perturbation in the water base conductivity that can be measured in a downstream river section. The main hypothesis of the method are: constant discharge (steady flow), no lateral inflows or outflows within the investigated reach; suspended load only (negligible bed load); minimal pools or backwater areas in general; complete vertical mixing and complete lateral spreading, which indeed occurs only after a certain distance called the complete mixing length (Day, 1977, Fischer et al., 1979).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Conductivity values must be therefore measured at very close intervals (a few seconds) in order to build the so called "breakthrough curve" representing the conductivity pattern over time.

The choice of common table salt (sodium chloride) as a tracer derives from many factors: it is not expensive and easily available, its effects can be rather accurately and almost continuously measured using an electrical conductivity meter and it is non-toxic for the concentrations and permanence times usually detected within the range of applicability of the method (Wood & Dykes, 2002). The procedure aimed to obtain a discharge estimation starts imposing the continuity of mass between the injection and the measuring section (Elder et al., 1990):

$$M = \int Q \cdot C(t) dt \tag{11}$$

where M = the mass of tracer injected; Q = the unknown flow (supposed steady); $C(t)$ = the tracer concentration over time; hence:

$$Q = \frac{M}{\int C(t) dt} = \frac{M}{A} \tag{12}$$

where A = the area under the graph of concentration over time.

Since no direct measurement of tracer concentration is provided, it is anyway proved that an almost linear relation exists between conductivity and concentration value. The concentration can be then calculated as:

$$C(t) = \left(\chi(t) - \chi_o(t)\right) \cdot \alpha \tag{13}$$

where $\chi(t)$ = the conductivity value, $\chi_o(t)$ = the baseline conductivity and α = the coefficient in the almost linear relation between conductivity and concentration.

Therefore, baseline conductivity ("background noise") has to be removed through a regression line that follows the trend of pre-existing conductivity in the river, in order to analyze only the effect produced by the tracer. Then the wave can be transformed from conductivity [μS/cm] into concentration [mg/l] with the linear relation obtained in laboratory in standard conditions during the calibration of the instrument.

Under suitable conditions, discharge measurements made by slug injection can reach up $\pm$5% accuracy (Day, 1976). Different sources of error may arise (ISO 9555: 1994), such as the incomplete dissolving of tracer, the injection solution in fact must be fully mixed across the channel at the section where the conductivity is recorded; the inaccuracy in measuring the mass of tracer injected; the uncertainty in the determination of the relation between conductivity and concentration; the unknown potential amount of tracer lost by adsorption or entrapped in a dead zone.

The slug injection method may also become unreliable when too low velocities are detected which means poor lateral mixing and excessive long salt wave durations.

4.1 *Experimental activity*

The experimental measures has consisted in 3 different injections, separated each other by 30 minutes. For each injection 8000 grams of salt have been diluted in almost 40 liters of water taken directly from the Navile Channel, producing therefore 200 g/l saline solutions in accordance with water temperature and similar experiences found in literature (Oestrem, 1964, Kite, 1993).

The solution has been injected from a bridge (Section A in Figure 1) whose piers induced slight turbulence effects for a few meters downstream, giving therefore a positive contribution to the vertical and also to the transverse mixing of the tracer within the stream.

Great attention has been paid in injecting solution in the center of the channel where the main streamline components flow, since it has been proved that lateral injections require a greater mixing length and increase the probability of tracer losses.

In order to check the achievement of complete transverse mixing, two conductivity meters have been installed in Section C (Figure 1) 300 m downstream the injection point. The first placed in the center of the cross section and the second about one meter from the right bank.

Due to a misfunctioning only 2 of the 3 curves have been recorded by the "lateral" probe (Figure 11), but they have anyway proved a good mixing state, in fact the area under the lateral probe graph is over 96% the one under the central probe graph, which is between the acceptable and optimal values of 95% and 98% (Rutherford, 1994; Kilpatrick & Cobb, 1985). This result was in accordance with the complete mixing length estimates of 200 m (Day, 1977) and 215 m (Fischer et al., 1979).

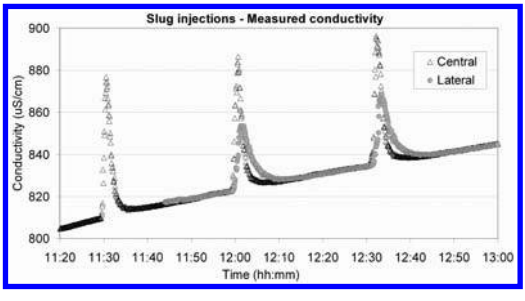

Figure 11. Measured conductivity in section C by 2 differently placed probes.

Copyright © 2006 Taylor & Francis Group plc, London, UK

4.2 *Data processing and results*

Water level upstream of the sluice gate appeared to be almost constant during the whole measuring campaign, but anyway small discharge fluctuation could not be avoided. Therefore it must be noticed that the discharge values presented in the following results are averaged on the 3 injections.

The determination of the discharge and of its uncertainties has required the development of some post processing strategies. The first issue concerns the baseline conductivity removal. In natural free surface waters the baseline pattern is usually quite easy to identify and/or to reproduce, but the decision of where to start and stop cutting as well as which point are to be included in baseline interpolation, leaves too much subjectivity in this sensitive part of the procedure. In addition, the presence of a waste water treatment plant a few kilometers upstream the experimental reach, gives the background noise a further variability (base line growth in figure 11).

In order to avoid this, a new baseline removal strategy has been introduced, which consist in generating a large number of interpolating lines, based every time on different, though acceptable, points. This technique produces therefore not just one, but several breakthrough curves as many as the number of the generated interpolating baselines. Each of those curves will then be used to calculate a range of discharge values with a Monte Carlo simulation.

Another important factor is given by the relation between conductivity and concentration. This relation must be experimentally determined and thus should be different, but known for each single conductivity probe. However, the coefficient α (13) is not a constant, since the conductivity itself certainly depends on stream temperature (for this a compensation is given by the instrument) and its relation with concentration is also affected by the background chemistry (Hongve, 1987), i.e. ion concentration and type. These effects constitute a potential source of error that has been here managed assuming a minimum and a maximum value for the coefficient α ("alfa"), whose mean value is the one experimentally found in laboratory. Laboratory calibration has been carried out with water having a conductivity value similar to the Navile one.

A third source of uncertainty comes from the exact weight of tracer injected. Depending on the amount of salt to be injected or on the precision of the balance adopted, this fundamental data which directly influences the resulting flow (12) has been given a tolerance of $\pm 1.5\%$.

The amount of tracer lost, due to vegetation adsorption or to the presence of dead zones along the investigated reach is the last source of uncertainty considered in this study and probably the most difficult to assess. The channel reach conditions at the time of measurements did not present excessive presence of vegetation within the streamflow, nor evident transient storage zones such as pools, however the effects produce by streambed adsorption or due to density currents can't be determined with enough precision. Possible values of tracer losses ranging from 0% to 15% have been therefore taken into account within the Monte Carlo simulation.

Figure 13 show the results in form of frequency histogram and of cumulated distribution obtained with 10000 generations considering all the previously introduced sources of uncertainty, while figure 14 represents the probability distribution of the resulting discharges as a function of the single source of error. This means, for instance, that the distribution related to the "mass" is the one obtained taking into account only the uncertainty of the mass value and assuming a fixed determined mean value for all the other sources. No appreciable differences has been found between the results obtained after 100 and 10000 generations, neither for the means, nor for the 95% confidence intervals.

Box plots reported in Figure 14 confirm what previously supposed about tracer loss, which is indeed the most impacting source of uncertainty among those

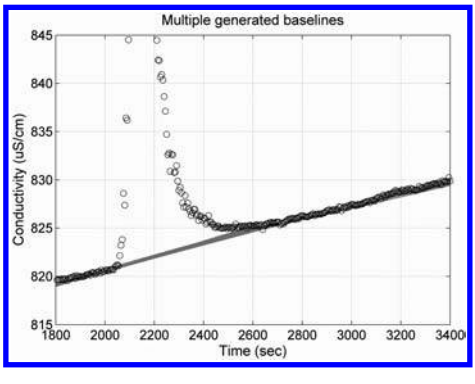

Figure 12. Generation of multiple linear interpolating baselines in order to reproduce the background conductivity value.

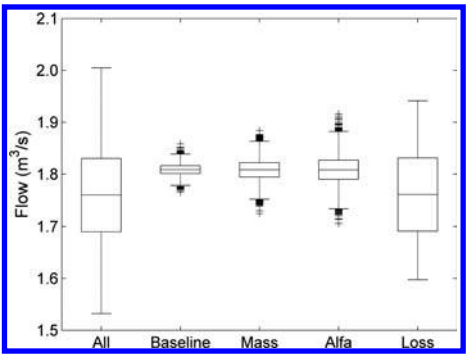

Figure 14. Probability distribution of the 10000 generated discharge values as a function of the single source of error.

considered. Anyway, the mean values range from 1.762 m^3/s to 1.809 m^3/s and the 95% confidence interval for the solution which considers all the sources is set between 1.607 m^3/s and 1.920 m^3/s, leading eventually to a satisfactory ±9% accuracy over the mean value.

5 CONCLUSIONS

In order to test the reliability of a relatively cheap and robust technique for measuring discharge in small streams within the Emilia-Romagna (Northern Italy) plain, the well known salt dilution method, widely adopted for turbulent upland streams, has been experimentally compared to the traditional current meter method.

Various potential sources of error have been considered for both the methods, performing Monte Carlo simulations and hence obtaining an uncertainty estimate for the computed discharge values.

Good agreement has been found between the global average values of each method (1.688 m^3/s and 1.762 m^3/s) and also between the boundary values, ranging approximately from 1.6 m^3/s to 1.9 m^3/s.

Important indications come from the different nature of the results. In fact, while the 5 scenarios simulated with the salt dilution method present similar mean values with different uncertainties, the current meter results show negligible uncertainties for each chosen integration method, but appreciably different mean values.

This implies that the final result obtained with the current meter method is affected by the subjective choice for the integration method. The tracer method instead gives a reliable mean value, whose uncertainty ranges can be reduced improving the accuracy on some experimental facilities and do not depend on an individual choice.

ABSTRACT: Downstream connection of abandoned channels during floods is a key process for the assessment of water exchange, sedimentation rate and biodiversity in oxbow-lakes. The flow-induced morphological evolution of the confluence (stability, occlusion, scour…) governs the frequency and the intensity of downstream submersion. Recirculating flow patterns at the junction between a former meander and the Ain river, France, have been investigated for different discharge values through detailed in situ measurements: acoustic Doppler current profiler (aDcp) and image-based velocimetry (LS-PIV). Detailed topographic data have been collected in order to feed a 2Dh hydraulic model representative of the study reach, using the RUBAR20 code. Post-processing tools were developed in order to get the mean velocity patterns from aDcp and LS-PIV data. Then observed velocity fields were compared to RUBAR20 outputs. The simulated distribution of velocity vectors in the natural dead-zone is quite in agreement with field measurements: the main flow pattern is a large plane recirculation in the mouth of the former channel. However the recirculating flow intensity is underestimated.

1 BACKGROUND AND PURPOSE

In its lower part, the Ain river, South-Eastern France, is a gravel-bedded river with gradients ranging from 0.12% to 0.18% and with a multi-annual mean annual discharge of 120 m^3/s (Piégay et al. 2000). During the first half of the twentieth century, the river channel pattern changed from braided to a free-meandering type. Though regulated by dams, the fluvial dynamics was still quite active so that many abandoned channels with very different origins and shapes remain.

The Ain abandoned channels constitute very important natural areas, some of them being protected, monitored and even restored. One of the main concerns lies in fine sediment deposition during the flooding of oxbow-lakes. This silting-up trend leads towards terrestrialization and vegetalization of such water bodies. So it was decided to study the flow properties of the river sediment-laden waters, at the downstream inlet of an abandoned channel. This paper reports how this recirculating flow was investigated through field measurements and numerical modelling. Specific details are given about field deployment and field data post-processing in order to get representative mean velocity fields.

The Port-Galand abandoned channel was previously a meander of the Ain river. This reach was artificially cut-off in 1964 in order to protect the new-built bridge visible on Fig. 1. As can also be seen in this picture, the new river channel largely bended in the opposite direction it previously did. This study site was chosen because its downstream mouth presents several advantages for hydrodynamical investigation: frequent connection to the river flow, easy access by car, overhanging embankment for visual and video observation, wide and slightly vegetalized former channel.

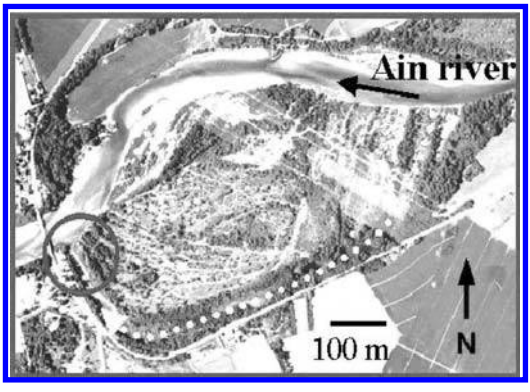

Figure 1. Aerial view of the study site. *Ain river flow (black arrow), Port-Galand former channel (white dot arrow), downstream entrance (circle).*

Upstream submersion of the Port-Galand abandoned channel occurs for discharges greater than 1000 m^3/s, which corresponds to a 2.5 year return period (Roche Campo 2002). In contrast, downstream

$\bar{Q}$ $[m^3/s]$	200	325	365	650
$var.\ Q$ $[m^3/s/h]$	+1	−6.5	+37	+22.5
$var.\ Q$ $[\%\bar{Q}/h]$	+0.5%	−2%	+10%	+3.5%

hydrological connection is almost continuous (about 300 days per year). Sedimentation rate is estimated to 1.4 cm.yr^{-1} in the oxbow-lakes and to 0.5 cm.yr^{-1} over the downstream alluvial "plug" in the vicinity of the river. From an ecological point of view, the Port-Galand abandoned channel is considered as a healthy ecosystem. Along this reach, the river bed showed a mean degradation rate of 0.8 cm between 1986 and 1999 (Rollet et al. 2005), i.e. almost no bed level evolution.

2 FIELD MEASUREMENT CAMPAIGNS

2.1 *Hydrodynamical conditions*

Field measurement campaigns took place during small floods from February to April. Two aDcp surveys and two LS-PIV surveys were achieved, each of them lasting from 30' to 2 hours (Table 1).

The river discharge is regulated by a series of dams, but flow conditions were not controlled specifically for our experiments. So each of the four surveys met with contrasted river hydraulic conditions (Fig. 2). Discharge time series is most stationary for the 200 m^3/s aDcp1 campaign, slightly changing for LS-PIV1 (end of falling limb) and aDcp2 (end of rising limb) campaigns, significantly rising for the 650 m^3/s LS-PIV2 campaign.

2.2 *aDcp transects*

Acoustic Doppler current profilers (aDcp) have been first used in rivers to estimate the total discharge through a given cross-section (Gordon 1989). Such a device can measure instant velocity components on vertical profiles, from the Doppler shift between emitted ultrasonic signals and echoes backscattered by suspended matters (e.g. Yorke and Oberg (2002), Le Coz et al. (2006)). Similarly, water depth and bottom apparent displacement are computed from dedicated acoustic pulses, which allows mobile measurements and valid discharge computation: most authors report

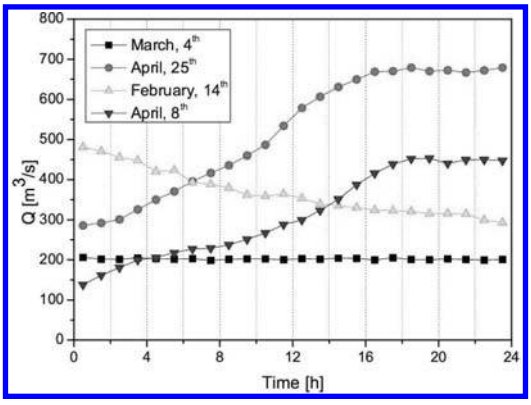

Figure 2. Measured hourly discharge during each campaign day (year 2005). *By courtesy of CNR hydrometric network.*

Figure 3. ADcp deployment during 2005, April 25th flood. *The Ain river is flowing from the top left corner; transects A, B, C are delimited by white tight ropes.*

a total discharge accuracy of about 5% for a few (4–8) transects across the river section. Significant errors may arise when the bottom is actually moving due to sediment transport. Even if aDcp measurement uncertainty has not been properly estimated yet (Muste et al. 2004a), aDcps have been used for velocity field survey (Shields 2005; Muste et al. 2004c), point velocity time series and even turbulence analysis (Barua and Rahman 1998; Muste et al. 2004b).

For the present study, moving-vessel aDcp measurements have been performed in order to get instantaneous and mean velocity data on transects across the area of interest. As the abandoned channel was not wadable, the aDcp was moved by two men in a boat maintained by tight ropes (Fig. 3). We used a Teledyne RDI WorkHorse Rio Grande 1200 kHz aDcp installed on a small buoyant board and equipped with a prism for topographic positioning. All water velocity data were acquired with the RDI default *Broadband* mode 1 and bin size 30 cm. In order to reduce dispersion, aDcp data were 5-ensemble-averaged afterwards as if we had

Copyright © 2006 Taylor & Francis Group plc, London, UK

chosen to get multi-ping ensembles (RDI command WP5). No apparent sign indicated any significant bed motion.

2.3 *Image-based surface velocimetry (LS-PIV)*

A solution to obtain an instantaneous 2D surface velocity field in natural flow is video image analysis, when tracers such as solid particles, bubbles or turbulence-driven patterns are advected by the river flow. The Particle Image Velocimetry (PIV) is a statistical technique which has been extensively used in laboratory fluid experiments for two decades (e.g. Adrian (1991)). The name of Large Scale PIV (LS-PIV) describes the application of the PIV method to natural scale systems with relatively large imaging areas. Readers could refer to Leese et al. (1986) for application to identify cloud motions using satellite images, or Bradley et al. (2002) and Creutin et al. (2003) for applications at different scales of rivers.

A commercially available digital camera (CANON MV 750i) was used to record the experimental area. Two video sequences of 2' (LS-PIV1 campaign) and 5'43 (LS-PIV2 campaign), sampled at a frequency of 1 Hz each (120 and 344 images respectively), were selected. The topography of the experimental site and the size of the area of interest forced the tilt angle of camera view axis to be very small (around 10 degrees). This causes important deformation in the recorded images. In order to conserve a maximum of reliable information, the PIV analysis is performed on images on their raw-state (perspective affected). A classical cross-correlation analysis (see section 4.1) is applied on each pair of successive images for the four videos in order to identify tracer displacements in the image coordinates system, i.e. in pixels per second, without artificially seeding the stream free surface. Vegetable fragments and turbulence-driven patterns acted as flow tracers.

To be usable, this velocity field must be converted into real velocities (in metres per second) in a Cartesian space coordinate system. We use here an implicit geometric transformations method based on Ground Reference Points (GRPs), i.e. points of known coordinates in both image and physical Cartesian coordinate systems, according to:

$$X = \frac{a_1 i + a_2 j + a_3}{a_7 i + a_8 j + 1} \qquad Y = \frac{a_4 i + a_5 j + a_6}{a_7 i + a_8 j + 1} \tag{1}$$

where $[i, j]$ are the coordinates of a point in the image coordinate system (in pixels), $[X, Y]$ are the coordinates of the same point in the field coordinate system (in meters), a_i are the height projective transformation parameters.

The elimination of the Z coordinate assumes a horizontal water surface and requires control points

Figure 4. LS-PIV picture during 2005, April 8th flood. *The left-bank 4 Ground Reference Points installed at the same elevation.*

to be chosen in the same horizontal plane for the determination of transformation parameters. Thus a set of 4 GRPs is sufficient to solve the 8 a_i parameters of Equation 1. Nevertheless, a set of at least 6 GRPs and a least-square method are advised for a better accuracy (Fujita and Komura 1992). In this study, 10 GRPs were placed on the field in order to be distributed as well as possible on the recorded images: 4 GRPs on the left bank (image near-field) and 6 GRPs on the right bank (image far-field). The GRPs used are white $30 \times 30\,\text{cm}^2$ squares with black concentric squares painted inside (Fig. 4).

3 2D-H NUMERICAL MODELLING

3.1 RUBAR20 *code*

RUBAR20 solves two-dimensional shallow water equations in unsteady flow conditions (equations 2, 3, 4 here below) on an irregular grid made of quadrangles and triangles. Numerical resolution is achieved by a finite volume method based on a second order Godunov-type scheme (Paquier 1995). RUBAR20 was developed by the *Cemagref* in order to simulate flooding along rivers either caused by dam failure or due to natural causes. Fudaa0.17 was used as a pre- and post-processing tool for model set-up and result visualization.

$$\begin{aligned} &\frac{\partial h}{\partial t} + \frac{\partial (hu)}{\partial x} + \frac{\partial (hv)}{\partial y} = 0 \\ &\frac{\partial (hu)}{\partial t} + \frac{\partial (hu^2 + gh^2/2)}{\partial x} + \frac{\partial (huv)}{\partial y} = -gh\frac{\partial z_b}{\partial x} \end{aligned} \tag{2}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$-gn^2\frac{u\sqrt{u^2+v^2}}{h^{1/3}}+\nu_{ef}\left[\frac{\partial}{\partial x}\left(h\frac{\partial u}{\partial x}\right)+\frac{\partial}{\partial y}\left(h\frac{\partial u}{\partial y}\right)\right] \quad (3)$$

$$\frac{\partial(hv)}{\partial t}+\frac{\partial(hv^2+gh^2/2)}{\partial y}+\frac{\partial(huv)}{\partial x}=-gh\frac{\partial z_b}{\partial y}$$
$$-gn^2\frac{v\sqrt{u^2+v^2}}{h^{1/3}}+\nu_{ef}\left[\frac{\partial}{\partial x}\left(h\frac{\partial v}{\partial x}\right)+\frac{\partial}{\partial y}\left(h\frac{\partial v}{\partial y}\right)\right] \quad (4)$$

in which h is the water depth, u and v are velocities along x- and y-axis, z_b is the bottom level, n is Manning's roughness coefficient, g is the gravity acceleration, ν_{ef} is the effective kinematic viscosity (set as one single constant value all over the domain).

3.2 *Model set up and calibration*

The computational geometry (Fig. 5) was built up from different sets of topographical data. The river main channel geometry and the abandoned channel geometry were respectively interpolated from 500 m-spaced cross-sections measured in March 2004 and from 50 m-spaced cross-sections measured in 2002. The simulated river reach was chosen long enough to get a well-organized velocity field near the confluence. Both domains were meshed and connected to each other. Quadrangle sizes are quite homogeneous over the whole domain and at the very confluence cells are close to 1 m squares. The mesh was that refined in order to compare flow patterns with field data, but it induced very long computational times (74,929 cells). For the same reason, the local geometry was also refined through extra sets of points measured in the area of interest (confluence and surroundings).

A uniform Strickler coefficient of $30\,m^{1/3}/s$ (Manning's $n=0.33\,s/m^{-1/3}$) was arbitrarily set over the whole domain, except for vegetalized areas where it was set equal to 20 or $10\,m^{1/3}/s$. As run tests with a wide range of ν_{ef} values induced very little change in the velocity field in the area of interest, ν_{ef} was eventually kept equal to zero. A constant $200\,m^3/s$ entering discharge was uniformly distributed on the upstream wetted cells. As a downstream boundary condition, the experimental rating curve $z(Q)$ established near the confluence was imposed at the model outlet. It was later shifted down in order to calibrate water levels in the river and in the cavity: differences between computed and observed water levels eventually don't exceed 10 cm.

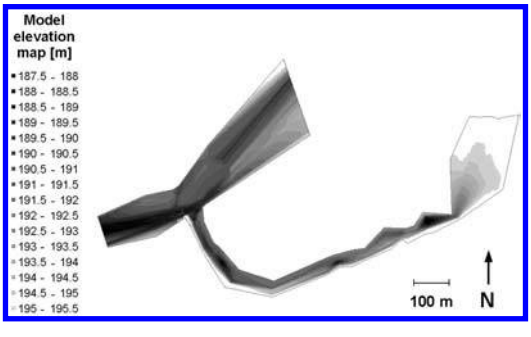

Figure 5. Geometry of the computational domain.

4 FIELD DATA PROCESSING

4.1 *LS-PIV data processing*

In this study, we use a PIV algorithm for large scale applications with low resolution images, developed by Fincham and Spedding (1997). It calculates the correlation between the interrogation area (IA) centered on a point a_{ij} in the first image (image A) and the IA centered at point b_{ij} in the second image (image B) recorded with a time interval of δt seconds (Fig. 6).

The correlation coefficient $R(a_{ij}, b_{ij})$ is a similarity index for the grey-scale intensity of a group of pixels contained in the two compared IAs, expressed as:

$$R_{ab}=\frac{\sum_{\substack{1\le i\le Mi\\1\le j\le Mj}}\left(A_{ij}-\overline{A_{ij}}\right)\left(B_{ij}-\overline{B_{ij}}\right)}{\left[\sum_{\substack{1\le i\le Mi\\1\le j\le Mj}}\left(A_{ij}-\overline{A_{ij}}\right)^2\sum_{\substack{1\le i\le Mi\\1\le j\le Mj}}\left(B_{ij}-\overline{B_{ij}}\right)^2\right]^{1/2}} \quad (5)$$

where Mi and Mj are the sizes of the interrogation areas (in pixels), and A_{ij} and B_{ij} are the distributions of the

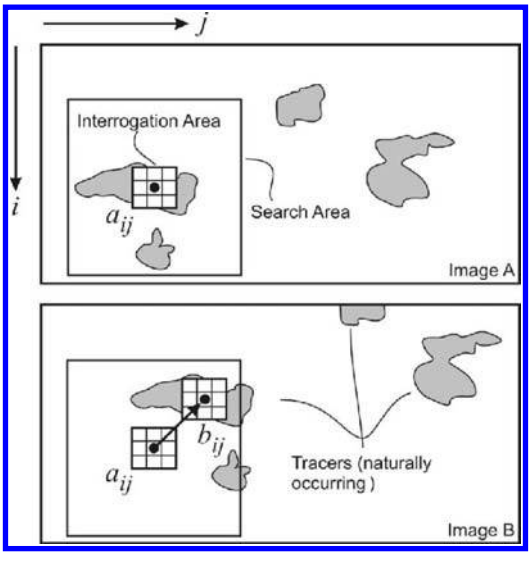

Figure 6. Principle of Particle Image Velocimetry.

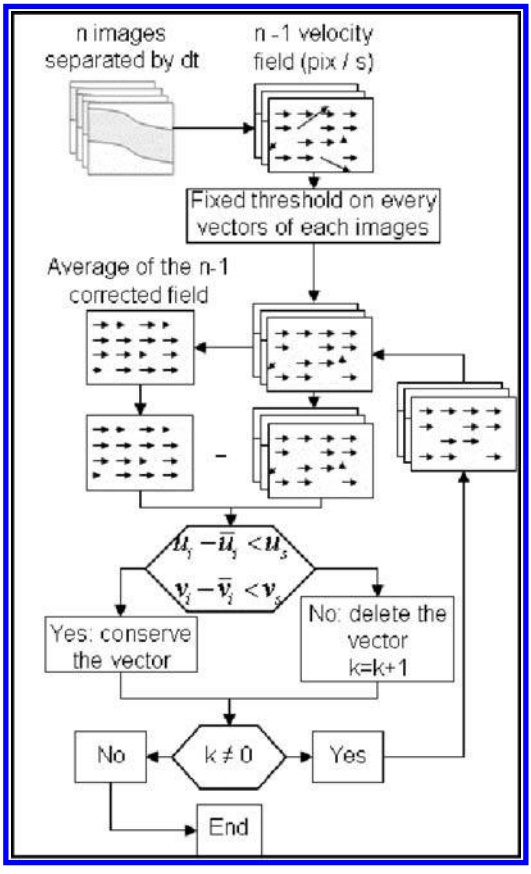

Figure 7. LS-PIV correction algorithm.

grey-level intensities in the two interrogation areas. Correlation coefficients are only computed for points b_{ij} within some search area (SA). The PIV approach assumes that the most probable displacement of the fluid from point a_{ij} during period δt is the one corresponding to the maximum correlation coefficient. Sub-pixel displacement accuracy can be reached using a parabolic fit (Forliti et al. 2000). Velocity vectors are derived from these displacements by dividing them by δt. The process is iteratively conducted for the whole image. Because of the flow recirculating pattern, no specific shapes could be given to the search area.

Due to the slight density of tracers, erroneous vectors are computed. Traditional erroneous vector correction algorithms (developed for river main channel flow, e.g. Fujita et al. (1998)) cannot be used in our experiments because of the flow complexity. Consequently a singular correction procedure has been implemented (Fig. 7): on every computed velocity field, a first filter is applied to remove spurious vectors with u or v components above a fixed threshold. Then, we compute the average of all the corrected displacement fields. Each corrected displacement field is compared with the averaged one. If the difference between a vector and the corresponding averaged vector is greater than a threshold, the vector is removed. Then a new averaged displacement field is computed, and a new comparison begins between the corrected displacement field and the averaged one. The final time-averaged velocity field is used for comparison with the model and aDcp results.

4.2 *aDcp data processing*

For more than 15 years, moving-vessel aDcp data have been routinely collected in rivers for river discharge measurement. But usual commercial aDcp software tools don't offer the required post-processing steps for hydrodynamical studies. Indeed, aDcp velocities post-processed by *WinRiver1.06* or *RiverSurveyor* in order to compute discharges are often difficult to compare with other field measurements or numerical modelling outputs. Consequently home-made routines were developed in *Fortran90* to post-process ASCII data files from Teledyne RDI ADCP™ data with reasonable computational times. The need for such post-processing tools has been recognized by several authors (e.g. Dinehart and Burau (2005)).

First we present the way vertical velocity profiles were finally depth-averaged once the data had been positioned, projected, interpolated, etc. As it is potentially difficult to calibrate theoretical profiles from this recirculating flow, we chose the simplest and most direct computation way:

$$\langle u \rangle = \frac{1}{h} \sum_{i=0}^{N-1} h_i \frac{u_{i+1} + u_i}{2} \qquad (6)$$

with $\langle u \rangle$ the depth-averaged velocity, $h = \sum_{i=0}^{N-1} h_i$ the water depth, h_i and u_i the heights and velocities depicted on Fig. 8 for $1 \leq i \leq N-1$. We assume that the bottom velocity is zero ($u_0 = 0$) and that velocities are constant in the upper flow layer ($u_N = u_{N-1}$).

Before this final depth-averaging step, the main problem stems from the moving-vessel deployment of the aDcp. This method allows to quickly scan large water bodies for depths, velocities and backscatter intensities. As practitioners usually do, we got several successive aDcp transects along more or less irregular vessel tracks, in order to average velocity field fluctuations. So velocity fields from different crossings are not distributed along the same horizontal segment, neither on the same regular grid. An illustration of various post-processing steps of aDcp velocity data is presented on Fig. 9. Depth-averaged post-processed velocities from 5 successive crossings on transect T1 (campaign aDcp1) are shown.

Copyright © 2006 Taylor & Francis Group plc, London, UK

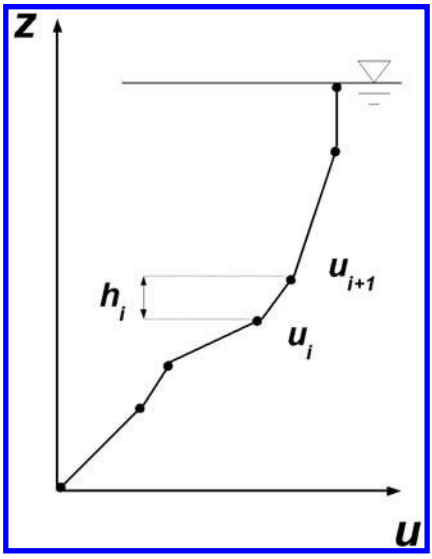

Figure 8. Depth average computation of aDcp velocities. *u stands for each velocity component and z for elevation above the bed.*

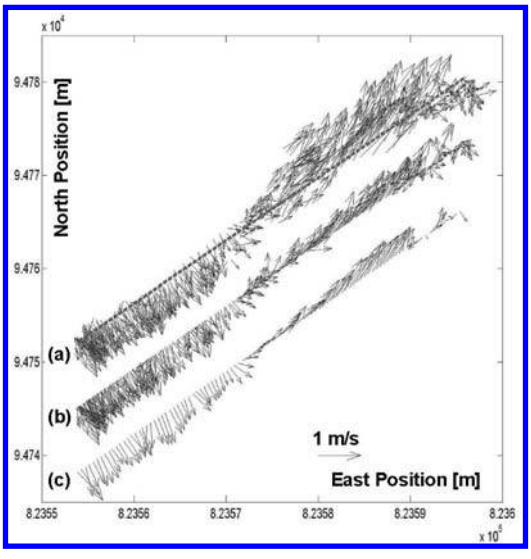

Figure 9. Depth-averaged post-processed aDcp velocities from 5 aDcp crossings of the same transect T1. *(a) repositioned velocities; (b) projected velocities; (c) interpolated velocities; the reference segment (dashed line) is shifted south for (b) and (c).*

First of all, all depth and velocity data had to be positioned in the same topographic reference system. As no GPS device was available to us, we measured the aDcp position by tacheometer at the beginning and the end of each crossing. As no bed motion occurred,

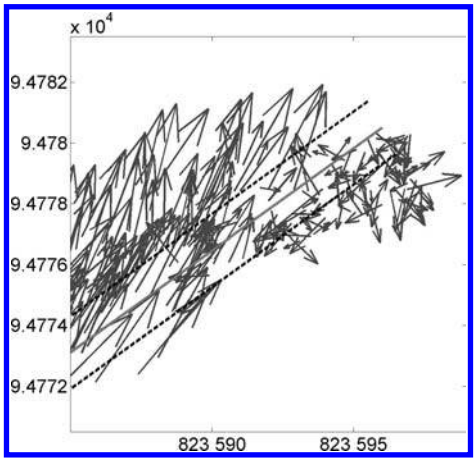

Figure 10. Close-up view of the end of transect T1.

the aDcp bottom-tracking data were used to compute the ship track and the Earth coordinates of the velocity and depth data (a). Then two methods can provide a representative velocity field on a straight user-defined cross-section. First, these referenced data can be projected on this mean cross-section, provided they are close enough to it ((b), >1 m far data are discarded). The referenced data can also be interpolated (c) on a regular vertical grid through inverse distance weighting averaging:

$$\bar{u}(x',z) = \left(\sum_{i=1}^{N_n} \frac{1}{d_i}\right)^{-1} \cdot \sum_{i=1}^{N_n} \frac{u_i}{d_i} \qquad (7)$$

with $\bar{u}$ each of the 3 interpolated velocity components, u_i each the 3 velocity components of the N_n closest neighbouring data, d_i their distances to the interpolation grid node (x', z).

Interpolation parameters – grid density, number of neighbouring data, search volume – must be chosen carefully to fit aDcp data spatial density. For instance, aDcp2 data were interpolated every 0.5 m in x' and 0.3 m in z from the 15 closest neighbouring data searched in a 0.6 m high and 1 m radius cylinder centered on (x', z).

Results are quite identical from different sets of interpolation parameters provided they are realistic. Interpolated velocities appear as an efficient way of representing space- and time-averaged velocity patterns from a dense enough set of moving-vessel aDcp data. However, the zoom on Fig. 9(a) presented on Fig. 10 illustrates the limitations that arise when the velocity field is unstable and data too scarce. At the end of transect T1 indeed, a small fluctuating gyre develops inducing some disorder in the local velocity data. One can easily see that available data for interpolation

(within the dashed lines) were not dense enough for a proper time and space interpolation.

5 COMPARATIVE ASSESSMENT OF MEAN FLOW PATTERNS

5.1 *Observed flow patterns*

Depth-averaged interpolated velocities from aDcp1 and aDcp2 campaigns are presented in Figs. 11 and 12. The first set of data measured during steady state conditions (200 m^3/s) presents a quite "harmonious" recirculating flow pattern: velocity directions and intensities are smoothly inverted from the beginning to the end of each transect.

The velocity inflexion points are located near the centre of each transect. Discharges to the abandoned channel (not presented here) are close to zero across each transect, and there is very little mass transfer to the oxbow-lake through transect T5.

The situation is quite different during the aDcp2 campaign, performed at the end of the several hour rising limb of a 650 m^3/s flood. The mean water level was 1 m higher than previously. The overall recirculating pattern is quite similar but velocities entering the oxbow-lake are much higher than outlets (transects TB and TC). Discharges (not presented here) are close to $-10\ m^3/s$ which means that a part of the river diverted inflow was actively filling in the abandoned channel. The main gyre being weaker than for the previous case, transect TA shows slightly more disordered and much lower velocities than transects T1, T2, T3 and even T4. It should be noted that due to operator safety concerns, no aDcp transect could be acquired as close to the river as transect T1.

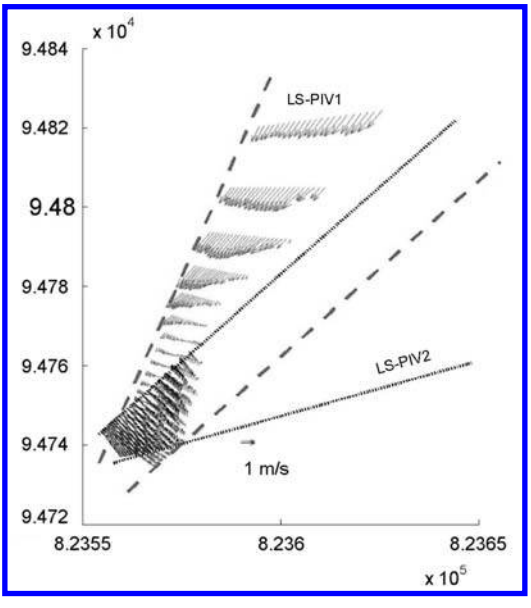

Figure 13. Mean velocity fields from LS-PIV1 (up, with a part of the river flow) and LS-PIV2 campaigns.

Figure 13 gives an overview of mean velocity fields from LS-PIV1 and LS-PIV2 campaigns. Camera view

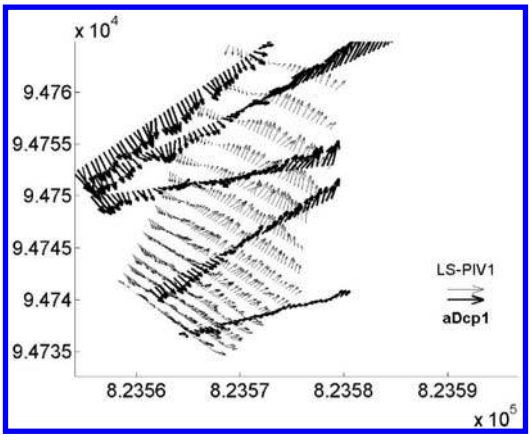

Figure 14. Comparison between aDcp1 and LS-PIV1 data.

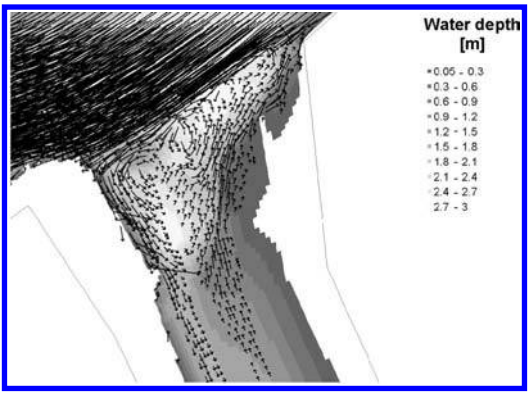

Figure 15. 2Dh modelling output – 200 m^3/s.

angles are indicated (lines) and spurious data out of free-surface areas have been discarded. The LS-PIV1 view angle (close to that of Fig. 3) gives an interesting view on the time-averaged river velocity field coming by the side-cavity. Unfortunately, we couldn't find a view angle allowing us to record the whole area investigated by aDcp. This problem could be solved in next campaigns by using a dedicated 10 m-high observation mast.

The recirculating flow patterns from both LS-PIV campaigns are very similar to each other and agree fairly well with aDcp1 results. For instance, mean velocity fields in the side-cavity from aDcp1 and LS-PIV1 (Fig. 14) are in acceptable agreement. Both sets of data correspond to similar river discharge values and quite stationary conditions. Velocity vector inflexions do occur by the same regions and velocity intensities are reasonably similar, despite the difference of nature between depth-averaged and surface velocities.

5.2 *A first comparison with 2Dh outputs*

As for the comparison of experimental velocity fields, no quantitative assessment of differences between computed and observed velocities has been achieved yet. A first example of a 200 m^3/s steady-state simulation is presented in Fig. 15. Velocities lower than 7 cm/s and water depths lower than 5 cm have been filtered out. The main recirculating pattern is correctly reproduced in the side-cavity, but the small intermittent gyre (Fig. 10) can't be clearly recognized. As observed in situ, highest velocities appear close to the cavity margins, and enter the abandoned channel a little further than suggested by field measurements.

But the main problem is a severe underestimation of velocity intensities: whereas maximum velocities from aDcp1 are close to 0.8–1 m/s, simulated velocities only reach 0.3 m/s for the same event. Velocity intensities in the side-cavity showed little sensitivity to friction or effective viscosity coefficient calibration attempts. As river flow velocities don't seem to be underestimated, there may be a problem in the way momentum transfer from the main flow to the gyre is taken into account in the model. Further analysis and tests are needed to investigate more precisely what is actually occurring.

6 CONCLUSIONS

In order to study the recirculating flow that develops at the downstream mouth of an abandoned meander, aDcp and LS-PIV data were acquired and compared with 2Dh modelling outputs. Beyond positioning in the same reference system, several post-processing steps were necessary to analyse and compare the mean velocity field measurements:

- because of the recirculating pattern of the flow, dedicated corrections had to be applied to the LS-PIV surface velocity field;
- LS-PIV velocities computed each second were averaged on sequences of a few minutes;
- 3D velocity scans from aDcp transects had to be ensemble-averaged, interpolated onto a regular grid, depth-averaged.

In situ measurements suggest some differences in flow patterns according to the river discharge value and evolution. Further field observation and numerical simulation will help for the accurate understanding of flow structure according to river flow conditions. A first comparison between observed and simulated velocity fields is encouraging even if velocity intensities are significantly underestimated.

ADcp and LS-PIV methods appear to give subsidiary results: once post-processed, depth-averaged and surface velocity fields can be successfully compared. Some tools have been developed but some others are still required to make the most of such spatially-distributed instantaneous velocities. Beyond

Copyright © 2006 Taylor & Francis Group plc, London, UK

the side-cavity recirculating flow studied here, aDcp and LS-PIV survey generally appear as promising tools for the analysis of complex flow dynamics in field conditions.

Filtering ADV data on highly turbulent free surface flow

L. Cea, L. Pena & J. Puertas
Civil Engineering School, University of A Coruña, Spain

ABSTRACT: In this paper the 3D instantaneous velocity registered with an ADV in a vertical slot fishway is analysed using several filters in order to eliminate the corrupted data from the sample. The filters used include the minimum/maximum threshold, the acceleration threshold, and the phase-space threshold. A new filter based on a cross-correlation threshold is proposed and tested. The influence of the filtering process in the mean velocity, turbulent energy and power spectrum is discussed. The flow in the vertical slot fishway is quite complex. The turbulence intensity and air entrainment vary widely within the flow, which produces data records of different quality depending on the measurement point. The filtering process has a significant influence on the computed statistics of the samples.

1 INTRODUCTION

Acoustic Doppler Velocimeters (ADV) are often used for the measurement of 3D velocity fields in turbulent flows. The ADV is a relatively simple to use device which registers the instantaneous 3D velocity at one spatial point. Although strictly speaking the ADV is an intrusive device, the distance between the control volume and the probe is large enough to avoid considering its effect in the measurements. The instantaneous data registered with an ADV is generally used to compute mean flow statistics such as the 3D mean velocity, the turbulent kinetic energy and the Reynolds stresses. The sampling rate of the ADV (50 Hz) permits also the computation of frequency spectra up to 25 Hz. Nonetheless, care should be taken when computing these flow statistics from the raw velocity data. The main problems which should be addressed are the Doppler noise and the aliasing of the Doppler signal.

The Doppler noise is a source of error which is present when measuring turbulence with any Doppler-based backscatter system (Lohrmann, Cabrera, and Kraus 1994). The relative importance of this error depends on the fluid characteristics as well as on the flow conditions (flow velocity, presence of particles in the flow, air bubbles, ...). The main consequence of the Doppler noise is that the turbulent kinetic energy given by the ADV is larger than the real turbulent kinetic energy of the flow. This energy is mainly introduced in the high frequency range of the horizontal components (meaning by horizontal components those ones perpendicular to the ADV's longitudinal axis). For this reason, the spectrum of the horizontal velocity components is biased high for frequencies above 5 Hz (Lohrmann, Cabrera, and Kraus 1994). Nikora and Goring (Nikora and Goring 1998) also studied the ADV measurements of turbulence under several flow conditions, obtaining the following conclusions: (1) the noise in the two horizontal components (those ones which are perpendicular to the ADV's longitudinal axis) is up to 30 times larger than the noise in the vertical component (which is parallel to the ADV's axis), and that is due to the sensor geometry; (2) there is a great increase of noise in the presence of bubbles (up to 5 times in the experiments by Nikora and Goring). These findings are of great interest, specially those ones regarding the nonisotropic distribution of the noise between the three velocity components, and the increase of noise due to the presence of air bubbles in the flow. If a measurement is made when one of these bubbles is inside the control volume, an erroneous velocity is registered, and a spike is introduced in the record. Considering the high turbulent kinetic energy, and the air entrainment which occurs near the vertical slot in the fishway, it should be expected a high level of noise in that region.

The other source of error is related to the aliasing of the Doppler signal. The ADV measures the phase shift between two acoustic pulses. This shift must lie between $-180°$ and $180°$. Otherwise the velocity is not correctly measured (for the ADV, a phase shift of $270°$ is identical to a phase shift of $-90°$). The aliasing of the signal introduces spurious data in the sample, increasing substantially the variance of the velocity (and therefore the turbulent kinetic energy), and modifying the power spectra, specially in the high frequency range.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In order to compute the correct flow statistics it is necessary to eliminate the corrupted values by filtering the raw data. If we are interested in computing the mean velocity and turbulent kinetic energy, then the filtering process consists only in removing the spikes (despiking process). On the other hand, if we are interested in computing the power spectra, it is convenient to replace the removed data with some kind of artificial data using a fitted polynomial or any other replacement technique (replacement process). The replacement technique is quite arbitrary. A cubic or any other high order polynomial might be a sensible option if the measurements are well correlated. On the other hand, in highly turbulent flows with a time integral scale of the same order as the sampling time step, its simpler to use a linear interpolation between adjacent values.

In this paper the 3D velocity data registered with an ADV in a vertical slot fishway is filtered using several despiking methods, including minimum and maximum thresholding, acceleration thresholding, and phase space thresholding. A new filter based on a cross-correlation threshold is proposed and tested. The influence of the filtering process in the mean velocity, turbulent energy, Reynolds stresses, and power spectrum is discussed.

2 EXPERIMENTAL MEASUREMENTS

The ADV's experimental velocity records were obtained from measurements carried out in a fishway scale model at the CITEEC (Centro de Innovación Tecnolóxica en Edificación e Enxeñería Civil, University of A Coruña, Spain). The experimental model was built in a 12m long channel, with a 1m width square cross section and a bed slope of 10%. The channel was divided into nine active pools. The water discharge was fixed to $125l = s$ at the inlet boundary. At the lower end of the flume, a tailgate causing over- flow was used to fix the water depth in order to obtain a uniform state of the flow in all the pools. The design of the fishway is shown in Figure 1. The location of the data points inside the pool is defined in Figure 2. All the data points are located 25 cm above the bottom of the pool.

The sampling volume of the ADV is a 6 mm length cylinder with a diameter of 4 mm (sample volume of 0:08 cm^3). The control volume is located 5 cm away from the probe in order to reduce flow interference (Figure 3). The maximum sampling rate of the ADV (50 Hz) was used in the experiments. Approximately 50000 samples were obtained at each point, over a total measuring time of 15 minutes.

The upper left corner of the pool (point P1) is a very quiet region. Point P2 is located in the middle of the pool. The velocity here is generally small, and, depending on the flow conditions, it can be the centre

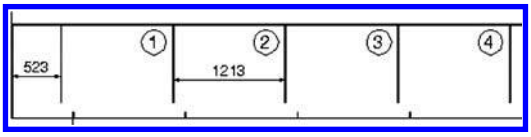

Figure 1. Fishway design.

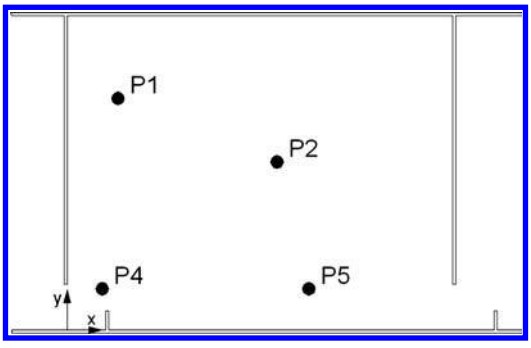

Figure 2. Experimental data points.

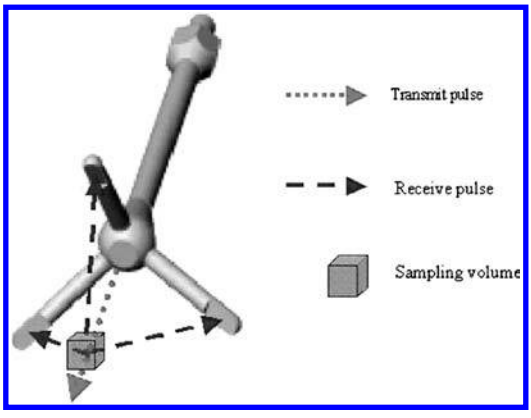

Figure 3. ADV's sampling probe.

point of a large eddy. The highest velocity and turbulent kinetic energy occur near the slot (point P4). The flow is accelerated just before going through the slot and decelerated afterwards, producing a high amount of turbulence. At this point there is also a large entrainment of air in the flow, which generates even more turbulence and produces a large concentration of air bubbles. Some bubbles are convected downstream to point P5, which is located in the main flow stream across the pool.

3 FILTERING METHODS

The filtering of the raw data consists in two processes: first, the spikes must be removed from the data (despiking process); and second, the removed data must be

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Time integral scales (seconds).

	P1	P2	P4	P5
$T_{int,u}$	0.15	0.32	0.009	0.02
$T_{int,v}$	0.35	0.35	0.015	0.02
$T_{int,w}$	0.38	0.44	0.018	0.005

replaced in order to compute the power spectrum (replacement process). If possible, it is convenient to use the maximum sampling rate of the measuring device (f_{max}) for two reasons: first, because the detection of corrupted data with the acceleration and phasespace methods is more accurate when using high sampling frequencies; second, because the accuracy of the replacement method increases as the time step decreases. This is true when using a fitted polynomial as the replacement method. In addition, the computed spectrum extends up to a frequency of $f_s/2$, where f_s is the sampling frequency, and therefore, it is convenient to use $f_s = f_{max}$ in order to compute the largest range of the power spectra.

Considering that in the fishway the turbulence level is very high, and that the time integral scale (Table 1) is of the same order as the sampling time step, we have used a linear interpolation as the replacement technique. In any case, the replacement technique is always rather arbitrary.

For the despiking process, four different filters have been considered: a maximum/minimum threshold, an acceleration threshold (Nikora and Goring 2000), a phase-space threshold (Goring and Nikora 2002), and a cross-correlation threshold.

3.1 *Minimum/maximum threshold filter*

This is the simplest filter of the four. It establishes a range defined by a minimum threshold and a maximum threshold. All the data lying inside this range are considered to be valid, while the data lying outside that range are considered to be corrupted, and therefore it is removed and replaced. The maximum and minimum thresholds are rather subjective, and must be established after visual inspection of the time series. Different thresholds are needed for each velocity component.

3.2 *Acceleration threshold*

The acceleration threshold filter (Nikora and Goring 2000) computes accelerations as $a_i = (u_i - u_{i-1})/\Delta t$ for each velocity component, and establishes a maximum acceleration a_{max} in order to detect spikes. The maximum acceleration is expressed as $a_{max} = k_g g$, where g is the gravity acceleration, and k_g is a constant. A data point is considered a spike if $a_i > a_{max}$ and $u_i > \bar{u} + k_\sigma \sigma$, or if $a_i < -a_{max}$ and $u_i < \bar{u} - k_\sigma \sigma$, where

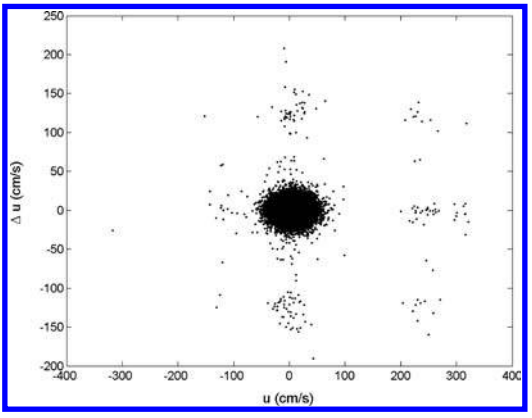

Figure 4. Raw velocity data in the x-direction at point P1 plotted in the phase space $u - \Delta u$.

σ and $\bar{u}$ are the standard deviation and mean velocity of the correspondent spatial component, and k_σ is a constant. The method has therefore two constants which must be fixed: k_g and k_σ. Based on their own experience, Goring and Nikora (Goring and Nikora 2002) suggest the following values: $k_g = 1 - 2$, and $k_\sigma = 1.5$. These values are only based on their experience, after filtering different experimental data, and it has no theoretical background.

3.3 *Phase-space threshold filter*

The phase-space threshold filter (Goring and Nikora 2002) is based on the fact that derivation of a signal enhances its high frequency components. The method plots the variable, its first time derivative and its second time derivative against each other in a three dimensional phase-space. It is assumed that all the valid data cluster inside an ellipsoid, and all the data points lying outside that ellipsoid are considered to be spikes. Figure 4 shows the projection of the raw velocity at point P1 on the space $u - \Delta u$.

Most of the data cluster in an ellipsoid, while some data are clearly out of that ellipsoid. Those points lying apart are considered to be corrupted data. In order to define the three axes of the ellipsoid which defines the valid data, a threshold based on a constant λ is used. Such a threshold was first used by Donoho and Johnstone (Donoho and Johnstone 1994), and it is obtained from a theoretical result which claims that the expected maximum of N independent, normal distributed, random variables, with zero mean and σ standard deviation, is equal to $\lambda\sigma$, with $\lambda = \sqrt{2Ln(N)}$. Nonetheless, it should be remarked that turbulence is not normally distributed and therefore, the theoretical result concerning the *universal* constant λ applies only approximately. A detailed description of the method is presented by Goring and Nikora in (Goring and Nikora 2002).

Copyright © 2006 Taylor & Francis Group plc, London, UK

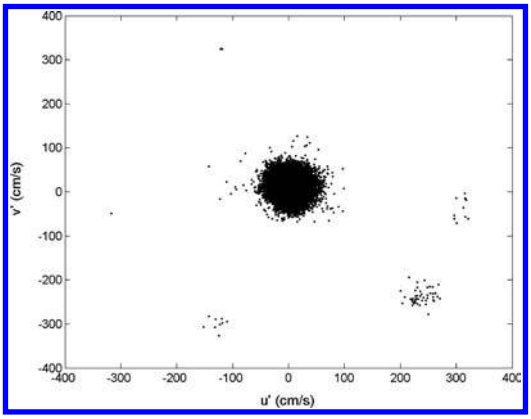

Figure 5. Raw velocity data at point P1 plotted in the correlation space $u' - v'$.

3.4 *Cross-correlation threshold filter*

All the previous methods filter each velocity component independently, and then, if a a spike is identified in one velocity component, the other two velocity components are also filtered. In order to include information of the three velocity components at the same time in the filtering process, and following the idea that valid data should cluster in a cloud of points, we tried a filter based on the representation of the three fluctuation velocities against each other. In a similar way as in the phase-space filter, it is assumed that the good data cluster inside an ellipsoid, the axes being given as a function of the constant λ, as $\lambda\sigma_u$, $\lambda\sigma_v$ and $\lambda\sigma_2$, where σ_u, σ_v and σ_w refer to the standard deviation of the fluctuation velocity in each of the spatial directions. All the data lying outside the ellipsoid are considered to be a spike, and it is removed and replaced. Figure 5 shows the projection of the raw velocity at point P1 on the space $u' - v'$. Again, most of the data cluster together, and the corrupted data, separated from this cluster, can be clearly identified.

3.5 *Comparison and application of the different filters*

The main advantage of the phase-space threshold method is that it requires no parameters, since the constant λ is claimed to be universal. On the other hand, the maximum/minimum and acceleration threshold methods require six and two parameters respectively, which makes the results rather dependent on the specific choice of parameters.

Trying to eliminate the rather subjective choice of parameters of the minimum/maximum and acceleration threshold methods we have used the constant λ in order to define them. In such a way, the maximum and minimum limits for the instantaneous velocity in the sample are defined as $u_{max} = \bar{u} + \lambda\sigma_u$ and $u_{min} = \bar{u} - \lambda\sigma_u$ for each velocity component, where $\bar{u}$ is the mean velocity. In the same way, in the acceleration threshold, the maximum and minimum accelerations are defined as $a_{max} = \lambda\sigma_a$ and $a_{min} = -\lambda\sigma_a$ for each spatial component, where it has been taken into account that the mean acceleration of the sample is zero. From this definition it follows that $k_g = \lambda\sigma_a/g$. The phase-space method can be seen as an extension of the acceleration method, because it considers not only the accelerations, but also the velocity and the derivative of the acceleration.

We have found that the acceleration filter is much more sensitive to the value of k_g than to the value of k_σ, and thus, we have maintained a value of $k_\sigma = 1$ in all the cases. A modification of the value of k_σ will increase or decrease the data which is filtered, but it does not have a great influence on the value of the filtered statistics, neither in the spectra obtained from the filtered data.

The cross-correlation threshold that we have applied in this work uses similar concepts to the phas-espace method, but instead of plotting the velocity and its derivatives, it plots the three components of the instantaneous velocity at a time.

Finally, we would like to notice that the fact of using universal parameters speeds and simplifies the filtering process. However, visual inspection of the data before filtering is also valuable and recommended, and, in some cases it can be used to fix the parameters of a filter in a relatively simple way. To this purpose, we have tried a methodology to fix the constant k_g in the acceleration threshold method, based on the inspection of the results obtained with several values of k_g. Although visual inspection might seem less accurate than using universal constants (it is more subjective, at least), we should remember that the universal constant is obtained after assuming that turbulence is normally distributed, which is not. In any case, visual inspection is always more tedious than a *universal* criterion.

4 RESULTS

The four filters presented in the previous section have been applied to the data records registered in the fishway flow. All of them produce quite similar results for the data registered at points P1 and P2. The number of corrupted data is not too large at these points. The filtering process at point P5 is more complex, because the turbulence level is higher and there are much more air bubbles in the flow, producing a rather large number of spikes. The concentration of air bubbles in the flow at point P4 is so large, and the turbulent kinetic energy is so high, that it is not possible to distinguish between valid and corrupted data. We have not been able to obtain satisfactory results with any of the filters at that point.

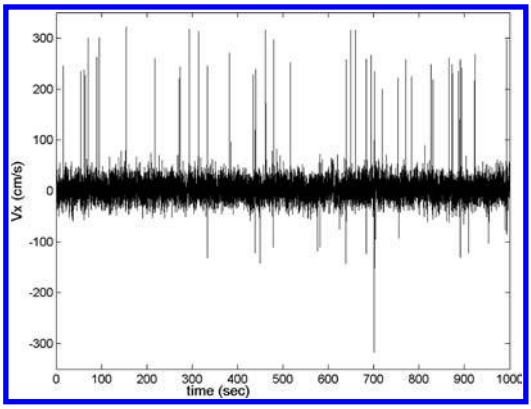

Figure 6. Instantaneous velocity in x-direction at point P1 before filtering.

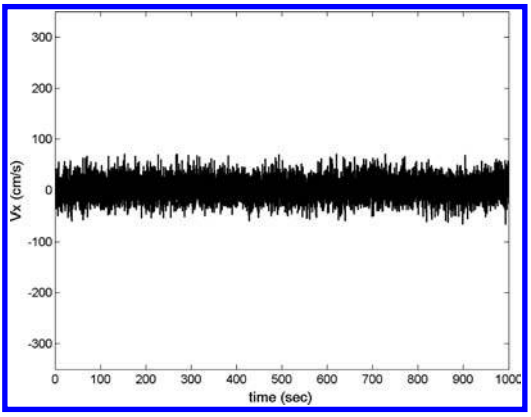

Figure 7. Instantaneous velocity in x-direction at point P1 after filtering.

4.1 *Results at point P1*

The measurement point P1 is located in the upper left corner of the pool. Figure 6 shows the x-component of the instantaneous velocity before filtering. The variance and the mean computed from the raw data for each spatial component are $\sigma_x^2 = 310\,cm^2/s^2$, $\sigma_y^2 = 377\,cm^2/s^2$, $\sigma_z^2 = 98\,cm^2/s^2$, and $\bar{u} = 3\,cm/s$, $\bar{v} = 18\,cm/s$, $\bar{w} = -32\,cm/s$.

In order to filter the data with the minimum/maximum threshold filter, we can establish by visual inspection a range given by $-100\,cm/s$–$100\,cm/s$. Similarly, after inspection of the other velocity components, the ranges of valid data can be established as $-100\,cm/s$–$100\,cm/s$ for the y-component and $-80\,cm/s$–$20\,cm/s$ for the z-component. Applying these minimum/maximum thresholds, 84 spikes are detected, the variance of the filtered data is $\sigma_x^2 = 234\,cm^2/s^2$, $\sigma_y^2 = 296\,cm^2/s^2$, $\sigma_z^2 = 98\,cm^2/s^2$, and the mean is $\bar{u} = 3\,cm/s$, $\bar{v} = 18\,cm/s$, $\bar{w} = -32\,cm/s$. Figure 7 shows the x-velocity component after filtering. It should be noticed that the variance of the x and y-components is reduced approximately 30%, while the variance of the z-component does not change after filtering. This is probably because the corrupted data is mainly caused by the air bubbles in the flow, and these ones only affect the x and y-components of the velocity. It should also be remembered here the finding of Goring and Nikora concerning the non-isotropic distribution of the noise between the 3 velocity components, which is in agreement with our results. The mean velocity computed from the filtered and the raw data are the same, which seems to indicate that the spikes are randomly distributed with zero mean.

If the constant $\lambda = \sqrt{2Ln(N)}$ is used in order to compute the maximum and minimum thresholds, as it was suggested in the previous section, then the number of filtered data is 114, and the variance of the filtered data is $\sigma_x^2 = 231\,cm^2/s^2$, $\sigma_y^2 = 294\,cm^2/s^2$, $\sigma_z^2 = 97\,cm^2/s^2$. The results are very similar to those ones obtained by visual inspection , but the process is much faster and simpler, since no parameter needs to be fixed.

Table 2. Number of spikes and normal Reynolds stresses computed with several filters at point P1.

	N_f	σ_x^2	σ_y^2	σ_z^2
Raw data	–	310	377	98
Max/min visual	84	234	296	98
Max/min λ	114	231	294	97
Accel. $\lambda, k_\sigma = 2$	189	234	299	97
Accel. $\lambda, k_\sigma = 1$	252	235	300	97
Accel. $\lambda, k_\sigma = 0$	300	236	301	97
Accel. $k_g = 1.5, k_\sigma = 1.5$	1562	212	280	96
Phase-space	623	232	295	96
Cross-correlation	169	230	292	97

In this case the acceleration threshold produces quite similar results. Using the constant λ to compute $k_g = \frac{\lambda \sigma_a}{g}$, and taking $k_\sigma = 1$, the number of filtered spikes is 252, and the variance of the filtered data is $\sigma_x^2 = 235\,cm^2/s^2$, $\sigma_y^2 = 300\,cm^2/s^2$, $\sigma_z^2 = 97\,cm^2/s^2$. Note that, when taking $k_g = \frac{\lambda \sigma_{ax}}{g}$ we are using three different values of k_g, one for each velocity component.

Increasing/decreasing the value of k_σ decreases/increases the number of filtered data, but it does not produce significant changes in the variance of the filtered signal (see Table 2). Notice that, even though the number of detected spikes is larger with the acceleration method, the variance is not smaller, even more, it is slightly larger. This is because many of the spikes filtered are in between the valid range defined by the min/max threshold. Those are spikes of small amplitude, with a relatively low energy level. Using

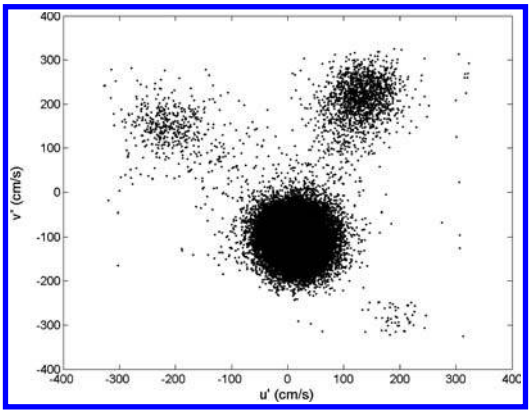

Figure 9. Raw velocity data at point P5 plotted in the correlation space $u' - v'$.

the values $k_g = 1.5$ and $k_\sigma = 1.5$ (Goring and Nikora 2002), the number of spikes increases considerably, and the variance diminishes.

4.2 *Results at point P5*

The flow around the measurement point P5 is much more complex. The turbulent kinetic energy is much higher, and there are many air bubbles present in the flow. This creates more spikes in the data, and at the same time, since the turbulent fluctuations are also higher, it is more difficult to identify the corrupted data. This is clearly shown in Figures 8 and 9, which show the raw velocity data at point P5 plotted in the phase space and correlation space. A main core of data can still be identified, but in this case, it is not so easy to identify the corrupted data lying outside of this core, specially when comparing with the data at point P1 (Figures 4 and 5).

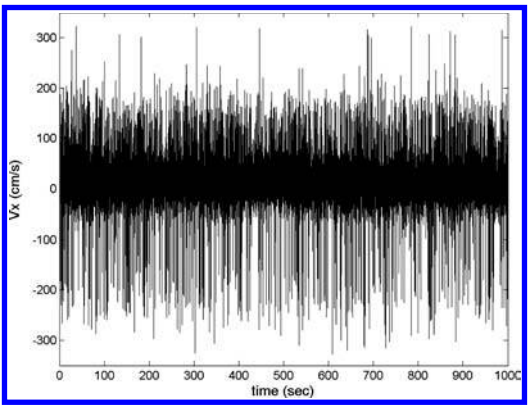

Figure 10. Instantaneous velocity in x-direction at point P5 before filtering.

Figure 10 shows the x-component of the instantaneous velocity before the filtering process. The variance and the mean computed from the raw data for each spatial component are $\sigma_x^2 = 1747\, cm^2/s^2$, $\sigma_y^2 = 4893\, cm^2/s^2$, $\sigma_z^2 = 368\, cm^2/s^2$, and $\bar{u} = 16\, cm/s$, $\bar{v} = -90\, cm/s$, $\bar{w} = -8\, cm/s$. The variance is much larger than the variance at point P1 for two reasons: first, because the turbulence level is higher; and second, because the number of spikes is larger.

In this case it is difficult to establish minimum and maximum velocity thresholds by visual inspection of the data. Therefore, the λ constant must be used in the minimum/maximum threshold filter. With this filter the number of spikes identified is 2141, which means that around a 5% of the data is filtered (at point P1 only 0.2%–0.5% of the data was filtered). The variance of the filtered signal is $\sigma_x^2 = 821\, cm^2/s^2$, $\sigma_y^2 = 1491\, cm^2/s^2$, $\sigma_z^2 = 371\, cm^2/s^2$. The x-component is reduced by a factor 2, the y-component is reduced by a factor 3, and the z-component remains the same. That means very large reductions in the turbulent kinetic energy. As it happened at point P1, there is no variation in the mean velocity, which remains mostly the same ($\bar{u} = 16\, cm/s$, $\bar{v} = -90\, cm/s$, $\bar{w} = -8\, cm/s$). Figure 11 shows the x-component of the instantaneous velocity after filtering with the minimum/maximum threshold.

We have done several tests with the acceleration threshold filter. Using the λ constant to evaluate k_g, we have tried several values of k_σ in order to see the sensitivity of the filter to its value (see Table 3). For values of k_σ different than zero the results are quite similar, which confirms that the sensitivity of the results to k_σ is low. Using the values $k_g = 1.5$, $k_\sigma = 1.5$ (Goring and Nikora 2002), the number of identified spikes increases to 12547, which is about 25% of the total data. This is excessively high, and in any case, if 25% of the data was corrupted the filtered record

would be very dependent on the replacement algorithm. Figure 12 shows the ratio $\Delta N/\Delta\sigma$ for different values of k_g, where ΔN is de difference in the number of spikes and $\Delta\sigma$ is the difference in the variance between different values of k_g. It can be clearly seen that there is a boost in the ratio for values of k_g smaller

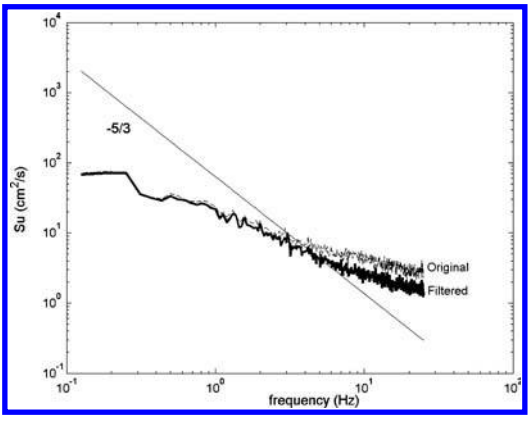

Figure 13. Power spectrum at point P1. Max/min threshold with λ.

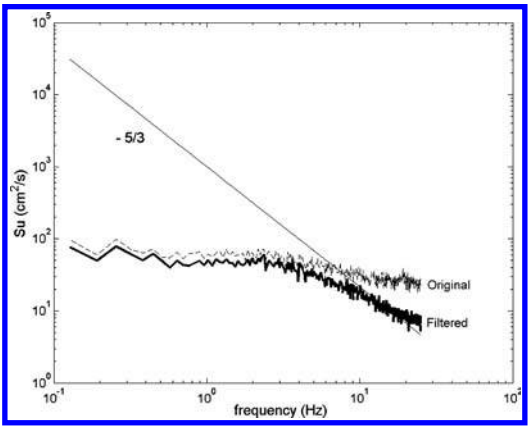

Figure 14. Power spectrum at point P5. Acceleration threshold with λ.

than 5. This sudden change in the slope of the curve might be related to the limit between spikes and valid data, i.e. large values of $\Delta N/\Delta\sigma$ might indicate that too much valid data is being identified as corrupted. Based on this assumption, we can establish an optimum value of $k_g = 5$. Using this value the number of spikes is 3244, slightly larger than the number of spikes obtained using the constant λ. In fact, taking $k_g = \frac{\lambda\sigma_a}{g}$ is in this case equivalent to use the values of the parameter $k_g = 7.8$, 10.5, 4.5 for each velocity component.

The largest number of spikes is given by the phas-espace filter, and the largest reduction in turbulent energy by the cross-correlation filter.

Figures 14 to 17 show the power spectra of the x-velocity component, computed from the original and filtered signals. No matter which filter is used, the main effect of the filtering process is to remove energy

from the high frequency range (the spikes are mainly high frequency oscillations with a large amplitude). Some energy is also removed from the low frequency range.

4.3 *Decreasing the sampling frequency*

In order to check the performance of the filters when the sampling frequency is smaller, we have picked up just one measure of each five. In this way we obtain the data which we would have measured if we had sampled at a frequency of 10 *Hz* instead of 50 *Hz*. Table 4 shows the results obtained at the measuring point P1. The difference in the turbulent kinetic energy between the record measured at 50 *Hz* and the record measured at 10 *Hz* is not significant (smaller than 5% in all cases). It should be noticed that the phase-space filter identifies around 3 times more spikes than the other filters, while the variance of the filtered signal is the same for all the filters.

5 CONCLUSIONS

From these results it is difficult to assess which filter works better. When applied to our data in the fishway, none of them can be considered to be clearly superior to the others.

The fact of using the constant λ removes much subjectivity from the choice of the parameters and at the same time it speeds the filtering process. For this reason we recommend to use this approach in order to determine the parameters of any filter.

All of the filters used produce a significant reduction in the variance of the instantaneous velocity, removing in such a way most of the spurious turbulent kinetic energy which is present in the raw data. At the measurement point P5 the turbulent energy can be reduced up to a factor 3. On the other hand, the mean velocity computed from the filtered and the raw data are almost the same, which confirms that the spurious spikes are randomly distributed with zero mean.

Accurate measurements of free-surface in the dam-break problem

Steve Cochard & Christophe Ancey
École Polytechnique Fédérale de Lausanne

ABSTRACT: The dam-break problem (i.e. the sudden release of a given volume of fluid along a slope) has attracted much attention from mechanicians and physicists over the last years. Of particular interest are the free-surface profile and the spreading rate. From the experimental viewpoint, impediments to accurate measurements of the free-surface evolution are many because of the significant variations in its curvature and velocity.

In order to accurately measure the free-surface variations (position, flow depth profile, leading edge, surface velocity) of a high-speed surge, a new imaging system has been developed at EPFL. The imaging system consists of a digital camera coupled with a synchronised micro-mirrors projector. The object surface is imaged into a camera and patterns are projected onto the surface under an angle of incidence that differs from the imaging direction. From the deformed pattern recorded by the camera, phase can be extracted and, by using unwrapping algorithms, height can be computed and the free surface is reconstructed. We measure the free surface of the flow to within 0.1 mm over a surface of $1.8 \times 1.1\,\mathrm{m}^2$.

1 INTRODUCTION

Shallow-water equations have been originally designed by saint venant (1871) to compute flood propagation along rivers. Their use was gradually extended to strongly time-dependent flows such as waves induced by a dam break (Ritter 1892). There is currently a growing number of models based on the shallow-water equations, which are used to describe natural flows such as flash floods (Hogg and Pritchard 2004), floods with sediment transport (Pritchard 2005), snow avalanches (Bartelt et al. 1999), debris flows (Iverson 1997; Huang and Garcìa 1997), lava flows (Griffiths 2000), subaqueous avalanches (Parker et al. 1986), etc. In the derivation of these models, a number of assumptions are used, the most important of which are: the long-wave approximation (no significant curvature of the free surface), hydrostatic pressure, blunt velocity profile, and no change in the bulk composition or rheology. Furthermore, in these models, the bottom shear stress is computed using either *ad hoc* expressions (e.g., Chézy friction) or non-Newtonian constitutive equations, with the difficult question of parameter fitting. Given the number of approximations and assumptions needed for obtaining these models, one can be legitimately be suspicious about their reliability and performance.

Essentially, our idea was to test the shallow-flow equations under extreme conditions in a well controlled environment—the laboratory—, where both the initial and boundary conditions are prescribed. Here, 'extreme conditions' mean that we focus our attention on time-dependent flows (surges with a front) mobilizing non-Newtonian fluids, experiencing different stages from release to run-out: acceleration (balance between inertia and pressure gradient), nearly fully developed regime (flow at equilibrium), and deposition (prevalence of dissipation processes). Preliminary experiments are run with viscoplastic materials.

The objective of this paper is to describe the experimental facilities and procedures. Emphasis is given to accurate reconstruction of three-dimensional flow depth profiles. These measurements are particularly difficult to perform, especially when fastness and accuracy are sought. Various techniques have been proposed over the last years (e.g., laser probe, videogrammetry). For our purpose, we have used image-processing techniques based on the projection of patterns (Desmangles 2003). In the following, we will describe the technique adapted to our particular case and provide an example of application.

2 FACILITY AND PROCEDURES

2.1 *Overview*

Figure 1 shows the experimental setup. The typical procedure is the following. A viscoplastic fluid is placed in a reservoir on the top of an inclined plane. The fluid is suddenly released by opening the dam

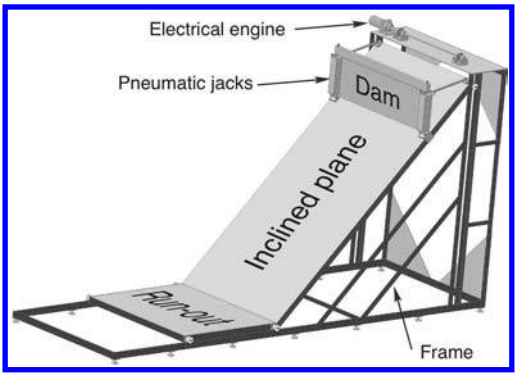

Figure 2. Schematic perspective of the facility.

sluice gate. Using a high-speed digital camera, we then record how a fringe pattern projected on the flow surface is deformed, which makes it possible to measure the flow depth at any place on the surface.

More specifically, our system operates in the following way. A micro-mirror projector projects periodic fringe patterns of incoherent light onto the surface (see Sect. 3.3). We place the digital camera above the flow, but with an offset and a given inclination so that the camerawork angle differs from the projection angle. This camera records how the projected fringes are deformed by the free surface. From the optical point of view, fringe deformation induces a phase offset, which is directly proportional to the flow thickness. Thus, measuring flow depth boils down to measuring phase offset. A phase map is calculated using a 3–4 image algorithm (as described in Sect. 3.4 and 3.4.1). Fast flows require adapting this algorithm and in that case, we use a 1 image algorithm (see Sect. 3.5). Once the phase map obtained, the flow depth can be deduced by unwrapping the phase signal (see Sect. 3.6). This last step requires a calibration procedure, which is described in Sect. 3.7.

2.2 *Experimental facility*

The facility is made up of a metallic frame supporting an inclined plane, horizontal plane (run-out zone), and reservoir (see Fig. 2). This structure is 6 meters long, 1.8 meters wide, and 3.5 meter high. The 4.5 m long aluminium inclined plane can be inclined from 0° to 45° by the means of an electrical engine. Its position is accurately determined using a laser-meter to within 1 mm, which means that the accuracy on slope inclination is of the order of 10^{-2} °. The 6 mm thick aluminium plate is supported by a frame made up of 40×80 mm profiled aluminium beams that ensure rigidity.

A PVC reservoir of varying volume and shape is positioned at the top of the inclined plane behind the dam wall. The maximum capacity of the reservoir is 120 kg. The dam wall is composed of a $1.6 \times 0.8\,\mathrm{m}^2$ ultralight carbon plate. The 35 cm high sluice gate is opened within 0.8 seconds by two pneumatic jacks on each side. Using ultralight dam wall was needed to reduce dam-wall inertia, induced vibration, and jerk. The two jacks are fast rose by injecting 7 mPa pressured air. Two electromagnetic sensors have been located at the tip of each jack to control its position and reset the clock.

The run-out plane has two functions: first, it collects the fluid flowing from the inclined plane, which makes the cleaning operations easier. Second—and this is the most important point—, the flowing material is forced to experience a transition from a flow regime to a deposition (run-out) regime. The 1.5 m long, 1.8 m wide run-out plane is maintained in a horizontal position and is connected to the inclined plane by a sealing plastic band. The projector and the camera are fixed on another frame, which is independent of the main frame.

2.3 *Experimental procedure*

A typical experimental run can be split into 4 phases. First, the fluid is prepared in advance (i.e., one or two days) and stocked in a 60 l drum to ensure sufficient resting time. Our viscoplastic fluid is a stable polymeric gel (Carbopol Ultrez). Polymer chains are vigorously mixed into a sodium-hydroxide/water solution at a given pH. This blend is left at rest for a long time so that all polymer chains have time to unroll and form a dispersion (repulsive interactions between chains). To ensure good light contrast, whitening Titanium Dioxide (TiO_2) is added when mixing Carbopol.

Second, the fluid is gently poured into the reservoir, while the inclined plane is kept in horizontal position. The material is then slowly mixed and its free surface is smoothed out by hand. A viscoplastic fluid does not flow if shear stresses are too low, which means that its free surface stays in the reservoir as it stands after pouring; there is no stress relaxation (viscoelasticity),

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 3. View on the sluice gate and the reservoir at the channel inlet.

nor creeping (viscosity), which would cause flattening of the free surface. The upper plane is then inclined at a given value and its position is checked using a laser-meter.

Third, the measurement device is calibrated. Calibration will be explained in detail in section 3.7. Just before starting the test, we collect a fluid sample and test it with a Bohlin CVOR rheometer to characterize its rheological properties.

Four, we lift up the sluice gate and the material starts accelerating and flowing. The surge motion is followed up by the digital camera. When there is no significant motion, we stop to record images. The material is then removed from the flume.

3 MEASUREMENT SYSTEM

3.1 *How to measure the free-surface variation with time?*

The crux of the difficulty in the dam-break experiments lies in the proper measurement of the free surface. We thought of different systems. Three criteria guided our choice. First, we needed a non-invasive system to avoid disturbing the free boundary. Second, our preference was on global methods that are able to capture the flow surface with a single pass in contrast with scanning methods, which are not well suited to providing snapshots. Third, we wished to develop a method consistent with high-speed acquisition rates.

Three global systems were considered:

1. A method, which involves projecting patterns onto the fluid surface. Pattern deformation is recorded by a camera. This method is described in section 3.2.
2. A stereoscopic system, with two cameras scrutinizing the same surface. This method performs well with surfaces of varying color and contrast since colored pixels can be used as reference points and tracked (Kraus and Waldhäusl 97). The height is computed by the taking the difference between two successive images recorded by the two cameras. Since our fluids are monochromatic, this method has been discarded.
3. A system based on the time of fly of emitted photons. Photons are emitted by a source, a number of which are back-scattered by the surface. The time between their emission and their reception provides an estimate of the travelled distance (Niclass et al. 2005). This method performs well only for static objects, but should be a promising technique for our purpose in the forthcoming years.

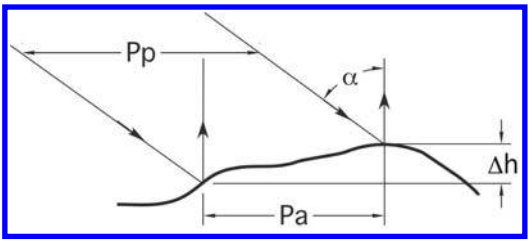

Figure 4. Projection of parallel lines on a surface and the retrieved height.

3.2 *Projecting patterns*

Measuring the shape of an object using the pattern projection can be broken down into three steps:

1. a given pattern is projected onto an object;
2. the object surface is imaged into a camera under an angle of incidence that differs from the imaging direction;
3. the surface height is retrieved from the image.

For the sake of simplicity, two parallel lines are projected onto a surface, as shown in figure 4. The height difference Δh can be then expressed as

$$\Delta h = \frac{\Delta p}{\tan \alpha}, \tag{1}$$

where $\Delta p = p_p - p_a$ is the difference between p_p the projected lines onto the object and p_a the apparent line on the surface viewed by the camera; α is the angle between the projected lines and the camera.

This simple relationship emphasizes two points. First, the closer the projected lines p_p are, the greater the accuracy in Δh is. Second, the closer to 90° the angle α is, the better the accuracy in Δh is.

A problem with projecting lines is that any valuable information between two lines is lost. There is another technical problem related to the camera resolution: for two lines to be distinguished by the camera, there must be a minimum distance of three pixels, which imposes a lower bound on the accuracy of Δh according to equation (1).

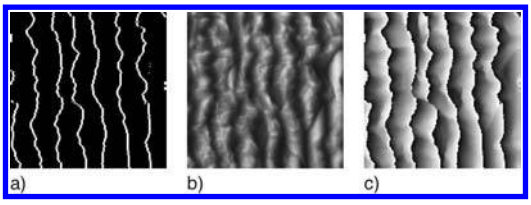

Figure 5. Comparison between: a) projection of lines, b) projection of fringes and c) the resulting phase map.

3.3 *Projecting fringes*

Cosine fringe patterns are projected instead of isolated lines. Information theory would say that we replace a 2 bit system into an 8 bit system, which should improve accuracy and robustness. Moreover, instead of relating height with light intensity, height is linked to fringe phase. The observed intensity at a given point (x,y) can be written as

$$I_k(x,y) = A_k(x,y) + B_k(x,y)\cos\phi_k(x,y), \qquad (2)$$

where A_k and B_k represent the background and the modulation intensities and ϕ_k the phase. The phase varies within the interval $[0, 2\pi[$.

Working with phase instead of intensity has the substantial advantage that alteration in surface reflectivity does not influence the outcome.

The imaging system consists of a digital camera coupled with a synchronized micro-mirror projector working at a maximum rate of 48 Hz. The 1000×1000 px CCD camera and the projector are synchronized by the frame grabber. The actual projection surface is 1.8×1.1 m^2. The main advantage of a micro-mirror projector (MMD) lies in its capacity to instantaneously project a given pattern. As mentioned in section 3, achieving high resolution in time and space requires global acquisition and projection. Compared to a laser interferometer, projecting fringe patterns with a MMD has also the advantage of versatility and safety. Any kind of pattern can be projected at any time and any rate. As an example, we can project images in 8 bit mode at a frequency of 150 Hz. There is, however, a price to pay when using a MMD instead of a laser interferometer: we have to use non-coherent light, which implies lower intensity. Perfect grabbed images would be characterized by intensity consistently with the intensity scale of a 8 bit camera; in other words, image intensity would range from 0 (deep black) to 255 (white). The technique is, however, quite robust since a phase map (see Sect. 3.4) can be can established using a limited range of 30 gray values.

The projector involves micro-mirrors. The light of a led is projected onto a micro-mirror device (MMD) composed of 1024×768 micro-mirrors oscillating between two positions; for one position, light is reflected through the projector lens, while for the other position, light is not reflected. It is a binary system: for a given pixel, light is on or off. A 8 bit grey level is achieved by changing the projection time of each micro-mirror.

At its maximum rate, the camera records an image within 20.7 ms, while the fringes are projected for 20.3 ms. A time lag of 0.1 ms separates two images. Special attention is paid to insuring that the whole projection occurs during the acquisition time and that there is no synchronization delay. This would have no consequence with projection continuously operating with time (as laser interferometry) but, as the MMD is a 2 bit projection system, relative intensity is controlled by the projection duration, which means that projection involves discretized time steps.

Capturing 48 images per second with a 1000×1000 px camera (i.e. 48 Mbytes/s) during time intervals as long as 10 minutes requires a CameraLink connection between the camera and the frame grabber. To store a huge amount of data within short intervals of time, we have implemented 4 hard disks in parallel. All the acquisition program has been developed using LabView.

3.4 *Phase map*

The phase map is only composed of the $\phi_k(x,y)$ term in equation (2). Optic convention is used here, high values (2π) are in white, whereas lower values (0) are in black.

Most algorithms for retrieving phase from an image or a series of images use either phase shifting , Fourier transform (Takeda et al. 1982), or wavelets (Liebling et al. 2004). The two first methods are explained in Sects 3.4.1 and 3.5. The phase map is often called the wrapped phase. During the first seconds of the test, a one-image algorithm is used and, after the flow has slowed down, a 3 or 4 image algorithm is used.

3.4.1 *Phase shifting*

Its principle consists in projecting $N \geq 3$ images of a fringe pattern shifted by $(i-1)2\pi/N$, with $i = 1 \ldots N$ (Desmangles 2003). The phase can be analytically computed from the series of images. An example with a series of $N = 4$ images is given in figure 6, with the following intensities:

$$\begin{cases} I_1(x,y) &= A + B\cos(\phi(x,y)), \\ I_2(x,y) &= A + B\cos(\phi(x,y) + \frac{\pi}{2}), \\ I_3(x,y) &= A + B\cos(\phi(x,y) + \pi), \\ I_4(x,y) &= A + B\cos(\phi(x,y) + \frac{3\pi}{2}), \end{cases}$$

where

$$\phi = f(I_1,I_2,I_3,I_4) = \frac{I_4 - I_2}{I_1 - I_3}. \qquad (3)$$

The phase map resulting from this method is accurate since it results from analytical calculation. A phase

Copyright © 2006 Taylor & Francis Group plc, London, UK

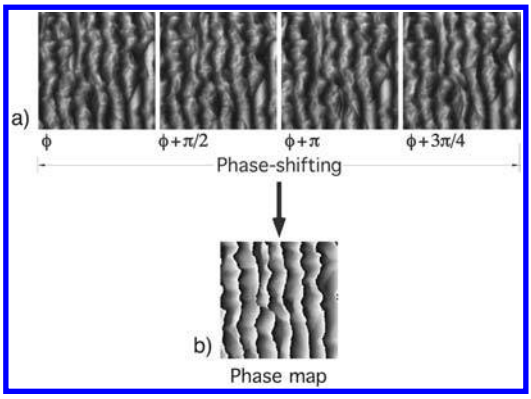

Figure 6. Phase shifting: a) with 4 images and b) the resulting phase map.

map can be extracted with each new image using the $N-1$ preceding ones.

The 3 fringe patterns can be projected at the same time using a red-green-blue (RGB) color coding. An independent phase map can be extracted with each new images. The idea is attractive, but requires a complicated and expensive setting (Jeong and Kim 2002).

The method based on 3 or 4 images is more appropriate when the fluid slows down and the relative motion between the first and the last images is less than a 1 or 2 pixels. This method is not suitable at earlier times, when the fluid is released because the displacement of the fluid between the first and the last images is too large. The resulting phase map is blurred and unusable. During the first instants of the test, the phase map must be computed with just one image; this computation can be done with a FFT algorithm, as explained in section 3.5 or with a wavelet algorithm.

3.5 *Fourier transformation profilometry (FTP)*

Fourier transformation profilometry (FTP) was first introduced by Takeda et al. (1982). The idea is to work in the frequency domain of the recorded images in order to filter and keep only the desired frequencies (Sansoni et al. 1999a).

In this subsection, we shall not explain how FTP works, but just provide some ideas on how we have implemented FTP in our setup. A cosine fringe pattern with 45° inclinations is projected onto the surface of the reference plane during the calibration, as shown in figure [see Fig. 7 (a), see also Sect. 3.7]. Two-dimensional Fourier transform analysis is then carried out on the recorded images, which consists in 5 points: first, the central peak related to frequencies close to zero is removed. Second, the frequency F_ϕ of the cosine fringe projected is located [see Fig. 7 (a)]. Third, the frequency map is filtered to keep only the

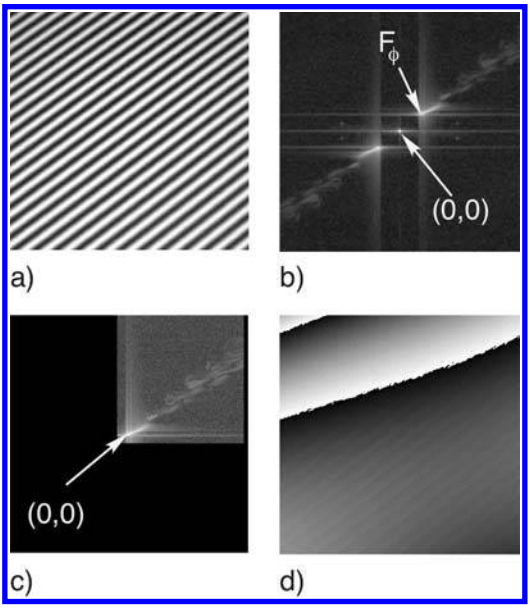

Figure 7. Reference plane: a) projected fringes, b) image in FFT domain with the frequency F_ϕ of the projected fringe, c) image filtered and shifted and d) reference plane phase map.

desired values [see Fig. 7 c)]. Fourth, the frequency map is shifted to position F_{cos} at the center $F=0$ [see Fig. 7 (c)]. Fifth, the angle of the inverse FFT is computed, which provides us with the phase map of the reference plane [see Fig. 7 (e)].

The same procedure is then repeated, during the test, with the recorded images except that the frequency map is shifted by F_ϕ (computed during the calibration). The wrapped phase is then obtained by subtracting the new phase and the phase of the reference plane [see Fig. 8 (f)].

FTP can be improved by removing image modulation so that the central peak of frequencies close to zero in the frequency map (related to the plane) is eliminated. This is achieved during the calibration procedure by shifting $N \geq 3$ fringe patterns by $(i-1)2\pi/N$ with $i=1\ldots N$, as explained in section 3.4.1. The modified image is then

$$I = I_1 - \frac{1}{N}\sum_{n=1}^{N} I_n.$$

FTP performs much better when the frequency of the projected cosine fringe is high and fringes are inclined at 45° in the recorded image because the cosine frequency F_ϕ in the FFT map is further away from the origin 0, filtering and shifting are more accurate.

Su and Chen (2001) discussed the influence of sampling in FTP. They emphasized that the recorded images as well as the discrete Fourier Transform (DFT)

Copyright © 2006 Taylor & Francis Group plc, London, UK

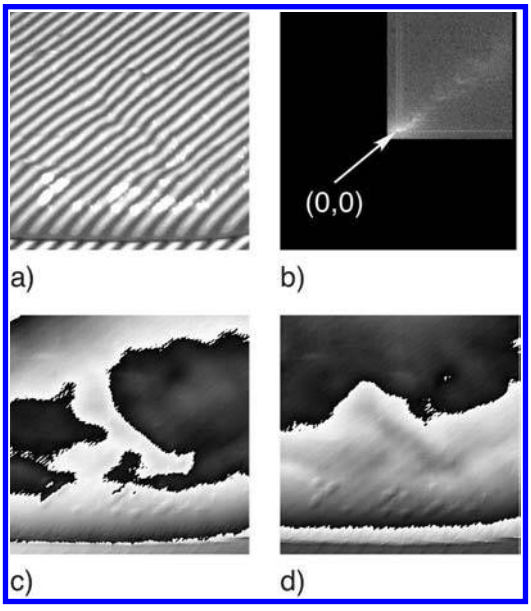

Figure 8. Object: a) projected fringes, b) object image filtered and shifted in Fourier domain c) resulting phase map and d) difference between the object phase map and the reference plane phase map.

are digital, whereas FTP theory is based on continuous Fourier transform. This inconsistency between theory and experience induces errors at high frequencies values. We are working to implement methods for reducing errors arising at high frequencies, even though we are convinced that this is a minor issue in our context (since our flows involve low frequencies most of the time).

FTP efficiency depends a great deal on filtering, i.e. which frequencies are kept or not. A good user can easily pinpoint frequencies that must be removed in order to obtain a more accurate phase map. Making this process automatic is, however, quite difficult.

It is almost impossible to know, in advance, when a phase-shifting algorithm can be used and can replace FTP. To avoid this issue, we project the 45° – inclined fringe with a phase shift of $2(i-1)\pi/N$ with $i = 1 \ldots N$. Both phase-shifting and FTP algorithms can then be used depending on the quality of their respective phase map.

3.6 *Phase unwrapping*

Once we have obtained the phase map, we can compute the height by unwrapping the phase map. The principle of phase unwrapping is fairly easy to understand in one-dimensional problems. Let us consider that we have a phase signal ϕ contained in the interval $[0, 2\pi[$ and we want to unwrap it. Every time the signal jumps

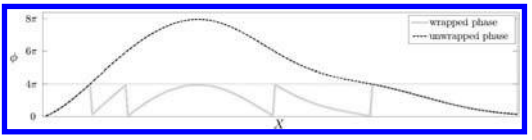

Figure 9. Example of phase unwrapping in 1D.

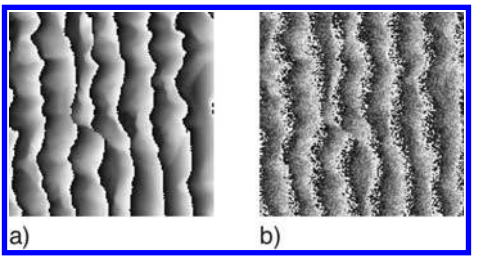

Figure 10. Phase map: a) original b) with noise.

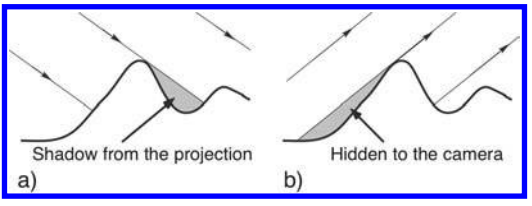

Figure 11. a) Shadow from the projector, b) hidden parts to the camera.

from 0 to 2π, we add or subtract 2π depending on the derivative $\partial_x \phi$, as is illustrated in figure 9.

Without noise and shadow, phase unwrapping would have a unique solution. Any unwrapping algorithm tends to provide a proper approximate solution.

Noise blurs the sharp frontiers of the phase jump between 0 and π, as shown in figure 10.

Shadow regions appear when the projection does not enlighten all the surface or when a part of the surface is hidden to the camera, as sketched in figures 11 and 12. All the information in the shadow or hidden parts is lost. In order to obtain results as good as possible, one should be careful and avoid having shadow or hidden parts, while keeping the angle between the projecting and acquiring beams as close as possible to 90°.

There is not a single solution, but several approximate solutions. Two-dimensional phase unwrapping algorithms aim to find the best approximation.

In their book, Ghiglia and Pritt (1998) reviewed the main different strategies to phase unwrapping. They also provided eight valuable C++ routines illustrating those strategies. There are two different approaches to phase unwrapping: one is based on path-following methods or local methods and the other one is based on minimum-norm methods or global methods. The path-following methods starts at a given point in the phase

Copyright © 2006 Taylor & Francis Group plc, London, UK

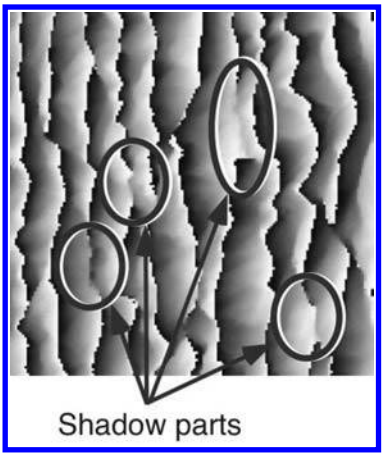

Figure 12. Shadow on an image.

map and computes the neighboring points by following a predefined path. The main difficulty is to choose 'the best path' to avoid shadowed or noisy parts in order to find the best approximation. Minimum-norm methods minimize the integral of the square difference between the gradients of the solution and the path obtained using different strategies. It is recommended to try the algorithm in the following order from the simplest and fastest ones to the more complex but slower ones.

1. Goldstein's branch cut algorithm, *path-following*,
2. Quality-guided algorithm, *path-following*,
3. Unweighted least-squares algorithm, *minimum-norm*,
4. Preconditioned conjugated gradient (PCG) algorithm, *minimum-norm*,
5. Mask-cut algorithm, *path-following*,
6. Multigrid algorithm, *minimum-norm*,
7. Flynn's minimum discontinuity algorithm, *path-following*, ,
8. Minimum L^p-norm algorithm, *minimum-norm*.

Better results are obtained with more complex algorithms. The last two algorithms are the most robust ones. We mainly use Flynn's method because its calculation time is much shorter than the Minimum L^p-norm. For our regular case, Flynn's method takes about 1'30" (Flynn 1997), while the Minimum L^p-norm requires 1 hr. However, using Flynn's algorithm on a 5 min sequence (14400 images) is quite impossible with a personal computer since it would take 15 days. One way for speeding up calculations is to run them on a computer cluster. To do so, we use the *distributed computing toolbox* from Matlab, with a cluster including up to 12 computers. Another way of reducing computation time is to unwrap the difference of the two phase maps (related to the flow

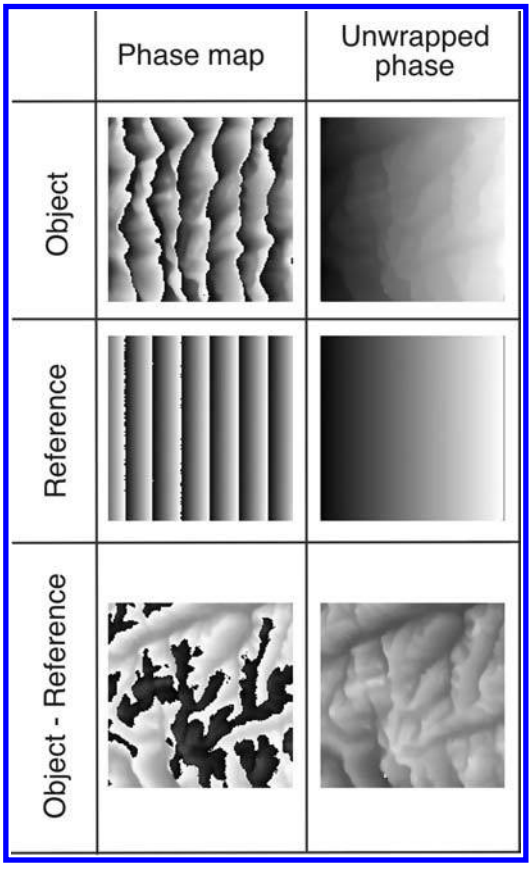

Figure 13. Unwrapping the difference of the object phase map and the reference phase map is equal to the difference of the unwrapped phases.

and the reference plane) instead of computing the difference of the respective unwrapped phase, as shown in figure 13. The resulting map shows less jumps of 2π, which makes the reconstruction of the unwrapped phase easier, faster, and more accurate.

These algorithm have many input parameters, which have not only a large influence on the execution time, but also on the quality of the results. Various techniques have to be tested to evaluate the quality of the results and make them less dependent on the user. Even though we prefer Flynn's algorithm because of its accuracy, the other algorithms ought be tested because occasionally, they might give better results and require lower CPU time.

3.7 *Calibration*

Equation (1) give the height as a function of the angle α and the distance between two line P_p. Behind this equation, there is the following assumption: projection

Copyright © 2006 Taylor & Francis Group plc, London, UK

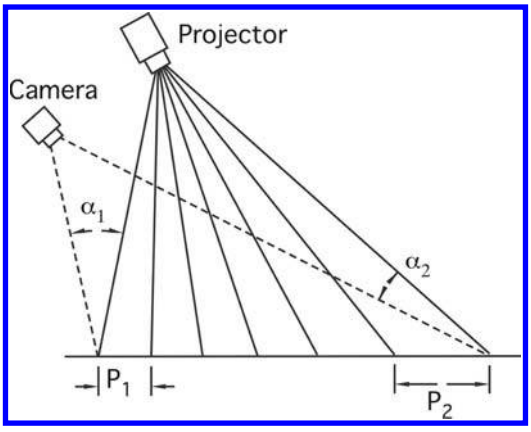

Figure 14. Variation of the angle α in a non-telecentric setup.

and acquisition are telecentric, which is not the case in our setup (Chen and Quan 2005). Figure 14 show how, in a non-telecentric setup, the angle α between the angle of projection and the angle of acquisition varies along the axe X; $\alpha_1 \neq \alpha_2$. The same also holds for the projected lines P_p and the apparent line P_a view by the camera; $P_1 \neq P_2$. A similar figure could be done along the Y-axis. Knowing the relative position of the camera, the projector and the inclined plane as well as the projection angle and the camera angle makes it possible to mathematically modify equation (1) and then have a height factor for each position (Desmangles 2003). This method requires accurately measuring the position of each elements of the setup, it is time-consuming, and does not take into account optical deformation. Instead of this method, we have chosen to use the more practical calibration based on a modified version of the virtual calibration plane method (Xiaoling et al. 2005).

The first step of the calibration is to project sharp patterns, such as squares, on the inclined plane to focus the projector and the camera. To check that the recorded images from the camera properly include the zone studied, the projection should envelop the acquisition zone, but should not be larger so that light power and projection resolution are optimized.

In order to relate the Cartesian coordinates XYZ of the plane with the unwrapped phase in the pixel coordinate ij, we need to calibrate our setup. A calibration plate, with gray circles of 2 cm in diameter and distant of 10 cm, is placed on the inclined plane at $z_0 = 0$. All fringe patterns, which will be used during the test run, are then projected on the calibration plane [see figure 15 (a)]. The module of the reference plane is computed [see figure 15 b)] and the position of the circle centers are found using a least-square approach [see figure 15 (c)]. The wrapped phase is referred as

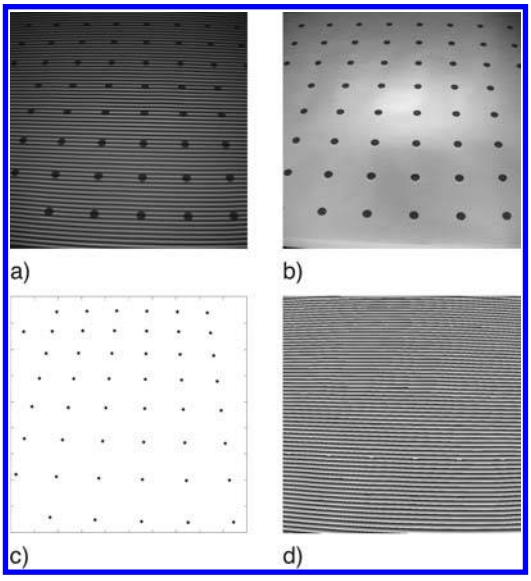

Figure 15. a) Projection of the fringe on the calibration plate, b) module with the calibration circles, c) position of the circle in the camera pixel coordinates and d) phase map of the calibration plane.

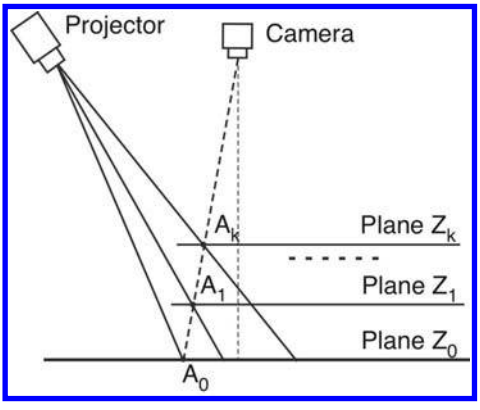

Figure 16. Calibration with virtual planes z_k.

ϕ_{z_0} [see figure 15 (d)]. A relation between the plane XY_{z_0} and the camera coordinates ij is obtained using a piecewise linear interpolation.

All the circles cut by the frame of the image are removed since their center can not be properly calculated (information is partly lost). If they were kept, they would introduce distortion.

The same procedure is repeated k times with the calibration plate placed over the inclined plane at an elevation z_k, with $k = 1, 2, \ldots, K$ (see Fig. 16). A relation between the plane $XY_{z_k} (k = 1, 2, \ldots, K)$ and the camera coordinates ij is obtained using

Copyright © 2006 Taylor & Francis Group plc, London, UK

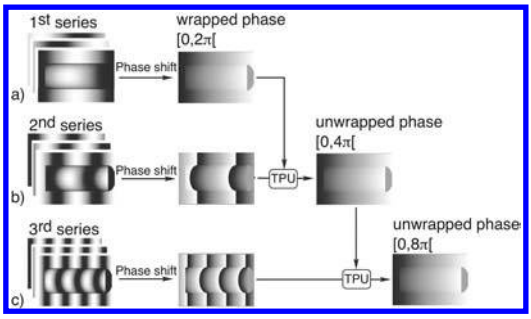

Figure 17. Temporal phase unwrapping: a) a first series of images with a large length wave, so the wrapped phase is set equal to the unwrapped one, is projected, b) the length wave is divided by 2 and a new series is projected, the unwrapped phase is obtained by looking up at the fist unwrapped phase, c) a new series is then projected with a length wave divided again by 2.

a piecewise linear interpolation. The corresponding wrapped phase ϕ_{z_k} is computed and the phase difference $\phi_{z_k} - \phi_{z_0}$ is unwrapped and denoted by ψ_{z_k}. ψ_{z_k} is not unique since $\phi_{z_k} - \phi_{z_0} \in [0, 2\pi[$. z_k is a function of $\varphi_{z_k} = \psi_{z_k} + j\pi$, with $j = 1, 2, \ldots$. A way to find j is explained in section 3.7.1. Once $\varphi_{z_k} = \psi_{z_k} + j\pi$ has been defined, a piecewise-linear-interpolation method is used to achiever Z-axis calibration. The unwrapped phases $\varphi_k (k = 1, 2, \ldots, K)$ at elevation $z_k (k = 1, 2, \ldots, K)$ are considered as reference phases. Based on the reference phases and their elevations z_k, every pixel height (Z-axis coordinate) can be obtained by linearly interpolating φ_k and z_k.

We end up with a calibration matrix M_{ijk}, which relates the value of the unwrapped phase φ_k in the pixel coordinates ij with the elevation z_k in the plane coordinates XY.

Compared with traditional way of calibration, this method reduces the hardware requirement of the system. It also simplifies the process of grabbing and processing data. Better accuracy is achieved by increasing the number of virtual calibrating planes z_k. The standard deviation error, using 5 virtual planes, is of the order of 1%.

3.7.1 *Temporal phase unwrapping*

Temporal phase unwrapping (TPU), presented in detail by Huntley and Saldner (1997), consists of unwrapping a phase with high sensitivity by means of others phases with lower sensitivity. First, a series of phase shifted images (see 3.4.1) is projected with a projected lengthwave L_{p_1} longer or equal to the surface to be measured. The wrapped phase ϕ_1 is then set equal to the unwrapped phase φ_1 [see figure 17 (a)]. Height resolution is low. A second series of phase shifted images is projected onto the surface, but with a lengthwave

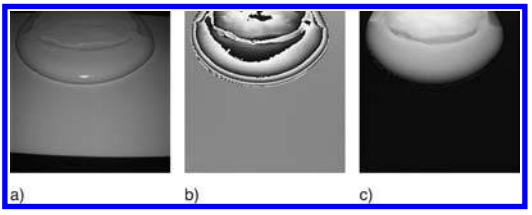

Figure 18. Free surface at $t_2 = 2.4\,s$: a) 1 image used for the FTP algorithm, b) the wrapped phase and c) the height of the free surface.

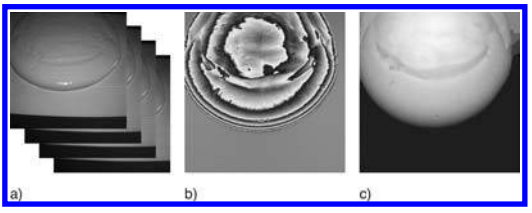

Figure 19. Free surface at $t_2 = 38.5$ s: a) 4 images used for the phase-shift algorithm, b) the wrapped phase and c) the height of the free surface.

$L_{p\frac{1}{2}}$ set to half the size of L_{p_1}. The wrapped phase $\phi_{\frac{1}{2}}$ is unwrapped by looking up at the wrapped phase φ_1 (see Fig. 17b)). This process is repeated n times until the desired $\phi_{\frac{1}{n^2}}$ is reached.

4 EXAMPLE

In this example, a 60 l volume of Carbopol Ultrez 10 at a solid concentration of 0.4% is released. The plane is inclined at 15°.

Figure 18(a) represents the grabbed image of the flow at time $t_1 = 2.4$ seconds. The wrapped phase [see Fig. 18 (b)] is obtained by a FTP. The unwrapped phase was computed using Flynn's algorithm. The final height is obtained using the calibration matrix [see Fig. 18 (c)].

The same test run but at $t_2 = 38.5$ seconds. The flow has slowed down and a 4 image phase-shift algorithm can be used. Figure 19 (a) shows the 4 images used to calculate the wrapped phase [see Fig. 19 (b)]. The wrapped phase is computed using Flynn's method. The height is shown in figure 19 (c).

5 CONCLUSION

New experimental facilities and procedures have been built to accurately measure the three-dimensional flow depth profiles in the dam-break problem. A mass of viscoplastic fluid is suddenly released by opening the dam sluice gate down a 4.5 m long inclined plane.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The three-dimensional flow-depth profiles are measured using a high-speed digital camera, which records how a fringe pattern projected onto the flow surface is deformed. To ensure uniform projection, a micro-mirror projector is used. The projector and the camera are synchronized at 48 Hz.

A cosine fringe pattern is projected onto the surface by the micro-mirror projector. A wrapped phase, from the recorded deformed images, is obtained using a 3–4 images phase shift algorithm or using a single image with Fourier transformation profilometry (FTP). The wrapped phase is then unwrapped using algorithms proposed by Ghiglia and Pritt (1998). The quality of the unwrapping algorithm depends on many parameters, which are user-dependent. Flynn's algorithm (Flynn 1997) tends to give the best time/accuracy ratio.

Height can be related to the unwrapped phase by a calibration matrix. The calibration matrix is obtained by placing a calibration plate at different elevation z_k and relating the pixel coordinates ij with circles on the plane to get the XY coordinates. At the same time, the phase of each z_k plane is recorded.

The 3 images phase-shifting method is used when the distance travelled by the surge is lower than one or two pixels between the first and the last image. Fourier transformation profilometry (FTP) is preferred when the flow is fast because only one image is needed. The drawback of this method is that a 'good' user dependent filtering is needed to remove parasitical frequencies.

Even though we are still improving the procedure to reduce the dependency of the results on the user, we are quite confident of the method expounded in this paper. The characteristics of the flow down the inclined plane (e.g., flow depth profile, front velocity) can be related with its rheogical properties. The precision on the surface height is of the order of 0.1 mm for a surface of $1.8 \times 1.2\,\mathrm{m}^2$.

Study on river-discharge measurements with a bottom-mounted ADCP

Y. Nihei & T. Sakai
Tokyo University of Science, Dept. of Civil Engineering, Chiba, Japan

ABSTRACT: To examine the accuracy of discharge measurements in rivers, continuous measurements of flood flows were conducted with a bottom-mounted ADCP. The observed data indicates that the vertical distribution of the velocity varied considerably in the rising and falling stages of a hydrologic event, in which the unsteadiness parameter α and H.W.L. were relatively larger. It should be noted from the observed data that the averaged coefficients of float were in good agreements with well-known empirical values, while the coefficients of float varied appreciably in each hydrologic event. The accuracy for evaluating river discharge is investigated by using the rating curves with H-Q and V-Q, showing that the rating curves with H-Q and V-Q are appropriate for the evaluation of discharge in the upper and lower reaches of the river, respectively.

1 INTRODUCTION

River discharge is essential for river planning and management. In measuring river discharge, rod-float measurements are widely adopted under flood-flow conditions. Using a rating curve between the observed discharge Q and water elevation H at a cross-section of a river, so called an H-Q curve, the continuous data for river discharge Q can be obtained from the observed water elevation H. Therefore a huge number of gauging stations recording water elevation have been developed.

However, under flood-flow conditions, the discharge in a rising stage tends to be higher than that in a falling stage at a same water elevation, producing a looped rating curve. Further the discharge monitoring with floats may have measuring errors due to various hydraulic phenomenon. From the above viewpoints, it is necessary to evaluate the accuracy and applicability of previous methods for discharge measurements. Moreover it is expected to develop a more accurate technique for measuring river discharge.

For this purpose, the continuous measurements of flood flows were conducted with a bottom-mounted ADCP (Acoustic Doppler Current Profiler) which can record a vertical distribution of velocity. An ADCP has already been used as a standard current meter of physical oceanography and coastal environments (*e.g.*, Pettigrew et al. 1986). The recent ADCP technology can realize to measure the three-dimensional velocity with fine vertical resolution in which the minimum cell size is 1 cm. Then the potential for applying the ADCP into current measurements in shallow-water flow like river flow has been increasing. In the present paper, the field measurements were done in the Oohori River in Japan, an urban small river. The analysis of the observed data was employed to examine the vertical distribution of velocity in rising and falling stages and then evaluate a coefficient of float which is the ratio of depth-averaged velocity to velocity in surface layer. In addition, the accuracy of rating curves with H-Q and V-Q (Huang 2004) is discussed, in which V means a depth-averaged velocity.

2 OUTLINE OF FIELD MEASUREMENTS

The Oohori River chosen as a field site inflows into the western part of Lake Teganuma, one of typical eutrophied lakes in Japan. As shown in Fig. 1, the measuring stations were in lower reach of the Oohori River at Stns.1 and 2 which were located at 1.5 km and 0.9 km upstream from the river mouth, respectively. The backwater from the lake was known to affect time variations

Figure 2. Cross-sectional view at both the measuring stations.

of the water elevation at both the stations. The influence from the lake appeared more appreciably at Stn.2 than at Stn.1. Figure 2 describes the cross-sectional view at both the stations. The Oohori River is a compound channel and the width of the flood plane with vegetation layer at Stn.1 is much larger than that at Stn.2. The ADCP is bottom-mounted in the center of the main channel.

The instrument used in the present study was a 1200 kHz WorkHorse Sentinel ADCP (RD Instruments, Inc.). The ADCP was installed on the river bed looking upward, to give the vertical profile of velocity, as indicated in Fig. 3. The configuration parameters of the ADCP are summarized in Table 1.

In the configuration, the blank zone, in which no measurements were taken near the head of the ADCP, was 0.14 m. The measurements of water elevation were also conducted with the pressure gauge (Diver, Eijikelkamp Co.).

The ADCP was installed at Stn.1 in 2004 and at Stn.2 in 2005, respectively. From these field measurements, the observed data in five hydrologic events were selected to perform the analysis of observed data. The information for the events are detailed in Table 2, in

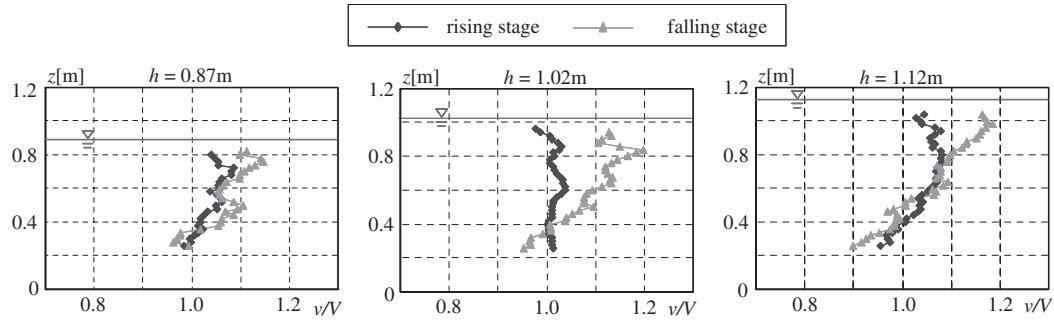
which the unsteadiness parameter α proposed by Nezu et al. (1997) is defined as

$$\alpha = \frac{\Delta h}{T_d}\frac{1}{U_c}, \tag{1}$$

where Δh is the difference of maximum flow depth and the base flow depth, T_d means the time duration of the rising or falling stage in the hydrograph and U_c represents the average of peak flow and base flow depth-averaged velocity. In Table 2, these parameters are displayed in the rising and falling stages of each event. Since two peaks of the hydrograph appeared in the event C, the period of the event is separately denoted as event C-1 and C-2 in Table 2.

3 VERTICAL FLOW STRUCTURE IN FLOOD EVENTS

3.1 *Vertical distribution of streamwise velocity*



To examine the fundamental vertical flow structure in the rising and falling stages, Fig. 4 indicates the vertical distribution of streamwise velocity in the events A and D. The horizontal axis in the figure means the streamwise velocity v normalized by the depth-averaged velocity V. For evaluating the depth-averaged velocity V, the velocity in the blank zone near the riverbed are estimated with the approximation described as $v = az^b$ (z: the height from the riverbed; a, b: constants).

The observed results in the event A shows that, in shallower water depth ($h = 0.87$ m), the velocity

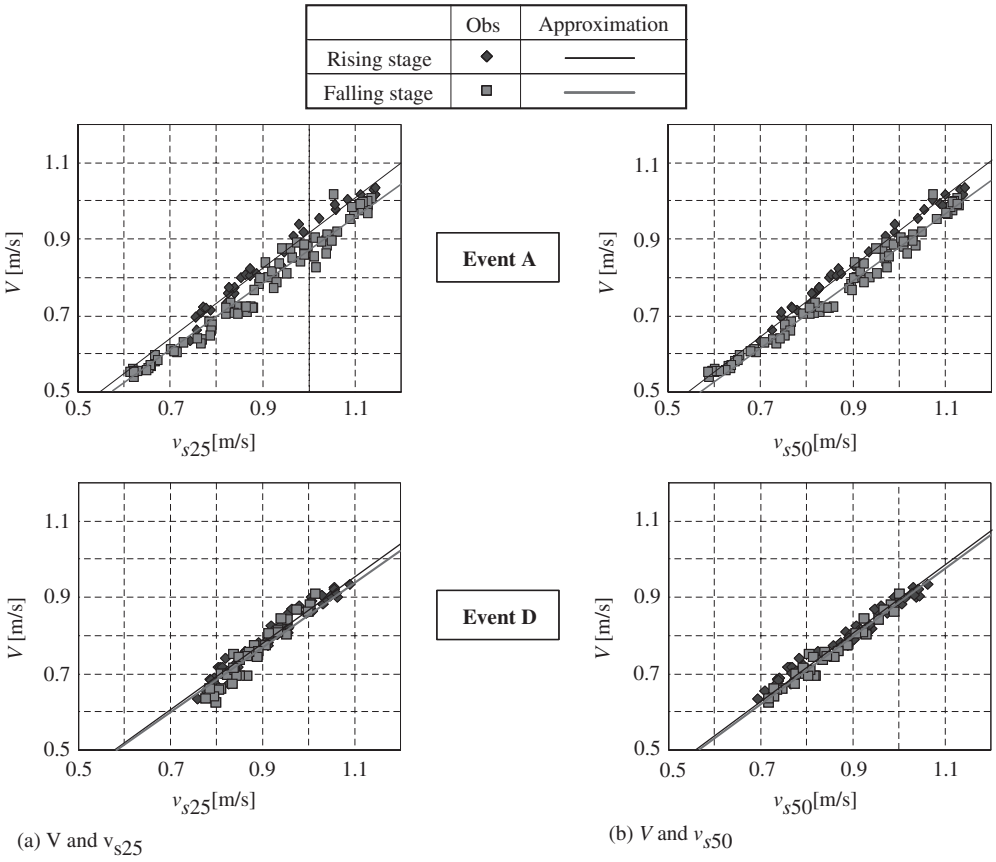
E	Stn.2	July 3 to 4, 2005	Rising stage	10500	0.217	0.446	4.6×10^{-5}
			Falling stage	10500	0.129	0.455	2.7×10^{-5}

(a) Event A (Peak depth = 1.66m)



(b) Event D (Peak depth = 1.20m)

Figure 4. Vertical distribution of streamwise velocity in the rising and falling stages (h: water depth).

distributions in the rising and falling stages almost coincided with each other. However, in deeper depth ($h = 1.02$ m and 1.12 m), the velocity in the rising stage tended to be uniform vertically, while the velocity distribution in the falling stage was inclined in the vertical direction. The results in the event A demonstrate that the vertical distribution of the velocity varied considerably in the rising and falling stages of the hydrologic event. On the other hand, the observed results in the event D reveal that the velocity distributions in the rising stage were almost agreements with those in the falling stage at three depth conditions.

The observed results for the vertical flow structure indicate that the appreciable differences of the vertical distribution of the velocity were found only in the event A. It is noted from Table 2 that the unsteadiness parameter α and depth difference Δh in the event A were larger than those in the other events. These parameters may be closely related to the difference of the vertical flow structure in the hydrograph. In near future, hence, it is necessary to collect further ADCP data to clarify the vertical flow structure under various flow conditions. It is also noteworthy that $\alpha = 8.9 \times 10^{-5}$ in the event A may be regarded as a weak unsteadiness

condition in the laboratory experiments done by Nezu et al. (1997).

3.2 *Coefficient of float*

In discharge measurements with rod floats flowing near water surface, it is necessary to convert measured surface velocity with rod floats into a depth-averaged velocity V. In the evaluation for the river discharge, one needs to use a coefficient of floats which is a ratio of the depth-averaged velocity to the surface velocity. The ADCP can monitor the vertical distribution of velocity. It is therefore possible to confirm the validity of well-known coefficients of float by using the vertical distribution of velocity obtained by the bottom-mounted ADCP. In general float measurements, a surface float and a 0.5 m long rod are adopted in $h < 0.7$ m and $0.7\,\text{m} < h < 1.3$ m, where h is water depth, respectively. The relationship between the depth-averaged velocity and surface velocity in the events A and D are illustrated in Fig. 5. Here two surface velocities v_{s25} and v_{s50} are introduced as the velocity averaged in the surface layer with the thickness of 25 cm and 50 cm, respectively. The surface velocities v_{s25} and v_{s50} corresponds to the velocities measured by surface float and a 0.5 m long rod, respectively. The observed results are separately depicted in the rising and falling stages in the figure.

Table 3. Coefficients of float in each hydrologic event.

Event	Rising stage	Falling stage	Rising stage	Falling stage
A	0.916	0.867	0.925	0.883
B	0.746	0.759	0.779	0.778
C	0.826	0.811	0.876	0.878
D	0.866	0.851	0.900	0.883
E	0.812	0.805	0.902	0.885
Average	0.830		0.874	

The correlations between the depth-averaged velocity V and the surface velocities v_{s25} and v_{s50} in the event A indicate that, under the same surface velocity,

Copyright © 2006 Taylor & Francis Group plc, London, UK

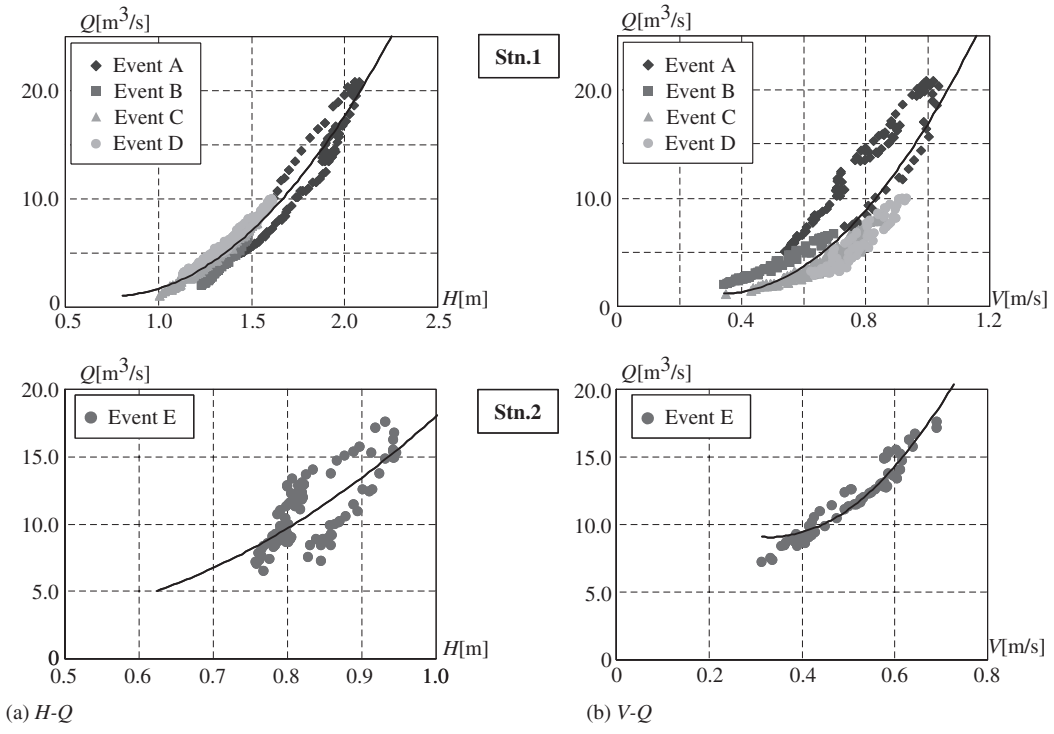

Figure 6. *H-Q* and *V-Q* curves at Stns.1 and 2.

the depth-averaged velocity V in the rising stage was larger than that in the falling stage. These tendencies were found in both the surface velocities. On the other hand, the difference of the depth-averaged velocity in the rising and falling stages was not observed in the event D. The relations between the depth-averaged and surface velocities are almost similar to the vertical flow structure mentioned in the above.

In Fig. 5, linear approximations for the correlations between the depth-averaged and surface velocities are also exhibited. The slopes of the linear approximations correspond to the coefficients of float ($=V/v_{s25}$ or V/v_{s50}). The evaluated coefficients of float in each hydrologic event are summarized in Table 3. In the event A, the difference of the coefficients of float in the rising and falling stages was 0.04–0.05, while, in the other events, the coefficient in the rising stage was comparable to that in the falling stage. The results are also similar to those shown in Figs. 4 & 5.

The averaged coefficients for v_{s25} and v_{s50} were 0.83 and 0.87, respectively, almost corresponding to well-known empirical values for the coefficients of float (=0.85 and 0.88, respectively). In each hydrologic event, however, the coefficients of float for the surface velocities v_{s25} and v_{s50} varied appreciably. The coefficients for v_{s25} and v_{s50} were from 0.75 to 0.92 and from 0.78 to 0.93, respectively.

4 ACCURACY OF DISCHARGE EVALUATION WITH H-Q AND V-Q CURVES

4.1 *Procedure of discharge evaluation*

Accuracy of discharge evaluation with rating curves is examined using the observed data with the ADCP. For this purpose, it is necessary to evaluate river discharge with the depth-averaged velocity obtained by the ADCP mounted at a point in a cross section. To obtain the transverse distribution of velocity in a cross section from the ADCP data, a dynamic interpolation method presented by Nihei & Kimizu (2006) is introduced, in which observed velocities can be spatially interpolated in the cross section with satisfying the fundamental dynamic principle of fluid motion. With the dynamic interpolation method, the time sequence of the discharge can be calculated from the depth-averaged velocity and water elevation.

4.2 *H-Q and V-Q curves*

The correlations of *H-Q* and *V-Q* at Stns.1 and 2 are displayed in Fig. 6. Approximations for the correlations are also depicted in the figures. At Stn.1, both the rating curves of *H-Q* and *V-Q* were looped in the hydrograph. The loop of the *V-Q* curve was larger than that of the *H-Q* curve.

Table 4. Comparison of the observed and evaluated discharge in each hydrologic event.

	Event	[m^3/s]	H-Q	V-Q
A	Total	8.4	101.5	78.8
	Rising stage	9.4	88.9	103.7
	Falling stage	8.0	107.0	67.9
B	Total	3.4	123.6	67.1
	Rising stage	4.5	115.3	75.4
	Falling stage	2.9	129.4	61.3
C	Total	3.8	96.6	123.9
	Rising stage	5.0	93.6	130.4
	Falling stage	3.1	99.3	117.7
D	Total	3.9	88.9	142.6
	Rising stage	4.5	86.1	151.9
	Falling stage	3.2	93.0	129.1
E	Total	12.4	100.0	103.7
	Rising stage	13.8	93.1	104.6
	Falling stage	11.0	107.1	102.8

In contrast, at Stn.2, the H-Q rating curve was looped more largely than the V-Q curve. The influences of the backwater from Lake Teganuma appeared more appreciably for water elevation at Stn.2 than that at Stn.1 due to the difference of the distance from the river mouth. Therefore larger loop of the H-Q curve was found at Stn.2.

4.3 *Results and discussion*

The discharge can be evaluated by using the approximations for H-Q and V-Q as shown in Fig. 6. Table 4 reveals the observed and evaluated discharges averaged during a hydrologic event. In the table, the observed discharge $\overline{Q}_{obs}$ and the ratio of the evaluated discharge $\overline{Q}_{cal}$ to $\overline{Q}_{obs}$ are separately expressed in the rising and falling stages and total period of each event. The results for the total periods of events A, B, C and D at Stn.1 illustrate that the ratio $\overline{Q}_{cal}/\overline{Q}_{obs}$ with the H-Q curve was from 89 to 124%, while $\overline{Q}_{cal}/\overline{Q}_{obs}$ with the V-Q curve was from 67 to 143%. This fact exhibits that the accuracy of the V-Q curve was lower than that of the H-Q curve due to larger loop of the V-Q curve at Stn.1 as mentioned in Fig. 6. Furthermore the accuracy of the H-Q and V-Q curves was lower in the rising stage or falling stage because of the existence of the loop of the rating curves. Then the temporal variations of discharge may not be accurately evaluated with H-Q and V-Q curves.

On the other hand, $\overline{Q}_{cal}/\overline{Q}_{obs}$ in the event E at Stn.2 suggests that the accuracy of the H-Q curve was lower than that of the V-Q curve. It should be noted from the result that at measuring stations with significant backwater influences from lakes like Stn.2, a V-Q curve is more appropriate to accurately evaluate river discharge than an H-Q curve.

5 CONCLUSIONS

The flood-flow measurements were done with the bottom-mounted ADCP. With the observed data, the vertical flow structure and the evaluation of the discharge with the H-Q and V-Q curves are discussed. Main conclusions in the present study are as follows:

(1) In the event A with relatively larger unsteadiness parameter α and stage variation Δh, the vertical flow structure and the coefficient of floats were found to be different appreciably in the rising and falling stages.
(2) The averaged values of the float coefficients for v_{25} and v_{s50} were 0.83 and 0.87, respectively, almost corresponding to the well-known empirical values. In each hydrologic event, however, the coefficients of float varied considerably. The coefficients for the surface velocities v_{s25} and v_{s50} were from 0.75 to 0.92 and from 0.78 to 0.93, respectively.
(3) The H-Q and V-Q curves are appropriate for the evaluation of discharge in the upper and lower reaches of the river, respectively, due to the difference of the backwater effect from the lake.
(4) The temporal variations of discharge may not be accurately evaluated with the H-Q and V-Q curves.

Experimental procedure to obtain 2D time-space high-speed water surfaces

A. Bateman, A. Granados, V. Medina & D. Velasco

M. Nalesso
Fluid Mechanics Institute, Central University of Venezuela

ABSTRACT: Numerical validations always require a major effort involving laboratory measurements. In 2D models, it is unusual to see comparisons between measurements (in space and time) and the numerical results of a model. Measuring a surface involves many problems because collecting sufficient data in space and time is very complex. This paper indicates how to measure a liquid surface by taking 2D measurements (in space and time) of a set of cross-sections of a water surface experiencing a dam-break phenomenon. This work was carried out by a research group (GITS-UPC) at the Hydraulics Laboratory of the Department of Hydraulic, Maritime and Environmental Engineering of the Technical University of Catalonia. The paper details our mathematical framework and experimental methodology, which involves 3 mW laser beams and high- and medium-speed cameras, and compares a numerical surface to an experimental surface. The numerical data were modelled using FLATMODEL, which was developed entirely by the research group.

1 INTRODUCTION

Mathematical sketching is a method that can deal with very complex problems. It is also very clear and introduces the new concept of making hydraulic laboratory measurements using images. This method can recreate 3D representations of high-speed flow surfaces in space and time, using a single photograph for each time step. Cameras have already been used in laboratories to recreate certain physical phenomena, but here an entire surface is recreated at each instant to calibrate a 2D model. Here we present the mathematical methodology used to scan surfaces and its application to a dam-break problem. We developed this technique for characterizing moving surfaces in order to calibrate a 2D Saint-Venant numerical code and evaluate the divergence of the model from reality.

2 POINTS, SPACE AND PLANE CORRESPONDENCE

Figure 1 shows that taking a picture is like projecting one point in space onto a point photograph through a point called the focus (F). This projection is determined by fixing a reference point in space, knowing the position of the camera plane and locating the focus. That is, for each point in space, it is possible

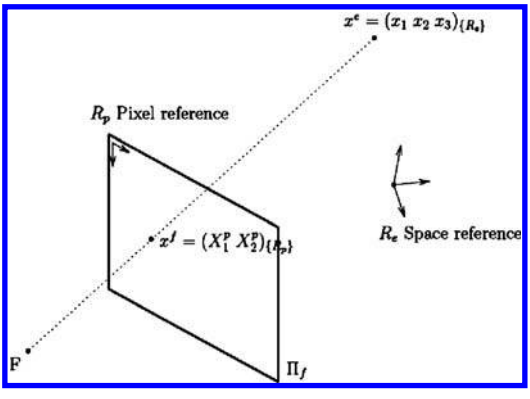

Figure 1. Space and photograph reference.

to determine the corresponding pixel of the photograph by noting where the straight line defined by the point and the focus intersects with the photograph plane. However, it is practically impossible and unnecessary to know all of these parameters directly. Through projective geometry, an application known as camera calibration can project the point from the reference in space to the coordinates in the photograph (real coordinates or pixels) without explicitly needing to know these parameters.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2.1 *From space to the photograph: Direct Linear Transformation (DLT) (Abdel-Aziz, 1971 and Faugeras 1993)*

How can the corresponding point in the photograph be obtained for a given point $x_e = (x_1\ x_2\ x_3)$ in space in any reference R_e (Figure 1)? If we know the equation of the photograph plane $\Pi_f: ax + by + cz + d = 0$, and the coordinates of the focus $F = F1\ F2\ F3$), then the point to be determined in the reference R_e is given by the intersection of the line r: $(x\ y\ z) = F + \lambda(F - x^e)$ with the plane Π_f (Figure 1). However, in addition to being nonlinear in the x_e coordinates, this equation depends on parameters that are impossible to define directly, i.e. the expression in the reference R_e for the photograph plane Π_f and the focus F. We need another way to find the projected point in the photograph.

Imagine that, instead of taking a space R_e as a reference, we take a reference R_c (Figure 2), which we will call the camera reference. The axis z of this reference is perpendicular to the plane Π_f, with origin at the focus F. This reference is located at a distance of 1 from the photograph plane (focal distance). In these conditions, the straight line r has the mathematical expression r: $(x\ y\ z)_{\{Rc\}} = \lambda(x1\ x2\ x3)_{\{Rc\}}$ and the plane is Π_f: $z_{\{Rc\}} = 1$. Therefore, their intersection is $x^j_{\{Rc\}} = \left(\frac{x1}{x3}\ \frac{x2}{x3}\ 1\right)$ Instead of projecting the point $x^e(x_1\ x_2\ x_3)_{\{R_c\}}$, a multiple of it, $\mu x^e = (\mu x_1\ \mu x_2\ \mu x_3)_{\{R_c\}}$, is projected, which is the same as projecting x^e. This is because both points are in the same straight line, $r = \lambda(x1\ x2\ x3)_{\{Rc\}}$, which is perpendicular to the projective plane Π_f. Therefore, the intersection with the plane is the same for both points.

Rather than relating points in the space with points in the plane, the idea is to relate the lines in $\mathbb{R}^3$ that pass through the origin (F) to points of the plane Π_f. Thus, we can relate the direction of the straight line $r = \lambda(x1\ x2\ x3)_{\{Rc\}}$, which is the point $(x1\ x2\ x3)_{\{Rc\}}$ and all of its multiples, with the point $\left(\frac{x1}{x3}\ \frac{x2}{x3}\ 1\right)_{\{R_c\}}$ of the photograph plane.

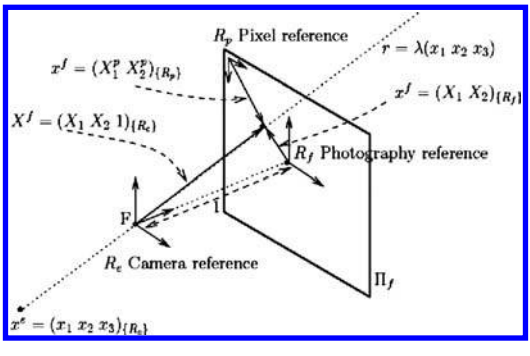

Figure 2. Camera reference.

We must also project straight lines that are parallel to the plane Π_f. To do so, we must construct an abstract mathematical object that defines points of infinity or improper points. This is the vectorial space known as projective plane $\mathbb{P}_2$, which is the same as plane Π_f, except for the improper points that we cannot see but can manipulate algebraically. In $\mathbb{P}_2$, we can use the following homogeneous coordinates: if $(x1\ x2\ x3) \in \mathbb{R}^3$ with $x_3 \neq 0$, the straight line will be represented by the point $\left[1\ \frac{x_1}{x_2}\ 0\right]$. The improper points are then represented by points whose third component is equal to 0 in the homogeneous coordinates.

With the sole aim of grouping all the representative elements of $\mathbb{P}_2$ in one element, it is common to use the generalized coordinates. This consists in eliminating the third coordinate when it is 1 (that is, when the point is not improper). Then, the rest of the coordinates are represented as: $(X_1\ X_2) = \left(\frac{x_1}{x_3}\ \frac{x_2}{x_3}\right)$. Whenever we work with improper points, which implies using a plane that is parallel to the photograph and passes through the focus F, it makes no sense. In such a case, we work with the region of $\mathbb{P}_2$ called D, which corresponds to the photograph paper and does not contain improper points.

We can identify the generalized coordinates $(X_1\ X_2)_{\{R_f\}} \in \mathbb{P}_2$ as the point x_f in real coordinates in the photo reference. This reference is obtained by orthogonally projecting the axes $x - y$ of the camera reference over the plane Π_f (Figure 2). That is, $x_f = (X_1\ X_2)_{\{R_f\}} \in \mathbb{R}_2$.

Now we want to work with a reference R_p (pixel reference) other than R_f, with the origin in the upper-left corner of the photograph (see Figure 2), in which the points of the photograph are expressed in pixels. A new change of reference must therefore be added.

A change of reference in the plane can be written in matrix form as

$$\begin{pmatrix} X_1^p \\ X_2^p \end{pmatrix}_{\{R_p\}} = \begin{pmatrix} r_{11} & r_{12} & t_x \\ r_{21} & r_{22} & t_y \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \\ 1 \end{pmatrix}_{\{R_f\}} \quad (1)$$

in which the vector $(t_x\ t_x)$ represents the translation of the origin and the matrix $(r_{ij})_{ij}$ represents the basis change due to the rotation of the axis system. Before performing the transformation in $\mathbb{R}_2$, it is a good idea to perform another change of reference in the projective plane. Thus, in homogeneous coordinates, the change takes the form of a linear application, Φ_2, of $\mathbb{P}_2$.

$$\begin{pmatrix} X_1^p \\ X_2^p \\ 1 \end{pmatrix}_{\{R_p\}} = \begin{pmatrix} r_{11} & r_{12} & t_x \\ r_{21} & r_{22} & t_y \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \\ 1 \end{pmatrix}_{\{R_f\}} \quad (2)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Hitherto we have seen how to relate points in space with those of the photograph if the former are expressed in some reference denoted by $\{R_c\}$ (camera reference). However, as detailed above, it is impossible to have the points in $\mathbb{R}^3$ in that reference because they depend on the position of the focus and the photograph plane, which cannot be determined directly.

If we have properly selected the points at reference $\{R_e\}$ (Figure 1), and we assume that there exists an application that passes the points from $\{R_e\}$ to $\{R_c\}$, this is a change of reference in $\mathbb{R}^3$ similar to (1) but in $\mathbb{R}^3$ instead of $\mathbb{R}^2$.

$$\begin{pmatrix} x_1^c \\ x_2^c \\ x_3^c \end{pmatrix}_{\{R_c\}} = \begin{pmatrix} r_{11} & r_{12} & r_{13} & t_x \\ r_{21} & r_{22} & r_{23} & t_y \\ r_{31} & r_{32} & r_{33} & t_z \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ 1 \end{pmatrix}_{\{R_e\}} \tag{3}$$

Like (2), it can change the reference in $\mathbb{R}^3$ into a linear application from $\mathbb{P}_3$ to $\mathbb{P}_3$.

$$\begin{pmatrix} x_1^c \\ x_2^c \\ x_3^c \\ 1 \end{pmatrix}_{\{R_c\}} = \begin{pmatrix} r_{11} & r_{12} & r_{13} & t_x \\ r_{21} & r_{22} & r_{23} & t_y \\ r_{31} & r_{32} & r_{33} & t_z \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ 1 \end{pmatrix}_{\{R_e\}} \tag{4}$$

By calling this linear application Φ_1, we can define a linear application A from $\mathbb{P}_3$ to $\mathbb{P}_2$.

The composition $\Phi_1 \circ A \circ \Phi_2$ as a linear application M between $\mathbb{P}_3$ and $\mathbb{P}_2$ includes the changes of reference and the projection in a strict sense. Therefore, this method is called Direct Linear Transformation (DLT).

The linear transformation can be written as

$$\begin{bmatrix} n.X_1^p \\ n.X_2^p \\ n \end{bmatrix} = \begin{pmatrix} m_{11} & m_{12} & m_{13} & m_{14} \\ m_{21} & m_{22} & m_{23} & m_{24} \\ m_{31} & m_{32} & m_{33} & m_{34} \end{pmatrix} \begin{bmatrix} x_1^e \\ x_2^e \\ x_3^e \\ 1 \end{bmatrix} \tag{5}$$

in which $M = (m_{ij})_{ij}$.

Why does n appear here? It was omitted in the previous reasoning. In fact, a change of reference in $\mathbb{R}^2$ is assumed to be a basis change in $\mathbb{P}_2$ in homogeneous coordinates. However, changes of this sort are determined by just three points in $\mathbb{R}^3$, except for proportionality factors. The $3x3$ basis-change matrix Φ_2 gives three points of $\mathbb{R}^3$ to determine a basis change in homogeneous coordinates in $\mathbb{P}_2$. However, four points are needed to determine the transformation uniquely. The same occurs in a change of reference in $\mathbb{R}^3$. Five points of $\mathbb{R}^4$ are needed to uniquely determine a basis change in $\mathbb{P}_3$, but only four points are given: the three vectors of the coordinates and the origin. Then, n represents the two proportionality factors of the basis change that are omitted.

Therefore, a projection of a point from $\mathbb{R}^3$ over a plane Π_f is determined by a linear application M of $\mathbb{P}_3$ in $\mathbb{P}_2$, except for a proportionality factor n. That is, the third coordinate of a point in $\mathbb{P}_2$ obtained by applying M is not equal to 1. To obtain $(X_1^p \;\; X_2^p)$, the first two coordinates of the obtained point are divided by the third component when changing from $\mathbb{P}_2$ to $\mathbb{R}^2$.

Finally, the matrix M can be obtained numerically by relating known points in space with points in the photograph. This process is known as camera calibration.

2.2 *From the photograph to space: the inverse process (Hatze, 1988) or (Chen, 1994)*

Once we have obtained the projectivity that connects the points in space with the points in the photograph through the focus, we can use the inverse process to obtain the point we need. However, a given point in the photograph plane is not represented by a single point in space but by a whole line projected through it. We need more information about the position of the point to be determined in space – for example, a plane that it belongs to.

Algebraically, the matrix M is not square, and it makes no sense to evaluate the inverse, at least not without limiting the starting space $\mathbb{P}_3$ to the homogenized points of $\mathbb{R}^3$ located in a certain plane. Then, the dimension of the arriving and starting space equals converting the projectivity in an isomorphism between the projective spaces.

From a practical point of view, it is a good idea to request that the points to be surveyed belong to a certain known plane.

Imagine that we know the projection matrix transformation M and that the point to be determined in $\mathbb{R}^3$, $(x_1 \;\; x_2 \;\; x_3)$, belongs to a known plane defined by the equation $\Pi : ax_1 + bx_2 + cx_3 + d = 0$. In homogeneous coordinates, the point x^f can be written as $x^f = [X_1 \;\; X_2 \;\; 1]$ and the plane can be written as

$$\Pi : ax_1 + bx_2 + cx_3 + dx_4 = 0 \tag{6}$$

The point to be determined is $x^e = [x_1 \;\; x_2 \;\; x_3 \;\; x_4] \in \mathbb{P}^3$ anti-image by M of x^f (in homogeneous coordinates) that fits equation (6). Using points x^f and x^e, the following equation is obtained from (5):

$$\begin{cases} 1 = m_{31}x_1 + m_{32}x_2 + m_{33}x_3 + m_{34}x_4 \\ X_1 = m_{11}x_1 + m_{12}x_2 + m_{13}x_3 + m_{14}x_4 \\ X_2 = m_{21}x_1 + m_{22}x_2 + m_{23}x_3 + m_{24}x_4 \end{cases} \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

In some way, x_4 plays the role of n in equation (5). If $a \neq 0$, we can write:

$$x_1 = -\frac{bx_2 + cx_3 + dx_4}{a} \tag{8}$$

By substituting the value of (8) in (7), the following system is obtained in matrix notation:

$$\begin{bmatrix} X_1 \\ X_2 \\ 1 \end{bmatrix} = \begin{bmatrix} \left(m_{12} - \frac{m_{11}b}{a}\right) + \left(m_{13} - \frac{m_{11}c}{a}\right) + \left(m_{14} - \frac{m_{11}b}{a}\right) \\ \left(m_{22} - \frac{m_{21}b}{a}\right) + \left(m_{23} - \frac{m_{21}b}{a}\right) + \left(m_{24} - \frac{m_{21}b}{a}\right) \\ \left(m_{32} - \frac{m_{31}b}{a}\right) + \left(m_{33} - \frac{m_{31}b}{a}\right) + \left(m_{34} - \frac{m_{31}b}{a}\right) \end{bmatrix} \begin{bmatrix} x_2 \\ x_3 \\ x_4 \end{bmatrix} \tag{9}$$

in which the matrix of (9) is the restriction for Π of M, which is square, and it is possible to find the points x_2, x_3 and x_4 (x_1 is defined by the known plane Π through (8)) . To obtain the point x_e, the homogeneous coordinates (x_1 x_2 x_3 x_4) are divided by x_4 to obtain 1 in the last element or coordinate. That is, it is de-homogenized:

$$\begin{pmatrix} x_1^e & x_2^e & x_3^e \end{pmatrix} = \frac{\left(-\frac{bx_2 + cx_3 + dx_4}{a} \; x_2 \; x_3 \right)}{x_4} \tag{10}$$

To sum up, given a point in the photograph $x^f = [X_1 \; X_2] \in \mathbb{R}^2$, it is homogenized to obtain $x^f = [X_1 \; X_2 \; 1] \in \mathbb{P}^2$.

Then, $x^e = [x_1 \; x_2 \; x_3 \; x_4] \in \mathbb{P}^3$ is calculated using equations (8) and (9). Finally, it is de-homogenized to obtain $x^e = (x_1^e \; x_2^e \; x_3^e) = \left(\frac{x_1}{x_4} \frac{x_2}{x_4} \frac{x_3}{x_4} \right) \in \mathbb{R}^3$.

2.3 *Determining the matrix M or projectivity: Camera calibration*

In the system of equations (5), the unknowns are the parameters of the M matrix m_{ij}. For each point in space (x_1 x_2 x_3) and its correspondents in the photograph (X_1 X_2), two equations (solved for n) can be obtained as follows:

$$\begin{aligned} &m_{31}x_1X_1 + m_{32}x_2X_1 + m_{33}x_3X_1 + m_{34}X_1 \\ &\qquad - m_{11}x_1 - m_{12}x_2 - m_{13}x_3 - m_{14} = 0 \\ &m_{31}x_1X_2 + m_{32}x_2X_2 + m_{33}x_3X_2 + m_{34}X_2 \\ &\qquad - m_{21}x_1 - m_{22}x_2 - m_{23}x_3 - m_{24} = 0 \end{aligned} \tag{11}$$

At first glance, then, it seems that we will need the correspondence of at least six points in space and six points in the photograph, since there are twelve unknowns and each pair of points gives two equations.

Nevertheless, the system defined by (11) is homogeneous, and a trivial solution $m_{ij} = 0$ always exists. In fact, the value of n is undetermined because it has a value of zero, which makes no sense.

If this parameter n does not exist, we can determine the values of m_{ij} simply by giving four points. However, this is not the case. In order to solve the problem, we must therefore add a restriction to the matrix M.

Suppose we have the points in space expressed in the camera reference used above (Figure 2). In these circumstances, the matrix projection M has the following form (Faugeras, 1993), (Olagué, 2001):

$$M_c = \begin{pmatrix} -f & 0 & u_0 & 0 \\ 0 & -f & v_0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \tag{12}$$

where (u_0 v_0) are the coordinates of the centre of the photograph (focus projection) in the pixel system and f is the focal (Chen, 1994). This matrix corresponds to $M_c = \Phi_2$. To work in the reference $\mathbb{R}^3$, $\{R_e\}$, M can be composed with the basis change Φ_1, that is:

$$M = M_c \cdot \Phi_1 \tag{13}$$

in which

$$\Phi_1 = \begin{pmatrix} r_{11} & r_{12} & r_{13} & t_x \\ r_{21} & r_{22} & r_{23} & t_y \\ r_{31} & r_{32} & r_{33} & t_z \\ 0 & 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} \mathrm{r}_1 & t_x \\ \mathrm{r}_2 & t_y \\ \mathrm{r}_3 & t_z \\ 0 & 1 \end{pmatrix} \tag{14}$$

is the basis change in $\mathbb{P}_3$ in Equation (4).

This decomposition makes it possible to find a projection matrix M through the intrinsic parameters (M_c) and extrinsic parameters (Φ_1) of the camera.

The submatrix $\Phi_1(r_i)_{(i)}$, in which r_i is a row vector of a composition of rotations, requires that $\|r_3\| = 1$ (Pizarro, 2005). From (13), it follows that

$$\sqrt{m_{31}^2 + m_{32}^2 + m_{33}^2} = 1 \tag{15}$$

With this restriction, there are now eleven unknowns instead of twelve. The new unknown matrix can be written as: (Chen, 1994)

$$L = \begin{pmatrix} \frac{m_{11}}{m_{34}} & \frac{m_{12}}{m_{34}} & \frac{m_{13}}{m_{34}} & \frac{m_{14}}{m_{34}} \\ \frac{m_{21}}{m_{34}} & \frac{m_{22}}{m_{34}} & \frac{m_{23}}{m_{34}} & \frac{m_{24}}{m_{34}} \\ \frac{m_{31}}{m_{34}} & \frac{m_{32}}{m_{34}} & \frac{m_{33}}{m_{34}} & 1 \end{pmatrix} = \begin{pmatrix} L_1 & L_2 & L_3 & L_4 \\ L_5 & L_6 & L_7 & L_8 \\ L_9 & L_{10} & L_{11} & 1 \end{pmatrix} \tag{16}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

By pairing n points in space $(x_i \;\; y_i \;\; z_i)_i$ with n points in the photograph $(X_i \;\; Y_i)_i$ and applying the change of variables to (11), the new system to be solved is made up of a system with eleven unknowns and $2n$ equations, as:

$$\begin{pmatrix} x_i & y_i & z_i & 1 & 0 & 0 & 0 & 0 & -x_i.X_i & -y_i.X_i & -z_i.X_i \\ 0 & 0 & 0 & 0 & x_i & y_i & z_i & 1 & -x_i.Y_i & -y_i.Y_i & -z_i.Y_i \\ & & & & & \vdots & & & & & \end{pmatrix}$$
$$\begin{pmatrix} L_1 & L_2 & \cdots & L_{10} & L_{11} \end{pmatrix}^T = \begin{pmatrix} X_i & Y_i & \cdots \end{pmatrix}^T \qquad (17)$$

This system is over-determined and can be solved using the least-squares method.

Once the system has been solved, to recover the projective matrix M, it follows that:

$$M = \frac{1}{\sqrt{L_9^2 + L_{10}^2 + L_{11}^2}} \begin{pmatrix} L_1 & \cdots & \cdots & L_4 \\ \vdots & \ddots & \ddots & \vdots \\ L_9 & \cdots & \cdots & L_{12} \end{pmatrix} \qquad (18)$$

thereby undoing the change of variables and imposing the restriction (15).

3 EXPERIMENTAL SET-UP

3.1 *Flume dam break*

We studied the changes over time in water-surface position (height) caused by suddenly opening the gate. The experiment involved high-speed movements in the water surface, which were recorded with two different digital cameras: a high-speed Basler camera and a medium-speed Lumenera camera.

The first experiment was a typical one. A flume filled with water was controlled by a sluice gate and connected directly to a platform, as shown in Figure 3. The platform was initially dry. The gate was removed manually from its original position and water flowed from the flume to the platform. The flume used in the first experiment was 9 m long, 40 cm wide and 60 cm high. It was tilted from 0 to 27°. The flume ended at a platform 4 m long, 2.4 m wide and 60 cm tall. In this experiment, the effective flume length was just 2 m (Figure 3). A fixed volume of water was held between two gates about 2 m apart. This part of the flume was connected to the platform by a manual sluice gate. A 50 cm deep volume of water was held.

Between 5 and 10 parallel laser beams were placed vertically over the platform, generating lines perpendicular to the flume axis in order to obtain cross-sections of the water surface. The water was mixed with milk at a concentration of 2% so that it would reflect the laser beams and make it possible to take photographs. Higher concentrations of milk caused more reflection, and lower concentrations allowed the light to penetrate the mixing fluid to a greater degree. We tried out different mixtures and found that the minimum concentration of milk was about 2% by volume. This allowed us to use as little milk as possible and obtain strips of light that were not too thick, thus preventing them from overlapping.

The Basler camera can capture images at up to 1000 fps with a resolution of 1200×1000 pixels or more, depending on the frame size. The Basler camera used normal Nikon lenses that produce high-quality images without optical aberration. The Lumenera camera had higher luminescence than the Basler because its lens had higher luminescence and also because the Basler's minimum shooting frequency was higher. The Lumenera had a wide-angle lens, which caused significant image deformation, which had to be corrected. A new MATLAB code was produced to correct this aberration.

A series of photographs of the light reflecting from the mixture were taken and processed. The idea was to obtain different cross-sections of the surface using the laser beams, in order to reconstruct the surface at

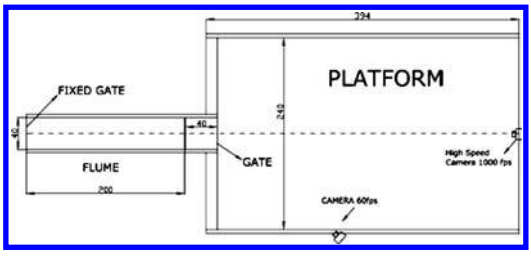

Figure 3. Flume and platform set-up and the positions of cameras, with dimensions in cm.

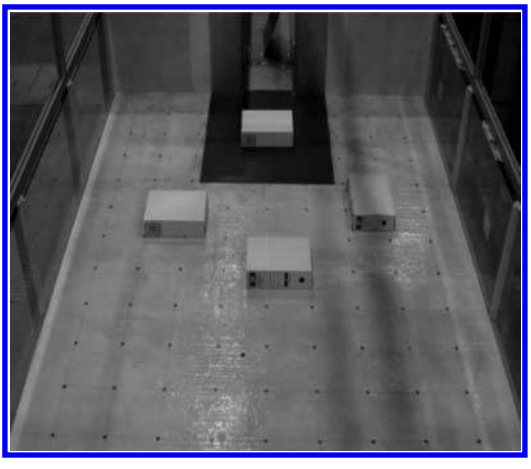

Figure 4. Lasers and general view of the experimental set-up.

Copyright © 2006 Taylor & Francis Group plc, London, UK

each time step. We could not use many lasers because the beams could have overlapped and the numerical process would have failed. A minimum distance was therefore maintained between lasers.

3.2 *Camera position*

The cameras were placed in such a way that the projection of the laser beams in the film did not cross at any time. They needed to be able to perceive water-level fluctuations accurately. In our experiments, the camera angle ranged from 20 to 30°. The camera distance depended on the area being analysed. Neither the distance nor the angle mattered because the camera needed to be calibrated and there were intrinsic values throughout the process.

3.3 *Camera calibration*

Once the aberration had been corrected, the camera needed to be calibrated. As mentioned above, at least six points must be identified in the space of known coordinates and correlated with six points in the photograph in order to determine the M projection matrix. As a calibration object, we used a meshed box located in a known position (Figure 5).

The points in the space used to calibrate the camera were located throughout the volume of study in order to avoid extrapolation problems that would increase the estimation error. We used a set of points taken from different positions of the meshed object in the area of interest.

3.4 *Detection of laser beams*

There are various techniques for finding the pixels that belong to a laser beam in a photo. Depending on the quality of the photograph, the layout of the laser beams, the contrast of the beams, the background of the image and other factors, one technique may be better than another. All techniques require a pre-filtering or post-filtering process. Here we present two different techniques, detection by maximum and morphological image treatment, which we applied to two cameras that observed the same experiment from different positions. Frontal (Basler) and lateral (Lumenera) points of view were used in the subsequent analysis, as shown in Figure 6.

The frontal view had certain advantages over the lateral view. The main advantage lies in the layout of the laser beams in the photograph. It was easy to apply an intuitive technique to detect the maximum of the column of pixels (by colour index), which match up with the laser beams.

The photograph resolution of the Basler camera was higher than that of the Lumenera camera. The area of study occupied the entire frame area and we were

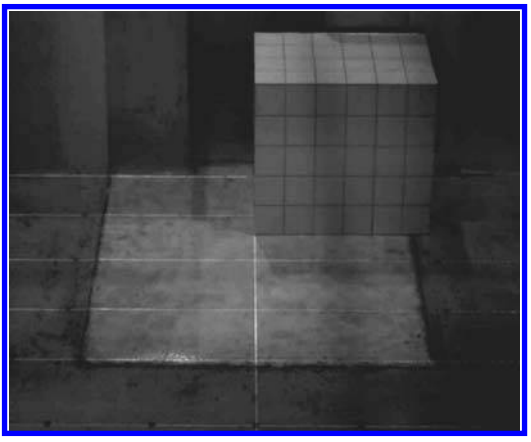

Figure 5. Meshed box used in the calibration procedure.

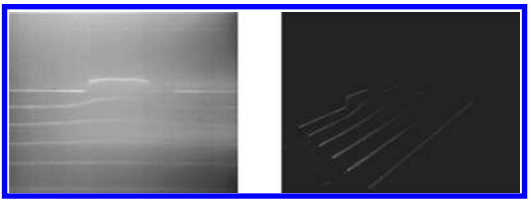

Figure 6. Frontal (left) and lateral (right) views.

able to obtain more information about the process. However, in this specific example, the frontal view presented a difficulty: the image could not describe the high lateral gradients of the flow as well as images from the lateral view did. See Figure 6 to appreciate this problem.

3.5 *Laser-beam detection techniques. Frontal view.*

First, we corrected the photograph by refining it. Because the illumination condition was poor, the Basler took the photographs with an artificial gain that introduced some noise, which appeared as fine vertical highlight lines. Because the analysis is performed by pixel columns, we needed to smooth the image horizontally. The selected filter presents a constant known as lag ($n/2$, where n is the order). Each pixel needed to be moved $n/2$ to the left in order to restore the image. Figure 7 shows the graph of the pixel values of column 500 of the original photograph and the filtered data, which appears very smooth.

Once the image had been filtered, we studied it, for example, by focusing on the pixels of column 460, shown in Figure 8. The maximum intensity (points with a high value) corresponds to the intersection between column 460 and the laser beams. The signal progressively descends from left to right. This implies that the bottom part of the photograph is a

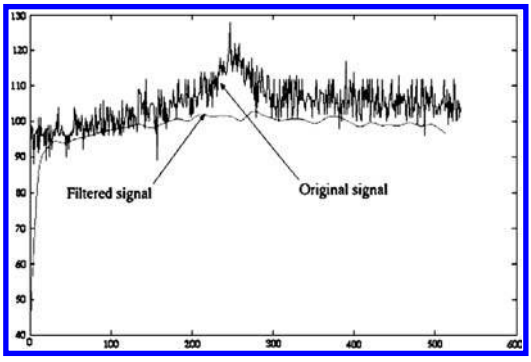

Figure 7. Filtered signal of column 500 of the image matrix.

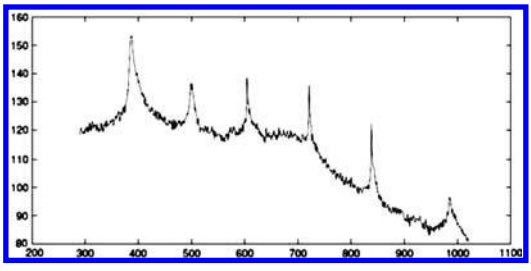

Figure 8. Pixel intensity distribution of column 460. The peaks are the laser beams.

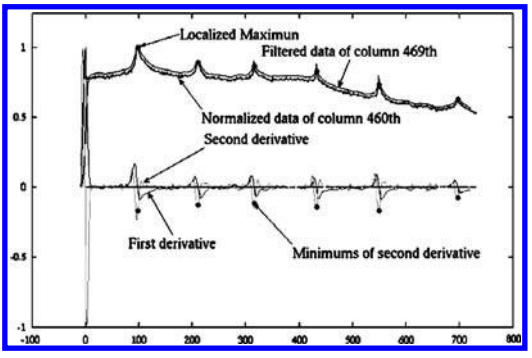

Figure 9. Column 460 filtered, localized and ordered by the lowest second derivative.

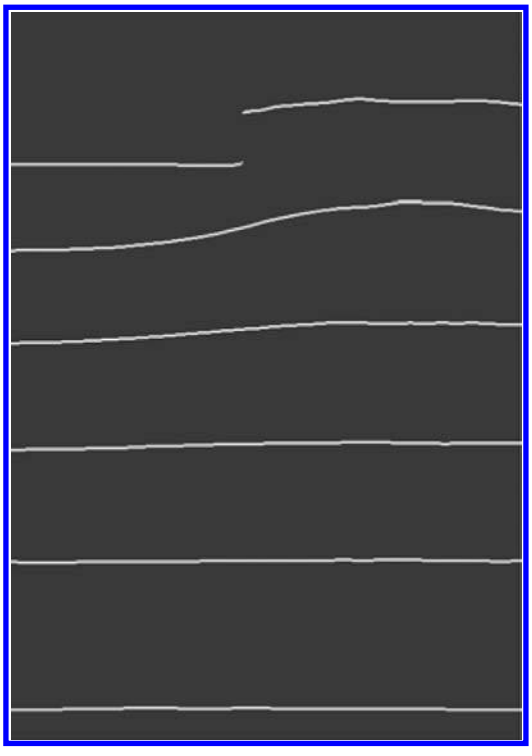

Figure 10. A frontal image taken by the Basler camera that has been treated mathematically.

little darker than the upper part. The six maximum points representing the position of the lasers cannot be obtained because there may be other relative maximums that do not correspond to a laser beam. A more detailed algorithm was applied in order to detect the laser beams. A new FIR filter was also applied to the image in order to smooth the high-frequency noise signal. Figure 9 shows column 460 after being filtered and selected according to the lowest second derivative. Once the column had been filtered, practically the only peaks that remained were those that needed to be determined. A series of different pre-processing steps were carried out on the image before it was in the best condition for the beams and the surface to be surveyed. That is, some pixels not correctly detected in the image needed to be eliminated, some maximums were not real, etc. After this process, Figure 10 was obtained.

3.6 *Laser-beam detection techniques. Lateral view.*

Certain problems appeared in this situation. First, the resolution of the camera was lower (460×640) than that of the Basler, the lens was wide-angle and precision was lost because the density of information in the final image was lower. Second, the laser beams were seen in a tilted view and the detection of the maximum by columns was therefore discarded. A new technique, morphological image treatment, needed to be used in this image view (Serra, 1994).

The first step was to convert the image to a binary image by means of a threshold: 1 was given over a certain pixel threshold value and 0 was given to the rest. The threshold was chosen by reaching a compromise between losing good information and adding extra bad information. This made image treatment difficult, i.e. there were gaps in white areas, overlapping laser

Copyright © 2006 Taylor & Francis Group plc, London, UK

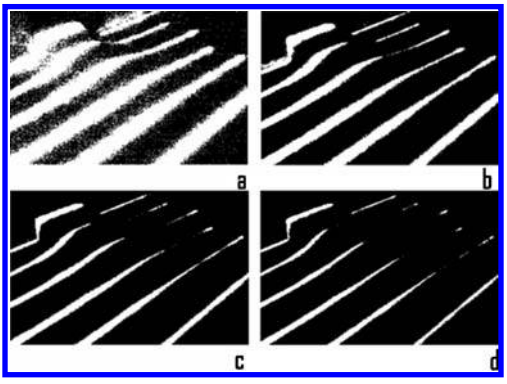

Figure 11. The process of applying different thresholds (a to d) caused a loss of information. The lines appear to be cut.

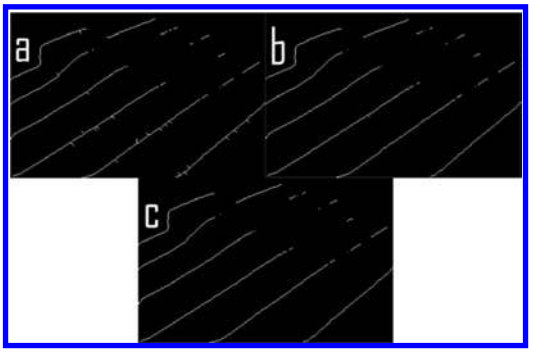

Figure 12. Results for different procedures. Dendrites are attached to the main lines.

beams, etc. Figure 11 shows the results obtained by applying different thresholds in the binary-conversion process.

Once the image had been processed, the skeleton of the image was found. First, however, we made a series of corrections, as in the frontal view. We eliminated some spurious points and groups of points that interfered with the detection of the main laser beams. To do this, we used a MATLAB image function called "*bwmorph*" with options such as "Clean, Fill or Spur". The image was then ready for the skeleton process.

We performed successive "*thinning*", so the lines became thinner and thinner and the border pixels were erased until no change was noticeable. We used MATLAB and the image function with the "*thin inf*" option. Finally, dendrite forms grew indiscriminately from the main laser beams, and we generated a new code to trim the skeleton. Figure 12 shows different skeletons obtained with different procedures.Another procedure that worked well was applying a filter, before applying the threshold, defined by the matrix

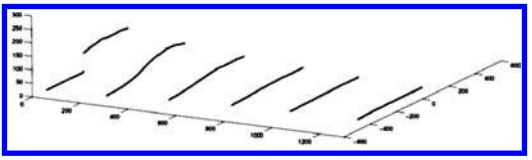

Figure 13. Reconstruction of laser beams from the Lumenera camera.

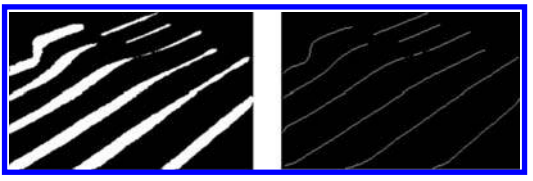

Figure 14. Result obtained by applying the mask given by the matrix of Equation (19).

$$h=\frac{1}{9}\begin{pmatrix}0&0&1&1&1\\0&1&1&1&0\\1&1&1&0&0\end{pmatrix} \tag{19}$$

which simply assigns the mean of the eight neighbours and itself and respects the laser direction. Figure 12 shows that the application of this mean smoothes the line and fills the gaps. The threshold is therefore necessary to obtain the skeleton.

4 RESULTS

We used frontal images taken with the Basler camera (Figure 10). The entire exercise involved 30 fps for 6 seconds.

Calibration: First, a vector x contains the calibration points in $\mathbb{R}^3$ and X represents its correspondents in the photograph. In this example, we added 195 calibration points from three different calibration box positions and some points on the floor in order to obtain the matrix projection

A column vector d was declared to contain the coordinates of the laser planes. The curve i belonging to the plane $x = d(i)$ was obtained.

Laser curve determination: If pixel value matrix A contains the photograph to be treated, the technique of maximum and the filter must be applied to smooth the image and to trim the dendrite forms attached to the main lines. Thus, we obtained a structure that had the proper pixel position and curve order.

Surveying: We then obtained the coordinates in $\mathbb{R}^3$ by applying the inverse transformation M, which converts pixel coordinates into real coordinates. Figure 13 presents the results, which show how the water formed a vertical wall near the exit wall.

Copyright © 2006 Taylor & Francis Group plc, London, UK

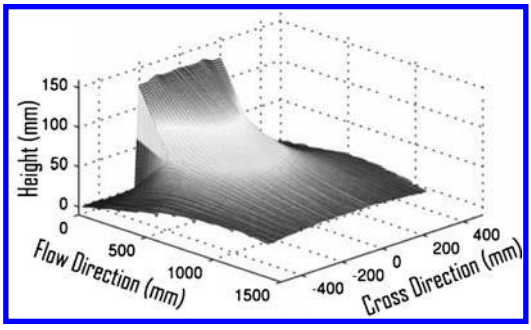

Figure 15. Experimental 3D surface from the Basler camera at 2.45 s.

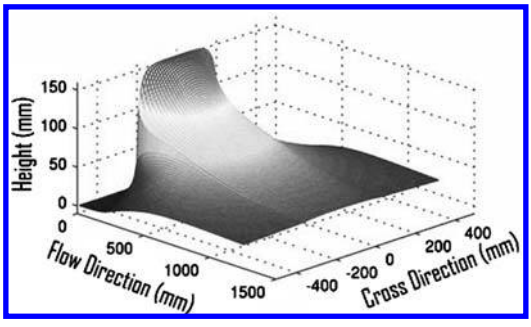

Figure 16. Numerical 3D water surface from FLATMODEL at 2.45 s.

Results from the Basler camera position: Due to the excellent position and high-quality information of the Basler camera, a numerical/experimental comparison is presented here. The mixture of water and milk flowed very quickly across the platform, producing a jet flow that increased in width from 40 to 240 cm. The front of the flow moved very quickly, close to 342 cm/s, which was faster than the theoretical value of 221 cm/s given by the Ritter solution.

Figures 15 and 16 show the experimental and numerical results respectively. The numerical data were taken from FLATModel, which was created by GITS (some aspects are discussed in Medina et al. 2006), and the experimental datea were obtained by interpolating Figure 13. The instant compared is 2.45 seconds after the flow passed the end of the flume. The numerical data has a smoother shape than the experimental data. Also, the flow of water is more vertical in the experimental images than in the numerical results. This is because reality is more complex than the 2D Saint-Venant solution. The vertical zones do not obey the Saint-Venant hypothesis. The shapes and heights appear similar in both representations but are slightly higher in the numerical results. The following comparison between experimental and numerical data refers to fan expansion. Figure 17 shows all data below a

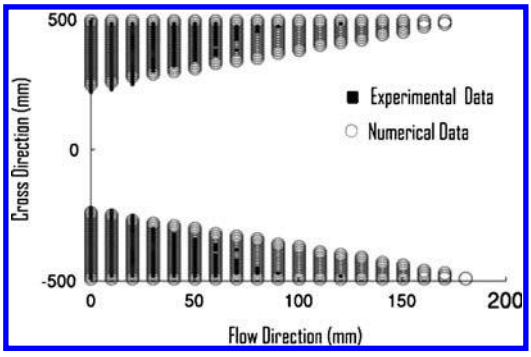

Figure 17. Comparison of the fan in the experimental and numerical data. T = 2450 ms. The data is cut off at a height of 2 mm.

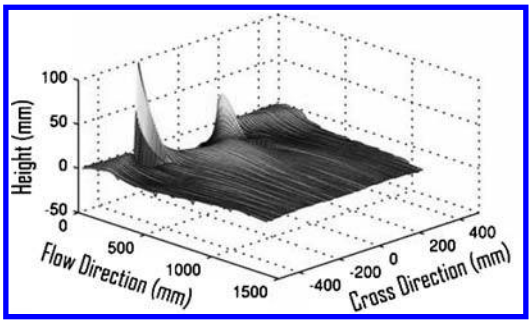

Figure 18. 3D diagram of absolute error. The highest errors are located in the area with high water gradients.

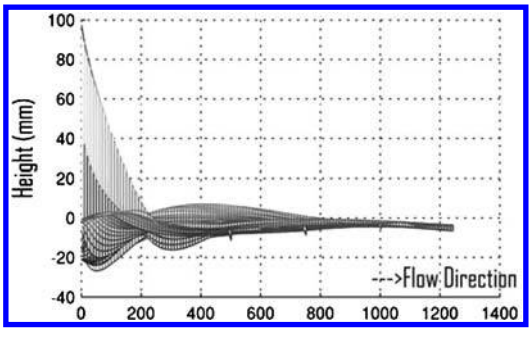

Figure 19. Lateral view of the absolute error surface data.

height of 2 mm. The resulting angles are 36 and 23° for the numerical and experimental data respectively. The experimental fan opens faster than the numerical one.

Figures 18 and 19 show the behaviour of the absolute error, which is calculated as the experimental data minus the numerical data. The numerical and experimental data agree throughout the area of study. The only regions that are very different are those which fail to meet the Saint-Venant conditions. Nevertheless,

Copyright © 2006 Taylor & Francis Group plc, London, UK

the comparison shows that the data that has an absolute error of less than 40% has a mean error of 13.9% throughout the area of study, whereas the data that has an absolute error of 20% has a mean error of 9%.

5 CONCLUSION

This paper presents a procedure that works well in 2D water-surface treatment. The camera must be properly calibrated and geometrical aberrations should be corrected if necessary. The use of Nikon or other high-quality lenses (and other pre-process corrections) clearly makes image processing easier. Milk is essential to obtaining clean, bright laser beams because only opaque liquids work well with laser light. The numerical/experimental comparison shows good agreement. The experimental data shows certain numerical difficulties in the high-gradient zone, where the Saint-Venant hypothesis fails due to the high curvature of the current lines and the non-hydrostatic pressure distribution. The overall absolute error for the surface showed good agreement, with a mean error of around 9% when the threshold is 20%.

A three-dimensional model of flow dynamics around paired deflectors for fish habitat enhancement

D.M. Carré & S.J. Gaskin

P.M. Biron
Concordia University, Montréal, Quebec, Canada

ABSTRACT: Schemes to restore fish habitat in rivers often involve installing instream structures such as current deflectors to create and maintain riffle-pool sequences. To improve the success rate of the many restoration schemes that fail or require costly maintenance, we need to develop tools such as numerical modeling to test scenarios prior to the implementation of structures. The objective of this research is to use a three-dimensional numerical model to characterize flow dynamics and sediment transport around paired deflectors used to enhance fish habitat in a natural river. Calibrating and validating such a model requires accurate measurements of these parameters in the natural river. Particle Image Velocimetry (PIV), typically used in laboratory flumes, was used to obtain detailed velocity measurements at the surface. These data serve to validate the 3D model of the study reach. It is hoped that this model will help maximizing deflector efficiency and success rate for future implementation.

1 INTRODUCTION

In many rivers, human impacts have resulted in a deterioration of the riffle-pool sequences, with serious consequences for fish habitat quality (Thompson, 2002a). A large number of restoration projects have thus focused on fish habitat enhancement, particularly on salmon and trout habitats which are of vital economic importance. Stream deflectors are considered the most successful instream-structure methods for restoring or enhancing low-gradient channels for trout (Hunter, 1991; Thompson, 2002b) and are in widespread use in stream restoration projects for salmonids (Brookes *et al.*, 1996; Roni *et al.* 2002). These in-stream structures constrict the channel section, and by consequence increase flow velocity, causing an increase in bed shear stress which should in theory create or maintain a deep pool downstream (Booker *et al.*, 2001). Many deflectors, however, are installed in rivers on a "trial-and-error" basis (Brookes *et al.*, 1996). Recently, some laboratory studies have shed more light on the complex flow dynamics and resultant bed topography around deflectors (Biron *et al.*, 2004). They compared design of deflectors with different angles, heights and lengths and provide useful design recommendation for paired deflectors.

To improve the success rates of restoration projects, however, tools need to be developed to examine different designs *prior* to the implementation of the structures in rivers. Three-dimensional numerical modelling, which has been successfully used over the last 10 years in many natural river studies (Lane *et al.*, 1999; 2002; Nicholas and Smith, 1999; Ferguson *et al.*, 2003), is well suited for this task as the flow field around deflectors is complex and cannot be properly simulated with a depth-averaged model (Biron *et al.*, 2005). Furthermore, the detailed near-bed velocity flow field is needed in order to predict bedload transport patterns around these structures. These models, however, require detailed spatially distributed datasets of three dimensional flow variables to be validated (Ferguson *et al.*, 2003; Lane *et al.*, 2005). With a few exceptions (e.g. Thompson, 2002b), there is very limited, if any, field data available on flow velocity around deflectors in natural rivers.

The objectives of this study are 1) to use a three-dimensional numerical model to simulate the complex flow field around existing deflectors in the Nicolet River (Québec, Canada), and 2) to compare the model output with detailed velocity measurements obtained with Particle Image Velocimetry (PIV). The ultimate goals of this project are to develop numerical modelling tools for river management and guidelines on optimal location of dug pools when installing flow deflectors in rivers.

2 METHODOLOGY

The Nicolet River, near Victoriaville (Québec, Canada), is located within the Nicolet sub-basin that covers an area of 265 km^2. Founded in 1988, the "Corporation de gestion des rivières des Bois-Francs" (CGRBF), has the task since 1993 to restore the physical habitat of the Nicolet River for sport fishing (Brook, Brown and Rainbow trout), mainly using single and paired deflectors. Field data collected in this study include topography surveying, velocity measurement and bedload sediment movement in a 115 m long reach on the Nicolet River which includes a set of paired boulder deflectors oriented upstream at 135° (Figure 1). This reach is characterized by a highly heterogeneous bed with a median diameter (D50) of 90 mm, and a D84 (where 84% of the particles are finer) of 180 mm. It has a bankfull width of around 35 m, and a discharge varying from about 1 m^3/s at low flow up to 16 m^3/s at bankfull.

Bed, bank topography and water surface were measured at several cross-sections using a total station, with a higher density of points where change was the greatest. The flow stage was monitored with a pressure transducer, and a stage-discharge rating curve was established based on local measurements of velocity using a propeller current meter, and data from an Environment Québec gauging station (# 030103) located around 65 km downstream of the field site.

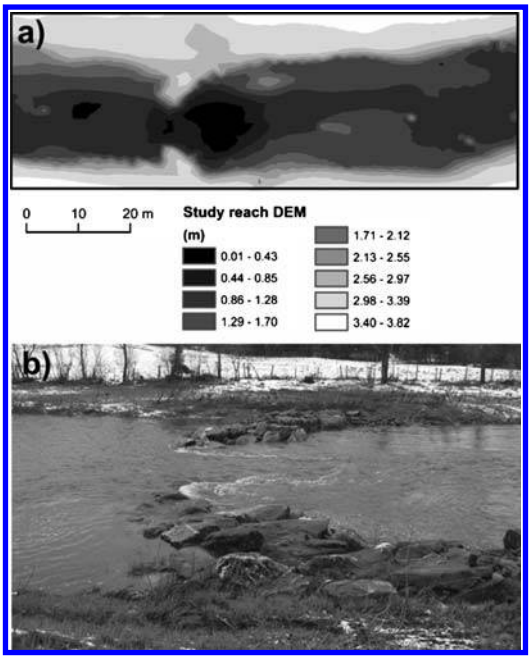

Figure 1. a) Bed topography of the study reach with paired flow deflectors in the Nicolet River. b) Photograph of the black box zone.

Bedload sediment transport movement was assessed using Passive Integrated Transponder (PIT) tags, a method that was recently developed for tracking individual particles in gravel-bed rivers (Lamarre et al. 2005). A total of 110 rocks were collected and sorted into four categories: <64 mm, <90 mm, <125 mm, and <250 mm. They were given three coats of fluorescent orange paint, drilled, and glass tags were implanted and sealed with resin. They were then assigned an ID code in order to follow individual particles using either a Stick Antenna (Texas Instruments), or a Gate Antenna (Texas Instruments), depending on whether rocks were located below the armour layer, or covered with sand and algae. Detailed information on this method is provided in Carré *et al.* (in review).

One of the major difficulties in validating a three-dimensional numerical model is to obtain field velocity data a density comparable to the output of the model. We have therefore decided to use PIV, a method typically used only in laboratory flumes (Grant, 1997; Weitbrecht *et al.*, 2002), but recently adapted to natural rivers (Fujita *et al.*, 1998; Creutin *et al.*, 2003) to obtain a high density of longitudinal and lateral velocity measurements at the water surface. A Panasonic digital camcorder (720 × 480 resolution) was equipped with a polarized lens to avoid reflection. Two docking stations for the camera were built on each bank near the deflectors to raise the camera by 2.5 m. The camera could be adjusted to cover the area around deflectors, in particular in the pool, the riffle, and the recirculation zones. Different methods of flow seeding were tested: foam generation (by mixing water and soap with a powered pump), natural foam, Cheerios™ cereals, and paper confetti. The latter was adopted as it permits a homogeneous tracer distribution, in addition to being inexpensive, easy to use and transport. The seeding density used was between 10 to 30% of the surface flow area (Meselhe *et al.*, 2004).

Mean values for both components of the surface planform velocity were obtained for different video sequences sampled at 30 frames per second. Films were taken from both banks in order to minimise the distortion, as pixel size increases towards the outer bank. The cross-correlation commercial software VIDPIV was used to obtain average longitudinal (Vx) and lateral (Vy) velocities for the centre of the interrogation window, based on 60 second films. Different sizes of interrogation window were tested, and it was found that a window of 32 pixels provided the best results. Further tests were carried out to determine the best sampling interval. It was found that 0.5 s worked well in the recirculation zone where velocities are markedly reduced, but that a faster sampling interval of 0.1 s was more appropriate in the faster zone between

Copyright © 2006 Taylor & Francis Group plc, London, UK

the deflectors in order to avoid "contamination" with the slower moving particles from the recirculation zone. Lastly, masks were used to focus only on one of the recirculation zones, or on the central zone, therefore minimising "contamination" in the area at the edge between the faster flow between the deflectors and the slower flow in the recirculation zones.

One of the problems in using PIV in a natural setting is the distortion created by the angle of the camera, inevitable even if the camera is raised as high as possible on the bank. Here, we have used the method developed by Fujita *et al.*, (1998) and adapted by Bérubé *et al.*, (2004) and Smith *et al.*, (2005) to orthorectify the images based on four control points taken at the water surface with the total station for each video sequence.

Near-surface velocities were also measured with an Acoustic Doppler Velocimeter (ADV) in order to validate the PIV data. The comparison showed good results for the magnitude of the vectors, with a coefficient of correlation of 0.93, with more variation when comparing longitudinal and lateral velocity components separately. This may be related to the difficulties in aligning the ADV exactly in the same reference frame as PIV vectors. A good agreement was also found when comparing our VIDPIV results with those obtained from the algorithm of Bérubé *et al.*, (2004) for the same video sequences (correlation coefficient of 0.91 and 0.90 for Vx and Vy, respectively). The differences were mainly observed at the edge of the recirculation zone, where the lateral gradient of velocity is large and where the size of the interrogation window can markedly affect the results.

The three-dimensional CFD model Phoenics (version 3.6.1, from CHAM) was used to run simulations of the flow field at the Nicolet River. The software uses the finite volume approach to solve the fully three-dimensional form of the Reynolds Averaged Navier-Stokes (RANS) equations in each cell of the modeling domain. The model is described in detail elsewhere (Bradbrook *et al.*, 1998; 2001) and has been used extensively in both laboratory (Bradbrook *et al.*, 2001) and field studies (Ferguson *et al.*, 2003). All simulations were performed using the RNG k-ε turbulence model, previously shown to perform well for simulation of flows in areas affected by high shear (Richardson and Panchang, 1998) such as regions of significant separation and recirculation (Ferguson *et al.*, 2003), as is the case near deflectors. Here, results from a simulation where PIV measurements are available are presented. Discharge was 3.6 m^3/s and the inlet velocity was 0.42 m/s. The water surface representation can be achieved by variable porosity in the surface layer cell (Ouillon and Dartus, 1997; Bradbrook *et al.*, 2001). However, a rigid-lid surface was used here, as tests in a laboratory flume simulation using the same model indicated that activating the porosity algorithm produced no effect on the simulations (Haltigin, 2005)

Designing the numerical mesh is an important and difficult step in a 3D model of a complex river reach. Here, there is the additional complexity of flow deflectors which create a sharp constriction of the flow field (Figure 1). Boundary-fitted coordinates (BFC) are typically used for natural rivers (e.g. Ferguson *et al.*, 2003) to properly represent the changes in bed topography from one cross-section to the next. However, using BFC in this case would have created highly skewed cells around the deflectors, and potentially numerical instability. Instead, following Rodriguez *et al.*, (2004), the detailed bed topography point data, up to a bankfull level, were interpolated to a regular grid of 0.5 × 0.5 m cells using GIS software (ArcGIS 9.1). This grid was then converted into a 3-D solid object using a graphic software (AC3D version 5). Thus, the bed, bank and deflector topography was included into one single object in a Cartesian grid. For near-bed cells that are partially covered by the object, the PARSOL (PARtial SOLid) extension was used in the model, so that the mass continuity equations were modified to reflect that flow is passing through only a fraction of the cells obstructed by the bed, bank or deflector. The key advantages of this method are that 1) different flow conditions can easily be tested using the same object, simply by varying the domain size, 2) the mesh resolution can also be modified easily without changing any other parameter, and 3) the angle between the cells always remain at 90°, thus minimising numerical instabilities.

An alternative method is to use a structured grid with a bed porosity assigned to each cell, based on a detailed DEM (Lane *et al.*, 2004; Hardy *et al.*, 2005). The disadvantage is that a new DEM is required each time the mesh resolution is changed. However, this has been shown to be a very reliable method to accurately represent roughness in a gravel-bed river (Lane *et al.*, 2004; Hardy *et al.*, 2005).Tests are currently under way to compare these two options, as an appropriate representation of the complex bed topography and roughness is critical in these types of simulation (Biron *et al.*, in prep.). Different mesh resolutions were tested here, and it was concluded that a 300 × 75 × 30 m grid (in the X, Y and Z direction, respectively) was sufficient to produce accurate results. However, due to time constraints, it was not possible to run a formal mesh sensitivity test such as the Grid Convergence Index approach (Hardy *et al.*, 2003).

3 RESULTS

Five video sequences (three taken from the right bank, two from the left bank) were used to obtain a dense coverage of two-dimensional velocity measurements

Copyright © 2006 Taylor & Francis Group plc, London, UK

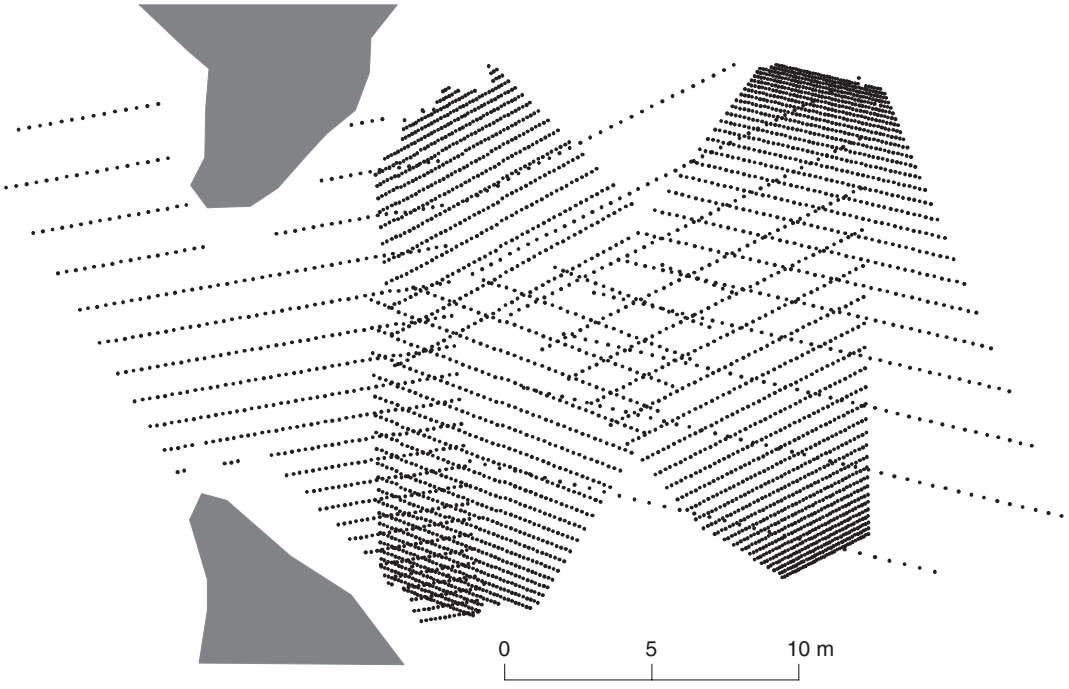

Figure 2. Position of the PIV measurements (black points) obtained from five video sequences (three from the right bank, and two from the left bank). Flow is from left to right, and flow deflectors are shown in grey.

(4310 points in total) near the deflectors (Figure 2). As can be seen on Figure 2, one of the difficulties with PIV taken from the banks is that the pixel size increases from the position of the camera to the outer bank. Hence, the quality of the computed vectors from the cross-correlation analysis decreases with increasing distance from the camera, as the size of the interrogation window increases in real distance (although it is constant in number of pixels). This is particularly problematic where large lateral velocity gradients are present, such as is the case here with two marked circulation zones downstream of the deflectors. In order to compare PIV results with the simulated flow field, we have decided to limit the analysis to the zones where the camera pixel size was sufficiently small to ensure reliable results. Figure 3 shows the velocity vectors obtained from the 3-D simulation, decimated by using one out of four simulated points to improve the readability of the vectors, with the nearest PIV measurements. It can be seen that the overall pattern is consistent, and that the limit of the two recirculation zones is in good agreement between the simulated and observed flow field. This is particularly the case for the recirculation zone near the right bank (looking downstream), but the agreement is less in the left recirculation zone. However, the quantitative agreement (based on all the simulated cells in the zone covered by the PIV) is not as strong as could be expected, with a correlation coefficient for the velocity magnitude of 0.67 between the simulated and PIV vectors. Figure 4 presents the simulated flow field for a larger reach of the Nicolet River, illustrating the marked acceleration between the deflectors, and the markedly reduced velocities both upstream and downstream of the deflectors. The left deflector is slightly longer than the right one, creating an increased deviation on the left side, as well as a larger recirculation zone.

The velocity pattern at the water surface shows a strong deviation of the vectors towards the centre, where the pool is located. This would seem to imply that bed shear stress would be larger in this area. Our observations of bedload transport with PIT tags, however, showed that particles were not moving much in the centre of the channel, but that the bedload movement was occurring on each side of the pool, with more important displacement overall on the left side (looking downstream) (Carré *et al*., in review). When examining the simulation results near the bed (not shown here), a divergence of the flow vectors towards each side of the pool can be seen, which is very different from the pattern observed at the water surface.

4 DISCUSSION

This is to our knowledge the first attempt to use PIV to validate a three-dimensional model of a natural river. The modeled reach is quite complex due to irregular bed topography (with a deep pool) and the presence of two deflectors generating two large recirculation zones. It is therefore not surprising that the quantitative agreement we have observed between the simulated vectors and those obtained from the PIV analysis is not as high as that obtained in other river modeling studies, where velocity measurements were obtained with an ADV (e.g. Ferguson et al., 2003). Furthermore, the points where the agreement between the model and PIV should be best are those located in the relatively simple flow dynamics zone in the centre of the channel. However, these are the points where the error in PIV will always be highest as it is always located at a large distance from the camera. Thus, the more accurate PIV points were located in areas with very high lateral gradients (the two separation zones), which is problematic when trying to validate the simulated flow field. More work is required to assess how different parameters such as the camera angle, the size of the interrogation window, the use of masks, the type of seeding, etc., affect PIV results. Nevertheless, the high density of velocity measurements obtained with PIV makes it an invaluable tool for validating 3-D models in the future.

5 CONCLUSION

Particle Image Velocimetry results were compared to a three-dimensional numerical simulation of the flow field around flow deflectors to enhance fish habitat in the Nicolet River. The PIV method was successfully tested against ADV measurements, and the agreement between PIV and the model was qualitatively good, particularly in terms of the size of the two recirculation zones downstream from the deflectors. These results are encouraging, and indicate that the 3D modelling

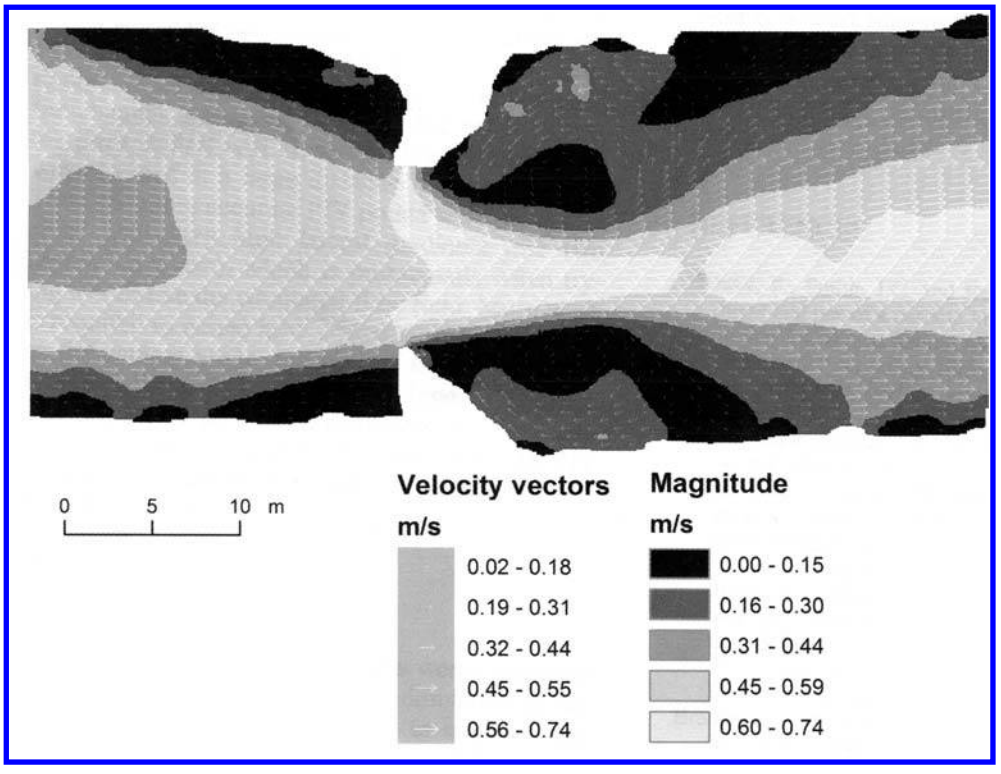

Figure 4. Simulated velocity field at the water surface.

approach to test different river restoration designs prior to their implementation should be pursued. More data at high flow, when water is overtopping deflectors, are required to fully understand the complex flow dynamics around these structures, and the resultant bedload transport. The "object-bed" method used here to design the computational mesh requires less fine-tuning than body-fitted coordinate methods, where problems of skewness or low angles between adjacent cells can be difficult to solve in a complex bed topography problem such as the Nicolet River one. It is therefore faster to test various designs in terms of deflector angle, height and length, and to assess their impact on the flow field and bed shear stress. This will hopefully improve the success rate of future river restoration projects. However, more tests are required to determine whether the object-bed method is adequate to properly represent roughness in gravel-bed rivers with highly heterogeneous bed particles.

ACKNOWLEDGMENTS

This research was funded by NSERC grants (Biron and Gaskin). It has also received the financial support from Project AWARE. We thank Patricia Brelle, Robert Massarelli, Karen Rodrigue-Gervais for field work and PIV analysis assistance. Thanks to the Corporation de Gestion des Rivières des Bois-Francs for permitting us to monitor this field site.

How advances in hydraulic modelling can contribute to solve real problems of flooding: Three examples

A. Paquier
Cemagref, Research Unit Hydrology – Hydraulics, Lyon, France

ABSTRACT: Three cases of flood studies are detailed. The Rivière aux Herbes in Guadeloupe shows an intense sediment transport that increases the water level during flood events. The works along a few hundred metres of the river proved to be dangerous using a 1-D sediment transport model while a simple flow model found lowering of the flood levels. Breaching of the dikes along Ill River is considered in order to define the more risky areas and 2-D modelling is necessary. Along Agly River, a 100-year flood occurred in 1999. This event demonstrated that details representation and model calibration should be improved to simulate more exactly what occurred but modelling met limits because of the lack of observations during the flood. Then, it appears that, by more relevant modelling, the uncertainty of the results could be evaluated and included in the communication process to the users of the potentially flooded areas.

1 INTRODUCTION

For assessing flooding risks, it is necessary to model rare floods that reach areas with specific high stakes. In hilly areas, sediment transport rate can be very high and change the water levels. The use of a model taking into account such a transport is illustrated on the case study of the Rivière aux Herbes (Weeds River). In flat areas when events inundate wide flood plains, 2-D modelling is often required (Paquier & Farissier, 1996). In the Ill flood plain as well as for the Agly River, the dikes and their casual breaching are the main concerns that should be taken into account in flood risk plans. The two cases mainly differ from the recent history: along Agly river, a huge flood occurred in 1999 while such an event has not occurred in the last 100 years along Ill river. The study of these three cases and the applied models are detailed hereafter.

2 FLOODING AND SEDIMENT TRANSPORT ALONG THE RIVIÈRE AUX HERBES

2.1 *Features of the case study*

The Rivière aux Herbes is a torrent of the Island of Guadeloupe in the West Indies. The average slope of the river is more than 5% for most of its length. Along the downstream kilometre, the riverbed has been narrowed because the river crosses the town of Basse Terre. Because of three bridges and a slope reduced to about 1%, flooding is feared along the downstream 200 meters inside the centre of the town.

Figure 1. The works (concrete section) of the Rivière aux Herbes in the town of Basse Terre.

In 1997, calculations showed that the design discharge of 180 m^3/s (corresponding to a 100-year peak flood) could not flow without overtopping of the banks at the second bridge site. In 2001, some works were performed, in particular, the construction of a concrete bed in a 100 m reach (Fig. 1). Sediment transport was not taken into account and the huge amount of boulders deposited in the bed after the first flood (November 2004) clearly showed that a risk of flooding still exists (Fig. 2). To illustrate the effect of these works on the peak water levels during a 100-year flood, it was decided to perform calculations with a model simulating the sediment transport and the change of riverbed during the flood (Paquier, 2005).

Figure 2. The Rivière aux Herbes crossing the town of Basse Terre after the flood event of November 2005.

2.2 *Description of the sediment transport model*

RubarBE is a 1-D model that has been developed by the Hydrology and Hydraulics Research Unit of Cemagref. The model has two components: a component to simulate the flow and a component to characterise the changes in river morphology due to erosion or deposition of sediment. The water routing component relies on De Saint Venant equations for water, solved by a second order Godunov-type explicit scheme (Paquier, 1995). The sediment routing component has the following major features:

1. computation of sediment transport capacity using a suitable *bed load* formula ((Meyer-Peter & Müller, 1948)'s equation in the present study),
2. computation of the actual sediment transport rate Q_s by introducing a space lag equation (the sediment transport capacity and the actual transport rate may differ if geometry is not uniform),
3. numerical solution of the continuity equation for sediment (Exner equation).

At each time step, sediment routing and changes in channel profile are calculated by a finite difference method, coupled with the water surface profile computations (El Kadi & Paquier, 2004).

RubarBE represents sediments by the mean diameter D_{50} and the standard deviation σ. The standard deviation is assessed as the square root of the ratio between d_{84} and d_{16} ($\sqrt{d_{84}/d_{16}}$). It was selected as it appears convenient to describe grain size distribution in a river for which sediments are homogeneous (Shih & Komar, 1990).

The boundary shear distribution τ_j in a cross-section can be calculated by two different methods: either from the uniform equation using water volumetric density ρ, gravity acceleration g, hydraulic radius R and energy slope J ($\tau_j = \rho g R J$, R is computed on the base of the total area and perimeter of the flow) or from the Merged Perpendicular Method (MPM). The first method assumes that the boundary shear stress is constant around the wetted perimeter. The second one is a geometrical method that assumes that the energy gradient is the same in all the sub areas. More precisely, it shares the wetted area in small sub areas using the lines perpendicular to the bottom following a complex procedure described in (Khodashenas & Paquier, 1999). The boundary critical shear distribution τ_{cj} in a cross-section can be calculated in two ways: either from the (Ikeda, 1982) relation that introduced the effect of the local side slope or kept constant as on a horizontal bottom. The mass of sediment eroded or deposited in one cross-section obtained by the computation is distributed along the section. RubarBE incorporates various empirical relationships between deformation and shear stress. In the case of erosion, the deformation ΔZ_j is assumed to be proportional to $(\tau_j - \tau_{cj})^{1.5}$. In the case of sedimentation, deposited sediment in one cross-section can be distributed in four different ways. The selection of the method should usually be based on field observations and on calibration by comparison to field topographic measurements. In the present case study, the deposition was simply set in horizontal layers.

2.3 *Results of the calculations*

In the calculation, the 100-year discharge hydrograph used was a triangular hydrograph that lasts one hour and rises from 1 to 180 m^3/s in half an hour. According to the various sediments covering the bed of the river, the mean diameter of the surface layer ranged from 1 cm (downstream) to 1 m (upstream).

Figure 3 shows that, during such a flood, the deposition or erosion can reach more than one metre and that the works that narrowed part of the river are rather increasing these depths (distance 1920 to 2070). This was in agreement with the observations for a lower flood (Fig. 2). Due to thicker deposits, the calculated water level after the works is higher (Fig. 4). The blockage of boulders there prevents deposits further downstream resulting in lower bed levels after the flood (Fig. 3) and lower peak water levels during the flood (Fig. 4). More precise calibration of the model is necessary to validate these results. However from now, the change in the location of overflows above the banks between the situations with and without works and between the calculations with or without sediment transport means that additional risk has been created by the works and that the calculation with fixed bed cannot provide a relevant estimate of peak water levels.

3 DIKE BREACHING ALONG ILL RIVER

3.1 *Description of case study*

The Ill River, a tributary of Rhine River, crosses the Alsace plain between dikes the crests of which are

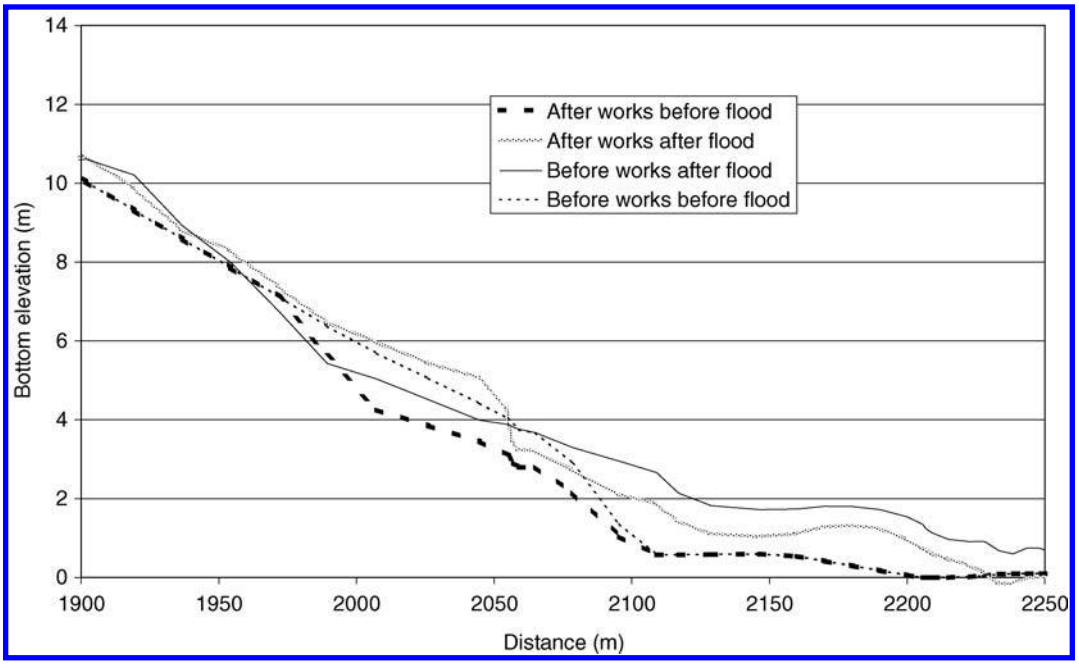

Figure 3. Bottom longitudinal profiles.

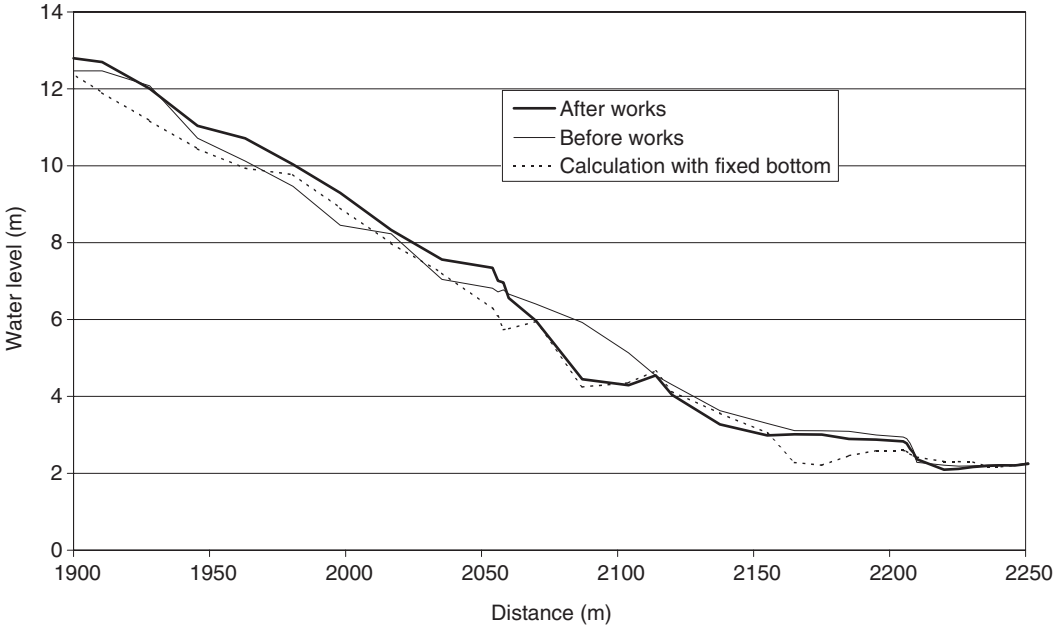

Figure 4. Peak water levels for a 100-year flood.

generally 1 to 2 metres above the mean ground level of the plain. Preparing the plan for flood risks mitigation (PPRI), a hydraulic study using 1-D model concluded that that the dikes are generally high enough for a 100-year flood; the possibility of flowing some discharge in the lower areas and some additional cultivated areas is enough to ensure that the dikes are not overtopped at the location of main villages and towns.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 5. The dikes of Ill River protecting the studied area seen from the river.

The main remaining risk is thus the breaching of these dikes (Fig. 5) because of piping or bank slip.

A first calculation with the hypotheses of instantaneous breaching and 1-D propagation downstream in a direction perpendicular to the dike concluded that there was a high risk in several villages. Thus, it was necessary to perform more detailed hydraulic calculations taking into account the progressive erosion of the embankment and the propagation in all the directions downstream. These two factors could result in less pessimistic results.

A sample calculation was performed in one village, Horbourg-Wihr near the town of Colmar, in order to evaluate the situation there. The model selected was RUBAR 20 that simulates 2-D flow upstream and downstream from the breach and includes the calculation of the breaching process.

3.2 *Description of the model RUBAR 20*

The finite volume scheme used is explicit and second-order accurate. It solves 2-D shallow water equations written as:

$$\frac{\partial h}{\partial t}+\frac{\partial (uh)}{\partial x}+\frac{\partial (vh)}{\partial y}=0 \qquad (1)$$

$$\frac{\partial (hu)}{\partial t}+\frac{\partial (hu^2)}{\partial x}+\frac{\partial (huv)}{\partial y}+gh\frac{\partial h}{\partial x}=\ldots$$
$$\ldots -gh\frac{\partial Z}{\partial x}-g\frac{u\sqrt{u^2+v^2}}{K_s^2 h^{l/3}} \qquad (2)$$

$$\frac{\partial (hv)}{\partial t}+\frac{\partial (huv)}{\partial x}+\frac{\partial (hv^2)}{\partial y}+gh\frac{\partial h}{\partial y}=\ldots$$
$$\ldots -gh\frac{\partial Z}{\partial y}-g\frac{v\sqrt{u^2+v^2}}{K_s^2 h^{l/3}} \qquad (3)$$

in which u and v are velocities along respectively x and y axis, h water depth, Z bottom level, g acceleration due to gravity, K_s Manning Strickler coefficient.

The mesh consists of quadrilaterals or triangles having 0 or 1 (full) common edge. The mixing of these 2 kinds of cells provides various possibilities to adapt to any detail of topography.

The scheme includes 4 steps:

1. computing slope of each one of the 3 variables h (or z water level), hu and hv in every cell on x and y axis by the method of the least squares and applying limitations of slopes.
2. computing values of $W=(h,hu,hv)$ at intermediate state $t_{n+1/2}$ in the middle of the edge m_{ij} of cell i

$$W_{m_{ij}^L}^{n+1/2}=W_{m_{ij}^L}^{n}-0.5\Delta t\ldots$$
$$\ldots\left[f_1'\left(W_i^n\right)W_{xi}^n+f_2'\left(W_i^n\right)W_{yi}^n\right]+0.5\Delta t\,S_i^n \qquad (4)$$

in which f_1 (respectively f_2) are the fluxes on x (respectively y) axis, S the second member, W_{xi}^n the slope of W along x-axis, index L (respectively R) means left (respectively right) side of the edge.

3. solving a 1-D Riemann problems in the direction normal to the edge (equation (5) similar to equations $(1)+(2)+(3)$ on x-axis as these last equations do not vary through a rotation) at $t_{n+1/2}$ in order to estimate the fluxes through edges for the conservative part of the equations. It is possible to use a Roe type linearization which directly gives an estimate of the fluxes

$$\begin{cases}\dfrac{\partial W}{\partial t}+\dfrac{\partial}{\partial x}\left(f_1(W)\right)=0\\ W\left(x,t_{n+1/2}\right)=W_{m_{ij}L}^{n+1/2} & \text{if } x<0\\ W\left(x,t_{n+1/2}\right)=W_{m_{ij}R}^{n+1/2} & \text{if } x>0\end{cases} \qquad (5)$$

4. integrating second member on the surface of the cell in order to add the corresponding contribution and obtaining final value of the 3-D variable W_i^{n+1} by adding second member $S_i^{n+1/2}$ at intermediate time:

$$W_i^{n+1}=W_i^n+\sum_j\frac{\varepsilon_{ij}l_{ij}}{A_i}\Delta t\,f_1\left(W_{m_{ij}}^{n+1/2}\right)+S_i^{n+1/2}\Delta t \qquad (6)$$

in which f_1 represents flux along x axis, summing on j cells which have a common edge with cell M_i (of area A_i) and ε_{ij} equals 1 or -1 according the orientation of edge m_{ij} (length l_{ij}) common to the cells M_i and M_j.

The contribution of the second member includes gravity or slope terms ($-gh\frac{\partial Z}{\partial x}$ or $-gh\frac{\partial Z}{\partial y}$) that are treated as fluxes in such a way as an horizontal water surface remains strictly horizontal, bed friction terms that are more simply assessed at the centre of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

cell. Their computation uses an implicitation in time (Paquier, 1995) in order to avoid numerical instabilities when a rapid change in water depth or velocity occurs.

Dry cells are specifically treated. A cell is considered as dry as long as the water volume entering a cell during one time step provides a water depth below a minimal value (0.1 mm generally). The drying process is the only source of error for the mass conservation; an error more than 0.01% of the total mass generally means instability during computation.

RUBAR 20 may be extended by integration of hydraulic structures where discharge is directly linked with water levels upstream and downstream. One of these structures can represent progressive erosion of an embankment by piping (Paquier et al., 1998). For calculation of flow in this structure, the main hypothesis is that the hydraulic characteristics of water are not modified by the high concentrations of sediment, even during the beginning of the erosion process. During a first step, water starts flowing through a circular pipe and erodes the walls of the pipe so that its diameter is increasing with time. In a second step, when the diameter of the pipe reaches 2/3 of the dam height, the vault of the pipe is assumed to fail; then, water flows in a rectangular channel the width of which is increasing due to erosion of its walls. The embankment is supposed to be of trapezoidal shape and of homogeneous material. Flow characteristics within the pipe are computed from Bernoulli equation with a head loss at the entrance and a linear head loss in the pipe, the sum of which is equalled to the head between the upstream and downstream sides of the embankment.

The initial conditions consist of a small pipe diameter so that the discharge is very low: it may be the median diameter of the material or a little more till 10 cm. The diameter of the pipe increases due to erosion. The volume of material V eroded at each time step Δt is computed from the sediment discharge Qs by $V = Qs * \Delta t$. The sediment discharge is computed from the hydraulic variables by the Meyer Peter Müller's formula. The volume eroded is distributed uniformly over the cross-section, so that the pipe remains circular. The only parameters of the sediment that are taken into account are the density, the diameter and the porosity.

Main result of the computation of the structure is the discharge hydrograph that flows through the breach but the size of the breach can be used as a calibration parameter.

3.3 *Results of the calculations*

The 2-D model (28 226 cells) was applied to 6 kilometres of the river with upstream and downstream boundary conditions defined from 1-D model results. The model was calibrated to obtain, for the 100-year flood calculation without breach, the same levels and flooded areas as the 1-D calculation. Breaches in four different places were successively modelled and, in the central location, three water elevations were supposed in order to estimate the influence of the dike height (Paquier et al., 2005). Several hypothesis on the dike material were also studied because there was uncertainty about the real behaviour of the dike material face to such a 100- year flood; the last extreme flood occurred in the 19th century and the more recent ones that breached the dikes occurred before the dikes were reinforced.

It appears that for a given water depth near the dike, the peak discharge (about 60 m^3/s for the 100- year flood) was mainly related to the final breach width that was set to about 40 metres. In fact, the flood lasts several days and, after the breach formation period, a steady discharge flows through the breach. However, it appears that, with similar discharge, the risk downstream from the breach is very different for different breach locations and depends mainly on local topography that can create local high velocities or local high water depths. However, it appears clearly that the 1-D hypothesis is too pessimistic for water depths and that the instantaneous failure hypothesis creates too high velocities that are not found if the erosion is more progressive.

For practical purpose, the "risky" areas are defined by the values of peak water depth h and peak water velocity v on the basis: $h > 1$ m or $v > 1$ m/s or ($h > 0.5$ m and $v > 0.5$ m/s). The maximum distance from the breach was in the range 60 to 350 metres (example of result with the central breach and instantaneous breaching on figure 6) depending on the case and if a continuous area is considered or not. This rather high range means that the extension of this result to other breach locations and to other villages will be very difficult, which implies that such a detailed calculation should be performed if vulnerability is high in the areas protected by the dikes. If the water elevation in the river is reduced by one metre (the water elevation near the dike goes below one metre), the risky area is limited to the breach area.

4 THE 100-YEAR FLOOD ALONG AGLY RIVER

4.1 *Hydrological context*

The high flood that occurred in the southern part of France near the Spanish Border in November 1999 was one of the highest of the 20th century in the lower reach of Agly River. On November 12 and 13, 1999, the studied area received rainfalls of between 200 and 400 mm within about one day.

The specific configuration of the process in which the higher catchments received less water than the middle and lower catchments, generated relatively

Copyright © 2006 Taylor & Francis Group plc, London, UK

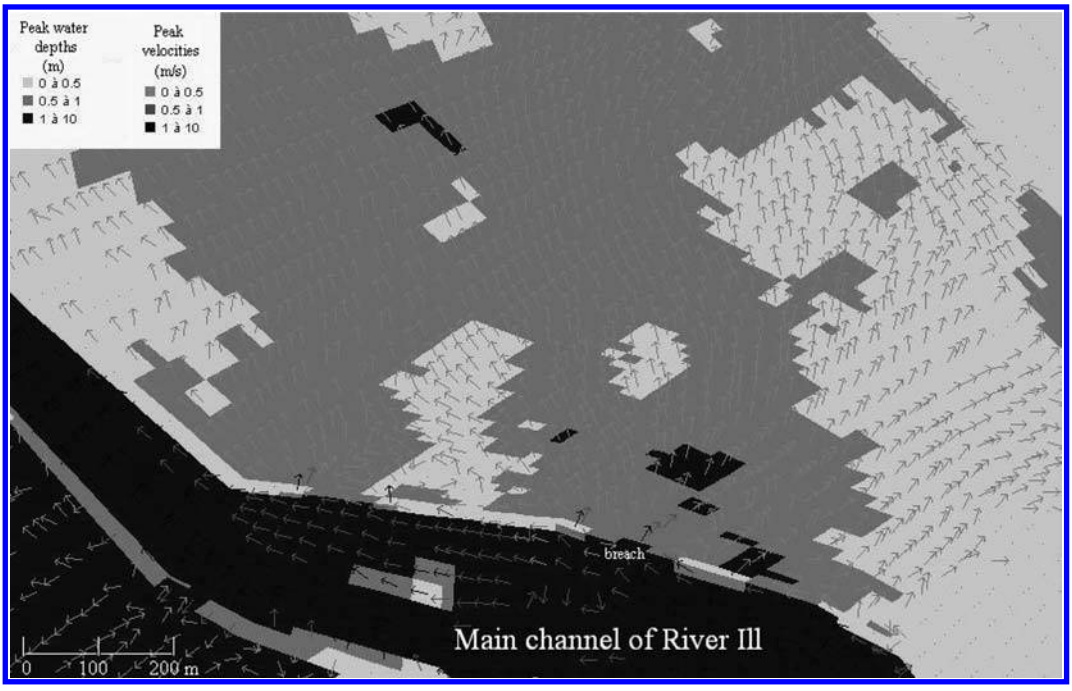

Figure 6. Ill River at Horbourg-Whir – Flooded area downstream the breach for the case of central breaching and instantaneous failure (with peak velocities represented by arrows).

common floods (peak discharge of 180 m^3/s) on the higher catchment of Agly river, which is controlled by a dam, whereas, in Rivesaltes, the main city of this plain, the peak discharge reached about 2000 m^3/s. This discharge was higher than the conveyance of the main channel between the dikes in the lower reach. The dikes and the channel widening carried out in the 1970's were designed for a discharge of 1250 m^3/s and may accommodate a discharge of about 1500 m^3/s without free board.

In November 1999, several overflows occurred along the dikes. These overflows were the cause of the flooding of large areas but only with a few centimetres of water. However, one of these overflows was the origin of a breach that suddenly released a two metre high wave that destroyed a sewage plant in Saint Laurent de la Salanque. This breach, which lowered the water levels in the downstream reach of the main channel, avoided other breaches by reducing or stopping the overflows.

4.2 *Steps of the study*

In 1996, a 2-D model was built in order to simulate the 100-year flood that was supposed to inundate the coastal plain in very limited extent. After completion of the building of a dam in the early 1990's and of dikes along the 13 kilometres downstream reach, the aim was to define the areas that may be considered as safe enough for extension of villages or of commercial areas. The study (BRL Ingénierie et al., 1996) considered the areas directly flooded by the overflows but also those flooded after a breaching of the dikes at some location. From the results of these calculations, some rules were established concerning building in the coastal plain in order not to increase potential damages in the case of a 100-year flood. However, it should be noted that, due to the change in land use (particularly, since 1940), only recent floods may be used for model calibration; thus, only the higher one, the 1992 flood that only inundated a small area, was selected for that purpose.

Immediately after the 1999 flood, the Authorities gathered observations concerning the event and particularly the highest water levels reached during the flood. Topographical campaigns surveyed 43 cross sections of the main channel and the longitudinal profiles of the dikes. In parallel, some urgent works were performed to repair the damage to the dikes (breach and places where either foot erosion or overtopping occurred).

A complementary study (BRL Ingénierie et al., 2001) was carried out in order to get a diagnosis of the state of the dikes and define the short term and long-term works necessary to increase their safety. The definition of some of these works required precise modelling of their effects relative to present situation.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Thus, it appeared necessary to make available a numerical model that would be calibrated from the 1999 flood. This flood was much closer to the 100-year flood (peak discharge: 2295 m^3/s) than the 1992 flood used for calibration of the 1996 model (peak discharge about 1200 m^3/s). To obtain the detailed calibration required, the 1996 model's 2-D grid was refined in order to better represent the main channel of Agly river as well as some places in the right bank near the town of Rivesaltes that was flooded in 1999. The number of cells increased from 8848 to 18568, which means that it was necessary to calibrate the model again.

4.3 *Calibration on the 1999 flood*

Although there was heavy rain over the area, a first simplification was to introduce only one discharge hydrograph at the upstream end of the Agly main channel. This hydrograph was determined from the measurements of water levels at the hydrometric station of Rivesaltes, situated near the RN9 bridge, and their extrapolations after the failure of the device. The peak discharge was estimated at 2000 m^3/s after calibration (comparison with 2-D model results) with a secondary peak at 1900 m^3/s. A sensitivity analysis showed that taking into account the rainfall does not change the general conclusions although it could imply a peak water depth a few centimetres higher in some locations.

Selected Manning coefficients varied from 0.0125 in the river at the crossing of the town of Rivesaltes to 0.14 in the old villages. The Manning values in the flood plain generally do not influence the results too much because of the influence of the embankments and ditches that cross the flood plain. However, it should be stressed that one of the difficulties of the model calibration is the choice of the Manning coefficient values in the Agly main channel because neither the flow discharge between the dikes nor the topography of the main channel during the flood were very certain: no flow measurement occurred at the time of the peak flow and, at the end of the flood, deposits occurred, which reduced the cross section. Thus it was necessary to use lower Manning coefficients to take into account the reduction of cross section between the peak flow and the topographic survey a few weeks after the flood. For some specific areas, other parameters should have been calibrated. Locally, to model some overflows, it was necessary to correct the interpolation of the crest level of the dikes. The sea water level and the Manning coefficient of the outlet to the sea have been modified to obtain the observed water level in the Agly reach downstream of the last bridge: it appeared that a local rise of the sea level, a strong wind or the deposition of sediment significantly raised the water levels there.

More upstream, in Saint Laurent, the modelling of the breach in the dike supposed a very rapid opening (corresponding to the related 2 metres high wave) with the full cross section of the breach as measured (about 40 m wide and 3 m high) and a relatively low Manning coefficient (0.02). The peak discharge through the breach was estimated to be 170 m^3/s; other modelling by a hydraulic structure, either a weir (from the time of the failure) or a specific structure modelling a progressive breaching, provided very similar results.

4.4 *Conclusions on calibration and planning*

It can be stressed that, after such a calibration, the mean difference between observed and calculated maximum water levels in the flood plain was about 10 cm. This difference originates mainly from the Saint Laurent area. The standard deviation was about 40 cm, which seems nearly the minimum possible value if one takes into account the uncertainty in the flood marks and in the topography of the flood plain. The flooded areas are shown on figure 7. To be consistent with observed flooded areas, the limits should be 0 or 20 centimetres water depths depending of the location. Such result is linked with the drainage system status or with local protection structures and no general explanation can be found. After calibration, the water levels remain low in Saint Laurent and slightly too high in Rivesaltes.

In this latter town, a few people discussed because model provided higher water levels than observed in 1999. Although the difference (about 30 cm) remains relatively low and agreed with the general precision of the model, some additional action was necessary. The uncertainty of the model was illustrated by casual events such as blocking of water evacuation structures by trees. However, as financial interests were concerned, simple explanations are not enough. Fortunately, as 100-year flood discharges are slightly higher than the 1999 flood, results of the calculation for the 100-year flood were kept for planning purposes. Moreover, as the model represents quite well the propagation processes, it was pointed out that the main requirement to improve the adequacy of the model was to incorporate additional data such as observations during next flood events.

5 CONCLUSIONS

For the simulation of a flood extending over a large flood plain or coming from a breach or a hydraulic structure in a dike, it is necessary to use 2-D shallow water equations completed by relations such as those of hydraulic structures (weirs, gates…). Such a tool is efficient to represent the main processes met during such events. However, during calibration, it is very difficult to represent all the details of a real event (Agly case). This implies that events selected for planning should be typical events (for instance, of a selected

Copyright © 2006 Taylor & Francis Group plc, London, UK

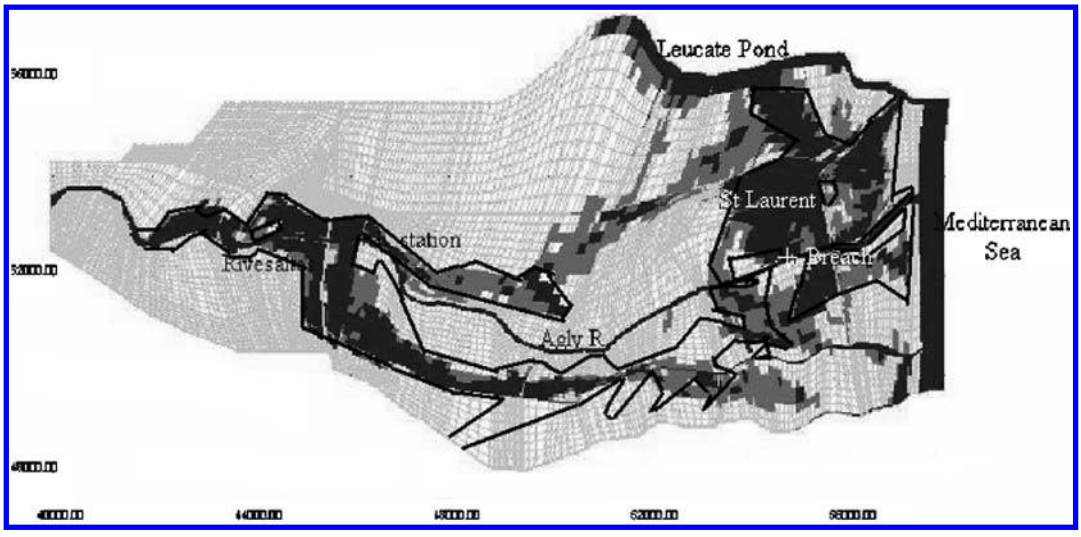

Figure 7. Lower Agly flood plain – Comparison of calculated flooded area (darker area means water depth more than 20 cm) with the limit estimated from observations (black line).

return period for all the durations) and not real ones to avoid discussions on the planning decisions.

When no similar event exists (Ill case), the use of such a 2-D model that reduces the uncertainty linked with the representation of the processes, could ensure that the level of mitigation measures is not too high.

In the context of high sediment discharge during the flood (case of Rivière aux Herbes but, also in a smaller extent, case of Agly river), it is necessary to use a sediment transport model that can take into account the change in bed elevation during the flood. For the Rivière aux Herbes, it is shown that sediment transport can imply a change in the location of the flooded areas and, sometimes, a rise in peak water level, which means an increase of the flood risk.

The calculations cannot provide precise results as often no calibration data are available neither for sediment transport nor for extreme flooding but they can contribute to assess the uncertainty of modelling and thus contribute to the awareness of the concerned people.

ABSTRACT: Solute transfer from soil surface to runoff is a complex process where soil characteristics,solute chemical kinetics and surface flow conditions interact. Up until now, it has rarely been included as a boundary condition in open channel flow models. The objective of this study is the characterization of this transfer process in shallow water flows. To this purpose, a series of experiments were carried out in a laboratory flume, 9 m long with a 0.002 slope, over a loam texture soil, where a tracer was located transversally over the surface of an area 0.05 m long, under different inlet flow conditions. The results show the temporal evolution of the tracer transfer to the surface flow, together with the parameterization of the load function obtained and its relation with flow characteristics.

1 INTRODUCTION

Solute transfer from soil surface to runoff constitutes a potential source of pollutants for surface waters and, indirectly, for groundwater as well. This is a complex process where the soil parameters and initial conditions that determine infiltration and runoff generation evolution, and the solute chemical kinetics interact with the surface flow characteristics, especially those related to advective and diffusive-dispersive transport (Ahuja 1990).

Moreover, the nonlinearity exhibited by solute transport in such conditions makes it necessary to obtain a good definition of solute transfer from soil as a boundary condition when modeling surface water flow quality, for both punctual and distributed sources of substances. This fact, which is important in Mediterranean basins, is a widespread phenomenon during the summer period when salt excess, nutrients or pollutants are concentrated in the upper layer of the soil due to the extreme atmospheric evaporative conditions, and where intermittent shallow flows frequently occur after summer storms. Furrow irrigation of crops is another good example.

Two approaches have been proposed to describe this process, depending on the predominant transport process considered: the first approach assumes the existence of a dead water layer in the soil-surface water interface, from which solute transfer to runoff takes place by molecular diffusion (Wallach et al. 1988), whereas the second approach defines a narrow surface layer of soil, called the mixing zone, where rainfall/irrigation water and the soil solution instantaneously mix (Zhang et al. 1997), and it is considered the only source for solute transfer to runoff.

Most previous work so far (Ahuja 1990) has been based upon the second theory, and has focused on solute transfer when runoff generation results from precipitation events, since there is little or no data available nor experimental studies of shallow flows, such as furrow irrigation, or intermittent summer flows in semiarid environments.

This research thus provides a first characterization of solute transfer from soil to runoff for the latter

Copyright © 2006 Taylor & Francis Group plc, London, UK

conditions, where the saturation of the soil top layer (ponding condition) almost instantaneously occurs. This differs from rainfall occurrence, where a ponding condition usually lags behind the initiation of rainfall, enhancing solute transport downwards through the soil profile to groundwater. The following sections describe the experimental work and data analyses carried out. The resultant load function is to be integrated as a boundary condition in a 1D numerical model of surface water-solute flow over a porous bed for application in furrow irrigation.

2 MATERIALS AND METHODS

2.1 *Experimental design and measurements*

In order to establish the effects of surface water flow characteristics on soil solute transfer potential, a set of laboratory assays was carried out in a 9 m long flume channel with a uniform rectangular 0.5 m wide cross section, and a uniform 0.002 longitudinal bed slope, where the top layer of a cropland soil was reproduced. Runoff was generated by the application of a constant water flow rate Q_0 at the flume head during each experimental performance, ranging from 0.54 to 4.72 L s^{-1} between assays, with no water column at any point of the flume as initial conditions (dry condition).

The soil filling consisted of a layer of 2 mm sieved soil, 30 cm deep, from an alluvial bank of the Guadalquivir River Valley in Córdoba (Southern Spain), where previous experimental work on fertigation had been carried out by the authors (Nofuentes et al. 2004). This soil filling was sampled from the three upper sublayers of soil, corresponding to 0–5, 5–18, and 18–30 cm deep divisions, and it was orderly packed in the flume to a bulk density value similar to the original field conditions. The soil layer was placed over a 10 cm deep filtering gravel bank, which had previously proven sufficient to ensure free draining conditions at the bottom of the flume bed.

The soil was classified as a *Typic xerofluvent* (Soil Survey Staff 1999), or *Eutric fluvisol* (FAO 1988), with a loam textural class, low organic matter content (1%), and significant calcic carbonate presence (20%).

A concentrated 5 cm long and 1 cm deep cross fringe of highly soluble non-reactive tracer (KBr) was located at a 4 m distance from the flume head to avoid border effects from the water source point. The tracer fringe was prepared after previous mixing of the upper soil sublayer with an excess quantity of tracer (calculated for each Q_0 interval and run duration from preliminary work) to ensure that the transfer process was not limited by the initial tracer concentration in the soil. Table 1 shows Q_0 values, applied KBr mass, and the initial water content of soil for each run performed.

The evolution of the KBr concentration in the runoff along the channel was estimated from EC measurements made with portable conductivity meters throughout each run at three different stations located at a distance of 3 cm upstream from the fringe, and 3 and 200 cm downstream from the fringe, known as stations 1, 2, and 3, respectively. Previously calibrated KBr-EC curves obtained from laboratory determination in standard solutions were used for the calculation of KBr concentrations. Stations 2 and 3 monitored solute transfer to runoff and loss along the channel by infiltration, along with dispersion effects, respectively, whereas station 1 was used to check the possible solute dispersion upstream of the source.

Advancing time and water depth evolution were measured at nine cross sections along the channel, which included the previously mentioned solute monitoring stations. The outflow at the end of the channel was gauged by volumetric measurements.

Figure 1 shows a schematic description of the experimental design and Figure 2 the experimental flume channel and a fringe detail.

Table 1. Head constant water flow rate applied (Q_0), initial tracer mass in the fringe (M_o), and initial soil water content (θ) for each experimental run.

Run	Q_0 (Ls^{-1})	M_o (kg)	θ ($kgkg^{-1}$)
1	0.54	0.372	0.076
2	1.00	0.672	0.140
3	2.50	0.372	0.150
4	3.22	0.372	0.155
5	4.72	0.372	0.180

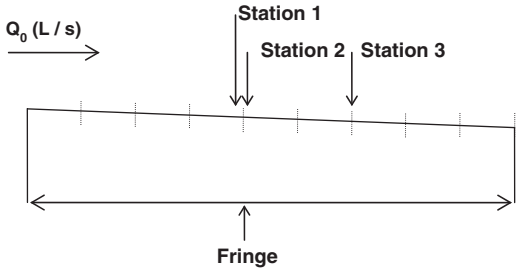

Figure 1. Schematic description of the experimental device along the flume channel. ……Depth and advancing time measuring section locations.

2.2 *Water flow modeling*

Instantaneous water flow rate values and section-averaged velocity were calculated along the channel from a 1-D numerical model following the MacCormack method (Burguette 2003, Maikaka 2004), applied to the cross integrated Saint Venant equations

for mass and momentum conservation in surface flow (Equations 1 and 2, respectively),

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}+\frac{\partial Z}{\partial t}=0 \tag{1}$$

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q^2}{A}+gI_1\right)= =gI_2+gA\left(S_0-S_f\right)+D_i \tag{2}$$

where, at a time t and a distance x from the water source, A is the cross sectional area; Q is the instantaneous volumetric water flow rate; Z is the accumulated infiltration volume per unit length; I_1 and I_2 represent the unit hydrostatic pressure force and unitary pressure force due to longitudinal width gradient, respectively; S_0 and S_f are the bed and friction slopes, respectively; g is the acceleration of gravity; and D_i the momentum transfer associated with seepage outflow in the direction of the flow (Playán et al. 1997).

These equations were developed in a one-dimensional approach, using the Manning equation to calculate the friction slope.

The temporal evolution of Z can be estimated from the Kostiakov – Lewis equation, commonly used for water irrigation infiltration modeling (e.g. Walker 1989),

$$Z=k\cdot t_{opp}^{a}+f_0\cdot t_{opp} \tag{3}$$

where t_{opp} is the opportunity time at a distance x from the water source ($t_{opp}=t-t_{ad}$, t_{ad} is the time the water front arrives at a point x, the advancing time); k and a are empirical parameters (see Table 2 for dimensions); and f_0 stands for the stationary value that the unit length infiltration rate tends to reach, provided sufficient time has elapsed.

Table 2. Kostiakov-Lewis equation parameter and Manning coefficient (n) calibration for each run.

Run	f_0 ($m^3m^{-1}s^{-1}$)	k (m^2s^{-a})	a	n (SI units)
1	$0.045\cdot10^{-4}$	0.0025	0.050	0.031
2	$0.131\cdot10^{-4}$	0.0180	0.018	0.020
3	$0.240\cdot10^{-4}$	0.0048	0.050	0.019
4	$0.062\cdot10^{-4}$	0.0075	0.052	0.019
5	$0.072\cdot10^{-4}$	0.0030	0.002	0.020

Table 2 shows the calibrated values for Equation 3 parameters and the Manning coefficient for each run, from the water flow measurements, assuming homogeneous soil behavior.

2.3 *Solute transfer from soil to runoff modeling*

An exponential load function, $W(\zeta)$, is proposed in this study to describe punctual solute transfer from soil to runoff (Chapra 1997),

$$W(\zeta)=W_0\cdot e^{\beta\zeta} \tag{4}$$

where W_0 [MT^{-1}], is the solute mass load at the initial time of the transfer process; $\beta[T^{-1}]$ is a transfer coefficient; and ζ is the time interval elapsed since the beginning of the transfer process. In this study ζ equals the opportunity time, t_{opp}, since solute transfer is initiated once the water front meets the fringe location (i.e. at the advancing time).

Experimental $W(\zeta)$ curves were obtained for each run from the calculated KBr concentration values from station 2 EC measurements, and the instantaneous water flow rate values from the numerical model for $x=4$ m, adjusting W_0 and β values by lineal regression. Dispersion effects at station 2 during the transfer process were regarded as negligible and thus not considered in our calculations.

2.4 *Longitudinal dispersion coefficient*

Non-reactive substance transport in longitudinal systems, such as streams or channels, can be described by the cross section integrated one-dimensional form of the advection-diffusion equation (e.g. Rutherford 1994), which can be written as Equation 5 for non-uniform flows,

$$\frac{\partial(AC)}{\partial t}+\frac{\partial(AvC)}{\partial x}=\frac{\partial}{\partial x}\left(AE\frac{\partial C}{\partial x}\right) \tag{5}$$

where C and v are the averaged values of solute concentration and velocity at a cross-section, for the time

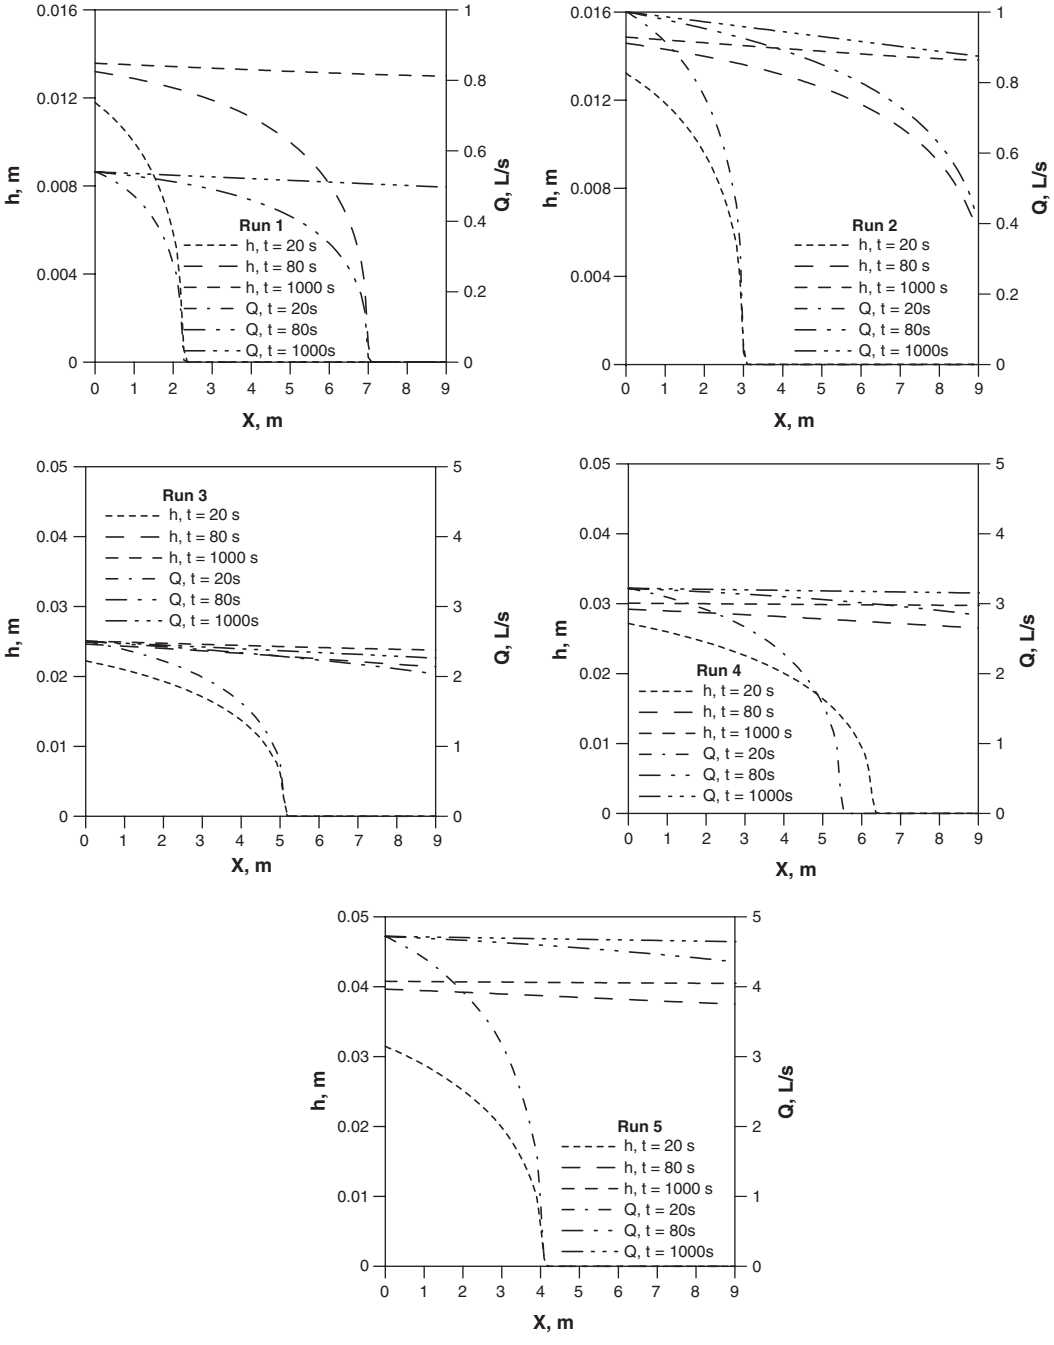

Figure 3. *Q* and *h* evolution along the channel for runs 1 to 5, respectively; x is measured from the water source point at the head of the channel; the tracer fringe is located at x = 4 m (station 2 in fig. 1).

Copyright © 2006 Taylor & Francis Group plc, London, UK

t, and E is the longitudinal dispersion coefficient, which accounts for vertical and cross velocity gradient contribution to the dispersion term.

The relative importance of the advection and dispersion term in Equation 5 can be tested by comparison of the Peclet number along the channel.

To that purpose, the stationary velocity value at the head cross section and the distance between the fringe location and the end of the channel were taken as characteristic velocity and length, respectively (v_0 and L, in Equation 6 after the non-dimensioning of Equation 5.

$$Pe = \frac{v_0 L}{E} \tag{6}$$

The local values of the longitudinal dispersion coefficient were estimated from the expression developed by Fischer et al. (1979) for logarithmic vertical velocity profiles in natural streams,

$$E = 0.011 \frac{v^2 b^2}{h u_*} \tag{7}$$

where b is the channel width, h is the cross section-averaged water depth, and u_* is the shear velocity. All of these variables are expressed in SI units. The shear velocity is given by

$$u_* = \left(\frac{\tau}{\rho}\right)^{1/2} \cong \sqrt{ghS_0} \tag{8}$$

where τ is the shear stress over the channel bed approximated by:

$$\tau = \rho g S_0 h \tag{9}$$

ρ is the water density, and h, the water depth at the section.

3 RESULTS AND DISCUSSION

Q and h evolution along the channel calculated by the numerical model described in section 2.2 for each run performed can be seen in Figure 3. The experimental water depths and advancing time measurements made during each run were used to calibrate the model (see Table 2 for Manning coefficient values).

From the results, it can be seen how soil surface saturation is promptly achieved, with a transient period very close to 20 minutes in all runs.

Figure 4 shows v evolution at station 2, where the tracer fringe was located, along with the Froude and Reynolds numbers.

The temporal evolution of KBr concentration at the three monitoring stations is shown in Figure 5 for each run, versus the opportunity time (t_{ad} = advancing time at station 2 for runs 1 to 5, respectively).

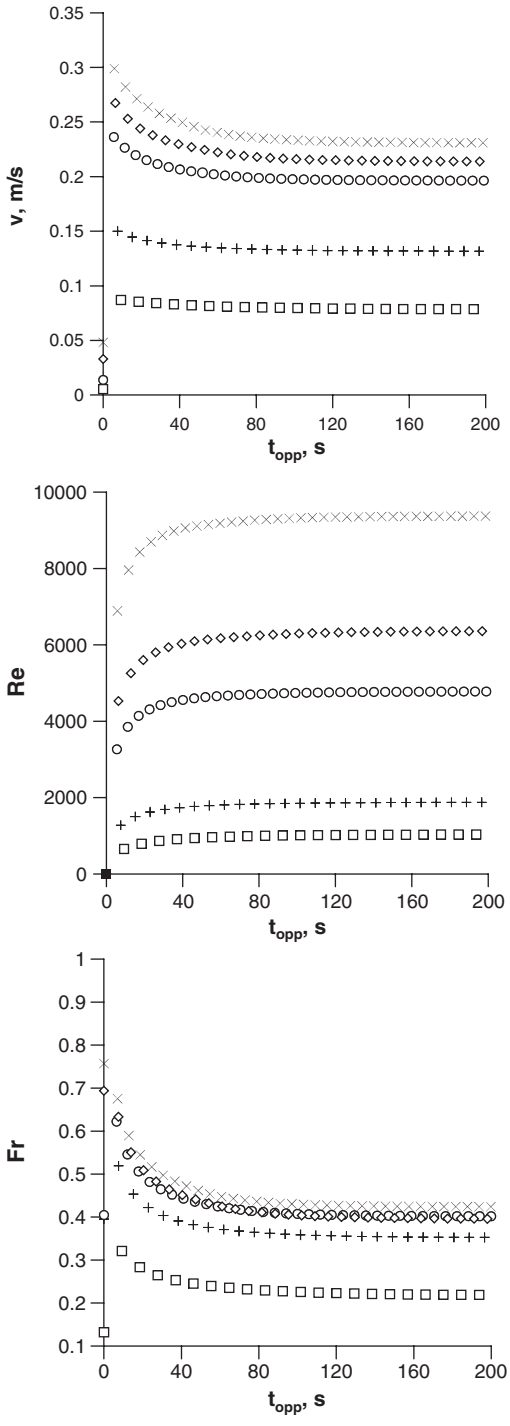

Figure 4. *v, Re*, and *Fr* temporal evolution at station 2 for each run performed; □ run 1, + run 2, ○ run 3, ◇ run 4, × run 5; t_{opp} is opportunity time at station 2.

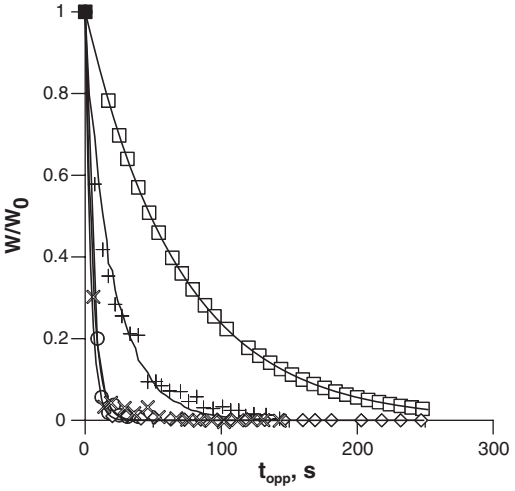

Figure 6. Observed and calculated non-dimensional $W(t_{opp})$ curves at station 2 for each run; □ run 1, + run 2, ○ run 3, ◇ run 4, × run 5; t_{opp} is opportunity time at station 2.

Table 3. W_0, β adjusted values in Equation 4 for each run, and solute mass recovery, at station 2.

Run	W_0 (kg s^{-1})	β(s^{-1})	R^2	$T_{0.99}$(s)	M(kg)
1	$0.077 \cdot 10^{-3}$	0.014	0.95	200	$5.1 \cdot 10^{-3}$
2	$0.123 \cdot 10^{-3}$	0.045	0.98	68	$2.6 \cdot 10^{-3}$
3	$1.237 \cdot 10^{-3}$	0.185	0.95	40	$6.7 \cdot 10^{-3}$
4	$11.56 \cdot 10^{-3}$	0.186	0.94	22	$61.1 \cdot 10^{-3}$
5	$13.58 \cdot 10^{-3}$	0.246	0.99	20	$54.8 \cdot 10^{-3}$

Higher concentrations were reached at station 2 over the fringe. As expected, non-detectable concentrations were found at station 1 in all cases. This result validates the hypothesis of negligible dispersion effects upstream of the solute source for these experimental conditions.

Concentration values are lower at station 3 not only because of the dispersion effects along the reach, but also because of the simultaneous advance of water and solute, as the initial concentrated flow was infiltrated immediately downstream of the fringe position. This effect decreases with time as stationary conditions are approached. The non-dimensional form of the load function points, calculated at station 2 as described in section 2.3, are presented in Figure 6 for each run, along with their respective adjusted curves W/W_0 after Equation 4.

Table 3 shows the calibrated parameter values obtained, and the corresponding correlation coefficient, with the total solute mass transferred to runoff, M, and the response time for a 99% solute mass recovery, $T_{0.99}$.

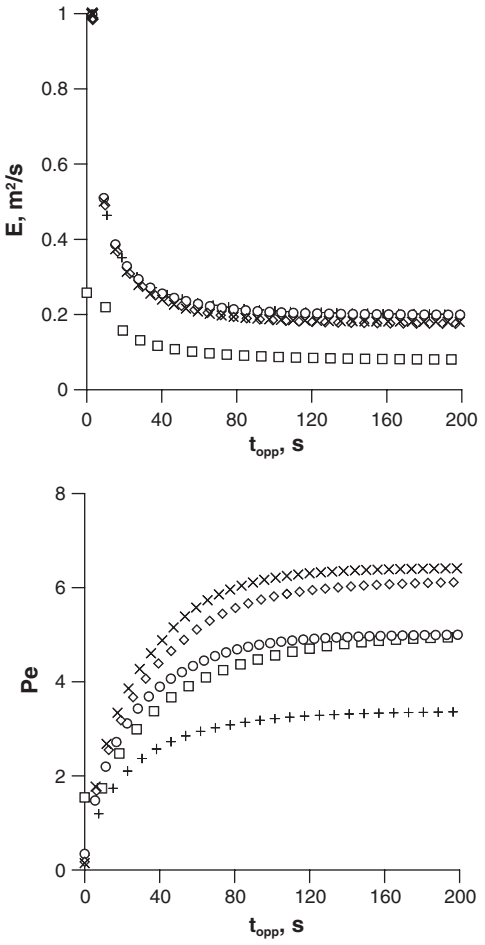

Figure 7. E and Pe evolution at station 2 for each run; □ run 1, + run 2, ○ run 3, ◇ run 4, × run 5; t_{opp} is opportunity time at station 2.

From Table 3 values, it can be seen that both W_0 and β grow with increasing flow rates. In other words, for higher Q values solute transfer rate is initially higher too, but it evolves more quickly, fading in a shorter period. Similar trends were reported by Wallach & Van Genuchten (1990), and Zhang et al. (1997), though with different mass recovery results due to runoff generation from rainfall occurrence dynamics.

Accordingly, the total solute mass transferred from soil to runoff, M, was increased for higher flow rate values, whereas the response time, $T_{0.99}$, decreased.

Finally, the temporal evolution of E and Pe in station 2 for each run, calculated after Equations 7 and 6, respectively, are presented in Figure 7. During each run, the highest E values were found at the transient period for water flow, decreasing with time, with the corresponding inverse trend for Pe. For stationary flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

conditions, runs 2 to 5 can be grouped separately from run 1. The reason can be found in Figure 4, where a different Reynolds regime applies for each group, with marked turbulence in runs 3 to 5, and very low Froude values for run 1. However, differences between E values between groups tend to decrease as stationary conditions are approached, whereas it is the contrary for Pe values.

4 CONCLUSIONS

Solute transfer from soil to runoff from a cross concentrated narrow fringe during transient flow advance conditions can be adequately described by an exponential load function, as shown in this research. The equation parameters W_0 and β have been quantified for different flow conditions, under a non-limited solute supply from soil, showing an intensification and shortening of the transfer process with growing water flow rates. In general, for the flow conditions experimented the process is very quick, with marked dispersive predominance during the transient period, whereas the stationary conditions exhibit a predominantly advective character. This behavior is not expected in slower flows with higher infiltration rates and/or wider sections.

The comparison between trends showed by E and Pe values at the source location underlines the relevance of taking into account the temporal aspects of the solute transfer to water flow when characterizing dispersion in surface waters: application time and duration of solute entry to flows.

The results of this work are being included in a 1-D numerical model for transient flow conditions, with application in fertigation modeling.

ACKNOWLEDGEMENTS

This work was funded by the National Plan of Research and Development of the Spanish Ministery of Education and Science, in the project AGL 03-01958 *Agrochemical and sediment transport in furrow irrigation*. The authors wish to thank the University of Castilla-La Mancha, Spain, for the use of the Hydraulics Laboratory of the Technical School of Civil Engineering for the experimental work. M.J. Polo would like to thank Gloria Gómez for her valuable help.

Loose-bed models for river structure design: Two example studies on river Po

M. Guerrero & A. Lamberti
DISTART Idraulica, University of Bologna, Italy

ABSTRACT: Objects of the study are the predictable effects on river Po local bed morphology of two structures of national interest: the new railway bridge between Revere and Ostiglia, and the entrance of the new Pontelagoscuro navigation lock. Aiming to adequately represent alluvial bed forms and local scour and deposition effects of the structures, two movable-bed physical models were constructed: one for the bridge in planimetric scale 1:150, vertical 1:120, and one in undistorted scale 1:100 for the lock entrance. The inner harbor physical model results were compared with bi-dimensional hydro-morphological numeric simulations carried out with the mathematical model Mike21C. Physical and numerical models provided results in good agreement and useful for the design of the inner harbor, the first physical model suggested a variant in the designed construction programme and confirmed the construction process and design of bridge piers, including the type and dimension of bed protections.

1 INTRODUCTION

Aiming to adequately represent the alluvial bed forms and local scour-deposition effects of two national projects on river Po, two movable-bed physical models were constructed: one for the railway bridge between Revere and Ostiglia (Bologna-Verona railway), and one for lock entrance of the inner harbor of Pontelagoscuro near Ferrara.

The first physical model had suggested a variant in the designed construction programme and confirmed the construction process and design of bridge piers, including the type and dimension of bed protections.

The inner harbor physical model results were useful in choosing the best lock entrance configuration in order to minimize sand deposition, and were compared with bi-dimensional hydro-morphological numeric simulations carried out with the mathematical model Mike21C by DHI Water and Environment (Danish Hydraulic Institute 1999).

2 PHYSICAL MODEL FOR THE REVERE OSTIGLIA NEW RAILWAY BRIDGE

The river reach between Risvolta di Ostiglia and Isola Boschina, 2100 meters long was modeled (Fig. 1). As can be seen in Figure 1 this branch will be crossed by the new Bologna-Verona railway bridge and is crossed by the existent railway bridge.

A movable-bed model was realized with a planimetric scale of 1:150 and with a vertical one of

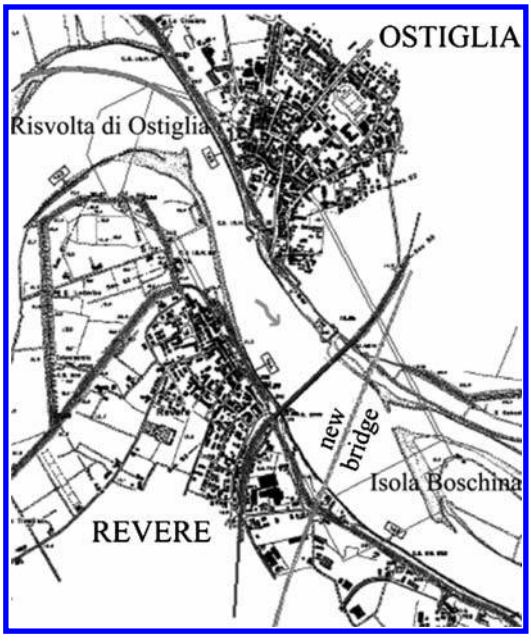

Figure 1. Modeled Po branch for railway bridge.

1:120, the little distortion aided in modeling river bed forms and roughness (Adami 1994, Hughes 1993). The model was realized mirrored compared to prototype because of the conformation of the existent laboratory model tank, and being the Corioli forces negligible in

Copyright © 2006 Taylor & Francis Group plc, London, UK

prototype and in the model. In Figure 1 can be seen contour of model tank mirrored and sketched over the modeled area.

Three prototype flow conditions were simulated: 2200 m^3/s is a medium water condition, 7600 m^3/s is a very unlikely flood during bridge construction period, it's occurrence probability during construction time is 1/200, 13500 m^3/s is the project condition for the new bridge, which has the occurrence probability of 1/200 or a time frequency of 1 year each 200.

2.1 *Principles of similitude and scale effects*

Two kinds of test were carried out; first sediment transport and bed forms process were simulated with a morphological criteria, then on the same model with the adjusted bed forms, surface waves were simulated using Froude velocity scale.

The mean diameter of prototype sand is 0.3×10^{-3} m, which would be scaled to clay by the geometric vertical scale. Fine sand, mean diameter 0.07×10^{-3} m, was used in the model instead of clay, in order to avoid the arising of unrealistic cohesive forces. Not perfectly scaled mean diameter introduces in the model a different densimetric Froude number (Hughes 1993):

$$F_* = \frac{\rho \cdot v_*^2}{\gamma_s \cdot D} \qquad (1)$$

where ρ and γ_s are water density and specific weight of grains in water respectively, which are the same in model and prototype, instead v_* and D, shear velocity and mean grains diameter respectively, are scaled in the model.

Densimetric Froude number is the ratio of shear bed stress to grains weight, and can be seen as a bed-load parameter defining bed form geometric characteristics and formation process (Yalin & Ferreira da Silva 2001). Model flows were increased respect to values scaled with velocity Froude criteria, in order to balance model densimetric Froude number, reduced by not respecting geometric scale for sediment diameter. Consequently Froud velocity scale was increased up to bed sediment transport and bed formation were similar to prototype, but assuring that Froude number model was less than 0.5 as in prototype and the surface waves not affecting sand bottom (Richards 1982). The morphological scale adopted for velocity was 1:5 instead of 1:11 Froude velocity scale. In that way was possible to simulate the prototype bed formation attitude: bed forms height decreasing while flow increasing to yield flat bed at high stages (Yalin & Ferreira da Silva 2001).

Suspended load concentrations measured in the model were compared to prototype data, in order to scale flows duration and decide simulation time length (Hughes 1993).

Figure 2. Detail of configuration C before tests, where pier and pit protections and provisional groin are visible.

Figure 3. Detail of configuration B before tests, where the old bridge is visible upstream the new bridge in construction.

Bed roughness, and suspended load rate, were proportionally greater in the model than in prototype, due to the impossibility to respect perfectly and at the same time: densimetric Froude number, grain size Reynolds number, vertical length to diameter ratio parameter and relative fall speed parameter (Adami 1994, Hughes 1993). These effects must be considered when simulation results are analyzed.

2.2 *Tested configurations*

Four configurations were tested, following the bridge construction program from the start, bridge absent, up to the final whole realization.

The configurations were: A, river in the actual configuration with the existent bridge and without the new bridge; B, first critical construction phase with the provisional groin for the construction of piers near Ostiglia river side realized up to pier 7 and the contemporaneous construction of pier 4, 6 and 7 inside their provisional pits; C, second critical construction phase with the provisional groin resized up to pier 8 and the contemporaneous construction of pier 3, 5 and 8 inside their provisional pits; D, final configuration with the whole bridge realized and without provisional structures. Construction configurations B and C were tested only with flows scaled from 2200 and 7600 m^3/s prototype values, the second being the value with the same occurrence probability during construction time of 13500 m^3/s, the project condition for the new bridge. The other configurations were tested with all three chosen prototype flows, scaled with morphological and Froude criteria.

Copyright © 2006 Taylor & Francis Group plc, London, UK

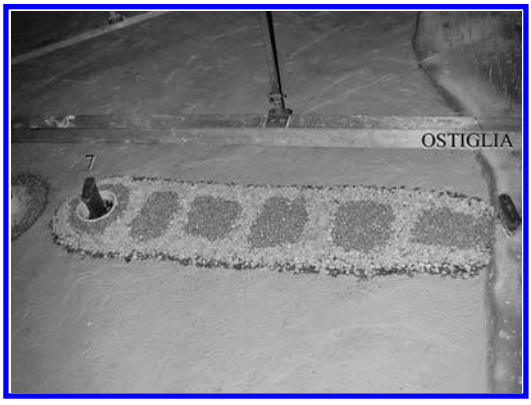

Figure 4. Detail of configuration B before tests, where provisional groin is visible at its maximal extension.

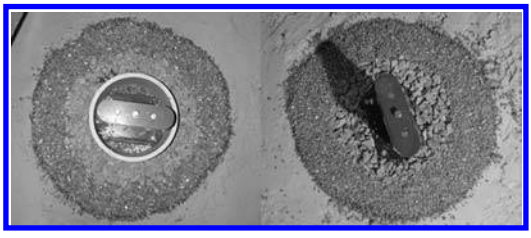

Figure 5. Details of provisional pits and of the final pier protection before tests.

Figures from 2 to 5 show some model details, where pier and pit protections and the provisional groin are visible. These structures were realized with natural granular material scaled with the morphological criteria from the prototype design, assuring the same mobility parameter in the model and in prototype.

At the end of each morphological test, when the equilibrium of the bed was achieved, a short time test was carried out in order to reproduce realistic surface waves with flow scaled with velocity Froude criteria.

2.3 *Simulation results*

The carried out tests gave some evidences about the fluvial processes of the modeled reach, due to bridge realization.

In particular the interesting aspect for the new bridge are: the embankment erosions on the bridge section, bed erosions near pier foundations, the erosions near provisional structures for bridge realization (i.e. pits and groin).

2.3.1 *Embankment erosions*

On the Revere side water flows in contact with the embankment. An important erosion was surveyed on the model at Revere embankment after tests carried out

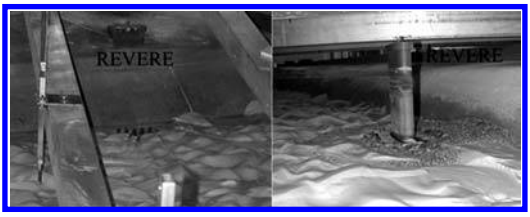

Figure 6. Pier 3: emerging foundation pails (configuration A), and stabilizing effect of pier protection (configuration D).

Figure 7. Pier 6 after tests (configuration D).

on the A configuration (bridge absent). The erosion was maximal for the lowest flow (2200 m^3/s in prototype) when water flows mainly on the Revere side, velocity field was more uniform along all river section for test carried out with greater flows.

The erosion on Revere side for the other three configurations was limited by bed protection of the pear 3 near Revere embankment, which made locally steady river bed. Figure 6 show the river bank erosion after tests carried out on the configuration A e D with the most erosive flow.

During physical simulations Ostiglia embankment was never eroded, in fact it is placed in a river deposition zone and water touches it only during extreme flood (13500 m^3/s in prototype).

2.3.2 *Bridge piers*

River bed protections around piers were steady for all simulated flows, only a little erosion on the protection of central pier number 6 was seen after test carried out on the final configuration with the greatest flow (13500 m^3/s in prototype).

For this reason an heavier protection was suggested with a mean diameter in prototype of $0.6 \div 0.8$ m, instead of the designed $0.3 \div 0.4$ m which was scaled in the model. Also a foundation of pier 6 four meters deeper in prototype would be useful in order to avoid bed protection erosion.

Copyright © 2006 Taylor & Francis Group plc, London, UK

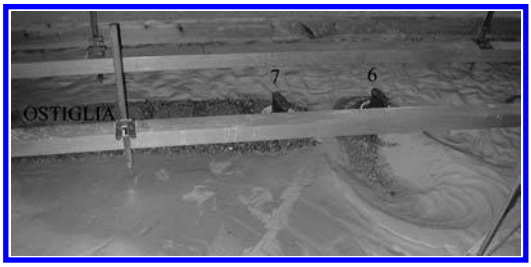

Figure 8. Erosion between provisional groin and pier 6 pit (configuration B), after test with lowest flow.

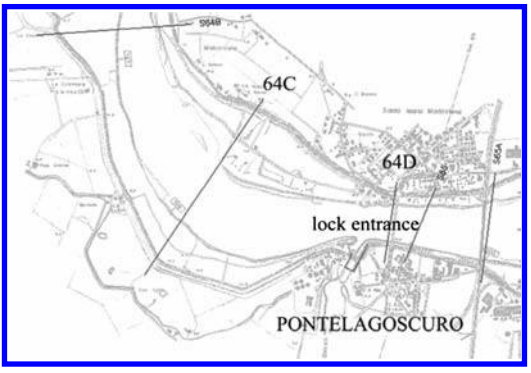

Figure 9. Modeled Po reach for inner port.

2.3.3 *Provisional structures*

B and C configurations simulated critical construction phases, when the provisional groin for the realization of piers near Ostiglia embankment and provisional pits for the realization of central piers obstruct the river.

Both piers pits and groin were steady for flows tested (2200 and 7600 m^3/s in prototype) on the construction configurations, and were not flooded by the lowest flow.

A big erosion was surveyed in the model for the configuration B, when groin length is maximal for the construction of pier 7, and the simultaneously construction of the adjacent pier 6 inside its pit.

This erosion was maximal for the lowest flow because in that case flow is gathered between pit 6 and groin head, greater flows floods pits and groin leading to a spreader flux. As can be seen in Figure 8 part of pit protection collapsed inside the hole between piers 6 and 7. Next test carried out with scaled flow from prototype value of 7600 m^3/s, covered part of the erosion, which at its maximal develop was 15 deep and 100 m wide meters, scaled in prototype.

A different construction bridge program was suggested in order to avoid the simultaneously construction of two adjacent piers which are respectively realized on the head of the provisional groin and inside a pit directly founded in the river bed.

3 PHYSICAL MODEL FOR THE PONTELAGOSCURO LOCK ENTRANCE

Goal of the inner harbour physical model was to choose between two possible lock entrance configurations, comparing the sand deposition and turbulent velocities in front of the entrance and inside the port.

The Po branch 1300 m long between sections 64C and 64D was modeled with a movable bed model at an undistorted geometric scale of 1:100, inside the same model tank where the railway physical model was realized. Figure 9 show the modeled river reach and the position of the inner port on the right river side.

3.1 *Principles of similitude and scale effects*

Tests were carried out with a morphological scale criteria, as for the Revere-Ostiglia physical model, to balance the increased grains weight in the model due to the not geometrically scaled mean diameter of bed sediment. In this way was possible to simulate the prototype bed formation process.

The velocity scale adopted (1:6) doesn't meet the velocity Froude scale (1:10) criteria and is impossible to respect at the same time all the dimensionless involved numbers. But measuring sediment concentration in the model and comparing it to prototype data, experiments time length was adjusted in order to achieve a steady bed configuration. Nevertheless, as for the railway model, due to scale effects, bed roughness and suspended load rate, were proportionally greater in model than in prototype, and these effects must be considered when results are analyzed.

3.2 *Tested configurations*

Two different configurations of the lock entrance were tested: the first with a 80 m long opening to the Po river, and the second one was only 60 m long, with the aim to decrease the sediment deposition in front of and inside the lock entrance.

The simulated flows were four between 1400 and 8000 m^3/s in prototype, starting from the lowest up to 8000 m^3/s, outside this range yearly sediment transport is negligible because of pour flow velocity or very short flow duration.

3.3 *Simulations results*

During all tests, velocities outside and inside the lock entrance were measured with a micro acoustic doppler velocimeter, which gives the three-dimensional velocities in one point with time resolution of 30 Hz. These data were used to compute mean velocities, velocity oscillations, Reynolds stresses and flow turbulence

Copyright © 2006 Taylor & Francis Group plc, London, UK

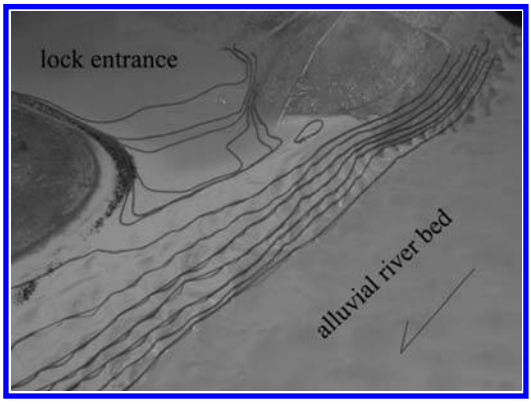

Figure 10. Sand bar at entrance after tests (wide opening).

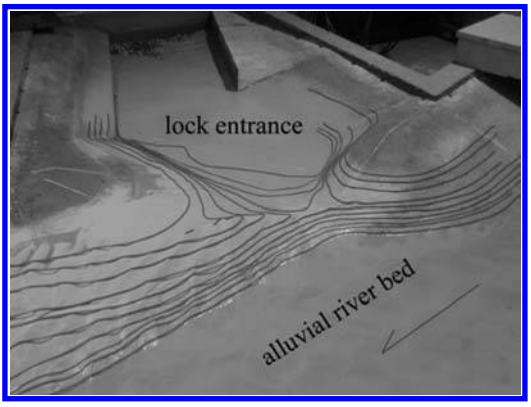

Figure 11. Sand at entrance after tests (narrow opening).

which is the cause of sediment diffusion and sediment transport processes (Jansen & al. 1979, Yalin & Ferreira da Silva 2001).

Bed topography near the lock entrance was surveyed in the model with a detailed digital image acquisition before and after each test in order to compute total deposition or erosion with a computer assisted image processing.

To suggest the best project configuration, bathymetries modifications (i.e. deposition or erosion) and turbulent velocity fields near the lock entrance were compared for the two tested configurations.

3.3.1 *Near lock entrance bathymetry*

A bar developing with flow, wide from the upstream embankment to the downstream one, was observed during tests (Figs. 10, 11).

The bar ridge was surveyed in the model at the end of the greatest flow simulation near the same height for both configurations. This bar was compared to prototype bathymetry, surveyed after a flood event in front of the old existent lock entrance. The bar observed on the prototype was not so high as in the model. This difference between model and prototype is due to the realized flow sequence during tests, which doesn't simulate the natural flood flow hydrograph but an artificial sequence with similar yearly flows grouped together.

Figure 12 shows bathymetries acquired on the model before and at the end of tests for both configurations. Inside the lock entrance a deposition of 33000 m^3 and 31000 m^3, prototype scaled, were computed from the acquired bathymetries, respectively for configuration with the 80 and 60 meters long lock entrance.

3.3.2 *Flow turbulence*

Measures of velocity acquired during tests showed a bi-dimensional velocity field, where the vertical components were negligible.

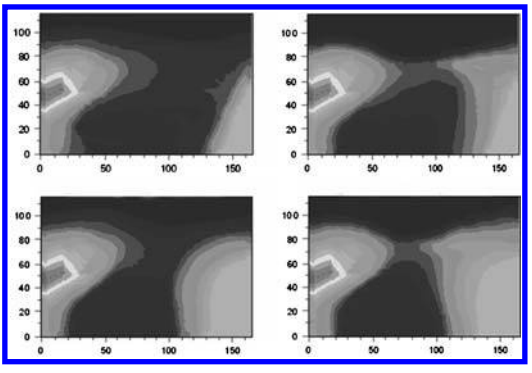

Figure 12. Starting (column 1) and final (column 2) bathymetries acquired on model; row 1 wide opening configuration, row 2 narrow opening configuration.

Reynolds stresses and tensor were computed from velocity data acquired inside and outside the lock entrance. Reynolds tensor eigenvalues and vectors identifies turbulent velocities modules and directions respectively (Jansen & al. 1979).

Figure 13 and 14 show mean velocities and ellipses of turbulent velocities centered on the measurement points. Turbulent ellipses were greater in the first configuration (Fig. 13) with lock entrance opening 80 meters long. The second configuration (Fig. 14) showed a lower turbulence in front of and inside lock entrance, which gave rise to a lower water circulation inside the port going in and out at downstream and upstream embankment respectively.

Lower turbulence of second configuration means lower sediment convection and diffusion near the lock entrance and inside the port, in conclusion decreased lock entrance opening dampens sediment transport processes, assuring a lower dredging frequency in front of and inside the port.

4 NUMERICAL MODEL FOR THE PONTELAGOSCURO LOCK ENTRANCE

Aiming to test the commercial numeric model Mike21C by Danish Hydraulic Institute, Pontelagoscuro physical model results were compared to numerical simulations carried out with the numerical model on the same river Po branch.

Numerical models has been improved in their capability to simulate river hydrodynamics and morphodynamics. Mike21C is a quasi-three-dimensional numerical model based on a curvilinear grid which can follow river embankments. It simulates river flow hydrodynamics, helical flow, sediment transport, alluvial resistance, bank erosion and plan form changes; with feedback from calculated bed forms and roughness

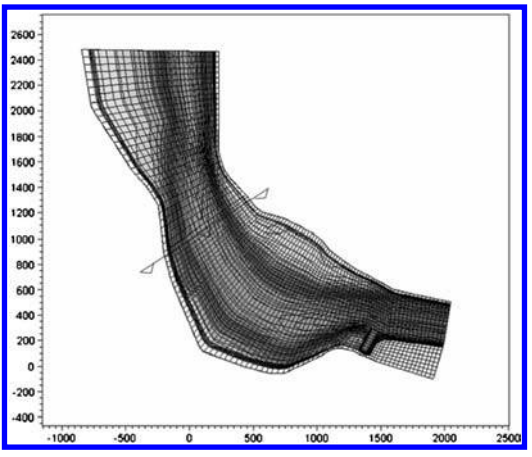

Figure 15. Bathymetry and computational grid.

changes on following hydrodynamic and morphological steps (Danish Hydraulic Institute 1999).

The same flow range used for the physical model was numerical simulated on the largest lock entrance configuration.

In order to investigate the effect of the position of upstream boundary condition, two different computational grid were realized: the first 2200 m long is only a bit upstream extended than the physical modeled reach 1300 m long, the second is 3700 m long and made the upstream boundary condition very far from the lock entrance. In that way was possible to make flows in front of lock entrance more uniform, as was achieved in the physical model with flow guides installed at the model tank intake.

Figure 15 shows the modeled bathymetry with the longest grid, and the upstream limit of the short one.

4.1 *Simulations results*

The longest grid gave results more reliable and similar to physical model results, because the flows trajectory in front of the lock entrance were similar to the velocity field achieved in the physical model.

Figures 16 and 17 compare velocity fields corresponding to 4000 m^3/s and over the physical model area, for the two different computational grids.

Velocity field is more uniform for the longest computational grid (Fig. 16), in fact in that case the main flow (clear gray-white track) in the middle of alluvium bed is more prolonged and uniform along the central fluvial line than for the short grid (Fig. 17). A strong deceleration (dark gray track) is evident in front of the lock entrance, and only for the longest computational grid a clear clockwise water circulation was achieved inside the port as for the physical model, see detail in Figure 18. Also the sediment deposition closing the lock entrance opening was similar to the longitudinal

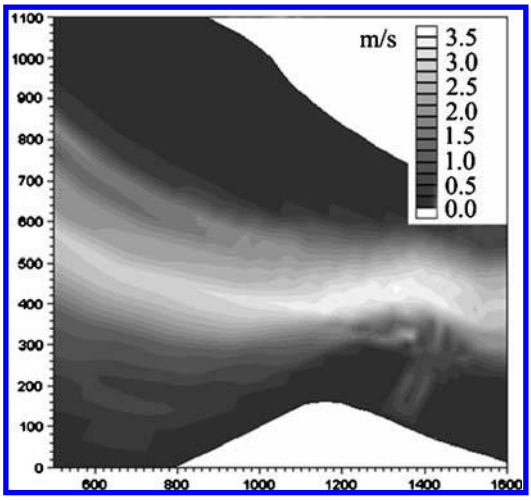

Figure 16. Computed velocity field (long grid).

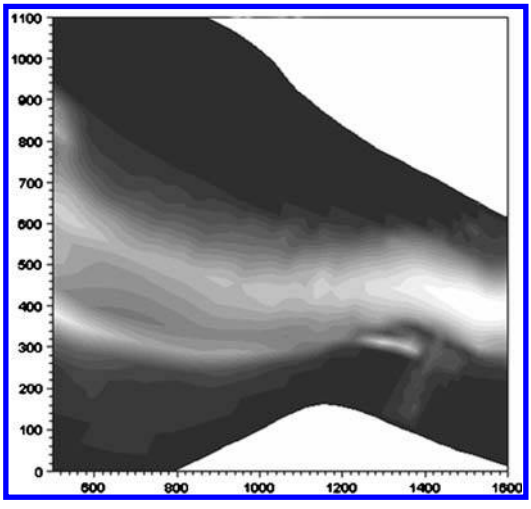

Figure 17. Computed velocity field (short grid).

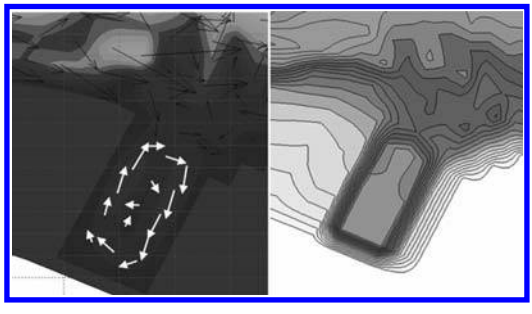

Figure 18. Details of water circulation inside lock entrance and sand deposition in front of entrance opening.

bar observed in the physical model, as can be seen in Figure 18.

5 CONCLUSION

Physical models give detailed and complete results not always available by computational models, especially when local turbulence and sediment processes near structures (piers, groins and embankments) are investigated.

Examples on river Po showed in this paper are emblematic.

Physical simulations gave answer to some questions regarding pier and provisional structures design for the Revere-Ostiglia railway construction. Mean mass diameter for bed protection around pier and construction program (groin length and pits realization time sequence) were suggested by model results.

The Pontelagoscuro physical model was useful for investigate turbulent flow near designed embankments of the new lock entrance, cause of sediment transport processes, local sand deposition and inner port water circulation.

Bi-dimensional numerical model for the Pontelagoscuro new lock entrance was able to extend simulations to a longer Po branch at a very low cost, not comparable to physical model cost. Results regarding the mean bi-dimensional velocity field and bar formation closing to lock entrance are comparable to physical models results, if the upstream condition is correctly represented. Instead local turbulent velocities inside and in front of inner port were not simulated by this kind of numerical models.

In general commercial numerical fluvial model are not able to investigate local turbulent and sediment processes due to interaction between structures and alluvial river bed, because they are designed in order to simulate the main fluvial processes of quite long reach and at a long time scale as river braiding and meandering or bed form developing.

In conclusion both physical and bi-dimensional numerical models are useful in order to investigate structures effects on alluvial river bed: the first testing structures design at a little scale (up to some meters), showing local turbulence and short time sediment transport processes, and the numerical ones investigating project effects at a higher scale, computing modifications on long time fluvial processes as bar formation or bend-meander modifications due to the designed structures.

River Energy Auditing Scheme (REAS) for catchment flood management planning

N.P. Wallerstein
University of Nottingham, Nottingham, United Kingdom

P.J. Soar
Jeremy Benn Associates Ltd, Atherstone, United Kingdom

C.R. Thorne
University of Nottingham, Nottingham, United Kingdom

ABSTRACT: An approach is presented that aims to provide a quantitative geomorphological audit of a river system to facilitate channel management and to better inform catchment flood management planning. This is a strand of research currently being undertaken at the University of Nottingham, UK in its role as a member of the Flood Risk Management Research Consortium. The auditing system uses a broad scale method (that is flexible to data availability) to classify reaches as acting predominantly as sediment sources (eroding), pathways (transfer links) or sinks (depositing) over a period of years. This is achieved by estimating the difference in time-integrated specific stream power between consecutive reaches to indicate potential continuity or imbalance in the sediment transfer system. A pilot study has been performed on the Hawkcombe Stream, Somerset, England. Initial results are encouraging and compare favorably with those of a previous geomorphological study that used the well-established Fluvial Audit technique.

1 INTRODUCTION

1.1 *Background*

Until recently, sediment dynamics were rarely taken into account when comparing options for flood defence schemes. However, imbalances in sediment supply and transport capacity may lead to progressive reduction in the standard of protection provided by a scheme (Fig. 1).

For example, channel bed degradation may undermine flood defence assets reducing their condition and increasing the risk of failure under load, while bed aggradation can significantly reduce conveyance and make overtopping more likely. In addition, flood defence infrastructure may impact on the sediment dynamics in a reach with, for example, enlargement of a channel resulting in a tendency for sediment trapping. Sediment dynamics in turn impact on river morpho-dynamics and the diversity and quality of river and floodplain habitats, which are increasingly recognized as key factors in achieving good ecological status, as required under the European Water Framework Directive (WFD) (The European Parliament and the Council of the European Union 2000).

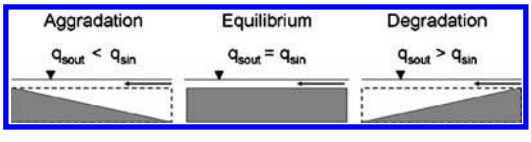

Figure 1. Schematic diagram of sediment fluxes that result in aggradation, equilibrium, and degradation of a reach: where q_{sin} = incoming sediment load; and q_{sout} = outgoing sediment load.

There is, therefore, a need for the planners and designers of flood defence schemes to predict and account for sediment dynamics and their impacts when appraising options for flood risk management. While available models of hydrodynamics, sediment transport and bed level change provide the capability to investigate sediment impacts at the reach scale, they are too data intensive and resource expensive to apply at the catchment scale.

In England and Wales, the Environment Agency is tasked with coordinating flood risk management at the system scale through the development of Catchment Flood Management Plans (CFMPs). Their statement of intent is that measurable modeling outcomes should be risk based and reach national targets for flood control, but also channel habitat diversity as stressed in the Water Framework Directive.

Copyright © 2006 Taylor & Francis Group plc, London, UK

At present in the UK, routine assessments of sediment-related problems within a wider, catchment context are performed using the qualitative Fluvial Audit (Environment Agency 2004, Sear et al. 2003). In this approach, a field and documentary investigation is used to divide the fluvial system into geomorphic reaches designated as: source (degradational); transfer (equilibrium); or sink (aggradational) reaches. The approach involves detailed field reconnaissance of the watercourse (Thorne 1998), performed by an experienced fluvial geomorphologist. While the Fluvial Audit has proven very useful in river conservation and restoration projects, in its present form it does not support quantification of the sediment dynamics required to interface effectively with the engineering components of strategic flood studies and CFMPs. Certainly, Fluvial Audits provide useful insights into catchment sediment dynamics, but the approach requires extended inputs by experienced geomorphologists and is of limited utility for strategic planning due to its somewhat subjective technical approach and qualitative outcome. To address the need for quantitative assessment of sediment dynamics at the catchment scale, a work package of the Flood Risk Management Research Consortium (FRMRC) was commissioned at the University of Nottingham. The intention of the research is to develop a quantitative method capable of validating and building upon the insights gained from qualitative assessments of sediment dynamics, such as the Fluvial Audit. The approach being sought must be credible from a theoretical stand point, while still being practical to apply to rivers with limited data. It was considered necessary therefore to develop a simple, yet robust, tool which fills the gap between empirical, qualitative and complex, sediment transport modelling approaches. Also, to support wide uptake, the method must be adaptable to varying data availability. These success criteria recognise that a balance must be struck between available resources, scientific method and acceptance by end users (Fig. 2).

It should be recognised that scientific complexity is only one of a number of criteria which must be considered in river management. Management technologies will only be taken up if the end user can fund such modelling given the resource constraints of time (many projects have completion times of only a matter of weeks), money (a numerical modeler is an expensive resource), and modelling capability (the results are only as good as their interpretation). Society (individual stake holders in a river and politicians) will also only sanction a scientific approach if it can be cognizised to some degree.

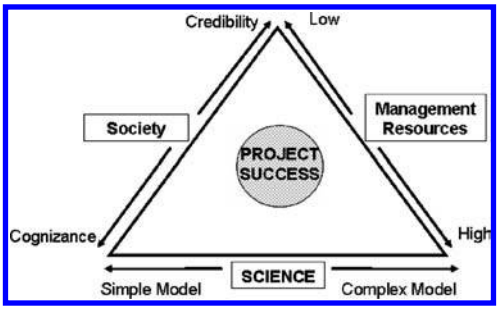

Figure 2. Balancing management resources, the science of predictive models and acceptance by society.

The need to place the new method in the centre of the triangle in Figure 2 dictated the specific objectives of the research, which are outlined in the following sections.

1.2 *Objectives*

Theoretically, system scale sediment dynamics could be quantified using established sediment routing models such as HEC-6 (HEC 1976) and ISIS (ISIS 2006), which predict bed material loads and bed level changes by solving the St. Venent equations for gradually varied unsteady flow, coupled with equations for sediment transport and continuity. However, these models are highly data and time intensive and the considerable input of resources, coupled with long run times, limits their application to studies of reach-scale scour/fill rather than issues related to catchment scale sediment transfers and imbalances. Also fully unsteady flow numerical models suffer from issues associated with convergence, consistency and stability (Versteeg & Malalasekera 1995), the understanding of which, and ability to mitigate these through code adjustment requires finesse and many years of knowledge. Finally, channel boundary adjustment models rely on sediment transport equations that characteristically predict sediment load to within $\pm 50\%$ about 60% of the time (Yang 1996). This makes selecting an appropriate sediment transport equation crucial to producing a successful simulation and there are no universally accepted rules concerning which equation is suitable for a particular river environment.

Counteracting uncertainty is a critical component of all research conducted by the FRMRC and so this capability was a primary objective of the research. The approach adopted here is aimed at a broad representation of a catchment scale potential for channel adjustment, it does not purport to represent local conditions in detail. The development of a numerical model at the whole catchment scale would be very time, labour, and resource intensive, commodities which the EA and its contractors simply do not have free reign to use. Thus in the approach adopted here numerical modelling schemes are replaced by an alternative reliable indicator of the river's potential to perform geomorphological work through expending energy which thus enables the transport of sediment. By invoking this approach the authors are not proposing that more complex models generate a worse representation of a river system,

Copyright © 2006 Taylor & Francis Group plc, London, UK

simply that the approach outlined below is robust and a good first approximation of geomorphological adjustment. Before discussing the approach a criticism of the model must be addressed, that being that it suffers from the same problems as complex numerical models but by not using sediment transport relationships provides less reliable results. This statement may be counteracted by the following observation made by Beven (2002), 'In science where unique local characteristics so affect local observations as to make the application of small-scale physical theory intractable at the larger scale we must look to alternative larger scale descriptions and must recognize that there may be many possible descriptions that provide equally good predictions of the observations'. With this in mind we shall proceed to describe the model invoked here.

The theoretical justification for this approach stems from the concept of specific stream power proposed by Brigadier R. A. Bagnold (Bagnold 1966), in which he defined specific stream power as a measure of the flow's ability to perform work on its boundary. The rate of doing work through sediment transport is defined by Bagnold in terms of the specific stream power multiplied by an efficiency factor. Bagnold's approach has been further developed by several authors to predict sediment movement and geomorphological adjustments in rivers (for example; Langbein 1964, Yang 1971, Chang 1979, Graf 1983, Lawler 1992, Magilligan 1992, Molnar & Ramirez 1998, Knighton 1999). However, the approach developed does not attempt to predict sediment transport or route sediment (or energy) through an event hydrograph. Instead, it calculates the balance or imbalance between the specific stream power available in a reach in a year (that is the annual stream energy in $KJyr^{-1}$) with that in the next reach downstream.

Further objectives were that the River Energy Auditing Scheme (REAS) must be generically applicable, amenable to use by river scientists and engineers with a modest amount of specialised training, applicable within the resources available for typical strategic catchment studies, and capable of producing robust results in situations with very limited data availability - albeit accepting a greater degree of uncertainty. The last and perhaps most important objective is for the REAS output to be readily understood by those responsible for river management and planning at the catchment scale.

With respect to data requirements, there are only five input variables to REAS for each study reach in the river system:

1 Representative bed material particle size (s);
2 Representative flow duration curve;
3 Representative channel cross-section;
4 Representative bed slope, and;
5 Representative roughness values for the channel and floodplain.

The manner in which these variables are employed is discussed in the next section. It must be stressed at this point that REAS is not a sediment routing model, but instead generates indicative, quantitative trends in river energy, and therefore the ability for the flow to perform work through sediment transport, during an average year in which runoff is similar to that associated with the long term flow duration curve. The REAS will only be judged a success if it can be operated by the end user community in the UK, both in the public and private sectors. To this end, in the latter half of the FRMRC project a working version of REAS will be tested by typical end users in the Environment Agency and training workshops will be held for a range of potential stakeholders and interested parties.

1.3 *Study area*

A pilot data-set comprising the variables required to run the model has been collected from the Hawkcombe Stream, in Somerset, England (Fig. 3). This is a steep, upland catchment with a relief of 436m over a length of about 8 km. Base flows are generally less than $1\,m^3\,s^{-1}$, with maximum discharges of up to $10\,m^3s^{-1}$. The channel has a boulder, cobble and gravel bed and is generally armoured. HEC RAS (Brunner 2002) modeling of the Hawkcombe suggests that at high discharges the flow is supercritical in many places, indicating that the stream is a high energy environment. In 2002, a Fluvial Audit of the Hawkcombe was performed (Thorne et al. 2002) and the main stream was divided into 17 reaches (Fig. 3) characterised as sediment sources (degradational), transfers (throughputs), exchanges (dynamic equilibrium), and sinks (aggradational). In 2004, the lower 4.5 km of the Hawkcombe was surveyed in detail. One hundred and twenty seven cross-sections were surveyed, located at major breaks of slope and positions of significant channel geomorphological change and fifty four bed material samples were taken. Bed material was analysed using size-by-number for particles

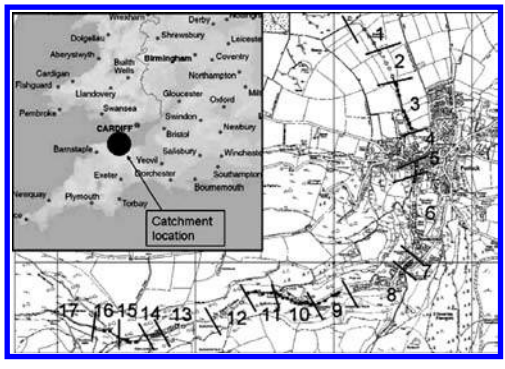

Figure 3. Hawkcombe stream location and geomorphological reaches.

Copyright © 2006 Taylor & Francis Group plc, London, UK

between 1025 mm and 8 mm, sieving and size-by-weight between 8 mm and 0.063 mm, and using a Coulter Counter below 0.063 mm.

The Hawkcombe has several hydraulic structures along it, including bridges, mill weirs, gravel traps, bed sills and bank protection works. It flows through an 83m long culvert, beneath the village of Porlock. This culvert has required maintenance de-silting in the past as sediment deposition has occurred, reducing its capacity to convey floods. In 2005, the floor of the culvert was re-profiled to reduce sediment trapping in a scheme designed by Royal Haskoning Consulting Engineers.

2 APPROACH

2.1 *Calculating available stream power*

Stream power per unit bed area (ω) is expressed in Wm^{-2} and is termed specific stream power. It is defined by:

$$\omega = \frac{\gamma Q S_e}{W} \quad (1)$$

where γ = bulk unit weight of water (Nm^{-3}); Q = discharge ($m^3 s^{-1}$); S_e = energy slope; and W = geomorphologically active channel width (m) for the discharge in question. S_e can usually be approximated by the bed slope (S_o) for channels with moderate to low slopes and this approach will be adopted here. Note that in Bagnold's (1966) version of Equation (1) he used water density (ρ_w: kgm^{-3}) in place of bulk unit weight, γ. The bulk unit weight of water is used in most derivations of specific power. This has often been a source of error in calculations of sediment load using Bagnold's transport functions (Bagnold 1977, 1980) i.e. as Bagnold did not use g (where g = gravitational constant: approx. 9.81 ms^{-2}) and because $\gamma = \rho_w \times g$ results can be out by a factor of 10 (Ferguson 2005).

The geomorphologically active channel width is defined as the area of channel bed and banks beneath the flow top width for a given discharge which is within the bankfull channel cross-section (Richards 1982), i.e. it does not extend onto the left hand and right hand floodplain if flow depth becomes higher than the bankfull elevation.

To calculate an excess specific stream power (ω_e), which is that actually available to perform work on the channel boundary by moving sediment, it is necessary to subtract the critical specific stream power for mobilizing the bed (ω_c) from the available specific stream power:

$$\omega_e = \omega - \omega_c \quad (2)$$

Bagnold (1980) defined critical specific stream power as:

$$\omega_c = 290 D_m^{1.5} \log\left[\frac{(12d)}{D_m}\right] \quad (3)$$

where; D_m = mean grain size in the size distribution representing the bed of the channel (m); and d = flow depth (m).

Ferguson (2005) provides a full derivation of the terms, but essentially, the term $290D_m^{1.5}$ is derived from the Shields equation and the log term is derived from the 'law-of-the-wall' velocity profile (Richards, 1982). The approach is further developed here by replacing an estimate of the critical specific stream power based on a single mean grain size with a formulation that better represents the range of grain sizes present on the bed. This is achieved by multiplying the critical power for the median grainsize in each size class (1024 mm, 724 mm, etc) by its frequency of occurrence, and then summing all values. Thus, for a given depth, excess power ω_e' is equal to:

$$\omega_e' = \sum_{i=1}^{n} \left[P_i (\omega - \omega_{ci})\right] \quad (4)$$

where P_i = proportion (from 0 to 1) of that size class in the whole sample; and ω_{ci} = critical specific stream power for a given grainsize class.

ω_{ci} is calculated using Equation (3) in which D_m is replaced by D_i (m), the median grainsize in each class. The justification for the formulation and use of Equation (4) is that use of a single particle size such as the D_m might not be a suitable parameter alone given a highly variable bed sediment gradation. Thus Equation (4) offers a more integrated approach which is preferable where sediment grainsize distribution data is available. It is recognized that for some applications of this model a full grain size sample may be too time-consuming and costly to collect and a single representative grain size for each reach may be all that is available. An option for using either a single grain size value or a full distribution has therefore been made available in the model.

Note that the recommendation is to use the size distribution of the surface sediment layer on the bed as research has shown that sediment transport equations best fit empirical data when this layer is used (Parker 1990, Wilcock & Crowe 2003).

2.2 *The REAS annual energy budget*

The annual energy budget for a reach must take into account the full range of discharges acting on the channel over a period of years. This is done by integrating ω_e' with a representative flow duration curve, adopting the procedure set out by Biedenharn et al. (2001). This is performed by taking the entire flow record available for the reach in question (15 minute or mean daily values), ranking the values from lowest to highest and producing a cumulative probability curve. The discharges are then split into ranges (usually 25–35 classes) and their frequency determined. If gauged data are not available for the reach in question, or the

Copyright © 2006 Taylor & Francis Group plc, London, UK

discharge record is short, surrogate methods have to be used. These include:

1 Scaling discharge from a gauge elsewhere in catchment. This can be achieved through simply scaling by the ratio of drainage areas;
2 Scaling discharge from a donor catchment with similar hydrological and morphological characteristics, or;
3 Calculation using hydrological modeling packages; for example HEC-1 (HEC 1998).

Integrating for the expected range of discharges yields:

$$\omega_e = \sum_{j=1}^{n}\left[F_j \sum_{i=1}^{n}\left[P_i(\omega - \omega_{ci})\right]\right] \quad (5)$$

where F_j = frequency (from 0 to 1) of each discharge class. Note that discharge, width and depth in Equation (4) are adjusted to the values appropriate for each discharge class.

The difference in excess annual specific stream power between consecutive reaches gives the balance for a reach ($\Delta\omega_e$):

$$\Delta\omega_e = \omega_{e(r=n)} - \omega_{e(r=n+1)} \quad (6)$$

where the subscripts r = reach; and n = reach number from 1 to n_t (where n_t = total number of reaches). Reaches are numbered sequentially from upstream to downstream. Equation (6) is then multiplied by the gravitational constant because Bagnold's formulation of Equations (1) and (3) do not incorporate g. This value is then multiplied by the number of seconds in a year to give a measure of annual excess energy in $KJyr^{-1}$ at a single point in a cross section.

Equation (6) is comparable in essence to a sediment budget calculation (refer to Fig. 1) except that the sediment transport rate has been replaced by a term representing excess specific stream power. Thus, if $\Delta\omega_e$ is greater than zero then the reach has the potential to aggrade (it is likely to be a sediment sink), while if $\Delta\omega_e$ is less than zero then the reach has the potential to degrade (it is likely to be a sediment source).

Initial trials using a prototype version of REAS were conducted using the Hawkcombe dataset. For each of the 17 reaches the most downstream cross-section was used to represent the geometry of that reach. Discharge for each reach was scaled from a donor catchment, the River Horner. An estimated lateral floodplain slope was set as 0.01; floodplain Manning's n was set as 0.07 and the active channel Manning's n set as 0.035. The full bed material sediment grainsize distributions were used. As the REAS output will be used in the context of risk it was felt that differences in excess annual energy in $KJyr^{-1}$ should be expressed in dimensionless form. The output from the Hawkcombe is therefore presented in Figure 4 using a scale between +1 and −1, where values between 0 and +1 indicate increasing potential for sediment storage, values between 0 and −1 indicate increasing potential for sediment scour, and values close to 0 indicate channel stability.

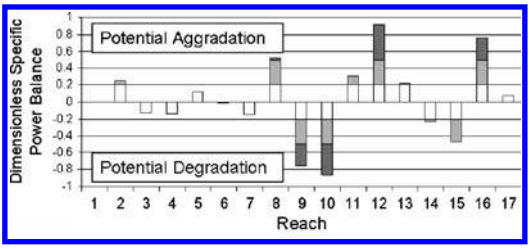

Figure 4. Excess energy budgets for the Hawkcombe stream.

This relative scale has been generated by dividing the differential values measured in $KJyr^{-1}$ by a user defined absolute sensitivity value. Methods to achieve this scaling in a less subjective manner are currently being explored. The grey scaling in Figure 4 represents bands of low, medium and high risk of aggradation or degradation based upon the magnitude of energy imbalance between consecutive reaches.

The distribution of sediment stores and sinks generated here using the REAS compares favorably with those that are based on the Fluvial Audit of the Hawkcombe, although it must be stressed that outputs from this model are preliminary at this stage of the project. Improvement of predictive capabilities is discussed in Section 4.

3 DISCUSSION

3.1 *Solution for flow width and depth*

Because REAS uses a range of discharges a flow depth and channel top width must be defined for each flow. Manning's flow resistance equation is used for this purpose (Chow 1959):

$$Q = \frac{1}{n}\frac{A^{5/3}}{P^{2/3}}S_e^{1/2} \quad (7)$$

where n = Manning's roughness coefficient; A = channel cross-sectional area (m^2); and P = channel wetted perimeter (m).

Values for Manning's n can be obtained from, for example, Barnes (1967) or Chow (1959).

It is acknowledged that in a simple model such as this obtaining the energy gradient may prove to be impossible due to the wide spacing of cross sections which would prevent generation of a gradually varied flow profile. This source of uncertainty will be small in channels with low bedslopes due to the fact that the energy slope will approach that of the bedslope. In higher gradient streams or channels with very variable bedslopes the source of error caused by the approximation of energy slope by using bedslope is

Copyright © 2006 Taylor & Francis Group plc, London, UK

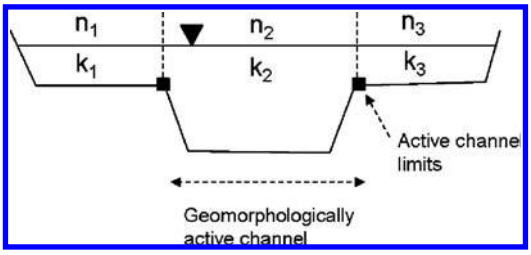

Figure 5. Definition of parameters required to solve Manning's equation. n = Manning's roughness coefficient; and K = conveyance.

acknowledged as potentially a significant source of uncertainty.

To solve Manning's equation a cross-sectional representation of the channel for the reach in question must be defined. This requires a survey of what is considered to be the geomorphologically active channel and, if out of bank flows are thought to be significant, the floodplain as well. It is recognised that field survey data will probably be the most costly input to obtain when using the REAS and the longstream spacing of cross-sections may have to be significant. This will inevitably reduce the resolution of the model in terms of the number of reaches that can be defined. To solve Equation (7) flow depth must be adjusted iteratively to solve for A and P until the value of the right hand side of Equation (7) converges to the value of the left hand side. Iterative techniques available include the Newton-Raphson and secant methods. The normal flow depth for a given discharge is solved by apportioning flow between the main geomorphologically active channel and floodplain areas (left and right) (Fig. 5). If the lateral topography of the floodplain is unknown, the model has the option for the user to assign an estimate of the lateral floodplain slope. This ensures that large flows are not contained within vertical walls either side of the main channel which would otherwise overestimate flow depth. Such a problem can occur in 1-D flow models such as HEC RAS if the floodplain is not extended either side of the channel. A value of n must be prescribed for the channel and floodplains, along with the limits of the geomorphologically active channel (Fig. 5). The term active channel is used here to describe that part of the channel within which the excess stream power acts to perform significant geomorphic work through transporting sediment.

Of significant importance in the calculation of in-channel power is how to account for channel area and wetted perimeter at those discharges that involve overbank flow. It is assumed here that a 'glass wall' extends vertically above the bank markers, thus defining the maximum width and discharge used in Equation (1). Flow depth within the bank markers above the bankfull depth is used but, importantly wetted perimeter is not extended vertically as there is no actual physical boundary. This last assumption grossly simplifies floodplain-channel flow interaction as there will be significant momentum exchange at this location. Methods are available to account for momentum loss (for example; Thorne & Soar 2000, Thorne & Soar 2001), but they are considered to be beyond the scope of this model as it is truly only one dimensional and thus designed to be simple in its representation of flow processes. Indeed many far more complex 1-D flow models such as HEC RAS and HEC 6 do not incorporate any momentum exchange calculations.

To solve Equation (7) for the full channel section it is normal to sum conveyances (K) for each section (Chow 1959):

$$Q = \sum_{i=1}^{n} K_i S_e^{1/2} \tag{8}$$

where K_i = conveyance for panel i. K_i is defined as:

$$K_i = A_i R_i^{2/3} \frac{1}{n_i} \tag{9}$$

where A_i = cross-sectional area for panel i; R = hydraulic radius for panel i; and n_i = Manning's roughness coefficient for panel i.

3.2 *Representing stream power in a variable cross-section*

Flow depth for a given discharge must be defined to solve Equation (3). Two approaches were identified:

1 Based on hydraulic radius, and;
2 Based on panels.

For case 1 Equation (3) becomes:

$$\omega_c = 290 D_i^{1.5} \log\left[\frac{(12 d_h)}{D_i}\right] \tag{10}$$

where d_h = hydraulic depth (m) = A/W.

This seems to be a reasonable and simple assumption on initial inspection but it can be a misleading interpretation in variable cross-sections. Imagine a geomorphologically active channel cross-section (within the in-channel markers) that has an irregular cross-section (Fig. 6). At low flows, when $W = W_1$ an increase in discharge will cause an increase in power (Eq. 1) because the rise in W is proportionally small compared to the rise in Q and critical power. Thus, excess power will increase with stage. Now, however consider the case where flow depth increases to W_2 due to an increase in discharge. It is possible at this stage that the rise in W is disproportionately greater than the numerator in Equation (1), causing excess specific stream power for a given discharge to actually fall or even go to zero, even though the shear stress applied to the bed below W_1 has increased. In reality this cannot

Copyright © 2006 Taylor & Francis Group plc, London, UK

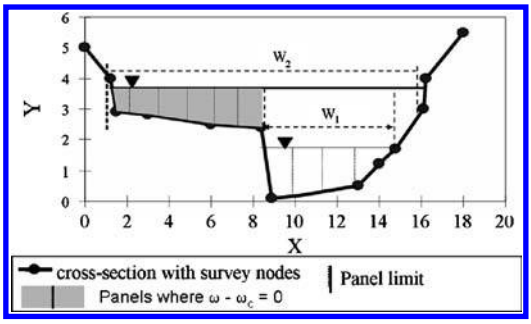

Figure 6. Width variation over a berm within the geomorphologically active channel.

be the case as in the inner low flow channel (W_1) particles will still be mobile, and to a greater degree because Q has increased. Thus, the mathematical definition in Equation (10) does not tally with the process which would actually occur in nature.

However it is considered that a fall in specific stream power for an increase in stage is tenable because excess power is a width averaged variable and must therefore take into account the full channel width, but powers falling to zero cannot be justified. An alternative approach has therefore been investigated and is the preferred option in REAS.

A better approximation of depth can be gained by sub-dividing the active channel cross-section into panels of equal width and with average panel depth d_z. Panels can be generated by interpolating areas between each node generated from the survey of a reach cross-section. For this case the excess specific power equation becomes:

$$\omega_e = \frac{\gamma Q_m S_e}{W} - \frac{290 D_i^{1.5}\left[N_m \log\left[\frac{12}{D_i}\right] + \sum_{z=1}^{n} \log d_z\right]}{N} \quad (11)$$

where Q_m = discharge for those panels where the bed is mobile; N_m = number of panels where the bed is mobile; and N = total number of panels.

The reason for not showing a division of the total power in Equation (11) by N is that the summed division of γQmSe in the total stream power term by the width for each individual panel and then division by the number of panels N, is exactly same as the use the whole width. That is:

$$\frac{\sum_{i=1}^{n}\left[\frac{\gamma Q_{mi} S_e}{dW_i}\right]}{N} = \frac{\gamma Q_m S_e}{W} \quad (12)$$

where dW = individual panel width.

Under this approach, for a given discharge and water surface elevation, the depth for each panel can be determined. Next, a check is made to see if bed particles would be mobile (each size class in the distribution is considered as discussed in Section 2.1) for a given flow depth. It would appear in the first instance that this could be achieved by simply calculating total stream power for a panel and subtracting its corresponding critical power using Equations (1) and (3). However this is actually not possible because of a phenomenon first recognised by Garbrecht & Brown (1991). If discharge is calculated based upon a single panel for an entire cross-section using Manning's equation a given depth and width will be determined. However if a cross-section is panelized and a conveyance is calculated for each, the implicit assumption is made that the channel elements have frictionless walls and no lateral momentum exchange, thus resulting in a lateral velocity gradient. This approach violates the postulate of a single mean velocity across the section for the application of Manning's formula. The result is that a panelized approach will overestimate conveyance, and therefore discharge and consequently flow depth for each panel, as compared with the calculation made using an integrated cross-section. This phenomenon appears to be little known and may result in conveyance over estimation in flow models where the user has the option of dividing the cross-section of a channel into a significant number of panels each with their own roughness coefficient.

An alternative approach has therefore had to be adopted. This has been achieved by simply using a form of the Shields entrainment function (Yang 1996):

$$\theta = \frac{\tau_o}{\gamma(G_s - 1)D_i} \quad (13)$$

where θ = Shields parameter; τ_o = bed shear stress = γRS_o (Nm^{-2}); G_s = specific gravity of the sediment; and R = hydraulic radius (m).

With some rearrangement of Equation (13) we get:

$$R = \frac{\theta(G_s - 1)D_i}{S_o} \quad (14)$$

To distinguish between mobile and immobile panels, Equation (14) is solved using a critical Shields value. Here, a value of 0.04 is used as this was the value used by Bagnold (1980) in his derivation of Equation (3). When Equation (14) is solved using a critical Shields value, R is equal to R_c, the critical hydraulic radius. R_c for a particular panel can then be compared with the actual hydraulic radius computed for the panel. If $R_c > R$ the panel will be immobile at the given flow and given grain size. When all panels are checked in this manner, N_m can be determined. The critical specific power is then calculated using Equation (11). Note that N is the total number of panels including those where $R_c > R$.

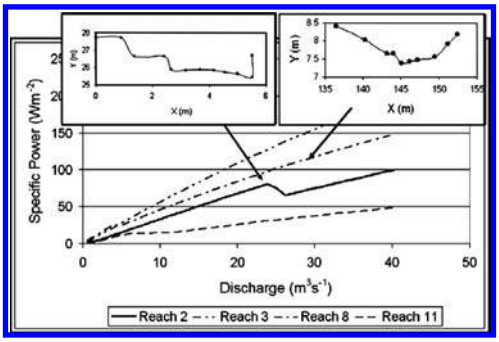

Figure 7. The relationship between channel cross-sectional geometry and specific power – discharge curves.

Once this has been done the total discharge for the mobile panels (Q_m) can be calculated using Manning's equation. Now we can calculate total specific power based upon the mobile panels using the first term on the right hand side of Equation (11).

Using this scheme excess specific stream power can fall if the width suddenly increases, but it should never fall to zero. An example of the functional relationship between discharge and excess power for the Hawkcombe data-set is shown in Figure 7.

It can be seen in this diagram that the cross-section for Reach 2 has a distinct berm and this has an impact on the discharge – power curve where, as the flow initially passes over the berm, the sudden increase in width results in a fall in power. As discharge for this larger width increases again so the upward trend between discharge and power starts again. The trend for Reach 8 is monotonic because the cross-sectional form is reasonably uniform.

3.3 *Relationship between total specific power and excess power*

When Equation (11) is applied to a single or whole range of grain sizes present in the cross-section a relationship is formed between total specific stream power and excess specific stream power. The form of this relationship is shown in Figure 8.

Here the relationship between total and critical power is shown for a nominal discharge of 100 m^3 s^{-1}. Depth for this discharge has been calculated using Manning's equation based upon an idealized, rectangular channel with a slope of 0.0001, a Manning's n coefficient of 0.035 and a channel width of 5 m. The total power which is calculated using the above parameters is indicated by the dashed horizontal line in Figure 8. An example of critical power and excess power values for a sediment size of 0.02 m is shown in the figure.

The relationship that is developed shows that, as grain size increases, critical power also increases thus reducing excess power (ω_e). The functional relationship between the critical power and grain size is formed

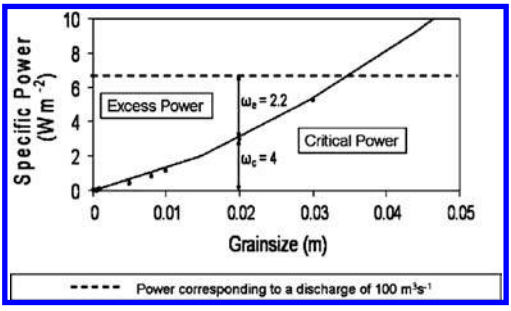

Figure 8. The relationship between critical and excess power over a range of grainsizes.

by a power-based curve. It can be seen that for a limiting value of 0.035 m, excess power falls to zero. The power form of the critical curve is explained by the fact that the term, $290D^{1.5}$ in Equation (3) is a power function. What is also apparent from Equation (3) is that, for the log term, as depth rises so critical depth will also increase relative to grain size. This means that for a greater flow depth the critical curve on Figure 8 should shift upward from, and parallel to, the critical specific power curve for a lower depth. However manipulation of depth values over a wide range shows that the position of the critical power curve varies only fractionally. This can be explained because the log term in Equation (3) is based upon the $\log_{10}$ of d/D and therefore even for a great range of depths the difference in the log term will be almost minimal (this can be illustrated by, for example, the fact the for $d = 2$, $\log_{10} d = 1$ and, for $d = 100$, $\log_{10} d = 2$). This has implications for the academic development of critical power equations as, for example, hiding functions such as that suggested by Ferguson (2005) are, in part, based upon the log term.

4 FUTURE DEVELOPMENTS

The next step in developing the model will be to add the ability to take into account lateral sediment inputs. It is envisaged that bank erosion/accretion might be accounted for using a width (and thus power) scaling factor of severe, moderate, and minor bank adjustment which would be represented by a scaling factor between 0.5 and 1.5. Another element of ongoing research is the introduction of greater robustness in the model if data are limited. Examples of limited data might include poor knowledge of bed material size and a limited number of cross-sections. Overcoming these limitations will require a degree of interpolation of data within the river network.

The type of model presented here lends itself well to fast scenario modelling such as predicting the effects of channel enlargement due to dredging or contraction due to levee construction as in such cases only top width need be changed.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The model is now undergoing sensitivity analysis whereby the full model will be compared with the predictive capability of the following formulations:

1 Simple QS calculation for each reach for a single discharge;
2 QS calculation for each reach integrated over a flow duration record, and;
3 Simple QS/W calculation for each reach.

A second comprehensive data set from the River Wharfe in Yorkshire, UK, is also currently being analysed to further test the model. This data-set has time series cross-sectional surveys that can be used to corroborate the model output.

5 CONCLUSIONS

Accounting for sediment dynamics in river channel networks must become a key component of flood risk management planning. To date the approaches for accounting for sediment in analysis of the fluvial system are generally based either on complex numerical models or qualitative interpretation of the results of stream reconnaissance. Both of these approaches have benefits but also considerable pitfalls in that highly trained modellers and geomorphologists are required to use such tools. Time and financial constraints are also a significant factor. A need for an approach which lies between these two techniques has therefore been identified in the UK as a key resource that will be used to facilitate river flood risk management within the context of meeting statutory requirements for ecological status and goals for habitat preservation and enhancement.

A novel approach, the River Energy Auditing Scheme (REAS), is therefore being developed as part of research performed by the Flood Risk Management Research Consortium (FRMRC). The approach is based on an audit of excess specific stream power in which excess reach-averaged specific stream power is used as a surrogate for sediment transport to give an excess specific stream power budget between consecutive reaches in the channel network. Excess power available to perform work on the channel boundary is defined as total specific stream power minus critical specific stream power, using Bagnold's (1980) formulation of both parameters. Only five input variables are required for the calculations: a flow frequency curve; channel cross-sectional geometry; a bed slope; a roughness coefficient and a representative bed material grainsize or grain size distribution. The approach given here has is mind the fact that geometry data available to the UK Environment Agency and its contractors has widely spaced cross-sections. Also a single representative grainsize can be used to solve Equation (4) if a full distribution is not available.

The approach for generating a flow duration curve has been described along with specific solutions for calculating flow top width and depth using Manning's equation. Interesting properties have been found in the relationship between the variables, showing that excess specific stream power can fall even as discharge rises. The reason for this apparent inconsistency is explained by the manner in which flow depth is derived. This leads to the justification of one particular solution (Eq. 11). The Shields equation is used to predict panel depth because of the phenomenon that calculating discharge using panels rather than using an integrated cross-section will overestimate conveyance and therefore flow depth for a given discharge. The functional form of the relationship between total power and critical power is discussed and indicates the importance of previously unconsidered factors in the derivation of critical power equations.

The test-bed data used for initial exploration of the model structure has been obtained from a comprehensive data-set collected from the Hawkcombe Stream in Somerset, UK. Results are at this stage preliminary and are, therefore, not discussed in-depth here, but in general they have been found to correlate reasonably with the results of a Fluvial Audit. A criticism that has been leveled at this approach is that it is of less utility in terms of predictive capability than more complex numerical models. The reader might bare in mind the following statement made by Overton and Meadows (1976), '…if a highly complex mathematical representation of the system under study is made, the risk of not representing the system will be minimized, but the difficulty of obtaining a meaningful solution will be maximized as much data will be required, and mathematical handling in computer models (e.g. convergence and consistency) and complexity of mathematical processes may even render the problem formulation intractable. Further, the resource constraints of time, manpower and money may be exceeded. Conversely, if a greatly simplified model is selected the risk of not representing the physical system will be maximized, but the difficulty in obtaining a solution will be minimized'. We suggest that the model presented here lies somewhere between the two extremes.

The model is still in the developmental stage and the intention is to add more predictive factors and increase functionality during the coming months.

Fluid–structure interaction modeling with a coupled 1D–2D free surface flow solver

S. Erpicum, P. Archambeau, B. Dewals, S. Detrembleur & M. Pirotton
Laboratory of Applied Hydrodynamics and Hydraulic Constructions, Civil Engineering Institute, University of Liege, Belgium

ABSTRACT: Wolf software is a set of coupled numerical tools developed for almost ten years for simulating a wide range of free surface flows and transport phenomena. In the scope of new applications in hydraulic structure design and fluid-structure interaction, additional developments have been implemented in the finite volume 2D model to deal with boundaries not aligned along axis or with moving structures. The cut cell based approach, simpler than other classical methods, is based on the division with a sub-grid of the initial Cartesian meshes. While keeping the advantages of regular grids in terms of simplicity, accuracy and storage capacity, it enables to compute instantaneous effects of a structure movement on the fluid or to deal with complex boundaries inclined compared to mesh axis. Several test cases are presented, as well as an application of the enhanced model, coupled with a 1D one, to the computation of the hydrodynamic fields induced by a lock-door movement.

1 INTRODUCTION

Today, hydraulic engineering studies use more and more numerical models to predict or assess flow conditions. Depth-integrated models are very efficient in this field as they represent a good compromise between problem implementation and computation times in comparison with results quality and accuracy. Discretization in two dimensions allows using fine meshes without leading to prohibitive memory requirements, while well-known equations sets and resolution schemes provide a reliable modeling of the most important flow variables for practical engineering applications.

On the other hand, the finite volume method seems to be currently the most suited to solve the hyperbolic partial differential equations system characterizing flow movement (Valiani et al. 2002). As the method is based on the integral form of the conservation equations, the derived numerical scheme is conservative (Hirsch, 1988) and satisfies the shock-capturing property (Toro, 2001).

The application field of such numerical models solving the so-called shallow water equations (SWE) is very broad. Among others, they are used for dam-break (Valiani et al. 2002, Erpicum et al. 2004a) or dam-breaching (Dewals et al. 2002, Froehlich, 2002) simulations, flood inundation mapping even in urban areas (Alcrudo & Mulet, 2005, Archambeau et al. 2004) as well as hydraulic structure design (Erpicum et al. 2004b, Dewals et al. in press) or sedimentation assessment (Dewals et al. 2004).

Generally, grids used for 2D simulation are classified regarding the type of meshes they use. The two main families are the structured and unstructured grids. While unstructured grids allow dealing with complex geometries, they are more computation time consuming than structured ones, even more if the latter are Cartesian. Indeed, to achieve the same global order of precision for the calculation, they need a higher precision of reconstruction of the unknowns (Mouzelard, 2002).

To limit the restriction of the Cartesian grids to fit to complex geometries, methods based on a cut cell approach (Causon et al. 2000) can be used. They can also easily be extended to the simulation of moving bodies (Ingram et al. 2003), and thus reproduce fluid-structure interaction. Such a method is presented in this paper.

Based on a sub grid approach to define complex geometries, the present method is simpler than classical cut cell approaches but is more easily implemented in an existing code. It constitutes thus an appropriate first approach in the domain.

In this paper, the developments realized to simulate fluid-structure interaction by means of mobile boundaries on a fixed Cartesian grid are presented in detail. After its implementation in the free surface flow solver Wolf2D (Erpicum et al. 2004a), the modified SWE model is applied to a bore reflection on

Copyright © 2006 Taylor & Francis Group plc, London, UK

a fixed inclined wall and to the simulation of a moving plate in a channel. Finally the modified 2D model, coupled with the one-dimensional free surface flow solver Wolf1D (Erpicum et al. in prep.), is applied to assess the hydrodynamic effects of a ship lock door movement.

2 EQUATIONS

2.1 *1D approach*

Consider a general 1D conservative law such as:

$$\frac{\partial}{\partial t}s+\frac{\partial}{\partial x}f=S \tag{1}$$

where $s=$ unknown; $f=$ advective term; $S=$ source term; $x=$ space coordinate; and $t=$ time.

Let us solve the equation using a finite volume method with a cell-centered approach (Fig. 1), considering fixed nodes but cell edges moving with velocity $v_{G,x}$ along x-axis. Integration of (1) over a finite volume i lead to:

$$\int_{x_{i-1/2}}^{x_{i+1/2}}\frac{\partial}{\partial t}s\,dx+\int_{x_{i-1/2}}^{x_{i+1/2}}f\,dx=\int_{x_{i-1/2}}^{x_{i+1/2}}S\,dx \tag{2}$$

After Leibnitz theorem application, time derivative integral becomes:

$$\frac{\partial}{\partial t}\int_{x_{i-1/2}}^{x_{i+1/2}}s\,dx-s\big|_{i+1/2}\frac{\partial}{\partial t}x_{i+1/2}+s\big|_{i-1/2}\frac{\partial}{\partial t}x_{i-1/2} \tag{3}$$

and is equal to:

$$\frac{\partial}{\partial t}\bar{s}\Delta x_i-s\big|_{i+1/2}v_{G,x}\big|_{i+1/2}+s\big|_{i-1/2}v_{G,x}\big|_{i-1/2} \tag{4}$$

where $\Delta x_i=$ cell i length; and symbol $\bar{a}$ stands for the mean value of a over the finite volume.

Green-Gauss theorem application to second term of (2) and source term integration lead to, respectively:

$$f\big|_{i+1/2}-f\big|_{i-1/2}\ \text{and}\ \bar{S}\Delta x_i \tag{5}$$

Using expressions (4) and (5), equation (2) becomes:

$$\frac{\partial}{\partial t}\bar{s}+\frac{\partial}{\partial x}\left[\left(f-sv_{G,x}\right)_{i+1/2}-\left(f-sv_{G,x}\right)_{i-1/2}\right]=\bar{S} \tag{6}$$

Grid movement affects advective terms by mean of additional exchanges through cells faces. For example, regarding mass conservation equation for a 1D flow in a rectangular channel, s is the water height h and f is the unit discharge q while S is zero if no mass exchange occurs with outside. Equation (6) writes:

$$\frac{\partial}{\partial t}h+\frac{\partial}{\partial x}\left[\left(q-hv_{G,x}\right)_{i+1/2}-\left(q-hv_{G,x}\right)_{i-1/2}\right]=0 \tag{7}$$

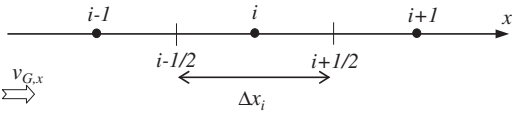

Figure 1. Sketch of 1D grid for cell-centered finite volume method.

It is the classical form of mass conservation equation for a 1D flow except additional mass transfers $hv_{G,i}$ through cells sides.

If the calculation grid is fixed but a boundary moves through the calculation domain with the velocity $v_{G,x}$, the equation is the same with term $v_{G,x,i}$ equals to zero everywhere except at instantaneous boundary location. For a solid boundary, as there is no mass exchange, fluid velocity u is equal to$v_{G,x}$ and corresponding advective flux in (7) is zero.

On the other hand, the cell length is changing along time. This can be taken into account by an occupancy rate parameter θ affecting the cell length.

2.2 *Generalization to shallow water equations*

Shallow water equations (SWE) can be written under a general form such as:

$$\frac{\partial}{\partial t}\mathbf{s}+\frac{\partial}{\partial x}\mathbf{f}+\frac{\partial}{\partial y}\mathbf{g}=\mathbf{S} \tag{8}$$

where $\mathbf{s}=$ unknowns vector; $\mathbf{f}$ and $\mathbf{g}=$ advective terms vector; and $\mathbf{S}=$ source terms vector.

Generalization of previous developments on a moving Cartesian grid provides for the integration over a finite volume of equation (7):

$$\frac{\partial}{\partial t}\bar{\mathbf{s}}\Delta x\Delta y+\oint\left(\mathbf{F}-\mathbf{s}\mathbf{v}_\mathbf{G}\right).\mathbf{n}\,d\Gamma=\bar{\mathbf{S}}\Delta x\Delta y \tag{9}$$

where $\mathbf{F}=[\mathbf{f},\mathbf{g}]$; $\mathbf{v}_G=$ grid velocity vector; $\mathbf{n}=$ normal vector; $\Gamma=$ cell outline; and $\Delta x=\Delta y=$ grid dimensions.

Developments are still the same if the grid is fixed but a boundary moves through the cell with ve locity $\mathbf{v_G}$.

Considering Figure 2, outline integral in (9) can so be expressed as:

$$\sum_{k=1}^{N}\int_{\Gamma^k}\left[\left(\mathbf{f}-\mathbf{s}\mathbf{v}_\mathbf{G}\right)n_x+\left(\mathbf{g}-\mathbf{s}\mathbf{v}_\mathbf{G}\right)n_y\right]d\Gamma^k \tag{10}$$

where $N=$ number of cell sides.

For SWE, without taking into account diffusive effects:

$$\mathbf{s}=\begin{Bmatrix}h\\uh\\vh\end{Bmatrix};\mathbf{S}=\begin{Bmatrix}0\\-gh\dfrac{\partial z_b}{\partial x}+ghJ_x\\-gh\dfrac{\partial z_b}{\partial y}+ghJ_y\end{Bmatrix} \tag{11}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

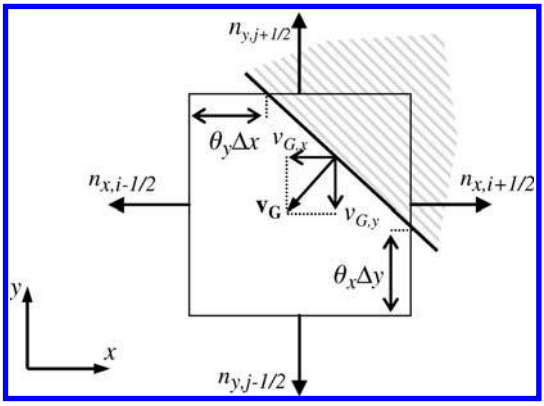

Figure 2. Sketch of the normal vector **n** components on a 2D finite volume and solid boundary moving with velocity $\mathbf{v_G}$.

$$\mathbf{f} = \begin{Bmatrix} uh \\ u^2h + g\dfrac{h^2}{2} \\ uvh \end{Bmatrix}; \mathbf{g} = \begin{Bmatrix} vh \\ uvh \\ v^2h + g\dfrac{h^2}{2} \end{Bmatrix} \quad (12)$$

where u, v = fluid velocity vector components along x and y-axis; g = gravitational acceleration; z_b = bed elevation; and J_x, J_y = friction slope components along x and y-axis, classically expressed by Manning's formula.

Considering sliding condition against boundary:

$$\mathbf{u}.\mathbf{n} = \mathbf{v_G}.\mathbf{n} \quad (13)$$

where $\mathbf{u}$ = fluid velocity vector.

Formulation for SWE, taking into account a solid boundary moving across grid, expresses finally using (11), (12) and (13) in (9) and (10) as:

$$\begin{aligned} &\frac{\partial}{\partial t}(\theta h) + \frac{\partial}{\partial x}(\theta_x uh) + \frac{\partial}{\partial y}(\theta_y vh) = 0 \\ &\frac{\partial}{\partial t}(\theta uh) + \frac{\partial}{\partial x}\left(\theta_x u^2 h + g\frac{h^2}{2}\right) + \frac{\partial}{\partial y}(\theta_y uvh) = \\ &\qquad -gh\theta\left(\frac{\partial}{\partial x} z_b - J_x\right) \quad (14) \\ &\frac{\partial}{\partial t}(\theta vh) + \frac{\partial}{\partial x}(\theta_x uvh) + \frac{\partial}{\partial y}\left(\theta_y v^2 h + g\frac{h^2}{2}\right) = \\ &\qquad -gh\theta\left(\frac{\partial}{\partial y} z_b - J_y\right) \end{aligned}$$

where θ = occupancy rate of the cell by water, i.e. percentage of the cell surface not occupied by solid; θ_x, θ_y = free portion of cell sides (Fig. 2), i.e. part of cell sides where mass and momentum exchanges can occur.

Pressure terms are not affected by a moving solid boundary, but other advective terms involving mass transfers are directly modified as the length of the cell side they can pass trough is reduced. Terms involving mean unknown value over the cell are also modified as the cell area decreases by solid intrusion.

3 NUMERICAL ASPECTS

3.1 *Wolf package*

Wolf software includes a series of interconnected numerical tools for simulating a wide range of free surface flows and transport phenomena, from hydrological runoff and river propagation to extreme erosive flows on realistic mobile topography. It has been entirely developed at the University of Liege for almost ten years and is still continuously enhanced (Pirotton et al. 2003).

In all the solvers, the space discretization of the conservative equations is performed by a finite volume method. Flux treatment is based on an original flux-vector splitting technique developed for Wolf. The hydrodynamic fluxes are split and evaluated partly downstream and partly upstream according to the requirements of a Von Neumann stability analysis (Mouzelard, 2002, Dewals, 2006). Optimal agreement with non-conservative and source terms as well as low computational cost are the main advantages of this original scheme. Constant or linear reconstruction of the variables is used to achieve a global first or second order of precision.

As we are mostly interested in transient flows and flood waves, explicit Runge-Kutta schemes are used for time integration.

Equations (14) have been implemented in Wolf2D, specifically devoted to the resolution of the SWE. It includes an efficient mesh generator and deals with multiblock Cartesian grids (Erpicum et al. 2004a). The algorithm is also designed to deal automatically with any moving boundary between wet and dry cells.

A spatially distributed hydrological solver, WolfHydro, a one-dimensional free surface flow solver, Wolf1D, and an optimization tool based on genetic algorithms technique, WolfAG, complete the Wolf software package (Pirotton et al. 2003).

3.2 *Coupling of models*

As an extension of the multiblock feature of Wolf2D, and thanks to the use of the same discretization and calculation techniques for all the solvers of Wolf software, a coupling between the 1D and the 2D models has been achieved. It allows simulating in a unified way large river reaches (in 1D) with a very fine computation of local areas (in 2D) without leading to prohibitive computation times (Erpicum et al. in prep.)

Copyright © 2006 Taylor & Francis Group plc, London, UK

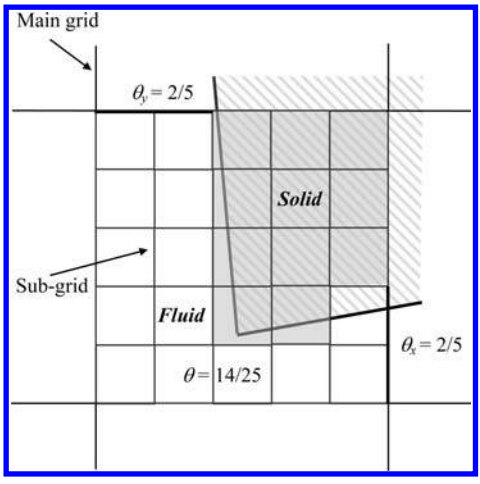

Figure 3. Example of application of the sub-grid to evaluate boundary location and occupancy rate in a mesh – *step* factor = 5.

3.3 *Sub grid approach*

In order to deal with mobile structures or boundaries inclined along mesh axis, a simple approach based on a regular sub-grid has been applied.

To calculate a cell water occupancy rate and the free length of its sides as a function of the solid boundary instantaneous position, the mesh is subdivided by a *step* factor. The position of the sub-grid cells gravity center automatically defines whether they are under water or not (Fig. 3).

The main advantage of this simple technique is that the cell water occupancy rate is never lower than one *step*, and thus calculation stability criterion is easily evaluated. In addition, updating the boundary position and cells occupancy rates is very easy and rapid.

If *step* equals one, boundary discretization is as rough as the initial Cartesian grid. When *step* increases, the representation of inclined boundary becomes better.

To solve the problem of a mesh leaving the calculation domain between to time steps while respecting the mass conservation principle, the following operation is performed. If the cell i leaving the calculation domain in time t:

$$0 < \theta_i^{t-\Delta t} \leq 1 \text{ and } \theta_i^t = 0 \tag{15}$$

Calculation in the entire domain is realized in time t for cells containing water, i.e. without cell i. After time step evaluation, water heights in the four cells adjacent to cell i is increased as a function of their respective occupancy rate:

$$h_l \rightarrow h_l + \frac{\theta_l h_l}{\sum_{k=1}^{4} \theta_k} \theta_l \text{ with } l = 1,\ldots,4 \tag{16}$$

On the contrary, when a cell enters the calculation domain, its hydrodynamic variables are initialized as a function of those of its neighbors containing water. The water height of all the adjacent meshes containing water and of the new mesh is leveled:

$$h_l = \frac{\sum_{k=1}^{M+1} \theta_k}{\sum_{k=1}^{M} \theta_k h_k} \text{ with } l = 1,\ldots,M+1 \tag{17}$$

where M = number of cells adjacent to cell i with θ higher than zero.

For the specific discharges, they are initialized to the mean value of the corresponding variables in the two adjacent cells containing water on the same axis.

3.4 *Stability criterion*

As explicit time integration scheme is used in the solver, the calculation stability criterion remains classically in the form of a Courant-Friedrichs-Lewy number *CFL* maximal value (Hirsch, 1988). For a Runge-Kutta scheme RK*PQ*, where P is the number of sub-steps to calculate one time step and Q is the order of precision of the method, *CFL* condition writes (Dewals, 2006):

$$CFL = \frac{(\|\mathbf{u}\| + c)\Delta t}{\Delta x} \leq \frac{R_0}{2} \tag{18}$$

where c = wave celerity; Δt = time step; R_0 = factor depending on the Runge-Kutta scheme.

In practice, *CFL* number is evaluated for each cell of the calculation domain to identify the local stable time step Δt_i, and the most restrictive one is chosen as the effective calculation time step Δt.

Because of the sub-grid, the effective size of the cells near an inclined boundary can be smaller than Cartesian steps Δx or Δy. A good approximation is the smallest length of the free sides of the cell (Fig. 3), and condition (18) becomes for cells near a mobile boundary:

$$CFL = \frac{(\|\mathbf{u}\| + c)\Delta t}{\min(\theta_y \Delta x, \theta_x \Delta y)} \leq \frac{R_0}{2} \tag{19}$$

4 VALIDATION AND CASE STUDIES

4.1 *Bore reflection*

The example of a bore reflection on an inclined bank in shallow water has first been investigated. A linear incident bore wave moves from right to left and encounters a solid boundary inclined at a fixed angle into the flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

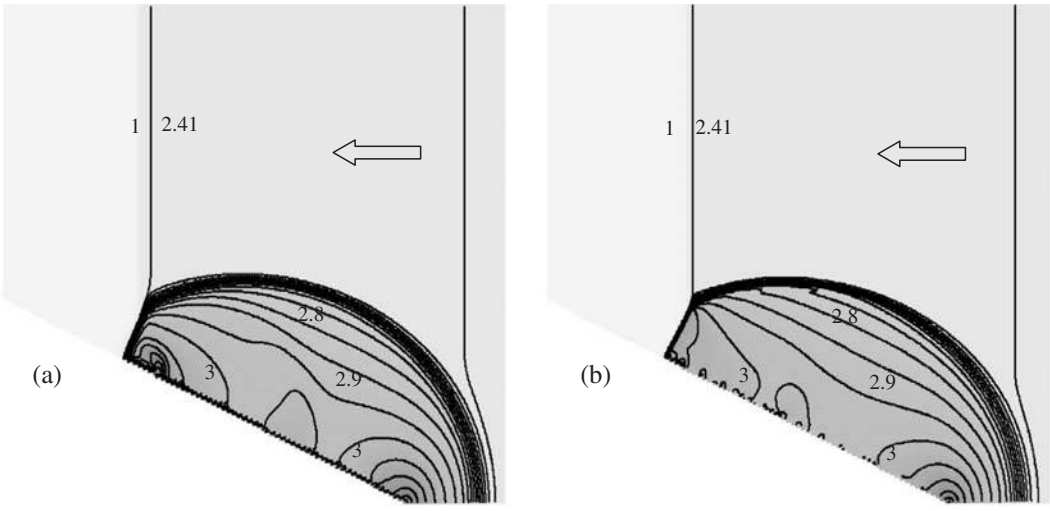

Figure 4. Single Mach reflection of a bore on an inclined solid wall. No sub grid (step = 1 – (a)) and sub grid with step = 5 (b) – Representation of water heights (m).

direction. The bore is therefore reflected (Causon et al. 2000) .

If the incident bore is defined by a Froude number F_s equal to 2.03 and the boundary is inclined of an angle α_w of 27°, a so called single Mach reflection occurs (Causon et al. 2000).

To assess the influence of the developments proposed in this paper, the simulations have been realized with the new model with and without a sub-grid (*step* = 5).

A grid with 200 × 200 meshes 5 cm long has been used. Initial conditions (Causon et al. 2000) were water at rest with a height of 1 m everywhere in front of the bore, and water height of 2.41 m with a specific discharge from right to left of 8.965 m^2/s behind the discontinuity. No roughness effects have been considered.

Results are presented on Figure 4. Even if the two calculations show physically meaningful results, less spurious effects near the inclined boundary are observed with the new model. Reflected shock is also sharper, and so the results are globally better.

4.2 *Moving plate*

Consider a plate moving with constant velocity v_P in a frictionless horizontal rectangular channel containing water initially at rest with height h_0 (Fig. 5). Under the assumption that fluid velocity near the plate is equal to the piston velocity, the analytical solution of the waves propagation in the channel can be calculated, both behind and in front of the plate.

Indeed, from mass and momentum conservation equations applied on both sides of the flow discontinuities, Rankine-Hugoniot shock propagation principle

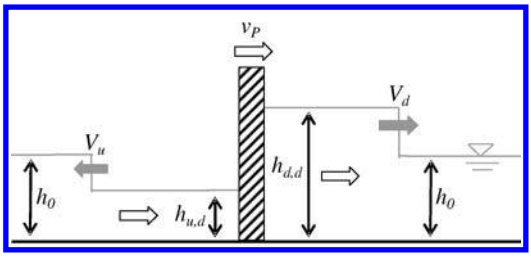

Figure 5. Sketch of shocks propagating around a plate moving with constant velocity v_P in a channel where water is at rest with height h_0.

provides two relations linking the two unknowns: front velocity V and water height of the waveh_d:

$$V = \underbrace{\frac{h_d v_P}{h_d - h_0}}_{mass} = \underbrace{\frac{v_P^2 h_d + \frac{g}{2}\left(h_d^2 - h_0^2\right)}{v_P h_d}}_{momentum} \quad (20)$$

For example, if $h_0 = 1$ m and $v_P = 0.2$ m/s, $h_{d,d} = 1.065$ m and $V_d = 3.28$ m/s downstream of the plate, while $h_{d,u} = 0.937$ m and $V_u = 2.98$ m/s upstream.

The numerical simulation of this test case has been realized.

A channel 1 km long and 1 m wide has been modeled using 1 to 1 m regular meshes. A plate 2 m thick divided it into to reaches 499 m long. No bed slope nor friction effects have been considered. All the simulation limits were assumed to be impermeable.

Hydraulic initial condition was water at rest with height $h_0 = 1$ m everywhere in the reaches.

Copyright © 2006 Taylor & Francis Group plc, London, UK

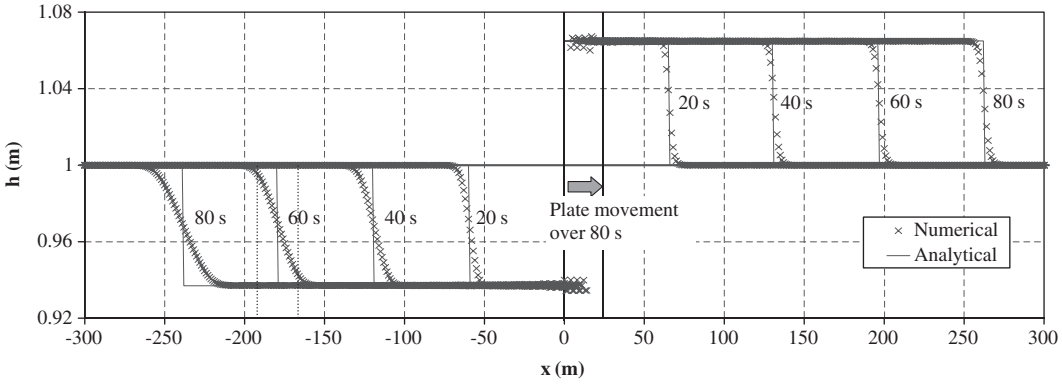

Figure 6. Waves propagation in a rectangular channel induces by the movement with a constant velocity $v_P = 0.2$ m/s of a vertical plate – Comparison between numerical results and analytical solution at times 20, 40, 60 and 80 s. Water level initially at rest at height $h_0 = 1$ m.

At time t = 0 s, the plate instantaneously began to move from left to right with a constant velocity $v_P = 0.2$ m/s. Sub grid 0.01 m ($step = 100$) has been used for plate movement.

Numerical results are illustrated in Figure 6. Water heights and propagation times are in satisfactory agreement with the analytical solution.

The shock propagation in front of the plate is well represented, with a sharp front moving in accordance with the analytical celerity. Behind the plate, the wave is smoother. This is in agreement with the physics of the problem and can be explained by the characteristics theory for shallow flows.

The celerity c of a wave in water with height h is:

$$c = \sqrt{gh} \tag{21}$$

In the channel, water height is $h_0 = 1$ m and thus waves celerity c_0 is 3.13 m/s.

In front of the plate, front velocity V_d is higher than waves celerity c_0 and thus a shock occurs. Beside the plate, front velocity V_u is a bit smaller than waves celerity c_0 and the front is smoothed as information propagates faster in the fluid than the wave.

Considering more precisely the characteristics curves behind the plate (Pirotton, 1994), only two lines exist. The faster one has a celerity $-c_0$, as explained above, and the second one has a celerity equal to:

$$\frac{3}{2}v_P - c_0 = -2.83\ m/s \tag{22}$$

Between the moving plate and this second characteristic, nothing else occurs and water height is constant.

For each time, the wave upstream the plate is bounded between two instantaneous positions defined by these two characteristic lines. For example, for $t = 60$ s, x-abscissa related to the faster characteristic is equal to 187.8 m and those related to the second one is equal to 169.8 (Fig. 6).

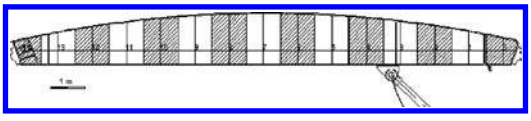

Figure 7. Shape of a downstream gate of the new Lanaye lock.

4.3 *Lock door movement*

In the scope of the studies of a new 225 × 25 × 14 m lock in Lanaye on the river Meuse in Belgium, numerical simulations of the hydrodynamic effects of the downstream mitering gates movements have been realized. Both opening and closure operations have been modeled.

The door is made of two gates, symmetrical regarding lock longitudinal axis and vertically articulated on lock walls. Plane dimensions of a gate are 14.3 m long and 0.9 to 1.5 m wide (Fig. 7). Its height is 17.5 m.

Water height in the lock and the channel, during door movement, is 4.8 m. Water is initially at rest.

By symmetry, only a gate and half a lock have been simulated. Cartesian meshes from 1 × 1 m to 0.2 × 0.2 m have been used. The coarser grid was for lock and downstream channel, while the finer one was for door location.

The lock layout has been modeled in 2D, with the upstream lock wall represented as an impermeable boundary. Downstream, the channel is going to the Meuse river. A suitable boundary condition has to be used to allow waves propagation without introducing spurious numerical reflections. 2D simulations domain has so been completed with a reach modeled in 1D. Thanks to this original approach, wave

Copyright © 2006 Taylor & Francis Group plc, London, UK

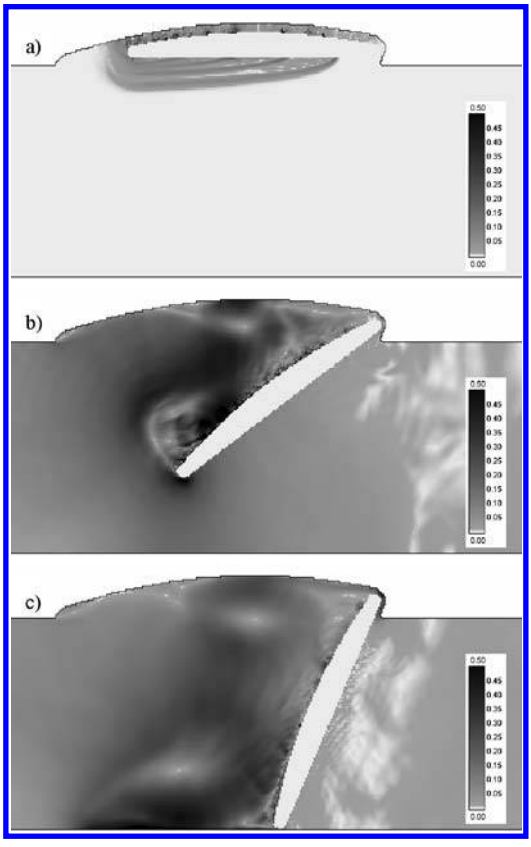

Figure 8. Instantaneous velocity fields (m/s) near the gate during closure operation to time t = 2 s (a), 50 s (b) and 100 s (c).

propagation is very well represented, without any numerical reflection at the boundary between 1- and 2D models (Erpicum et al. in prep).

The area for the 2D simulation is 470 m long and 30 m wide, with 27,000 meshes. The 1D reach is 8 km long with finite volume cells of 1 m.

A sub-grid with *step* equal to 10 has been used. A representation of the door with regular meshes of 0.02×0.02 m is thus performed.

Electromechanical engineering designers have provided the kinetics of the door movement. Time for a gate operation is 105 s. The course angle is 68.1°. Maximal angular velocity is 0.8°/s.

Examples of instantaneous results for the gate closure are shown on Figure 8 in terms of flow velocity fields. The simulations allowed assessing water levels variation along the gate faces, and thus evolution of the hydrostatic resultant along time to be counterbalanced by the door mechanism.

To complete this numerical approach, experiments are currently carried out at the Laboratory of Hydraulic Constructions of the University of Liège.

5 CONCLUSIONS

2D finite volumes free surface flow solvers are of great interest in most fields of hydraulic engineering. Among them, those based on Cartesian grids, such as Wolf2D, are simple, accurate and require less storage capacities than models using unstructured meshes.

Even if Wolf2D multiblock or coupling potentialities allow mesh refinement near interesting areas without increasing dramatically the number of cells and thus computation time, the main problem of structured grids remains their inability to model boundaries inclined compared to Cartesian axis, and thus complex geometries. Fluid-structure interaction modeling has to face the same problem to accurately take into account the movement of a solid on the simulation domain.

A first approach has been developed and presented in this paper to deal with boundaries inclined compared to axis or moving structures on Cartesian grid in Wolf2D. Based on the cut cell approach, the method is simpler than classical ones as it uses a sub-grid of the initial Cartesian meshes to assess structure instantaneous position. It allows keeping the advantages of regular grids in terms of simplicity, accuracy and storage capacity and is weekly restrictive on solver stability criterion.

The model showed its potentialities through several test cases and an application to the computation of the hydrodynamic fields induced by a lock-door movement. In this last case, 2D model has been coupled with a 1D one to extend the simulation domain without increasing too much computation time.

Improvements of the model should be considered to increase the precision of fluxes evaluation near moving boundaries and to refine the representation of inclined ones. For example, more precise calculation of the structure occupation rate in a cell should be realized.

ABSTRACT: Remote sensing contributes high resolution data permitting a-priori parameterization for automation of the model generation process in hydroinformatics. This likewise holds for the representation of the fluvial topography and the roughness parameterization of river systems. The later is considered throughout this paper, focusing on parameterizations based on spaceborne QuickBird imagery, currently providing the highest resolution commercial data source of its kind. An automated method to derive reproducible roughness classes from a panchromatic and multispectral image bundle is presented, suiting to extract land cover with sub-meter pixel resolution via a knowledge-based classification. A scheme to aggregate, parameterize and assess the quality of transformations to hydraulic roughness classes in discrete meshes is presented and illustrated for an alluvial stream in the North German lowlands. The impact of high resolution roughness parameterization is validated for a comparison with a parameterization based on a coarse field survey.

1 INTRODUCTION

Roughness parameterizations together with representations of topographic gradients are essential concerns while building hydronumeric models to solve the shallow water equations. This paper assesses benefits for the physical quality of 2D hydronumeric models from high resolution roughness parameterization via spaceborne imagery.

For this purpose this paper suggests to exploit the panchromatic and multispectral image layers of highest-resolution commercial remote sensing satellites. It focuses on QuickBird imagery and suggests the use of knowledge based classifications to derive land cover classification with 0.61 m resolution. This accuracy of this classification is shown to be highly reliable. It exceeds rough aggregations of field surveys or cadastral coarse data sets. Ultimately it provides an up-to-date definition of the land cover.

Successive aggregation together with a series of transformations converts the pixel-based land cover classes to an adequate set of discrete, hydraulic distinct roughness classes. An automation of this processing stage primarily uses the definition of hydraulic relevant classes being aggregated on pixel level prior to a discrete transformation. Whereas this automation conceptually behaves similar to manual assignments it inherently provides the opportunity to express the quality of the discrete parameterization as metadata, which can be used for mesh adaptations enhancing the roughness representation.

Apart from being far more efficient in the parameterization than initial captures via field surveys, this concept provides a reproducible and highly accurate parameterization for physical based modeling concepts.

2 IMAGE SOURCE

The QuickBird image has been acquired on September 21, 2005. Purchased via Eurimage, European representative of DigitalGlobe™, its acquisition to no-cloud cover conditions and an off-nadir angle of 7° was initialized at 10:39:50. Delivered in WGS84-projection ($\mathrm{Lat/Lon_{NW}} = 54.045°/9.643°$; $\mathrm{Lat/Lon_{SE}} = 53.919°/9.822°$) it covers 64 $\mathrm{km^2}$ and represents 17 km river as buffer along the river and its floodplains at Kellinghusen. The total coverage

Copyright © 2006 Taylor & Francis Group plc, London, UK

denotes the minimum order size. The lateral coverage of about 5 km reflects the minimum requirements of the viewing geometry. The covered reach of River Stör ranges from Wittenbergen up to Willenscharen. It's tributary Bramau in covered to Wrist. Since October 2005 this image is listed in the DigitalGlobe ImageLibrary™.

Achieved as standard imagery the image processing level two of three includes radiometric and geometric corrections for the panchromatic (PAN) and multispectral (MS) image layers. Subsequent pansharpening merges both image layers via wavelet transformations, fusing the lower resolution of the multispectral channels (B, G, R, NIR at 2.4 m) with the higher resolution information of the panchromatic channel (B/W at 0.61 m) to enhance high resolution feature identification via strong edge detection in the image.

3 LAND COVER CLASSIFICATION

Unsupervised pixel classification concepts adequately amend attempts to automate meshing processes in hydroinformatics. The hierarchical scheme accounting for the classification of QuickBird image pixels to land cover classes (LC_{QB}) is illustrated in Figure 1, comprising a set of methods and associated rules.

The pre-structuring-stage of the image classification scheme reduces inter-band correlation via principal component analysis. This image transformation essentially minimizes the redundancy in the multispectral bands, reduces the dimensionality of the original data set and serves to speed-up the subsequent automated classification. Additionally the pre-structuring-stage determines texture measures. The frequency of tonal change on an image, aggregated by units of features that can be smaller than the image pixels (e.g. leaves of trees and their shadows) reflects their individual size, shape, pattern, shadow and tone. Image texture supports separation of features with similar reflectance. Results of the pre-structuring-stage are a series of individual image layers identifying suitable areas for extractions of land cover specific spectral signatures. These characteristic reflection properties over the bands of the image ultimately provide the means to assign each pixel to a specific land cover class in an iterative classification involving three classes of rules throughout the knowledge based modeling-stage: formalized experience of the human interpreter (e.g. 'trees cause shadows'), spectral characteristics derived from large sample sets (e.g. 'clear water has a NDVI below zero') and existing 'old' or 'coarse' land cover data enhancing the classification of pixels with similar spectral signatures (e.g. CORINE land cover classifications).

Rules for the iterative, knowledge-based pixel classification are derived throughout classifications in the

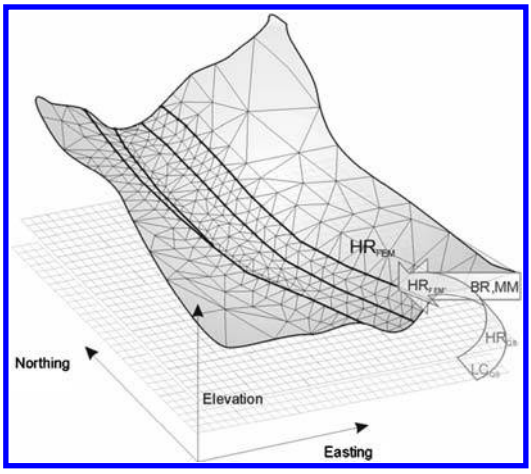

Figure 2. Roughness parameterization scheme.

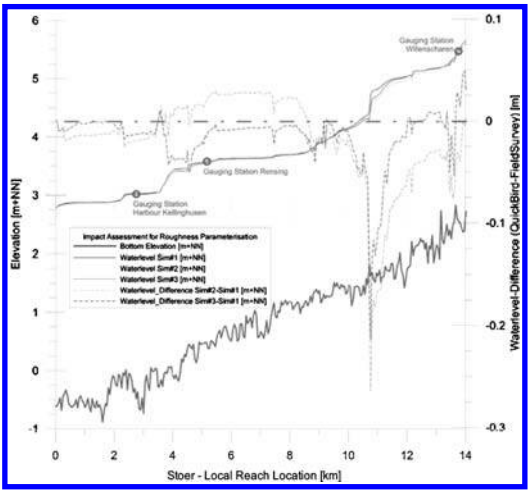

Figure 3. Impact of high resolution roughness parameterization on water level. Reach bottom track.

The aggregation of pixel based land cover classes LC_{QB} to pixel based, hydraulic relevant roughness classes HR_{QB} involves specific aggregation schemes based upon hydraulic consciousness for considered fluvial domain, the considered boundary conditions and the classification potential of the classification scheme. However, for any aggregation this simple key ensures reproducible HR_{QB}-classifications.

Identification of hydraulic roughness classes via this transformation maintain an average user and producer accuracy exceeding 80%, based on a field validation four weeks after image acquisition (Rath, 2006), facing similar challenges throughout identification of relevant features in the fluvial domain as Leckie et al. (2005) in the vicinity of shadows. This aggregated global accuracy slightly exceeds recent publications addressing the roughness parameterization, e.g. van der Sande et al. (2003) using IKONOS imagery. However it can be acknowledged that specific habitat types may be identified higher classification accuracies exceeding 90% while remaining on the land cover level (Frick et al., 2005).

4 ROUGHNESS AGGREGATION

Integral roughness parameterizations for a discrete area, e.g. a finite element E comprising all HR_{QB}-contributions represented within its area are neither computationally adequate nor physically required. Similar to visual analysis, statistical distribution of individual contributions of HR to E are considered. The simplest yet coarsest approximation for roughness class assignments to E is expressed via the dominant HR member in the finite element, subsequently being referred as majority fraction.

$$HR_{E,ideal} = \int_{i=1}^{m} HR\,d\Omega_E \quad , i = \{1,...,m\}^T \tag{1}$$

$$\overline{HR}_E \; ; \; HR\left(\max_i \left(\frac{A_{HR(i)}}{\Omega_E} \right) \right) \quad , i = \{1,...,m\}^T \tag{2}$$

Suitable indicators for the roughness parameterization are the majority fraction (MF), reflecting by the ratio A_{HR}/Ω, as well as the number of competing roughness classes inside a discrete surface element, i.e. $m \in E$, shortly being referred as diversity index (DI). The majority index suits an indicator for the element adequacy for the discrete representation of the hydraulic impact of the land cover. The diversity index reflects the spectral homogeneity in the discrete element and likewise describes the adequacy of the global mesh discretisation for roughness parameterization.

An aggregated composition of ten roughness classes is considered (i.e. sealed, open soil, mewed grassland, high dry grass, tall moist grass, intensive field/meadows, swamps/canebrake, tree, shrubs, water). For these ten classes and the river system being modeled (17 km length, average element size 230 m^2) it has been revealed that the standard-deviation of the diversity for all classes ranges relatively stable in a range of 1.2–1.7, whereas the mean diversity may vary by a magnitude of two. Sealed surfaces and the bathymetry (or the water surface) are relatively homogeneous represented in the considered mesh with an average diversity of about 2.2 (while the MF = 40% indicates DI = 1), whereas an average diversity of

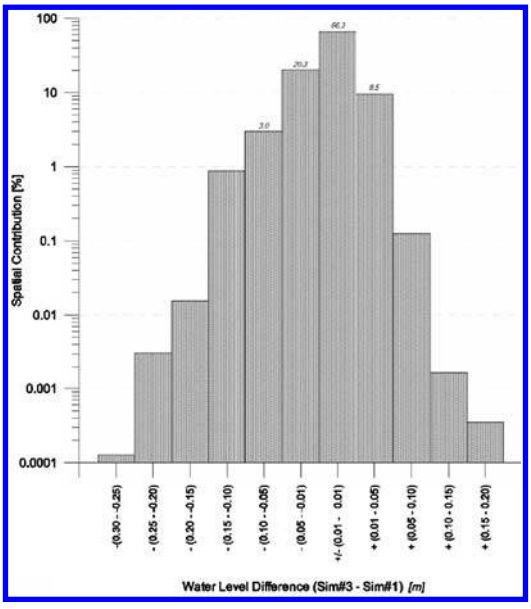

Figure 4. Impact of high resolution roughness parameterization on water level. Spatial contributions.

four is exceeded by the representation of rather heterogeneous land covers, i.e. mowed grassland, tall moist grass, swamps/canebrake (where the MF = 36% indicates DI = 4).

Denoting the lacking opportunity to publish colored prints this paper refers to Rath (2006), revealing the spatial correlation of the pansharpened image, the classifications and the validation of the mesh parameterization.

Prior to proceed with the parameterization of this automated roughness parameterization this chapter refers to Figure 2, to point out that a continuous transformation of HR_{QB}-classes from image space to discrete model space, i.e. HR_{FEM}, requires to acknowledge two additional data sources in hydroinformatics, ensuring continuity in the surface parameterization within the hydraulic context. These classes comprise spatial information on man-made structures (MM) and the parameterization of the bottom roughness (BR). Their implementation can be likewise use the MF-criterion, whereas the elimination of unclassified elements (about 2%) requires supervised assignments overcoming misleading parameterizations particularly in the vicinity of the stream, e.g. shadows due to trees ranging above the river.

5 HYDRONUMERIC VALIDATION

Apart from providing a fast, efficient and physically accurate parameterization coming along with a quality review, this parameterization provides the means to achieve parameterizations that are by far more physically realistic. This particularly holds for simple roughness models, here comprising the constant eddy viscosity concept to represent the Reynolds stresses, a product of depth-averaging the Navier-Stokes equations. In analogy to modeling viscous shear stresses this concept assumes proportionality for the turbulent shear stresses to the velocity gradients of the average flow. The constant representation of the turbulent viscosity ν_T is a major simplification which particularly reveals its impact when focusing on the resistance of vegetation, being substituted mixing length concepts. However, the constant eddy viscosity concept is widely used and its parameterization frequently exceeds physical based ranges of rarely available measurements by several orders of magnitude (Lippert, 2004), introducing a dampening of the fluid motion.

This effect for constant eddy viscosity models is significantly reduced via the presented high resolution roughness parameterizations. It enables more heterogeneous roughness assignment to individual finite element representation as assignments on the basis of field surveys or rather coarse base data would support. This higher heterogeneity can indeed physically be justified on the basis of the pan-sharpened image. This heterogeneity requires and permits that model calibrations remain with their parameterizations in tighter bounds of physically based measurements. Maintaining comparable parameterization for the bottom roughness on the basis of Nikuradse's equivalent and roughness k_s this paper achieved reductions of ν_T for class aggregations being referred as sealed, field, grass and bathymetry. A reduction factors between three and five could be achieved, leading to a parameterization of the turbulent eddy viscosity exceeding measured magnitudes merely be two. However, apart from enabling to achieve higher adequacy for the physical basis of the model, the higher resolution supporting the roughness parameterization does not reveal a significant spatial on the global water level. For the shallow topography of the considered stream Stör in the North German lowlands Figure 3 reveals that merely regions of higher surface inclination or constraint due to bridge are sensitive towards the resolution roughness parameterization.

The effect of strongly localized water level differences is illustrated in Figure 4, revealing that two third

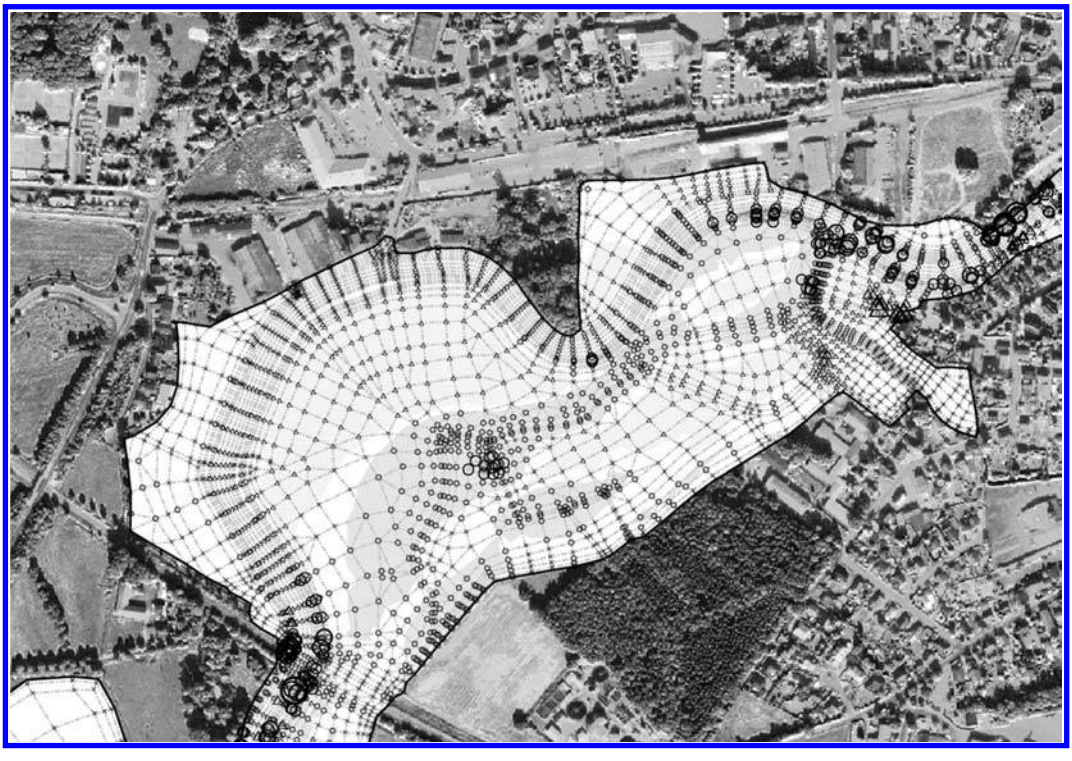

Figure 6. Flood peak breaking out of the meandering river bed. Flow field deceleration on the short-cut of the floodplains.

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the fluvial domain comprises a neglectable range of ±1 cm. The water level and the flow velocity merely differ in 4% of the considered fluvial domain more than ±30 cm.

6 CONCLUSIONS

Within the limitations of grey-scale image reproduction this paper points out that high resolution imagery may contribute to accurate and efficient roughness parameterizations. Their performance in the context of water level computations is similar. Differences to parameterizations from field surveys affect localized areas which in the considered lowlands amount to 4%. However the physical parameterization can be shown to be more accurate, which particularly holds for simple turbulence models. Consequently, high resolution roughness parameterizations might particularly contribute to enhance model predictions for steeper topographic gradients and likewise suit to generate fast model updates in regions where insufficient or aged data bases are available.

Multi-attribute decision making and cost-sharing tool for planning urban river rehabilitation schemes

M. Brilly & S. Rusjan
Faculty of Civil Engineering, University of Ljubljana, Slovenia

ABSTRACT: River rehabilitation is a long-term, costly and complex process involving numerous actions. The process of development via a bottom-up approach is described in the paper. The emphasis in the presented methodology is in active involvement of stakeholders and citizens who are driven with their particular interests. The integrity of action-taking is established at a lower level and in a smaller stretch of a river and its relevant corridor. Crucial is the direct involvement of interested parties in the decision making process and actions. The willingness to cooperate and the level of social capital are the key elements. The operation is integrated and driven by a steering committee recognised by the involved parties. The consideration of stakeholder's interests is provided through the application of the Multi-Attribute and Cost-Sharing model developed on the Glinscica stream case study.

1 INTRODUCTION

Urbanisation and river regulations go back to ancient times. They gradually evolved in the 19th century and intensified in the second half of the 20th century with irrigation, water power development and river regulations for urbanisation of inundated land. River regulation and deterioration have a long history lead by economically defined interests and simple decision-making schemes. Today, urban river corridors are loaded with different interests, which are the main obstacles to river restoration, which involves the enlargement of the stream channel and rehabilitation of river banks. That is also the reason why river rehabilitation is costly and time consuming. It is difficult to perform river restoration only by short and intensive action, thus trying to re-establish the entire river watershed. Mostly, river restoration is a set of broad actions different in scale, size, timing etc., which step by step redesign the river and its watershed. The implementation depends on different financial sources and decision-makers driven by different interests, which should all be coordinated in a common task. Such a complex process with numerous actors should include social analysis and tentative actions.

Many guidelines and manuals have been written on river restoration and environmental protection (UNEP, 2004; Fogg and Wells, 1998; EU 2002). Quality ideas for implementation should be adapted to the own specific natural situation and social conditions. Examples of good practice could provide encouragement but they cannot simply be transferred or copied elsewhere without a critical review of actions. Action-taking should be tailored to the local natural and social conditions.

The problem of different, conflicting interests has been frequently translated into the Multi-Attribute Decision Making procedures which try to ensure active and transparent consideration of involved stakeholders and their effective communication with decision makers (Moshkovitch et al., 2002). Therefore, in the concluding section of the paper, a description of the Multi-Attribute Decision Making and Cost-Sharing model developed on the Glinscica case study in the urban area of Ljubljana, Slovenia, is given.

2 STRATEGY OF IMPLEMENTATION

2.1 *Establishing the framework*

Water management policy proceeds from development to management. The importance of environmental sustainability has been recognized overall. The decision making should integrate more interests, calls for a greater decentralization, more participation and greater financial viability. A new paradigm of Integrated Water Resources Management (IWRM) has been developed in the guidelines of WFD and worldwide. The IWRM is complex, requiring an almost idealistic approach (Brilly 2001). Today, there are no economically well-defined interests and simple decision making schemes that would involve few stakeholders. The results should provide an environmental benefit, which is, however, difficult to evaluate financially.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Actions should be organised and driven by a body recognised by all involved parties (UNEP, 2004). Efforts must involve a pro-active participation and contributions of both governmental and non-governmental stakeholders. An NGO or the private sector can act as a partner in action. The form of organisation depends on the local practice, legislation and size of action. Actions should take place at the lowest possible level, then demand-driven approaches can be applied. The lowest level of participation is usually considered by means of providing the access to information and active dissemination of information (HarmoniCOP, 2005). All stakeholders should be involved from the beginning in selecting the appropriate solution and management options. Attention must be given to local demands. Comprehensive analyses of present and future societal demands are required, and strong support and acceptance from the local communities should be secured. With such analyses realistic choices can be made from a wide range of technological, financial and management options. River rehabilitation must include maintenance and care, which is not possible without full co-operation of locals and stakeholders.

In management and decision-making processes transparency should be ensured, establishing trust of the inhabitants. Early, continuous, targeted and transparent communication between all parties is required to establish firm partnerships. Management of problems is related to the interests, knowledge and experience. The idealistic technical approach lies in sophisticated modelling with all necessary data including the assessment of possible risk. The lack of data and knowledge asks for a more simple analysis with good expert estimation, but such a system fails if experts develop a particular interest or if they want to promote particular solutions. Independent facilitators of the decision making process could be beneficial when problems are particularly difficult with opposing interests of stakeholders. A third party also helps to avoid that the competitive authorities dominate in the process.

Regardless of the approach chosen, each river restoration asks for a flexible, tailor-made set-up. Each necessary step can be taken at different points in time, depending on available resources and capabilities. It is thus advisable to apply a well-defined logical framework, consisting of a comprehensive set of logically related tasks:

1. Identification of the need for action
2. Establishing a steering committee
3. Setting boundaries
4. Development of preparation plan
   - Review of information
   - Goals and objectives (new techniques)
   - Identification of needs and opportunities (RBD plan)
   - Identification of financing sources
   - Formulation of management plan
   - Setting objectives
   - Formal adoption.
5. Implementation
   - Operational management: on-site versus off-site
   - Institutional arrangements, such as capacity building, awareness raising, and
   - Public participation
6. Monitoring and evaluation
   - Monitoring
   - Evaluation

The incentive for action may come from several sources: state, town council, NGO, stakeholder or interested groups, and individuals. The administration may initiate the restoration effort as a result of a directive to implement the RBD plan. Citizen groups or groups with special cultural or economic interests (e.g. landowners, sport fishermen) may also initiate a restoration effort. Others might undertake river restoration as part of a broad initiative that is funded from various sources and addresses a diversity of interests and objectives. The local representatives familiar with the situation should be involved from the start.

2.2 *Steering committee*

An important step in the process is the formation of a steering committee. The steering committee includes key stakeholders, interested citizens, public officials, and any other groups or individuals who are interested in or might be affected by the restoration initiative (Fogg and Wells, 1998). Local citizen groups comprise multiple interests that hopefully share a common concern for environmental conservation and interest of local community. Such broad-based participation helps ensure that self-interests of administration do not operate the process from the top down. The steering committee ensures high level participation in the development and implementation of the revitalization action. Interested parties will participate actively in the planning process by discussing issues and contributing to their solution as members of the steering committee. They will share the decision making and objectives. Shared decision-making implies that the interested parties not only participate actively in the planning process, but also become partly responsible for the outcome (EU, 2002).

The steering committee generally takes care of the following:

- Carrying out restoration planning activities.
- Coordination of development of the preparation and implementation plan.
- Identifying public's interest in the restoration effort.
- Making diverse viewpoints and objectives known to decision-makers.

Copyright © 2006 Taylor & Francis Group plc, London, UK

– Ensuring that local values are considered during the restoration process.

It is important to remember that the true role of the steering committee is to advise the decision-maker or sponsor (the agency, organisation, or individuals that support the restoration effort) on the development of the restoration plan and execution of restoration activities. The primary decision-making authority should be in the hands of the stakeholders. The steering committee will provide recommendations and inform the decision-makers of various restoration options and the opinions of the various participants. It is important to note that the decision-maker, as well as the steering committee, may be composed of a collection of interests and organisations. Other relevant sectors should be included, such as urban development and implementation of the RBD plan. Although the steering committee will play an active planning and co-ordinating role, it will not always make the final decisions. It is thus important that all members of the steering committee understand the issues, develop practical recommendations, and achieve consensus (Fogg and Wells, 1998). The identification of the key participants is the most critical issue. The exact number of groups or individuals that will compose the steering committee is difficult to determine and is different from situation to situation. Membership in the steering committee should be free and open. In general, it is important that the group should have representatives of all involved stakeholders, landowners and citizens, who are in touch with the action.

The steering committee activities require a lot of precious voluntary work. The members are in place according to their interests. The steering committee could collect its own funds from donors or own participatory financing action or technical support. There might be cases where a landowner or stakeholder chooses to take on all the responsibilities of the steering committee group in addition to playing the leading or decision-making role. Regardless of the number of individuals involved, it is important for all project participants to note that the usual duration of a project is 2 to 3 years (Fogg and Wells, 1998). There are no guarantees that every project will be a success, and in some cases a project may fail simply due to lack of funds, lack of time or lack of the willingness to act. All participants must be reminded at an early stage to set realistic expectations for the project and for themselves.

2.3 *Preparation plan*

The preparation plan is an essential document for the task force action. It contains major information for possible solutions, including cost, legislative issues and control of possible funding. An interdisciplinary team should carry out the study with the suggested contents. The size of the document differs from a short memorandum to full-sized detailed project documentation, and is situation-specific. Each stream corridor that is targeted for restoration is unique. Each stream targeted for restoration is unique. A project goal of restoring multiple ecological functions might include the channel systems, the active floodplain, and possibly adjacent buffer areas that have the potential to directly and indirectly influence the project. In the urban areas, land uses close to the stream bank are a major obstacle for environmental protection; however, the restoration of the surrounding land is an opportunity for restoration of the nearby river. The restoration stretch of the river should be as wide as possible. The steering committee should optimize the interests of the participants with the available funds. A wide river corridor restoration is possible outside of urban areas, but inside, the development is limited by land use and town development plans. The objective of the past river regulation works was to take the minimum space for the river flow and demand for flood protection produced channelisation of the river with the minimum roughness coefficient. Any restoration work in such a channelized stream will increase the roughness and the water level during floods. The additional space for flood flow inside the river corridor is crucial for possible restoration measures. The problem is how much public land is available in the corridor and how high is the willingness of landowners to support such project.

Identification of funding sources is often the first and most important step toward an effective stream restoration. The funding may be minimal or substantial, and it may come from a variety of sources. Funding may come from EU, country or local sources that have recognised the need for restoration. Funding may come from any entity that has taxing authority. Charities, non-governmental organisations, landowners' associations or any developer that invested in river corridor and voluntary contributions are other funding sources. Regardless of the source of funds, the sponsor will almost certainly influence restoration decisions or act as the leader and decision-maker in the restoration effort. The attributes in the tool for assessing the potential for rehabilitation are weighted taking in account financial sources for action.

3 MULTI-ATTRIBUTE DECISION MAKING AND COST-SHARING MODEL FOR THE GLINSCICA CASE STUDY

Problems of Multi-Attribute Decision Making (MADM) are encountered under various situations where a number of alternatives and actions or candidates need to be chosen based on a set of criteria or attributes (Aouami et al. 2003; Cagno et al., 2001). Advantages of MADM are that it facilitates community-based collaborative

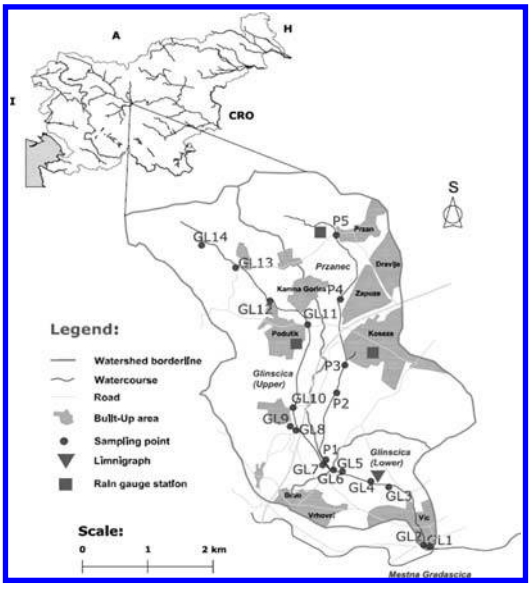

Figure 1. Glinscica stream study area with ecohydrological monitoring system.

Figure 2. Heavily regulated channel of the Glinscica stream.

Table 1. List of the main stakeholders.

Stakeholders	Interests
Biotechnical faculty	– Stream as a natural scientific testing ground – Ecology: Bio-diversity, Composition and abundance of aquatic flora, vertebrate fauna, Channel vegetation, Bank vegetation – Aesthetics: Welcoming area – River- Flood vulnerability – Accessibility: River crossings
Residents of the Municipality of the city of Ljubljana	– Water quality: Colour, Odour – Ecology: Nature of surrounding catchment – Aesthetics: Landscape perception, Natural components – Social importance: Activities on river front (recreation), Accessibility
Fish angling society	– Water quality: Dissolved oxygen, BOD, pH, Pollutants, Temperature – Ecology: Abundance and bio-diversity of fish population, River morphology, Water abundance (pools), Channel and bank vegetation
Municipality of the city of Ljubljana	– Ecology: Planning of the green system of the city, Development of thematic parks – Urban development: University center, Development of traffic infrastructure – Aesthetics: Natural components inside the urban area

decision-making, avoids some of the ethical, theoretical and practical shortcomings of conventional economic approaches, does not require assigning monetary values to ecological services, allows consideration of multiple attributes and is not culturally biased (Prato, 1999).

Comparing the alternatives is the key to decision-making in such cases. Often in planning a river rehabilitation project, we are faced with making a choice among various options – alternatives. If the only consideration is costs, we can use economic principles to guide our selection. Many times, however, the choice involves both strictly quantitative measures (such as costs) and strictly qualitative measures (aesthetical aspects or even political viability). In such cases we must use a process to approximately "quantify" all measures at a similar, numerical scale, so that we can perform mathematical calculations which assist the decision maker to consider preferences and interests of all parties involved (stakeholders).

3.1 *Structure of the model*

The Glinscica stream watershed is positioned in the urban area of the city of Ljubljana, Slovenia. The study site area with the ecohydrological monitoring system is shown in Figure 1.

The Glinscica stream MADM and Cost-Sharing model is based and developed on the database which includes hydrological data, data on water quality, water flora and fauna data of the study site (Brilly et al., 2004). A two-year ecohydrological monitoring established on the Glinscica watershed showed that the ecohydrological degradation of the stream is mainly the consequence of the heavily regulated stream channel (Brilly et. al., 2004), Figure 2. Additionally, main stakeholders were identified together with the range of their interests. These stakeholders were the Biotechnical faculty of the University of Ljubljana as the major owner of the land in the study area, residents of the Municipality of Ljubljana as the users

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the surrounding urban green areas, the fish angling society and the Municipality of the city of Ljubljana. Their interests are listed in Table 1.

When developing the model the problem we tried to solve was not only how to achieve an agreement and cooperation between key stakeholders with their different, potentially contrasting interests. We were trying to develop a tool that would enable decision makers or key stakeholders (organized in the steering committee) the distribution of costs for rehabilitation measures among interested parties.

The model consists of five main parts:

1. *Interface*. The "Interface" spreadsheet enables the analysis of different combinations of relative importance weights assigned to the main objectives and the numerical and graphical comparison of different alternatives (Fig. 1). The combination or the preference of a certain objective expressed by a relative importance factor should be based on the stakeholder agreement.
2. *MADM-WAM*. The "MADM-WAM" spreadsheet is used for rating the impact of a certain alternative on the attribute. An attribute is by definition a measure (criterion) which enables the assessment of the amount of satisfaction of a certain objective.
3. *Alternatives*. Alternatives are combinations of certain elements of a rehabilitation scheme. The selection of the elements of the rehabilitation scheme and the alternatives are made by the decision maker. The elements of the rehabilitation scheme should be expressed by approximate costs for their implementation. The development of different alternatives (combinations of the elements of rehabilitation scheme) should consider possible budget restrictions which are not included into the model.
4. *Stakeholders*. The list of main stakeholders together with their interests is included in the model so that the decision maker has an overall picture of the preferences for a certain state of the water body and also possible conflicting interests.
5. *Cost-Sharing.* The main idea of Cost-Sharing is distribution of costs for realization of selected alternatives among interested stakeholders. The basis for Cost-Sharing derives from performance of each alternative regarding the pre-defined objectives of river rehabilitation and satisfaction of stakeholders' interests.

3.2 *Application of the model*

The steps for the application of the model are as follows:

1. In agreement, stakeholders determine the main objectives that should be considered in choosing the best alternative. These objectives should be reasonably independent. To assure better independence between different main objectives the proper attributes should be assigned. Main objectives in our case study were improvement of river ecology, habitats, flood protection, recreation and urban green space.
2. Determine the relative importance of these objectives to each other. A common approach is to select the least important objective and assign it a value of 1. Then for each of the other objectives, ask the question "*How many times more important is this objective than the least important objective?*" The answer will relate to the value assigned, for example, if the selected objective is twice as important as the least important objective, it would receive a value of 2, or if it were equally important it would have a value of 1. It is necessary to limit the maximum value that is assigned to any objective. A maximum value of 3 or 4 is a good choice (Goicoechea et al., 1982). If the maximum value is too large, it has the numerical effect of reducing the problem to a single objective problem. After a relative importance value is obtained for each objective then a normalized importance "weight" for each attribute is obtained by dividing the individual relative importance value by the summation of all the relative importance values. This produces a set of "importance weights" that sum to one.
3. Use a process similar to Step 2) to assign normalized importance weights to defined attributes in spreadsheet "MADM-WAM".
4. Select the alternatives to consider. Costs for the elements of the rehabilitation scheme are just illustrative. For each alternative, evaluate the performance of that alternative with respect to each objective or its attributes. This performance might be described as a number or it might be a word (such as good or poor). It is advisable that one alternative represents the present condition of the stream or "do nothing scenario". This alternative can be used for comparison with other alternatives and for assessment of the improved conditions which are expected to be achieved by applying the selected alternative.
5. Convert the evaluations of Step 4) to a common numerical score called "rating". A commonly used scale is 1 to 5, where 5 represent the best condition and 1 represents the worst condition. A scale of 5 fits word descriptions such as: Poor(1) Fair(2) OK(3) Good(4) Excellent(5). It is important to make sure that none of the alternatives is completely "dominated" by the others. The results of ranking are summarized in the so called "impact matrix" as shown in spreadsheet "MADM-WAM".
6. The ratings for each alternative are combined into a final score for each alternative. One of the most common MADM methods used for this is the *weighted average method (WAM)*. The score for

Copyright © 2006 Taylor & Francis Group plc, London, UK

an alternative (S_i) is defined as the summation of the products of the normalized weights (W_i) times the rating for each objective ($R_{i,j}$). For example, the overall score for alternative 1 would be computed as:

$$S_1 = \sum_{i=1}^{4} W_i * R_{i,1} \quad (1)$$

where i represents the various criteria. In general then, the score for alternative j is found by:

$$S_j = \sum_{i=1}^{4} W_i * R_{i,j} \quad ; \text{where } j = 1, 2, 3 \quad (2)$$

The alternative with the highest score (maximum value of S_j) is the preferred alternative (Fig 3). It is said to have a "rank" of 1. The second highest score is the second preferred alternative (rank 2) and so forth.

7. The spreadsheet for Cost-Sharing evaluation enables the analysis of the financial aspects of the implementation of the selected alternative. The stakeholders are encouraged to define their involvement (financial contribution, volunteering work) into the project. This involvement depends on the proportion of the satisfaction of their interests. For example, stakeholder No.1 is prepared to contribute 10 % of the expenses for the project if the selected alternative raises the objective of river ecology (as one of the objectives) to a minimum acceptable value of 3 (according to the selected scale of 1 to 5 where 1 means poor and 5 means excellent). In the case when the selected alternative provides even better river ecology, then our stakeholder No. 1 agrees to contribute additional 3% for the realization of the selected alternative. Analyses as the one presented in the example above should be done for each stakeholder. The final result is the proportion of expenses for selected alternatives (or only for the few preferred alternatives) that could be covered by stakeholders' contributions (Table 2).

Alternative No. 1 represented the "do nothing scenario". Alternative No. 2 was oriented towards the improvement of the flood protection and recreation areas near the Glinscica stream channel with widening of the regulated channel, provision of footpaths along the banks but without the removal of the concrete paving from the channel. Alternatives Nos. 3 and 4 were directed towards the improvement of the ecological state of the channel which included removal of the concrete paving from the channel bottom and banks (Fig. 2). Alternative No. 3 considered the introduction of structural elements such as pools and small stone weirs into the channel. Alternative No. 4, which has been assessed as the most expensive one, included the reconstruction of the channel to provide meandering appearance of the stream and prevision of a dry retention area upstream of the studied reach. Alternative No. 5 considered mainly the flood vulnerability issue with widening of the cross section and arrangement of levees along the stream and some limited improvements of the ecohydrological state of the channel, such as selective clearing of riparian vegetation without the removal of the concrete paving. While using the model it was easily noticed how the selection of the preferred alternative depends on the combination of the relative importance weights assigned by stakeholders to each proposed rehabilitation alternative (Fig. 3).

Table 2. The cost sharing evaluation of urban river rehabilitation alternatives.

	Alternatives				
Stakeholders	1	2	3	4	5
Biotechnical faculty	0	5	31	28	18
Residents of the Municipality of Ljubljana	0	10	13	18	3
Angling society	0	0	25	15	0
Municipality of the city of Ljubljana	0	25	15	25	10
SUM	0	40	84	86	31

4 CONCLUSION

In our case study each set of the alternative preference is a result of the combination of relative importance weights assigned to the main objectives of the urban river rehabilitation. The selected key objectives identified by the stakeholder who should be included into the steering committee were river ecology, habitats, flood protection, recreation and urban green space. Thus the resultant objective and attribute weights and rankings of alternatives reflect both the subjective considerations of a decision maker, stakeholders and the objective information of the expert.

The agreement of the stakeholders on the importance of certain objective is the crucial aspect for the application of the model. Otherwise, if the agreement of the stakeholders on the importance of defined objectives is not reached, the selection of the preferred alternative can be easily manipulated (Fig 3). On the other hand, Cost-Sharing provides an insight into the preparedness of stakeholders to realize their interests through their actual involvement in the selected alternative.

The influence of errors in Digital Terrain Models on flood flow routes

S. Néelz & G. Pender
School of the Built Environment, Heriot-Watt University, Edinburgh, UK

ABSTRACT: The modelling of flood inundation patterns on rural and urban river floodplains is making increasing use of high-resolution and high-accuracy Digital Elevation Models (DEMs) based on LiDAR (airborne laser scanning) data. LiDAR measurements are reported to be subject to root mean square errors of 0.15 m vertically and 0.50 m horizontally. The aim of the paper is to investigate the implications of these uncertainties in terms of the reliability of model results, concentrating on the modelling of overland flood flow using a 2D fully hydrodynamic model. A flood event caused by overflow from a river is simulated using three different DEMs: a benchmark error-free DEM, and 2 "altered" DEMs with added LiDAR errors of different magnitudes. These altered DEMs are a less accurate representation of reality, and also have an artificial roughness that is typical of LiDAR-based DEMs used in practice. The main conclusions are that: (1) this artificial roughness can significantly slow down the flow in the simulation, resulting in an incorrect representation of the flow dynamics, and (2) the LiDAR errors can have a significant impact on the routes taken by the flow, and on modelled water levels and velocities.

1 INTRODUCTION

Since 1994, the modelling of flood inundation patterns and flow routes on rural and urban river floodplains has made increasing use of high-resolution and high-accuracy Digital Terrain Models (DTMs) based on LiDAR (Light Detection And Ranging or airborne laser scanning) data. LiDAR is a modern technology in the field of remote sensing that can rapidly generate high-density, high-accuracy, geo-referenced digital elevation data. LiDAR measurements are claimed to be subject to errors smaller than 0.15 m vertically and 0.50 m horizontally (Root Mean Square Errors). This is increasingly recognised as one of few technologies (with for example photogrammetry) that can provide topographic data with suitable accuracy and resolution for applications in river and floodplain flow modelling.

Despite their great future potential, the availability of LiDAR-based bathymetric DTMs for rivers is scarce and very few studies on the subject have been published to date. Such data are at present very rarely used by engineers and consultants. Most river flow models (at least at catchment scale) still rely on cross-sections surveyed using ground-based techniques.

LiDAR-based DEMs and DTMs of the floodplains are used in different ways depending on the type of hydraulic model used. In 1D models they allow the extension of channel cross-sections onto the floodplains. In quasi-2D (storage cell) models, they are used to calculate storage (volume vs. water level) curves. In 2D models they provide cell or node elevations (Bates & De Roo 2000, Cobby et al 2003). In addition, they may provide the geometry of any spill cross-section in storage cell models and combined 1D/2D models. In all these models, water depths are calculated by subtracting DEM/DTM elevations from the computed water levels.

The suitability of LiDAR for such applications has been extensively investigated (Gomes Pereira and Wicherson 1999, Marks & Bates 2000), but the effects of any errors and uncertainties in LiDAR digital elevation data on hydraulic model results have been scarcely studied to date.

2 BACKGROUND

2.1 *LiDAR and LiDAR-based Digital Elevation Models*

LiDAR is based on the combination of three different data collection tools: a laser scanner mounted on an aircraft; a Global Positioning System (GPS) providing the laser sensor position; and a Inertial Navigation System (INS) or Inertial Measurement Unit (IMU) providing the orientation of the aircraft (yaw, pitch and roll). Light pulses directed towards the ground are provided by the laser at a specific frequency (up to 100 kHz in state-of-the-art systems). The sensor oscillates at a frequency and within a scan angle that can

Copyright © 2006 Taylor & Francis Group plc, London, UK

be set to provide the required swath width and data density (these also depend on the flight height). Each laser pulse (a decimeter-wide beam) is reflected by the ground or by objects above the ground. In some modern systems multiple returns from the same laser pulse can be recorded (for example high vegetation, low vegetation, and ground). Each laser return provides a measured distance, which is then combined with the simultaneous INS and GPS measurements to provide a georeferenced "raw" LiDAR data point. Typical swath widths are between 0.25 h and 1.5 h, where h is the flight height (h is typically between a few hundred meters and 1000 m), and a typical raw data density is of a few points per square meter (but data collection at a much higher resolution is feasible and is becoming less onerous). It should be noted that most LiDAR systems to date do not penetrate water, so that LiDAR data are presently available mainly for floodplains. However, some modern systems do provide river and coastal bathymetric data.

Raw LiDAR data are normally turned (often by the companies by which they are collected) into Digital Elevation Models (DEMs), or "raster" grids, where elevation data are presented on a georeferenced square regular grid. Such grids have a cell size of 1 m at best (in most UK studies), so that each cell elevation is based on many raw data point elevations averaged in some way. Triangular Irregular Networks (TINs) are less common, largely because many data processing techniques have been designed for raster grids. Data processing techniques include such tasks as feature extraction, filtering, and segmentation. For applications such as flood modelling, it is often necessary to perform a segmentation process, i.e. to separate the DEM into areas such as bare earth, vegetation, buildings, etc. These features may be extracted, resulting in a DTM (Digital Terrain Model), which contains only ground elevations (Mason et al 2003, Sithole & Vosselman 2004).

2.2 *LiDAR accuracy*

Accuracy of LiDAR data is neither thoroughly understood nor well documented. Many surveyors and data providers quote accuracy figures such as 0.15 m Root Mean Square Error (RMSE) vertically, or h/1000 horizontally (the flight height is usually below 1000 m), which are meant to refer to the raw LiDAR data. However, errors are subject to considerable variability, depending on system characteristics, observation angle, type of land cover, slope of the terrain, etc. (Ahokas et al 2003, Gomes Pereira & Wicherson 1999, Hodgson & Bresnahan 2004, North Carolina Floodplain Mapping Program 2006). In addition, the figures reported refer to bulk statistics and do not reflect any spatial distribution. It is indeed the case that most sets of LiDAR data examined at a local scale would exhibit a significant systematic or smoothly varying component (Ahokas et al 2003). Such systematic errors would result for example from difficulties in the functioning of the GPS (the positioning data are collected by the GPS at a relatively low frequency of between 1 and 10 Hz).

In addition to the errors affecting the raw LiDAR data, additional errors are introduced during the data processing stage. These are mainly due to the difficulties in automatically segmenting the DEM between vegetation and bare earth, or between buildings and bare earth. DTMs are often of poor quality in densely vegetated areas and in urban areas large buildings are easily mistaken for small scale land forms. In addition, features that critically affect flow routes, such as thin embankments, may be erroneously removed by filtering algorithms.

3 EXPERIMENTAL SETUP

This study considers the 2D modelling of a hypothetical flood event affecting a $\sim$0.5 km^2 area in Greenfield, a suburb of Glasgow, UK (see map in Figure 1). Simulations were carried out using three different DEMs: a benchmark high-resolution DEM (DEM1) and two DEMs (DEM2 and DEM3) based on DEM1, but with LiDAR errors of different magnitudes added according to a process described in section 3.2. Results were compared in terms of flow routes, maximum velocities and depths, and inundation timing.

3.1 *Study site*

The study site is a $\sim$0.5 km^2 area (Fig. 1), consisting of a combination of small apartment blocks and semi-detached houses, some of which are set within small fenced gardens. It also comprises some open park land covered mainly with short grass with some thick low vegetation in places. The modelled flood is assumed to originate from the entrance of a culvert carrying a local stream (the Camlachie Burn), and it is supposed

Figure 1. Map of the study area. Darker areas indicate higher ground. The origin of the flood is indicated by an arrow. (© Crown Copyright Ordnance Survey. An EDINA Digimap/JISC supplied service.)

Copyright © 2006 Taylor & Francis Group plc, London, UK

to be caused by this culvert reaching capacity. This is a simplification of a real flood that occurred in this location in July 2002. From the culvert entrance at altitude ~31 m, most of the excess water flows down a ~1.5% terrain slope until in reaches a low-lying area at altitude ~24 m in the south-western quarter of the study area.

3.2 *Building the Digital Elevation Models*

It is emphasised that although DEM1 is the outcome of an attempt by the authors to build an enhanced high-accuracy DEM of Greenfield based on an available 1 m (grid resolution) LiDAR, the issue of whether or not DEM1 is a more accurate representation of the real site than the original LiDAR DTM is irrelevant to the present study. Its strength lies instead in the fact that the relationships between DEM1, DEM2 and DEM3 are well known.

DEM1 is based on the combination of a 1 m LiDAR DTM provided by Infoterra and OS Mastermap® data (high accuracy topographic information, mostly in the form of polygons, representing all landscape features such as roads, pavements, buildings, etc.) provided by Ordnance Survey, the national mapping agency of Great Britain. The work was carried out using a Geographic Information System (GIS) software and some ad hoc programming. The Mastermap® data were used to identify the different land-cover categories, and a different treatment was applied to each of these categories. For the reason stated in the previous paragraph, the details of the procedure followed to build DEM1 are not relevant to this study. The main characteristics of DEM1 are that it is of very high-resolution (a 0.1 m grid), with all surfaces exhibiting a smoothness that reflects reality. The camber of the roads is represented as well as 10 cm high kerbs. Buildings are also included, but the DEM is vegetation-free. A 3D sample of DEM1 is shown in Figure 2.

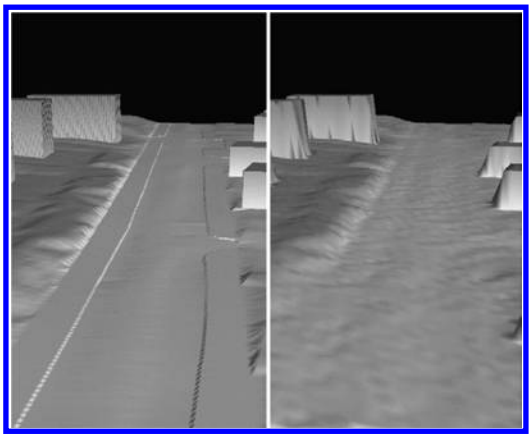

Figure 2. Sample of DEM1 (left) and the corresponding view in DEM3.

DEM2 and DEM3 were built according to a procedure similar to the way in which LiDAR DEMs are normally produced. Points at a density of 5 points per m^2 (meant to represent raw laser hits) were first projected onto the surface of DEM1. Then vertical and horizontal errors were applied to these points. These errors were applied randomly but in such a way that the vertical errors and the horizontal errors were distributed according to normal distributions with zero mean and specified standard deviations. The values of these standard deviations, σ_V and σ_H (respectively vertically and horizontally) were chosen to reflect typical LiDAR accuracy characteristics (RMSE values of 0.15 m horizontally and 0.50 m vertically). However, as mentioned in Section 2.2, these RMSE values include a component that at the scale of the present study can be identified as systematic or quasi-systematic (for example a general tilt of the terrain). Such systematic and quasi-systematic errors are beyond the scope of this paper. They can be partly suppressed in theory by DEM calibration (for example using evidence from a limited number of high-accuracy GPS point measurements), and whenever they remain they have very specific implications in terms of flood modelling results which are not studied here. For these reasons the values of σ_V and σ_H were chosen smaller than the reported RMSE values, as follows:

Finally, DEM2 and DEM3 were formed by gridding the raw LiDAR elevation modified as explained above onto 2 m grids (with each cell elevation calculated as the average value of all point elevations contained in the cell). A remarkable feature of DEM2 and DEM3 is that they possess the characteristic roughness and irregularities of most LiDAR-based DEMs used in the industry, unlike DEM1 (see Figure 2).

It should also be noted that since DEM1, DEM2 and DEM3 do not include any vegetation, the study focusses on LiDAR errors on bare surfaces. LiDAR errors in vegetated areas and filtering errors are beyond the scope of this paper.

3.3 *TUFLOW model*

TUFLOW is a computational engine that provides dynamically linked 2D and 1D solutions of the free-surface flow equations to simulate river flow and flood propagation. TUFLOW's 2D solution is based

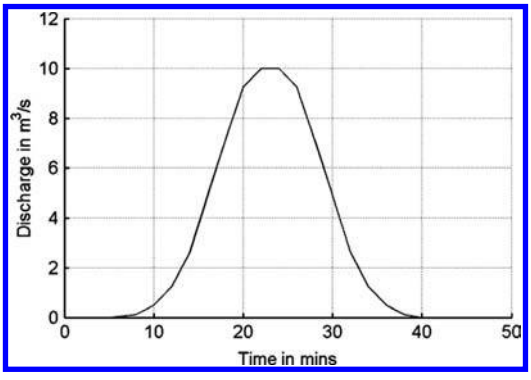

Figure 4. Upstream boundary condition.

on the Stelling finite difference, alternating direction implicit (ADI) scheme that solves the full 2D St-Venant equations (Stelling 1984) on a regular square mesh.

Only the 2D solver was used in this study, with a flow vs. time upstream boundary condition at the location indicated in Figure 3. A water level vs. time downstream boundary condition was used at a location outside Figure 3, several hundred meters away from the left-hand edge of the figure. The grid size used was 2 m. Grid cell elevations were directly taken from the underlying DEMs throughout the domain, including the buildings. Results were output either as flood depth maps at specific times, or as time series at locations indicated in Figure 3. Free surface elevation and velocity time series were output at point locations 1 to 10. Flow time series through lines 1 to 4 were also recorded.

3.4 *Simulations*

The upstream boundary condition was as shown in Figure 4 in all simulations. The downstream boundary condition was simply in the form of a constant water level set beneath the ground surface. Appropriate sensitivity checks were made to ensure that none of the results in the area of interest depended on the downstream boundary condition.

Table 2. Manning's *n* combinations used in simulations.

	1	2	3	4	5	6
Roads	0.008	0.009	0.010	0.011	0.012	0.013
Land	0.015	0.020	0.025	0.030	0.035	0.040
	7	8	9	10	11	12
Roads	0.014	0.015	0.016	0.017	0.018	0.019
Land	0.045	0.050	0.055	0.060	0.065	0.070
	13					
Roads	0.020					
Land	0.075					

Three initial simulations where carried out using respectively DEM1, DEM2 and DEM3. In these, Manning's n was set to 0.015 for any paved surface (roads, pavement and footpaths) and to 0.05 for all other areas (this is combination 8 in Table 2 below). These values are in line with standard values for floodplain roughness coefficients (see for example Chow 1998), but they were adjusted in an attempt to take into account obstacles such as hedges, fences and bushes.

An additional 12 simulations based on DEM2 and the Manning's n values listed in Table 2 were made, for the reasons detailed in section 4.4.

Sensitivity checks were made to ensure that the reported results were not dependent on the choice of time step. Also the maximum mass error was kept below 5% in all simulations. This implied the use of time steps of either 0.25 s or 0.5 s.

4 RESULTS

4.1 *Routes taken by the flow*

The LiDAR errors had a limited effect on the extent of inundation: a visual comparison of inundation extent maps could not reveal any significant differences. However, a significant impact on the flow distribution between the different routes was observed at least with the DEM based on the larger errors, DEM3. This was assessed by monitoring the discharges flowing through 4 lines indicated on Figure 3. These discharges are referred to as Q1 through to Q4, for which time series are shown in Figures 5 and 6. The results show that the LiDAR errors changed the peak values of these discharges by 11% at most in the case of DEM2 compared to DEM1 (Fig. 5a). In the case of DEM3, the proportion of the flow flowing southwards through a park (Q1) instead of flowing westwards along a street (Eskbank Street – Q2) increased from ~28% to ~44% because of the LiDAR errors (this is in terms of the peak discharge). The corresponding total volume of water (area under the Q curve) flowing through the

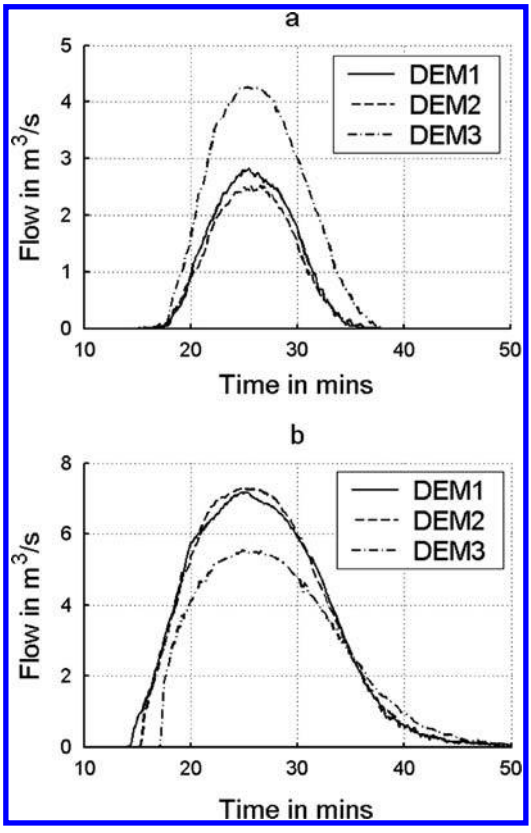

Figure 5. Results from initial simulations with DEM1, DEM2 and DEM3. Time series of discharges Q1 (a) and Q2 (b).

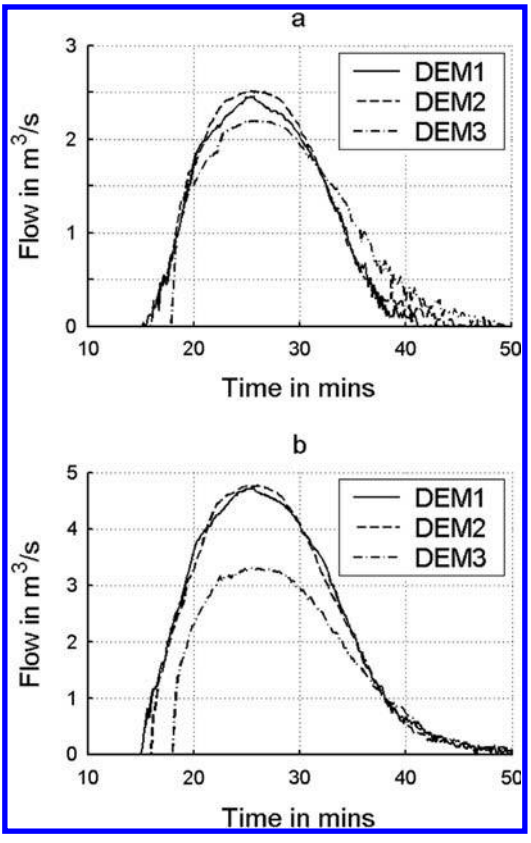

Figure 6. Results from initial simulations with DEM1, DEM2 and DEM3. Time series of discharges Q3 (a) and Q4 (b).

park increased by 1215 m^3, from 1616 m^3 to 2831 m^3, or from 19% to 34% out of a total of ~8300 m^3. Similarly, the proportion of water flowing down into a perpendicular street (Cockenzie Street) through line 3 (Q3) instead of westwards along Eskbank Street through line 4 (Q4) increased from 31% to 39% (out of the total flowing through either 3 or 4).

Such differences are explained by the fact that fine features such as kerbs and narrow land forms are not adequately represented in DEMs with errors as large as in DEM3. These features may play a significant role in channelling overland flow particularly for shallow flood depths, and their correct representation is critical to the accuracy of the results. It should also be noted that the choice of too coarse a model grid resolution would have similar implications even though this is outside the scope of this study (all the simulations reported used the same 2 m grid).

The magnitude of the differences reported above is such that cases where this would result in large differences in terms of final or maximum inundation extent and water levels are possible. However, the study did not highlight any major effect on the flow routes in the case of the DEM with the smaller errors, DEM2. More research results from the remote sensing community are needed to clarify whether (non systematic) errors in LiDAR DEMs can be as large as the errors involved in building DEM3.

4.2 *Maximum water levels*

The topography of this particular study area meant that most of the flood finished its course in the same "pond" located in the lower part of the catchment (southwest quarter of Figure 3). Therefore no significant difference in terms of the final water level was observed in this location (Fig. 8a). However the flow progressed in different ways along the catchment slopes as indicated in the previous section, so that for example differences of up to 10 cm were observed for example at location 1 (see Figure 7a). This lies in the path of the flow going through line 1 for which large flow rate differences are reported above. Such differences were observed in the

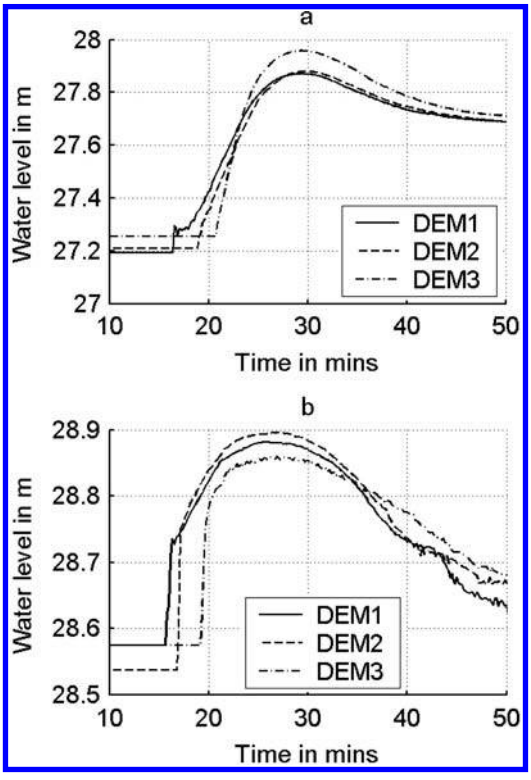

Figure 7. Free surface elevation vs. time at locations 1 (a) and 2 (b).

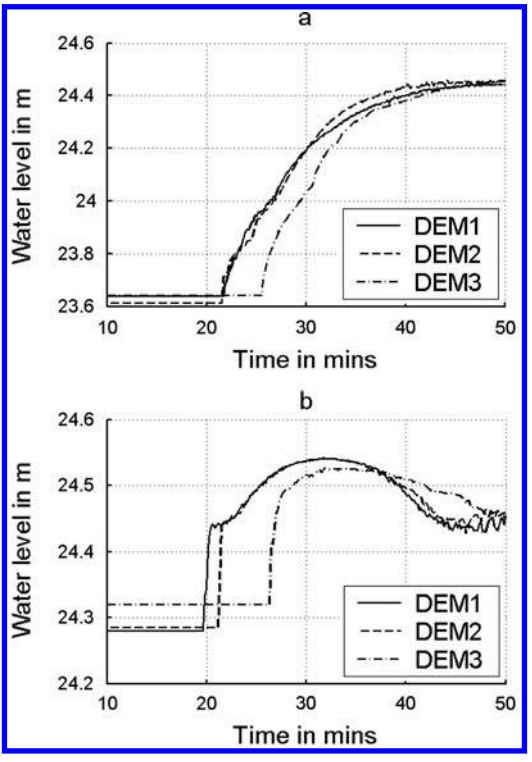

Figure 8. Free surface elevation vs. time at locations 3 (a) and 4 (b).

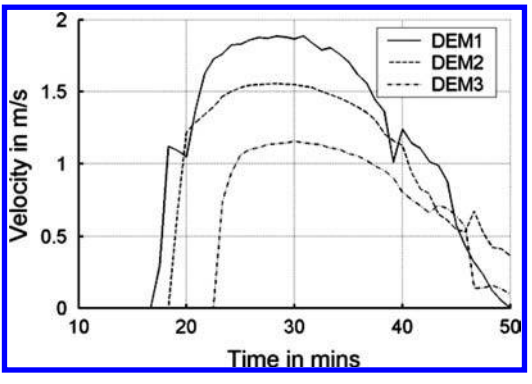

Figure 9. Velocity vs. time at location 10.

case of DEM3 but again much less so for DEM2. It is emphasised that even though the ground elevations at the output points varied from one DEM to the other by a few cms, this does not explain the differences in observed water levels. This was verified by analysing the shape of the water surface which was smooth and did not reflect in any way the cell-to-cell differences in ground elevations.

4.3 *Maximum velocities*

The effects of LiDAR errors in terms of modelled flow velocities were difficult to assess because they resulted from complex interactions between several factors. On the one hand, there were effects in terms of the flow discharge going down the different routes (section 4.1), and this affected the velocities. For example, the flow going through line 1 (Fig. 5a) was much larger with DEM3, which should have led to higher velocities as well. On the other hand, it was also observed (see next section) that the progression of the flow was slower with the DEMs containing LiDAR errors. Velocities were generally found lower with DEM2 and DEM3, particularly so with DEM3. A representative example is location 10 where the modelled velocity was as shown in Figure 9. The figure shows that the peak velocity at this location was lower by ~39% with DEM3 compared to with DEM1. This is partly attributed to the lower flow going along Eskbank Street through line 4, see section 4.1. Figure 9 also shows that the modelled velocity was lower (by ~19%), even with DEM2. The effects of the choice of DEM in terms of flow propagation speed are shown more extensively in the next section.

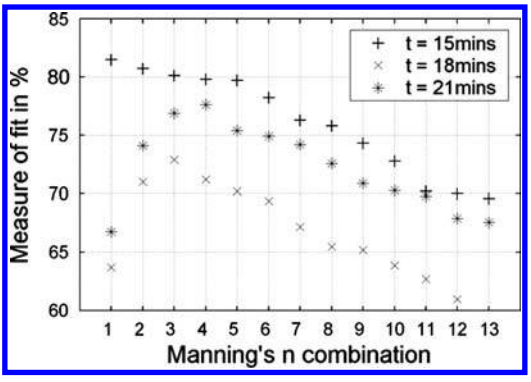

Figure 11. Goodness of fit between results based on DEM2 and 13 sets of alternative roughness values, and results based on DEM1.

The effects in LiDAR errors in terms of velocities can be of concern if an estimation of flood flow velocities is required.

4.4 *Progression of the flow*

In the simulations using the DEMs with errors and the original roughness values, the flow propagation speed was found lower than in the simulation using DEM1. This is illustrated by Figures 7 and 8 that show that the flow reached gauges 1 to 4 at a later time than in the benchmark simulation. The time lag was up to ∼2 minutes with DEM2 (although close to zero at gauge 3), and up to ∼10 minutes with DEM3. This is also illustrated by Figure 10, which shows snapshots of inundation extent at time t = 18 mins using the different DEMs.

Such effects can be explained by the additional head losses involved in the modelling of the flow between adjacent computational cells featuring larger elevation differences. For example, the flow along a smooth downhill road is incorrectly modelled as a succession of downhill and uphill segments. The effects in terms of inundation timing may be of concern particularly for larger areas, for example in real-time flood forecasting applications where end-users of flood forecasting systems (such as local authorities) may need an estimation of the time taken for the flood to reach particular locations. More importantly, discrepancies in terms of timing or velocities reflect the fact that the flow dynamics are not adequately modelled. This can impact on flood depths and flow routes in various ways.

As mentioned earlier, a set of simulations using DEM2 and alternative values of Manning's n were carried out, in an attempt to calibrate out the discrepancies between the results using DEM1 and DEM2. The purpose of this was to identify the values of n that result in a case of equifinality as defined in, for example, Aronica et al 1998. This was not done using DEM3, because as detailed in section 4.1, the results using DEM 3 showed differences in terms of the flow distribution between different flow routes which clearly could not be calibrated out simply by adjusting the roughness parameters.

The calibration exercise was made using the Manning's n combinations listed in Table 2. The agreement between the results using the DEM1 and the results using DEM2 and these roughness parameters was calculated using a measure of fit F defined as $F = Num(A)/(Num(A) + Num(B))$, where A is the set of wet cells predicted to be inundated in both simulations, B is the set of cells predicted to be inundated in either simulation but not both, and Num() represents the number of cells within each of these sets. This was calculated at times t = 15 mins, t = 18 mins, and t = 21 mins for all 13 simulations based on DEM2. The results are reported in Figure 11 above.

Figure 11 shows that the best agreement was found with the parameter combination 1 (or lower values, not tested) at time t = 15 mins, with the combination 3 at time t = 18 mins, and with the combination 4 at time t = 21 mins. This represents Manning's n values of between 0.008 and 0.011 for the roads and of between 0.015 and 0.030 for land, instead of the original values of 0.015 for the roads and 0.050 for land. An alternative method based on the time at which water depth reached 10 cm at all output gauges was also used and it reached similar conclusions.

The main implication of these results is that if roughness coefficients in a flood model are to be set according to published guidelines (where Manning's n values are advised with a precision of 0.001 for many types of surface cover types), the choice of an appropriate value of n may be much less important than the understanding of the artificial roughness introduced by the errors in the DEM/DTM. Also, if attempts are made to calibrate Manning's n values using field measurements during a real flood event, large discrepancies will occur depending on the quality of the DEM/DTM used in the model, and it is unlikely that such calibrated values will be transferable to another site in

Copyright © 2006 Taylor & Francis Group plc, London, UK

another model, even if the nature of the land cover is clearly similar.

5 CONCLUSION

The implications of LiDAR measurement errors in terms of the reliability of flood model results have been investigated using experimental tests based on the modelling of overland flood flow in an urban area using a 2D fully hydrodynamic model, a benchmark error-free DEM and 2 DEMs with errors of various magnitudes. The first conclusion is that the distribution of the flow between the different flow routes was significantly affected by the choice of DEM. The magnitude of the observed differences is such that cases where this would result in large differences in terms of final or maximum inundation extent and water levels are possible. Significant effects were also observed in terms of modelled water levels and flow velocities. Also, the artificial roughness of the DEMs with errors significantly slowed down the flow in the simulation, in a manner similar to what is achieved by greatly reducing values of Manning's *n*. This results in an incorrect representation of the flow dynamics, and has implications in terms of the choice or the calibration of roughness coefficients in river and floodplain models.

ACKNOWLEDGEMENTS

The research reported in this paper was conducted as part of the Flood Risk Management Research Consortium. The FRMRC is supported by grant GR/S76304 from the Engineering and Physical Sciences Research Council, in partnership with the Natural Environment Research Council, the DEFRA/EA Joint Research Programme on Flood and Coastal Defence, UKWIR, the Scottish Executive and the Rivers Agency (Northern Ireland). This financial support is gratefully acknowledged. The authors are also grateful to Glasgow City Council and Infoterra for providing LiDAR data for Glasgow, to WBM for the use of their TUFLOW software, and Ordnance Survey for providing Mastermap® data.

One-dimensional flow modelling and a case study of the River Rhine

Tobias Bleninger & John D. Fenton
Institute for Hydromechanics, University of Karlsruhe, Kaiserstrasse, Karlsruhe, Germany

Rolf Zentgraf
Federal Waterways Engineering and Research Institute, Postfach, Karlsruhe, Germany

ABSTRACT: The simulation of rivers by one-dimensional models is examined. The German Federal Waterways Engineering and Research Institute's model CasCade was applied to a comprehensive case study for a long non-uniform section of the Rhine river with extensive floodplains. Results obtained show that the one-dimensional long-wave equations are more accurate than often believed. Large real-time data sets allow model calibration and optimisation beyond the matching of field data, and reproducing unsteady wave characteristics over the whole flow regime. It is then shown theoretically that, possibly surprisingly, river junctions require no special treatment in one-dimensional modelling. However some improvements are suggested – for curved rivers, over flood-plains, and in the treatment of friction. It is concluded that one-dimensional models, including the results of this paper, preserve a balance between requirements of accuracy and simplicity, and have much to offer in the understanding of river systems.

1 INTRODUCTION

1.1 *Rhine River engineering – the CasCade model*

The Rhine river (1320 km, 2000 $m^3 s^{-1}$ average discharge) is one of the longest and most important rivers in Europe (www.iksr.de). Its watershed is highly populated (about 50 million people) and connects the world's largest sea harbour (Rotterdam) with the inland European markets and its large and important industrial complexes. Ships up to 3000 t can navigate one of the most frequented waterways of the world from Rotterdam to Basel (800 km). The Rhine is also an important ecological habitat, source of major drinking water supplies and is of recreational and cultural importance. River engineering therefore has to guarantee optimised navigation conditions and flood protection combined and balanced with natural preservation (Figure 1). The German Federal Waterways Engineering and Research Institute (BAW, www.baw.de) is the central technical and scientific governmental agency of the German Federal Ministry of Transport, Building and Urban Development and the Federal Waterways and Shipping Administration. Its responsibilities are the operation and maintenance of federal waterways such as defining dimensions of fairways, regulating waterways structures or measures for stabilising the river bed. The assessment concerning the short-term and long-term hydraulic-morphological effects as well as the water management and environmental aspects is realised using physical as well as one-dimensional and multi-dimensional hydro-numerical models complementing one another.

Figure 1. Rhine River at Ketsch near Heidelberg, showing large flood plains, branches and lakes, being flow effective during high flows, but ineffective during low flows (Source: Landesmedienzentrum Baden-Württemberg).

Copyright © 2006 Taylor & Francis Group plc, London, UK

A computer model for a 500 km long section of the river Rhine has been developed and operated by the BAW using the in-house software CasCade, a one-dimensional, hydro-numeric modelling system for unsteady, unconfined flow conditions in branched or meshed networks of rivers, canals and flood fields. CasCade covers a major part of the river Rhine and therefore allows a unique system-wide river analysis. Its applications regard the following objectives:

- *Real time flow dynamics – online computation of water level elevation and depth*: CasCade models can easily be connected to the Rhine water gauge online-database, which is continuously updated with real-time data. Unsteady model runs include the previous flow history and use the actual water level time-series as boundary conditions at open boundaries. Additional water gauge data furthermore allows for a real-time model accuracy check. Waterway authorities already operate these models to improve fairway definitions, thus improving navigation conditions.
- *Navigation dynamics – computation of ship travel times*: CasCade post-processors allow for detailed data analysis. For example mean flow velocities can be computed for the navigation channel and used for further analysis of the navigation dynamics, thus transformed into ship travel times. Knowledge of unsteady hydrodynamic features therefore allows for improved logistical handling and better traffic control.
- *River bed dynamics – computation of mean shear stress in main channel*: CasCade post-processors may also compute section-wise shear stress. A system-wide analysis covering the whole flow regime allows for defining critical sections regarding erosion or sedimentation, especially after large floods, thus providing important data reducing the amount of costly field measurements and improving maintenance programs.
- *River engineering dynamics – simulation of impacts of regulating waterways structures*: The continuously updated and operated model allows for more accurate impact prediction beyond the calibrated flow regimes (Figure 2). The model is setup with all geometrical features regarding the whole flow regime. Although changes of regulating waterways structures are included only in an aggregated sense and not as higher-dimensional features, reasonable predictions are possible due to the additional unsteady calibration of the model.
- *Modelling dynamics – nesting/coupling optimisation*: A good knowledge of the system wide river flow behaviour, covering local characteristics over large discharge regimes allows optimising the complementary or coupled usage of additional models (i.e. more dimensional models). More detailed but costly 3-D hydrodynamic or morphology models are therefore applied especially to these sections and flow-regimes, where the 1-D model is passing its limits of applicability, exceeding desired accuracies.

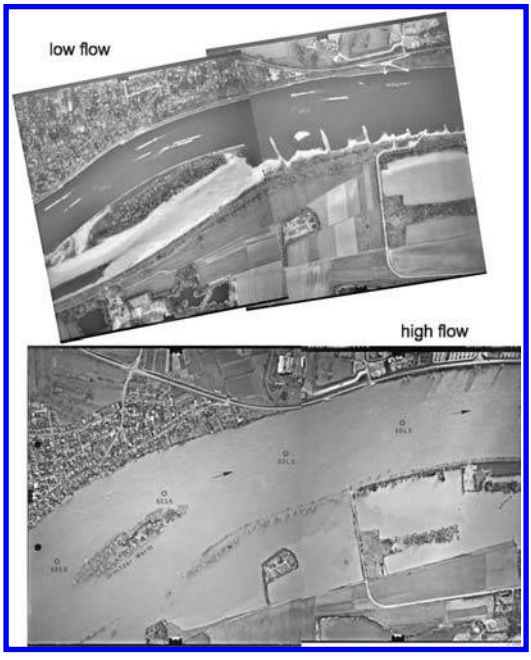

Figure 2. Short section of Rhine River showing waterway structures (groynes) and natural characteristics (islands), resulting in a strong change of the already complex flow characteristics during increasing flows.

1.2 *Case-study – section from Speyer to Worms*

A brief illustration of CasCade capabilities and limitations is shown for the application on the Rhine section from Speyer to Worms (Rhine-km 400.6–443.4). Along this streamwise 42.8 km there is an approximate bed height difference of 6 m resulting in an average bed slope of 0.015%. The width of the main channel ranges from 200 to 350 m and the depth from 2 m (during low flow conditions at 400–900 $m^3 s^{-1}$) to 5 m (during medium flow conditions at 900–1600 $m^3 s^{-1}$). This river section is characterised by its strong heterogeneity with partly very large flood plains (a few kilometres wide), including side branches, lakes and other retention areas (Figure 1). Another part is almost canal-like, where the river passes the cities of Mannheim and Ludwigshafen including the junction with a major tributary river, the Neckar (Figure 3).

The BAW maintains an extensive database, where topography and bathymetry data are available from recent laser and sonar scans respectively, with high spatial resolution. Cross-sections are extracted at each 100 m distance in the streamwise direction and used for the 1-D model setup. River sections separated by

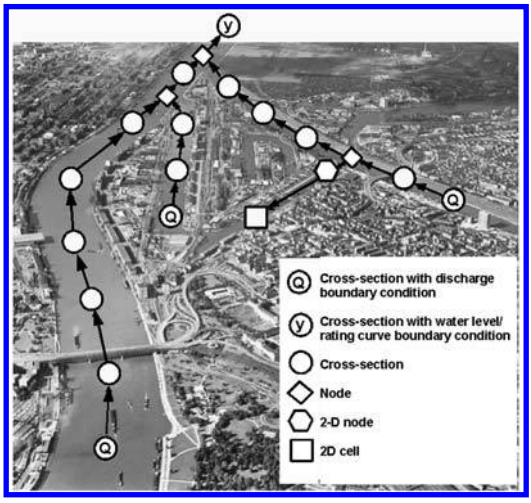

Figure 3. Rhine-Neckar junction and model schematisation as branched network.

islands or old river arms are modelled as separate branches, leading to a looped network model (Figure 3). Aerial photographs, geographical and geological maps, as well as navigational charts, allow locating and including important hydraulic structures and features in the model. The model Pre-Processor allows for subdividing cross-sections according to main roughness characteristics: the main channel, the floodplains, groyne fields or flow ineffective areas (encroachment approach). Model calibration is usually done using longitudinal water level measurements from recent field campaigns where ships travelled with the flow velocity and recorded position and elevation with high accuracy for low and medium flow conditions. Further unsteady calibration is done using the continuous water gauge recordings, with stored data of the last 10 years. Results show, that standard deviation of measured and calculated water level elevations in the main channel are around 2–4 cm for low flow conditions, 4–10 cm for medium flow conditions compared with the field campaign data and even less difference for the unsteady data compared with the water gauge time-series, also for high flow events. Nevertheless higher discrepancies can be observed at sections with strong curvature, at junctions and large floodplains not necessarily only due to limitations of 1-D modelling, but also to restrictions in the actual governing equations as seen by running sensitivity analyses.

Improvements to the 1-D numerical models are proposed, focusing on calibrating the model to adequately represent the observed flow characteristics and not only matching field data. Besides the attempt to improve the 1-D model itself the presented modifications should also clearly be seen as extensions beyond the 1-D approach as an interface to either more dimensional models or coupling to other models (hydrology, water quality, sediment transport, *etc.*).

1.3 *Research needs and achievements*

The simulation of flows and waves in rivers for a long time has been undergoing a development in terms of the sophistication of models which are actually applied, which has been related to computational facilities available. Once only steady gradually-varied problems were studied. Then unsteady one-dimensional problems were able to be simulated, followed by two-dimensional problems. Methods such as the development of the $k - \varepsilon$ model and then Large Eddy Simulation have meant that three-dimensional turbulent problems can now be simulated over limited domains. In general however, for practical problems the data requirements are inordinate, and the actual boundary conditions, the manner in which the fluid encounters resistance, are little better modelled than in the one-dimensional case.

Often field data is limited, and it is superfluous to try to model in a more sophisticated manner than the data warrants. This leads to the desirability of using a relatively simple model, but by performing inverse modelling (calibration) to extract the gross features of physical parameters. The use of one-dimensional modelling enables rather more physical understanding. With more sophisticated models the plethora of results often mean that physical intuition and understanding, perhaps the main benefit of computation, are not forthcoming. Also, in many rivers such as the Rhine, the physical extent is such that only a one-dimensional model is feasible.

In the case of the one-dimensional formulation, however, there remain areas where theoretical developments have not developed as they might. This paper examines several aspects of the one-dimensional modelling used by CasCade and by other one-dimensional computational models and tries to show that there is still much that one-dimensional modelling has to offer, especially if some of the suggested improvements are made:

- The one-dimensional long wave equations are examined, and it is shown that they have fewer essential approximations than has generally been believed.
- Generalised long wave equations are presented for curved rivers. The effects of curvature are examined.
- The problem of a junction of two rivers is considered, and it is shown that no special treatment is necessary; the only modification of the model necessary is that dynamic momentum flux of incoming streams should be included, and that this will be small in many cases.
- Friction in rivers is considered and it is observed that one-dimensional modelling is commensurate

Copyright © 2006 Taylor & Francis Group plc, London, UK

with the information usually to hand. However there has long been room for improvement in the modelling of friction. It is shown that the Weisbach friction formulation has advantages over the traditional Gauckler-Manning-Strickler version, and it is shown how compound friction can easily and rationally be included in 1-D models.

2 THE LONG WAVE EQUATIONS

2.1 *Equations for straight channels*

The one-dimensional equations usually used to model flows and waves in rivers are the long wave or Saint-Venant equations. They are a pair of partial differential equations for mass and momentum conservation, shown here in terms of the surface elevation η and the discharge Q, depending on distance along the channel x and time t, where the stream is assumed to be straight. The equations are

$$\frac{\partial \eta}{\partial t} + \frac{1}{B}\frac{\partial Q}{\partial x} = \frac{q}{B} \tag{1a}$$

$$\frac{\partial Q}{\partial t} + 2\beta\frac{Q}{A}\frac{\partial Q}{\partial x} + \left(gA - \beta\frac{Q^2 B}{A^2}\right)\frac{\partial \eta}{\partial x} = \beta\frac{Q^2 B}{A^2}\bar{S} - gA\frac{Q|Q|}{K^2} + \beta_q q u_q - \frac{Q^2}{A}\frac{\partial \beta}{\partial x}, \tag{1b}$$

where

q	is inflow volume per unit length,
B	is width of surface,
A	is cross-sectional area,
β	is the Boussinesq momentum coefficient,
$\bar{S}$	is mean bed slope at a section,
K	is conveyance, giving the effect of friction,
β_q	is the Boussinesq coefficient of inflow, and
u_q	is the inflow x-component of velocity.

Fenton (2006) suggested that the derivation of the equations can be made with few essential assumptions. The only non-trivial ones are not particularly limiting. They are:

- Variation in the streamwise direction is slow, such that pressure at a point is given by the equivalent hydrostatic pressure due to the water above that point, which is almost everywhere the case, except in the vicinity of local structures;
- The friction forces are given by an empirical formulae such as the Weisbach or Gauckler-Manning-Strickler formulae for the section as a whole, which in the absence of very detailed knowledge of the roughness, nature, and drag force of the bed, is a reasonable one; and
- The integral of the square of the horizontal velocity over a section is approximated by $\beta Q^2/A$, where β is a coefficient of magnitude about 1.1; this is a rough approximation, but the factor β only occurs in terms which are of a relative magnitude of the square of the Froude number $\mathbf{F}^2 = Q^2 B/gA^3$, which is small for many streams.

Generally the one-dimensional long wave equations are a good compromise between requirements of accuracy, and the scarcity of data, especially the nature of shear forces. Equation (1b) contains features worthy of note:

- The quantity $\bar{S}$ actually contains all the details of the underwater topography, and with it the equations are valid for non-prismatic sections (Fenton (2006). It is

$$\bar{S} = -\frac{1}{B}\int_B \frac{\partial Z}{\partial x}\,dy + \text{term from vertical diverging walls,} \tag{2}$$

  where Z is the bed elevation, such that $\bar{S}$ is obviously the mean bed slope at a section. Some formulations include a term like $\partial A/\partial h$, usually known as the non-prismatic contribution, but it seems simpler to represent it in terms of the mean slope. The form of equation (2) shows that to evaluate it accurately, one needs to have a detailed knowledge of the underwater topography. In the case of the Rhine River, such a detailed knowledge is available. But often this is not the case, however, and the term is written only as a representative slope of the river as a whole. As this term is largely counterbalanced by the friction term, which is also usually poorly known, this is quite justifiable.
- The friction term $gAQ|Q|/K^2$ is shown in terms of the conveyance K, which is obtained from friction laws:

$$K = \frac{1}{n}\frac{A^{5/3}}{P^{2/3}} = k_{St}\frac{A^{5/3}}{P^{2/3}} = \sqrt{\frac{8g}{\lambda}}\frac{A^{3/2}}{P^{1/2}} = C\frac{A^{3/2}}{P^{1/2}} \tag{3}$$

  in which P is the wetted perimeter, and n, k_{St}, λ, and C are respectively the roughness coefficients of Manning, Strickler, Weisbach, and Chézy. The friction term is based on boundary stress, which is clear from the derivation of the Chézy and Weisbach forms – what is most notable about this formulation is that it is *not* based on energy, and the dimensionless term $Q|Q|/K^2$ is *not* an "energy slope", as described by many sources.
- The term $\beta_q q u_q$ is the contribution to momentum flux from lateral inflow. In many cases it is poorly known, when it is not zero, but in the case of a

Copyright © 2006 Taylor & Francis Group plc, London, UK

tributary, the β_q is technically necessary to express correctly the momentum transport. Some texts write the whole term as $q(u_q - Q/A)$, which is not correct (and is based on a double counting of the momentum of the inflow as it enters and leaves the control volume).

2.2 *Channels curved in plan*

Fenton and Nalder (1995) derived the one-dimensional equations for the case where the river is curved. A long-stream co-ordinate s was used, generally expected to pass down the perceived centre of the stream. The equations were obtained in terms of the discharge Q, as for the straight-channel case, but in terms of the cross-sectional area A rather than the surface elevation η, which in this case can vary across the channel due to centripetal acceleration. The difference between the equations obtained and the straight channel equations are linear terms in two quantities, $\kappa n_m = n_m/r$ and $\kappa\bar{n} = \bar{n}/r$, where $\kappa = 1/r$ is curvature of the longitudinal s axis along the river and r is the radius of curvature, n_m is the transverse distance between the s co-ordinate axis chosen and the centre of the free surface, and $\bar{n}$ is the distance between the s axis and the centroid of the cross-section. In addition to the approximations for the straight-channel case, also terms proportional to $(n_m/r)^2$ and $(\bar{n}/r)^2$ are ignored. That is, the extra approximation is that the radius of curvature be rather larger than the channel width. This level of approximation is similar to the usual one for the conventional formulation of the Saint-Venant equations for channels presumed to be straight, where the approximation is that (depth / disturbance length)$^2 \ll 1$. The equations are

$$(1-\kappa n_m)\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial s} = q, \tag{4a}$$

$$(1-\kappa\bar{n})\frac{\partial Q}{\partial t} + \beta\frac{Q}{A}(2+3(\kappa n_m - \kappa\bar{n}))\frac{\partial Q}{\partial s} + \left(\frac{gA}{B} - \beta\frac{Q^2}{A^2}(1+2(\kappa n_m - \kappa\bar{n}))\right)\frac{\partial A}{\partial s}$$

$$= gA\bar{S} - gA\frac{Q|Q|}{K^2}(1-\kappa\bar{n}) + \beta_q q u_q \tag{4b}$$

where terms involving $d\kappa/ds$ have been ignored, and the inflow term has been simplified. The latter equation is slightly different from that in Fenton and Nalder (1995). It includes the momentum coefficient β and the friction term has been written more correctly in terms of conveyance rather than "energy slope". The coefficient β may be important particularly in a curve where the longitudinal velocity is greater on the inside of a curve than on the outside so that β is rather larger than 1. In the original paper no attempt was made to solve the field equations to obtain the longitudinal or lateral velocity distributions – the momentum formulation does not require that knowledge in detail.

Equations (4) are of a very similar nature to those for straight channels, equations (1). The only differences are the presence of the dimensionless coefficients κn_m and $\kappa\bar{n}$ in terms of curvature and cross-channel dimensions. The behaviour of waves and flows, the development of numerical methods, the behaviour and properties of those methods, and the re-writing of software, all should be able to be relatively simply done.

3 RIVER JUNCTIONS

3.1 *The canonical problem – rectangular channels*

Almost all research on river junctions has been for the case of steady flow in two rectangular channels with co-planar bottoms, where one enters the other, whose width remains unchanged thereafter. The belief that the problem is difficult, even for this relatively simple geometry, has stultified extension to more complicated geometries and to the general unsteady case. Here we examine a momentum approach to the problem, to guide our extension to more general problems. The energy principle does not contribute much – all that it yields is the energy loss, which is not as important as the relation between upstream and downstream depths that is obtained from momentum considerations.

Consider a rectangular stream entering another at an angle δ as shown in Figure 4. The main stream has the same width upstream and downstream of the junction. The plan of a vertical-sided control volume is shown by a heavy dashed line and the flow force contributions are shown by double-headed arrows. The downstream face of the control surface has not been taken across the region of separation, but it is supposed sufficiently far downstream that the velocity defect due to the separation has been substantially dissipated.

The flow force **M**, consisting of a static component, the hydrostatic force and a dynamic component,

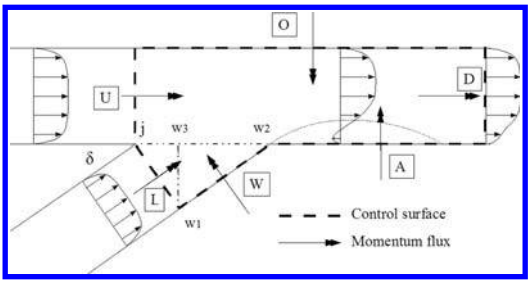

Figure 4. Definition diagram for momentum analysis of a junction of two uniform rectangular streams.

Copyright © 2006 Taylor & Francis Group plc, London, UK

the momentum flux, across a planar part of a control surface, where the velocity crosses the section perpendicularly is $\mathbf{M} = \rho(gAh_c + \beta Q^2/A)\ \hat{\mathbf{n}}$, where symbols are the same as above, with the addition of h_c, the depth of the centroid of the section below the surface, such that Ah_c is the first moment of area of the section about a transverse axis at the water level, and $\hat{\mathbf{n}}$ is a unit vector, normal to the section, directed outwards from the control volume.

The vertical boundaries across which momentum flows, with the corresponding reference letters on Figure 4, are a transverse **U**pstream face across the stream, a similar **D**ownstream face, a **L**ateral stream entering at an angle of δ to the main stream, the side of the main stream **O**pposite to the inflowing stream, and the side **A**djacent to it. The analysis we are about to perform assumes that the square of the Froude number of the incoming flow at L is not large so that the disturbances to the free surface are also not large.

It is the *dynamic* contribution from L that is the most important factor in the analysis. If we consider a momentum balance *transverse* to the main stream, then by a simple theorem from hydrostatics, the component of a static force on any surface is equal to the component of the static force on a projection of that surface perpendicular to the component direction (*e.g.* §2.6 of White (2003)). This means that the static component from L in the transverse direction is approximately equal to that on the rectangular section from the junction point j to w_3, and the component from the wall W is approximately equal to that on the projection w_2w_3. Hence the static component of the whole lateral entry region is approximately that of a hypothetical wall from j to w_2, just as if the tributary were not there. This leaves the only transverse contribution that of the dynamic contribution from the tributary, which can only be balanced by the force contribution from O being slightly larger than that from A and jw_2, so that the water level along O opposite the tributary will be slightly higher and the water level along the junction and A will be slightly lower – the transverse dynamic contribution causes the river locally to tilt slightly transversely. While this seems to violate the initial assumption that the water level does not vary much because of the tributary, the overall deduction that the effect is small for small Froude number is true.

Similarly, if we consider longitudinal flow force, along the main stream, it can be seen that the longitudinal static contribution on L will be approximately equal to the contribution due to its projection, the vertical rectangle marked on the surface by w_1w_3, while the contribution on the wall W is only static, and has the same projection area but its contribution is the reverse of that due to L, and so the static contributions almost completely cancel each other out, and the only flow force contribution to the inflowing stream is its dynamic component in the longitudinal direction, which will be usually relatively small.

To quantify this, we write the longitudinal momentum balance, assuming that on each contributing face the water level is constant, but not for the moment assuming that $h_w = h_L$, to give, after re-arrangement:

$$\tfrac{1}{2}Bh_D^2 + \frac{\beta_D Q_D^2}{gBh_D} - \left(\tfrac{1}{2}Bh_U^2 + \frac{\beta_U Q_U^2}{gBh_U}\right) - \cos\delta\,\frac{\beta_L Q_L^2}{gbh_L} + \tfrac{1}{2}b\cos\delta\left(h_w^2 - h_L^2\right) = 0, \qquad (5)$$

in which b is the width of the tributary. A good approximation is that the water level in both confluent streams is the same, such that $h_L = h_U$, which is supported by evidence (Hager 1987, citing Favre and Vischer). The last term in (5) shows mathematically the approximate balance between the contribution of the wall and that due to the lateral stream. However the actual depth along the wall is not known *a priori*, although in many cases, the water surface drops very little as the tributary enters the main stream, and so $h_w \approx h_L$. As a first approximation a factor $\gamma = h_w/h_L$ could be introduced in the spirit of Hager (1989), and a numerical value slightly less than 1 assigned. The result is an equation connecting h_U and h_D in terms of all the β and Q of the three component streams. If we were to make the further approximation that all the dynamic terms, of magnitude proportional to the square of the Froude number, then the solution of the momentum equation is simply $h_D \approx h_U$.

3.2 *Unsteady flow through junctions of arbitrary section*

Consider a natural river junction as shown in Figure 5. The treatment here is of some generality, so we abandon the nomenclature of Upstream and Downstream, and prefer to identify the channels as 1, 2 and 3. Shown is a possible control volume with vertical planar flow boundaries C_1, C_2, and C_3.

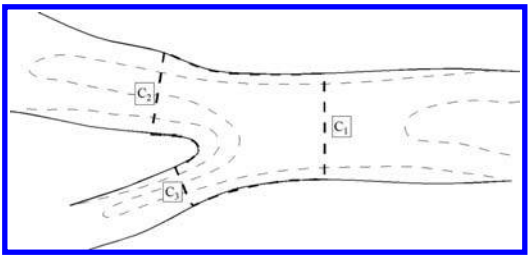

Figure 5. Definition diagram for momentum analysis of a junction of two irregular natural streams.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this case the solid boundaries that give contributions to the momentum from hydrostatic forces, are irregular, complicated, and very difficult to evaluate, if indeed the bottom topography is known at all well. However for rectangular channels in both transverse and longitudinal directions it was seen above that significant cancellations and simplifications occurred. That suggests further exploration for the case of irregular geometry. The reason is to be found in Gauss' Divergence Theorem in one of its lesser-known forms, (#2.61, equation 3 of Milne-Thomson (1968)) to replace the integral of the pressure contributions over *all* parts of the control volume by an integral of the pressure gradient through the volume, as used by Fenton (2006) in a derivation of equations (1). Gauss' relation is

$$\int_{CS} p\hat{\mathbf{n}}\,dS = \int_{CV} \nabla p\,dV. \tag{6}$$

The basic approximation throughout river hydraulics is that the pressure distribution is equal to the equivalent static head of water above, such that at any point with elevation z, and where η is the water surface elevation above, $p = \rho g(\eta - z)$, and ∇p is the vector with components $\rho g(\partial\eta/\partial x, \partial\eta/\partial y, -1)$. As we will not consider vertical momentum here, we can take just the x and y components of the right side of (6), such that $\nabla_2 = (\partial/\partial x, \partial/\partial y)$ and use these results to give the pressure force $\mathbf{P}_2$ in the two-dimensional horizontal plane on the fluid in the control volume:

$$\mathbf{P}_2 = \int_{CS} \nabla_2 p\,dV = \rho g \int_{A_s} h\nabla_2\eta\,dA_s \tag{7}$$

where the last term is the integral over the surface area A_s of the junction, of the depth h times the surface gradient. In this form the contribution can be approximated readily without gross error, in the spirit of much river hydraulics. If we take the component of the net pressure force along part of the control volume, and just consider the x-component along the volume, in a slice of length Δx and elementary volume ΔV, the term becomes, as $\partial h/\partial x$ is closely constant across the width,

$$\rho g \int_{A_s} h\frac{\partial\eta}{\partial x}\,dA_s = \rho g\frac{\partial\eta}{\partial x}\Delta V = \rho g\frac{\partial\eta}{\partial x}A\Delta x, \tag{8}$$

and this results in the term $gA\,\partial\eta/\partial x$ in the momentum equation for the channel, (1b). This underlying simplicity leads us to suggest that for all the physical processes governing motion in the junction, there is nothing which requires special modelling if momentum is considered. Energy is quite different, because the mixing of two streams at an angle to each other causes extra losses. For momentum, however, all processes are similar to those which occur in the body of the river itself. The process of friction drag is similar, although extra currents will cause some minor differences.

In the case of a junction of two rectangular channels, the water surface slope does vary around the junction, and for higher speed flow, it does dip as it passes the sharp corner w_2 in Figure 4. However, for natural junctions as in Figure 5 we assert that the river surface shows little unusual variation, and that it becomes possible to do away with the concept of a special control volume at the junction. It seems easier and in keeping with the usual one-dimensional approach to rivers if instead, the river junction is considered as a junction between different one-dimensional streams, as shown in Figure 6. This might have been the simplest and most obvious approach from the beginning, but the junction problem has been traditionally believed to be too complicated for such a simple representation.

The CasCade model already incorporates this representation in its looped network formulations. A major problem for the actual case study, as presented previously, has been the lack of data regarding the lateral inflow volume flux. There is no rating curve existing for the Neckar tributary nearby the junction, because of the influence by the Rhine river superimposed on the unknown discharge control by upstream hydropower plants. Furthermore it is not possible to develop a rating curve for a long section upstream of the junction, due to the influence of the Rhine discharge on Neckar water levels and even more important, the influence of the Neckar discharge on Rhine water levels. A calibrated CasCade model was therefore used to artificially develop a rating surface at the junction point. Given downstream water level and discharge, together with given upstream discharge allows computing the Neckar flow and upstream water levels for both. An *a priori* calculation of the rating surface using Equation (5) would improve the modeling of junctions considerably, which still has to be proven.

In view of this apparent simplicity, it seems that the only consideration at a junction is to include the dynamic momentum contribution from the tributaries. Equation (5) for rectangular channels clearly contains

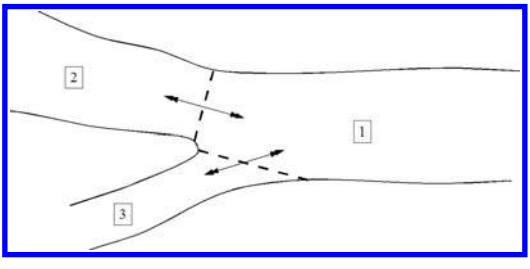

Figure 6. The schematisation which can be used in practice at a junction of two irregular natural streams.

Copyright © 2006 Taylor & Francis Group plc, London, UK

a dynamic contribution from the inflow that becomes, after multiplying through by g:

$$\cos\delta \frac{\beta_L Q_L^2}{b h_L} \quad (9)$$

that does affect the main stream. Here we examine the adequacy of the inflow term $\beta_q\, q\, u_q$ in the general momentum equation (1b) to represent this. We multiply by the length of the finite computational length Δx in the downstream river. It is clear that $\beta_q = \beta_L$, $q\Delta x = Q_L$, and $u_q = \cos\delta\, Q_L/bh_L$, and the expressions are equivalent. Hence we suggest that the only effort or modification necessary to allow for a river junction is to add the dynamic momentum contribution as an inflow contribution, such that over the first computational length the term $\beta_q\, q\, u_q$ be incorporated as a total contribution of $\cos\delta\, \beta_L Q_L^2/A_L$ where the subscripts L pertain to the lateral stream and δ is the angle it makes with the downstream channel.

4 THE CALCULATION OF FRICTION

4.1 *Friction formulations*

The Gauckler-Manning-Strickler equation is empirical – it has no theoretical justification. It is simple and describes friction for a river cross-section as a whole. Rouse (1937) wrote

> "… hydraulicians have been forced to rely to a great extent upon empirical relationships for the expression of energy loss due to turbulence; and as empiricism is at best a rather haphazard means to an end, such relationships in themselves are seldom likely to suggest the correct nature of underlying physical principles. Thus it is that the subject of hydraulics now finds itself somewhat hobbled in its thought by those very methods which contributed greatly to its prestige in past generations.

However, an alternative was already at hand, Keulegan (1938) noted that the theoretical investigations of Prandtl and von Kármán, and the experimental work of Nikuradse, led to rational formulas for velocity distribution and hydraulic resistance for turbulent flow in circular pipes in terms of the dimensionless Weisbach friction coefficient λ. He went on to show how similar rational formulas could be deduced for open channels, although rather than allowing for a general treatment by allowing for the local depth to vary over a section, he adopted the overall section hydraulic radius as the characteristic length.

The optimism of the 1930s was misplaced – the Gauckler-Manning-Strickler law continues to appear as some sort of universal standard, such that experimental and field results are related to it, arbitrary formulae are used to apply it to compound sections and more general problems, and books and tables are published suggesting that friction can be calculated from visual similarity with other rivers. There are a number of arbitrary formulae for calculating the effective friction coefficient for a section, not based on rational criteria. Indeed the ASCE Task Force on Friction Factors in Open Channels (1963) wrote:

> "Many engineers have become accustomed to using Manning's n for evaluating frictional effects in open channels. At the present stage of knowledge, if applied with judgement, both n and λ are probably equally effective in the solution of practical problems. The design engineer who prefers to use n in his (*sic*) computations should continue to do so, but he should recognize the limitations on his method … It is believed that experimental measurements of friction in open channels over a wide range of conditions are better correlated and understood by the use of λ. Furthermore, λ is commonly used by engineers in many other branches of engineering and probably provides the only basis for pooling all experience on frictional resistance in both open and closed conduits. It is recommended, therefore, that engineering teachers and research workers emphasize the use of the friction factor λ …

Clearly the Task Force believed that Manning's n was sufficiently entrenched in practice that it could continue to be used but that it was desirable for researchers and teachers to move the profession in the direction of λ.

4.2 *A drag-force approach to channel friction*

The resistance to flow in open channels has often been thought of, incorrectly, in energy terms, giving rise to the concept of energy gradient. Energy dissipation processes are internal to the flow and are complicated and difficult to describe and quantify. However the concepts of the Chezy resistance coefficient C and the closely allied Weisbach coefficient λ are derived from considerations of wall stress, hence momentum. Also, research into the effects of vegetation on flow has used a momentum approach, in terms of drag forces on individual elements, which has usually then been converted to an equivalent overall Gauckler-Manning-Strickler roughness by processes whose validity is doubtful.

Using momentum/drag it is possible to unify effects due to boundary roughness, bed-forms, vegetation, and structures – using the empirical Gauckler-Manning-Strickler law that is not possible. Consider the combined drag force ΔT on a number of discrete

Copyright © 2006 Taylor & Francis Group plc, London, UK

roughness elements and/or vegetation elements in an elemental slice of channel of length Δx:

$$\Delta T = \frac{\rho}{2} \sum C_D v^2 a, \tag{10}$$

where the summation is over all the drag-producing elements, each of projected area a normal to the flow of local velocity v and with drag coefficient C_D. Theoretically the sum contains a huge number of terms of small quantities (every sand grain, for example). It is not intended that the sum ever be actually evaluated, it is here only as a representation. If the local velocity v is assumed given by a factor γ related to the mean horizontal velocity in the channel Q/A, then $v^2 = \gamma Q^2/A^2$, and

$$\Delta T = \frac{\rho}{2} \frac{Q^2}{A^2} \sum C_D \gamma a. \tag{11}$$

The *mean* shear stress on the channel wall is given by (p 63, Montes (1998)):

$$\tau_0 = \rho \frac{\lambda}{4} \frac{(Q/A)^2}{2}, \tag{12}$$

where λ is the Weisbach friction coefficient, so that, using $\tau_0 = \Delta T / P \Delta x$ gives λ expressed in terms of the drag components:

$$\lambda = \frac{4 \sum C_D \gamma a}{P \Delta x}. \tag{13}$$

This gives a fluid-dynamical explanation for the behaviour of λ, and shows how it is actually made up of *local* components, and how a rational theory of channel friction becomes possible:

- In general, the elements of the sum $\sum C_D \gamma a$ will vary around the boundary, as the bed material changes, as vegetable matter of a different kind grows at the edges, as the local value of γ depends on the local depth, and so on.
- Clearly the drag coefficient terms can be added linearly so that we could write it as a *finite* sum of various contributions

  $$\lambda = \lambda_1 + \lambda_2 + \ldots, \tag{14}$$

  where 1, 2, *etc* might denote gravel on bed, reeds at the side, and so on, each of which can be determined separately by research.
- In the case of the Gauckler-Manning-Strickler equation it is not at all clear how individual components should be combined, and there are several alternatives.
- With some research and experience it would be possible to calculate the sum, and hence the friction coefficient λ, from a knowledge of bed materials of the same form.
- In general, the sum and hence the friction factor λ, will be a function of depth and flow. It, unlike Manning's n (Strickler's k_{St}), is not expected to be constant. Its variability is an expression that we are modelling the actual physics. We do not expect a magic constancy for such a complicated problem.

In the case of a channel with particles of sand or gravel, we can use previous research which has obtained expressions for λ. Colebrook and White proposed an implicit equation for λ in a pipe in terms of relative roughness k/D, the equivalent sand grain roughness divided by the pipe diameter D, and the Reynolds number $\mathbf{R} = UD/\nu$. For channels this can be used with $D = 4A/P$ (Henderson (1966, p 93)). As λ appears implicitly in the equation, it has been thought of as being more difficult than it really is. To try to overcome this Moody (1944) produced a well-known chart for λ as a function of $\mathbf{R}$, with k/D as a parameter; it is not always known that most of the results are simply those corresponding to the Colebrook and White equation. The best solution of all is to use the explicit approximation produced by Haaland (1983):

$$\lambda = \frac{1}{1.8^2} \log_{10}^{-2} \left(\left(\frac{k/D}{3.7} \right)^{10/9} + \frac{6.9}{\mathbf{R}} \right), \tag{15}$$

where again, $D = 4A/P$ for a channel.

4.3 *Use in practice*

In equation (3) the conveyance K in terms of λ is given by

$$K = \sqrt{\frac{8g}{\lambda}} \frac{A^{3/2}}{P^{1/2}} \tag{16}$$

so that in the 1-D momentum equations (1b) and (4b) the friction term appears as

$$-\frac{gAQ|Q|}{K^2} = -\lambda P \frac{Q|Q|}{8A^2}, \tag{17}$$

with an extra curvature factor in the latter case. The friction coefficient λ appears linearly, as does perimeter P, as they are directly related to the force on the boundary, to which the whole term corresponds. If the boundary were a compound boundary, for example, or with different roughness elements, one could write the friction term in terms of a sum

$$-\left(\sum_i \lambda_i P_i \right) \frac{Q|Q|}{8A^2}. \tag{18}$$

If this approach were adopted, it may be less necessary to resort to 2-D or 3-D modelling, as the characteristics of the whole cross-section are incorporated in this 1-D model.

5 CONCLUSIONS

The simulation of rivers has been examined, by one-dimensional models in general, and by the program CasCade in particular. Extensive data management allows for analysis of real-time flow dynamics coupled with navigation dynamics, river bed dynamics and impact analysis of regulating waterway structures. The governing equations have been shown to require few limiting assumptions. Furthermore the problem of the confluence of two or more natural streams has been considered, and the problem has been shown to be able to be approximated by conventional one-dimensional approaches, with the incorporation of the momentum from and to any tributaries or effluent streams. The problem of simulating flood-plain flows was considered, and it was concluded that even though the one-dimensional approach does not solve the problem as well as might be desired, irregularities of roughness, channel and geometry are such that no great sophistication is warranted and further developments of a simple nature are warranted. Methods for calculating friction have been considered, and it has been suggested that the Weisbach formulation is characterised by its universal applicability beyond the main channel hydraulics. It is concluded that the knowledge of frictional characteristics in the bed and the floodplains of a river, and the detailed geometry of both, are usually so limited that the one-dimensional model represents a good compromise between requirements of fidelity of simulation and the greatly increased effort and intrinsic limitations of highly accurate simulation by two- and three-dimensional models.

River Po low water training: The importance of mathematical modeling to support designing activities

L. Schippa, S. Pavan & S. Colonna
Engineering Department, University of Ferrara, Italy

ABSTRACT: An extended reach of the major Italian river, the river Po, is suitable for navigation. Regulation works are however needed to ensure good navigation conditions also during low water periods. Designing has been supported by hydraulic mathematical modeling in order to evaluate long term and middle term effects. Mobile bed simulations have been performed using a mathematical model based on one-dimensional shallow water equations and on Exner equation. The model has been numerically implemented with an implicit finite difference algorithm based on the four points Preissman scheme. Both actual and designed river configurations have been modeled in order to evaluate effects on design navigation channel, on sediment balance and bottom evolution, on hydraulic risk and on solid mass fluxes to the river delta.

1 INTRODUCTION

Progresses and improvements in the field of hydraulic research led to significant achievements and developments for what concerns hydraulic modeling. The possibility of creating a mathematical or numerical model based on the deep knowledge of physical phenomena, is of utmost importance in river engineering, and it is going to become one of its fundamental tools.

The value of hydraulic models during the project phase of considerable river regulation works is easy to understand, since they give the opportunity to know in advance the effects of human actions on the natural system and on the surrounding environment. Moreover, they permit to better evaluate project decisions, and to accurately choose the operative procedures which will lead to job's successful outcome.

In this paper, an example of the role of hydraulic modeling in river management is proposed, with the description of the various phases of work and of the interactions with the designing party.

The project's issue is the low water training of river Po, the major river in Italy. Thanks to its depth and to its noticeable width, the Po river results suitable for navigation for a long reach of about 400 kilometers, starting upstream from the city of Cremona, where an important harbor has been built, and closing downstream near the town of Porto Viro, in correspondence of the navigation lock of Volta Grimana, which links the Po river with another navigable channel. However, the lack of river regulation structures dramatically reduces the navigation possibilities during low water periods along the middle reach, between the tributary Mincio's mouth and the city of Ferrara.

To ensure navigability features for an extended period of time, a river regulation work has been planned. It involves a 60 Km long river reach, and includes several submergible groynes and riverbank stabilization structures. The aim of the modeling work here presented is to investigate morphological changes expected in river bed configuration, the overall sediment balance along the river, the consequent flood risk assessment and the variation of solid mass fluxes to the Po delta. Beside these environmental aspects, the model will also give useful indications about low water river course regarding navigation purposes, and about effects induced on the existent structures along the river.

Simulations have been performed with a mobile bed one-dimensional mathematical model based on shallow water equations and on sediment continuity equation, numerically implemented with an implicit computational scheme. Though natural rivers flow patterns are predominantly 2-D, a one-dimensional model has been chosen in order to have the possibility of long term and middle term simulation performance. Since the aim of this analysis is to capture the river evolution trend and the regulation works global effects, the choice of a 1-D model, seems to be the most convenient from the computational point of view. The use of a 2-D model, in fact, would have not result in a more accurate representation of macro-phenomena, in front of a larger computational effort. An appropriate method has however been applied to take in

Copyright © 2006 Taylor & Francis Group plc, London, UK

account bends curvature for morphological changes evaluation. The examined river reach has been properly extended downstream and upstream in order to correctly evaluate its evolution trend. Boundary conditions have been derived from hydrologic historical data and rating curves.

The modeling work has been applied considering two different geometrical configuration: the actual river condition, and the river setting after regulation operations. Simulations results have been analyzed in comparative and absolute terms.

2 THE MATHEMATICAL MODEL

2.1 *Governing equations*

Since physical celerities associated to liquid phase are much greater than the one characteristic of sediment transport phenomena, an uncoupled treatment is allowed. Indicating with h, water depth, and with Q, liquid discharge, the state variables, the one-dimensional shallow water equations written in non-conservative form are:

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q^2}{\Omega}\right)+g\Omega\frac{\partial h}{\partial x}+g\Omega s_f=0 \quad (1)$$

$$\frac{\partial \Omega}{\partial t}+\frac{\partial Q}{\partial x}-q=0 \quad (2)$$

where g is the gravitational acceleration, Ω the wetted cross-section, x the distance along the river, t the time variable, s_f the friction slope and q the lateral incoming discharge for unit length.

Equations 1–2 constitute a non linear mathematical system, which may be numerically solved once proper initial and boundary conditions are imposed.

From the hydraulic point of view, river cross-sections are clearly divided in two different zones: main channel and over banks. This distinction reflects also on the sediment transport evaluation: the channel, where low flow and moderate flow discharges are contained, is generally covered by granular material and takes part to sediment exchanges; on the contrary over banks are only interested by flood events and can be considered as not erodible zones. Equations 1–2 are applied only within main channel, while over banks hydraulics is treated using a quasi-uniform flow scheme, assuming the same water surface slope as main channel.

Slope friction has been calculated under the hypothesis of uniform flow by means of the Gauckler-Strickler formula:

$$s_f=\frac{Q|Q|}{\Omega^2 gRC^2}\ ;\ C=\frac{K_S R^{1/6}}{\sqrt{g}} \quad (3)$$

where R indicates the hydraulic radius. The Gauckler-Strickler coefficient K_S has been calibrated and it resulted homogeneously equal to $38\,m^{1/3}/s$ for the main channel, while for over banks it varies within the range $3\,m^{1/3}/s$–$30\,m^{1/3}/s$ with a mean value of $15\,m^{1/3}/s$ (Agriculture Ministry, 1990).

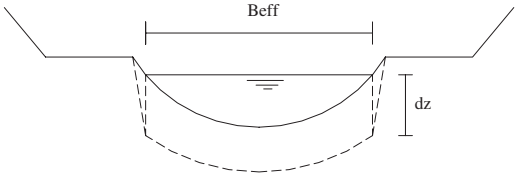

Figure 1. Cross-section uniform evolution model.

Equations 1–2 have been numerically solved applying the Preissman semi-implicit scheme, with implicity parameter equal to 0.7 and spatial weight of 0.5, commonly used values which guarantee computational stability and results accuracy (Chaudry, 1993).

Cross-sections evolution process is influenced by longitudinal and transversal solid transport gradients, mainly associated to the concentration gradient and to lateral gravitational bottom transport. (Lamberti & Schippa, 1996) The present approach assumes the sediment redistribution effect across the cross-section to be complete and homogeneous. As represented in Figure 1, this leads to a uniform vertical translation of channel bed, which corresponds to the eroded sediment volume per channel length.

Solid phase balance equation is written as:

$$\gamma_S B_{eff}\frac{\partial z}{\partial t}+\frac{\partial Q_S}{\partial x}-q_S=0 \quad (4)$$

where Q_S is the apparent volumetric solid discharge (the bed porosity is assumed equal to 0.4), γ_S is the apparent specific weight, B_{eff} is the effective cross-section width which takes part to sediment exchange processes, z is the elevation of channel bottom, q_S is the sediment discharge per unit length deriving from external mass exchanges (e.g. mining activities).

The unknown in Equation 4 is the uniform bed level variation ∂z. Here the Preissman scheme has been applied assuming the spatial weight equal to 0 in the upstream cross section of every single reach, and equal to 1 in its downstream cross-section. This is allowed considering the limited daily evolution of bed level, and ensures high computational stability. The implicity parameter is kept equal to 0.7 as for the liquid phase.

Through comparison with measured values of sediment transport (Agriculture Ministry, 1990), the relation which gives the best solid discharge estimate is the Engelund-Hansen formula:

$$Q_S=0.05B\gamma_S U^2\sqrt{\frac{d_s}{g(s-1)}}\theta^{3/2} \quad (5)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where s is the relative sediment density 2.65, B is the water surface width, d_s is the representative sediment diameter, U is the mean flow velocity, θ is the Shield's parameter.

2.2 *Boundary conditions*

For liquid phase, the upstream boundary condition is the temporal sequence of daily mean discharge values, both for the Po reach upstream end and for each of the 14 tributary comprised in the analyzed reach.

For what concerns solid phase, the incoming sediment discharge and the transport mass at tributaries mouths are evaluated assuming a local uniform flow condition and the correspondent transport capacity, as it results from the Engelund-Hansen monomia formula:

$$Q_S = 15.54 \frac{1}{d_s \cdot B^7} k_S s_f^{1.65} Q^{1.7} \tag{6}$$

At a distance of about 90 Km from the upstream cross section, a transversal regulation structure (operating since 1969) is located, in correspondence of a river island named Isola Serafini, immediately upstream of the tributary Adda's mouth. From the modeling point of view, it represents an internal boundary condition, which requires the definition of a relationship between flowing discharge and upstream and downstream water levels. This relation has been derived considering the structure management rule, that is the maintenance of a water surface elevation equal to 41.00 m, except in case of huge flood events, when the barrier is set as wide open and its presence may be neglected.

To represent this internal boundary condition, a fictitious cross-section has been added 100 m downstream the blockage location, in order to isolate this anomalous reach, for which particular balance equations have been used instead of Equations 1–2:

$$Q_{IS} = Q_{IS+1} \tag{7}$$

$$h_{IS} = 41.00\ m\ ;\ h_{IS} = h_{IS+1} \tag{8}$$

in which the under script IS indicates the Isola Serafini cross-section, while $IS + 1$ stands for the downstream fictitious cross-section. Equation 7 expresses the continuity of the flowing discharge, while Equation 8 regulates the structure water elevation respectively in case of ordinary operation and flood event.

The downstream boundary condition consists of a rating curve in correspondence of Polesella station. It has been provided by the hydro-meteorological service, and it is based on measures carried out between 1988 and 1993. It is considered as representative of the last decade with a ±10% variation, and it is actually

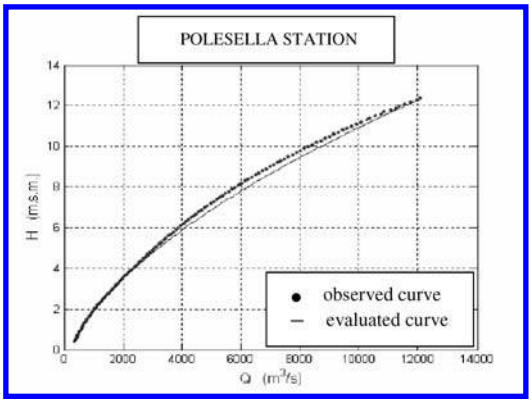

Figure 2. Rating curve at Polesella station.

under validation process. In the model, the discharge scaling is expressed as follows:

$$Q = a\left(h - h_0\right)^b \tag{9}$$

where h is the water level corresponding to the discharge Q, h_0 is the virtual water surface elevation corresponding to null discharge at Polesella, a and b are characteristic parameters dependent on cross-section shape, extrapolated by the minimum square method ($a = 118.89$, $b = 1.76$, $h_0 = 1.50$ m).

Beside, an evolution analysis of the rating curve in correspondence of Pontelagoscuro (about 20 Km upstream from Polesella), has been carried out. On the basis of several measures effectuated between 1988 and 1993, considering a rating curve elaborated in 2000 (G. Benatti, 2000), and the most recent study dated 2003 a stability trend of the bed level configuration is clearly noticeable. This deduction may be extended to the overall low course of the river Po, in particular downstream of the Pontelagoscuro station. This means that the Polesella rating curve may be assumed as invariant for the simulation period and substantially independent from the weak evolution processes of the reach.

3 RIVER DESCRIPTION

The mobile bed model has been applied to a Po reach which starts upstream at La Becca and extends till Polesella with an overall length of 307 Km.

This extension has the function to include the river reach subject to regulation works, to mitigate any discrepancy effect which may derive from boundary conditions, to have reliable data at upstream and downstream ends, and to evaluate works effect over the whole river.

Copyright © 2006 Taylor & Francis Group plc, London, UK

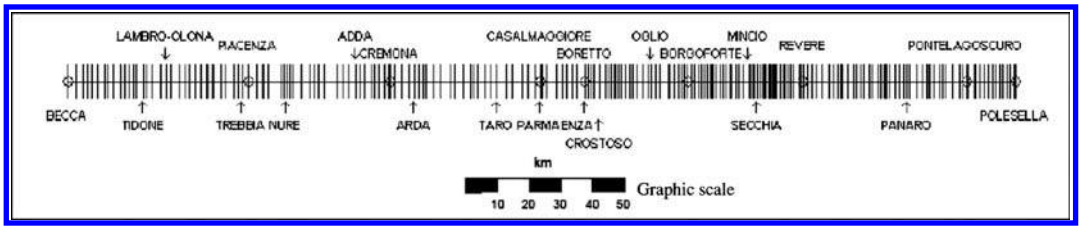

Figure 3. River reach scheme.

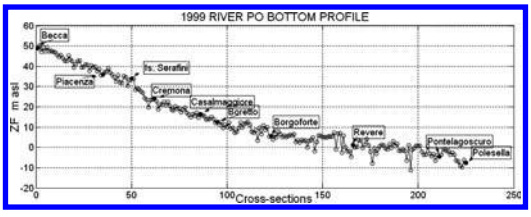

Figure 4. AIPO 1999 surveys: longitudinal profile.

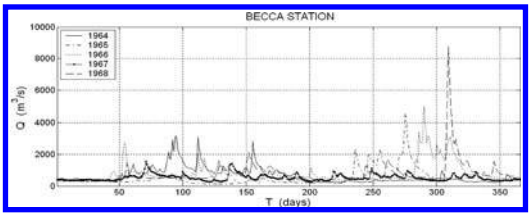

Figure 5. Example of daily discharge hydrogram at Becca station in representative years.

Along the considered reach, river Po receives water from 15 tributaries, that have been schematized with 14 localized incoming discharge.

The cross-section geometry has been described by means of recent field surveys (AdPo, 2001), however proper fictitious cross-sections have been added in order to represent more completely the design configuration in the surroundings of the low water channel settlement work. The resulting river scheme is therefore composed by 225 computational sections meanly spaced by 1.5 Km, each one described by 100 points of known coordinates. In particular, over banks are each described with 30 points, while 40 points are reserved to channel representation.

3.1 *Hydrologic data*

For what concerns hydrologic data, the daily mean incoming discharge at the upstream station, is known in the period 1954–1971, while from 1972 to 1983 only data starting at Piacenza station are available. After statistical considerations, a quantitative relationship has been found between the discharge passing by Piacenza and the upstream water flow at La Becca, assuming a traveling time of a day.

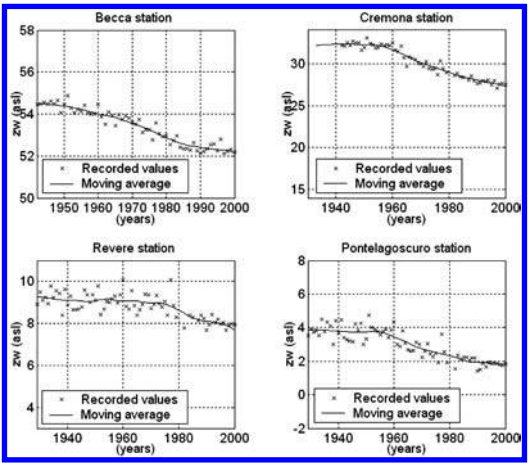

Figure 6. Minimum water elevation trend.

In this way, the discharge data sequence at disposal covers a period of 30 years, and may be considered as a long period representative sequence. It can therefore be used to represent the hydrologic succession of the fifty year simulation time.

3.2 *Hydrometric data*

Water surface elevation data are known in 8 hydrometric stations: Becca, Piacenza, Cremona, Casalmaggiore, Boretto, Borgoforte, Revere and Pontelagoscuro. Among them, minimum annuals elevations have been isolated and examined. In fact, the hydrometric level is a reliable indicator of bed elevation lowering trend, since it is not affected by local anomalies as bottom elevation, usually assumed as the cross-section lowest point elevation, can be (e.g. localized rocks or pits) (Schippa & Pavan, 2004). Referring to Figure 6, one can see a progressive reduction of the noticeable lowering trend initiated in the fifties. In particular at Cremona station erosion is particularly evident because of the presence of Isola Serafini structure, while at Pontelagoscuro station the lowering trend is no longer perceptible, also because of the sea proximity, which level strongly influences low water flow.

Copyright © 2006 Taylor & Francis Group plc, London, UK

3.3 *Sedimentological data*

The sedimentological channel characterization has been derived from field measurements carried out in the nineties (Agriculture Ministry, 1990). Two main aspects are to be highlighted: the granulometric distribution is substantially one-modal, except for the upstream reach where the torrential stream effects lead to a bi-modal distribution; secondly, the sediment diameter progressively reduces as a consequence of sorting.

In the model, the channel has been longitudinally divided in distinct portion, each one characterized by a d_S constant in time and not affected by the bed altimetric evolution, with a lognormal distribution:

$$d_S = 2^{-\left[0.029+(1.89-0.029)(x/L)\right]} \tag{10}$$

where x is the distance from the Becca station (m) and L is the reach extent.

3.4 *Mining activities*

Generally speaking, the causes which affect bed evolution are: the main channel narrowing for navigation purposes, the Isola Serafini transversal structure presence, and the mining activities, which had a predominant role from fifties until nowadays. (Lamberti & Schippa 1994).

Recently, specific laws have been created for river sediment exploiting regulation. It seems therefore reasonable to take in account a progressive reduction of the extractive action, which leads to an hypothetical realistic residual amount of 3 Mm^3/year within the overall reach. This value will be taken as the representative one across the fifty year simulation period. However, to compensate the uncertainty towards mining activities data, a sensitivity analysis has been performed.

The spatial distribution of the extracted volumes along the reach is worked out from the mining installations layout. Consequently, 10% of the extractions has been attributed between Becca and Piacenza, the 40% between Piacenza and Boretto, the 30% between Boretto and Borgoforte, and the remaining 20% between Borgoforte and Polesella.

4 REGULATION DESIGN

Concerning fundamental designing criteria, there are some significant aspects which rule the navigation path project and the preliminary works sizing.

Straight connection reaches between two consequent curves must be avoided, since they may favor shallow water zones and erratic changes in flow direction. To this purpose, the low water channel design tends to go along with the existent roughed out curves, keeping unchanged the natural navigation path length.

Analyzing forces acting on curved flows (centrifugal force and gravitational force), a proportionality between flexure and arch length ($1/R \propto L$) is noticeable, and leads to the choice of a path made of a clotohoids sequence, osculating at inflection points with different expansion parameters and vertexes.

The height of regulation works crest has been set equal to the low flow water elevation (discharge equal to 450 m^3/s), augmented by one meter next to curves vertexes in order to take in account the water surface rise caused by the centrifugal force. Then the height gradually decreases to the lower profile level from the vertex to the work extremes.

From the operative point of view river regulation structures can be longitudinal or transversal regarding flow direction. The position and the conformation of a bend can be fixed and protected by longitudinal over bank defenses, which can be made of loosen rocks (rip-rap) or have wooden retaining walls filled with granular material. Beside, low stage main channel narrowing is obtained by means of low-dipping cross dikes extended from the river banks and pointing to the river axis so as to direct the water flow into the central channel.

The evaluation of the designed configuration leads to the transversal profile reshaping of the involved cross sections. As far as a one-dimensional model is used, simulations are referred to the final morphological setting, neglecting the transient period during which regulation works will not be fully operative. On the other hand, even if the assessment time of a water stream could have relevant effects, its actual influence is hard to evaluate, (Lamberti & Schippa, 1995), and can reasonably be ignored in long term analysis.

The design transversal profile of the examined reach has been drawn accounting for centrifugal force in curved streams, which produces motion field deformations and typical 3-D effects. A transversal secondary recirculation stream adds to the main longitudinal one, resulting in an overall helicoidal motion. At the concave bend side, sediment particles move downward, depositing, while at the convex side they move upward causing bed erosion.

To represent these morphological phenomena, the simple Engelund-Bridge model has been chosen:

$$\frac{D}{D_C} = \left(\frac{r}{r_C}\right)^{\alpha} \quad ; \quad \alpha = 11\tan\varphi \tag{11}$$

Referring to Equation 10 and to Figure 7, φ is the soil slope friction, r is the flexure radius, D the local depth, r_i and D_i are respectively the bend internal radius and depth, r_e and D_e refer to the external bend side, r_C and D_C to the middle channel.

Copyright © 2006 Taylor & Francis Group plc, London, UK

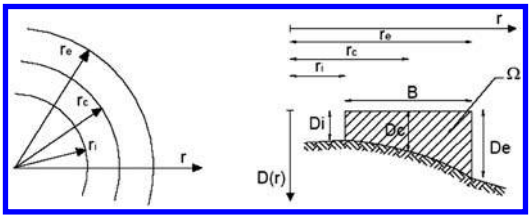

Figure 7. Engelund-Bridge model.

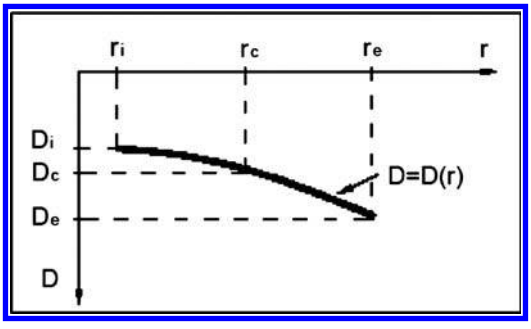

Figure 8. River bend design profile.

In this case the flexure radiuses are known, and correspond to those of the designed low flow channel, defined by a the discharge $Q_P = 450\ m^3/s$.

Assuming quasi-uniform flow conditions for the low flow event, one obtains:

$$\begin{cases} \Omega = \dfrac{Q_P}{C\sqrt{g}\sqrt{s_0}D_c^{1/2}} \\ \Omega = \int_{r_i}^{r_e} D\,dr \end{cases} \tag{12}$$

where s_0 is the longitudinal bottom slope.

Substituting the D expression obtained from Equation 10 inside Equation 11, and balancing the two expressions of Ω, leads to the value of D_C:

$$\frac{Q_P}{C\sqrt{g}}\frac{1}{D_C^{1/2}} = \frac{D_C}{r_C}\frac{1}{(\alpha+1)}r^{\alpha+1}\Big|_{r_i}^{r_e} \Rightarrow D_C \tag{13}$$

The application of Engelund-Bridge formula gives then the bend transversal configuration:

$$D(r) = \frac{D_C}{r_C^{\alpha}}r^{\alpha} \quad , \quad r \in [r_i, r_e] \tag{14}$$

It is very important to consider the definitive river configuration, since the regulation works presence strongly affects the channel geometry, consequently conditioning sediment balance through modifying the effective cross-section width. As an example, Figure 9 depicts the effect of a cross dike, highlighting the noticeable main channel narrowing produced in the final design configuration.

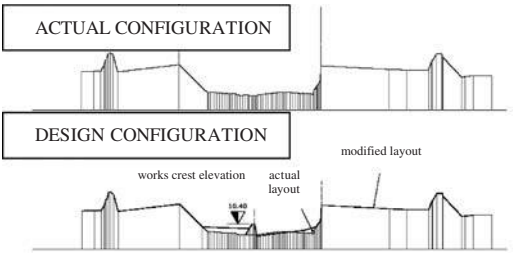

Figure 9. Example of definitive design morphology.

5 SENSITIVITY ANALYSIS

The sensitivity analysis is a useful tool for results comprehension, since it puts in evidence data sets influence on model behavior and simulation outcomes.

In particular, among the parameters affected by an uncertainty grade, the most interesting seem to be those regarding mining activities, on which sediment balance directly depends, and flow resistance, because of its influence on flow regime and transport capacity. They have therefore an important role in defining the river morphologic evolution.

Anyway, it is important to keep in mind the comparative purpose of this work, which mainly aims to analyze the differences in the evolution process of the actual and of designed river configuration (*ante and post operam*) instead of giving an overall evaluation of the phenomena.

The reference values for the sensitivity analysis are the minimum annual water surface elevation zw_{min} and the bed elevation z. As pointed before, zw_{min} can be considered as the more reliable one, since it is not affected by isolated irregularities and localized flow pattern effects.

In view of the fact that the model sensitivity cannot depend from the geometry configuration assumed, the analysis has been performed considering the actual state, correspondent to the surveys of 1999 (AdPo, 2000).

To determine model sensitivity to mining activities, different scenarios have been hypothesized:

1) no mining activities
2) extracted volume equal to 1.5 Mm^3/year (50% less than the reference volume)
3) extracted volume equal to 3.0 Mm^3/year (reference volume)
4) extracted volume equal to 4.5 Mm^3/year (50% more than the reference volume).

Copyright © 2006 Taylor & Francis Group plc, London, UK

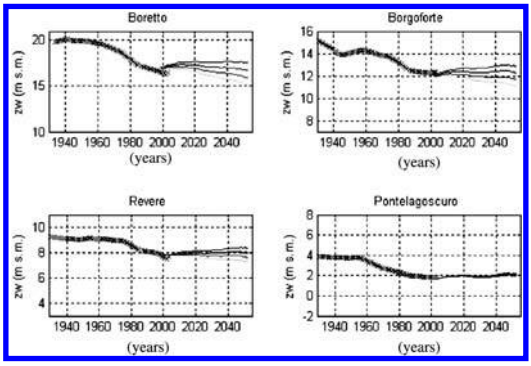

Figure 10. Sensitivity analysis to mining activities in terms of minimum water level evolution trend.

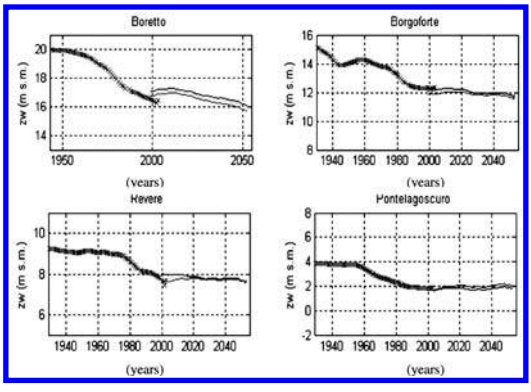

Figure 11. Sensitivity analysis to flow resistance in terms of minimum water level evolution trend.

The graphical results for the main stations located in the river reach mostly involved by regulation works are shown in Figure 10.

Referring to the trend evolution analysis of the last decades (see Fig. 6), the prudential approach which suggests a mining activity of 3 Mm^3/year seems to be the more consistent one, since it continues the observed stabilization tendency. This is particularly evident at Pontelagoscuro station.

As expected, the model sensitivity to sediment extraction is predominant in correspondence of the reaches to which a greater excavation activity is assigned, that is Boretto and Borgoforte.

For what concerns the influence of the flow resistance coefficient, the three chosen possibilities are:

1) $k_S = 34\ m^{1/3}/s$ (10% less than the reference value)
2) $k_S = 38\ m^{1/3}/s$ (reference value)
3) $k_S = 42\ m^{1/3}/s$ (10% more than the reference value)

Figure 11 shows the modest model sensitivity to the flow friction parameter, especially in the downstream zone.

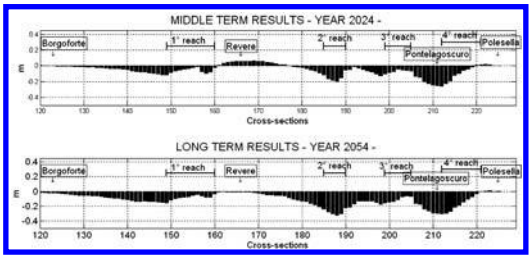

Figure 12. Minimum water elevation variation during simulation: middle term and long term results.

6 RESULTS

6.1 *Bed elevation evolution trend*

As already explained in the previous sections, the most reliable trend indicator is the minimum water level, since it is independent from local effects. However, within long and middle term analysis, it should be properly filtered to eliminate inconsistent values deriving from particular hydrologic events, as for example the 2003 exceptional low flow.

Another possible indicator of bed lowering or overloading is the low flow wetted cross section, estimated assuming quasi-steady conditions. Its value is however influenced by energy slope, which is in turn a channel bed evolution result.

Moreover, the uncertainty grade of data sets and the difficulty of correctly quantifying all linked and involved phenomena, suggest to focus on a comparative evaluation of results, instead of referring to absolute estimates.

Figure 12 shows the difference between the annual minimum water level of actual and designed configuration. Graphics have been obtained from the moving average of minimum water level elevations simulated in each cross-section $\overline{zw}$. The ordinate axis represents the difference for the N-th year of the i-th cross-section: $diff^N(i) = zw_D^N(i) - zw_A^N(i)$, where the term $zw_D^N(i)$ refers to the design configuration, and $zw_A^N(i)$ to the actual state.

The overall bar chart representation puts in evidence a substantially unchanged sediment balance over the reach, showing a sub-reaches succession with stable evolution trends over the time.

Figure 13 represents the annual minimum water level differences between the beginning and the closing of simulations, for both design and actual river geometry:

$$diff_D(i) = \overline{zw_D}^{2054}(i) - \overline{zw_D}^{1999}(i) \quad (15)$$

$$diff_A(i) = \overline{zw_A}^{2054}(i) - \overline{zw_A}^{1999}(i) \quad (16)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

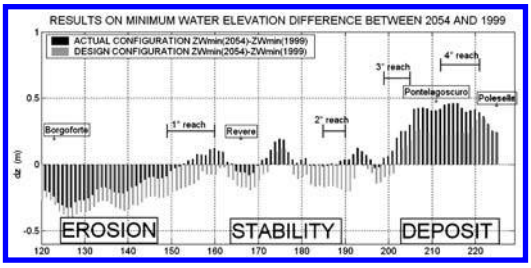

Figure 13. Annual minimum water level differences at the end of simulation.

The notation $\overline{zw}$ indicates the moving average over 5 annual values.

For what concerns the actual configuration, from the analysis of Figure 13, one can see that the first zone, localized between Borgoforte station and the tributary Secchia, presents a slight lowering tendency; from Secchia's mouth until Panaro's mouth the bottom configuration seems to be stable; then, from Panaro's outlet to Polesella station, a channel overloading tendency is noticeable.

Referring to the results of the design configuration simulations, the same reach splitting can be drawn, and the same considerations can be derived for the three sub-reaches, even if from the quantitative point of view the evolution effects seems to be smoother. This result can be interpreted as an assessment of the future bed evolution trend along the considered reach. Beside, it seems that the presence of regulation works would not affect the natural river morphologic development (i.e. lowering or overloading), though a smoothing effect should be taken in account.

The same conclusions may be evinced from the analysis of bottom elevation, always referring to the moving average values over five points. The results analysis also permits to border the regulation works influence zone, which extends to about 5 km upstream and terminates about 20 km upstream of the first modified cross-section.

6.2 *Effects on navigation channel*

To establish the efficiency and the stability of the navigation channel, the analysis has been based on channel bottom morphologic evolution and on annual minimum water depth trend along the reach, at simulation beginning and closing.

The assumption of the definitive channel geometry as design configuration simulation input data, leads to a progressive canalization of modified cross-sections. It is worth keeping in mind that navigability benefits are strictly connected to the river low flow channel canalization grade.

This phenomenon could be evaluated considering middle-long term minimum water depth. To this

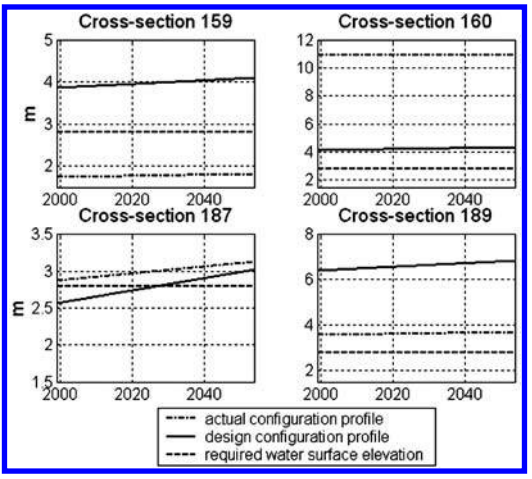

Figure 14. Example of the effects on navigation pattern.

purpose, design low flow ($Q_P = 450\,\mathrm{m^3/s}$) foreseen water depth could be used, in addition to the lowering action expected over fifty years. For the *i*-th cross-section, the estimated water depth at the end of simulation for the actual configuration is:

$$y_A^{2054}(i) = y_A^{1999}(i) + \left|dzw_A(i)\right| \tag{17}$$

$$dzw_A(i) = zw_A^{2054}(i) - zw_A^{1999}(i) \tag{18}$$

where y_A^{1999} is the water depth correspondent to the design discharge ($Q_P = 450\,\mathrm{m^3/s}$) at the simulation beginning (year 1999), zw_A^{1999} and zw_A^{2054} are respectively the minimum water surface elevations at the beginning and at the end of simulation. The same procedure applies to the design configuration.

Figure 14 reports some exemplificative situations, occurring at four different cross-sections representative of the middle river course (between Revere and Panaro's mouth). At a preliminary view one can see that in the long term scene the designed configuration ensures greater water depths than the minimum required for class V boats navigation (dashed line). At section 159 this condition is not fulfilled considering the actual geometry. In some reaches, for example at section 160, the water level consequent to river regulation results lower than the undisturbed one, even remaining over the designed depth. This condition depends on the severe channel modifications due to localized works, and does not affect the deepening tendency of the reach. In certain cross sections, works effects take a longer time to get the definitive navigation setting, like section 167, where an initial unfavorable situation is recuperated within the middle term scene.

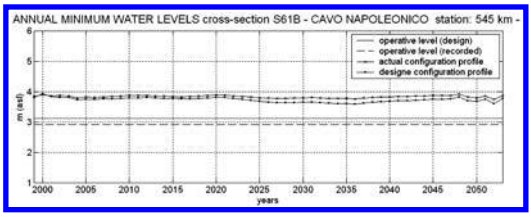

Figure 15. Cavo Napoleonico pump station operation analysis.

6.3 *Effects on existent water supply plants and pump stations*

Within the considered reach, six water supply plants are located. The effects of the designed works are evaluated by controlling if the minimum simulated water levels are in accordance with pumps operation conditions.

The operative water level of every structure has been evaluated considering both the design operation conditions and the minimum recorded water level at which pumps guaranteed their functionality.

Long and middle term simulation results does not show any relevant effect on existing structures, always keeping minimum water levels suitable for their activity.

Results are clearly influenced by hydrologic events, however long term differences between design and actual configuration are unimportant (about 10 cm in 50 years), and regulation works effects may substantially be neglected.

Figure 15 reports as an example the situation at the main pump station present in the analyzed reach.

6.4 *Effects on the Delta sediment feeding and on channel efficiency*

In order to evaluate the effect of regulation works on the sediment feeding to the Po Delta, there are two main aspects to account for: the possible changes in the stable setting of the downstream reach, and the variation of sedimentary fluxes directed to the delta.

For what concerns setting stability, let us consider the model structure: it applies sediment balance to single river reaches delimited by adjacent cross-sections. Referring to Figure 16 for the ending part of the computational scheme one can write:

$$V = \int_T Q_u\,dt - \int_T Q_i\,dt + E \qquad (19)$$

where V is the apparent volume which concludes the sediment balance over the time T, Q_i is the instant incoming discharge, Q_u is the instant outgoing discharge, E is the volume mass associated to external sediment exchanges over the time T, and T is the integration period.

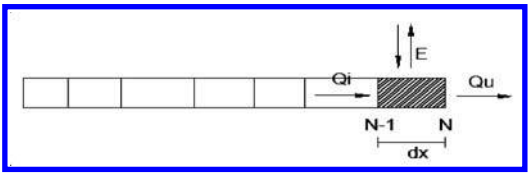

Figure 16. Sediment balance on downstream reach.

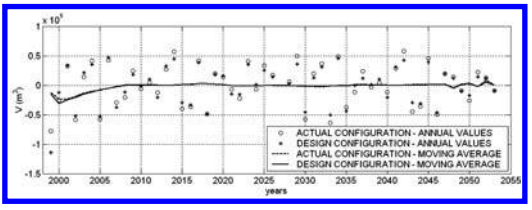

Figure 17. Annual volume balance referred to downstream reach.

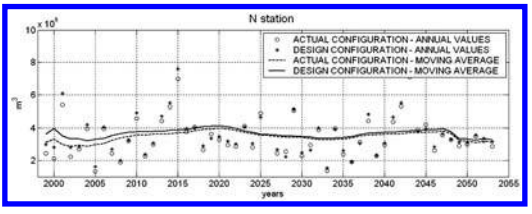

Figure 18. Outgoing apparent solid volume.

Assuming T equal to a year, the closing volume V can be calculated and represented year by year for the design and actual configuration.

Figure 17 does not show any appreciable variation in the long term sediment balance evolution trend of the Po downstream reach. The results can be easily interpreted referring to the moving average representation.

For what concerns the second aspect, let us consider the apparent solid volume coming out from the last model section (towards the delta):

$$V_u^i = \int_T Q_u^i\,dt \qquad i = 1,\ldots,55\,years \qquad (20)$$

The computed values are represented in Figure 18. The sediment flux increase rapidly decreases during simulation, passing from an initial value of about 28% to approximately 13% after five years, 5% after 10 years and 3% after 20 years.

The fundamental equilibrium condition featuring the downstream Po reach suggests a gradual spatial redistribution along the delta 70 km extension of the expected little disturbance effects.

6.5 *Effects on hydraulic risk*

The effects of designed works on flood stage, and therefore on hydraulic risk, have been evaluated by

Copyright © 2006 Taylor & Francis Group plc, London, UK

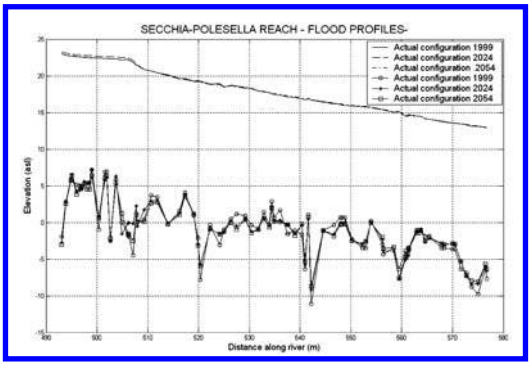

Figure 19. "94 + 51" scene applied to the actual river configuration: simulation of years 1999, 2024, 2054.

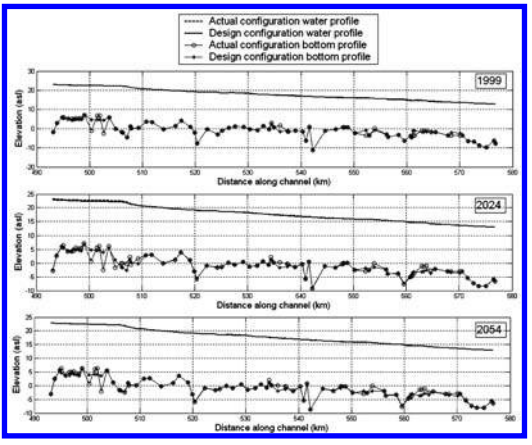

Figure 20. Comparison between design and actual configuration simulation results.

means of a quasi-stationary simulations set. The simulated reach starts from Secchia's mouth and ends at Polesella, including all the designed regulation works locations. It is long about 84 km and it is described by 80 cross-sections.

Simulations have been performed assuming the gradually varied flow, accounting for the reference flood discharge.

Three different phases of river evolution process have been analyzed, considering both design and actual configurations: the initial setting, referred to 1999, the middle (year 2024) and long term (year 2054) settings. Summarizing, the following configurations have been assumed:

- Actual configuration 1999, 2024, 2054
- Design Configuration 1999, 2024, 2054.

Model calibration has been based on the flood reference profile named "94 + 51" (AdPo, 2001), built on Po drainage basin behavior, including the observation of the two main flood vents of the last fifty years. The reference predicted discharge is 13000 m^3/s, the downstream boundary condition has been set as a constant level of 12.89 m above sea level at Polesella station, which corresponds to 13000 m^3/s.

After the calibration phase, a first simulations set has been carried out to see the flood profile evolution trend linked to the actual geometry configuration. Resulting profiles are shown in Figure 19, showing little variations with time.

Subsequently simulation have been performed using the design geometry. The three phases results are represented in Figure 20. By comparing computed profiles, the difference between the design and the actual setting is comprised within the range +10 cm\−25 cm (∼1\2% of local water depth).

The regulation works presence, therefore, does not produce any flood risk increase all over the considered simulation time.

7 CONCLUSIONS

The effect of designed regulation works on the river Po, planned to increase its navigability, have been investigated in order to determine effects on design navigation channel, on sediment balance and bottom evolution, on hydraulic risk and on solid mass fluxes to the river delta.

A mobile bed mathematical model has been used, based on a non-conservative form of shallow water equations and on Exner equation. For numerical implementation the four point Preissman implicit scheme has been used.

An accurate river system description, covering several important aspects, has been carried out. It includes a geometrical description, based on recent field surveys, hydrological and hydrometric data, sedimentological data and information about mining activities.

Simulation have been performed both for the actual and for the designed river setting, in order to have the possibility of comparing results. The geometrical configuration of the design river setting has been drawn following the usual indications about river regulation, and considering the designed works as already fully operative.

A sensitivity analysis has been conducted, in order to evaluate model response to two fundamental parameters variation, that is the amount of mining activities and the value of flow resistance. The analysis confirmed the reliability of the chosen parameters.

Simulation results have then been evaluated from various points of view. First of all, the works influence on the bed elevation evolution trend has been considered, resulting not to be relevant for what concerns the morphological trend.

Positive effects have been find out for what concerns navigation channel efficiency, while supply

Copyright © 2006 Taylor & Francis Group plc, London, UK

plants operating functionality is not affected along the whole examined reach.

The evaluation of the sediment balance in the downstream reach permits to affirm that also the morphological configuration of Po delta will be marginally influenced by regulation works.

Finally, the possible hydraulic risk variation has been investigated, checking that there will be no flood risk increase.

In conclusion, mathematical modeling is not only necessary to confirm individual design work geometrical effects (for which a 2-D model is required), but mainly to evaluate middle and long term effects produced on the overall river system.

ACKNOWLEDGEMENTS

Grateful thanks are due to Ing. Galvani and ARNI for their kindness and for the fruitful discussions.

ABSTRACT: To facilitate sustainable navigation for the Rhine Delta branches, extensive research is being carried out in the Netherlands. A first step of this research is a reconnaissance of potentially feasible fairway improvement strategies. This reconnaissance comprises a wide range of measures and their indicative hydraulic and morphological effects, against the background of ongoing degradation of the main channels and the adverse effects of climate change. Future intensification of fairway traffic calls for enlargement of the fairway channel. With the current maintenance strategy, dredging frequency and volumes will also strongly increase. Hence, apart from other dredging strategies, structural measures are considered so as to reduce the increasing maintenance dredging effort. The reconnaissance of potential measures includes efficacy, practical feasibility, maintenance efforts and economy. Attention is also paid on sustainability. The present paper presents a review of problems, general results and illustrates some potentially feasible measures.

1 BACKGROUND

Navigation at the largest rivers in The Netherlands, the Rhine/Waal system as a part of the Rhine Delta, see Figure 1, has been important for inland transport for some centuries. In the last decades, this importance is even strongly increasing due to further intensification of fairway traffic between the main ports of Rotterdam and Duisburg (Germany) in the years to come. A further growth of navigation commodities in the near future is to be expected. One of the short-term objectives of the project 'Sustainable Fairway Rhine Delta' is the enlargement of the present navigation channel dimensions from 150 m (width) and 2,50 m (depth) to 170 m (width) and 2,70 m (depth) at Agreed Low Discharge and the accompanying Lowest Available Depth (exceeded in 95% of time).

At the same time, ongoing degradation of the main channels and effects of climate change poses upcoming threats to navigability.

The degradation rate in the upper part of the Waal River amounted to 1 to 1.5 m in the last 50 years, although degradation seems to slow down more recently. Due to this bed degradation, problems may arise such as the access to locks, to mooring facilities and to river harbour entrances. In addition, the groynes near the banks are becoming over-exposed during high flows and under-exposed during low flows and groundwater levels drop. On the longer term, even the filled up stabilization of sharp outer bends (fixed layers), in order to maintain sufficient width, may form a barrier on the river bed, limiting the water depth during low flow conditions.

Figure 1. Impression of navigation on the Waal river at low flow.

Ongoing bed degradation in the Rhine/Waal system is, amongst others, a long term consequence of river

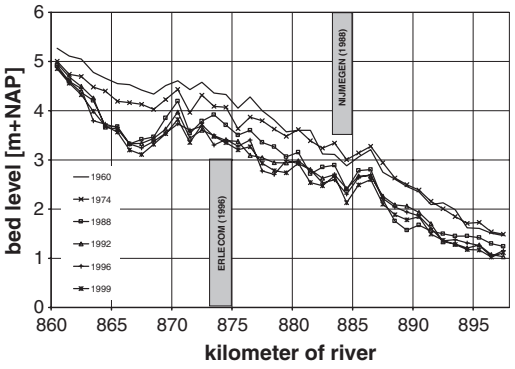

Figure 2. Degradation of part of the main channel of the Waal (longitudinal profile).

training works and flood plain occupation over the last century and a shortage of sediment influx from across the German border. The latter is due to normalisation works and subsidence of the riverbed in the upstream mining areas. This is not a problem that is exclusive to the Rhine Delta rivers: at present, many European rivers suffer severe bed degradation due to the same causes.

The bed degradation on the Waal is illustrated in Figure 2. It is clearly visible how the fixed layer Nijmegen has become more pronounced in time.

Present dredging estimates amount to 300,000 to 500,000 m^3 (measured in profile) on a yearly basis. The exact amount varies strongly over the years, mainly due to the variation in annual (peak) discharges. Recent figures are not known accurately, due to the recently negotiated performance contract with the dredging company. The planned enlargement of the navigation channel dimensions may increase the yearly maintenance dredging to about 1,000,000 m^3 as an order of magnitude, if other measures would not be implemented.

The last decade, the dredging strategy has been changed so as to mitigate the ongoing degradation: nowadays the dredged material is not removed from the river system anymore, but is dumped upstream at deeper locations at a minimum distance from the dredging site (1.5 km). In this way the dredged material is 'circulated'. Although less effective from a dredging point-of-view, it is a more sustainable methodology since it contributes significantly to mitigating the degradation.

2 RESEARCH OBJECTIVES

The present research focuses on an inventory of potential measures that may contribute to improvement of navigation and, at the same time, add to the sustainable development of the river system. An important item for sustainability is reduction of the degradation trend.

The inventory of measures has been based on the outcome of workshops with experts from different disciplines.

In order to elaborate the potential measures to a practical level, the measures have been detailed to a level of functional design. This allowed also providing a rough estimate of the costs involved. Different measures may have a total different distribution of costs during their life cycle: hence, the net present value (NPV) over a 50 years period has been assessed, including maintenance and intermediate reconstruction (if required). The research is to provide directions for further elaboration of sustainable fairway improvement measures and combinations thereof in a subsequent step.

3 RESEARCH METHOD

The working methodology for this research was as follows. At first, a brief analysis was made of the present and future major navigation bottlenecks and the present main measure to maintain sufficient depth and width: maintenance dredging. Figures 3 and 4 illustrate some major bottlenecks on the Waal River.

Navigation bottlenecks can be grouped into two types:

1) Structural bottlenecks which mainly occur in sharp bends and which sustain after high flows recede. The position of these bottlenecks is rather stable. Because of the vast extent of the dredging activities required to maintain sufficient width and depth, this dredging is denoted 'profile dredging', see Figure 3.
2) Bottlenecks which occur during floods, as well as during low and medium flows on a more erratic basis, due to e.g. retarded scour and large bed forms (sand waves). Dredging these local shoals is dispersed and is denoted 'occasional dredging'. While the first type can be checked quite well after the floods recede, the second type has to be monitored on a (nearly) day-to-day basis, see Figure 4.

Next a framework for analysis of potential improvement measures was drawn up (see also [2] and [3]).

The *potential efficacy* was assessed on the basis of engineering judgement, within a team of nautical and morphological experts.

As regards the *impacts* a distinction was made between: impacts on flood levels, change of the discharge distribution at the bifurcation points and interaction with other planned river measures.

Sustainable issues related to the effect on bed degradation, adaptability (=preservation of functionality)

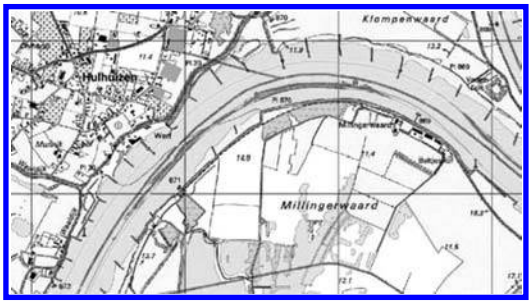

Figure 3. Profile dredging locations near sharp bend in the Waal River (coloured bands).

Figure 4. Occasional dredging locations on the Waal river (red dots).

in case of further climate change, maintenance and navigation hindrance.

The *practical feasibility* addresses the practical workability to realize the measure.

Risk and uncertainties, other than stemming from the realization, relate to e.g. the probability of failure during the lifetime, uncertainties on efficacy, adverse impacts and sustainability.

A *rough cost assessment* was carried out to explore the economical feasibility.

It should be remarked that the measures were judged separately: combinations of measures were not explored yet in this phase of the research.

4 TYPES OF MEASURES

Two groups of measures have been considered:

1) *Sediment management measures*, e.g. dredging of shoals, levelling of scour holes and sediment nourishment;
2) *River training measures*, e.g. application of bed groynes or fixed layers, adaptation of groynes and roughness elements in inner bends.

Some twenty preliminary concepts of individual measures have been identified and explored in the present reconnaissance study. These measures have been analyzed against the background of the aforementioned framework for analysis.

Figure 5. Example of nourishment of external bed material.

Some typical measures are indicated hereafter:

Sediment management measures

- Alternative dredging strategy with dumping a part of the dredged material farther upstream to compensate for the sediment transport deficit upstream;
- Filling of sharp outer bends and reduction of transport capacity by applying 'Smart Soils' technology;
- Dredging of inner bends and nourishment of external coarse material in outer bends, see Figure 5;
- Intensification of the stirring action of ships sailing close to shallows;
- Suppletion of a thin semi-stable upper layer to control the bed degradation;

Structural measures

- Continuation of the proven methodology of applying fixed layers in sharp outer bends;
- Filling up of scour holes near groynes ('flames') and scour holes downstream of present fixed layers, see Figure 6;
- Continuous stable layer along the whole Rhine/Waal river system;
- Bank alignment measures: a 'flow guidance dam' to close-off groyne sections in inner bends at low flows; a flow guidance structure for groyne heads; a 'turbulence dam' to promote erosion in the inner bends.

Some of these measures are proven technology, others however are highly innovative.

5 GENERAL FINDINGS

The current dredging strategy would lead to high efforts and costs for maintaining the enlarged

Copyright © 2006 Taylor & Francis Group plc, London, UK

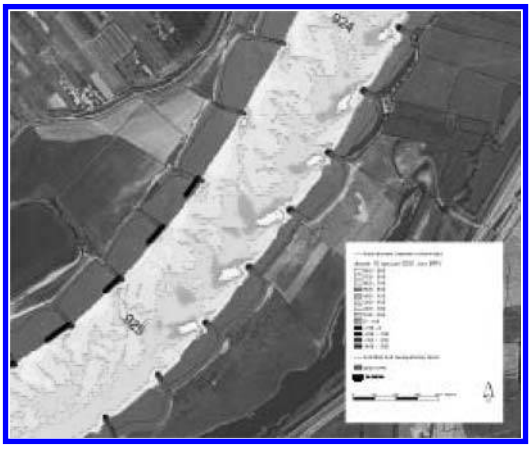

Figure 6. Typical erosion pattern near groynes.

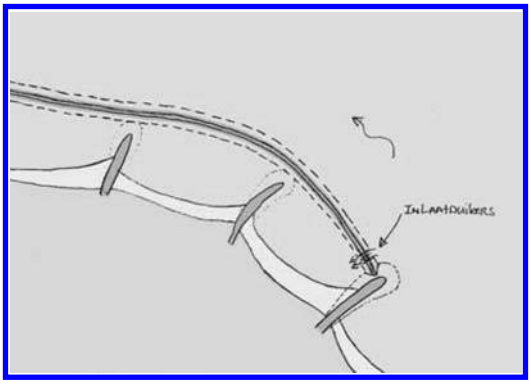

Figure 7. Top view of the flow guidance dam (upstream section).

navigation channel in the new situation. The net present value of these activities could be well over € 200 M. Moreover, hindrance to navigation will be significant. The additional costs for the alternative dredging strategy with dumping of dredged material farther upstream will hardly increase this cost figure but appears to be much more sustainable.

The efficacy of other large-scale sediment management measures, such the as suppletion of a thin semi-stable upper layer, seems to be highly uncertain. At the same time, the savings on the anticipated dredging is not known as well. Other measures, e.g. the deployment of vessels to increase the stirring up action are far beyond practical application. Local measures, i.e. nourishment of coarse (semi-stable) materials in outer bends may be feasible and economical: the net present value for two major bends at the Waal indicate a cost figure of around € 20 M.

The most efficient measures may still be of the structural type, especially when applied locally in bends. These measures may contribute significantly to the reduction of maintenance dredging. Other promising measures are various bank alignment measures. Hereafter, some of these will be highlighted. The efficacy of filling up present scour holes is uncertain, although this measure may contribute well to reducing 'occasional dredging' in an economical way: the net present cost is nearly € 20 at the major occasional dredging sites of the Waal.

Sustainability of the structural measures is especially positive in terms of durability and low cost of maintenance. However, they do not actively mitigate bed degradation. Therefore, structural measures should be combined with sediment management measures, e.g. the alternative dredging option, supported by nourishment with external coarse bed material.

6 ILLUSTRATION OF TWO PROMISING BANK ALIGNMENT MEASURES

The study indicates a number of potentially feasible measures. For illustration purposes, two concepts deemed feasible are described hereafter in more detail.

6.1 *Flow guidance dam*

The flow guidance dam is a dam that is installed in front of the present groynes, see Figures 7 and 8, and serves different purposes:

- Additional resistance at low flows, so as to increase low water levels;
- Reduction of the irregular riverbed patterns in the vicinity of groynes;
- Shelter to the groyne beach section so as to promote environmental conditions.

To avoid adverse effects on flood water levels, the adjoining groynes may need to be removed partly, e.g. by lowering of the crest level.

It is anticipated that this type of flow guidance will give significant savings on the quantity of profile dredging.

The anticipated costs (NPV) of this guidance dam are relatively modest: € 2.5 M per inner bend of 2 km length.

6.2 *Flow guidance structure near groyne heads*

This structure, as shown in Figure 9, is meant to guide the flow more smoothly during low flows in inner bends and, at the same time, provide additional resistance to increase low water levels (these functions do compare with the flow guidance dam).

To promote a more regular flow pattern near the groyne head, the structure consists of separate poles.

Copyright © 2006 Taylor & Francis Group plc, London, UK

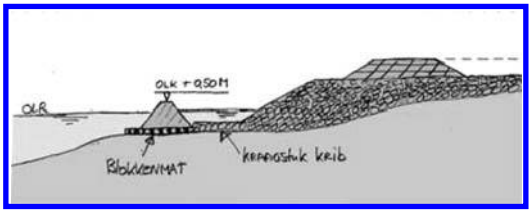

Figure 8. Sketch of the flow guidance dam near a groyne.

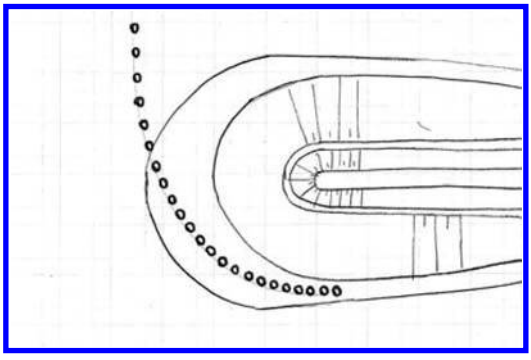

Figure 9. Top view of the 'spoiler' near a groyne head © Royal Haskoning.

The poles introduce small-scale turbulence that disturbs the irregular flow separation around the groyne head and thus impose a 'spoiler' action. The height of the poles will be modest: the top level of the poles may go down from groyne level to around Least Available Depth + 0.5 m at the downstream end. It is likely that adverse impacts on flood water levels can be avoided.

The anticipated costs of this concept (NPV) are around € 5 M for two major sharp bends in the Waal River.

7 CONCLUSIONS

The present study points out that adaptation of current practices on maintaining and extension of the nautical profile may be needed for safeguarding sustainable and economical solutions in the future. New dredging strategies, nourishment of external (coarse) bed material and innovative bank alignment measures can contribute to reduce future maintenance dredging.

Predicting maintenance dredging for future scenario's was proven to be complex and uncertain. Further study is needed.

The potential measures need further detailing and in-depth morphological and hydraulic research of their adequacy in reducing maintenance dredging. Such research may comprise field pilots, scale model investigations, desk studies and mathematical model studies. In addition, lessons learned from field pilots carried out in the German part of the Rhine River should be incorporated.

Mathematical modeling of the biogeochemistry of dissolved and sediment associated trace metal contaminants in riverine systems

Arash Massoudieh, Fabian A. Bombardelli, Timothy R. Ginn & Peter G. Green
Dept. of Civil and Environmental Engineering, University of California, Davis, CA, USA

ABSTRACT: A quasi two-dimensional model is presented which is able to simulate biogeochemical processes of metal contaminants in river sediments. The model takes into account horizontal transport of dissolved and particle associated species and the effects of erosion and resuspension on the sedimentary chemistry, using coupled advection-dispersion-reaction equations for both suspended sediments and dissolved species. Transport of species in the sediments is modeled using a set of vertical one-dimensional sub-models which take into account the reactive transport of chemicals, burial, sorption/desorption to/from the solid phase, and diffusive transport of species. A kinetic reversible assumption is used to simulate the mass exchange between suspended sediments and bulk water, as well as the mass exchange between bed-sediments and pore-water. The model is applied to simulate the methylation of mercury in a hypothetical river reach.

1 INTRODUCTION

Biogeochemical processes in sediments have an important role on the mobility and bioavailability of toxic trace metals in aquatic ecosystems, as well as on the cycling of other elements, including carbon, nitrogen and sulfur. The latter elements have in turn important implications for plant productivity and human health (Gadd, 2004). The state of metals in terms of mobility depends highly on the organisms involved and the oxidation state of the environment. The role of microorganisms in the metal speciation and mobility has received more attention recently. As examples of the effects microbial activities on the mobility of metals, it is possible to mention reduction of Fe(III) to Fe(II), Mn(IV) to Mn(II), Cr(VI) to Cr(III), U(VI) to U(IV) and biomethylation of Hg, As, Se, Sn, Te and Pb.

There have been several recent modeling efforts to predict biogeochemical cycles in sediments in lakes and coastal zones (Berg et al., 2003; Boudreau, 1996; Van Cappellen and Gaillard, 1996; Van Cappellen et al., 1993; Van Cappellen and Wang, 1996). In all of these efforts, a one-dimensional column of sediments with fixed or varying boundary conditions at the surface has been adopted in order to model the diverse processes; in other words, the effects of horizontal heterogeneity and hydrodynamic transport of dissolved compounds, sediments, and sediment associated species have been disregarded. This approach may be suitable for water bodies such as lakes and coastal zones, with small lateral heterogeneity; however it does not work well in rivers where the horizontal transport of species in the water body is of critical importance in the cycling of elements. In a riverine system, transport in the water body is responsible for supplying many compounds such as oxygen and sediments containing organic carbon to the bed surface. Also, hydrodynamic transport processes in the water body can influence the redox biogeochemistry of the sediments by resuspending the top sediments and exposing the lower levels to the water column with different chemical composition. For example tidal cycles usually have a very crucial influence on the redox state in tidal marshlands (Neubauer et al., 2005; Twilley and Rivera-Monroy, 2005).

In this paper, a multi-scale model is presented in order to couple the hydrodynamic transport of species in the river with the diffusive transport in the sediments. This model considers transport of dissolved and particle associated species in rivers as well as transport within the sediments due to molecular diffusion, bioturbation (due to activities of benthic organisms), burial and resuspension. The model can be used for any reaction network with a high degree of complexity in reaction kinetics. An application of the model is presented by performing a demonstration simulation on the methylation of mercury in a hypothetical river reach.

Copyright © 2006 Taylor & Francis Group plc, London, UK

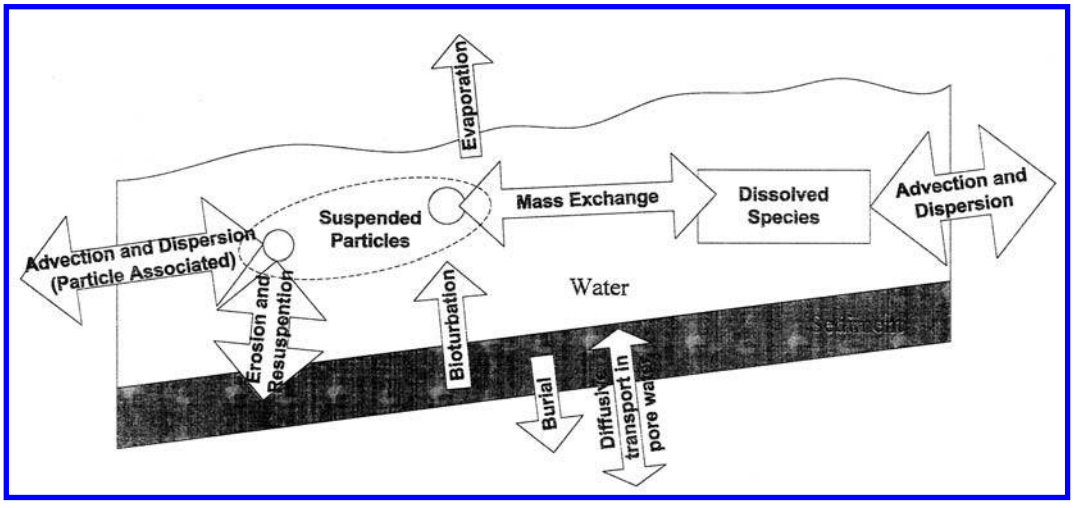

Figure 1. Physical processes considered in the model.

2 MODEL DESCRIPTION

2.1 *Physical transport component*

The multicomponent and multiphase model includes one-dimensional advective-dispersive transport of both dissolved and particle-associated species, as well as suspended particles in the river. The river module is fully coupled with a series of one-dimensional diffusive transport columns representing active bed sediments (See Fig. 1). Bioturbation and burial of species are modeled in the bed sediments using a two-domain diffusive transport process.

Bed sediments exchange species with the water column via both deposition and resuspension of chemical species attached to the grains, and through a diffusive boundary layer between sediments and water column. First order kinetic reversible sorption is assumed for the exchange between solid phase and bulk or pore water in the water column or bed sediments respectively.

A one-dimensional model is used for the transport of species in the river. For each species being modeled a set of two coupled 1-D advection-dispersion equations, one for dissolved species and one for particle associated species are used, respectively:

$$\frac{\partial(C_i)}{\partial t}+\frac{\partial(vC_i)}{\partial x}=\frac{1}{A}\frac{\partial}{\partial x}\left(D_h A\frac{\partial C_i}{\partial t}\right)+k_b\frac{P}{A}\left(c_i(0)-C_i\right)-C_s k_r\left(K_D C_i-S_i\right)+R_i+\frac{q_{in}}{A}\left(C_{i,in}-C_i\right)+k_{at}\left(C_{i,at}-C_i\right) \quad (1)$$

$$\frac{\partial C_s S_i}{\partial t}+v\frac{\partial C_s S_i}{\partial x}=\frac{1}{A}\frac{\partial}{\partial x}\left(D_s A\frac{\partial C_s S_i}{\partial x}\right)+Er.w_p.\frac{P}{A}s_i(0)-w_p r_0.\frac{P}{A}.C_s S_i+\frac{q_{in}}{A}\left(C_{s,in}S_{in}-C_s S_i\right)+k_r C_s\left(K_D C_i-S_i\right) \quad (2)$$

in which, t(s) is time, x(m) is the longitudinal river axis, $C_i(\mu g/mL)$ is the dissolved concentration of chemical i in bulk water, v(m/s) is the velocity along the river, $D_h(m^2/s)$ is the mechanical dispersion coefficient along the river axis, $k_b(s^{-1})$ is the sediment-water exchange coefficient for the dissolved species, $c_i(0)(\mu g/ml)$ is the pore-water concentration at the topmost layer of sediments, P(m) is the wetted perimeter of the stream, $k_r(s^{-1})$ is the mass exchange coefficient between suspended particles and water, $C_s(g.mL^{-1})$ is the concentration of suspended particles, K_D(L/g) is the water-solid distribution coefficient, $S_i(\mu g/g)$ is the sorbed phase concentration, $R_i(\mu g/mL.s)$ is the sum of reaction terms for species i, $q_{in}(m^3s^{-1})$ is the amount of lateral water flux, $C_{i,in}(\mu g/mL)$ is the concentration of species i in the lateral flux, $k_{at}(s^{-1})$ is the atmospheric exchange rate coefficient, $D_s(m^2/s)$ is the dispersion coefficient for suspended particles, $Er(g.m^{-3})$ is the entrainment coefficient, w_p(m/s) is particles fall velocity in the water column, r_0 is the ratio between the concentration of suspended particles at the bed and the average concentration of suspended particles, and $C_{s,in}(\mu g/mL)$ is the concentration of suspended particles in the lateral inflow. In Eq. (1) the second term in the left hand side represents the advective transport of dissolved species; the first term of

Copyright © 2006 Taylor & Francis Group plc, London, UK

the right hand side is the mechanical dispersion; the second term is the exchange of species with benthic sediments; the third term is the exchange of species with suspended sediments; the fifth term is lateral flux of chemicals; and the last term represents exchange of species with atmosphere. In Eq. (2) the second term from the left hand side represents advection of chemicals sorbed to particles due to movement of particles, the first term from the right hand side represents the effect of mechanical dispersion of particles, the second and third terms simulate effects of resuspension and erosion respectively, and forth and fifth terms are respectively lateral inflow of chemical species associated with suspended solids and mass exchange with bulk water.

The one-dimensional transport model described above is coupled with the transport of chemical species in bed sediments. The horizontal diffusive transport of chemicals in bed sediments is ignored due to the larger horizontal scale with respect to the vertical scale. In addition, it is assumed that the effects of bioturbation can be simulated using a diffusive model with a modified diffusion coefficient. Therefore the equations governing the diffusive transport of chemicals in the bed sediments can be written as:

$$\frac{\partial c_i}{\partial t} + w\frac{\partial c_i}{\partial z} = \frac{1}{\theta}\frac{\partial}{\partial z}\left((D_m + D_B)\theta\frac{\partial c_i}{\partial z}\right) + \frac{B_d k_r}{\theta}\left(K_D c_i - s_i\right) + R_i \quad (3)$$

$$\frac{\partial s_i}{\partial t} + w\frac{\partial s_i}{\partial z} = \frac{1}{B_d}\frac{\partial}{\partial z}\left(D_B B_d \frac{\partial c_i}{\partial z}\right) - \frac{B_d k_r}{\theta}\left(K_D c_i - s_i\right) + R_{s,i} \quad (4)$$

where $c_i = c_i(x,z,t)$ is the dissolved concentration in pore water in the bed sediments, $s_i(\mu g/g)$ is the mass concentration of sorbed species, B_d(g/ml) is the bulk density of the sediment materials, D_b(cm^{2}s^{-1}) is the biodiffusion coefficient, D_m(cm^{2}s^{-1}) is the molecular diffusion coefficient of the species in the pore water, θ is the porosity of the bed material, w(cm.s^{-1}) is the burial velocity which depends on the rate of accumulation of newly deposited sediments at the bed surface, and $R_{s,i}$ is the production or elimination of species i due to total intra-phase reaction rate. If we assume that porosity (compaction) is solely a function of depth, the burial velocity (which is the shift occurred in the position of a grain particle in a coordinate system with its origin fixed on the bed surface due to deposition or erosion) can be approximated using the following equation:

$$w(z) = \frac{C_s w_f - Er.C_s}{B_d(z)} \quad (5)$$

in which $C_s w_f$ is the deposition rate and B_d is assumed to be only dependent on depth or the weight of materials above it.

Boundary conditions for equation (3) can be written as:

$$(D_m + D_B)\theta\frac{\partial c_i}{\partial z} = k_b(c_i - C_i) \quad \text{at z=0} \quad (6)$$

$$\frac{\partial c_i}{\partial z} = 0 \quad \text{at z=L} \quad (7)$$

and for equation (4):

$$s_i\big|_{z=L} = 0 \ \text{for w<0} \quad \text{erosion} \quad (8)$$

$$s_i\big|_{z=0} = S_i \ \text{for w>0} \quad \text{deposition} \quad (9)$$

2.2 *Numerical techniques*

A first order in space with an implicit Crank-Nicholson time weighing finite difference method is used to solve coupled equations (1) and (2) for each species. A similar approach is also used to model the vertical transport of chemicals in each column associated with one grid cell of water column (Eqs. 3 and 4). The coupling between the water column and sediment components is performed explicitly using the boundary conditions defined in equations (6)–(9). The reaction terms are computed explicitly as source and sink terms. Fractional time steps are used to simulate fast reaction rates. In this way, a different time step is chosen automatically by the model based on the variation of each reaction term.

3 MODEL APPLICATION (BIOMETHYLATION OF MERCURY IN RIVER)

In order to test the model, it was applied to simulate methylation of mercury in a vertical sediment column and also a hypothetical river reach. For this purpose, the reaction network for the cycling of oxygen, nitrogen, sulfur, iron and manganese was adopted from a previous work (VanCappellen and Wang, 1996) with some simplifications; also a simplified reaction network was built for methylation of mercury. Methylation of mercury is thought to be mainly caused by Sulfate Reducing Bacteria (SRB) (Compeau and Bartha, 1985; Gilmour and Henry, 1991; Winfrey and Rudd, 1990) and thus a relationship is for methylation rate that takes into account the SRB activity was proposed.

3.1 *Microbially-mediated transformations model*

In order to compute the rate of methylation of mercury the activities of SRBs and concentration of H_2S are required. For this purpose, the fate and transport of some major species affecting the activities of

Copyright © 2006 Taylor & Francis Group plc, London, UK

SRB such as O_2, NO_3, Fe and Mn needs to be modeled as well. Since mercury concentration is usually small compared to other major components such as organic matter, oxygen, nitrate, sulfate, iron, etc., the effect of mercury reactions on the concentration of major components was ignored. The reaction network was adopted from recent models (Hunter et al., 1998; VanCappellen and Wang, 1996) with some slight modifications and simplifications. Monod type kinetics with inhibition was used for the oxidant inhibitor multipliers as suggested by Boudreau, 1996; Van Cappellen et al., 1993, (Eq 10a–f). The complete reaction network used in the model can be seen in figure 2.

$$R_1 = -k_1[OM]\frac{[O_2]}{K_{O2}+[O_2]} \quad (10\text{-a})$$

$$R_2 = -k_2[OM]\frac{[NO_3]}{K_{NO3}+[NO_3]}\frac{K'_{O2}}{K'_{O2}+[O_2]} \quad (10\text{-b})$$

$$R_3 = -k_3[OM]\frac{[MnO_2]}{K_{MnO2}+[MnO_2]}\frac{K'_{NO3}}{K'_{NO3}+[NO_3]}\frac{K'_{O2}}{K'_{O2}+[O_2]} \quad (10\text{-c})$$

$$R_4 = -k_4[OM]\frac{[FeOOH]}{K_{FeOOH}+[FeOOH]}\frac{K'_{MnO2}}{K'_{MnO2}+[MnO_2]}\frac{K'_{NO3}}{K'_{NO3}+[NO_3]}\frac{K'_{O2}}{K'_{O2}+[O_2]} \quad (10\text{-d})$$

$$R_5 = -k_5[OM]\frac{[SO_4]}{[SO_4]+K_{SO4}}\frac{K'_{FeOOH}}{K'_{FeOOH}+[FeOOH]}\frac{K'_{MnO2}}{K'_{MnO2}+[MnO_2]}\frac{K'_{NO3}}{K'_{NO3}+[NO_3]}\frac{K'_{O2}}{K'_{O2}+[O_2]} \quad (10\text{-e})$$

$$R_6 = -k_6[OM]\frac{[CH_4]}{[CH_4]+K'_{CH4}}\frac{K'_{SO4}}{[SO_4]+K'_{SO4}}\frac{K'_{FeOOH}}{K'_{FeOOH}+[FeOOH]}\frac{K'_{MnO2}}{K'_{MnO2}+[MnO_2]}\frac{K'_{NO3}}{K'_{NO3}+[NO_3]}\frac{K'_{O2}}{K'_{O2}+[O_2]} \quad (10\text{-f})$$

Secondary reoxidation reactions are assumed to obey simple rate laws as K[reactant1][reactant2] as done by VanCappellen and Wang, (1996).

3.2 *Mercury partitioning and speciation reactions*

As mentioned above, Sulfate-Reducing Bacteria (SRB) have been identified as a primary agent for methylation of mercury. Also recent studies have illustrated that, production of methylmercury is inhibited by accumulation of sulfide, the by-product of activities of SRBs (Gilmour and Henry, 1991). This can be explained by the fact that high concentrations of sulfide will convert a large portion of mercury into HgS and reduce the amount of reactive mercury available for methylation. Therefore the following simplified geochemical reaction network was utilized to simulate mercury cycling:

$$HgS \xleftarrow{k_{Hg,1},k_{Hg,2}} Hg^{2+} + S^{2-} \quad (11\text{-a})$$

$$Hg^{2+} + DOC \xrightarrow{SRB} MMHg \quad (11\text{-b})$$

$$MMHg \xrightarrow{k_d} Hg^{2+} \quad (11\text{-c})$$

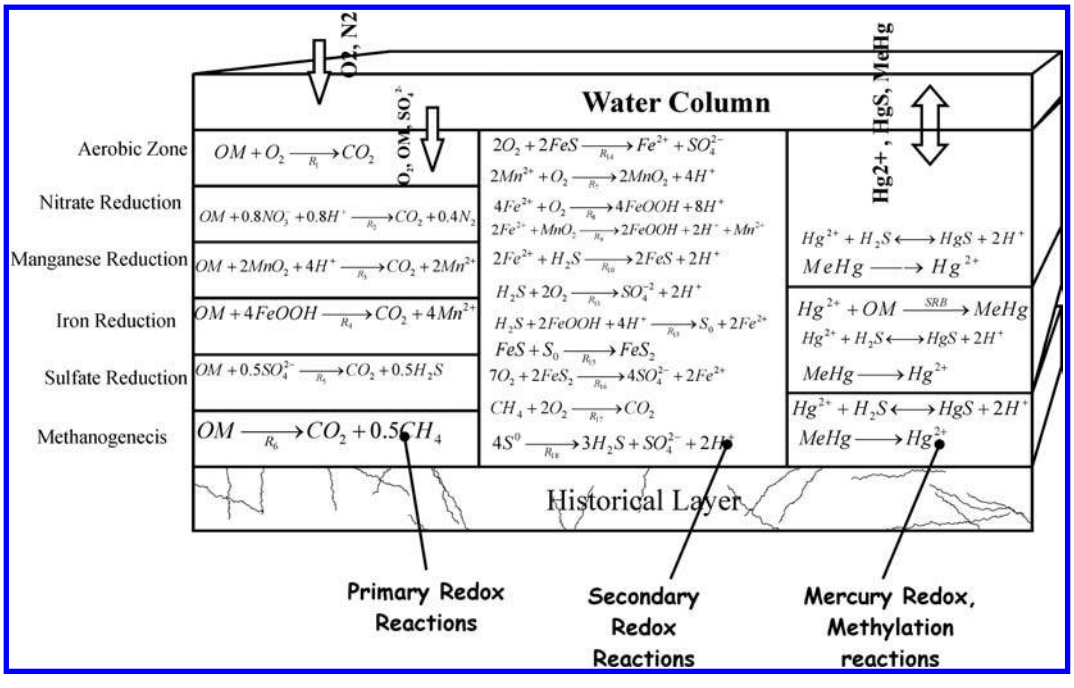

Figure 2. Reaction network used for bacteria mediated biogeochemical transformations of mercury.

Copyright © 2006 Taylor & Francis Group plc, London, UK

$$Hg^{2+} \xrightarrow{k_r} Hg^0 \qquad (11\text{-d})$$

$$Hg^0 \xrightarrow{k_o} Hg^{2+} \qquad (11\text{-f})$$

Because oxidation, reduction and demethylation of mercury are known to be both biotically and abiotically mediated in this work a mass action kinetic rate was used to simulate these collective processes. Methylation rate on the other hand is assumed to be a function of the activity of SRBs and so single Monod kinetics are used. Therefore the system of differential equations describing the mercury reaction network can be written as:

$$\frac{\partial[HgS]}{\partial t} + \ell([HgS]) = \frac{\theta}{B_d} k_{Hg,r}[Hg^{2+}][H_2S] - k_{Hg,f} \qquad (12\text{-a})$$

$$\frac{\partial[Hg^{2+}]}{\partial t} + \ell([Hg^{2+}]) = -k_{Hg,r}[Hg^{2+}][H_2S] + \frac{B_d}{\theta} k_{Hg,f} - k_m[SRB]\frac{OM}{K_{OM}+OM}[Hg^{2+}] + k_d[MMHG] - k_r[Hg^{2+}] + k_o[Hg^0] \qquad (12\text{-b})$$

Table 1. Reaction rate parameter values.

$k_{Hg,f}$ (yr^{-1})	1.2×10^{-5} (estimated)	$k_{Hg,r}$ (yr^{-1})	1.58×10^{-4}
k_m (yr^{-1})	20.1(b)	k_d (yr^{-1})	1.65(b)
k_r (yr^{-1})	11(b)	k_r (yr^{-1})	11(b)
k_0 (yr^{-1})	8.76×10^2(b)		

a. (Berg et al., 2003), b. (Kim et al., 2004)

$$\frac{\partial[MMHg]}{\partial t} + \ell([MMHg]) = k_m[SRB]\frac{OM}{K_{OM}+OM}[Hg^{2+}] - k_d[MMHg] \qquad (12\text{-c})$$

$$\frac{\partial[Hg^0]}{\partial t} + \ell([Hg^0]) = k_r[Hg^{2+}] - k_o[Hg^0] \qquad (12\text{-d})$$

In the above equations, ℓ is the transport operator representing all processes described in the previous section, $k_{Hg,r}$, $k_{Hg,f}$ are rates of dissociation and production of cinnabar (HgS), [SRB] is the activity of sulfate reducing bacteria which will be discussed later, k_m, and k_d are methylation and demethylation rate coefficients respectively, and k_r and k_o are respectively reduction and oxidation rate coefficients for elemental mercury.

For testing the model a demonstration simulation was performed using parameters obtained from literature on a hypothetical river reach. A 30 cm-deep bed-sediment layer was considered. The parameters used for the simulation are listed in tables 1 to 3. Biodispersion was simulated as exponentially decreasing with depth and the compaction effect was taken into account in calculating the diffusion coefficient, dry density and porosity of sediment vs. depth. The profiles were obtained by running the model for a 25 day time frame starting with uniform concentrations of species with depth. Figure 3 shows the concentration of primary components and mercury species in the river. It is noticed that oxygen and nitrate diminish quickly with depth. Also MnO_2 and FeOOH disappear within the top 10 cm of the column. On the other hand the sulfate concentration does not vanish in the top 30 cm due to its high concentration at the surface and the sulfate reduction condition can be seen at depth higher than 10 cm in the sediments (figures are not included). Concentrations of Mn^{2+}, Fe^{2+}, H_2S, FeS, S^0, Hg^{2+}, Hg^0, and MeHg were assumed to be zero in the upstream boundary. The initial concentration of total mercury was assumed to be uniform and equal to 1 nmol/g of sediments which is close to typical values found in San Fransisco Bay (Choe et al., 2004). It is noticed that methyl mercury is mainly produced in the depths greater than 7 cm in the anoxic layers. The magnitude of MeHg produced in the model also

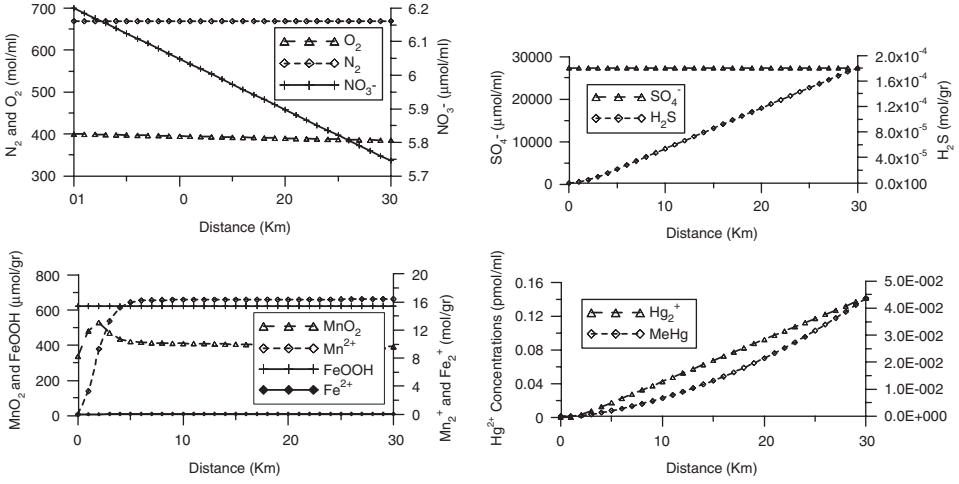

Figure 3. Profiles of species in the river after 25 days of simulation.

conforms with the values found by (Choe et al., 2004) in San Fransisco Bay.

The reach was assumed to have 30 km river length with 5 m depth. The erosion rate was assumed to be constant and equal to 2.16 g/cm^2/day and the deposition rate (fall velocity) was considered to be 0.5 cm/s. The inflow concentration of mercury was assumed to be zero so the only source of mercury was the contaminated sediments. Also in this case oxygen and nitrogen was assumed to be supplied to the water column through kinetic first order Henry's law. Figure 3 shows the variation of concentration of major species in the model. As it can be seen, the concentrations of dissolved oxygen and nitrogen are almost constant in the river reach due to high rate of exchange with the atmosphere, whereas nitrate is consumed by the diagenetic processes in the sediments due to its small concentration at the upstream boundary. Also concentrations of Manganese and Iron species reach to equilibrium relatively quickly. The concentration of Fe^{2+} in the water body is small due to its high oxidation rate in the aerobic water body. The sulfate concentration at the upstream boundary is relatively high and so its concentration remains

Copyright © 2006 Taylor & Francis Group plc, London, UK

almost constant in the reach with a small drop and H_2S concentration is low as expected. In addition Hg^{2+} and MeHg are supplied through the sediments and so their concentration increases monotonically as expected.

4 CONCLUSIONS

A multi-component and multi-species model for the prediction of transport and transformations of metals in riverine systems has been presented. The model couples the advection-dispersion governing equation for dissolved and particle associated species in the water column and diffusive transport of species in the bed sediments through a diffusive boundary layer and also deposition and resuspension mechanisms. The model was applied to simulate transport, transformation and particularly biomethylation of mercury in a hypothetical riverine system. For this purpose a multi-component, biotic/abiotic redox reaction network representing the cycling of major components involved was linked to a simplified reaction network governing mercury transformations. Also the activity of sulfate reducing bacteria (SRB) in the sediments was assumed to control the production of methyl-mercury. Two demonstration calculations for a hypothetical river reach were performed using literature values. Using the total mercury concentration observed in natural systems, resulted in reasonable methylmercury concentrations based on measured data in contaminated water bodies (Choe et al., 2004). Model validation and calibration using field and lab study results is currently underway. Further details and results on the distribution of species in the sediments can be found in a recently submitted paper (Massoudieh A., Bombardelli F. A, and Ginn, T. R., 2006).

The application of hydrodynamic models as integrative tool between flood protection and ecological demands using a morphologically based evaluation method

C. Hauer, M. Liedermann & H. Habersack

University of Natural Resources and Applied Life Sciences Vienna, Department of Water – Atmosphere and Environment, Institute of Water Management, Hydrology, and Hydraulic Engineering

ABSTRACT: On the basis of a case study at the Kamp River/Lower Austria the possibilities of an integrative evaluation of an ecologically oriented flood protection measure are discussed. Beside the hydrodynamic modelling of predefined flood events, low and mean discharge situations were simulated to evaluate the abiotic conditions for main fish species. The morphological developments of the flood protection measure were documented by terrestrical survey in 2003 and 2004. Furthermore it was possible to create a digital terrain model (DTM) of the former, natural river bed (1890) which was used as the "Leitbild" situation. With a geomorphologically based evaluation method the success of ecologically orientated flood protection measures was discussed according to the "Leitbild" situation using ecological and economical parameters.

1 INTRODUCTION

In August 2002 a catastrophic flood event occurred in Austria and in several countries of Central Europe (Habersack & Moser, 2003). Beside deaths the huge economic damage reflected in some cases the suboptimal management of our river systems. As a reaction to these catstrophic events some governments decided to build so called initial measures for flood protection. In Lower Austria river widenings have been chosen as the first step for an improved flood management. Additionally it was tried to reconstruct typical natural river patterns in these areas of cross section enlargement. A main project is performed at the Kamp River. Such an integrative river restoration aiming for improved better flood protection consisting the European Water Framework Directive (WFD) is only found in pilot protects so far. River widening for flood protection including river restoration was documented in the Netherlands (Baptist et al., 2004). More studies are dealing with river restoration. In Denmark two major projects on River restoration were performed. At the River Brede and the River Skjern the straight, regulated river bed was reconstructed with the former natural meandering character, better hydraulic interaction between the river and its meadows was introduced and former lakes, bogs, ponds and marshes were established (Neilsen, 2002). An example for a restoration protect from France is presented by Poudevigne et al., 2002, where at the River Seine the method of simplification of river processes on certain units was tested. In this study the work was focused on two attributes of the ecosystem at different scales: community organisation and landscape organisation. Reach scale hydraulic assessment of instream restoration is presented by Lacey & Millar (2004). Other river restoration projects and their benefits to aquatic ecology are discussed in Rohde et al., 2004 and Kamp et al., 2004. A target setting for river restoration is presented in Pedroli et al. (2001). Their work concentrates on the concept of setting targets for river restoration as exemplified by the Meuse River. A modelling exercise shows the restraints of current habitat configuration and the potential for habiat restoration along the river. State of the art in relationships between form and processes in a river according to river restoration were discussed in Niezgoda & Johnson (2005) and standards for ecologically successful river restoration were defined by Palmer et al. (2005). The development of an ecohydraulic model for stream and river restoration was tested in a British River by Bockelmann et al. (2004). Further numerical modelling for river restoration processes was also included by Larsen & Greco (2002).

The aim of this paper is to discuss the effectiveness of an integrative method for analysing flood protection and the possibility of achieving a good ecological status (WFD) using a one dimensional cross sectional based model.

* NQ = low flow, ** MQ = mean flow, *** HQ = high flow.

2 STUDY REACH

The study reach of this paper is situated in the northern part of Lower Austria. The origin of the Kamp River is near the village Karlstift (920 m.a.sl.). Its 160 km course discharges into the Danube River (182 m.a.sl.) at Altenwörth. The total catchment area is defined with 1.753 km^2 (Fig. 1).

In the recent past (1954–1957) three large hydropower plants were build. The reservoirs of Ottenstein, Dobra and Thurnberg influenced the sediment transport and the hydrological regime significantly. The whole part of the Kamp River from river station km 73 + 500 to the Danube river can be described as a residual flow zone with no bedload input from upstream and reduced input from tributaries since that time. The hydrologic characteristics of the catchment area are described in Table 1.

The area of riverbed widening for flood protection and for detailed analysis is found between the river station 20.650 km and 21.700 km with a length of 1.050 m. The average bed slope in this part of the Kamp River is defined with 0.0007 m m^{-1}.

3 METHODS

Based on terrestrical surveys, which were taken in the years 1890, 1900, 2002 and 2003, different Digital Terrain Models (DTM) could be constructed of the investigation area at the Kamp River. The historical geometry of 1890 was derived from a data set of 290 points which showed the main characteristics of the river section (riffles, pools, bankfull, etc.). Based on that information breaklines were constructed and based on the interpolation method of Kriging a DTM model with 450 points could be made. The geometry of the year 1900 was taken from a river regulation project. The data set provided cross sectional information every 50 m. The measurement of the river topography in 2002 was done before the riverbed widening (350 points), the geometry data of 2003 (320 points) is representing the situation immediately after the cross sectional enlargement. The data of the cross sectionally based surveys were transferred to a one dimensional hydrodynamic numerical model (HEC – RAS) for analysing different discharge scenarios. These scenarios were split into below bankfull analysis (1.4 m^3s^{-1}; 3 m^3s^{-1}; 5 m^3s^{-1}; 8 m^3s^{-1}; 12 m^3s^{-1}; 16 m^3s^{-1}; and 87 m^3s^{-1}) and into calculations of specific flood events (40 m^3s^{-1}, 50 m^3s^{-1}, 60 m^3s^{-1}, 70 m^3s^{-1}, HQ_1, HQ_5, HQ_{10}, HQ_{30}, HQ_{50}, HQ_{100},HQ_{200}). Only the results of below bankfull analysis were taken for studies on ecological benefits. To link the hydraulic simulation results with suitability indices the method of Bovee (1986) was used. This method of multiplying suitability indices was first utilized in the PHABSIM model (Milhouse, 1989) and is shown in equation 1.

$$SI_{ges} = SI_d \cdot SI_v \cdot SI_{CI} \quad \text{or.} \quad SI_{ges} = \prod_{i=1}^{I} SI_i \qquad (1)$$

where SI_d = Suitability Index depth, SI_v = Suitability Index velocity, SI_{CI} = Suitability Index channel index, SI_{ges} = Suitability Index total, SI_i = Suitability index variable

For generating suitability curves of nase (*Chondrostoma nasus*) the results of the observations by snorkelling at the Pielach River were taken. From the surveyed fish (by snorkelling) Melcher (1999) developed the following suitability classes (Table 2).

For analysing the effects of riverbed widenings to flood protection, the calculated water surface levels of the year 2002 (before widening) and 2003 (after widening) were compared.

4 RESULTS

4.1 *Riverbed widening and flood protection*

The effects of the cross sectional enlargement of 2003 to the water surface levels are presented in Figure 2.

Table 2. SI of nase (Melcher, 1999).

Suitability index [SI]	very high	high	low	no SI
Spa. depth [cm]	15–30	30–45	45–90	<15, >90
Spa. velocity [cm s^{-1}]	100–110	80–120	70–80 130–140	<70, >140
Spa. substrate	Microlithal	Mesolithal		
Juv. depth [cm]	0–30	30–60	60–120	>120
Juv. velocity [cm s^{-1}]	0–5	10–15	20–35	>35
Juv. substrate	Pelal Microlithal	Mesolithal Macrolithal	Psammal Megalithal	

Ad. Table1: Pelal (<0,063 cm), Psammal (0,063–0.2 cm), Akal (0,2–2 cm), Microlithal (2–6.3 cm), Mesolithal (6,3–20 cm), Macrolithal (20–40 cm), Megalithal >40 cm
Spa. – Spawning/Juv. – Juvenile

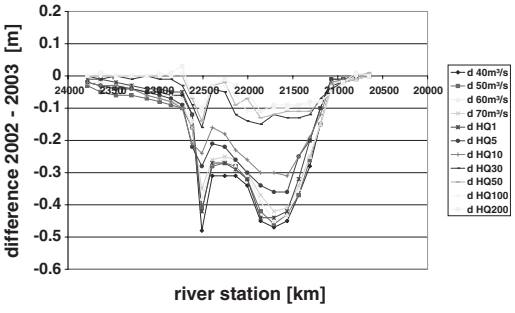

Figure 2. Effects of cross section enlargement on flood protection (d = discharge).

It is obvious, that the lowering of the water levels is clearly found at discharges beneath bankfull (<190 m^3s^{-1}). At discharges with recurrence intervals >10 years the positive effect for flood protection can be neglected (reduction <0.1 m).

Beside the local effects of riverbed widenings, the influence of theses artificial measures is found additionally in upstream direction. The increase of the conveyance through the cross sectional enlargement is documented up to 300 m upstream for discharges around 50 m^3s^{-1}.

4.2 *Effects of restoration measures*

To evaluate the benefits of the restoration measures to aquatic ecology the method of habitat modelling was used. The abiotic data were combined with the preference function of nase, one of the main fish species (Table 2). The analysis was performed for below bankfull discharges. In Figure 3 (a), (c) the percentage of Weighted Useable Areas (WUAs) is documented for the historical natural "Leitbild situation" (1890), the regulated river bed of 1900, the geometry data of 2002 (before widening) and 2003 (after widening).

It was found as an interesting result, that the modelling of the historical "Leitbild" situation showed a

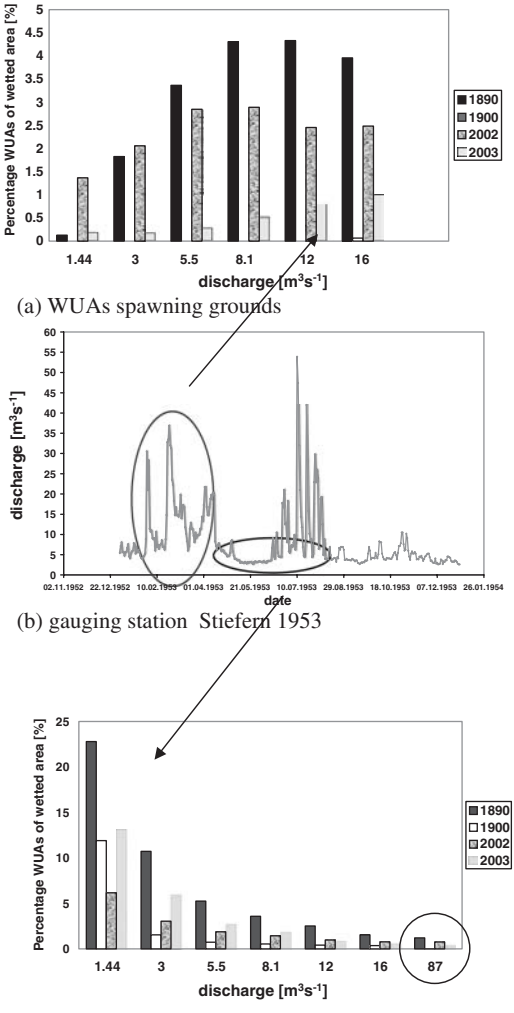

Figure 3. Development of fish habitat quality 1890–2003.

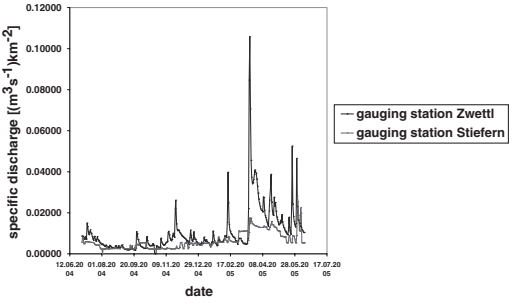

Figure 4. Specific discharge Zwettl/Stiefern (06.2004–06.2005).

good correlation between the maximum percentage of useable areas and the hydrological regime (Fig. 3). Spawning of nase is highly correlated to a certain water temperature and is found in spring-time (Lelek & Penaz, 1963; Maier, 1993). In this period the average flow of the Kamp River is increased caused by the natural regime (Mader et al., 1996). Frequently discharges around 15 m^3s^{-1} (Figure 3b) were documented. During the low flow season in summer with discharges $<3\ m^3s^{-1}$ the channel geometry of the historical river morphology provided also the best habitats for the juvenile nases which are described in Table 2. In cases of small to mid-size flood events ($87\ m^3s^{-1}$), which may happen in summer (Fig. 3b), the historical geometry provided additionally the best refugial habitats (Fig. 3c). The regulation project of 1900 with its straight course caused a total reduction of riffles (Fig. 3a) which are well known as spawning habitats of nase (Stein, 1992; Keckeis, 1991; Maier et al., 1992). Also the juvenile habitats, defined as shallow water areas (Table 2), were reduced compared to the historical "Leitbild" situation. Following on, the construction of the three large power plants caused a massive change in the hydrologic characteristics. In Figure 4 the gauging stations of Zwettl (non influenced, Fig. 1) and Stiefern (influenced by power plants since 1954, Fig. 1) are compared.

Figure 4 shows the reduction of small and mid-size flood events by the hydrological management of the power plants. Therefore a cross sectional decrease of the originally regulated cross section of 1900 arose, from the loss of stream power, for almost 30%. As a result of this loss in dynamics, the bankfull discharge was reduced from $170\ m^3s^{-1}$ to $145\ m^3s^{-1}$. During this 100-years of morphological development (50 years with an influenced regime) the habitats (spawning, juvenile) became a similar characteristic like in the historical "Leitbild" situation (Fig. 3a and Fig. 3c). Only the quantified usable areas were reduced.

The effects of the flood protection measures and the effects of the restoration features are presented in the modelling results of the year 2003 (Fig. 3a and Fig. 3c).

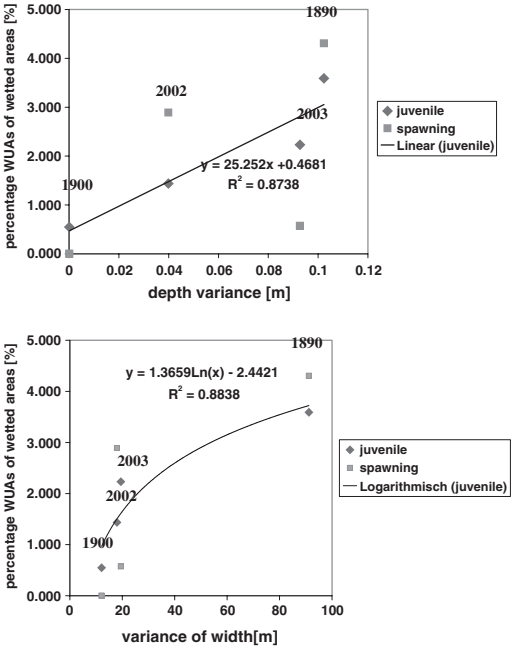

Figure 5. Depth and width variance/useable juvenile habitats.

It is obvious that the habitat characteristics changed totally by the cross section enlargement. The spawning areas were drastically reduced and the shallow water areas, preferred by juveniles, increased.

4.3 *Evaluation method*

For evaluating the benefits of these measures to flood protection and aquatic ecology, according to the Water Frame Work Directive, a morphologically based evaluation method was tested. At the beginning it was necessary to define parameters for channel characterization. Depth- and width variance are often used for describing channel – habitat characteristics (Jungwirth et al., 1984). In Figure 5 the depth and width variance are presented for mean flow ($8.1\ m^3s^{-1}$).

It is obvious that the variance of depth and width is correlating with the percentage of weighted useable areas (WUAs) of juveniles nases (Fig. 5). The modelled spawning grounds, based on the surveyed preferences, showed no response to these parameters. Therefore a new parameter derived from the 1-D modelling results had to be taken to characterize a linear relation between the increase of the 1-D variable and the percentage of the useable spawning areas. Various analysis were performed and finally the variance of bottom shear stress showed the best response to the occurrence of spawning grounds. These results are presented in Figure 6.

Copyright © 2006 Taylor & Francis Group plc, London, UK

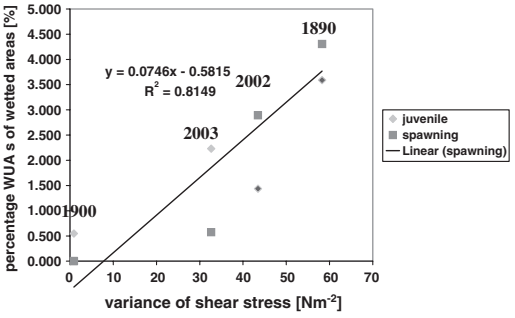

Figure 6. Bottom shear stress/useable spawning habitats.

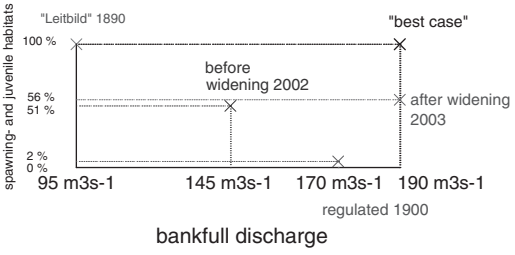

Figure 7. Integrated evaluation of geometric datas.

In Figure 7 the integrated evaluation of the measures at the Kamp River are shown. In x-direction the improvement to flood protection is shown. The increase of the bankfull discharge was taken as parameter to evaluate the success according to flood protection because, as it was proven in Figure 2, the events with a high recurrence interval (>10 years) were only less influenced by the artificial riverbed widening.

In y-direction the percentage of natural habitat characteristics is presented. The values are describing the morphological conditions for spawning- and juvenile habitats based on the variance analysis of the 1-D model (Figs 5–7). Juvenile and spawning habitats were equally weighted. A splitting was further done for depth and width variance.

For interpretating the evaluation method, two totally different points of Figure 7 can be mentioned. The "Leitbild" situation of 1890 is representing the non influenced morphological conditions with its natural characteristics (100%). The opposite situation can be seen in the river regulation of 1900. The natural morphological characteristics was reduced to 2% of the former river bed structure. During the 100 years development (50 years influenced by the hydropower plants) the river restructured itself by erosion and deposition of material (influenced since 1954 by power plants, Fig. 3). Therefore the 51% of natural characteristics calculated for 2002 can be seen as the maximum possible heterogeneity under the consisting boundary conditions (reduced coarse sediment input and discharge regime). The artificial widening, with its restoration measures in 2003, caused an increase of the bankfull discharge up to 190 $m^3 s^{-1}$. Furthermore the morphological situation changed. The analysis of variances of depth, width and shear stress (according to the correlation to certain habitat types) showed that 56% of the natural geomorphologic habitats were found in these areas of artificial widening. But it can be mentioned, based on the knowledge of the River System (literature and modelling), the situation 2003 (190 $m^3 s^{-1}$/56%) is not sustainable. Caused by the reduced sediment transport capacity, effected by the Riverbed widening, aggradation of material is expected. This will lead to a shift of 2003 (190 $m^3 s^{-1}$/56%) towards the situation of 2002 (145 $m^3 s^{-1}$/51%). 2002 can be seen, as it was mentioned, as the best possible morphologic characteristics under the existing boundary conditions. A monitoring of the morphologic development has started to proof the assumption.

5 DISCUSSION

For some cases the problems of mid- to long term development of riverbed widening were documented (Habersack & Nachtnebel, 1995). Hauer et. al. (sub.) investigated the effects of riverbed aggradation to the habitat quality of the rheophilic cyprinid nase over a three year time period at the Sulm River. The results showed that fish react immediately to changes in morphological characteristics. Similar effects can be expected for the initial measures at the Kamp River. The problem of such artificial measures is that in these areas of artificial river bed widening the rivers are not "in regime" anymore. Therefore a regime analysis was done based on the work of Simond & Albertson, 1960. Their studies were taken because their regime equations were found comparable to rivers with less sediment transport like the Kamp River is. The results showed for the historic bankfull discharge (95 $m^3 s^{-1}$) that a bankfull width of 41 m and a bankfull depth of 2.8 m are characterizing a river in regime. Compared to that, the results of the hydrodynamic modelling with the historical geometric data (1890) showed an average width of 48 m and a depth of 2.2 m. That means, there are differences in the singular parameters (width, depth) but the wetted areas [m^2] are quite similar. Therefore it can be mentioned, that the study reach was in regime before river regulation (1900). The regime calculations also emphasis the thesis that the riverbed widening of 2003 is not sustainable. Based on the geomorphologic characteristic and the aggradations of suspended sediments, which increased by the change of wood- to farmland in the catchment area beneath the reservoirs, the bankfull capacity will be reduced and will lead to a development of the measures towards the situation of 2002 (145 $m^3 s^{-1}$/51%).

6 CONCLUSIONS

The results of this study demonstrate that it is possible to use a one dimensional model for an integrative analysis according to the demands of the European Water Framework Directive (WFD). It was shown that variables of the 1-D models (depth-, width- and shear stress variance) are well correlating with the occurrence of spawning- and juvenile fish habitats which were defined by preference analysis. Furthermore an evaluation method was tested, based on the one dimensional parameters, and showed a good response to river characteristics comparing flood analysis and fish habitat characteristics.

River habitat model using energy budget characteristics and experiment on improvement of river physical environment

H. Yabe
Civil Engineering Research Institute for Cold Region, Sapporo, Japan

ABSTRACT: The Cherry salmon (*Oncorhynchus masou formosanum*) spend much of their life in rivers. As is true for any organism, the population of Cherry salmon is influenced by the habitat. The purpose of this study is to make clear the relationship between the population of Cherry salmon parr and the river habitat, toward gaining knowledge necessary for conservation and improvement of the river environment.

This study evaluated the living environment for Cherry salmon parr by their feeding activities. Knowledge on physiology and ecology of Cherry salmon was used for calculation of acquired energy after feeding, and consumed energy for maintaining their position and resting against current. The budget between the two kinds of energy was also calculated. And it verifies the validity of the evaluation by analyzing the relationship between the energy budget and fish population in the sections of river, pools and riffles, and created experimental pools. As a result the optimal environmental conditions for Cherry salmon were clarified. Additionally we conducted the experiment that river channel structure and the amount of organic matter were artificially altered. It was verified that it is possible to increase food for cherry salmon by creating physical structures that improve the retention and accumulation of organic matter, which in turn improves the food environment.

1 INTRODUCTION

River conservation and restoration have become increasingly pressing issues. Cherry salmon (*Oncorhynchus masou formosanum*) are anadromous salmonids that inhabit cold parts of the North Pacific Ocean of Asia and spend much of their life in rivers. Because the fish are susceptible to changes in the riverine environment, they are considered to be an indicator of a river's ecological soundness. However, an efficient method for evaluating a river's ecological soundness has not been established because it is dependent on various factors whose complex interactions greatly influence aquatic life including cherry salmon. Also, the populations of cherry salmon have recently been declining, which has prompted the fishery and tourism industries to call for clarification on the relationship between the changes in a river's physical environment and the fish population. The purpose of this study is to establish a method that quantitatively evaluates a river in terms of its ability to support cherry salmon. Established methods for clarifying the physical environmental factors preferred by the salmon give us knowledge necessary for selecting riparian conservation areas and for improving and restoring the river environment.

The life of cherry salmon is divided into the fry and parr stages (from spring to autumn), the wintering stage, the seaward migration stage, and the upstream spawning stage. The habitat a fish chooses depends on the fish's stage of life. Conservation and improvement of the habitat for fry and parr, which spend one or two years in a river after hatching, are considered particularly important for the preservation and growth of the population. That is why this study addresses the parr stage. The Physical Habitat Simulation Model is a common method for evaluating the habitats of fish. However, existing habitat models including it are not applicable to cases in which the habitat of the target species is difficult to identify; therefore, data on the direct relationship between the population (density/suitability) and the physical environment cannot sufficiently be collected by field surveys or other means. We propose a new habitat evaluation method that incorporates the fish's physiology and behavior, including feeding and resting behavior. The validity of the model is examined by comparing its results with field data.

Next, we attempt to understand the influence of physical structures on fish population. The knowledge from this attempt can be used in habitat improvement and restoration efforts. It has been assumed that a decrease in the number of pools can affect the population of cherry salmon. To test this assumption, we artificially created pools to improve the physical habitat structure of a river reach. The findings in the

Copyright © 2006 Taylor & Francis Group plc, London, UK

examination were applied in our habitat evaluation model described above. Also, it has been pointed out that the straightening of rivers influences the habitat of the benthic animals on which cherry salmon feed. To clarify this, we demonstrated that the habitat for benthic animals could be improved by installing groin works and iron piles that change how organic matter accumulates in a river.

2 FISH HABITAT MODEL

Application of the Physical Habitat Simulation Model (PHABSIM) requires the calculation of a preference curve for each physical-environment factor of a river (Stalnker *et al.*, 1994). Each factor is then converted to weighted usable area (WUA) and evaluated as a total value. Preference curves obtained from field studies conducted in a target river, or from laboratory experiments that reproduce the preferences of fish in a target river, accurately describe the distribution of fish. However, the evaluation of fish distribution is difficult when the data on the direct relationship between population (i.e., density as an indicator of suitability) and the physical environment cannot sufficiently be collected by field surveys or other means, and the preference curve thus lacks accuracy. During a single life stage, a fish does not stay in one microhabitat. Depending on its behaviors such as feeding, resting, and taking refuge during flooding, a fish often changes its microhabitat. Because of this, it is desirable that a preference curve be calculated separately for each behavior, including feeding and resting, with equal consideration given to the interrelation between the relevant factors. Previous studies that addressed this problem – targeting pale chubs, sweet fish or dace – include one that that used equations to calculate preferences separately for feeding, resting, refuge, and spawning, and evaluated the habitat by weighting these behaviors. One study analyzed, based on the disturbance frequency that relates to flow velocity and the amount of food, the energy budget during feeding. Another study improved the fish habitat preference criteria to accommodate the structural features of pools and riffles and their seasonal variations. As described above, it is important to improve on PHABSIM, which quantifies a river's suitability as a fish habitat based solely on a one-to-one relationship between a target species and the physical habitat component of a river, and to evaluate fish habitat based on growth of a target fish and the seasons and by giving consideration to the physiology, and behaviors of the fish.

For cherry salmon, there have been studies in which the fish's distribution points and the corresponding physical structures of a river were collected and analyzed in the wintering period, when the fish tend to be resting. In these cases, application of PHABSIM seems feasible. However, identification of the fish's habitat is difficult in the parr stage, between summer and autumn, when the fish are actively feeding. This is because salmonids, such as cherry salmon, are cautious by nature and exhibit avoidance behavior even when only seeing the shadow a researcher casts, so study through visual observation is difficult, except at certain locations such as pools, due to the fish's extremely rapid movement. Therefore, few studies have directly collected habitat data on the fish, and no clear preference curves have been calculated for the species. Instead, many studies identified the limiting factors and clarified the importance of habitat factors such as flow velocity, water depth, and the availability of pools and cover by analyzing the population density and environmental variables in terms of stream reach and channel unit.

Toward evaluating the habitat of cherry salmon in the parr stage, this study focused on parr feeding activities, attempting to calculate the energy taken in from feeding, the energy expended to maintain optimal position or take rest in the current, and the budget between those, based on physiological and ecological information of the fish. In this study, the validity of the proposed habitat evaluation method was examined for summer and autumn through an analysis of the relationship between energy budget and population density according to river sections (reaches), riffles, pools, and artificial pools in the target river. It is likely that these calculated values can be used to determine fish quantitative populations in various rivers as well as to evaluate the relative distribution of species.

3 HABITAT MODEL BY ENERGY BUDGET

3.1 *Survey procedures*

One-kilometer reaches were studied on the Hidarimata River and the Migimata River, a tributary of Shiribeshi-toshibetsu River in Japan. The rivers are designated as protected rivers, where all aquatic animals and plants are prohibited from being collected. The population density of cherry salmon in these rivers is very high, making the rivers ideal for ecological studies. Eight river sections (Hidarimata River 1 to 4, Migimata River 1 to 4; each section is approximately 50 m long) were chosen for study sites. Investigations of the river conditions and field surveys on fish, drifting insects, the river physical environment and the like were conducted once in late July and once in early October 2004.

To make the fish surveys as accurate as possible, sampling by net casting was combined with sampling by electric shock. Each 15-minute net casting survey was followed by electric shock sampling from the downstream limit to the upstream limit of each survey section. Three sets of net casting plus electric shock

Copyright © 2006 Taylor & Francis Group plc, London, UK

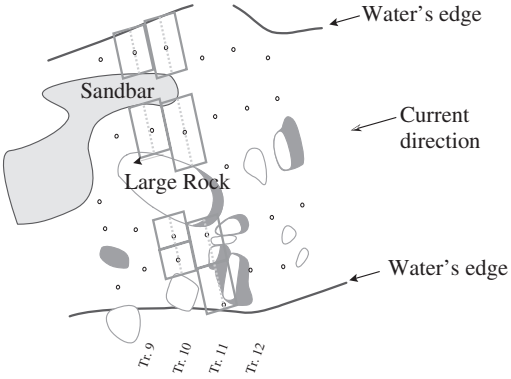

Figure 1. Measurement of river physical structure.

sampling were done, with a between-set interval of 10 minutes. Captured fish were measured for body length and weight.

In the physical habitat structure surveys (Figure 1), each river section was subdivided into cells where channel configuration, flow regime (water depth and flow velocity), riverbed material (loose rock, sunk rock, and grading (roughness)) were measured. In each river section, 30 transects were drawn perpendicular to the center of stream at equidistant intervals, and four survey spots per transect were set at equidistant intervals (total of 120 survey spots). At each survey spot, physical environment, such as the distance from the riverbank, water depth, flow velocity at 60% depth (i.e., 60% of the distance from the surface to the bottom) and flow velocity at the bottom, were measured, and visual observations were made on bottom sediment type, type of microhabitat such as riffle and pool, and canopy opening (closed (0) or open (1)).

Drifting insects were collected with a drift net (50 × 50 cm or 25 × 25 cm) that was set on a flat (i.e., medium water depth and flow velocity) for 30 minutes in the early morning (around 6 a.m.). The flow velocity and the flow rate (water filtered) at the front of the net were measured. To collect falling insects, water pan traps were placed for a whole day on a warm, fine day on both sides of each river section. The mass per area of benthic animals, amount of attached algae, and the sunshine duration were calculated. Discharge observation was made six times each for the Hidarimata River and the Migimata River to record the flow rate and water-surface gradient. The maximum daily rainfall during the study period (July to October) at the Imagane Observatory was 48 mm per day, on August 20, and 50 mm per day, on September 13. There were rainfalls of about 30 mm/2 days and 10 mm/2 days in late August and early September. In both rivers, the peak water level followed two hours after each peak rainfall, and the maximum water level increase was about 60 cm.

3.2 *Results of fish surveys*

3.2.1 *Distribution of cherry salmon*

Summer surveys were conducted in late July, the high-growth period for (under-yearling) parr, and autumn surveys were conducted in early October after the spawning period of adult fish. Figures 2 and 3 show the survey results for each survey section. In autumn, the number and weight of captured fish per area, which was calculated by dividing the number and weight of fish by the water-surface area of each survey section, decreased. In summer on the Hidarimata River, both the number and weight per area were greatest in Section 2, and on the Migimata River the number and weight per area were greatest in Section 1. In autumn on the Hidarimata

River, both the number and weight per area were greatest in Section 2, and on the Migimata River the number of small-sized fish was great in Section 1 and that of large-sized fish was great in Section 3.

3.2.2 *Physical environment of the rivers*

Table 1 shows the average physical environment values for each section. The weight of falling insects recorded between August 10 and 12 is extremely small; it is possible that terrestrial insects had already become less active by then. Sections 1, 2, 3 and 4 of the Hidarimata River are respectively characterized as a reach with rapid flow and many large rocks; a reach with large rocks, pools, and sandbars; and straight reaches with series of riffles and flats. Sections 1, 2, 3 and 4 of the Hidarimata River are respectively characterized as a straight reach with dispersed large rocks; a right-curving reach with large rocks, pools, and sandbars; and straight reaches with series of riffles and flats. The number of tree species of the riparian woods is similar for the eight sections on the two rivers (from 149 to 160 species), and the species compositions do not differ significantly between the two.

3.3 *Analysis methods*

3.3.1 *Classification of riffle and pool clusters based on the river physical environment*

Habitats were evaluated on the scale of channel unit (i.e., riffle/flat/shallow edge or pool) as well as stream reach (i.e., river survey section). Surveyed sections were quantitatively categorized into riffle, flat, shallow edge or pool clusters according to their physical structures, since distribution of such structures in a river habitat is important for the growth of cherry salmon parr. Principal component analysis did not extract composite variables (principal components) that could explain the overall variation in surveyed sections as a whole; therefore, principal component points were not used. Instead, cluster analysis was conducted using physical measurements (water depth, flow velocity at 60% depth, bottom flow velocity, bottom sediment type, and the rate of loose rock). The degree of dissimilarity among clusters was calculated using Ward's method, which is based on the squared Euclidean distance. Four cases were analyzed: the Hidarimata River in summer and autumn, and the Migimata River in summer and in autumn. As a result of the analysis, all surveyed river channel units were categorized into four clusters. Similarity in water depth, flow velocities, and bottom sediment was fairly strong within each cluster. The four clusters were a pool cluster with great water depth and low flow velocity, a riffle cluster with shallow water depth and high flow velocity, a flat cluster with medium water depth and flow velocity, and a channel-edge shallow cluster with small water depth, low flow velocity and small amount of bottom sediment. Comparison with the river bottom morphology maps, which were produced by field investigation conducted for the sections classified into the cluster types, confirmed the reproducibility of the clusters. The classification reflected the variation in the physical conditions, which is hard to visually identify, such as transverse variation in flow velocity and water depth, and enabled us to describe the channel-edge shallow conditions.

3.3.2 *Application of the energy budget model*

To evaluate habitats in terms of suitability for cherry salmon parr, an energy budget model that incorporates the salmon's feeding characteristics was applied. Salmons have the habit of maintaining their position while facing the current in wait for drifting insects. Flow velocity strongly influences the behavior of

Copyright © 2006 Taylor & Francis Group plc, London, UK

cherry salmon engaged in feeding, and flow rate (and drifting insect supply rate) positively correlates with flow velocity (i.e., the greater the flow velocity, the more insects drift down, making it easier for the fish to feed). However, greater flow velocity means that more energy is required for a fish to maintain position. It was predicted that cherry salmon would choose locations (i.e., optimal position) where they could feed most efficiently.

In this study the energy budget of cherry salmon was evaluated based on the physiology and life of the species as described above. The relationship between energy budget and population density was analyzed. Assuming that the survey spots for physical structure survey set within the surveyed sections are optimal positions of the fish, the net energy intake (NEI) at each optimal position was calculated by subtracting the swimming cost (SC, the energy expended in swimming) from the gross energy intake (GEI, the energy obtained by feeding) (Equation (1)).

$$NEI = GEI - SC \quad (1)$$

The following hypothetical conditions are assumed in models used for estimating GEI and SC:

- The fish rests at whichever depth has the lower flow velocity: the bottom (3 cm above the riverbed), or the 60% depth. (The bottom tends to have lower flow velocity.)
- SC is determined by the flow velocity at the fish's optimal position.
- The fish feeds at whichever depth has the higher flow velocity: the bottom, or the 60% depth. The fish's capture area is defined by maximum capture distance (MCD), which is determined by the flow velocity at the feeding depth.
- The fish eats all the food that drifts into its capture area.

GEI, an index of collectability of food by fish, is calculated by Equation (2) (Hughers *et al.*, 1990):

$$GEI\ (cal/h) = CA \cdot V_{fg} \cdot D \cdot I \quad (2)$$

Where,
CA (m^2): Capture area
V_{fg} (m/s): Flow velocity at a feeding depth
D (cal/g): Drifting insects, converted into energy (4,823 cal/g (dry weight))
I ($g/m^3 \cdot h$): Drifting insect supply rate

MCD was calculated to obtain CA. As shown in Figure 4, MCD can be calculated using Equation (3) (Hughers *et al.*, 1990). In this study, the following values were adopted: RD = 45 cm, V_{max} = 69 cm/s for fish shorter than 10 cm and V_{max} = 93 cm/s for fish 10 cm or longer.

$$MCD = (RD^2 - (V_{fg} \cdot RD/V_{max})^2)^{1/2} \quad (3)$$

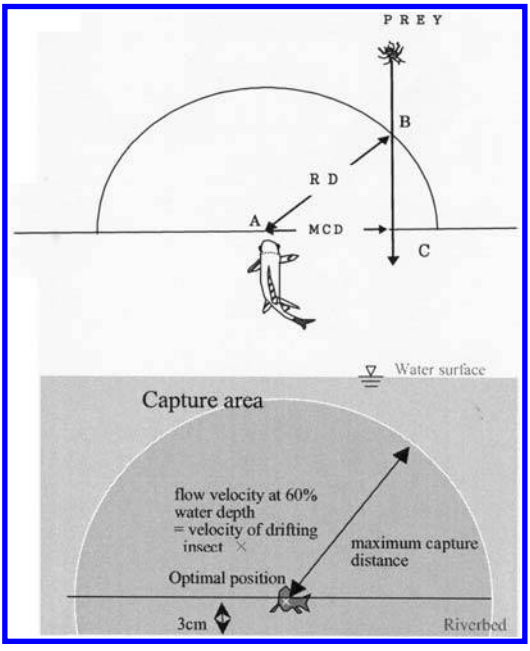

Figure 4. Maximum capture distance (MCD) and capture area (CA).

Where,
RD (m): Distance from food at which fish reacts to it
V_{max} (m/s): Maximum sustainable swimming velocity

CA was calculated using Equation (4) when a hypothetical fish's position was the bottom point (see Figure 4), and using Equation (5) when the position was the 60% depth. When MCD + 3 cm is greater than water depth (d_{fc}), Equation (6) in which calculated CA was the area above the riverbed is used. In that case, areas outside the MCD are included in CA for the simplification of calculation; however, such areas were expected to be relatively small.

$$CA = \pi \cdot MCD^2/2 + 0.03 \cdot 2MCD \quad \text{(Bottom position)} \quad (4)$$

$$CA = \pi \cdot MCD^2 \quad \text{(60\%-depth position)} \quad (5)$$

$$CA = d_{fc} \cdot 2MCD \ (MCD > d_{fc}) \quad (6)$$

SC was obtained using Equation (7) (Fausch, 1984), which allowed the calculation of energy required for the fish to maintain its position in the current. The equation can be adjusted by body weight and thus fish species and growth stage. In this study, the average body weight and the average body weight for fish between 5 and 10 cm long and between 10 and 20 cm long, which were determined by our fish surveys, are

Copyright © 2006 Taylor & Francis Group plc, London, UK

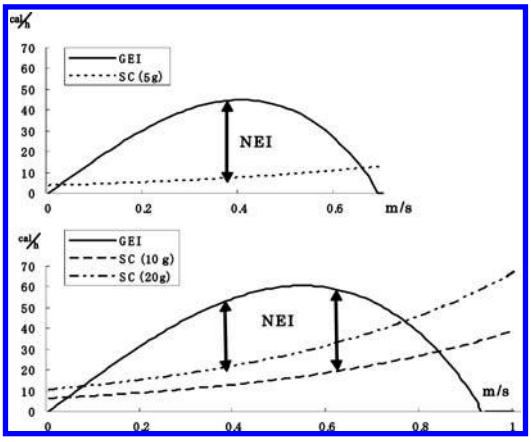

Figure 5. NEI, GEI, SC, and flow velocity.

set for each river and study period. In this way, NEI is calculated.

$$SC\ (cal/h) = 0.9906 \cdot BW^{0.784} \cdot e^{(0.0186 \cdot Vfc)} \quad (7)$$

Where,
BW (g): Body weight
V_{fc} (m/s): Flow velocity at position for rest

3.4 *Results*

3.4.1 *Evaluation based on energy budget and surveyed population density*

Figure 5 shows how values obtained from the energy budget model change according to the flow velocity at position for rest and feeding points. In this case, it was assumed that the flow velocity at optimal position and feeding points were the same and the drifting insect supply rate was constant. The values differed depending on body weight of fish: the lower the body weight and the shorter the capture distance, the narrower is the suitable flow velocity range, and the smaller are the GEI and SC; whereas, the greater the body weight and capture distance, the greater are the GEI and SC. The flow velocity at a feeding point that maximizes GEI was calculated for different body weights. SC becomes smaller as the flow velocity at the optimal position decreases. In using this model to calculate energy budget, it is necessary to use various flow velocities and consider various drifting insect supply rates. By using this model, the mutual relationships between habitat factors during the feeding period of cherry salmon can be expressed, and suitable physical environment based on NEI can be identified for a target river. SC starts rapidly increasing after the flow velocity exceeds 1 m/s, indicating the need for refuge areas in the event of flooding.

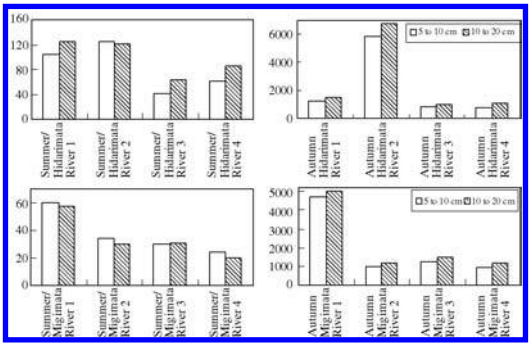

Figure 6. Net energy intake (NEI) (left: summer, right: autumn).

Next, the validity of the values calculated using the energy budget model is examined. The calculated values and surveyed results were compared for the river section cells (120 cells per section) Equation (8) was used to obtain the average NEI per unit water-surface area for each river section and for summer and autumn. Comparisons based on the two body-weight categories were also made.

$$NEI = 1/A \left\{ \sum_i \left[(GEI\ i - SC\ i) A\ i \right] \right\} \quad (8)$$

Where,
Ai: Water-surface area of Cell i

In the Hidarimata River, NEI is the highest in Section 2 in summer and in autumn (Figure 6), which is consistent with the surveyed population density. In the Migimata River, NEI is highest in Section 1 in summer, which agrees well with the surveyed population density. Evaluation of NEI and population density in the Migimata River in autumn was difficult because the population density did not show any variation. NEI was calculated for the four categories classified by cluster analysis. In Section 2 of the Hidarimata River and Section 1 of the Migimata River, where the population densities were high, pool cluster as a share of the total area of the section was high in both seasons (around 30% in summer and 20% in autumn), and the average water depth was high (0.4 to 0.6 m). The values for flow velocity in these two sections resulted in large NEI values (Figure 6). The average flow velocities at 60% depth in the two sections in summer were 0.37 m/s and 0.57 m/s when the average bottom flow velocities were 0.22 m/s and 0.24 m/s. Flow velocity tended to decrease in autumn in both sections. Cells classified as pool clusters in summer that retained that status in autumn accounted for 23% of cells for Section 2 and 29% for Section 1. These percentages were higher than those for the other sections, indicating that there were more stable pools in these sections. Figure 7 shows NEI for the pool cluster (shallow stream-edge

Copyright © 2006 Taylor & Francis Group plc, London, UK

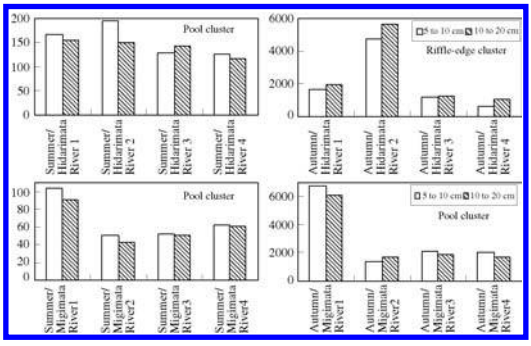

Figure 7. NEI for the pool clusters (left: summer, right: autumn).

cluster for the Hidarimata River in autumn), which clearly shows the relationship between NEI and population density. The results for the Hidarimata River are similar to results for all the clusters regardless of season (Figure 6). However, NEI in autumn for Sections 1, 2, and 4 is greater for smaller fish (5 to 10 cm) than for larger fish (10 to 20 cm), which shows that there is agreement between the population density from captured fish and the density calculated based on NEI. For the Migimata River, NEI for Section 4 is high in summer, which accurately reflects the surveyed population density. But NEI for the same section in autumn is about the same as NEI for other sections, from which it is not possible to identify the relationship between NEI and the surveyed population density.

3.4.2 *Habitat evaluation during flooding*

Whether flooding influences the population density of cherry salmon was evaluated by using the SC, i.e., energy required to maintain optimal position or to rest in the current. In the evaluation we assumed that it is easy for the fish to take refuge during flooding if the SC is small. SC analysis focused on the August 20 flooding, when there was the greatest water level increase recorded during the study period. The flow volume during the flooding was set at 3.8 m^3/s, based on HQ curves (Hidarimata River: $Q = 20.6 \cdot (H + 0.137)^2$; Migimata River: $Q = 13.17 \cdot (H + 0.183)^2$), and the roughness coefficient was set at 0.065 to 0.075, based on observed values. To obtain SC, five or six cross sections for each river section (summer survey results), and the water level and the flow-velocity increase estimated for each survey point (cell) were used in a non uniform flow calculation (Figure 8). In the Hidarimata River, the survey showed that the population density decreased almost uniformly in all four sections from summer to autumn, although SC was high for Section 4 and relatively high for Section 3. In the Migimata River, SC was high for Sections 3 and 4 ,the surveyed population density significantly decreased in Section 4.

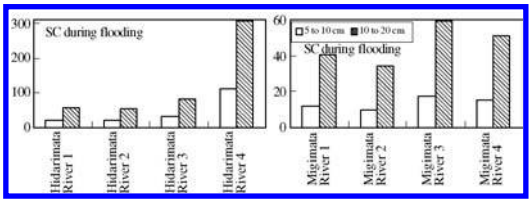

Figure 8. Swimming cost (SC) during flooding.

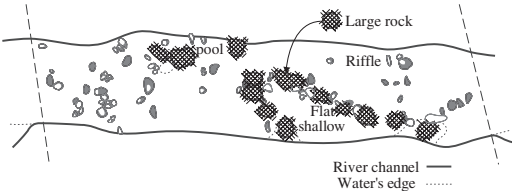

Figure 9. Pool creation experiment (Migimata River 4).

During the flooding it was clarified that flow velocity and water depth increased uniformly in Sections 3 and 4 of the Hidarimata River and Sections 3 and 4 of the Migimata River, where channel physical structures are relatively simple. Increase in water depth and flow velocity were not uniform in Sections 1 and 2 of the Hidarimata River and Sections 1 and 2 of the Migimata River, where channel physical structures are complex, with many sandbars and large rocks. Increase in SC based on the autumn flow regime from SC based on the summer flow regime in the Hidarimata River was great in Section 4, and increase in SC for Section 3 was greater than those for Sections 1 and 2. In the Migimata River the increases in SC for Sections 3 and 4 were 5 to 20 cal/h greater those for Sections 1 and 2.

3.5 *Experiment on improvement of river physical environment*

3.5.1 *Pool-creation experiment*

It was predicted that there would be sections where SC would be high during flooding, and that this would predict to the decrease in population density of cherry salmon there. It is also pointed out that a decrease in the number of pools caused by river improvement works and changes in land use in the river basin can contribute to the decrease in cherry salmon population. To address decrease in the cherry salmon population, we conducted an experiment where pools were artificially created to minimize the energy expenditure required for the fish to maintain position. SC and fish distribution were compared using the evaluation model described above.

In April 2005 in the Migimata River, pools were created in Sections 3 and 4 by repositioning riverbed rocks (Figure 9). Section 2 was used as the reference section. To calculate SC, physical environment surveys

Copyright © 2006 Taylor & Francis Group plc, London, UK

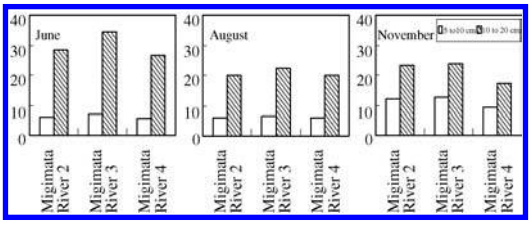

Figure 10. SC of pool creation and reference section.

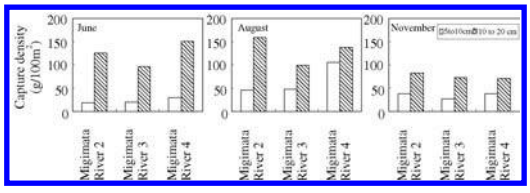

Figure 11. Population density in pool creation and reference section.

were conducted in June, August, and November 2005, using the method described in 3.1 *Survey procedures*. SC was similar in all sections, although it was slightly high in Section 3 in June and August and low in Section 4 in November (Figure 10). Figure 11 shows the survey results of population density for each survey section. The number of small-sized fish was great in Section 4 in June, August. And the population density was almost the same in each section, even though flooding with water-level increase of 50 cm or more occurred three times during the study period. Therefore, it is suggested that the creation of pools did not adversely affect the cherry salmon population. In the November survey the pools we had created in Sections 3 and 4 in April became smaller as the result of natural changes in channel configurations. I will continue monitoring and conducting hydrological investigations, such as by calculating SC during flooding and studying the disappearance process of pools.

3.5.2 *Improvement of the food environment*

GEI changes with the drifting insect supply rate. So the experiment were attempted to improve the food environment of cherry salmon by improving the habitat for benthic animals. The fish feed on both terrestrial and aquatic insects. They mainly eat benthic animals, most of which are aquatic insects, except in summer when there are fewer aquatic insects and cherry salmon become increasingly reliant on terrestrial insects that originate in riparian woods. It is becoming more evident from studies that water quality, flow velocity, riverbed material, organic matter, and other factors influence the benthic habitat. It has been pointed out that the straightening of rivers has reduced the supply of organic matter into rivers and the retention of organic matter, particularly at the upper reaches.

In this study, we artificially altered a channel structure and the amount of organic matter and then monitored changes in the distribution of benthic animals to increase food for cherry salmon. This examination used existing knowledge with which it is possible to characterize the habitat in the most parts (riffles) of the river, except in pools, based on the relationship between the channel's physical structural factors (e.g., water depth, flow velocity) and food factors (e.g., organic matter). This is one of the first empirical studies of its kind, and it is expected to be useful in establishing a method of using benthic habitat factors to evaluate the fish habitat.

We conducted an experiment to increase the accumulation of coarse particulate organic matter (CPOM) by reducing water depth and flow velocity at a section with several riffles on the Atsubetsu river of the Ishikari River System. Through this experiment we examined the changes in benthic animal populations (Negishi *et al.*, 2003).

It was predicted that sedimentation on the riverbed would increase following the creation of experimental river sections where flow velocity was reduced by groin (spur dike in sandbag) installation. Also, iron piles were installed to promote accumulation of CPOM and other matter (i.e., food environment factors). The effect of changes in the physical and food environments on benthic animal populations was examined in mid October 2003. The river section for the experiment is shown in Figure 12. Three riverbed/flow regime modified sections were established downstream of a reference section. Iron piles were installed in the first and second sections, and a groin was made between the second and third sections. The first section had rapid flow because it was upstream of the groin (fast-flow pile works section) and the second section, immediately upstream of the groin, had slow flow (slow-flow pile works section). The third section was downstream from the groin, and the physical environment of the section was affected only by the groin (energy-dissipated section).

The posteriori study was conducted in late November, one month after the preliminary study. Sampling was conducted at 12 locations (i.e., three sampling sites for each section) for benthic animals, organic matter and attached algae. Physical conditions were also measured at each sampling site. The flow velocity decreased most in the slow flow pile works section followed by the energy-dissipated section. The flow velocity decrease was smallest in the fast-flow pile works section. The water depth decreased most in the energy-dissipated section followed by the slow-flow pile works section and the fast-flow pile works section. The flow velocity and water depth also decreased in the reference section. Both the flow velocity and

Copyright © 2006 Taylor & Francis Group plc, London, UK

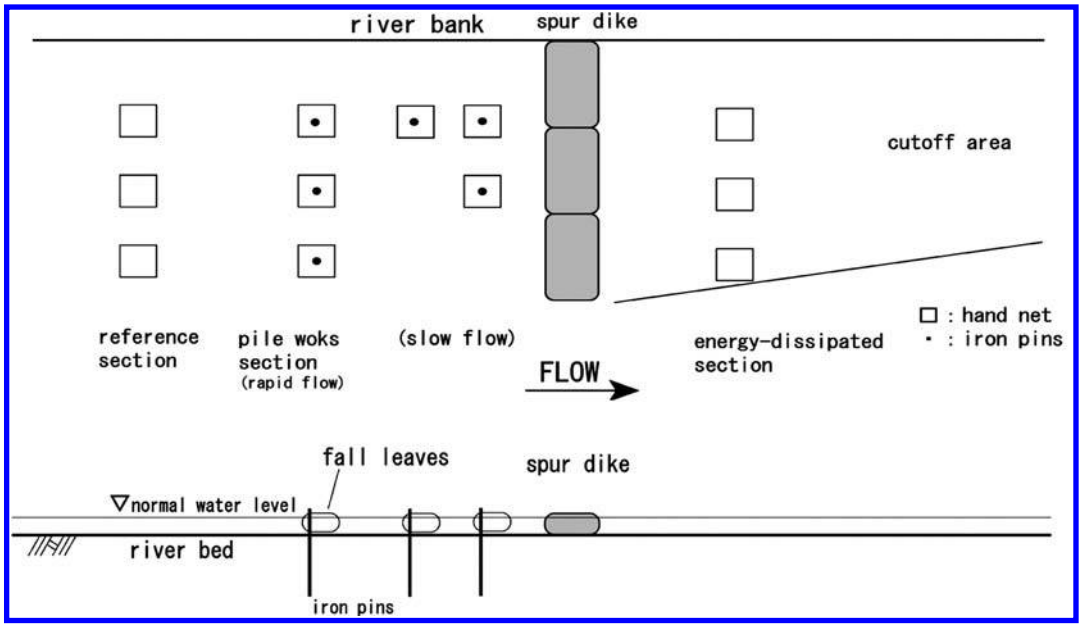

Figure 12. Physical structure improvement experiment on the artificially modified river section (riffle) (upper: plan, lower: cross section).

the water depth increased in the slow-flow pile works section, both slightly decreased in the fast-flow pile works section, and the water depth decreased and the flow velocity increased in the energy-dissipated section. The size of riverbed material decreased in the energy-dissipated section and the slow-flow pile works section, and slightly decreased in the fast-flow pile works section and the reference section. Loose rock as a share of riverbed surface rock decreased by half in the energy-dissipated section, and decreased in the fast-flow pile works section and slow-flow pile works section. As for the food environment, CPOM and fine particulate organic matter (FPOM) greatly increased in the pile works sections, increased in the reference section, but decreased in the energy-dissipated section. Amount of attached algae increased in all sections. Based on these results, the physical conditions and food environment of the pile works sections, particularly the section with slow flow, improved to become close to those of the natural streams. In the energy-dissipated section the physical environment improved but the food environment did not.

Figures 13 and 14 show the result on benthic animal populations. The number of benthic animals decreased in the reference and energy-dissipated sections, but increased in the pile works sections. The taxonomic diversity (number of taxa) did not change in the reference section and decreased in the energy-dissipated section, but nearly doubled in the pile works sections. Changes in population of benthic animals categorized

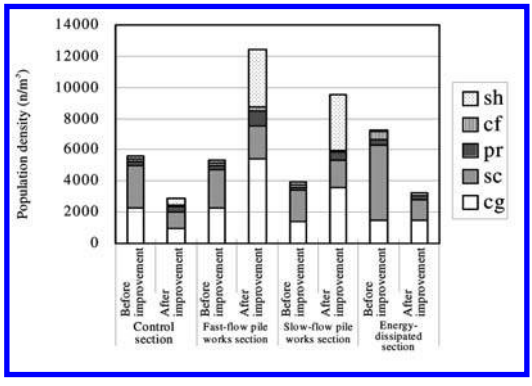

Figure 13. Changes in the number of benthic animals in each section.

by feeding pattern are as follows. In the reference section the number of scrapers and collectors decreased. Shredders slightly increased both in population and taxonomic diversity.

In the pile works sections, shredders sharply increased in population and taxonomic diversity, and collectors and predators increased in population and taxonomic diversity. As a result, scrapers as a share of the total population decreased. In the energy-dissipated section, the number of scrapers sharply decreased, collectors as a share of the total population increased, and shredders were not found. The diversity

Copyright © 2006 Taylor & Francis Group plc, London, UK

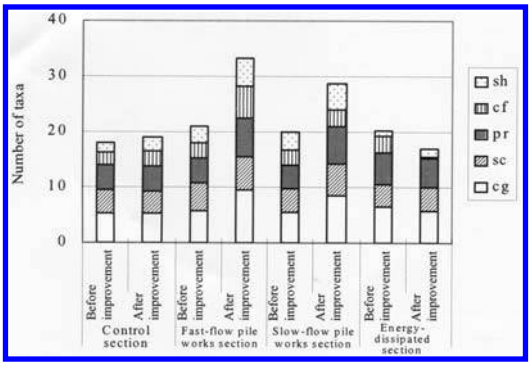

Figure 14. Changes in taxonomic diversity in each section.

index increased in all sections, although the increase was not marked in the energy-dissipated section. In the energy-dissipated section the physical conditions were improved, but the supply of organic matter such as fallen leaves was reduced by groin works, preventing CPOM from accumulating. Therefore, the energy dissipation from groin work installation did not positively influence the population of benthic animals. It was predicted that the physical and food environments in the slow-flow pile works section would improve and the population of benthic animals would increase more than that in the fast-flow pile works section; however, no clear differences were observed between the two sections. Contrary to our prediction, the population of benthic animals slightly increased in the fast-flow pile works section.

For riffles in autumn in the river sections studied, the food environment, not the physical environment, was a limiting factor for the population of benthic animals. It was verified that it is possible to improve the habitat for cherry salmon by creating physical structures that improve the retention and accumulation of organic matter, which in turn improves the food environment.

4 CONCLUSIONS AND FUTURE WORK

Habitat for cherry salmon parr in the feeding stage was evaluated by the energy budget method. The values obtained by this method agree fairly well with the salmon population density obtained by field survey. To hone this method of describing the relationship between the physical structures of habitat and the population distribution of cherry salmon, it is necessary to improve models for the fish's feeding and positioning in the current. The possible parameters that will be considered in developing such models include a physical unit of a series of a riffle and pool, and the distribution of such series in the river channel, detailed three-dimensional data on flow velocities and water depths, and the volumes of each habitat. It will also be necessary to obtain detailed knowledge on the relationship between the insect drift rate and the river channel environment. Further more, we have plan to examine river channel designs and maintenance technologies, including creation of riffles and pools, suitable as cherry salmon habitat. This can be achieved by applying the method developed in this study to fish habitats of rivers with various physical structures and discharge characteristics.

ACKNOWLEDGMENTS

This study was conducted under a grant for sponsored research from the Hokkaido Development Bureau. And it was supported by Hokkaido fish hatchery. Nakajima (Director of salmon resource) and Urabe (Researcher in Donan branch) cooperated and advised in examining. Additionally Sasage, Nakahara, Nunokawa (Engineer of consultants CO) conducted field surveys. We express their gratitude.

ABSTRACT: A good understanding of the interaction between flow, vegetation, and sediment is a key issue for successful river restoration and sustainable flood management. However, many of the relevant hydraulic and sedimentological processes are not fully understood. Flow in rivers and floodplains is complex as it is affected by several interconnected factors such as topography, relative submergence, and vegetation characteristics. These factors directly influence the turbulent flow field and thus sediment dynamics. On the basis of recent field and experimental studies with natural vegetation this paper highlights problems associated with existing computational approaches. Key parameters and characterisation concepts for vegetation are discussed with respect to requirements for reliable modelling of sediment dynamics and river morphology. To tackle the problems, integrated research strategies based on the combination of field studies, laboratory experiments, and numerical modelling are proposed.

1 INTRODUCTION

Traditional river engineering in Europe in the last centuries focused mainly on increasing the agricultural production and protecting people and property from flooding. Particularly in densely populated areas, the function of the rivers was minimized to a system to convey effectively water. This development resulted in straightened river courses along with significant reduction of wetland and natural flood retention areas and an ecological degradation of sensitive riverine habitats. It is nowadays often assumed that river engineering works and intensified catchment landuse have increased the magnitude and propagation of flood waves, though the knowledge of the relative importance of the associated mechanisms remains incomplete (e.g. Pinter et al. 2006). There is ample evidence, however, that river scientists are attempting to integrate principles of hydrology, geomorphology and ecology into synthetic frameworks to better understand and predict how river systems function and respond to manipulation (Wohl et al. 2005). New design approaches and decision support systems for river engineering and management can be developed only on the basis of an improved understanding of fluvial processes and more advanced modelling in combination with improved field monitoring and data elaboration (Klaassen 2002). Recent interest in river restoration, environmental flood management, and the application of bioengineering techniques has brought new perspective to the analysis of environmental hydraulics with special regard to vegetated channels (see e.g. Oplatka 1998, Copeland et al. 2001, Shields et al. 2003, Järvelä 2004b, Rauch 2005, Boelscher et al. 2005).

Flow conditions in open-channels depend on many factors such as discharge, cross-sectional shape, bed forms, sinuosity, sediment and substrate, ice cover and vegetation. In this paper we highlight the effect of vegetation on flow phenomena in open channels. Riparian vegetation is a ubiquitous feature of riverine landscapes providing habitat and food sources, aesthetic appeal as well as erosion control (Andrews 1984, Hey & Thorne 1986). The proper understanding of associated physical processes is the basis for the development of reliable modelling tools for hydraulics, sediment transport, river morphology, and pollutant transport. Such models are needed for the development of sustainable river management strategies as well as ecological and biological considerations. The purpose

of this paper is to provide a state-of-the-art review of current approaches to address flow-vegetation-sediment interaction and to propose potential solutions to close the gaps in our knowledge.

2 STATE-OF-THE-ART

Vegetation increases flow resistance, changes backwater profiles, and modifies sediment transport and deposition (Yen 2002). The quantification of the net impact of vegetation is, however, difficult and depends on many complex interacting factors, including the geomorphic setting of a channel, physical properties, extent, species, age, and health of vegetation (Darby 1999) and temporal variations such as water stage and growth of vegetation (Bakry et al. 1992, Fisher 1995, Sellin & van Beesten 2002) (Fig. 1). For example, dense vegetation within a channel can alter the effective area of a cross section that conveys the flow and significantly influence local flow properties (Hicks et al. 2006). In vegetated compound channels, floodplain flow interacts with the main channel flow or vegetated zones resulting in additional energy losses (Sellin 1964, Pasche & Rouvé 1985, Knight & Shiono 1996, Thornton et al. 2000, Helmiö 2004).

Besides the influence of vegetation on hydraulics, vegetation is a key player also in erosion, transport, and deposition processes of solids, nutrients, and pollutants. The range of associated problems is widespread including the influence of aquatic vegetation on fine sediment dynamics (e.g. Paterson & Black 1999, Aberle et al. 2004), the proper design of wetlands (Hayes et al. 2000), and the influence of terrestrial vegetation on overland flow that carries sediment to the river system (e.g. Rey 2004). The last issue is of particular interest for hydraulic engineering applications since sediment deposits on the floodplain may significantly reduce the conveyance capacity for future flood events (Dittrich & Järvelä 2006). On the other hand, deposited polluted sediments can be washed away during floods, which may be harmful to the riverine ecosystem.

An important issue to be considered when investigating vegetated river systems is the scale of analysis. Investigations of how vegetation influences the turbulent flow field are generally conducted either at point, cross-sectional or reach scales. The knowledge gained from such investigations is often implicitly upscaled to model flow in long river reaches and catchments. Such models require detailed data on bathymetry and ground cover (e.g. bed roughness, vegetation). Techniques to gather the required data are already available and include airborne laser scanning (ALS), vertical aerial photography, and multi-spectral (MS) scanning (e.g. Hicks et al. 2006). Using GIS systems it is possible to generate Digital Elevation Models (DEM) and to determine ground cover (Hicks et al. 2006), type, structure and density of vegetation (Hug et al. 2004) and bed roughness parameters such as characteristic grain-sizes (Carbonneau et al. 2005). However, the reliability of these models depends on the accurate modelling of the critical physical processes. Therefore, we focus in the following section first on the current knowledge concerning the relationship between vegetation characteristics and flow. This knowledge is a prerequisite for the second part of the literature review, flow-vegetation-sediment interaction.

2.1 *Flow-vegetation interaction*

In this section, advances in the knowledge of flow-vegetation are reviewed beginning with the development of methods to determine bulk resistance coefficients. Thereafter the review is directed towards a more detailed description of the flow processes including velocity distributions and turbulence. In the analysis of vegetal flow, non-submerged and submerged conditions are typically separated, since the flow field considerably changes when flow depth exceeds the height of vegetation. In addition, usually two types of vegetation are defined: rigid and flexible plants. On the basis of this classification, a considerable amount of research has been carried out in developing resistance laws for channels with rigid vegetation (e.g. Li & Shen 1973, Petryk & Bosmajian 1975, Lindner 1982, Pasche & Rouvé 1985, Musleh & Cruise 2006), flexible vegetation (e.g. SCS 1954, Kouwen & Unny 1973, Temple et al. 1987, Kouwen & Fathi-Moghadam 2000, Carollo et al. 2005), and various combinations (e.g. Flippin-Dudley et al. 1998, Freeman et al. 2000, Järvelä 2004a). In these conceptual models, numerous different variables have been used to describe the relationship between the flow and vegetation properties. The variation is for the most part due to the differences in vegetation type and relative submergence.

2.1.1 *Bulk approaches*

In traditional approaches, vegetation is typically reduced to boundary roughness by adjusting the channel and/or floodplain roughness coefficient which combines all sources of flow resistance, including vegetation, into Manning's n. Such cross-section or reach-averaged bulk coefficients have been used widely in the analysis of practical engineering problems and are typically selected with the help of reference publications, such as Chow (1959), Barnes (1967), Arcement & Schneider (1989), Coon (1998) and Hicks & Mason (1999). Simple approaches, such as the Cowan (1956) summation method, have given some guidance to combine the effect of various sources contributing to the total resistance. Another often-used methodology to determine the total flow resistance is the Einstein and Banks (1950) linear superposition principle, which can be applied to point as well as reach scales.

To design vegetated (grass-lined) waterways, Palmer (1945) introduced the *n-VR* method relating Manning's n to the product of average velocity V and hydraulic radius R for various channel slopes and plant-stands. For fully submerged vegetation, Kouwen et al. (1969) criticised the *n-VR* method and introduced a stiffness parameter MEI, flexural rigidity per unit area, which reflects the overall resistance to deformation of a plant stand as a result of a flow passing over it. Three decades later, Temple (1999) argued that the *n-VR* method has remained the primary tool for practical application to grass-lined channel conditions, although alternate approaches for predicting vegetal flow resistance have been proposed.

2.1.2 *Vegetative drag*

For non-submerged flow with cylindrical roughness, Li & Shen (1973) and Petryk & Bosmajian (1975) used plant diameter, longitudinal and lateral distances between the plants, and drag coefficient as independent variables. Li & Shen (1973) identified four factors that need to be taken into account in determining the drag coefficient: 1) the effects of open-channel turbulence; 2) the effect of non-uniform velocity profile; 3) the free surface effects; and 4) the effect of blockage. Lindner (1982) concluded that, in densely vegetated channels, the first two of these are of minor importance and can be neglected. Vogel (1994) reported that the major contributor to the drag of most trees is the drag of the leaves. He found that reshaping of the leaves is a critical process in generating drag. Therefore, branched and leafy plants cannot be treated as simple cylinders. Freeman et al. (2000), Kouwen & Fathi-Moghadam (2000), and Järvelä (2002) reported for natural woody vegetation great variations in the flow resistance with the mean flow velocity, because of plant bending and changing flow depth. Fathi-Moghadam & Kouwen (1997) stated that the vegetation density is always a dominant parameter regardless of tree species or foliage shape and distribution. Kouwen & Fathi-Moghadam (2000) related flow resistance to velocity and a species-specific vegetation index ξE, which accounts for the effects of shape, flexibility, and biomass. Järvelä (2004a) concluded that the essential factors in formulating a resistance equation for woody vegetation are density of vegetation and deformation of plants in a flow. He suggested characterization of leafy woody vegetation based on three variables: 1) leaf area index (LAI); 2) a species-specific drag coefficient $C_{d\chi}$; and 3) a vegetation parameter χ, which accounts for the effects of plant deformation in a flow (velocity effect) and is unique for a particular species.

2.1.3 *Turbulent flow field*

Recently, several studies (e.g. Shimizu & Tsujimoto 1994, Tsujimoto et al. 1996, Naot et al. 1996, Nepf 1999, López & García 2001, Stephan & Gutknecht 2002, Järvelä 2005) have focused on velocity distribution and turbulent characteristics of vegetated channels and floodplains. This field of research was founded in the 1970's to investigate the effect of wind on tree stands and canopies; a review of this topic is given by Finnigan (2000). In the 1990's with an increasing interest in river restoration, this research approach was extended to aquatic vegetation with the aim to characterise the vertical velocity profile above submerged plants. With the development of measurement techniques such as Acoustic Doppler Velocimetry (ADV), the spatial and temporal resolution of flow measurements was improved, revealing the turbulence structure for some simplified cases, such as flow around cylindrical obstacles. Most of these studies have been directed towards an adaptation of the logarithmic law of the wall for flow above submerged aquatic vegetation (López & García 2001, Stephan & Gutknecht 2002, Baptist 2005). The differences in the approaches are due to the modifications of the zero-velocity displacement and roughness height (e.g. deflected plant height; see Stephan & Gutknecht 2002 for a review). Another conceptual modelling approach for velocity distribution is based on the assumption that the vertical velocity profiles have a form of a hyperbolic tangent function. Such profiles are characterised by an inflection point (Ghisalberti & Nepf 2002) and can be derived with the help of the mixing layer analogy (Raupach et al. 1996). Using this approach, the location of the inflection point was found to coincide with the top of the bent vegetation in the physical model by Carollo et al. (2002).

Freeman et al. (2000) reported significant influence of the vegetation canopy on the velocity distribution in the wake. The authors observed that shrubs with open areas beneath the primary leaf mass diverted significant amounts of flow beneath the canopy, leading to an accelerated sub-canopy flow and an increase of the bed shear stresses around the plants. Similar velocity profiles have been measured by Boelscher

Copyright © 2006 Taylor & Francis Group plc, London, UK

et al. (2005) in a field study with natural willows. Their study revealed the dependence of velocity profiles on a seasonal and hydrograph time-scale, which had not been taken into account before. Nepf (1999) investigated flow through groups of emergent cylinders and found a direct relation between the turbulent kinetic energy and the vegetative drag. The fraction of mean energy, which was transferred into turbulence, was dependent on the ratio between form and surface drag of the stems. Turbulence intensities increased with sparser element density due to larger wake zones, but decreased with increasing density due to a reduced mean velocity and eddy scale. For submerged conditions, the turbulent length scales can be classified vertically according to the phenomenological concept of Poggi et al. (2004): 1) the lower regions which are dominated by von Karman vortices associated with the flow around the elements; 2) a mixing layer between the topmost region of the vegetation and the outer flow above; and 3) a boundary layer flow considering the whole vegetation as a rough wall with a zero-velocity displacement towards the vegetation. Further studies revealed the importance of coherent vortex structures similar to near-bed sweeps and ejections for the vertical momentum transfer above the plant canopies (Ghisalberti & Nepf 2002, Stephan & Gutknecht 2002). These flow structures are associated with waving motions of flexible plants, the so-called "honami" phenomenon. Honami enhances the vertical momentum transfer and reduces the stresses on the plants (Ikeda & Kanazawa 1996, Ghisalberti & Nepf 2002, Stephan & Gutknecht 2002).

2.1.4 *Spatial variability*

The spatial variability of the velocity and turbulence characteristics in a group array of cylinders was investigated by Lopez & Garcia (1998) and Choi & Kang (2004) on the basis of the Reynolds Averaged Navier Stokes (RANS) equations. However, the flow field within a canopy is highly three-dimensional, and therefore, it is not clear how to address adequately the spatial heterogeneity of the flow. In fact, most applications deal with spatially averaged roughness parameters that cannot be linked explicitly with local flow properties provided by the RANS equations. These conceptual contradictions have been ignored in most studies. Nevertheless, all the above studies have significantly contributed to the understanding of how vegetation influences flow resistance, and they provide the basis for the current standard in modelling flow-vegetation interaction using 1D (e.g. Yoshida & Dittrich 2002), 2D (e.g. Beffa & Connel 2001), and 3D numerical models (e.g. Stoesser et al. 2003). The shortcoming of how to describe the turbulent flow field in complex flow situations has only recently been specifically tackled in environmental hydraulics by using the Double Averaging Methodology (DAM). The majority of DAM related studies have focused on rough-bed flows (e.g. Nikora et al. 2001, 2005b, Aberle & Koll 2004, Campbell et al. 2005). DAM studies related to flow resistance of vegetation have been reported by Lopez & Garcia (1998, 2001), Nepf & Vivoni (2000), and Righetti & Armanini (2002).

2.2 *Flow-vegetation-sediment interaction*

Numerical models for the assessment of morphological development of river reaches have been developed by Tsujimoto (1999) and Baptist (2005). In these models, state of the art approaches for numerical flow simulations, turbulence modelling as well as sediment transport have been combined to simulate morphological development. Dittrich et al. (2005) used a 3D hydrodynamic model to evaluate flow patterns on floodplains and in vegetated areas to identify areas prone to erosion and sedimentation. The results of their numerical studies were used to assess morphological development and to refine flood management strategies at the River Rhine. Successful numerical simulations of the transportation of fine sediments through emergent vegetation have been carried out by Lopez & Garcia (1998) and Choi & Kang (2004) on the basis of experimental data of Tollner et al. (1982). The challenge within such investigations is the adequate modelling of the turbulent flow field, which is needed to estimate reliably suspended sediment transport. The altered turbulent flow field around plants and the reduced bulk flow velocity may result in enhanced deposition of suspended sediments (Fig. 2). However, vegetation may have also a destabilising effect on the sediments due to high local turbulent intensities and vertical velocity components in their wake. In this context, Choi & Kang (2004) concluded that the use of an isotropic turbulence model results in a significant underestimation of suspended sediment load for open-channel flow with emergent vegetation. Furthermore, Elliot (2000) showed that settling of suspended

Figure 2. Sediment deposits after a flood event on a vegetated riverbank and floodplain (photo H.H. Bernhart).

Copyright © 2006 Taylor & Francis Group plc, London, UK

sediment onto vegetation has the potential to additionally increase the rate of removal of sediment from the flow, indicating the complexity of the relevant processes.

Detailed experimental studies of how bed load is transported through vegetation have only recently been carried out by Specht (2002) and Jordanova & James (2003). Specht (2002) investigated in a series of laboratory experiments how vegetation influences bed load transport rates in compact river channels. Based on these experiments he derived a coefficient which can be used with various bed load transport formulae to account for the effect of both symmetrical and asymmetrical bank vegetation. Besides the altered transport rates, Specht (2002) found that vegetation significantly influences the geometry of sand dunes, which became steeper and more regular in length. Jordanova & James (2003) found that bed load rate through emergent stems is closely correlated with excess bed shear stress. In the study, shear stress exerted on the bed was calculated by subtracting the total stem drag from the total force applied by the flow in the flow direction. However, the results of Jordanova & James (2003) cannot be generalized, since they were obtained for only one sediment size, stem diameter, and stem spacing.

The influence of bank vegetation on gravel bed channel pattern has been investigated, e.g. by Ikeda & Izumi (1990) and Millar (2000). Both studies revealed that bank vegetation does represent an important and quantifiable control on alluvial river patterns. Similar results have been obtained by Gran & Paola (2001) and Coulthard (2005), focusing on the influence of riparian vegetation on braided stream patterns and dynamics. These laboratory studies revealed that vegetation can substantially alter channel geometry and flow characteristics in braided rivers by stabilizing the banks, constraining channel migration, and allowing deeper and narrower channels to develop (Gran & Paola 2001). Furthermore, Coulthard (2005) found that relatively sparse levels of vegetation can alter flow dynamics and cause the deposition of islands in the lee. When vegetation starts to grow on such islands, they can then develop not only downstream but also in upstream and transverse directions (Tsujimoto et al. 1998).

Huang & Nanson (1997) performed a field study in small streams and showed that it is necessary to distinguish between bank vegetation and vegetation growing on the channel bed. They found that dense bank vegetation results in narrower channels whereas channel vegetation increases flow resistance, causes channel widening and hence reduces flow velocity but not necessarily flow depth. Jeffries et al. (2003) investigated in a field study the influence of large woody debris on patterns of sediment deposition within a small forest floodplain and found that patterns of sediment deposition were both greater and more variable than for non-forested floodplains. Boelscher et al. (2005) found in their field study strong local scouring around tree stems, often enhanced by clogging of floating debris and increased sub-canopy flow velocities. Toda et al. (2005) used field observations and numerical modelling studies to determine the effects of the flood flow on the riparian vegetation and the soil environments of floodplains in a gravel-bed river. They found that the amount of particulate nutrients on the floodplain increased during small floods, whereas it decreased during large floods. The latter effect was explained by the removal of fine sands and hence nutrients from floodplains during large flood events.

3 DISCUSSION AND CONCLUSION

The literature review revealed that the effect of the natural characteristics of vegetation on flow resistance and sediment dynamics have not been adequately addressed in hydraulic design and modelling. This is due to the complexity of the flow as it is affected by several interconnected factors such as topography, relative submergence (flow through and over vegetation), vegetation characteristics (e.g. coverage, patchiness), and plant characteristics (e.g. deformation of plants with increasing velocity). Yet, it is not fully clear at which spatial and temporal scales the key flow processes should be investigated. On the other hand, it appears that the available knowledge of the key processes is not fully exploited in current modelling and management approaches because of a lack of appropriate feedback mechanisms between model developers, river scientists, and managers.

It is obvious that solving a local flow problem requires a different approach compared to the hydraulic analysis of a large catchment. In addition, the scale of the analysis is dependent on the nature of the problem. For example, estimation of water stage can be based often on cross-section and reach averaged variables. However, for predicting erosion and sediment transport such averaging may result in significant errors, and a more suitable solution would probably require a 2/3D analysis. To quantify flow-vegetation interaction, a formula or model that will relate measurable characteristics of vegetation to flow properties is desirable. Theoretical (or semi-empirical) approaches should provide a better general understanding of the variation in flow processes. From a practical point of view, a suitable approach should be transparent and straightforward enough to be applied by a practising engineer. However, no approach can deliver reliable results if the physical reality is excessively simplified or if the source data are of low quality. Gathering field data for natural vegetation is far more complicated and time-consuming than describing the properties of simulated vegetation in laboratory conditions. Therefore, a preferable approach uses clearly

Figure 3. Bending and streamlining of vegetation is a critical process, which must be taken into account in developing flow resistance models and in designing scale model experiments; natural willows (a) in comparison to rigid cylinders (b) (photos J. Järvelä).

defined variables, which can be easily and objectively determined. In contrast, many of the hydraulic design methods used currently rely on the professional judgment of an experienced engineer, e.g. in selecting a roughness coefficient.

Although simulation of vegetation under laboratory conditions seems to be preferable, there is still a lack of appropriate methods to incorporate the effect of natural vegetation in hydraulic models. Several methods or formulas have been developed to determine bulk (averaged) flow properties, but most are based on the simulation of vegetation by artificial rigid cylinders. However, in reality natural vegetation exhibits a wide variety of forms and flexibility (Fig. 3). Furthermore, if such cylinders would be upscaled to the nature, they typically would be unrealistically large in diameter. The effect of scale on experimental design and data interpretation needs to be elaborated. Recent experimental investigations with natural plants have provided new insight into the identification of important mechanisms with which vegetation react to flow stresses. These mechanisms comprise 1) the bending of the main stem and branch structure in flow direction; 2) the width and height compression of the leaf mass; and 3) the dynamic, waving motions of the plant induced by the vortex shedding in the wake (Schnauder 2004). This knowledge is important in order to quantify drag exerted by plants (e.g. Armanini et al. 2005, Wilson et al. 2005) and hence for the quantification of flow resistance. As a next step, the research should focus on detailed investigation of the bulk dependencies and the turbulent flow field.

The interaction between the turbulent flow field and vegetation has been investigated mainly with respect to the time averaged velocity profile within and above vegetated areas. However, the flow field within the canopy is highly three-dimensional, and therefore, it is not clear how to adequately address spatial flow heterogeneity. Herein, a promising direction is the DAM approach. Nikora et al. (2005a) showed that this approach is a useful tool for developing numerical models, designing laboratory, field, and numerical experiments, and for data analysis and interpretation. E.g., by adopting the DAM approach, similarity hypotheses and two-dimensional assumptions can be developed and applied even for the flow region in the canopy, which is impossible using the conventional time-averaged variables. Thus, this methodology may significantly improve research tools for studying a wide range of flow-vegetation-biota interaction phenomena (Nikora et al. 2005b).

Although the spatial pattern of the vegetation and plant characteristics significantly influence sediment dynamics, numerical and experimental studies have been based on idealized conditions and are thus far from being generalized for practical purposes. For example, most of the numerical approaches are based on k-ε models, which assume isotropic turbulence, though it is not clear if such turbulence models allow for adequate modelling of turbulence in vegetated zones (Choi & Kang 2004, Baptist 2005). Furthermore, turbulent and form induced stresses significantly influence the flow forces acting on the bed and hence bed shear stress (Nikora et al. 2005a). Bed shear stress, on the other hand, is the key parameter for modelling incipient motion and bed load transport. However, in complex geometries it is not straightforward to determine bed shear stress unambiguously (Rowinski et al. 2005, Nikora et al. 2005a). This is only one of the problems in modelling geomorphologic development. The amount of transported sediment depends not only on flow but as well on sediment characteristics. There is a wide range of empirically derived sediment transport formulae available which yield, for the same hydraulic conditions, differences of up to several hundred percent when estimating bed load transport (Specht 2002). The reason for these differences is associated with experimental boundary conditions, flow forces, grain size distribution, sediment shape, density, etc. So far it is not possible to adequately model movement of natural shaped particles to simulate morphological development. There

Copyright © 2006 Taylor & Francis Group plc, London, UK

remains an abundance of challenges regarding the interaction flow-vegetation-sediment. One challenging question is to what extent turbulence is modulated by moving bed material such as gravel particles (see e.g. Campbell et al. 2005) and dunes (e.g. Maddux et al. 2003). Such knowledge is the prerequisite to relate sediment dynamics to both vegetation patterns and turbulence characteristics, and hence to establish reliable models for morphological development.

Of concern is the fact that the use of some of the hydraulic design methods that were originally derived based on idealised or site-specific conditions, has been extended far beyond the limits of their applicability in current models. For example, approaches suitable for only large relative submergence have been applied to shallow flows because of a lack of information and even ignorance. The shortcomings follow from the very complexity of vegetated flow. The deficiencies in our knowledge should be tackled with novel, scientifically based approaches – not with repetition of conventional ones. Simplification is indeed needed and justified, but first we should get a good understanding what we are simplifying. Otherwise, we face the risk that we focus on modelling and calibrating something irrelevant. Unfortunately, such cases are not rare in the literature. More specifically, the domination of laboratory studies that use simple artificial roughness has not allowed for the identification and assessment of all the important processes and mechanisms that control flow-vegetation-sediment interaction. Such experiments were very important at the beginning of the new field of research, but today there is not much idea to repeat these experiments without questioning the original approaches. The use of new, sophisticated gadgets such as ADVs, LDVs and PIVs does not straightforwardly give reason for the repetition, if real advances in our understanding of the flow processes are to be made.

To conclude, the key to the development of sustainable river management strategies is the proper identification and assessment of physical processes, which dominate the complex interaction between water flow, vegetation, and sediment fluxes. These challenging tasks can only be tackled successfully by a combination of experimental and numerical studies together with theoretical advances in hydrodynamics. Specifically designed laboratory experiments are needed to provide high-quality data for the analytical investigation of flow and sediment transport dynamics. Results of these studies can be used then to further develop numerical models. These models will, once successfully validated with the help of laboratory experiments, reveal the issues, which need to be investigated in more detail in the field and laboratory. Comparative field studies are necessary for the quality control and evaluation of the numerical simulations and laboratory data. Such an integrated research strategy will systematically advance our knowledge in environmental hydraulics and stimulate the exchange between science and practitioners.

Multi-purpose shallow reservoir: Synergies between ecology and energy production

P. Heller, E. Bollaert & A.J. Schleiss

M. Pellaud & R. Schlaepfer
Laboratory of ecology management, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

ABSTRACT: During the last century, most European river networks have been trained, mostly for energy production, flood prevention, and land use. Today, these rivers cope with severe deficiencies. Partially due to climate changes, flood safety becomes an increasing issue. Artificial morphologies and regulated hydraulic regimes disconnected rivers from their floodplain and often strongly disturb river ecology. Also, due to training works, the river's potential for leisure activities is often reduced. Nevertheless, these rivers still offer an important potential for recovery of their initial characteristics. They remain essential for irrigation, drinking water or navigation, as well as energy production. It is possible to reduce such deficiencies and to develop river potential with a multipurpose project. Such a project may become very complex and defining the most feasible solution (for both design and management) requires a new and original approach. A qualitative study of the system highlighting the project's key variables was linked to a quantitative study providing specific answers regarding the project's dimension and management variables. Trough the optimization of the design and management of a shallow reservoir, it was found that returning to a near-natural hydraulic regime for the downstream part of the river was possible without losing over 10% of potential energy production. Ecological aspects of the reservoir have been optimized directly with a specific simulation module. Besides, the reservoir's stable water levels during the summer season allowed development of social activities. This paper provides an integrative approach to optimize energy production while protecting ecological components of a river network.

1 INTRODUCTION

1.1 *Complex problem*

The demographic pressures of last centuries (i.e. population growth, land use) dramatically reduced the space allocated to rivers in industrialized countries. Rivers have been canalized and their flow regulated in order to promote navigation, energy production and flood protection. The ecological processes once associated to the rivers are strongly disturbed and various negative effects on the environment are observed. A particularly brutal impact on the system is caused by hydropeaking. Hydropeaking is defined by the sudden water discharges of power plants during peak energy production and affect the hydraulic, sediment and thermal regimes of rivers (Meile et al. 2005 and Meier 2002).

Nevertheless, rivers still offer great opportunities for development. The growth of electricity demand in addition to the willingness of reducing CO2 emissions and the social rejection of nuclear power stimulates use of hydropower. In parallel, restoration of aquatic biotopes has a strong legal leverage and cannot be overlooked in a river development project.

To guarantee acceptability, new projects have to consider these different aspects in an integrated manner. Hence, satisfying solutions become much more complicated. To agree on a reasonable compromise, many participative methods have been developed (Leach et al. 2001). Stakeholders are included in the projects from its very beginning and in order to satisfy all parties, projects have to become multi-purposed. Models are good candidate to deal with the numerous interactive effects of these complex systems. According to Coyle (2000), a complex system has to be analyzed with a qualitative model followed by a quantitative study. System dynamic is defined as "a complex system analysis method done by a causal analysis, followed by a dynamic transcription, completed by a model and processed with a computer simulation" (EuroDicauTom 1982). A qualitative study is performed with the help of a generic network method (Gomez et al. 1995).

1.2 *Results of qualitative study*

According to the nature of the problem, a preliminary qualitative study has been performed to understand the complexity of the problem (Heller et al. 2005). The study was divided into hydraulic, energetic, financial, socio-economic, underground water and ecological topics. The qualitative results highlight three groups of variables. The first one regroups the size variables which define the construction and the general aspect of the project (i.e. reservoir surface, dam elevation, project configuration). The second group contains the reservoir's operation management (focusing mainly on the downstream flow characteristics) and the third group the project's indicators. The most important indicators are the ecological improvement, the financial viability and the leisure development. This qualitative study also permits to compare the different purposes. The global model is then built on these results.

1.3 *Quantitative expectation and Pareto results*

Based on measured values on the upper Swiss Rhône River, the global model provides quantitative results for costs, energy production and its repartition during the year, flow mitigation and its consequences on the ecological aspects. The model considers the reservoir itself as well as the downstream river.

Results are expressed with the Pareto dominance concept. This concept allows generating many solutions of interest without determining any set of weights (Goldberg 1989).

This project focuses on run-of-river power plants with a shallow reservoir for hydropeaking mitigation and energy production. Such a project is proposed on the strongly canalized upper Rhône River in Switzerland (Bollaert et al. 2000). Due to several retention reservoirs upstream, the river flow regime is considerably influenced by daily and seasonally hydropeaking. As the catchments area contains many glaciers, the water is highly laden with fine sediments (glacial floor). Figure 1 represents such a reservoir in a conceptual manner and Figure 2 a candidate site.

This paper focuses on the relations between energy production and ecological integrity for both the downstream river and the reservoir.

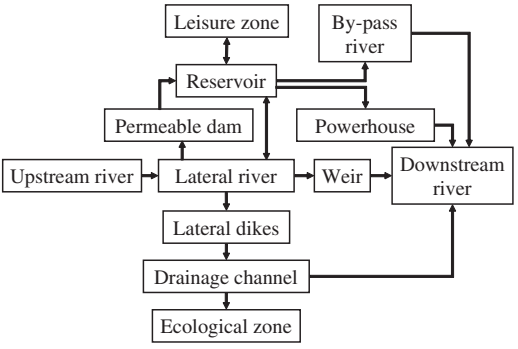

Figure 1. Concept of multi-purpose reservoir.

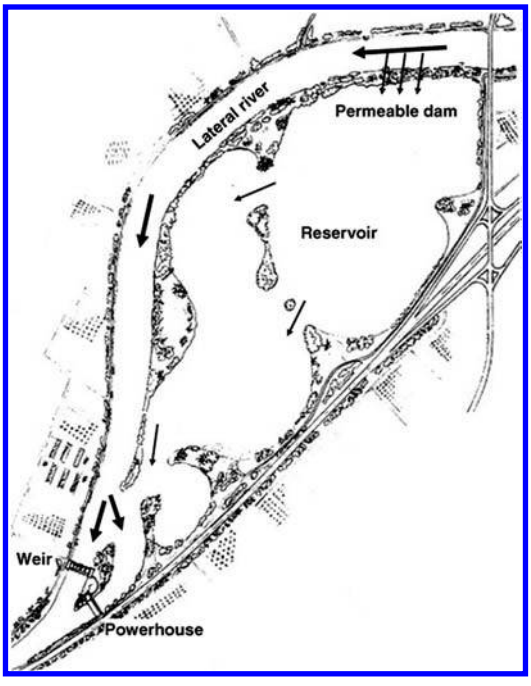

Figure 2. Multi-purpose reservoir potential site (Bollaert et al. 2000).

2 GLOBAL MODEL

2.1 *Global flow-chart*

Results of the qualitative study highlight the necessity of a quantitative analysis. This analysis has to consider the various aspects of the problem (multi-purpose) as well as to permit a sound interpretation of the results (multi-criteria). This quantitative study is performed with a global flow-chart based on the Queuing Multi-Objective Optimizer (QMOO). This optimization tool is presented at §2.2.

Based on the results of the qualitative study, the size variables of the project have to be independent from the management variables. According to an hourly simulation step, a whole year simulation produces 8760 management variables (the downstream flow for each hour during a year). Added to the 20 size variables, this number of variables would excess the capacity of any optimizer. This clearly points out the need for separation of management and size optimizations in

Copyright © 2006 Taylor & Francis Group plc, London, UK

two successive steps. The management optimization is presented further on (§3).

The global flow-chart starts with an arbitrary vector for the internal variables (project size and global management constraints). The external variables represent uncontrollable data (upstream flow, external temperature, upstream water temperature, substrate,…). This vector is dependant from the site characteristics.

According to the data (internal and external) the second step performs the ordinary management optimization. Since this reservoir is also configured to reduce a flood peak, an extraordinary flood optimization tool is provided for extreme flows.

The third step is composed by the different simulation tools. The first one simulates the hydraulic behavior of the project. Based on the hydraulic results, the other tools are run to predict the water temperature in and downstream of the reservoir as well as energy production. In a third round, the ecological, socio-economical and financial simulations are performed. These different tools constitute the multi-objective approach of the problem.

The fourth step aggregates the simulation results into objective functions. Since the QMOO optimizers as well as the usual three-dimensional representation are able to deal with three different objectives, the aggregation must reduce the result into three indicators. Energy and economic aspects of the multi-purpose reservoir can be reduced to a financial assessment. Social and ecological aspects are quantified with different units and therefore constitute the two other axes.

The fifth step contains the global optimizer and produces Pareto solutions. To generate them, the optimizer changes the internal variables vector. Figure 3 illustrates the global flow-chart with its five steps.

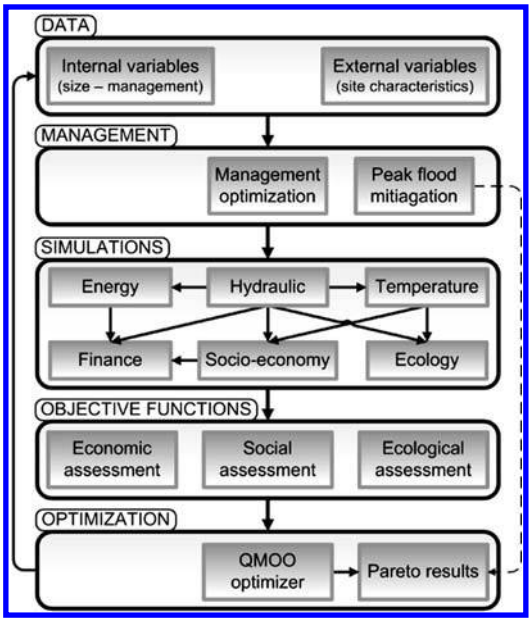

Figure 3. Global flow-chart with its 5 steps.

2.2 *Optimization tool QMOO*

The optimization tool QMOO, namely 'Queuing Multi-Objective Optimizer', has been developed at the EPFL in the Laboratory for Industrial Energy Systems (Leyland 2002). It is based on an evolutionary algorithm. Such algorithms are particularly suited to conflicting multi-objective optimizations (Prasad et al. 2004). Since they are also able to deal with non-linear, discontinuous, disjoint and multi-modal problem (Sharif et al. 2000), they are well adapted for the resolution of complex problems.

The optimizer first generates a random population of solutions. Each member of that population represents an internal variables vector. Performance is then computed for each vector (i.e. its related objective functions vector). The optimizer uses then the performance of the current population to generate, by mixture, the next population. The optimizer stops after a defined number of populations or when the performance seems to be optimal. To reduce the computation time and to produce separate local optima simultaneously, QMOO generates clusters and then focuses its search of solutions. It nevertheless conserves the 'tail regions' of population to explore the full extent of the problem's optimal regions.

Conserving the best solutions produces the optimum Pareto solutions. A Pareto solution is defined as a solution which improves at least one performance dimension without deteriorating any others. This kind of solutions allows generating the best physical solutions independently from any weighted method. It clearly distinguishes a political choice for one solution from the scientific generation of the best solutions.

3 MANAGEMENT OPTIMIZATION MODULE

3.1 *Objective function*

The management of the reservoir is based on an hourly step for a whole year of simulation. It is transformed into a system of equations. This system is written in AMPL code (Fourrer et al. 2002) and solved with the Cplex solver. It is solved with a seven days prediction for a validity of only two days. It is composed of an objective function, variables, data and constraints.

The objective function maximizes, for every hour, the reservoir filling rate, as written in Equation 1.

$$Max\left(\sum_{t} Accumulation(t)\right), t \in [1;168], t \in \mathrm{N} \qquad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

According to an increasing derivative of the function "height-volume", this objective function minimizes, for a required volume, the variations of the reservoir level. For an accepted downstream water level variation (hydropeaking tolerance), it minimizes the reservoir hydropeaking. This function also implicitly maximizes the energy production (useful head).

The variables are composed by one vector of 8760 positions, i.e. the downstream flow for each hour. This vector constitutes the solution for the management.

The data contain the initial reservoir level and the upstream flow. According to the accepted forecast, the upstream vector is composed by 168 values.

The system constraints are the common physical constraints for such a system, i.e. a maximal reservoir volume (Eq. 2), a minimal reservoir volumes (Eq. 3) and positive downstream flows (Eq. 4).

$$Accumulation(t) \leq \text{Volume_max}, \forall t \quad (2)$$

$$Accumulation(t) \geq 0, \forall t \quad (3)$$

$$Q_{downstream}(t) \geq 0, \forall t \quad (4)$$

They also contain two parameters for the management. The first parameter constraints the rate of downstream water level variation (mathematically the derivative of the level) and the second constraints the maximum variation around the average level. Typical values for these two constraints are 8 cm/h of variation limited by deviations from the mean of ± 15 cm. These constraints are defined for both winter and summer seasons with different values. The seasons are defined according to the average week of forecasted flows. For the transition season (spring and autumn), transition values are computed linearly to the averaged week flow. These four constraints (two for the winter season and two for the summer season) clearly define the major objective of the reservoir, which is to limit the artificial hydropeaking towards downstream. Two additional constraints (one winter and one summer value) limit also the reservoir maximum variation. They are comprised between 0.5 m and 4.5 m, respectively for the summer and winter value. In case of inconsistent mathematical system, the downstream limitations are slightly relaxed by steps of 5%.

The system is solved consecutively 180 times in order to generate 8760 downstream flows, which compose the global year management of the reservoir. This management is called "ordinary management" and does not take care of peak flood events. The splitting of the management optimization from the size optimization corresponds to a reasonable process of optimization and allows reducing, for QMOO, the number of management variables from 8760 to 6 positions.

4 ECOLOGICAL MODEL

4.1 *System overview*

The hydrosystem of interest is comprised of (1) the water detention basin and (2) the downstream portion of the river (Figure 2). The design and management of the basin (point element, scale in the order of a square kilometer) is to influence the whole downstream hydrosystem (scale in the order of hundreds of square kilometers). The scale differences (grain) require different methods to develop an adequate protocol for the assessment of the ecological integrity of each of the two elements. One of the reasons that models were developed was to simplify complex systems and to identify key variables affecting the behavior of such a system. A tradeoff was loss of information on the operating processes with hidden influences (i.e. long term consequences, 'cocktail' effects …). At the resolution of the water detention basin, and based on available knowledge of the ecological processes and parameters at stake, a theoretical ecological model of the basin has been developed with an expert knowledge-based approach to reach ecological integrity. It has been assumed that the current knowledge of artificial ponds/lake engineering would yield better results and convey less risk than following design and management environmental guidelines issued by a model. For the downstream section (i.e. downstream Rhône River), the scale, length of processes and complexity require a model-based approach in order to asses its ecological integrity.

4.2 *Ecological considerations – multi-purpose basin*

The purpose of the water detention basin is to buffer sudden water level variations of the river. The discharge variations will be absorbed by the basin, meaning that the basin's water level is to vary considerably. Within this multi-objective basin, a surface is to be allocated for an 'ecological zone'. These zones are to be protected from anthropologic disturbances and the ecotonal zone (aquatic – terrestrial interface) is to be enlarged and preserved from the harsh disturbances caused by sudden and frequent water variations. To do so, a protective submersible dike is to be engineered (Figure 4). The periodic filling of the ecotonal shallow

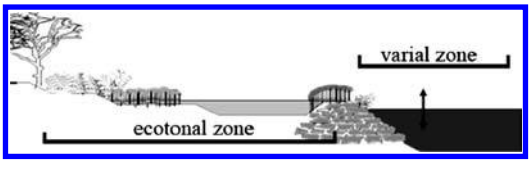

Figure 4. Ecotonal stabilization of the banks for the multi-purpose basin.

Copyright © 2006 Taylor & Francis Group plc, London, UK

zone (<0.5 m) takes place when the basin water level is high, and the water remains trapped when the water basin level falls, ensuring permanent submersion.

Development of vegetation (e.g. reeds, various helophytes) is expected and is necessary to provide shelter and trophic resources for associated fauna.

4.3 *Connection to the downstream channel*

Longitudinal connectivity has to be maintained to perturb as little as possible the migrating patterns of fish and macro-invertebrate populations. Various kinds of artificial-river like bypasses are indicated (Figure 5). Fish-ladder structures alone should be avoided since they are often species-specific and do not work well for aquatic invertebrates.

Particularities of the shown river are (1) the 'natural' segment, and (2) the basin ladder. The natural segment mimics a 'natural' sequence of riffles and pools with vegetated banks of a rather smooth gradient. The basin ladder offers a second chance for migrating fish who 'missed' the river entrance and are blocked by the turbines. The basin ladder plays an important role reducing delays which may derogate fish reproduction (Amoros et al. 1993).

4.4 *Ecological considerations – downstream river*

The downstream part of the river plays a role in the basin management. Literature and expert-knowledge jointly recommend that, under normal conditions, daily fluctuations caused by water restitution should not exceed +/−15 cm with a variation rate inferior to 10 cm·h^{-1} (Valentin 1995; Poff et al. 1997). Moreover, river bed maintenance is to be assured by the periodic transit of morphogenic floods through the basin (Richter et al. 2000; Murle et al. 2003). The ecological integrity of the downstream river is assessed by the aggregation of three modules, (1) a zoobenthos module (2) a fish module and (3) a vegetation module.

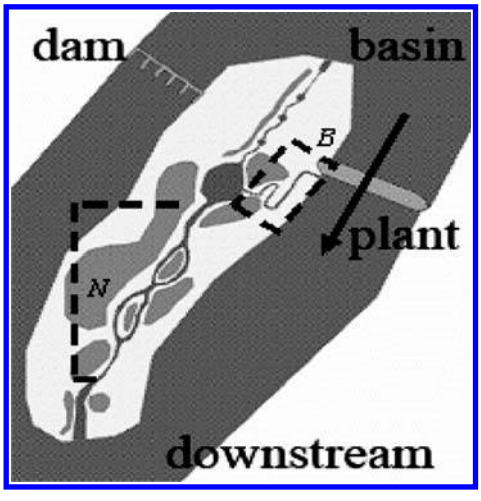

Figure 5. Representation of an artificial river ensuring longitudinal connectivity. (N) represents a 'nature – like' suite of riffles and pools (B) a basin ladder.

4.4.1 *Zoobenthos module*

This module predicts zoobenthos richness on homogenous reaches and is based on (1) river-specific taxonomic richness surveys, (2) associated point physical variables, and (3) hydropeaking effect. Radial Basis Functions (RBF) (Dowla et al. 1995; Lek et al. 1999; Obach et al. 2001; Zhang et al. 2005) are used to model a Preliminary Standardized Richness Index (PSRI). PSRI predicts reach richness reflecting actual hydropeaking conditions (variation rates and variation length). A hydropeaking coefficient zeroed on actual hydropeaking conditions is determined using fuzzy logic (Zadeh 1995; Silvert 2000; Adriaenssens et al. 2004). The hybridization of the PSRI with the fuzzy hydropeaking coefficient yields the predicted zoobenthos richness by reach (Figure 6).

4.4.2 *Fish module*

The fish module predicts the results of an instream habitat model such as PHABSIM (Bovee 1982) or EVHA (Ginot 1998) for four fish habitat guilds following the methodology by Lamouroux (Lamouroux et al. 2002). The habitat indices for each fish habitat guild are subsequently adjusted by independent fuzzy coefficients simulating (1) hydropeaking effects and (2) thermal alteration effects (Valentin 1995). The outputs are guild-specific habitat convenience indices that can be multiplied by reach surface to yield weighted usable surfaces per guild.

4.4.3 *Vegetation module*

The vegetation module is currently under development and will consist in a system of differential equations

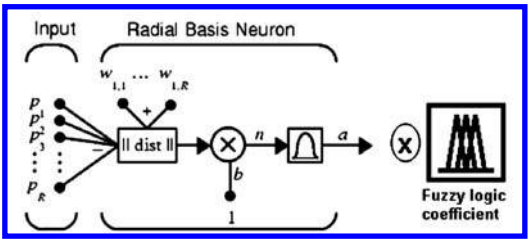

Figure 6. Schematic model representation of the zoobenthos module (modified from The MathWorks Neural Network Toolbox (2004)). Inputs are river-specific taxonomic richness surveys associated with point physical variables; the radial basis neuron yields the PSRI; the fuzzy logic coefficient simulates the hydropeaking effect; the output is a predicted taxonomic richness per reach.

Copyright © 2006 Taylor & Francis Group plc, London, UK

aiming at predicting (1) submerged aquatic vegetation biomass (2) habitat convenience index for helophytes (Wade et al. 2001).

4.4.4 *Aggregation process*

By assessing a weight to each module (i.e. zoobenthos, fish and aquatic vegetation) based on case-specific ecological objectives, actors contribute directly to the aggregation process. A single grade will represent the ecological integrity of the downstream part of the river. Stakeholders are provided with a simulation tool set on sound scientific bases linking a design or management action to an ecological consequence predicted for the downstream section of the river.

5 UPPER SWISS RHONE RIVER STUDY CASE

5.1 *Current state*

Sub-alpine hydrosystems' ecological integrity suffers from various anthropologic actions such as canalization, hydrologic alteration, landscape fragmentation and others. These actions were meant to facilitate man's life around fluvial hydrosystems (i.e. flood protection, navigation, agriculture) and to benefit from the considerable energetic potential of sub-alpine rivers. The resulting pattern is a straight, monotonous and embanked river apparently totally disconnected from its floodplain.

After three decades of large dams' construction, it also suffers from an acute artificial hydropeaking. This hydropeaking transfers significant water flows from summer season to winter season. Reducing the summer morphogenic flood, it generates daily peak flows. Historically the Rhône winter flow was very stabile with an average value of about 50 m^3/s. Nowadays the winter flow varies from 35 m^3/s during the week-end to more than 160 m^3/s during the working days. This represents a water level variation of more than 1 m, which is produced on a very short time (less than one hour).

The dam hydropeaking also generates a thermal transfer from summer to winter season. Consequently, winter water is about one degree warmer than historically and summer season one degree colder (Meier 2002).

These three modifications (geographical uniform flow, hydropeaking and thermal disturbances) have strong effects on the river ecology. It is currently in a very poor state.

5.2 *Smooth hydropeaking flows*

The major reason of such a multi-purpose reservoir is the mitigation of the downstream river hydropeaking. Management optimization based on the year 2003 with following maximal values (Table 1), produces a strong improvement of the downstream flow (Figure 7).

Table 1. Key values of the management optimization.

Variables	Unit	Value
Reservoir surface	km^2	1
Dam elevation	m	8.68
Winter downstream water level speed variation	cm/h	8
Winter downstream water level variation	cm	30
Winter reservoir level variation	m	4.5
Summer downstream water level speed variation	cm/h	15
Summer downstream water level variation	cm	50
Summer reservoir level variation	m	0.8

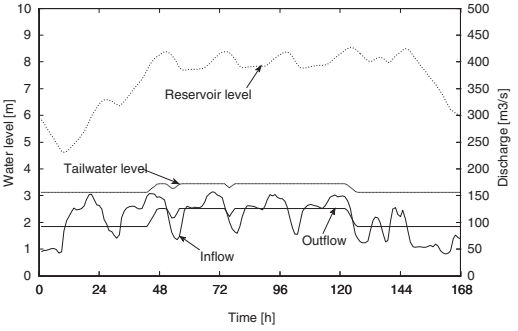

Figure 7. Typical winter week with an improved downstream flow.

The downstream flow improvement is well highlighted with the hydropeaking indicator. This indicator is based on a yearly cumulative flow variation curve. The flow variation, on the horizontal axis, is expressed in $m^3/s/min$. The vertical axis expresses the probability of non-exceeded variation. Since the flow variations are accepted as a major stress on the aquatic ecosystem, this indicator represents the human influences on the hydraulic regime and its effects. The current state can then be compared to a historical state. The same indicator also integrates hydraulic regime improvements of the reservoir. The area between the curves aggregates this improvement into one unique value. Figure 8 illustrates the result.

According to this indicator and to a reduction of 85% of the hydraulic variation stress, it can be accepted that such a reservoir reproduces a near-natural flow.

5.3 *Energy production*

For this multi-purpose reservoir, energy production is seen as an opportunity and not a major objective. Real energy production is always compared to the maximum (physically) possible energy production with a run-of river dam, i.e. the management with a constant reservoir water level. Summarized for the whole year, optimized management produces about 90% of

Copyright © 2006 Taylor & Francis Group plc, London, UK

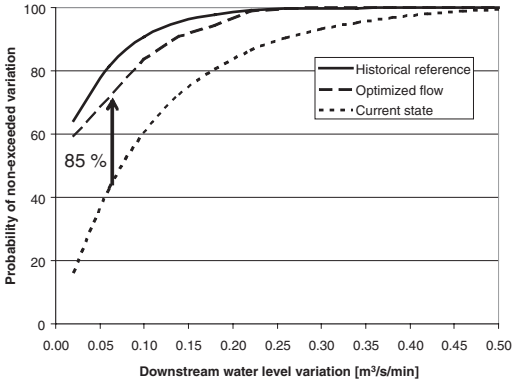

Figure 8. Hydropeaking indicator and reservoir improvement.

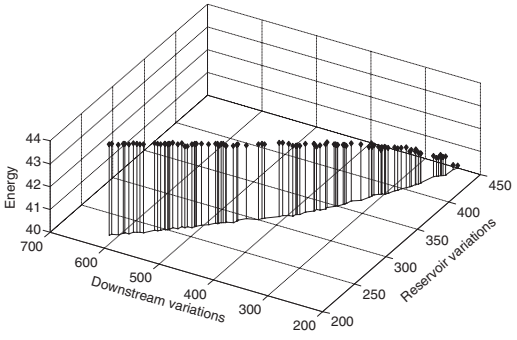

Figure 9. Pareto optimization with energy production (GWh/year), downstream variations (m^3/s/min/year) and reservoir variations (m/an). Z axis starts at 40 GWh/year.

the maximum possible energy. This loss of 10% is principally the consequence of a current deep flow during the winter week-end (Figure 7). To respect the maximum flow variation constraints, the reservoir greatly supports the minimum flow. Therefore it requires over one day to be filled again. During the much more unstable summer flows (historically observed), the reservoir conserves its maximum level nearly permanently (variations less than 30 cm).

5.4 *Pareto results*

The two previous results (hydropeaking and energy) can be summarized with a Pareto illustration. The well-shaped form of the curve obtained from the computations strengthens the *a priori* choice of a Pareto representation.

Figure 9 illustrates the three relations between the reservoir level variations (expressed in m/year), the downstream water level variation (in m^3/s/min/year) and the energy production (in GWh/year).

	Actual	R3	R3 + Basin
Discharge	Branson 2002	Branson 2002	from hydraulic model
Bed width	Actual (50 m)	x 1.5 (75 m)	x 1.5 (75 m)
Bank slopes	Actual (1:2.2 / 1:2.5)	Smooth (1:6)	Smooth (1:6)
Granulometry	d50*=0.1 m	d50=0.07 m	d50=0.07 m
Water temperatures	Branson 2002	Branson 2002	from thermal model

Figure 10. General characteristics used for the three scenarios – Branson stands for discharge values at the gauging station.

Figure 9 underlines a constantly decreasing relation between energy production and reservoir fluctuations. This corresponds, with the equation of the hydropower (Eq. 5), to the relation between the head and the power

$$P = \rho * g * h * Q \tag{5}$$

where ρ = water density, g = normal acceleration, h = water head and Q = water flow. The same figure (Figure 9), on the horizontal plan, highlights another constantly decreasing relation between the downstream and the reservoir water level fluctuations. Following the continuity equation, this result clearly illustrates the antagonistic purposes between reservoir ecological preservation and downstream restoration.

Based on two continuous equations, this optimization presents relative continuous results. The links between the hydraulic aspects and the ecological consequences is the purpose of the next paragraph. Directly related to the final impacts, the hydraulic improvements can generate less continuous results.

5.5 *Aquatic ecological improvements*

In the scope of the current and projected states of the Rhône River, three scenarios were retained for a numerical application of the zoobenthos and fish modules: (1) The Swiss Upper Rhône in its actual configuration, (2) A hypothetic Swiss Upper Rhône River after a third correction (R3) (Canton du Valais, 2006) and (3) a hypothetic Swiss Upper Rhône River after its third correction and with a multi-purpose basin as previously described (Figure 10).

The zoobenthos richness (Figure 11) was predicted as the lowest in the actual configuration of the river and showed to increase subsequently in the R3 configuration and even more in the R3 + Basin configuration. The predicted increase of taxonomic richness is probably due to the river widening (causing a decrease in flow velocity and depth). The subsequent richness increase observed when shifting from the R3 to

Copyright © 2006 Taylor & Francis Group plc, London, UK

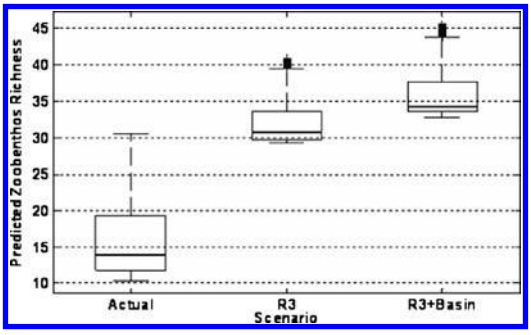

Figure 11. Zoobenthos predictions for the three scenarios.

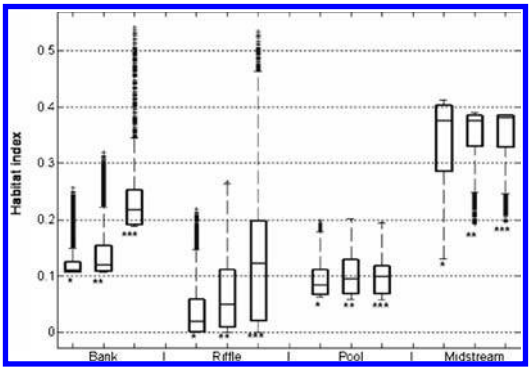

Figure 12. Predicted habitat index for each fish habitat guild (Bank – Riffle – Pool – Midstream) in actual (*), R3(**) and R3 + Basin (***) scenarios.

the R3 + Basin scenario reflects the buffering of the hydropeaking effect in this type of configuration.

Bank habitat guild as well as *Riffle* habitat guild seemed to benefit the most when shifting from the actual scenario to R3 and R3 + Basin (Figure 12). The *Pool* and *Midstream* habitat guilds seemed less affected by a decrease in hydropeaking. Shallow zones as well as riffle zones are most exposed when water fluctuates and should benefit the most when hydropeaking is buffered.

6 CONCLUSION AND PERSPECTIVES

'All models are wrong but some are useful' (Box)

A qualitative approach is required to understand the complexity of a multipurpose project. Qualitative results allow defining rules of design and management for a quantitative model. The purpose of the here presented model is to provide sound scientific bases for an optimized multipurpose management and design of a run-of-river retention basin by integrating social, economic and ecologic aspects. This paper focuses on hydraulics, energy production and ecology.

Establishment of the model's general flow-chart (Figure 3) clearly distinguishes design optimization from management optimization. The formal is based on an evolutionary algorithm. The latter is based on a linear optimization method. The results (Figure 9) permit to separate the scientific aspects (generation of Pareto optimal solutions) from the political aspects (evaluation of weighted criteria to choose of a unique solution). The presented simulation results quantify the predicted improvements of the Rhône River.

The hydraulic model highlights the general improvement of the downstream hydraulic regime. Hence, a near-natural regime may be expected. The energetic model underlines an acceptable loss of energy (about 10% of the theoretical maximal energy production) required for the hydraulic regime restoration. The zoobenthos and fish modules ecologically illustrate the hydraulic regime improvements (Figures 11 and 12). These two modules are the first steps towards a final ecological tool already showing promising results. Consequent tuning and training of the ecological model is still needed before its application is undertaken. However the integration of three different models into a global structure has set the framework for a truly transdisciplinary and innovative approach.

Optimizing the flow pattern in culverts for small upstream migrating fish using a numerical 3D Code

R. Feurich
Institute of Hydraulic Research, University of Innsbruck, Austria

J. Boubée
National Institute of Water & Atmospheric Research Ltd., Hamilton, New Zealand

ABSTRACT: After improving passage for upstream migrating fish in a culvert on Cardinia Creek, Australia, field trials were conducted to test the effectiveness of the modifications. These included velocity measurements, catch and release experiments with fish, electrofishing, and numerical simulations of flow patterns through the culvert. Results indicated that the use of spoiler baffles facilitated the upstream passage of fish, and that numerical simulation was an appropriate tool to predict flow patterns in modified culverts, and could potentially be used to advance the design of spoiler baffle arrays.

1 INTRODUCTION

To complete their life cycle, diadromous freshwater fish need to have free access to and from the sea. These migratory fish are often blocked by natural and anthropogenic instream structures such waterfalls, weirs and overhanging road culverts, with large numbers found congregating below such barriers (Thorncraft & Harris 1996). High mortality from predation, competition, and disease can occur as a result, and some populations may become locally extinct.

In 1980, the Dandenong Valley Authority, Melbourne, Australia, constructed a drop structure on Cardinia Creek at the end of Thompson Road to stabilise a 6.2 m high erosion head. A flood retention basin was formed behind the structure, with low flows diverted into a 42 m long, 1.35 m diameter ARMCO culvert at a slope of 1.19%. From there, flows passed down a rock-lined galvanised chute at 6.7% slope before rejoining the original creek channel. Flood flows were directed over a concrete spillway into the original creek channel.

A total of 15 indigenous fish species are recorded in the Cardinia Creek catchment. Nine of these fish are diadromous, with many returning to freshwater as juveniles. Fish distribution studies by Close et al. (2001), and McGuckin (2001) concluded that the combination of the steep, rock-lined chute and the ARMCO culvert limited fish passage at the Thompson Road drop structure. As the swimming ability of fish is related to their length (Boubée et al. 1999), ensuring upstream passage at potential barriers requires the installation of facilities that cater for the smallest fish species that migrate at that site.

Fish distribution records for Cardinia Creek indicate that the common galaxias (*Galaxias maculatus*) is the dominant species in the lower reaches, particularly during summer. Juveniles return to freshwater in spring when between 45 and 70 mm in length, and slowly make their way upstream during spring and summer. Because of its abundance, this species would benefit from improved access to the upstream catchment. More importantly, Boubée et al. (2003) considered that providing passage for common galaxias would also ensure passage of other indigenous species, including the Australian grayling (*Prototroctes maraena*) that is listed as a vulnerable species by the International Union for Conservation of Nature and Natural Resources (Allen et al. 2002).

In 2002, a rock ramp fishway with a slope of 4.8% was installed to replace the rock-lined galvanised chute at the Thompson Road drop structure. At the same time, the culvert was shortened to about 32 m (Fig. 1). Mark-recapture trials with common galaxias showed that the remaining 32 m of the ARMCO culvert was still a significant barrier to migration (Boubée & McGuckin 2004). In addition, the rock ramp fishway progressively reduced fish migration as flows increased above 0.5 m^3/s.

Due to the poor structural condition of the remaining 32 m of ARMCO culvert, Melbourne Water Corporation, which now manages the structure, judged that it had to be replaced, and this provided an opportunity to improve fish passage. The replacement structure had to

retain the ability to control floods. Of the options considered, the most effective was to replace the ARMCO culvert with concrete reinforced pipes that had spoiler baffles and resting areas for fish installed on the base. Although spoiler baffles are more complex than the weir system of baffles (Ead et al. 2002), observations of common galaxias swimming through different fish baffle systems indicated that these fish are reluctant to pass over weir baffles, but easily negotiate spoiler baffles where they can remain close to the bottom at all times (Authors, pers. obs.). As long as spoiler baffles create a zone 50–100 mm wide with velocities below 0.3 m/s, Boubée et al. (1999) found that small fish could progress upstream in the sustained swimming mode.

Flow records at the Thompson Road drop structure indicated that during the October to January upstream migration period, mean monthly flows were usually below 0.5 m^3/s, but flows up to about 1 m^3/s were occasionally recorded. Passage of fish was therefore required for flows of up to 1 m^3/s.

Field trials (Boubée & McGuckin 2004) and simulation studies (Kopeinig 2004) showed that fish passage was possible in the fishway and existing pipe fitted with spoilers at flows of up to 0.7 m/s, but passage became increasingly restricted at higher flows. Therefore, the chosen design had a pipe connected to the rock-lined channel for fish, with a weir and bypass pipe to progressively take flows above c. 0.2 m^3/s away from the fishway (Fig. 1). Steel flow restriction plates were installed on the headwall to ensure floods could still be controlled. To maximise fish passage, the rock-lined fishway was extended by c. 20 m, and the pipe section for fish reduced to 26.2 m, of which c. 7.3 m was formed out of a box section with a grill over the top to maximise light entry (Figs 2, 3). The slope of the pipe section was also reduced to 0.76%, and rows of five and six rectangular wooden blocks 120 × 120 × 250 mm at 450 mm spacing were attached to the invert (Figs 2, 4).

This paper presents the results of the monitoring and simulation undertaken following installation, and discusses the potential use of numerical simulation for resolving fish passage issues at culverts.

Copyright © 2006 Taylor & Francis Group plc, London, UK

2 METHODS

Field trials were conducted between 15 and 18 November 2005 at the peak of the common galaxias migration. Trials were made following a rain event, and three sets of flow and velocity measurements within the culvert were obtained for calibration of the numerical model.

2.1 *Flow and velocity*

Longitudinal and cross sectional water velocities within the culvert were measured with a Marsh MCBirney meter. Flows both within and outside the culvert was estimated from cross sectional water velocities with RHYHABSIM (Jowett 1989).

2.2 *Numerical simulation*

The complex geometry of a spoiler baffle array in a culvert, together with the need to calculate the free water surface, requires the use of a 3D numerical Code. Consequently, Flow-3D produced by Flow Science Inc. was used in this study.

Flow-3D uses a very simple structural mesh consisting of a hexahedral block subdivided into hexahedrons. In order to account for complex geometries, a multiblock mesh consisting of several adjacent blocks can be built. Into this simple mesh the geometry is inserted as obstacles, which can either be:

– Simple elements termed "Flow-3D primitives"
– XYZ-data, or
– 3D file formats like IDEAS or STL originating from CAD software.

To track the free surface, the VOF (volume of fluid) method is implemented. The principle of the VOF method is very similar to the FAVOR (fractional area volume representation) approach used to represent complex geometries in Flow-3D (Premstaller et al. 2004). Both the free surface and a geometric boundary cutting through an element are represented by additional scalar information indicating the percentage of water and obstacles, respectively, being present in a particular cell. The exact position where the free surface and/or the obstacle cuts through the cell is determined by the scalar information of that and adjoining cells (Fig. 5). Similarly, the normal vector on the plan can be determined. The scalar information is used to fulfill continuity, and in the case of the VOF method, is also used to ensure conservation of momentum.

In addition, so called fixed lines can be set. These force the grid generator to insert a volume boundary at the specified location.

Three numerical simulations were conducted using the three measured culvert discharges and a grid of

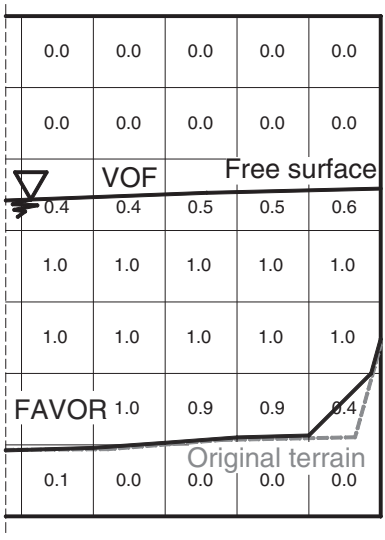

Figure 5. VOF and FAVOR method (from Premstaller et al. 2004).

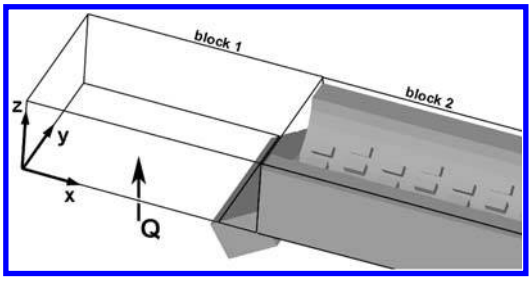

Figure 6. Inflow design used in the model.

700,000 cells with an x, y and z width of 80, 40 and 30 mm respectively. Two blocks were used for the entire grid: one for the inflow area and a finer one for the culvert.

The inflow block used in the model had a 2.5 × 2 m opening on the bottom as this provided slow inflow velocities, and an undisturbed flow field downstream (Fig. 6).

As the outlet flow observed in the field did not affect conditions within the culvert, a free water outflow was used in the model (Fig. 7b) and a 1 m long section free of baffles was added at the end of the culvert (Fig. 7a).

2.3 *Fish passage*

To determine the ability of fish to negotiate the structure, a 3 mm mesh trap that blocked the entire channel was set upstream of culvert inlet. Stained fish (Boubée & McGuckin 2004) were released at the

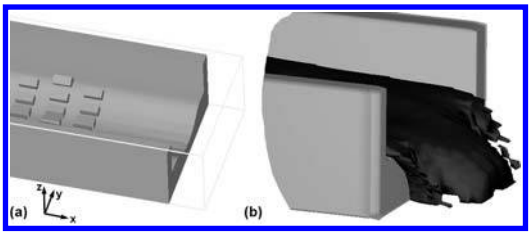

Figure 7. Extension at the end of culvert (a) and free outflow condition (b), used in the model.

Table 1. Flow measured in the stream above the structure and through the fishway.

	Flow (m^3/s)	
Date	Stream	Fishway
15/11/2005	1.45	0.74
17/11/2005	0.34	0.21
18/11/2005	0.26	0.15

culvert outlet, and the proportion recaptured in the trap determined. In addition, the entire rock-lined fishway was electrofished to determine if fish were accumulating in or below the structure. Results were compared with those obtained in 2002 (Boubée et al. 2003).

3 RESULTS

3.1 *Flows and effectiveness of bypass*

Three flows were measured and showed that the bypass pipe was effective at reducing flows in the fishway (Table 1).

3.2 *Numerical simulation*

At the two lowest experimental flows, predicted and measured velocities in the zone important for the fish migration (100 mm above the culvert floor) were very similar (Figs 8–9, 10–11). At the highest flow, for safety reasons no measurements could be made within the culvert, but the simulation indicates that fish migration would have been possible (Fig. 12).

3.3 *Fish passage*

Close to 53% of the 172 stained common galaxias released at the culvert outlet on 17 November 2005 was recaptured at the culvert inlet within 22 hours of release. Flows at this time were 0.21 m^3/s. This compares with only 8.5% making it through the structure over a similar period in 2002 when flow through the culvert was 0.1 m^3/s (Boubée et al. 2003).

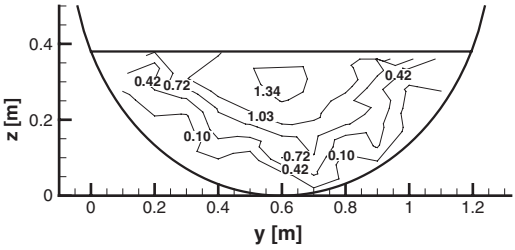

Figure 8. Measured water velocities (m/s) at cross-section x = 17.65 m with Q = 0.211 m^3/s.

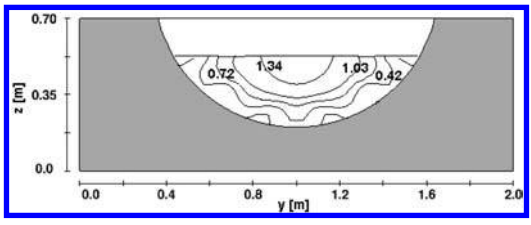

Figure 9. Simulated water velocities (m/s) at cross-section x = 17.65 m with Q = 0.211 m^3/s.

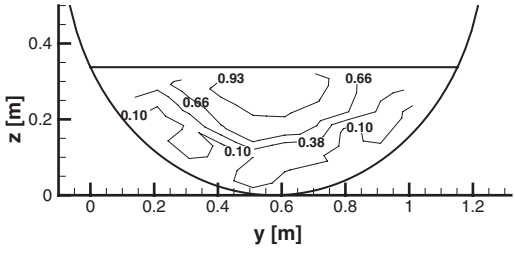

Figure 10. Measured water velocities (m/s) at cross-section x = 17.65 m with Q = 0.1559 m^3/s.

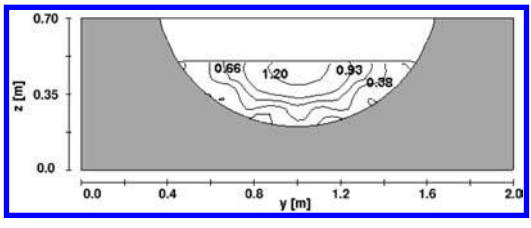

Figure 11. Simulated water velocities (m/s) at cross-section x = 17.65 m with Q = 0.1559 m^3/s.

In addition to the stained fish, 159 unmarked (wild) common galaxias, 24 lamprey (*Mordacia mordax*), 23 juvenile eels (*Anguilla australis*) and 2 tupong (*Pseudaphritis urvillii*) were captured at the culvert inlet. Electrofishing results did not indicate a concentration of fish below the culvert as was seen in 2002 (Boubée et al. 2003). This indicates a considerable improvement in fish passage since modifications were completed.

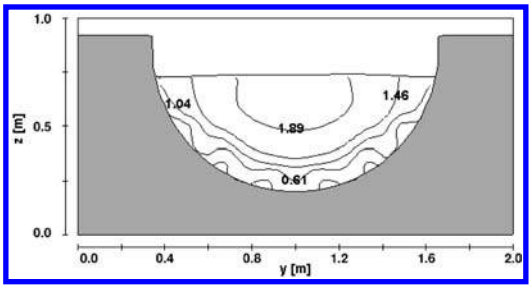

Figure 12. Simulated water velocities (m/s) at cross-section x = 17.65 m with Q = 0.7437 m^3/s.

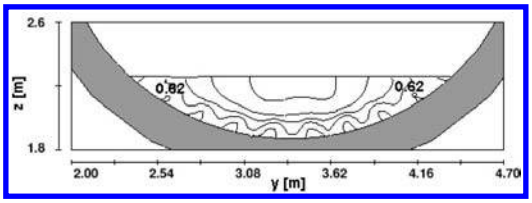

Figure 13. Simulated cross sectional water velocities (m/s) in a 3 m diameter culvert with Q = 0.6 m^3/s.

4 DISCUSSION

Modifications made to the Thompson Road drop structure, including the use of spoiler baffles within the culvert, allowed fish to successfully negotiate what was previously a migration barrier.

The numerical model correctly predicted flow patterns within the modified culvert, and could therefore be used to predict the effects of baffle configuration (e.g. spacing and size) on fish passage in culverts of varying size. For example, our numerical model shows that spoiler baffles of the same size as used in the 1.3 m culvert on Cardinia Creek would produce a low velocity fish passage zone in a 3 m diameter culvert of similar slope and flow (Fig. 13). This may mean that for small fish, baffle height does not need to be increased with culvert size as indicated by Engel (1974 in Rajaratnam et al. 1991). If further modeling and field verification prove this assertion correct, it would considerably simplify the installation and retrofitting of fish passage facilities in culverts of varying size as it would mean that spoiler baffles of the same size and orientation could be installed in a range of culvert.

ACKNOWLEDGEMENTS

We would like to thank David Fisher of Melbourne Water Corporation for the opportunity to undertake this study. Thanks are also due to John McGuckin for field assistance and Tanja Kopeinig for providing the results of her initial modeling studies.

Fuzzy modelling of habitat suitability using 2D and 3D hydrodynamic models: Biological challenges

ABSTRACT: The last 10 years has seen a considerable improvement in our ability to measure and to model the complex flow fields in a range of river environments, even to the point that we have numerical schemes and data acquisition strategies that allow us to model the interaction between the detailed geometry of individual clasts and clast clusters and the associated three-dimensional flow and sediment transfer fields. At the same time, habitat modeling has developed significantly, as we have developed methods for coupling hydrodynamic models to measured habitat preferences. Here, we show how we have developed this linkage through coupling of a depth-averaged hydrodynamic model to habitat preferences, using a fuzzy rule-based approach. We demonstrate how this approach can be used to determine habitat suitability for two fish species (Atlantic salmon and Brown trout), in relation to spawning, nursery and rearing habitat, and related to proposed changes in compensation flow releases downstream from a dam, and possible future climate changes to the 2050s. The results demonstrate the crucial need to explore flow-biology interactions at the *within*- reach scale, especially in relation to low flows. In reflecting on these findings, we show that whilst three-dimensional modeling may reduce some of the uncertainties that follow from a depth-averaged approach, its applicability is limited by both the small scale of predictions generated and the lack of ecological knowledge of how to interpret those scales of prediction. The scales of habitat that matter in ecological terms are larger and more continuous, questioning approaches based on modeling 'representative reaches' and necessitating exploration of new ways of coupling biological and hydrodynamic knowledge.

1 INTRODUCTION

In this paper we develop a model for predicting available habitat for two species of fish (*Salmo salar* and *Salmo trutta*) using a combination of two-dimensional hydrodynamic modelling with fuzzy modelling of the consequent habitat, for three different life stages (spawning, nursery and rearing). The model is used: (1) to evaluate the compensation flows required to improve instream habitat for fish; and (2) to understand how future climate changes might impact upon instream habitat. Our examples lead to critical reflection of this kind of habitat modelling as a means of informing river management activities in relation to ecological enhancement.

1.1 *The move from one-dimensional to two-dimensional approaches*

The ecologically-available habitat in a river depends on several key physical parameters, notably flow velocity and depth, wetted perimeter, substrate, temperature and pH (e.g. Elso & Giller, 2001, Maddock et al., 2001, Leclerc, 2005). These are often combined into some form of habitat score such as a Weighted Usable Area (WUA) (see Leclerc, 2005, for review). The best-known example of this is PHABSIM (e.g. Milhous et al., 1984) which is widely used to assess habitat suitability. PHABSIM is based upon a simplified form of the one-dimensional St. Venant equations for width- and depth-averaged flow. It uses a combination of the mass continuity equation and the Manning equation, the latter supported by the Bernoulli equation in order to determine the slope of the energy line. If we make a diffusion wave approximation of the St. Venant equations (i.e. we ignore temporal and spatial accelerations), and specify a Manning type friction law, then this gives the mass continuity and Manning equation used by PHABSIM. This approximation limits PHABSIM to situations where flow is uniform, or approximately uniform (Milhous et al., 1989). Leclerc et al. (1995) note that this will not produce reliable results for areas of river less than $10\,m^2$, so limiting its suitability for smaller streams or where spatial variation in habitat is high. This was confirmed by Ghanem et al. (1996) who obtained a

Copyright © 2006 Taylor & Francis Group plc, London, UK

more accurate representation of spatial patterns of flow velocity with a two-dimensional (2D) model than with a one-dimensional (1D) model. Indeed, application of PHABSIM at smaller spatial scales appears to lead to over-estimation of the amount of available habitat (Crowder & Diplas, 2002).

The main motivation for moving away from a modelling approach like PHABSIM and towards 2D habitat models is that they can deal with the fact that fish are relatively mobile organisms and hence may move over a range of spatial scales. This may include the within-reach scale over a range of time scales, as organisms move between resting and feeding, or as external forces (e.g. river flow) change. Adopting a 2D approach is important as 1D approaches do not represent the substantial within-reach variability in hydraulic variables and this has been commonplace since the 1990s. For instance, Leclerc et al. (1995, 1996) used a finite element solution of the depth-averaged flow equations, including a wetting and drying treatment, with a Habitat Suitability Index (HSI), to explore habitat changes on the Moisie River, Quebec (Leclerc et al., 1995) and the Ashuapmushuan River, Quebec (Leclerc et al., 1996). The HSI was derived from observed vertically-averaged velocity, depth and substrate characteristics for Atlantic salmon fry and parr, using multivariate statistical techniques. The HSIs were driven by the hydraulic model predictions and were used to determine how the percentage usable area varied as a function of discharge. The advantage of using a 2D approach is that it recognises that as some habitat becomes less suitable as flow depth and/or velocity locally rises, so other habitats become more suitable (e.g. if they were originally dry but become wet). This showed that there was a rapid increase in the percentage usable area for both parr and fry habitat up to 50 $m^3 s^{-1}$. Above this threshold, it remained relatively constant for fry, but rose more slowly for parr. Most importantly, they noted that the spatial scale of model predictions was more similar to that of known ecological function: salmonids defend territories that rarely exceed 4 m^2. In a similar study Tiffan et al. (2002) used a depth-averaged model to simulate flow depths and velocities at 36 steady state discharges. The biological model was based upon multivariate logistic regression in which the probability of subyearling fall Chinook salmon presence was predicted from physical habitat parameters predicted by the model. The results showed that estimates of rearing habitat decreased as flows increased and that estimates of the area that fish could become stranded in initially rose, but then fell. However, they noted that even the 16 m^2 resolution adopted was too coarse to characterise adequately the habitat needs of the subyearling fish. The Tiffan et al. biological model was based upon a habitat probabilistic model and Guay et al. (2000) used a similar approach, but compared it with Habitat Suitability Index approaches. They found that the HPI produced better results than the HSI, and they noted that this may be because of the multivariate nature of the HPI approach in which predictions from the hydraulic models are considered simultaneously rather than independently, so dealing with a common criticism of approaches like PHABSIM.

Crowder & Diplas (2000) extend these approaches to determination of energy gradients and 'velocity shelters'/refugia in gravel-bed streams. They recognise that point predictions of hydraulic variables may not always provide a sufficient representation of habitat as spatial variation in those variables is also a crucial fish (e.g. Hayes & Jowett, 1994) and macroinvertebrate (e.g. Lancaster & Hildrew, 1993) requirement. Crowder & Diplas undertook a higher resolution modelling study, which included mesoscale topographic features (e.g. boulders), to generate predictions for input into spatial habitat metrics. These seek to capture the physical habitat difference between two locations with the same velocity but different surrounding velocities in terms of velocity and kinetic energy gradients. For instance, by scaling the spatial change in kinetic energy between two points by the kinetic energy at the point with the smaller velocity, they were able to derive a metric that represents the kinetic energy that must be spent by an organism to move from an area of lower velocity to an area of higher velocity. As these are gradient-based, they will depend upon the spatial scale over which calculations are made, and this will need to be evaluated in relation to the spatial resolution of the mesh used in the model in relation to the behavioural aspects of the organism being considered. The research showed that boulders resulted in a substantially more complex spatial metric and so a greater habitat range for fish. Linking this to observed fish behaviour (Crowder & Diplas, 2002) confirmed that boulders enhanced the potential availability of the right habitat.

1.2 *Why habitat modelling needs to be fuzzy*

The above review emphasises that there has been significant development of habitat modelling approaches using hydrodynamic models over the last 10 years. This progress aside, a number of difficult issues remain. Central to these difficulties is the fact that hydrodynamic models need to be informed by ecological knowledge. Much of this is traditionally based upon field measurements (e.g. of depth and velocity) of where individual organisms have been observed at particular life stages (e.g. Rimmer et al., 1983, Heggenes, 1990, Heggenes, 1991, Heggenes, 1996, Bardonnet & Baglinière, 2000, de Crespin de Billy & Usseglio-Polatera, 2002, Armstrong et al., 2003). Typically, these measurements record a preferred organism preference (where they are living) and not a possible organism preference (where they could live). The latter

Copyright © 2006 Taylor & Francis Group plc, London, UK

is more difficult to estimate, not least because exposure to certain extreme conditions (where an organism could temporarily live) means that certain conditions may only be suitable for a specific period of time, but also because designing experiments to evaluate possible organism habitat is almost impossible. It is quite possible that a number of possible different *combinations* of habitat parameter values are similarly suited to an organism (Jorde et al., 2001). Habitat will only limit organism growth and survival if the densities of fish are sufficiently high relative to the size of the fish (Armstrong et al., 2003). If ecological measurements are made when this is not the case, the organism-habitat relationships will partly reflect other processes and hence will be noisy/uncertain with respect to what could be possible habitat.

Fuzzy models are designed for applicability to situations where only imprecise information is available (Ross, 1995) and they were introduced into habitat modelling by Jorde (e.g. Jorde et al., 2001, Schneider & Jorde, 2003). Given the above observation about the noise that will be implicit in ecological preference data, fuzzy modelling has real appeal for habitat modelling. Fuzzy models are particularly valuable for situations where the noise in our knowledge is non-random and not necessarily quantifiable: the situation is ambiguous (Ross, 1995) rather than uncertain (in the classical statistical sense). Thus, fuzzy analysis commonly maps onto linguistic definitions (good, bad) rather than numerical definitions. The ecological uncertainty surrounding habitat preference, both methodological and substantive, means that developing fuzzy habitat models it is possible to explicitly retain the ambiguity that is implicit in habitat preferences knowledge.

2 METHODOLOGY AND APPROACH

Our methodology and approach has two key dimensions: (1) the development of two-dimensional predictions of flow depth and velocity for shallow gravel bed rivers, using hydrodynamic models; and (2) application of these predictions to a fuzzy habitat model in relation to the species requirements for Atlantic Salmon (*Salmo salar*) and Brown Trout (*Salmo trutta*). Here, we consider two case-studies: (1) possible impacts of changing the release rate of water from a dam to improve instream ecology; and (2) possible impacts of climate change, to the 2050s, upon habitat suitability for instream ecology.

2.1 *Two-dimensional hydrodynamic modelling*

The two-dimensional hydrodynamic modeling was based upon the Finite Element Surface Water Modelling System (FESWMS, Froehlich, 1989). This solves the finite element form of the depth-integrated conservation equations for mass and momentum. This is not a widely adopted numerical scheme, although it has been used in a similar habitat modeling application by Pasternack et al. (2004). Importantly, it allows representation of complex geometries through use of a finite element mesh, that can include individual habitat relevant features such as cobbles and boulders. The model does not make a hydrostatic pressure assumption and has a wetting and drying treatment that allows for the representation of changing discharge. The model can include both wind-driven and Coriolis stresses, but these are assumed to be negligible in the scales of application used here. The model treats the turbulent stresses introduced during depth-averaging using a zero order Boussinesq type turbulence model, with an empirically specifiable eddy viscosity (see Lane, 1998) for review. The model uses a Manning-type parameterization of a quadratic friction law (see also Lane, 1998). Taken together, the eddy viscosity and Manning's n represent the two key calibration parameters available during model simulation. In terms of data requirements, and for application to a reach with a single outflow and inflow, the model requires: (1) a stage-discharge relationship as input to one of the boundaries; (2) stage hydrographs at both boundaries; and (3) channel geometry. At each model node, the model predicts the depth-averaged velocity and water depth, and these are used as input to the habitat model. We do not report on the validation of the hydrodynamic modeling in this paper. We have done this using distributed measurements of water surface elevation and depth-averaged flow velocity with very good levels of agreement. Pasternack et al. (2004) also report on model validation.

2.2 *Fuzzy modeling of habitat suitability*

Our approach focuses on depth and velocity alone. As it is two-dimensional, it implicitly includes consideration of the wetted usable area, as nodes are predicted as wet (depth > 0) and/or dry as a function of model solution.

After verbal consultations with habitat researchers in relation to depth and velocity requirements of Atlantic Salmon and Brown Trout, we classified each into: poor, medium and good; and habitat into six classes: unsuitable, very poor, poor, good, very good and excellent. We then define fuzzy subsets for depth (*Di*) and velocity (*Vi*) that define the grade of membership of each predicted depth (d) or velocity (v) of each of the i (poor, medium or good) subsets:

$$\begin{aligned}
D_p &= \{[d, \mu_{Dp}(d)]; d \in D, \mu_{Dp}(d) \in [0,1]\} \\
D_m &= \{[d, \mu_{Dm}(d)]; d \in D, \mu_{Dm}(d) \in [0,1]\} \\
D_g &= \{[d, \mu_{Dg}(d)]; d \in D, \mu_{Dg}(d) \in [0,1]\} \\
V_p &= \{[v, \mu_{Vp}(v)]; v \in V, \mu_{Vp}(v) \in [0,1]\} \\
V_m &= \{[v, \mu_{Vm}(v)]; v \in V, \mu_{Vm}(v) \in [0,1]\} \\
V_g &= \{[v, \mu_{Vg}(v)]; v \in V, \mu_{Vg}(v) \in [0,1]\}
\end{aligned} \quad (1)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where: p is poor, m is medium and g is good; and $\mu Li(l)$ is the grade of membership of the predicted value l(d or v) in Li(Di *or* Vi), which equals one for at least one value of L for each i. In this scheme, when $0 < \mu Li(l) < 1$, l has a partial membership of Li, and this is the sense in which the analysis is fuzzy, with l potentially being a partial member of more than one Li. We then specify a fuzzy rule for Habitat (Hk) based on two premises (for D and V):

$$\text{If } Di \otimes Vj \text{ then } Hk, \text{ for } K \text{ values of } k \tag{2}$$

where K is the number of habitat classes, i is the subset of Depth and j is the subset of velocity. In this case, $i = j = 3$, there are 9 rules, and potentially nine values of k. In order to capture the fuzziness of the analysis, membership of Di and Vj is expressed as a grade that varies between 0 and 1. Thus, we use a product operation rule (Wang, 1994) to define the degree of fulfilment of a particular habitat class:

$$\mu_{Hk} = \mu_{Hk,Di(d)}\mu_{Hk,Vj(v)} \tag{3}$$

where, μHk is the degree of fulfilment of Habitat class k, as defined by each possible combination of Di and Vj (from (2)), given the predicted values of d and v. The nine rules that come from (2) could be used to provide nine habitat classes. However, we use a symmetrical habitat classification, weighting D and V equally in the determination of habitat suitability (Table 1). This can be made more sophisticated by changing the weightings to reflect the known importance of velocity and depth in contributing to a particular habitat class, possibly informed by field data or traditional habitat suitability analyses, or calibrated onto measured relationships between habitat and productivity for a specific reach or set of reaches. We do not explore this here.

The analysis so far provides nine outcomes which indicate the degree of fulfillment of each rule. If there was no fuzziness in the system, then there would only be a single outcome. As the level of fuzziness increases, so the number of outcomes increases to the maximum of nine. In order to provide a single habitat suitability index we defuzzify the analysis to produce a single 'crisp' number. This can be done in a number of ways. Here we scale the total degree of membership of all classes to one, and then introduce the weightings shown in Table 1.

2.3 *Salmo salar and Salmo trutta habitat preferences*

The main additional data source necessary to run the habitat model relates to habitat preferences. On the basis of available data (e.g. Rimmer et al., 1983, Heggenes, 1990, Heggenes, 1991, Heggenes, 1996, Bardonnet & Baglinière, 2000, de Crespin de Billy & Usseglio-Polatera, 2002; Armstrong et al., 2003), we have mapped habitat preferences onto the following set memberships. We have also set a precision as per the table, this defines the fuzziness.

Table 1. The (symmetrical) definition of habitat classes in relation to the rule set defined in (2).

	Velocity		
Symmetrical	Poor (presence rarely found)	Medium (presence sometimes found)	Good (presence often found)
Depth Poor (presence rarely found)	Unsuitable Habitat 0	Very Poor Habitat 1	Poor Habitat 2
Depth Medium (presence sometimes found)	Very Poor Habitat 1	Good Habitat 3	Very Good Habitat 4
Depth Good (presence often found)	Poor Habitat 2	Very Good Habitat 4	Excellent Habitat 5

Table 2. Habitat preferences. All velocities have units ms^{-1} and all depths have units m.

	Poor (rarely found)	Medium (sometimes found)	Good (often found)
Salmo salar (Atlantic Salmon)

Figure 1. Case study 1: compensation flow redesign.

Figure 2. Case study 2: climate change impacts on low flows.

2.4 *Case-study applications*

We use two case studies. They share the common characteristic of being upland gravel/cobble streams in the Pennines region of northern England, with established populations of Brown Trout. We also include Atlantic Salmon in the analysis as these were thought to be found in these systems before the onset of major regulation and industrialization downstream (and hence both barriers and water quality), which would have most likely precluded salmonid migration to spawning, nursery and rearing grounds. The inclusion of Atlantic salmon is valuable as this is a potential target species in relation to what an undisturbed river catchment might look like. The prime difference between the two systems is in terms of the content for the modeling.

2.4.1 *Designing optimal compensation flow releases*

The first case study is concerned with the optimal way of setting compensation flow releases downstream from a dam, in order to deliver ecological improvements. Traditionally, in the U.K., compensation flow releases were set according to downstream industrial needs. With the decline of industry, opportunities have arisen to redefine releases to deliver ecological enhancement. In the case study here (Fig. 1), the aim was to increase the compensation flow from the current level of 0.03 $m^3 s^{-1}$, to the target level of 0.10 $m^3 s^{-1}$, and then subsequently to much higher levels than feasible: 0.50 $m^3 s^{-1}$ and 1.0 $m^3 s^{-1}$. We modeled a single riffle-pool unit (Fig. 1).

2.4.2 *Assessing future climate change impacts*

In the second example, we explore the impacts of estimated changes in low flow due to climate change. This uses output from a continuous simulation of climate from the start of a baseline period (1960) to 2069. We apply it to a distributed continuous simulation model of runoff. The model was calibrated on measured flows for the 1990s and early 2000s. Model output allowed determination of annual flow duration curves over the full 109 year period. We used this to determine characteristic drought period Q95 flow percentiles for the baseline period and for the 2050s

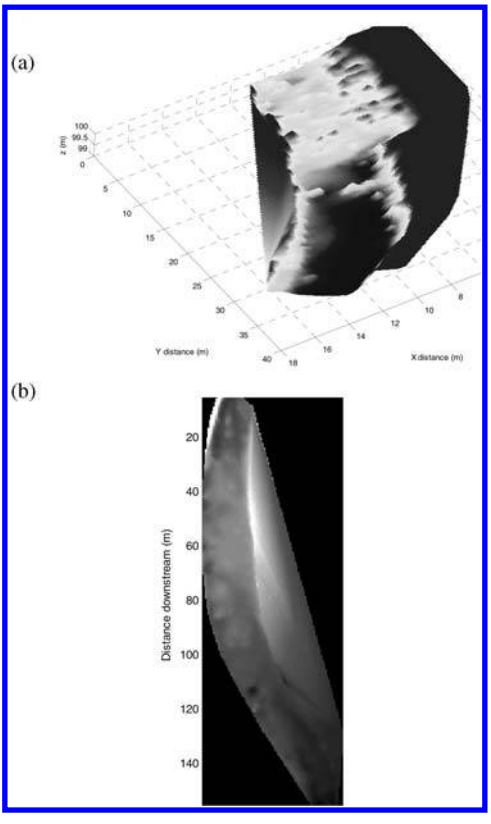

Figure 3. Shaded relief model of the topography at Case Study 1 (3a) and shaded contour model of the topography at Case Study 2 (3b).

(0.106 $m^3 s^{-1}$ and 0.078 $m^3 s^{-1}$ respectively). The modeled site comprised a weakly curved reach with a riffle at the downstream end (Fig. 2).

2.5 *Model geometry and mesh*

For both studies, we determined model geometry (Fig. 3) using high density field survey with Total

Copyright © 2006 Taylor & Francis Group plc, London, UK

Stations. These yielded data files with point spacings of better than 1 point per m^2. The density was varied to reflect the topographic variability of the river bed, including mapping of individual boulders and cobbles where it was clear that these were having (or would have) a substantial impact upon the associated flow characteristics. Topographic data were mapped directly onto the finite element mesh, locally interpolating nodes where the local rate of topographic change necessitated a higher node spacing. Achieving mesh independence in a study like this is not straightforward: as mesh resolution is progressively fined, so the model starts to resolve aspects of topography that are a consequence of data point spacing and data interpolation rather than the real topography (Lane et al., 2004) and this necessitates exploration of different approaches to topographic data representation in models of this kind. This is beyond the scope of this paper, but methods for doing this are reported elsewhere (Lane et al., 2004; Lane, 2005; Hardy et al., 2005).

3 RESULTS

Here, we begin by showing the importance of a two-dimensional analysis as the underlying context for the subsequent quantified changes in habitat suitability index. We then present results for: (1) compensation flow design; and (2) climate change impacts.

3.1 *Spatial patterns of habitat suitability*

Figure 4 shows the spatial patterns of HSI for Atlantic salmon (spawning) in response to the reduction of the characteristic drought period Q95 from 0.106 $m^3 s^{-1}$ (Fig. 4a) to 0.078 $m^3 s^{-1}$ (Fig. 4b). The results demonstrate the crucial role that is played by the bed geometry at these low flows: as the flow is reduced to the 2050s, so the bed topography becomes more strong topographically forced, as indicated by the greater steering shown in the superimposed flow vectors. There is a clear change in the amount of suitable habitat between the two simulations: there is a change in scale between the two Figures, showing that the general suitability is reduced under the 2050s scenario. Further, there are subtle spatial patterns to the associated changes. For instance, by the 2050s, the zone of most suitable habitat has switched towards the true right, 80 to 100 m downstream, reflecting the changing partitioning of flow around the upstream mid channel bar. Particularly at these low flows, small changes in flow magnitude can lead to very different flow routing, and this will have a major impact upon habitat suitability.

Figure 5 shows the spawning habitat changes but for Brown trout. As compared with Figure 4, the changes are much less dramatic. There is a smaller reduction in habitat suitability. However, there are some subtle

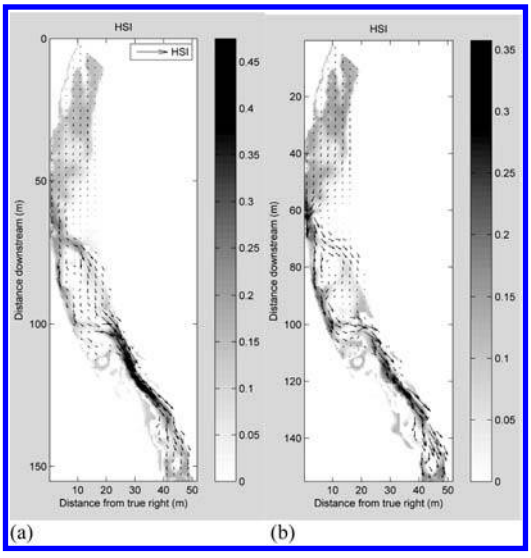

Figure 4. Habitat suitability index estimates for Atlantic salmon spawning habitat in response to climate change. 4a shows the baseline scenario and 4b shows the 2050s scenario.

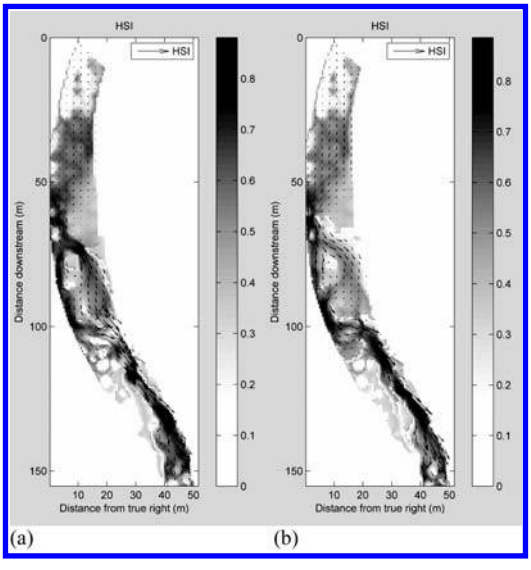

Figure 5. Habitat suitability index estimates for Brown Trout spawning habitat in response to climate change. 5a shows the baseline scenario and 5b shows the 2050s scenario.

changes in the spatial distribution of habitat suitability, notably the emergence of suitable habitat on the true right, between 130 and 150 m downstream. Much of this reflects the upstream steering of flow onto the true right which, as a result, wets part of a previously bar, creating new habitat. As with the case of

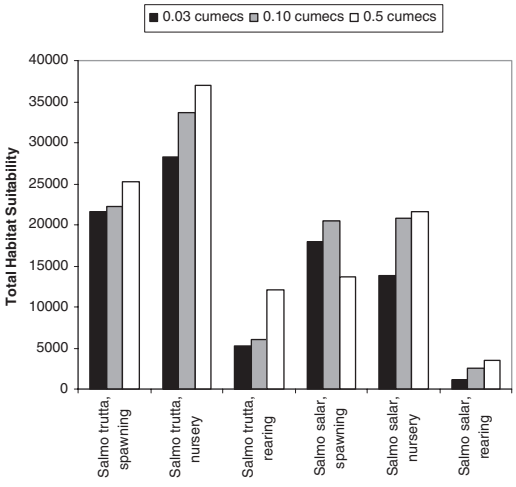

Figure 6. The total habitat suitability for case study site 1, for the three lowest compensation flows simulated.

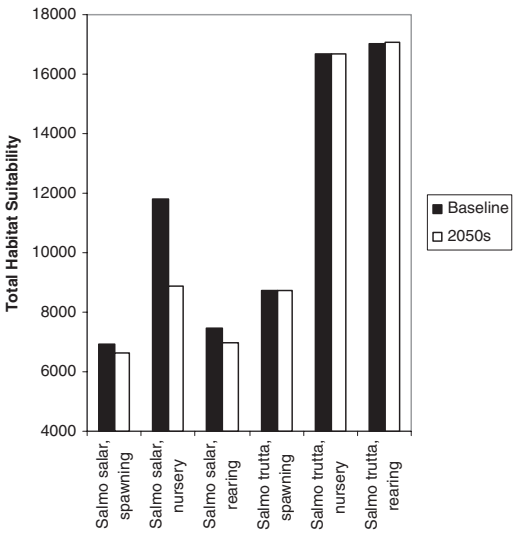

Figure 7. The total habitat suitability for case study site 2, for the drought period Q95, for the baseline and the 2050s.

Atlantic salmon, the spatial changes in flow distribution at these low flows are crucial for determining the spatial patterns of available habitat.

3.2 *Quantitative results: compensation flow redesign*

Figure 6 shows the effects of the three lowest compensation flows tested on the model of Case Study 1.

Figure 6 suggests that the current level of compensation ($0.03\,m^3s^{-1}$) is sub-optimal in terms of habitat suitability for Brown trout as compared with both the $0.10\,m^3s^{-1}$ and $0.50\,m^3s^{-1}$ simulations. However, for Atlantic salmon, this is only true for nursery and rearing life stages: increasing the compensation flow to $0.50\,m^3s^{-1}$ actually leads to a reduction in suitable spawning habitat. There is also variability between life stages and organisms in response to sensitivity to change. However, the key conclusion from this analysis is that the suitability of this reach for both Atlantic salmon and Brown trout habitat, for all life stages, might be improved by an increase in the magnitude of the compensation release.

3.3 *Quantitative results: climate change impacts*

Figure 7 compares simulated total habitat suitability for Case Study site 2, where the drought period Q95 is perturbed from baseline to the 2050s. The most striking aspect of Figure 7 is the difference between the species response in terms of habitat suitability. For *Salmo salar*, the simulations to the 2050s suggest a reduction in suitability for all three life cycles, with a dramatic reduction for nursery habitat, and smaller reductions for spawning and rearing habitat. However, for *Salmo trutta*, there are almost no changes. The reason for this difference in response could be two fold. First, it could reflect differences in organism traits in relation to the distinguishability of different habitat classes: if *Salmo trutta* had less clear preferences, it would be less sensitive to discharge changes. However, inspection of Table 2 suggests that this is not the case. Second, and more likely, it reflects the facts that, in habitat terms, *Salmo trutta* is more tolerant of the reduced Q95 under the 2050 scenario, in relation to the interaction between that flow and the bed topography. The reduced flow produces a velocity and depth field that is still within the range of habitat suitabilities found under the baseline scenario. Again, this emphasizes the important contextual influence of particular local river geometries and individual organism habitat preferences in mediating climate change impacts, as was shown in Figures 4 and 5. In terms of climate change, for in rivers in this region with similar gravel-beds, there is likely to be a net loss of *Salmo salar* suitable habitat due to the impacts of discharge changes upon velocity and depth, and the associate habitat suitability. However, there are important caveats to this observation, and these are discussed below.

4 DISCUSSION

In the discussion, we seek to set this work into broader context by looking at the above research from two perspectives: (1) hydrodynamic; and (2) biological; and then linking these together to think of future ways forward.

Copyright © 2006 Taylor & Francis Group plc, London, UK

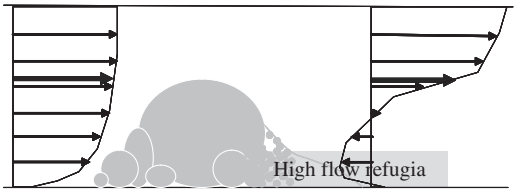

Figure 8. A simple cartoon illustrating the problem of depth-averaged velocity predictions (the thicker arrow) in the presence of a classic gravel-bed river feature (a pebble cluster): as stage rises and the flow depth to obstacle height ratio rises, so the depth-averaged velocity contains progressively less ecologically relevant information, not least because at these higher stages the separation zone in the lee of the cluster may become ecologically critical.

4.1 *Habitat modeling and hydrodynamics*

The starting point for many in terms of depth-averaged modeling of velocity and depth were the perceived inadequacies of representing spatial variability in velocity and depth in one-dimensional schemes. Even if the observed inadequacies of 1D modeling of habitat using diffusion wave approximations are accepted, there remains a logical limit to the extent to which such models can represent the real variability in depth and velocity that matters for organisms. Most life stages of fish, for instance, can readily move upstream or downstream in order to find suitable habitat, refuge or food, and 1D approaches tend to emphasize variability in section rather than downstream (Leclerc, 2005). The question then arises as to whether or not a 2D approach is any better. The process of depth-averaging yields a velocity prediction that (if the profile is semi-logarithmic) is found at approximately 40% of the flow depth above the bed. This will vary substantially where there are deviations from this profile form, notably if there is some form of flow separation such as above or around cobbles or boulders (e.g. Fig. 8), features that are known to be crucial components of good salmon and trout habitat. In theory, organisms can occupy any part of 3D space where there is flow and will do, according to whether they are feeding (where food sources in faster flowing water may be more available), resting (where slower velocities are critical) or seeking refuge (such as behind boulders or in deeper pools). Further, the kind of habitat that is produced by a given bed geometry will change as a function of discharge and stage and, from a hydrodynamic perspective, the information content of the depth-averaged velocity will partly reflect relative submergence effects rather than describing purely changes in velocity at the elevation associated with depth-averaging.

The initial response to this might suggest 3D approaches are needed, supported by the observation that we can now measure three-dimensional river bed topography in both laboratory and field environments

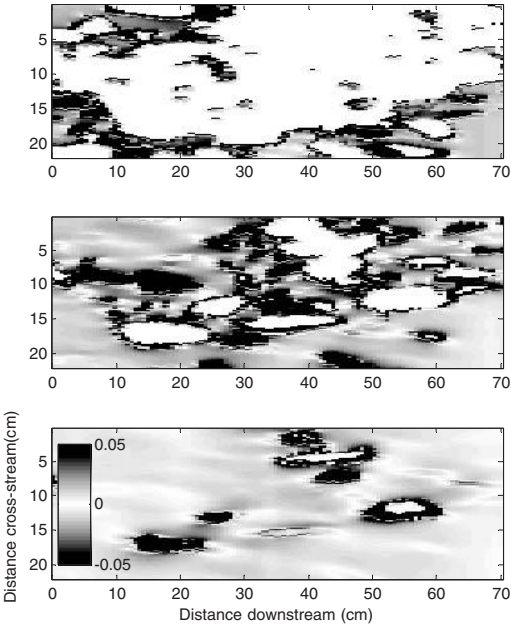

Figure 9. Predictions of planform vorticity at 10, 15 and 20 cm above a gravel/cobble surface from a 3D numerical model. White areas are blocked out by individual stones.

to mm precision and resolution (Butler et al., 2002). There are also novel methods available for representing this topographic information without recourse to boundary-fitted co-ordinates, such as by using blockage or porosity methods (Lane et al., 2004, Hardy et al., 2005). These methods can be used to derive ecologically-relevant information such as vorticity (Fig. 9), which has been linked to habitat usage (Crowder & Diplas, 2002).

The sophistication of these tools is appealing. However, these kinds of predictions immediately represent a problem in terms of ecological interpretation, as the scale of model predictions is commonly significantly smaller than the size of the organisms that the predictions are to be linked to. Figure 10 shows a three-dimensional visualization of the 5 cms^{-1} velocity surface for the same predictions shown in Figure 9. The length of the domain is 0.70 m and the width 0.30 m. The spatial structure of this field is less than the cm scale and will be largely irrelevant to the scale of a fish. We have almost no biological guidance on how to scale up these data to those biologically relevant scales. Thus, the move to 3D may satisfy the reductionist desire of removing progressively more of the uncertainty associated with modeling flows for habitat studies but, even if issues such as data availability and numerical representation, can be dealt with, this does not necessarily yield information that is biologically relevant.

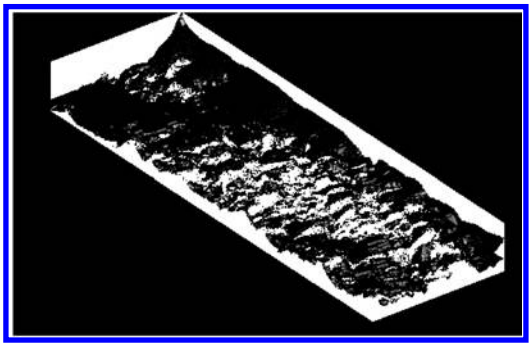

Figure 10. Three-dimensional visualization of the 5 cms^{-1} velocity surface for the same predictions shown in Figure 9, with a 70 cm length and 26 cm width gravel surface.

4.2 *Biological perspectives*

The previous section considered the hydrodynamic modeling presented in this paper in terms of process representation. Here, we look at the issue from a different angle: biological perspectives. The first point to emphasize is that the methodology that described in Section 3 and demonstrated in Section 4 is only relevant for predicting changes in *habitat*.

These can only be ecologically relevant if habitat is the limiting variable (Armstrong et al., 2003). Second, the analysis we present focuses only on depth and velocity and, because this analysis is 2D, wetted area. Velocity, depth and wetted area should map reasonably well onto system productivity if habitat is limiting. For the spatial scale and case-studies that we present, spatial variations in substrate are not significant. However, both compensation flow and climate change will cause adjustment in other variables (e.g. temperature, fine sediment delivery) and these may be as or more important than depth and velocity. In some cases, velocity and depth may be a surrogate for some parameters: for instance, high velocities and deeper flows will have cooler temperatures; faster velocities will have lower fine sediment contents. This is implicit in the habitat preference data used to populate these models (Table 2), because the data are based on observations, where temperature, substrates etc. are themselves difficult to control. This contamination probably can't be avoided. The main issue to be established is the extent to which depth and velocity capture these other variables and, if not, what the other variables are that are required and how they might be incorporated into habitat models.

The third, and final, issue is probably the biologically most relevant. In the same way that hydrodynamic models become most reliably closed at the very smallest of spatial scales, with boundary conditions absolutely and reliably specifiable, this is the scale at which they are likely to be least biologically valuable. Even with the 2D analysis presented in Sections 3 and 4, there are a number of key assumptions made that restrict the biological relevance of the associated results. The key assumption is that the analysis that we present requires us to assume that our reaches are *representative*, which they may not be. Central to this is the question of scale in fisheries biology. In salmonid research, the hierarchical view of scale is well established: larger scale catchment processes (e.g. basin scale sedimentary patterns) are assumed to create the environment within which smaller scale processes (e.g. riffle-pool dynamics) create a template that drives ecology (e.g. Folt et al., 1998, Armstrong et al., 1998). However, it is now recognized that this is a bi-directional process in which small–scale heterogeneity creates the spatial framework within which larger patterns of mobility emerge (Fausch et al., 2002). This represents a crucial challenge to habitat modeling, especially in relation to fish, because different spatial scales of mobility are associated with different stages of the salmonid life cycle (Armstrong et al., 1998). The habitat changes predicted, for instance in response to climate change, may be over-ridden by the ease with which salmonids can migrate to find other locations to spawn. Clearly some life stages are more critical than others: adapting to declining nursery habitat through migration is more difficult as the organisms are less able to migrate.

Both of the case studies we present are biased to the spatial scale at which we can feasibly generate bed geometrical data at ecologically-relevant scales, something that has been observed as common in many habitat studies (Folt et al., 1998). The result is a need to scale upwards (Cunjak, 1996, Lewis et al., 1996, Folt et al., 1998), without sacrificing the local spatial detail that is a crucial part of larger scale salmonid behaviour. This will involve considering the river as a continuously varying (Fausch et al., 2002) patchy environment. Focusing upon single or multiple representative reaches will not capture the ecological footprint available to mobile organisms.

5 CONCLUSION

Herein lies the challenge. On the one hand, the need to generate hydrodynamically meaningful data encourages us to think of progressively smaller spatial scales of enquiry. On the other, biologists are increasingly showing us that biological relevance emerges at much larger scales and over longer time periods than our models can possibly capture (but note, for example, Morin et al., 2000). One way forward may be system scale description of habitat parameters (see Carbonneau et al., 2004, 2005 for a 1 m mapping of an 80 km length of salmonid spawning river). The other is to begin to think about the link between hydrodynamics

Copyright © 2006 Taylor & Francis Group plc, London, UK

and biology in the conventional ways in which we have approached other parameterization difficulties in river research. In hydrodynamic modelling, for instance, because we cannot measure all relevant scales of geometrical variability we parameterise those scales that are not measured into a roughness parameter. This parameter is 'effective' (Lane, 2005): it is designed to represent those sources of friction loss that are not explicitly modeled, and it may not always easily map onto field or laboratory measurements. From a biological perspective, we need a similar research effort that seeks to couple hydrodynamic and biological expertise to develop effective parameters for coupling hydrodynamic and biological models in ways that are practical and feasible for river management.

Modeling approach to simulate habitat dynamics

S. Wieprecht, A. Eisner & M. Noack
Universität Stuttgart, Institute of Hydraulic Engineering, Chair of Hydraulic Engineering and Water Resources Management, Stuttgart, Germany

ABSTRACT: Today habitat modeling is a successful and commonly used method for the assessment of river ecology and for the evaluation of mitigation measures. Such models link morphohydraulic parameters with the biological needs of the aquatic fauna and flora. Presently state of the art in habitat modeling is restricted to calculations of habitat availability for different discharge scenarios just under steady state topographical and morphological conditions. However, the consideration of alternating morphological processes plays a key role for many species. In particular the life-cycles of gravel-spawning fish species depend on the temporal and spatial variability of the substrate layer and the accessibility of the interstitial zone. This paper presents the procedure how morphodynamic aspects are implemented in a habitat simulation process with the model CASiMiR. The consideration of these dynamic aspects upgrades the application of habitat modeling as a decision support tool in the framework of River Management issues.

1 INTRODUCTION: HABITAT MODELING

In the field of ecohydraulics habitat modeling is a river management methodology to assess – amongst others – the anthropogenic impacts on aquatic communities. Habitat modeling incorporates key hydro-morphologic parameters that are determined specifically to be used to review the availability of habitats for any particular e.g. target fish species, or life stages of such species. In turn, a number of key indicator species are used to indicate overall ecological integrity.

Habitat models analyze e.g. hydraulic and morphological attributes and perform the linkage to biological preferences or ecological needs respectively. As a result habitat suitability is calculated for different scenarios and visualized by graphs or maps.

1.1 *Applications*

Habitat models are applied in a wide range of river management issues. Among others the assessment of the ecological status of rivers and the identification of habitat deficits are basic applications. The key benefit of habitat simulation models is the possibility to predict – under consideration of certain limitations – biological and ecological developments for given river engineering measures or water management scenarios, which is in particular valuable for decision makers, investors, and stakeholders.

Minimum Flow Requirements, Revitalisation Projects or Environmental Impact Assessments are typical tasks in practice.

The state of the art in river habitat modeling including a wide range of applications is well elaborated by the COST Action 626 “European Aquatic Modeling Network” (2004), funded by the European Union.

1.2 *Parameters for fish habitat modeling*

One main focus in river habitat modeling lies on the simulation of fish habitats, because the integrity of fish habitats is generally accepted as a substantial factor to assess river ecology. Compared to other river organisms a good knowledge about the habitat demands of fish populations is available and the number of species is relatively small. The significant dependency of many fish species on hydraulic and morphological river characteristics is beneficial as well.

To be able to simulate fish habitats three basic parameters are required:

- Water Depth,
- Flow Velocity,
- Substrate Condition.

Further parameters (e.g. temperature or suitable hiding habitat conditions) can be taken into consideration well depending on target fish species and focus of foreseen investigation.

In order to get information about the hydraulic conditions for a certain range of discharges or single flow events, habitat models are usually connected by interfaces to 1D- or 2D hydraulic models that are able to predict water depth, flow velocity, and inundated area for steady and/or unsteady flow.

Copyright © 2006 Taylor & Francis Group plc, London, UK

On the other hand substrate, as a third basic parameter, is generally mapped by visual observation in the field. Thus, this parameter is normally recorded for only one situation. At present the consideration of morphodynamic processes and substrate variability in habitat modeling is missing.

However, morphodynamic processes play a key role for ecological integrity of river habitats. Among other species morphodynamic is of particular importance for gravel-spawning fish species. Their specific habitat demands are described in the following section.

2 BIOLOGICAL RELEVANCE OF HABITAT DYNAMICS: REQUIREMENTS FOR GRAVEL-SPAWNING FISH SPECIES

Many river species require, throughout their life cycle, an array of different habitat types, e.g. spawning habitats, juvenile habitats, or hiding habitats against predators or during extreme events such as floods or high temperature periods. The availability of such habitat diversity in rivers is primarily determined by the flow regime, morphology, and temperature.

Gravel-spawning fish species (e.g. Brown Trout, Grayling, Barbel, and Atlantic Salmon), that are exemplified in this paper, have particular demands on morphodynamic processes.

Beside the essential need for loose gravel of a specific grain size in low flow sections of a river for spawning fish individuals, the deposited eggs are dependent on specific conditions (e.g. oxygen availability) during their growth while hatching fishes must be able to emerge as alevins. Therefore, the significance of substrate characteristics is essential for the ecological assessment of spawning habitats.

In the past human impacts changed the established pattern of natural river dynamics. Today limiting morphological factors to disrupt the reproduction cycle of gravel-spawners are mainly:

– Embeddedness
– and fixed armored layers.

Embeddedness describes the grade of filling of coarse bed material with fine sediments. Thus, especially during the spawning period the interstitial zone is not accessible for fish to deposit their eggs and sufficient oxygen support is missing. Another consideration is the accumulation of fine material after fish eggs are deposited in the spawning habitat. Consequently, the consideration of embeddedness is twofold: one aspect is that fish eggs may be buried; the second aspect is that fry may be blocked from emerging. It is important to note that an increase of fine sediment may result from changed land-use practices in the watershed and must not necessarily be a direct result of alterations of the river course itself, although both usually occur more or less simultaneously and contribute to degradation of habitats.

Secondly, fixed armored layers inhibit the possibility for spawning fish to move the substrate with their tails and bodies in order to clear spaces to deposit their eggs.

To enhance the substrate conditions in potential spawning habitats particular attention should be paid to high-flow events, considering both their frequency and intensity. These flow events are crucial in maintaining a variety of habitats. High-flow events are periodically necessary to remove and transport fine sediment, that would otherwise fill the interstitial spaces in productive gravel habitats, as well as to entrain the armored layer.

According to that, morphydynamic processes and their occurrence must be considered, if spawning habitat suitability is to be modeled.

3 CASIMIR-CONCEPT

The habitat model CASiMiR (Computer Aided Simulation Model for Instream Flow Requirements) was developed in the early 1990s at the Universität Stuttgart, Germany, in order to assess fish and benthic habitats on microscale.

In contrast to most habitat models that use univariate preference curves for the linkage between hydromorphological parameters and biological needs the model CASiMiR is based on a multivariate fuzzy-logic approach (Schneider, 2001). The principle mode of operation of the fish habitat simulation model CASiMiR is described in Figure 1.

This progressive approach allows the implementation of qualitative expert knowledge in a numerical calculation. Furthermore, significant combinations of

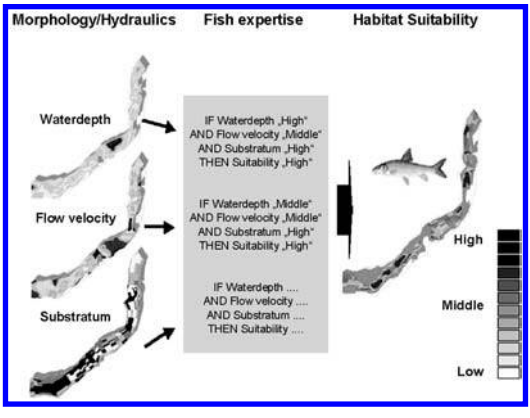

Figure 1. Principle mode of operation of CASiMiR for fish habitat simulations.

Copyright © 2006 Taylor & Francis Group plc, London, UK

abiotic parameters are considered for the examination of habitat suitability, which cannot be performed directly by using univariate preference curves.

In CASiMiR the three basic parameters mentioned above are primarily used for fish habitat modeling: flow velocity, water depth, and substrate condition. While flow velocity and water depth are calculated by conventional hydraulic models, substrate condition is a mapped parameter – usually observed for one situation. Additional parameters, e.g. different cover-types to assess hiding habitats or temperature, can easily be added.

The information that is used to describe the biological preferences in CASiMiR is:

- A set of Fuzzy-rules:
  to define the coherence of selected parameters by imprecise expert knowledge (see Figure 1).
- Related Fuzzy-sets:
  to define the range of each parameter-class, e.g. "high" flow velocity or "middle" water depth.

The implementation of the biological input data into the simulation process in CASiMiR is based on literature review, electro-fishing evaluation, and/or expert knowledge.

As a result the predicted habitat quality can be analyzed for each cell separately and illustrated as habitat maps (right map in Figure 1) or as integrated values over the observed reach. The habitat quality of each cell is expressed by the Habitat Suitability Index (HSI = 1,0 for optimal habitat suitability; HSI = 0 for insufficient habitat suitability).

Depending on the application the habitat simulations are run for unsteady or steady state flow. Near baseflow conditions, steady flow can often be assumed over longer periods of time. Simulation of unsteady flow usually is important for investigations of flood events. For habitat modeling purposes, mostly steady state time steps are used, except for single flood events or surge and sink issues. It is already mentioned, that at present no changes in river bed morphology or topography is considered for hydraulic modeling.

Usually one species and life-stage is modeled at a time. The results can show steady state conditions and discharge dependencies as well as seasonal aspects or single flow events by animation of habitat maps or graphs of integrative values.

Although CASiMiR has already been applied successfully on projects in Europe and the United States, it continues to be improved, becoming more extensive in scope. The improvements include the extension of applicability in habitat modeling from microscale (several hundreds meters) to mesoscale (several kilometers up to river catchment) and the linkage to morphodynamic issues.

4 APPROACH: CONSIDERATION OF MORPHODYNAMIC PROCESSES IN HABITAT MODELING

4.1 *Objectives*

This approach acts as an extension of the conventional habitat modelling with CASiMiR. The consideration of substrate conditions in rivers as a static parameter should be complemented by including morphodynamic processes to converge the overall aim of modeling habitat dynamics.

The following ecological issues are supposed to be answered:

- Improvement of ecological evaluations and predictions of anthropogenic influences. Moreover, it enables the modeling of mitigation scenarios, especially for spawning and rearing habitat conditions of gravel-spawning fish species.
- Identification of spots in river reaches where habitat suitability is reduced due to embeddedness or armored layers.
- Determination of discharges to entrain armored layers.
- Development of biocompatible water management concepts (dynamic flow regulations, reduction or surge and sink impacts that are mainly caused by hydropower operation).

4.2 *Development*

4.2.1 *Influence of embeddedness and armored layers on spawning habitat suitability*

The first part of the approach contributes to identify river reaches of decreased habitat suitability due to the limiting factors embeddedness and armored layer. Based on the fuzzy-logic methodology implemented in CASiMiR the specific morphodynamic attributes will be included by imprecise expert knowledge.

As it takes high efforts to define fuzzy-rules for more than four different parameters simultaneously it is convenient to divide the approach into two subsequent steps. The flow chart in Figure 2 provides its concept.

At first the conventional habitat modeling approach using basic habitat parameters (see Figure 1) is applied, resulting in a Habitat Suitability Index "HSI 1". If "HSI 1" is less than a predefined threshold value (in this example 0.4), habitat suitability is defined as low, based on conventional parameters. In that case the "basic" morphohydraulic conditions do not match the requirements for spawning activities anyway, and therefore no further investigation of embeddedness or armoring processes has to be performed.

For "HSI 1" higher than 0.4 the second step of the concept is applied to consider morphodynamic processes in terms of embeddedness, packing (armored

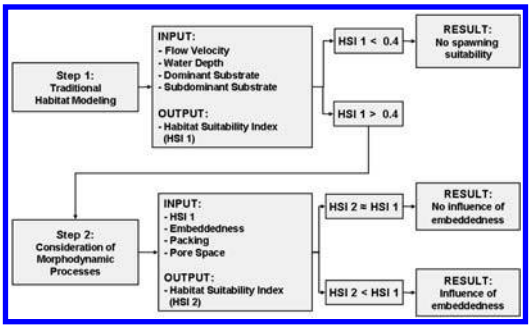

Figure 2. Flow chart to evaluate the influence of embeddedness and armored layers on spawning habitat suitability.

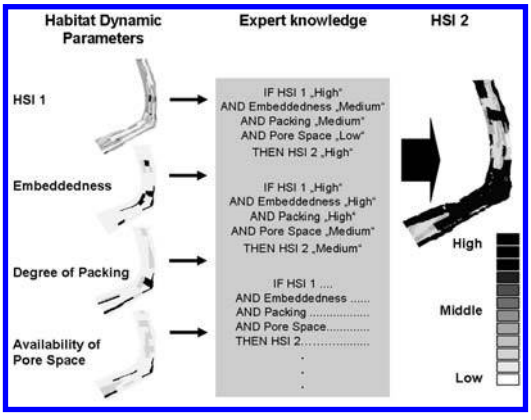

Figure 3. Implementation of "Habitat Dynamic Parameters" into habitat modeling.

layers) and pore space, which constitute the most drastic effect on spawning habitats. Again these so called "Habitat Dynamic Parameters" are linked to biological demands of certain fish species by using fuzzy-rules (see Figure 3) resulting in a "HSI 2"-value. The comparison between "HSI 1" and "HSI 2" describes the influence of additionally considered "Habitat Dynamic Parameters" and therewith their importance.

If "HSI 2" is similar to "HSI 1", embeddedness, packing, and pore space have no influence on habitat suitability. For "HSI 2" less than "HSI 1", the "Habitat Dynamic Parameters" affect the spawning habitat suitability in a negative manner.

In this context the investigation of embeddedness, packing and pore space is done by visual assessment and simple measurements during field observations. Eastman (2004) describes a proposed investigation method of each parameter and its classification.

4.2.2 *Concept for modeling of mitigation measures*

The evaluation of mitigation scenarios to improve spawning habitats for gravel spawners is aimed by the second part of this approach.

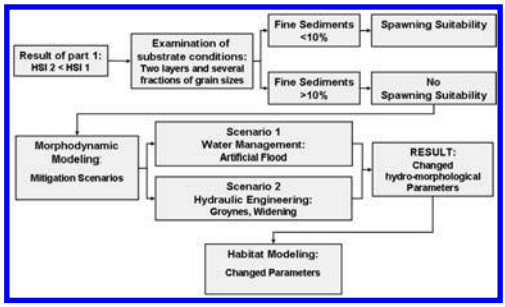

Figure 4. Concept of modeling mitigation measures.

Basically, mitigations are needed if the habitat suitability is affected by embeddedness or armoring processes ("HSI 2" < "HSI 1").

As shown in Figure 4 the major component of this part of the approach is the morphodynamic modeling to simulate the changes of substrate compositions and distributions caused by mitigation measures. For that reason morphodynamic models have to be applied that are able to calculate graded sediment with several particle fractions. Section 5 will explain the procedure in connection with two case studies.

First of all, one or several criteria have to be defined that are useful to evaluate whether a mitigation scenario is beneficial or not. That might be e.g. critical shear stress, thickness of moveable sediment layer or, as mentioned in Figure 4, a certain percentage of fine sediments in the upper layer (<10%).

Mitigation measures in this context can be divided into two main groups:

- Water management scenarios
  (artificial flood, flow regulations, surge and sink effects of e.g. hydropower operation)
- Hydraulic Engineering scenarios
  (Revitalisation projects, widening of river beds, structural measures such as groynes)

Significant changes in morphological and hydraulic characteristics are initialized and can be simulated by morphodynamic modeling.

Afterwards the verification of the fulfilment of the predefined threshold criteria (e.g. percentage of fine sediment <10%) as well as the evaluation of the effects of these modified morphological and hydraulic conditions on habitat supply have to be performed.

This concept enables an optimization process of planned mitigation measures as well as the comparison of different proposed scenarios with regard to habitat quality enhancement.

5 CASE STUDIES: WATER MANAGEMENT AND HYDRAULIC ENGINEERING

The mentioned approach was applied to two mitigation scenarios in Norway and Austria to improve

Copyright © 2006 Taylor & Francis Group plc, London, UK

spawning habitats for gravel-spawning fish species (Noack, 2005).

5.1 *Water management: Artificial flood*

5.1.1 *Situation*

This scenario was applied to the river Surna in Norway in cooperation with SINTEF (Foundation for Scientific and Industrial Research at the Norwegian Institute of Technology).

Due to flow regulations in the catchment area of river Surna in order to optimize hydropower usage, the river is characterized by more or less steady state minimum flow conditions. The natural hydrological characteristic is: MQ $\approx 56\,m^3/s$ with extreme flood discharge up to $400\,m^3/s$. The flow is reduced to about 60% of the annual flow. High flood events are missing. Therefore extensive parts of the river bed of the representative investigated diversion-reach Sandehølen are influenced by embeddedness and armoring processes significantly affecting spawning habitat suitability for Atlantic salmon.

5.1.2 *Objectives*

Based on the CASiMiR approach the influence of embeddedness on spawning habitat suitability had to be quantified.

Additionally it has to be investigated whether an artificial flood before the spawning season of Atlantic salmon would provide suitable substrate conditions for spawning habitats.

Finally an ecological oriented management strategy should be developed on the basis of simulations of different flow regimes.

In this context it must be considered that during spawning and rearing season salmons are endangered by insufficient supply of oxygen due to accumulation of fine sediments in the interstitial zone. Furthermore the mechanical damage to eggs and juvenile fish caused by sediment transport of big grain sizes is also a high potential of danger. Freshly hatched Atlantic salmons react more sensitive to higher discharges than eggs as they depend on shelter in the interstitial and have limited mobility whereas eggs are more resistant due to their stream lined shape.

Consequently, critical discharges have to be determined and strategies developed to avoid sedimentation as well as transport of cobbles and stones during the incubation period.

5.1.3 *Definition of threshold values*

To consider the requirements mentioned above the threshold values listed in Table 1 have been presumed for the study site Sandehølen by consultation of Norwegian fish experts.

Table 1. Threshold values for habitat parameters, Sandehølen, Surna (particularly adapted to specific situation).

Assumptions	Value/threshold
Critical "HSI 1"	>0.4
Grain size of fine particles	<2 mm
Critical percentage of fine sediment	10 %
Critical Shields-Parameter to avoid sedimentation	0.041
Critical grain size to provide shelter for hatched Atlantic Salmon	40 mm

5.1.4 *Input data and modeling base*

The hydraulic input data for the two-stepped fuzzy-logical approach in CASiMiR was processed by using the 2D-hydrodynamic software MIKE 21C provided by DHI (Danish Hydraulic Institute), while the parameters embeddedness, packing, pore space as well as the dominant, subdominant, and present substrate classes were mapped by visual observation. In detail the distribution of graded sediment was mapped for the upper and lower sediment layers separately, whereas the thickness of the upper layer covers approximately 20 cm of substrate. Based on these investigations simplified sieve curves were derived representative for each layer of mapped habitat areas. The dominant grain size of the cover layer is between 12 and 16 cm.

Within the simulation of different artificial flood events the morphodynamic modeling with MIKE 21C incorporates the modules "Graded Sediment Model" and "Morphological Update" allowing the interaction between morphological and topographical changes and the resulting hydraulic conditions. To calculate the sediment transport for each fraction the approach of Meyer-Peter & Müller (1947) has been applied.

As biological input data spawning habitat requirements for Atlantic salmon were provided by Norwegian fish experts based on electro fishing, experience and literature review.

5.1.5 *Results*

Exemplary results are illustrated by habitat suitability maps generated on basis of various simulation runs. For the representative discharge during spawning season of $15\,m^3/s$ Figure 5 illustrates the influence of embeddedness on spawning habitats. In the left map the habitat suitability "HSI 1", determined from basic habitat parameters flow velocity, water depth, and substrate, and in the right map the situation for "HSI 2" after consideration of "Habitat Dynamic Parameters" embeddedness, pore space, and packing.

It is obvious that the consideration of morphodynamic attributes is crucial for the assessment of spawning habitats for Atlantic salmon in that reach. The spawning habitats are widely and significantly reduced by embeddedness.

Exemplarily two areas are marked to demonstrate the influence of cumulative effects of the mapped

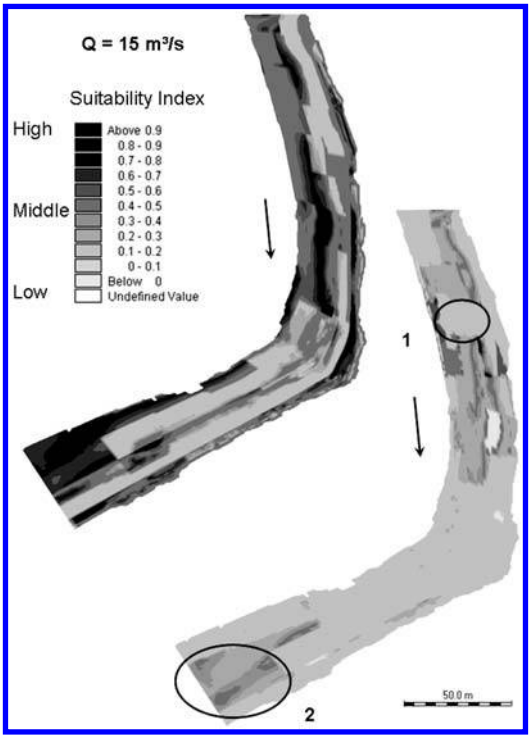

Figure 5. Comparison of habitat modeling without (left map) and with (right map) consideration of embeddedness.

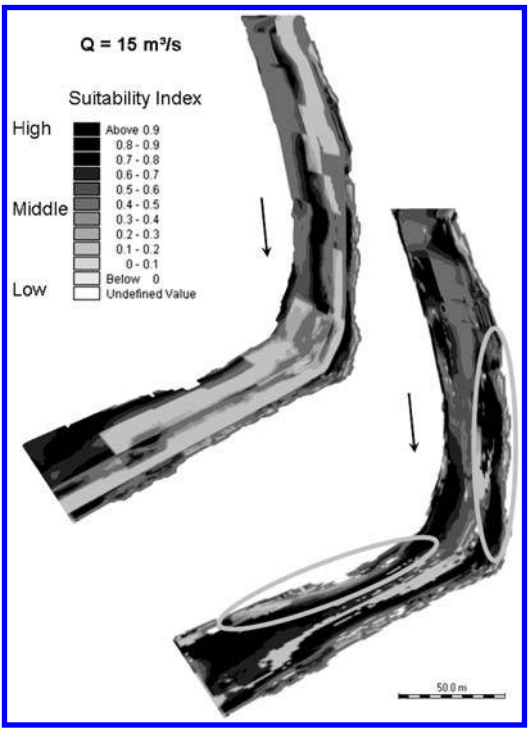

Figure 6. Comparison of habitat modeling before (left map) and after (right map) the proposed artificial flood.

parameters: The impairment of embeddedness (circle 1) results in no suitability and the influence of relatively suitable pore space conditions (circle 2) results in a minor reduction of spawning habitat quality.

To prevent hatched Atlantic salmon from mechanical damage by transported grain sizes larger than 40 mm, it is recommended that the discharge should temporary not exceed a critical limit at which grain sizes larger than 40 mm begin to move. Moreover, a drifting of both, eggs and hatched salmons could be avoided if this critical discharge is not exceeded.

On basis of numerous simulations of different flow events it is recommended that the flow regime during incubation period should not go beyond a discharge of 120 m^3/s. On the other hand the discharge should not drop below 25 m^3/s in order to prevent the deposition of fine sediments into the interstitial zone.

In fact, a smaller flood after the hatching period is recommended to provide nutrients as during this phase the first external feeding is necessary. However, the point in time of such a flood has to be chosen carefully due to the strong relation between hatching and water temperature on the one hand while it might endanger the survival of freshly hatched salmons if they are not strong enough to resist the flow and might be drifted away loosing their protection against predators.

Figure 6 describes the results of the habitat modeling before (left map) and after (right map) the proposed artificial flood under consideration of changed distribution of dominant and subdominant substrate and changed bed topography.

The artificial flood results in an increasing of habitat availability and habitat quality in the investigated reach. Particularly the circled areas in the right map could be improved by redistribution of sediment composition, where before the mitigation measure high percentages of fine sediments reduced the spawning habitat suitability.

5.2 *River engineering: Groynes, widening*

5.2.1 *Situation*

The second application was performed as part of the Interreg III B project ALPRESERV, funded by the European Union. The study site is located at Gestütshof (river Mur) in the Austrian Alps.

The investigation area is situated immediately downstream of the runoff power plant Bodendorf with a concrete weir construction of 17 m height backing up a reservoir of 2.6 km. The natural hydrological characteristic of river Mur at Bodendorf is: MQ $\approx$ 33 m^3/s

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 2. Threshold values for habitat parameters, Gestütshof, Mur (particularly adapted to specific situation).

Assumptions	Value/threshold
Critical "HSI 1"	>0.4
Grain size of fine particles	<2 mm
Critical percentage of fine sediment	10%
Critical Shields-Parameter to initiate entrainment of armored layer	0.051

and $HQ_1 \approx 130\,m^3/s$. Resulting from the heavily affected sediment regime the reservoir suffers from significant aggradation processes while the downstream section at Gestütshof is predominated by strong armored layers and significant embeddedness.

In addition, the flow velocities as well as the water depths exceed the tolerable values for spawning suitability because of fixed river banks and as a consequence an apparent degradation and narrowing of the river bed.

These conditions cause a significant reduction of spawning habitats for grayling.

5.2.2 *Objectives*

In a first step the influence of the presently existing morphological conditions on spawning habitat suitability has to be analyzed.

Following the basic analysis the effects of a proposed mitigation scenario on the improvement of spawning habitats must be investigated. The mitigation scenario includes the construction of groynes, the implementation of widenings of the river bed, and an adapted sediment flushing concept of the reservoir upstream.

With the aim to reduce armoring and embeddedness processes within the observed river reach the design of groynes and river bed widening has to be optimized.

5.2.3 *Definition of threshold values*

The assumptions mentioned in Table 2 were particularly made for the evaluation and morphodynamic modeling of grayling spawning habitats at the study site Gestütshof:

5.2.4 *Input data and modeling base*

Again, the hydraulic input parameters for the two-stepped fuzzy-logical approach in CASiMiR were provided by the hydrodynamic model MIKE 21C. To analyze the influence of existing morphological conditions on spawning habitat suitability the mentioned sediment attributes were mapped.

For the morphodynamic modeling with MIKE 21C the specification of different substrate layers was investigated by freeze-core sampling up to 60 cm in depth (by 10 cm intervals). Considering the significant interstitial zone for grayling spawning habitats the upper layer for morphodynamic modeling was

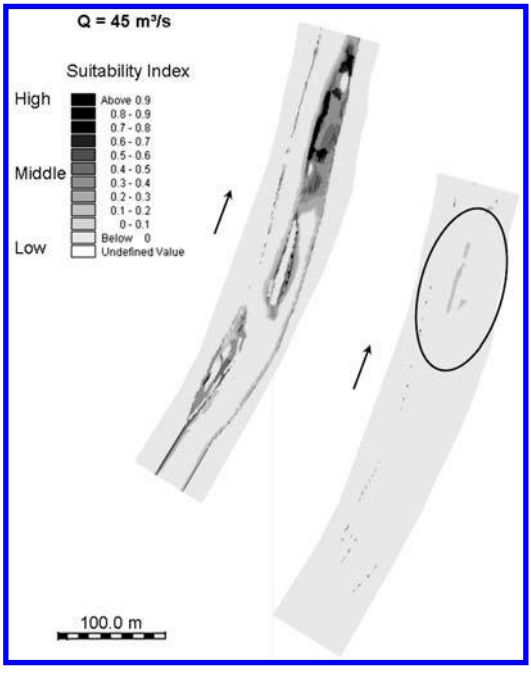

Figure 7. Comparison of habitat modeling without (left) and with (right) consideration of embeddedness.

defined to be 20 cm with a characteristic grain size of 72 mm. Similar to the previous case study the formula of Meyer-Peter and Müller was used to model sediment transport, while the approach of Günter (1971) was applied regarding armoring processes.

The spawning habitat demands for grayling were provided by Austrian fish experts based on electro fishing, experience and literature review.

5.2.5 Results

To be able to analyze the influence of "Habitat Dynamic Parameters" the modeling results are again compared with (left map) and without (right map) consideration of embeddedness, packing and pore space. Figure 7 shows the situation for a discharge of $45\,m^3/s$, as these flow conditions are representative for the grayling spawning season with minor variations between ca. $40\,m^3/s$ (minimum) and ca. $60\,m^3/s$ (maximum).

Consideration of the parameters embeddedness, packing and pore space emphasize that almost no suitable habitats for spawning graylings can de detected anymore. The strong impact of the mapped parameters, particularly packing and pore space, is directly affecting the suitable areas at the end of the study site resulting in a significant reduction of spawning habitat suitability compared to the habitat modeling with just the basic hydraulic parameters water depth, flow velocity and substrate condition. These results correspond

Copyright © 2006 Taylor & Francis Group plc, London, UK

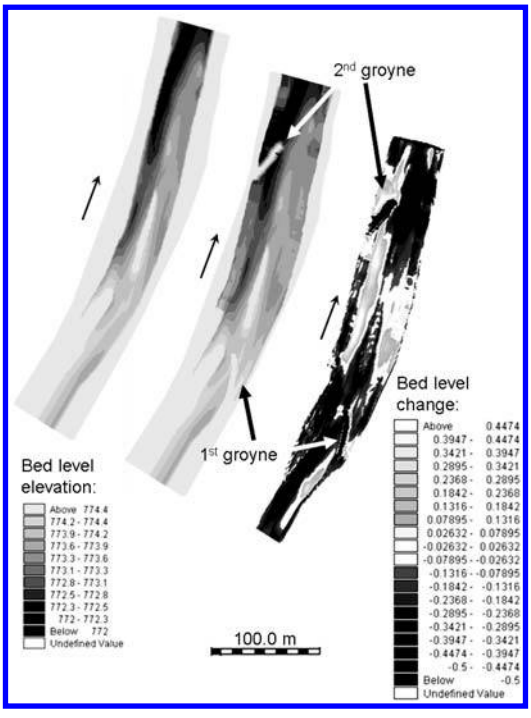

Figure 8. Mitigation measures: Effects of river bed widening and implementation of two groynes on bed elevation (original situation on the left, modified river bed after a 1-year-flood event in the middle).

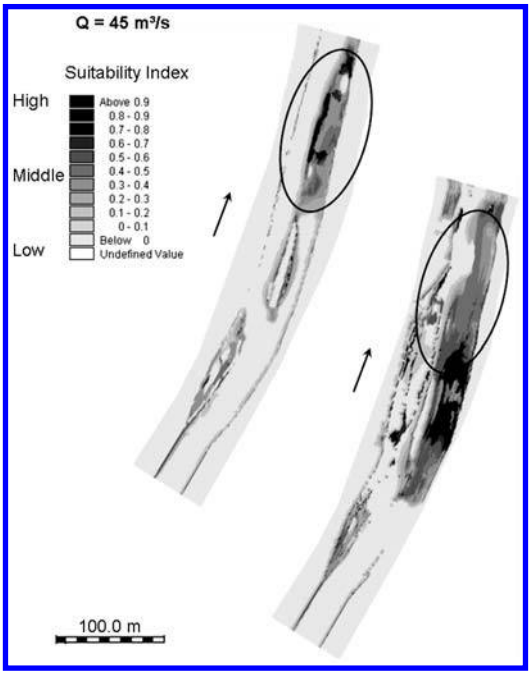

Figure 9. Results of habitat modeling with (right) and without (left) river engineering mitigation measures.

to the biological observations for that specific river section.

Concerning the habitat demands it can be stated that regarding the large areas of no suitability in the basic habitat modeling approach (Figure 7, left map) the flow velocities and water depths are too high for spawning activities.

Consequently, the main purpose of the proposed mitigation scenario includes the implementation of two groynes plus a widening of the river bed combined with a modified flushing concept to change the distribution of flow velocities and water depths as well as the substrate conditions to increase habitat suitability for spawning graylings.

In Figure 8 the bed elevation of the unmodified reach is shown on the left map, while the map in the middle represents the modified reach considering the changed bed topography due to the mitigation measures. The right map illustrates the bed level changes (erosion and accumulation) after a one year flood event. Particularly on the left hand side of the river, the sedimentation results in minor water depths and, combined with river bed widening, a reduction of local flow velocities. Erosion at the end of the study site results in significant substrate changes, however, water depths in this section are still in a tolerable range for spawning activities.

Figure 9 compares modeling results with and without the proposed mitigation measures.

Comparing the resulting suitability of both situations it is obvious that the formerly good habitats (circled in the left illustration) would be reduced by the proposed measures due to coarser substrate conditions and erosion processes caused by the second groyne. However, significant improvements in spawning habitat suitability can de detected in large areas on the right side of the river reach. As an integrated result the habitat availability could be almost doubled by the proposed mitigation measures.

These results could be incorporated in the development of a modified ecological oriented sediment flushing concept at the reservoir upstream.

6 CONCLUSION

Exemplified by two case studies of river reaches with different characteristics in Norway and Austria it is evident that morphodynamic processes, in particular embeddedness and armored layers, have to be considered, if spawning habitat suitability for gravel-spawning fish species has to be assessed.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The significant influence of these "Habitat Dynamic Parameters" on the achieved habitat simulation results corresponds to the attended electro-fishing investigations and fish expert expectations.

The linkage between morphodynamic and habitat models offers a valuable and reliable basis to optimize mitigation measures in river management issues efficiently. The need to integrate habitat modeling in general and a morphodynamic approach particularly into the planning process of mitigation measures has been illustrated by the case studies. It is obvious that the linkage is an important progress for both, habitat modeling as well as morphodynamic modeling, in order to be established as a decision support tool for river managers and stakeholders.

However, further studies are necessary: To be able to improve the efficiency and applicability an operational interface between the morphodynamic and habitat simulation models has to be developed. Intensive research is required to increase the biological knowledge about dependencies between "Habitat Dynamic Parameters" and their limitations on specific river organisms. The habitat demands regarding morphodynamic requirements and threshold values are mentioned in this paper depending on specific conditions at the investigated river sites and which are subsequently not transferable to other sites without an in-depth analysis.

Finally, the consideration of suspended load processes is of high importance to be able to incorporate the parameter embeddedness into the simulations of mitigation scenarios as well. In the approach presented in this paper embeddednessis considered as a mapped parameter to quantify the influence of "Habitat Dynamic Parameters". The simulation of embeddedness processes itself is not included yet.

ABSTRACT: It is necessary for inhabitation of aquatic lives such as fish, crab and so on, to preserve the structure consisting of both pool and rapid. Because some fish prefer pools and the other some fish prefer rapids. In particular, the ayu, *Plecoglossus Altivelis*, prefers rapids. The ayu is one of the most expensive fish in fishery in Japan. However, the reason why the ayu prefers rapids has not been investigated. In this study, the field survey, i.e., velocity measurements, flow depth and bed level measurements, recording the behavior of the swimming ayu and also gathering attached algae on the rocks, was conducted both in the pools and rapids under the condition that the ayu cannot feed attached algae in some area (non-ayu area) and also can feed in the other area (normal area). It was found that the growth of attached algae in the rapid is higher than that in the pool. The growth of attached algae in non-ayu area is higher than that in the normal area, due to the ayu feed attached algae on the rocks in the normal area. A logistic model was used for the evaluation of the growth of attached algae. As a result, the difference in the growth of attached algae between in the pool and rapid and also between in non-ayu and normal area can be investigated quantitatively.

1 INTRODUCTION

Ayu, *Plecoglossus altivelis*, inhabits in Japan, Korean peninsula and the east of the continent of China (see Picture 1.). They spawn at the lower reach of the river in autumn and drift downstream to the sea as soon as hatching (see Tsukamoto & Uchida, 1992). After about half year, they migrate to the upper and middle reach of the river and feed on algae adhering on rocks. In autumn, mature ayu spawn and then die. Ayu is one of the most important fish for fishery in Japan so that it is important to conduct the environmental assessment before construction of the hydraulic structures in the river.

It is known that sometimes strong ayu makes a territory almost in the rapids and rarely in the pools.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Picture 1. Ayu, *Plecoglossus altivelis*.

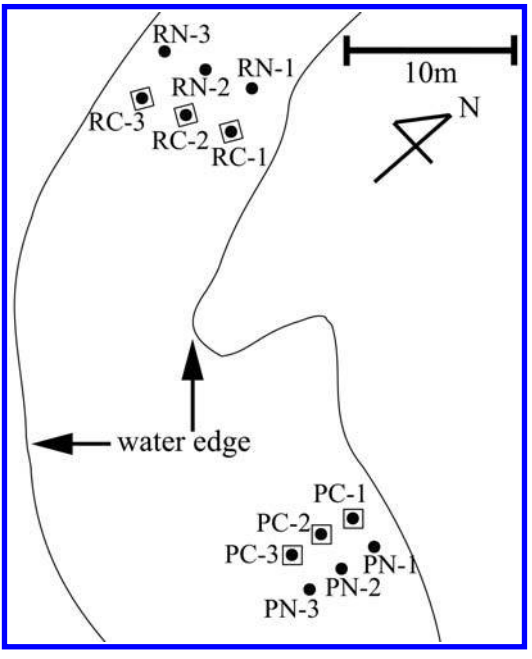

Figure 1. Survey points in pool and rapid (Kitagawa river).

It is supposed empirically that the good attached algae grows up in the rapids in comparison with that in the pools. However, this supposition has not been verified as yet. Further, the difference of behavior of ayu between pools and rapids is not known.

In this study, the field survey, i.e., velocity measurements, flow depth and bed level measurements, recording the behavior of the swimming ayu and also gathering attached algae on the rocks, was conducted both in the pools and rapids under the condition that the ayu cannot feed attached algae in some area (non-ayu area) and also can feed in the other area (normal area).

2 TARGET RIVER AND FIELD SURVEY

Nobeoka city where is located at the middle part of Kyushu Island in Japan. The Gokasegawa river, Hourigawa river and Kitagawa river are running through the Nobeoka city. Those rivers belong to Class A river. The administrator of the Class A river is Ministry of Land, Infrastructure and Transport (MLIT). The Gokasegawa river has a branch. The length and watershed catchment area of the Gokasegawa river are 106 Km and 1820 Km^2, respectively.

The field survey was conducted at 15 K 700 m upstream from the river mouth of the Kitagawa river. The reason of choosing this site, Kitagawa fisherman's cooperative association pointed out that a lot of ayu inhabits in the rapid. Figure 1 shows the sketch of field survey site. The field survey was carried out through 9th to 12th August in 2005.

In contrast, it is well known that the attached algae on the rocks is seceded by the flood. Figure 2 shows the variation of the discharge in the Kitagawa river in 2004, together with another year. Although, a small flood can be seen just before the survey period, the

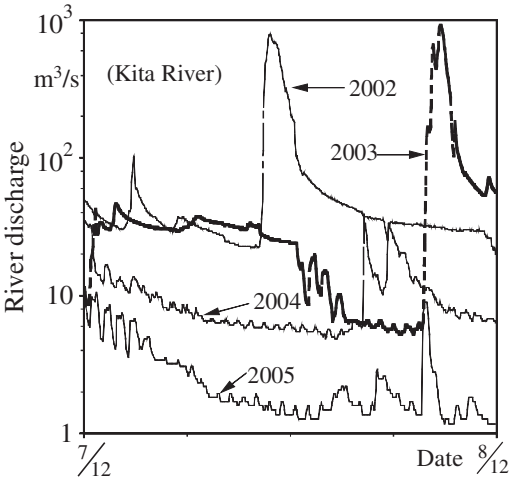

Figure 2. Variation of river discharge in Kitagawa river.

discharge is relatively small. As a result, attached algae was not seceded by this flood.

The number of survey points was 12 as shown in Figure 1. Table 1 shows the survey points and condition. 6 points are located in the rapid and pool, respectively. At the points of RC-1, RC-2 and RC-3 in rapid and also of PC-1, PC-2 and PC-3 in pool, the rock is surrounded by the cage as shown in Figure 3. Therefore, ayu cannot feed the attached algae at such

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Survey points and measurements items.

Case name	Averaged case name	Rapid or pool	Cage	Measurements items
RC-1, RC-2, RC-3	RC	Rapid	Cage	Velocity and attached algae

RC-1(NC)	–			Velocity
PC-1, PC-2, PC-3	PC	Pool	Cage	Velocity and attached algae
PN-1, PN-2, PN-3	PN		No cage	
PC-1(NC)	–			Velocity

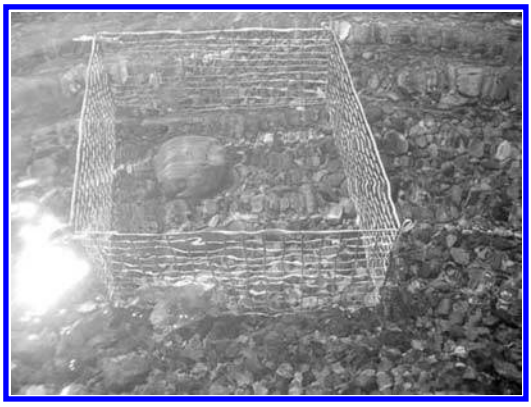

Figure 3. Picture of wire netting (PC-1).

points. On the other hand, ayu can feed on the attached algae at the points of RN-1, RN-2, RN-3, PN-1, PN-2 and PN-3. The flow depth at the pool and rapid was 0.4 m and 1.0 m, respectively.

All the attached algae and also fine sediments adhering on the rocks at all points were scratched by a hard brush and taken off on the first survey day (9th August in 2005). After that, all rocks put back on the river bed for each point. Attached algae and also fine sediments adhering on rocks were collected every 24 hours during the survey period (9th to 12th August). After field survey, TR (total residue) was measured.

The velocity profiles in the vertical direction were measured by an electromagnetic current meter at all the 12 the points. The measuring frequency and measuring time were set to 20 Hz and 51.2 s, respectively. Further, the velocity measurements were also conducted at the RC-1 and PC-1 in the condition that the cage was eliminated (RC-1(NC) and PC-1(NC)) to confirm whether the cage affects on the hydraulic structure or not (non-ayu area).

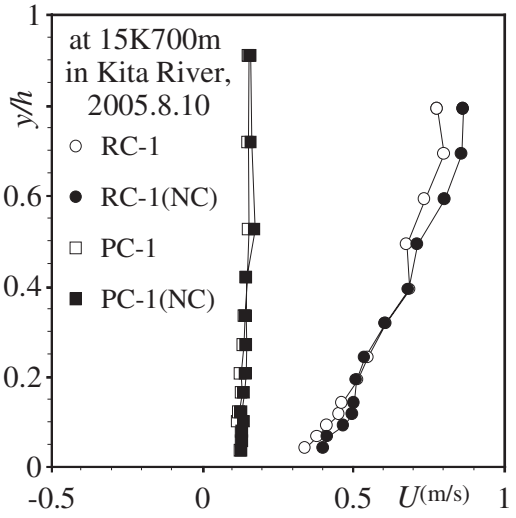

Figure 4. Velocity profiles in pool and rapid with cage and without cage.

The trajectories of swimming ayu both in pool and rapid were recorded by an underwater digital video camera. After recording, the swimming position from the bed, population, the number of feeding were analyzed.

3 RESULTS AND DISCUSSIONS

3.1 *Effect of cage on hydraulic structure*

Figure 4 shows the velocity profiles at the points of RC-1 and PC-1, together with those at the points of RC-1(NC) and PC-1(NC). In which h is the flow depth, y is the vertical coordinate, U is the time averaged flow velocity in the streamwise direction x, U_* is the friction velocity. The calculation method of the friction velocity U_* will be described later. A considerably difference of velocity between with cage and without cage cannot be found.

Figure 5 shows the distribution of the turbulence intensity u' normalized by the friction velocity U_* in pool and rapid, respectively, together with the empirical formula proposed by Nezu (1977) (see Nezu & Nakagawa, 1993).

$$\frac{u'}{U_*} = D_u \exp\left(-\lambda_u \cdot \frac{y}{h}\right) \quad (D_u = 2.26, \quad \lambda_u = 0.88) \qquad (1)$$

The empirical coefficients D_u and λ_u were obtained by Nezu & Rodi (1986).

The distribution of the turbulence intensity in almost cases near the free surface deviate upward from the Nezu's universal formula (1), due to the fluctuation

Copyright © 2006 Taylor & Francis Group plc, London, UK

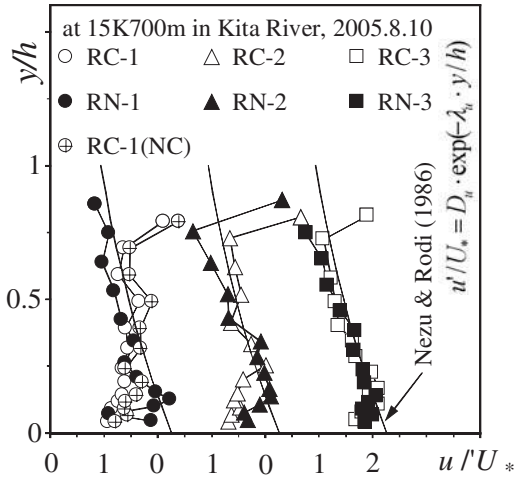

Figure 5(a). Distributions of turbulence intensity in rapid.

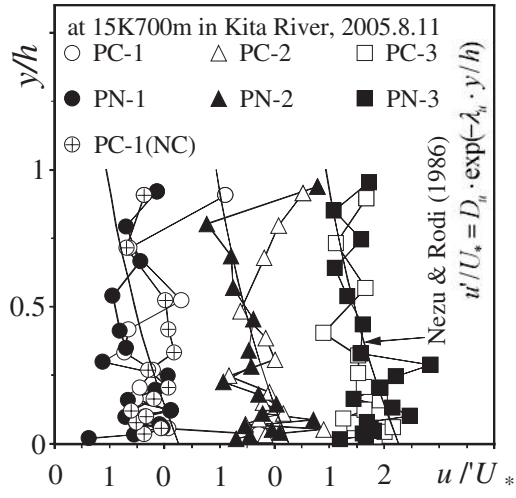

Figure 5(b). Distributions of turbulence intensity in pool.

of the free surface. Further, the distribution of the turbulence intensity at PC-1(NC) is almost the same as that at PC-1. Therefore, it can be said that the cage does not affect on the hydraulic structure and also the Nezu's universal formula is also valid in the natural river. The difference of the volume of attached algae depends on the feeding volume of ayu.

3.2 *The modeling of growth of attached algae considering ayu's feeding*

(a) Time variation of attached algae

Takami et al. (2005) measured both of TR (total residue) and chlorophyll-a in the Gokasegawa river and

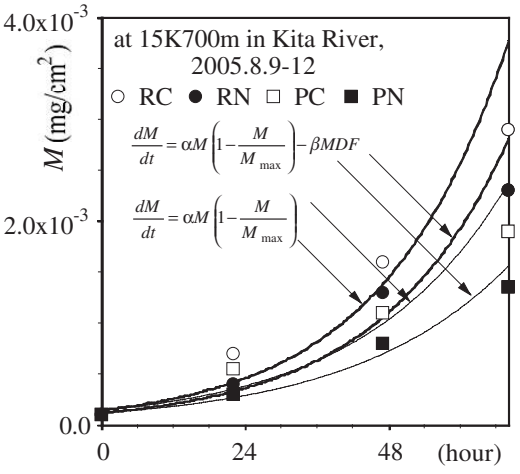

Figure 6. Time variation of TR in pool and rapid.

pointed out that weight of chlorophyll-a is almost equal to 0.1% of TR during April to October. Therefore, it is possible to evaluate the weight of attached algae on the basis of TR data. Figure 6 shows the time variation of the TR.

In which M is the weight of TR. It was found that the variation rate of TR in the rapid is higher than that in the pool and also the variation rate with cage is higher than that without cage. Toda et al. (2005) pointed out that the variation rate of attached algae depends on a balance of growth rate, importation rate, metabolic rate and separation rate per unit area. However, this model is complicated so that a lot of known coefficients are included. In this study, the following simple logistic equation is used for the cases with cage.

$$\frac{dM}{dt} = \alpha M\left(1 - \frac{M}{M_{\max}}\right) \tag{2}$$

In which t is the time, α is specific growth rate and $M_{\max}$ is the environmental capacity of TR which was calculated from chlorophyll-a (see Takami et al., 2005). Eq. (2) can be used under the condition that the importation and separation rate is negligible small. It is known that such a condition is keeping a few days after new attached algae start to grow.

On the other hand, Eq. (2) is valid for the cases with cage, but not valid for the cases without cage. Because ayu feeds the attached algae on the rocks which are not surrounded by the cage. It is necessary for proposing a new logistic model considering ayu's feeding to investigate on the feeding behavior of ayu.

(b) Behavior of feeding ayu

After ayu feeds attached algae on rocks, ayu goes away from the rocks. After that, ayu feeds again soon.

Copyright © 2006 Taylor & Francis Group plc, London, UK

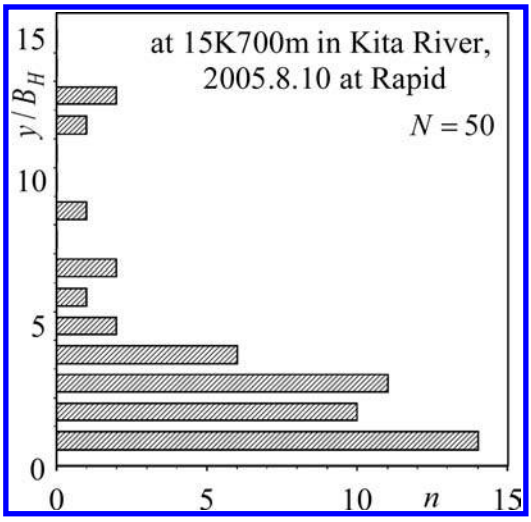

Figure 7(a). Swimming positions of ayu in rapid.

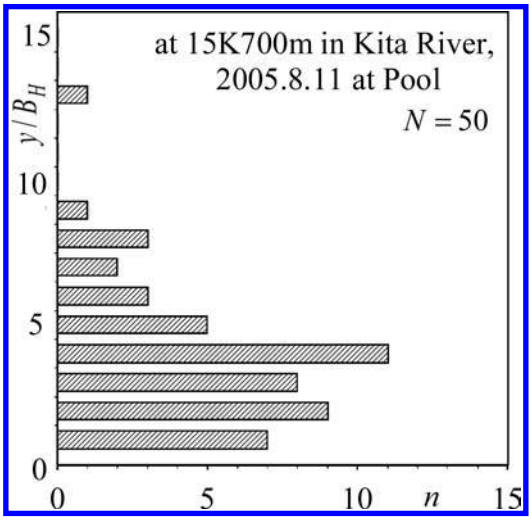

Figure 7(b). Swimming positions of ayu in pool.

Therefore, ayu swims near the rocks. Figure 7 shows the histogram of the swimming position of the ayu from the bottom y normalized by the body height of ayu B_H. In which N is the amount number of observed fish, n is the number of the fish in each layer. It was found that the swimming position of ayu both in the rapid and pool is lower than 10 times of body height of ayu. This implies that the reason why ayu likes the rapid does not depend on the flow depth.

The food intake of the ayu per unit time of unit area is proportion to the population of the ayu per unit area D (number/m^2) and the number of feeding per unit time F (number/s). Table 2 shows the results of D and F. The relative growth rate α is calculated from Eq.(2) by using of data with cage.

Table 2. Coefficients in modified logistic model.

Case name	D number/m^2	F number/s	α	β
RC	0	0	0.021	0
RN	5	0.714		3.63
PC	0	0	0.018	0
PN	25	0.909		1.08

(c) Proposal of a new logistic model considering ayu's feeding

A new logistic model which is considering the feeding of ayu is proposed as the following formula.

$$\frac{dM}{dt} = \alpha M\left(1 - \frac{M}{M_{\max}}\right) - \beta MDF \qquad (3)$$

In which β is the coefficient. When the second term on the right hand side in Eq.(3) is eliminated, Eq.(3) is equal to Eq.(2), because the second term on the right hand side has a significance of the effects of feeding. The coefficient β can be calculated on the basis of data without cage, adopting the relative growth rate α which is obtained from the data with cage. The calculated TR from Eq.(3) is also described in Figure 6 as fine lines. It can be recognized that Eq.(3) can describe the variation of TR without cage cases. Therefore, Eq.(3) can predict the time variation of weight of attached algae in the river.

3.3 *Physical meaning of proposed logistic model*

It is already pointed out that the relatively growth rate α in the rapid is higher than that in the pool, due to the deference of DO (dissolved oxygen), nutrients, velocity and so on between pools and rapids may difference. Kono et al. (2004) measured DO and nutrients both in rapid and pool in the Osegawa river and pointed out that the value of DO and nutrients are the same. Therefore, the difference of α between pool and rapid may depend on the difference of shear near the rocks.

The friction velocity can be calculated from the log-law.

$$\frac{U}{U_*} = \frac{1}{\kappa}\ln\frac{y + \Delta y}{k_s} + A_r \quad (y/h \le 0.2) \qquad (4)$$

In which κ (=0.412) is von Karman constant, A_r (=8.5) is the integration constant, k_s is the equivalent sand roughness and Δy (=0.25k_s) is the reference

Copyright © 2006 Taylor & Francis Group plc, London, UK

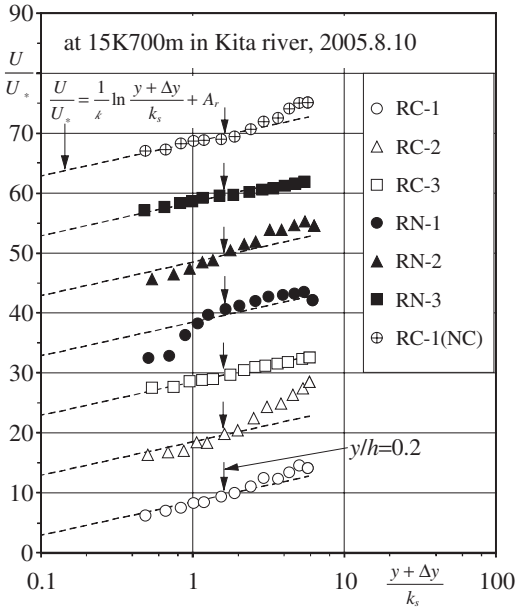

Figure 8(a). Velocity profiles in the rapid.

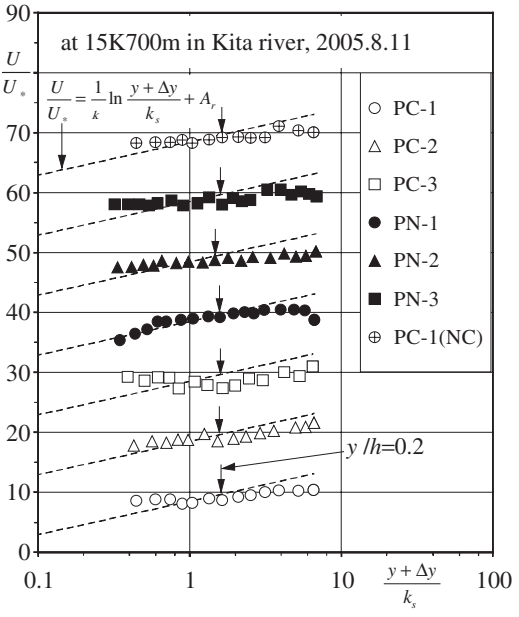

Figure 8(b). Velocity profiles in the pool.

bed level. The equivalent sand roughness k_s can be calculated by the Einstein method as follows:

$$k_s = d_{65} \tag{5}$$

Figure 8 shows the velocity distribution in the pool and rapid, together with the log-law as dashed lines. Although, the velocity profiles slightly deviate from the log-law in the outer region ($y/h > 0.2$), the velocity profiles in the inner region ($y/h \leq 0.2$) can be described by the log-law both in the pool and rapid. Therefore, the evaluation of the friction velocity from the log-law is valid.

Figure 9 shows the relationship between the relative growth rate α, coefficient β and the friction velocity U_*. Although, there is a few data, it is seen that the relative growth rate α increases with an increase of the friction velocity.

Figure 10 shows the relationship between the population of the ayu per unit area D (number/m^2), the number feeding per unit time F (number/s) and the friction velocity U_*. The population of ayu D decrease with an increase of the friction velocity U_*. This is because strong ayu makes the territory in the pool and turn off the other ayu from the territory. The feeding rate F also decrease with an increase of the friction velocity U_*. In the pool, feeding attached algae on the rocks is easy for ayu. On the other hand, in the rapid, feeding is difficult due to ayu must stay near the bed in the high velocity flow.

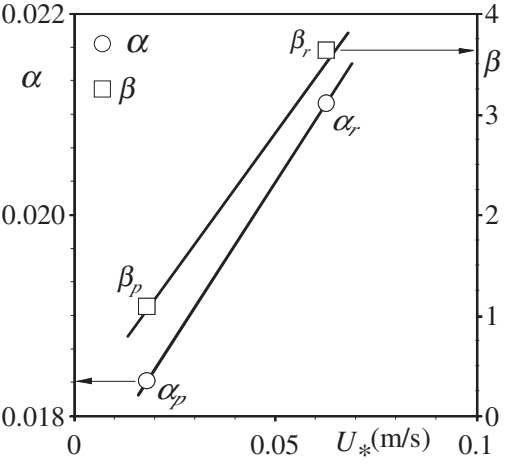

Figure 9. Relationship between the relative growth rate α, coefficient β and the friction velocity U_*.

4 CONCLUSIONS

In this study, the field survey, i.e., velocity measurements, flow depth and bed level measurements, recording the behavior of the swimming ayu and also gathering attached algae on the rocks, was conducted both in the pools and rapids under the condition that

Copyright © 2006 Taylor & Francis Group plc, London, UK

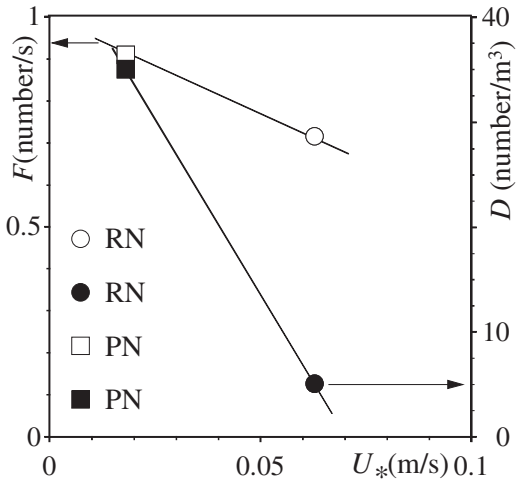

Figure 10. Relationship between the population of the ayu per unit area D, the number feeding per unit time F and the friction velocity U_*.

the ayu cannot feed attached algae in some area (non-ayu area) and also can feed in the other area (normal area).

It was found that the growth of attached algae in the rapid is higher than that in the pool. The growth of attached algae in non-ayu area is higher than that in the normal area, due to the ayu feed attached algae on the rocks in the normal area. A modified logistic model considering feeding of ayu is proposed to evaluate the growth of attached algae. As a result, the difference in the growth of attached algae between in the pool and rapid and also between in non-ayu and normal area can be investigated quantitatively.

ACKNOWLEDGEMENTS

The authors are thankful to K. Nagase who is a manager of Kitagawa fisherman's cooperative association. He taught us not only characteristics of ayu, but also river dynamics. The authors also to M. Suda, H. Kudoh, M. Kai and S. Tsuchida who belong to Nobeoka Gokasegawa fisherman's cooperative association. The authors are also thankful to H. Takao, H. Tsurusaki, K. Kawagoe, T. Takahashi, K. Interaction between flow and growth of Periphyton in sand river

Y. Toda, T. Tsujimoto, T. Ikeda & Y. Tadakuma
Department of Civil Engineering, Nagoya University, Furo-cho, Chikusa, Nagoya, Japan

ABSTRACT: Priphyton is known to be one of major primary producers in river ecosystem. While the growth of periphyton is usually seen on the relatively stable substrata in flowing water such as stone surface of gravel bed streams, large growth of periphyton is sometimes observed in sand river where the flow discharge and water depth are small enough for providing stable habitats for periphyton. In the present study, the field observation was performed to know the growth of periphtyon in a sand river, in which the growth of periphyton on sand bed and the spatial distribution of periphyton were measured at the Yahagi River in Japan. A numerical simulation model was presented to describe the spatial distribution of periphyton biomass at the observed reach. The present numerical simulation model can predict the spatial distribution of periphyton well.

1 INTRODUCTION

Periphyton is known to be one of major primary producers for river ecosystem, and it develops bio-film type communities on solid surface in water (MacIntire (1973), Minshall (1978), Saravia et al. (1998)). In natural streams, the periphyton communities are usually seen on the surface of gravel stones of shallow river bed and/or on the surface of submerged structures. The growth of periphtyon is expected to be rarely observed in sand river reach because of high mobility of bed materials and shortage of solar illumination at the vicinity of river bed due to relatively large water depth compared with gravel reach. Nevertheless, the large growth of periphyton is sometimes seen even in sand rivers where river discharge and water depth are small enough to provide the stable habitats for periphyton.

As for rivers running through agricultural area, river water is often diverted to the agricultural fields for irrigation use, which reduces river discharge during ordinary water stage. This decrease of river discharge may induce the stabilization of bed materials and the resulting large growth of periphyton even on sand bed. In order to understand the base of river ecosystems in sand rivers, it is important to know the growth characteristics of periphtyon on sand bed.

In the present study, the field measurement was performed in a sand river to understand the time growth and the spatial distribution of periphyton biomass on sand bed. Numerical simulation was conducted to know the effect of flow characteristics on the growth of periphyton in the sand river.

2 FIELD OBSERVATION

2.1 *Observation area*

The field observation was performed at the Yahagi River in Japan (figure 1). The length of the river is 117 km, and the catchment area of the river is about 1,830 km^2. The large part of the middle and lower basin of the river is used for agriculture field, and about 30 m^3/s of the river discharge is continuously distributed to the agricultural field during irrigation season at a diversion weir locating at 34.6 km upstream from the river mouth. This water intake reduces the river discharge at the lower reach of the river from 50∼60 m^3/s down to about 20∼30 m^3/s,

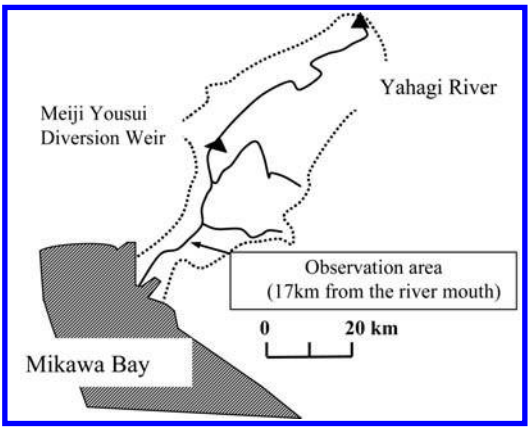

Figure 1. Map of the Yahagi River.

Copyright © 2006 Taylor & Francis Group plc, London, UK

which depresses mobility of river bed materials. Consequently, the river bed at the lower reach of the Yahagi River has been strongly stabilized during ordinary water stage, and the growth of periphyton is sometimes seen on the sand bed surface.

The observation area locates at 17 km upstream from the river mouth. The cross-sectional bed elevation of the observation site is depicted in figure 2. The cross-sectional averaged water depth of the observation site is less than 1 m during ordinary water stage, indicating that the large part of solar illumination can reach to the bed surface.

2.2 *Methods of the observation*

The field observation was conducted to know the growth of periphyton on the surface of the sand bed from July to December in 2005. The discharge during the observation period at the observation area is shown in figure 3. High water stages due to typhoon were observed around September 7 and October 19, and the discharge during November and December had been relatively small and stable. The sand sampled at the observed area was pasted on the square-shaped acrylic plates, each of whose has a dimension of 8 cm × 8 cm. The acrylic plates were settled on a frame, and the frame was installed onto the river bed (figure 4). 3 acrylic plates were picked up weekly, and the periphyton growing on them was removed by a tooth brush. The amount of periphyton was quantified in terms of the amount of chlorophyll a which is known to be a major photosynthetic pigment of plant. The amount of chlorophyll a was measured by using a spectrophotometer in accordance with the method proposed by SCOR/UNESCO (1975).

At October 31, November 16 and December 12 2005, the growth area of periphyton at the observed reach was recorded by D-GPS, in which the boundary between growth and non-growth area was detected by eye observation. The bed material sand was sampled at growth and non-growth area, and the grain size distribution of the sand was measured by using sieves.

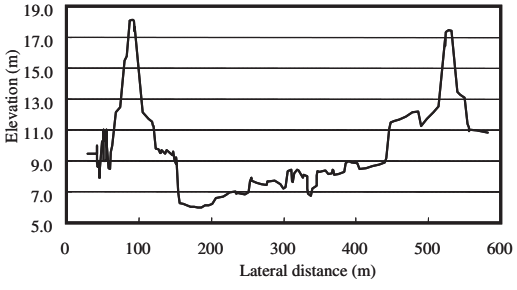

Figure 2. Cross-section of the observed area.

Figure 4. Fixed sand plates settled on the river bed of the observed area.

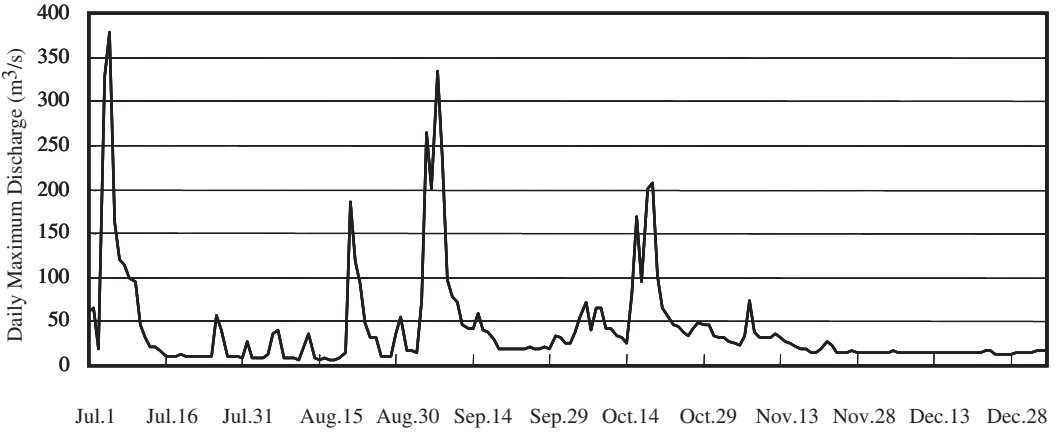

Figure 3. Daily maximum river discharges during observation period.

Copyright © 2006 Taylor & Francis Group plc, London, UK

At December 12, the periphyton growing on the bed surface was sampled, and the amount of periphyton biomass sampled was measured in terms of ignition loss.

3 NUMERICAL SIMULATION

3.1 *Outline of the numerical simulation model*

Flow chart of the present numerical simulation is illustrated in figure 5, which consists of the analysis of frequency of bed material movements and the simulation of growth of periphyton during the period that the bed material sands had been at rest. In the computation of frequency of bed material movements, Shields stress on river bed τ_* was estimated by calculating shallow water equations on the observed river discharge and bed geometry. The critical Sheilds stress τ_{*c} was calculated by using following Iwagaki formula (Iwagaki (1956)):

$$\begin{aligned} d \geq 0.303: \quad & U_{*c}^{\,2} = \tau_c/\rho = 80.9d \\ 0.118 \leq d \leq 0.303: \quad & = 134.6d^{31/22} \\ 0.0565 \leq d \leq 0.118: \quad & = 55.0d \\ 0.0065 \leq d \leq 0.0565: \quad & = 8.41d^{11/32} \\ d \leq 0.0065: \quad & = 226d \end{aligned} \tag{1}$$

in which d is grain size in cm, and U_{*c} is critical friction velocity in cm/sec. Comparing between τ_* and τ_{*c}, the amount of periphyton M was estimated to 0 during the period of $\tau_* > \tau_{*c}$, and it was calculated by the numerical integration of the logistic equation during the period of $\tau_* < \tau_{*c}$.

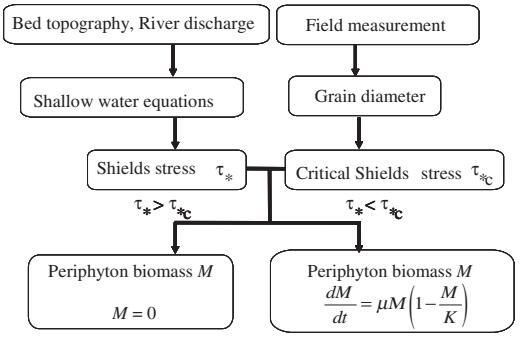

Figure 5. Flowchart of the present numerical simulation.

3.2 *Flow modeling*

The depth-averaged continuity equation and the depth-averaged Reynolds equations in curvilinear coordinates were used for calculating horizontal flow field. Eddy viscosity was estimated by using 0-equation type turbulence closure.

The governing equations for flow field were solved by finite volume method on a staggered grids system. Crank-Nicholson scheme was used for time integration. The 3rd order upwind scheme was employed for advection terms, and the 2nd order central difference was used for the other spatial derivatives.

3.3 *Modeling of growth of periphyton*

The logistic equation, Eq. (2), was used for the governing equation for periphyton growth:

$$\frac{dM}{dt} = \mu M\left(1 - \frac{M}{K}\right) \tag{2}$$

in which M is periphyton biomass per unit area, μ is specific growth rate of periphyton and K is environmental capacity. It is expected that the parameters μ and K are the functions of the environmental conditions relating the periphyton growth. In the present simulation model, the specific growth rate μ was assumed to be a function of solar radiation, water temperature and nutrient concentration. The environmental capacity K was represented by a function of solar radiation at bed surface;

$$\mu = \mu_{\max} f_I(I_b) f_T(T) f_N(N) \tag{3}$$

$$K = K_{\max} g_I(I_{b0}) \tag{4}$$

in which $\mu_{\max}$ is maximum specific growth rate, I_b is daily-averaged solar radiation at river bed, T is water temperature, N is nutrient concentration, $K_{\max}$ is maximum environmental capacity and I_{b0} is daily-averaged solar radiation under fair weather at river bed, respectively. The influence functions of solar radiation f_I, g_I, water temperature f_T and nutrient concentration f_N represent the effects of each environmental factor on specific growth and environmental capacity, and they are expected to take the value between 0 to 1.

The influence functions of solar radiation $f_I(I_b)$ and $g_I(I_{b0})$ were assumed to obey Monod type function;

$$f_I(I_b) = \frac{I_b}{I_{bc} + I_b}, \quad g_I(I_{b0}) = \frac{I_{b0}}{I_{b0c} + I_{b0}} \tag{5a, b}$$

in which I_{bc} and I_{b0c} are the half-saturated values of solar radiation. The influence function of water temperature was given by the following equation;

$$f_T(T) = \exp\left[\alpha_T \frac{(T - T_{opt})^2}{(T_c - T_{opt})^2}\right] \tag{6}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

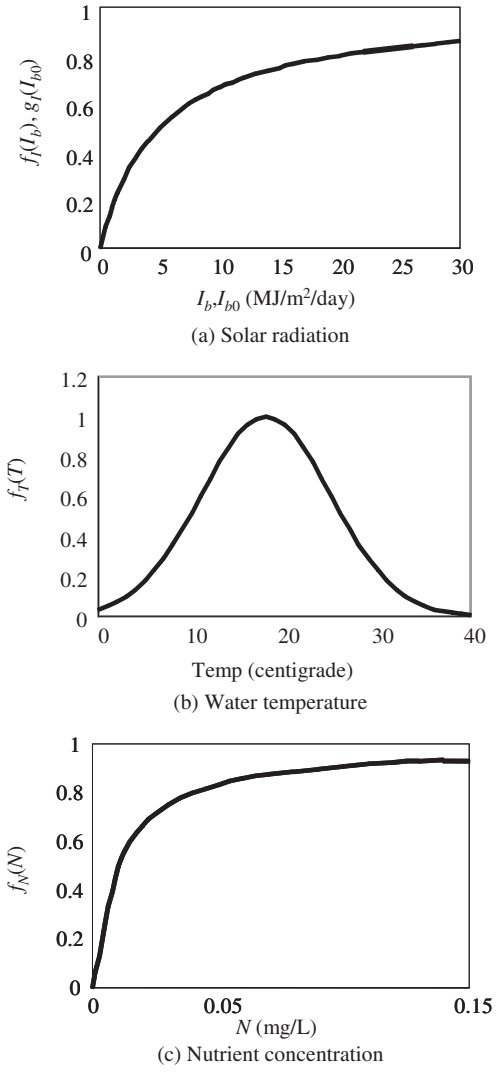

Figure 6. Influence functions used in the present numerical simulation.

in which T_{opt} is the optimal water temperature for the growth of periphyton, α_T and T_c is the numerical parameters. The function for nutrient concentration f_N was modeled by Monod type function;

$$f_N(N) = \frac{N}{N_c + N} \tag{7}$$

in which N_c is the half-saturated value of nutrient concentration. The profiles of the influence functions are depicted in figure 6.

3.4 *Computational conditions*

The computational domain was taken at a reach between 16.8 km and 17.6 km from the river mouth. The domain was divided into 20 grids in longitudinal direction and 22 grids in transverse direction. The bed elevation data measured at the observation area was used for the topographical condition for the computation.

The numerical computation was performed under the hydrological and metrological conditions during September 1 and December 31, 2005. The downstream boundary condition for water level was given to the interpolated value of the daily maximum water levels measured at 4 km downstream and 7.5 km upstream from the observation site. The inlet water discharge at the upstream end of the domain was given to the discharge observed at 4 km downstream from the study site, because there is no confluence between the interval. The water temperature and the nutrient concentration during the computational period were given to the values measured at 7 km downstream from the study site.

In the present computation, grain size of the bed material was set to be 1.0 mm, since the mean sand size at the periphyton growth area is about 1.0 mm (figure 9, broken lines). The Manning's roughness coefficient was given to 0.032 by calibrating the result of computation of flowing water area to that observed in the field. The physiological parameters used in the growth simulation for periphyton are summarized in table 1.

4 RESULTS

4.1 *Results of the field observations*

The growth of periphyton on the fixed sand plate was illustrated in figure 7. It is clearly shown that the periphyton biomass rapidly increased during 2 to 3 weeks after the installation. This result suggests that

Copyright © 2006 Taylor & Francis Group plc, London, UK

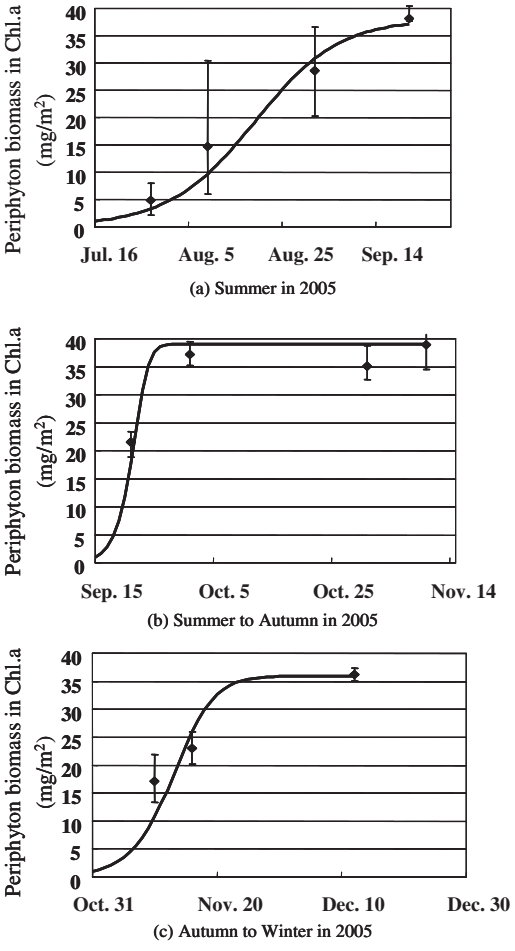

Figure 7. Growth of periphyton on fixed sand plates.

the periphyton can grow on sand surface if the sand has not moved. The fitting results of logistic curves, Eq. 2, were illustrated in solid line in the figure. In fitting the logistic equation, the environmental capacity, K, was given to the maximum value of the periphyton biomass observed during each growth period, and the specific growth rate, μ, was estimated by least square of residuals from the biomass measured in the field. The fitting results of the specific growth rate and the environmental capacity are summarized in table 2. While the variation of environmental capacity is found to be small among the season, a large specific growth rate was observed during September and October at the present study site. The specific growth rate is know to represent the activity of photosynthesis of periphyton, and the result indicates the growth activity becomes large at autumn while solar radiation becomes maximum in summer in Japan.

Table 2. Specific growth rate and environmental capacity estimated from the growth curves measured in the field.

	μ (day^{-1})	K (mg/m^2)
Jul. to Aug.	0.11	38
Sep. to Nov.	0.70	39
Nov. to Dec.	0.33	36

The spatial distribution of periphyton growth area is illustrated in figure 8, in which the solid line indicates the boundary between land and water. At October 31, small periphyton communities were seen at the vicinity of the right side bank. At the October 19, river discharge increased over 200 m^3/s, which might remove the periphyton communities from the river bed. Therefore the small periphyton communities were seen at October 31. During December to November, the river discharge and the fluctuation of it were relatively small compared with September, which might provide stable habitat for periphyton. Therefore the periphyton expanded their communities from the right side bank (figures 8 (b) and (c)).

Since the periphyton growth on sand bed depends on the stability of substrata, the grain size of bed materials might be important for the periphyton growth. The figure 9 shows the grain size distribution of bed materials sampled at the growth and non-growth area of periphyton. The grain size distribution has a considerable scatter for each location, and there is no significant difference between growth and non-growth area.

The spatial distribution of periphyton biomass in terms of ignition loss at December 12, 2005 is illustrated in figure 10. The periphyton biomass becomes large where the water depth is shallow. The difference in grain size was not large between growth and non-growth area, and therefore the growth of periphyton is expected to be affected by the flow characteristics such as water depth and bottom shear stress.

4.2 *Results of the numerical simulations*

The computational results of the spatial distribution of periphyton biomass are represented in figure 11. The computational results of the growth area of periphyton are more diffused than the area measured in the field (figure 8). In the field measurement, the growth area was detected by eye, and the boundary between growth and non-growth area was very clear. However, the periphyton biomass computed varies continuously with the continuous variation of hydraulic properties, which induces more diffused estimation of the growth area of periphyton.

The periphyton biomass computed tends to becomes large near the right side bank, and the growth

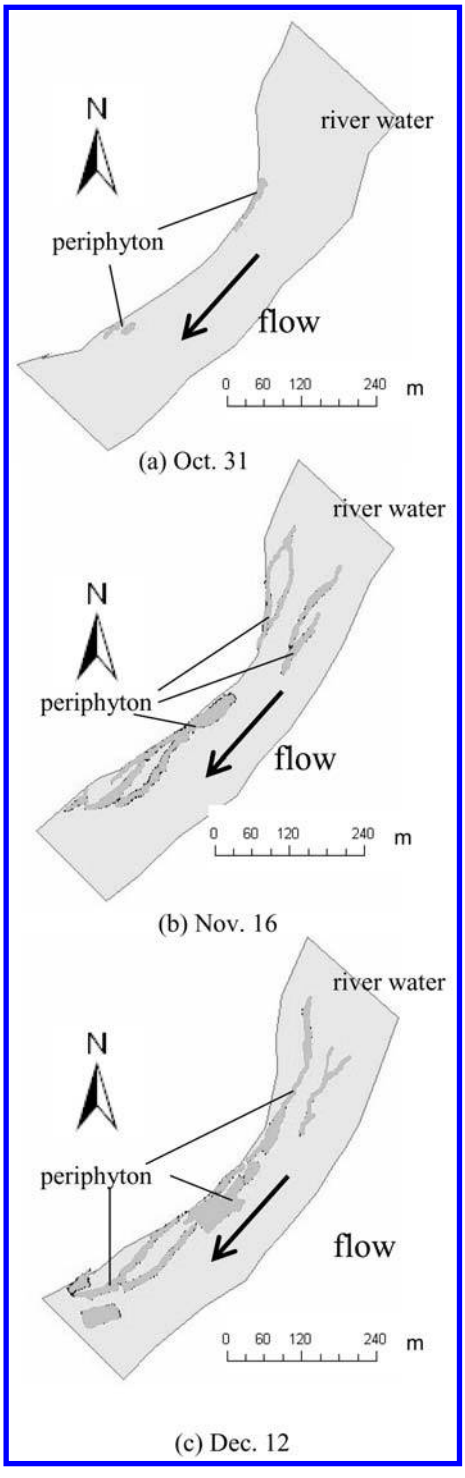

Figure 8. Growth area of periphyton on the observed river bed.

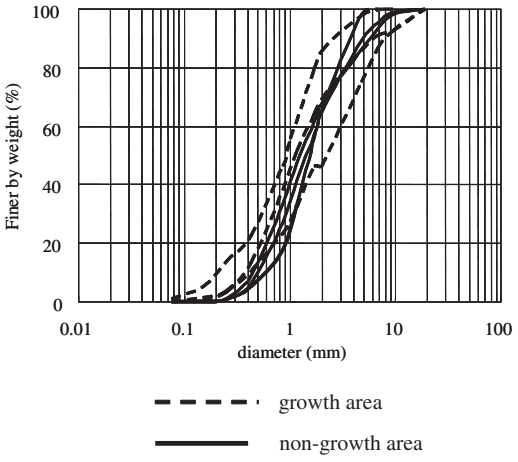

Figure 9. Grain size distribution of bed material sands sampled at growth and non-growth area.

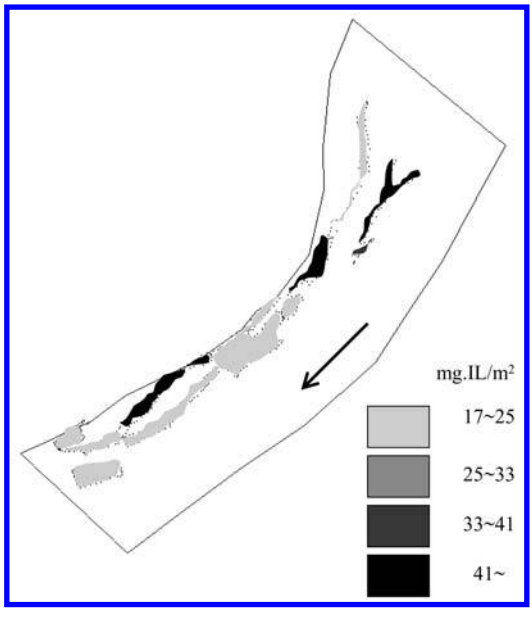

Figure 10. Spatial distribution of periphyton biomass measured at Dec. 12 in 2005.

area expanded in order of October 31, November 16 to December 12. These results agree with the results of field observation, and therefore the present computation can qualitatively estimate the growth of periphyton in the sand river. These results suggest that the growth and the spatial distribution of periphyton are closely correlated with stability of bed material sand, and the flow characteristics strongly influence primary production of periphyton in sand river.

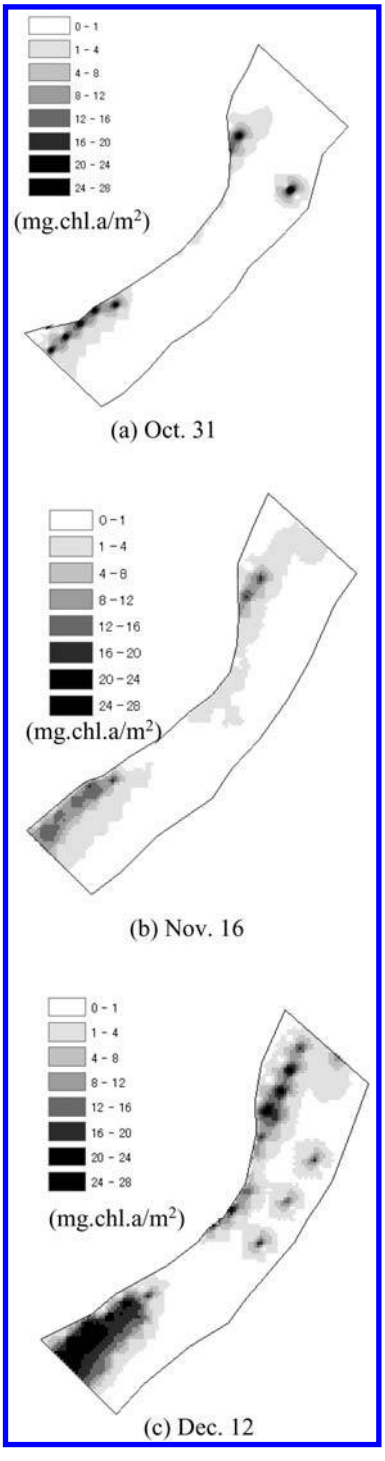

Figure 11. Spatial distribution of periphyton biomass computed.

5 CONCLUSIONS

In the present study, the field observations and the numerical simulations were performed to know the growth characteristics of periphyton in a sand river. The results of the observation and the numerical simulation have revealed the followings;

1) Periphyton can grow on the sand bed river if the bed material sand has not moved.
2) A numerical simulation model is proposed to describe the growth and the spatial distribution of periphyton in sand river. The model can estimate the growth area of periphyton, and the flow characteristics strongly influence primary production of periphyton in sand river.

APPENDIX

The following symbols are used in this paper:

d = grain size of sediment
I_b = daily-averaged solar radiation at river bed
I_{b0} = I_b under fair weather at river bed
I_{bc}, I_{b0c} = half-saturated values of solar radiation
K = environmental capacity for periphyton growth
$K_{\max}$ = maximum environmental capacity
M = periphyton biomass per unit area
N = nutrient concentration
N_c = half-saturated value of nutrient concentration
T = water temperature
T_{opt} = optimal water temperature for periphyton growth
T_c, α_T = numerical parameters representing temperature effect
U_{*c} = critical friction velocity
μ = specific growth rate of periphyton
$\mu_{\max}$ = maximum specific growth rate
τ_* = Shields stress
τ_{*c} = critical tractive force

ABSTRACT: Modifications observed on the hydraulic regime of river systems caused by engineering works led to growing awareness of the impacts caused by these engineering constructions. The need to harmonize and integrate both the hydraulic and the ecological/environmental components has been growing, namely in Portugal. This paper presents the work of a multidisciplinary team that carried out, from 1998 to 2003, an evaluation of the ecological impacts of realignment and construction works implemented at the lower part of Mondego river, in central Portugal, in the 80's. The hydraulic and hydrologic alterations in Mondego river, caused by regularization works, have been analyzed and quantified. The main conclusions of the study are that the changes in the Mondego river geometry induced more homogeneous physical and hydraulic conditions and reduced life diversity. However, the construction of a set of transversal groynes, and discontinuities of the bottom elevation, had an opposite effect. Similar conclusions are reported in the literature.

1 INTRODUCTION

1.1 *River corridors and anthropogenic modifications*

It is very important that rivers are approached to as components of a system that include its bordering and connected environment as well. The understanding of the ecological value of river corridors has been gradually assimilated in the last decades, after observations of the serious damages caused in the past by straight engineering interventions, namely, channelization and changes in rivers cross-section geometry. Modifications on the hydraulic regime of river systems cannot be isolated from the total system that comprehends the river basin, groundwater and the supported ecosystems (e.g.: Brooks, 1988).

Presently it is well known that river biological diversity and productivity are a result of habitat diversity and ecological connections. They are kept and balanced by the dynamic river processes of erosion and deposition which, in turn, depend on the water course hydrologic and sedimentation regimes (Brooks, 1988). Therefore, alterations on any of these physical processes, or a loss of connectivity between any of the three spatial borders of a river, may lead to serious changes on the aquatic communities.

In addition to the spatial variables, a forth temporal variable needs to be taken into account, and it is within these four dimensions that any river system must be comprehensively evaluated and managed (Ward, 1989).

The ecological impacts of dam and diversion channels construction, channelization and changes in the river cross-section geometry, may be synthesized as follows:

i. Significant reduction of habitats diversity, since hydraulic works interfere with the natural continuity of the river physical borders, and make more homogeneous both the river bed and the flooded areas.
ii. Reduction in the native species diversity, caused by the disappearance of the species that depend on seasonal flow differences, and spatial habitat variations to survive. Simultaneously, the exotic species

Copyright © 2006 Taylor & Francis Group plc, London, UK

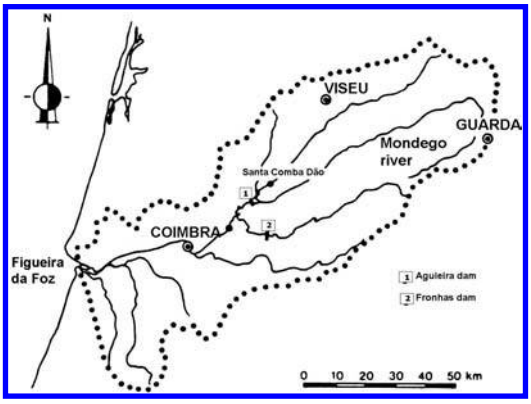

Figure 1. Mondego river basin.

gain a competitive advantage due to the before mentioned alterations.

1.2 *Project framework*

The need to harmonize and integrate both the hydraulic and the ecological/environmental components has been growing since the last four decades. In the past, in Portugal there was a weak connection between such fields of knowledge that today are known to be interdependent.

This paper presents the work of a multidisciplinary team, from two universities (UTAD and ISA) and a state laboratory (LNEC) that carried out, from 1998 to 2003, a study financed by the Portuguese Foundation for Science and Technology. The objectives of the project were to evaluate and quantify ecological impacts of realignment and construction works implemented in rivers. The selected case study was the lower part of Mondego river, in central Portugal (Figure 1), that has been channelized as part of a large river regulation scheme implemented in the 80's.

The study permitted an understanding of the modifications provoked by the river channelization on the local ecosystem. The report by Barbosa *et al.* (2005) presents the study in detail.

1.3 *Study methodology*

The study has been split in different components, being each of the three institutions involved responsible for a sector, as follows:

i) LNEC, in charge of the Project coordination, was responsible for the description of the case study history, including the engineering interventions implement in the Mondego river. The hydraulic and hydrologic alterations caused by the referred to regularization works, have been analysed and quantified by the LNEC team.

ii) LNEC made a literature review in order to synthesize the impacts of river training works, and the concepts of river channelization, restoration and rehabilitation. The aim was to emphasize the need to understand rivers as elements of complex catchment's system that combines surface, subsurface and underground water, quantitative and qualitative variables, all in dynamic interaction, and that are a support to the local ecosystem. The UTAD team put into perspective the importance of biomonitoring results as indicators of the impacts of river regularization works.

iii) The ISA research team was responsible for studying the responses of river plants to channelization, and the effects of habitat disturbance in the ecosystem's invasibility. A comparative study of floral features was conducted among sites in the channelized segment of the Mondego river, and in the near-natural river reaches upstream Coimbra. General differences in plant species composition, distribution and relationship with environment were investigated, with particular attention paid to shifts in richness and cover of native species assemblages, and in the dominance of exotic species (as defined per Richardson *et al*., 2000).

iv) The study of macroinvertebrate and ichthyic communities of the regulated fluvial ecosystem of Mondego river has been the responsibility of the UTAD team.

In order to find out how the hydraulic works in the lower Mondego river affected the aquatic communities (fish and invertebrates) field work campaigns were implemented during June and September of 2000 and 2001. Fauna was sampled and registered and water quality parameters were measured both in the field and in the laboratory.

2 CASE STUDY – MONDEGO RIVER TRAINING AND CHANNEL IMPROVEMENT

2.1 *General description*

The Mondego river is the largest entirely Portuguese river with a catchment area of approximately 6644 km^2. It originates at an elevation of 1547 m in "Estrela" Mountains and flows through a very narrow valley till Coimbra town, where the valley spreads to form a vast alluvial plain, the Lower Mondego region, which consists of 15000 hectares of land with high agricultural aptitude. The river reaches the Atlantic Ocean near the town of Figueira da Foz (Figure 1).

The hydrological regime of the Mondego river is very irregular, with discharges that can be less than 1 m^3/s during several days in a year, and flood discharges up to 3000 m^3/s (natural situation, before river basin interventions). The average annual rainfall is 1124 mm. The river presents torrential

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 2. Flooding in the lower Mondego river.

Figure 3. Mondego river: trained main channel.

characteristics due to the precipitation regime and the strong slopes of the river basin.

Along several centuries, the lower part of Mondego river basin was subject to periodic flooding and many attempts to regulate and channelize the river were performed. The construction of a new river bed downstream Coimbra, at late XVIII century, was kept functional along the years but was judged to be insufficient by mid-XX century due to the erosion of the upper part the river basin and the resulting silting and sanding up of the river and the marginal fields, which caused more frequent flooding of the agricultural lands (Figure 2).

2.2 *River training and flood protection works*

In order to attenuate the annual flood effects (inundation of river banks) thus increasing the agricultural potential of the downstream flood plains, and protect the population, a large river regulation project was implemented in the 80's. This project implied the construction of three large dams: Aguieira, Raiva and Fronhas to control the flood discharges, and a significant training of the river in the lower, flat area of its basin, with the opening of adequately designed channel flanked by unsubmergible embankments, in a distance of about 36 km.

In the design of alluvial bed river training the main objective was to define a dinamically stable channel, i. e., a channel with movable bed where the sediment transport capacity is equal to the equilibrium value.

The main channel (Figure 3) was designed for the modified 100-year flood of 1200 m^3/s (at Coimbra) associated with the 25-year flood of the Lower Mondego tributaries. The bankfull cross sectional geometry is of trapezoidal type. The bottom width varies between 88.0 m and 142.2 m and the maximum depth is 6.5 m. To maintain the desired cross section, the channel banks are protected by riprap with mean diameter of 0.15 mm.

The levees along the main channel have lateral fuse-plug weirs, to permit controlled flooding for discharges higher than the design ones.

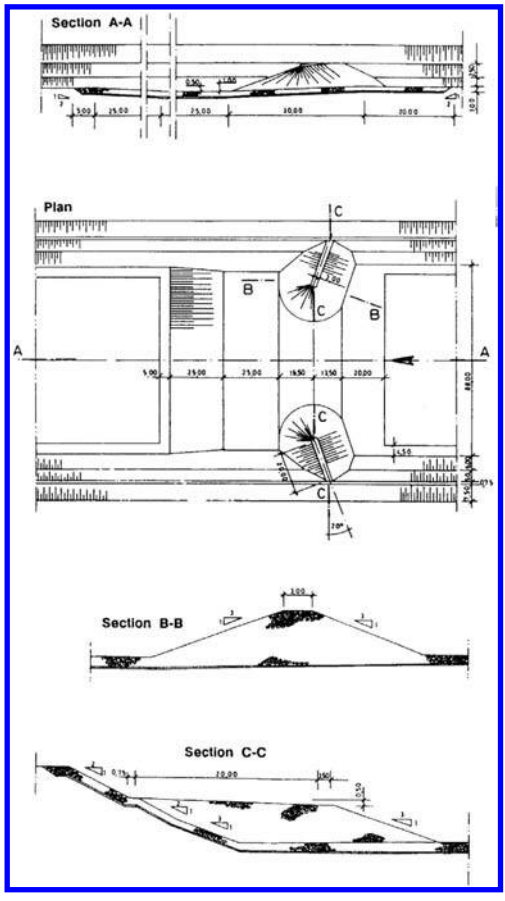

Figure 4. Mondego river groynes. Plan and sections (Lemos *et al*., 1991).

The Lower Mondego river training project included, within an extension of 11873 m downstream Coimbra town, the construction of a set of groyne-type structures, placed in pairs, and combined with discontinuities of the bottom elevation (Figure 4). Groynes

Copyright © 2006 Taylor & Francis Group plc, London, UK

have 20.0 m length and an angle to the flow direction of 70°. Upstream and downstream from each groyne, the channel bed is protected by riprap to prevent streambank erosion.

3 HYDROLOGIC AND HYDRAULIC CONSIDERATIONS

The flow regime of the lower Mondego channelized river reflects the variability of the climate and the physiographic conditions in the river basin and the type of operation of Aguieira, Raiva, Fronhas and Coimbra reservoirs. These reservoirs are part of the Mondego river regulation scheme and are associated with a diversity of water uses (e.g. urban supply, agriculture, industry, energy production). In general, the operation of reservoirs causes changes in either total flow volume or annual distribution of the flow, or both, and in the frequency and magnitude of floods.

To characterize the hydrologic modifications occurred in Mondego river due to the interventions in the river basin two measuring stations were considered: Ponte Santa Clara and Coimbra dam, near Coimbra town. These stations represent the integrated runoff of 74% of the entire Mondego basin and are located immediately upstream the channelized reach of the river.

Historical data from Ponte Santa Clara station between 1939/1940 and 1979/1980 (41 years) was used to analyse the river flow regime before the interventions. This station was discontinued after the construction of Coimbra dam. On the other hand, the period of 1986/1987 to 2003/2004 (18 years) was considered as representative of the present situation (Barbosa *et al*., 2005), after an analysis of the number and size of reservoirs and the date of their construction.

Based on the analysis of the mean daily flows and flood hydrographs some modifications on Mondego flow regime have been identified:

- The average total runoff is 2424 hm^3. This value reflects a slight reduction (14%) in the total runoff due to water diversion for agricultural, urban and industrial supply.
- Although river flows maintain a marked seasonal pattern, there has been a reduction of the monthly mean discharges, between February and June, and an increase of the low flows between July and September. The mean monthly discharges may vary between 16 m^3/s and 205 m^3/s. The flow duration curve presents a more gentle decline, without long periods of zero streamflow, as occurred in natural conditions.
- Aguieira and Fronhas reservoirs ensure the regulation of 80% of the river basin upstream Coimbra town. For approximately 20 consecutive years these reservoirs managed to control the river flood discharges and no inundation of the agriculture fields was registered. However recent flood events (January 27, 2001) have demonstrated that high peak discharges can occur due to the contribution of the many Mondego tributaries. In this event, the maximum flood discharge reached 2000 m^3/s exceeding the design value of the river Mondego main channel, leading to levee failure and extensive flooding of the marginal fields. The flood water remained on the plain for several days destroying many farms and causing severe damages to agriculture.

Concerning the hydraulic conditions on the Mondego river, no information on the trained river bed evolution was available during the present study. However, due to human activities upstream Coimbra dam, namely sand mining, and the construction and operation of Aguieira and Fronhas dams, it is sup-posed that a reduction on the sediment transport had lead to a degradation of the trained mobile river bed.

Accordingly with the work of Belo and Cardoso (1993) significant bed degradation was observed since 1977, in a 33.2 km reach of river Mondego up-stream Coimbra town due to the aforementioned activities.

4 RESPONSES OF RIVER PLANTS TO CHANNELIZATION EFFECTS OF HABITAT DISTURBANCE IN THE ECOSYSTEM'S INVASIBILITY

4.1 *Sampling procedures*

Fito-ecological surveys were carried out in May–June 1999 at six sites placed at regular intervals along the channelized segment and at three sites in the "natural" river. Three longitudinal transects of five 5×25 m plots were laid out at each studied site. The first transect was positioned instream and in the waterlogged margin, while the others were placed on each of the two-stage terraces, whilst the "natural" transects were located in the corresponding areas of the fluvial corridor – i.e. the in-stream and waterlogged margins, inner-bank and outer-banks. The richness and percentage of foliar cover in each plot were visually estimated for each exotic and native species by averaging the results from 2.5×2.5 m sub-plots ($n = 10$ in each plot). Environmental variables that potentially influence the vegetation establishment were estimated for each plot (e.g. substrate, distance from the water) or measured (e.g. conductivity). Site-specific variables were also achieved (e.g. river corridor width).

4.2 *Data treatment*

A correspondence analysis was carried out, so as to evaluate channelization effects by comparing plant

Copyright © 2006 Taylor & Francis Group plc, London, UK

species composition and distribution in 'natural' and channelized plots. The number and foliar cover of native and exotic species were also compared, using non-parametric Mann-Whitney U tests. Data from plots of the channelized river segment were subjected to a canonical correspondence analysis and to a classification using the unweighted pair-group arithmetic average clustering.

4.3 *Results and discussion*

Exotic plant species in fluvial ecosystems are known to be associated with human-disturbance and its establishment and invasive spread frequently conduct to an over-turning of native species assemblages (Hood & Naiman, 2000).

In this study, significant differences in the distribution and vegetation features (richness and cover) were observed, however the number of plant species recorded was very similar, with 150 species present in the 'natural' corridor, 160 species on the channelized part, and 98 were common to both. A small number of exotic species was recorded (around 10% of the total flora), which was coupled with low exotic species richness found per plot (maximum 8 species, average 2.8). However, exotic species were dominant in some plots, especially in the channelized river. *Eryngium pandanifolium*, a swamp-dwelling plant from the South-American subtropical zone, dominated the instream plots and the first terrace at downstream sites, but was substituted by another exotic species, the knotgrass (*Paspalum distichum*) at the upstream ones. The exotic hydrophytes *Azolla filiculoides* and the parrot feather (*Myriophyllum aquaticum)* were also largely disseminated in instream plots. Below the riparian woody vegetation, in shady and wet habitats, dense stands of the South-American species *Tradescantia fluminensis* were established. On the second terrace the increase in exotic cover was due mainly to the presence of the silver wattle (*Acacia dealbata*), a woody Australian species. Knotgrass, silver wattle and *T. fluminensis* were also found at the 'natural' sites, but with the exception of the latter on the inner bank, consistently had a lower degree of cover. Figure 5 presents the comparison of native and exotic species cover between the "natural" and channelized river segments, at the three transects.

Aguiar *et al*. (2001) pointed out two potential reasons for the channelized river's higher susceptibility to exotic invasion. Firstly, the strong disturbance of the physical environment caused by the channelization, regulation and expansion of the irrigation area led to new and favorable environmental conditions to invasion, including a reduction in the intensity and frequency of scouring floods and an increase in the fine sediment and nutrient load. Secondly, the synergistic effect of higher propagule pressure and the successful dispersal capability of the exotic species that were already present.

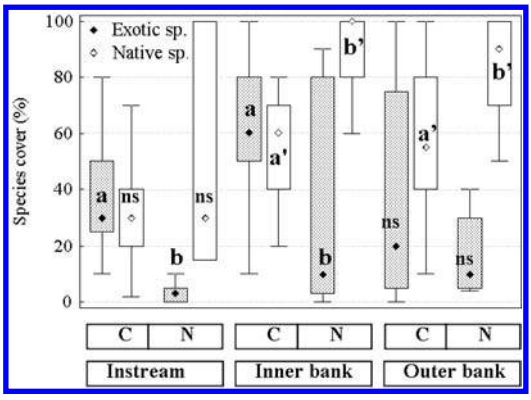

Figure 5. Comparison of species cover for exotic and native species between the channelized (C) and the "natural" (N) river at the three transects. Median (black or white lozenge), non-outlier range, and 25%, 75% percentiles are represented. Columns with different letters indicate significant differences at $p < 0.05$, using Mann-Whitney U tests for comparison tests, within each group of species (a′, b′ for native species, and a, b for exotic species; ns = non-significant test). Note that inner bank and outer bank corresponds to 1st terrace and 2nd terrace for the channelized segments, respectively.

The riparian woody species have rapidly recovered after the channelization project, and the structure and composition of the riparian woody layer of the first terrace, is rather similar with the riparian gallery of the "natural" river, however overstorey herbaceous species had a varying composition, whilst the vegetation of the 2nd terrace clearly diverges in species composition from the "natural" area. This experimental evidence can be related with the loss of interactive pathways, which are maintained in non-impacted floodplain rivers, namely the vertical and lateral connectivity with the river channel (Ward & Stanford, 1995). In the channelized segment of Mondego river, the first terrace is located 2 m above the water, and the original river connections were preserved, but the second terrace, which is positioned 4 m above the water, led to the likely disruption of vertical and lateral interactions with the river channel.

Figure 6 presents the canonical correspondence analysis biplot of the channelized segment data (sites from 1 to 6, with 1 being the site closer to the estuary and 6 the most upstream site), with the selected variables obtained by a forward selection procedure. The first axis clearly represented a transverse gradient of moisture (water→terraces), whereas the second axis displayed the longitudinal gradient of the river (upstream→downstream). Conductivity and channel depth were also aligned with the distance

Copyright © 2006 Taylor & Francis Group plc, London, UK

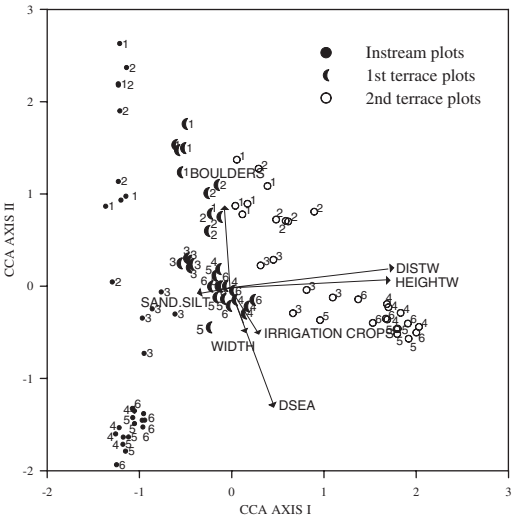

Figure 6. Axis one and two of the canonical correspondence analysis biplot using the floral composition of the channelized Mondego segment. Numbers indicate sites (each site with five plots per transect). Substrate: BOULDERS – boulders (%); SAND.SILT – sand and silt (%); WIDTH – channel width (m); DSEA – distance to the sea (km); DISTW – distance of the plot to the water (m); HEIGTHW – height of the plot above water (m); IRRIGATION CROPS – land use on the site surroundings: irrigation crops and rice fields (adapted from Aguiar *et al*., 2001).

from the sea, channel width and irrigated cropland. Site 3, approximately in the middle of the channelized river is a transitional zone in terms of species composition.

Differences in species composition within and along the channelized segment can be observed, regardless of the same engineering procedures and materials used in the channelization process. This suggests the development of microtopographic variations and habitat patches that influenced vegetation establishment, associated with differences in adjacent land-use along the impacted river, and the diverse existing species pool.

5 STUDY OF MACROINVERTEBRATE AND ICHTHYIC COMMUNITIES OF THE REGULATED MONDEGO RIVER FLUVIAL ECOSYSTEM

5.1 *Sampling sites*

Three sampling sites were set in the regularized central bed of the Mondego river (M2, M3, M4), between Coimbra and the river mouth (Figueira da Foz), and

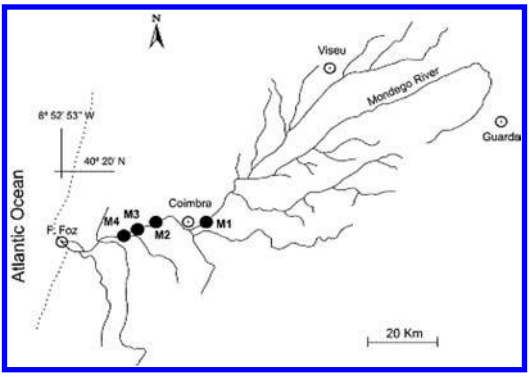

Figure 7. Location of the sampling sites within the Mondego basin. M1 – Reference site; M2, M3 and M4 – Sites on channelized sector.

one located approximately 14 km upstream of Coimbra (M1) – (Figure 7). This last one, was a control site since it was not affected by channelization, although it is located approximately 20 km downstream of the Aguieira Dam. This site has well developed riparian vegetation on the left bank. In contrast, the right bank presents scarce vegetation due to its clear cutting and to the high deposition of materials (small stones, gravel and sand).

The sites in the artificial segment exhibit extensive riprap along the banks, with constant slope of 45°, partially colonized by shrubs and trees (mainly *Populus* spp.). Medium fraction materials (stones and gravel) dominated the riverbed, but were replaced by a lower grain size fraction in the second part of the study after the flood events of 2001. M2 showed a semi-disaggregated groyne with resulting shear stress in the wet channel. A more detailed description of the different characteristics of each meso-habitat is in Table 1. Macroinvertebrate (M) and fish (F) sampling was carried out simultaneously in June (the 6th) and September (the 9th), of 2000 and 2001. Physical and chemical parameters (dissolved oxygen, pH, temperature, conductivity, alkalinity and total suspended solids) were also analysed at the sampling sites during the same periods (Table 2).

5.2 *Benthic macroinvertebrates communities*

Benthic invertebrates were collected from reaches of approximately 100 m in length during a fixed time of 5 minutes (CPUE) by disturbing the substratum upstream of the net using a vigorous kicking and/or feet action. The sampling was performed using a 350 μm mesh net with 600 cm^2 aperture and embraced all the existent biotopes, with an effort proportional to the relative importance of each habitat

5.3 *Ichthyic communities*

In contrast with benthic collections, fish sampling allowed the discrimination between habitat types in order to detect the influence of hydraulic structures and erosion sedimentation processes (Table 1). Fish were captured using na Electrocatch apparatus, model WFC7-HV, powered by a generator (Honda GX160) of 4.0 KW. Electrofishing used DC current and the voltage was set between 150 to 200 V in order to produce a current from 2.5 to 4 A. This fact, together with a constant capture effort of 7 minutes in each meso-habitat (CPUE), allowed comparable results among the different inventoried habitat types. Electrofishing captures were complemented by 30×2.5 m static multimesh gill net (mesh types: 32 mm, 43 mm, 50 mm, 65 mm and 85 mm), which was placed in the deeper pools for 3–4 hours.

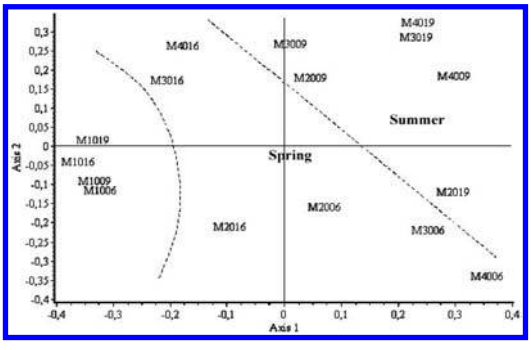

Figure 8. MDS ordination of sampling sites based on benthic invertebrates. Example: M1006 means reference site (M1) sampled in 2000 (second and third code's cypher) in June (last code's cypher).

5.4 *Data treatment*

To compare sites and periods for both sampled communities, the total number of individuals and Shannon diversity index were computed through PRIMER 5.2.2 (Clarke & Gorley, 2001). Multivariate methods were used to detect the spatial and temporal patterns underlying the biotic and abiotic data. Metric Dimensional Analysis (MDS) was used through the package SYN-TAX 2000 (Podani, 2001) and non-Metric Dimensional Analysis (n-MDS) through PRIMER 5.2.2 (Clarke & Gorley, 2001). N-MDS operated on a sample similarity matrix of the Bray-Curtis coefficient instead of the original data matrix, converting the similarity values to rank order (in order to preserve the original relationships between samples). MDS is a related technique, in the sense that it also uses a distance or dissimilarity matrix but, on the contrary, it assumes the existence of linear relationships between variables. The data files were not transformed to enhance the effect of the density variation of organisms among sites.

5.5 *Results*

5.5.1 *Macroinvertebrates communities*

The differences between the reference site and the channelized sector, and the potential effects of the floods in the macroinvertebrate communities were assessed through MDS ordinations of sampling sites. Figure 8 shows a clear separation of the reference

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 9. n-MDS ordination of sampling sites based on benthic fauna. In each site was overlapped one circle with proportional radius at relative importance of the sand on the substrate. Abbreviations of the sampling sites are given in Figure 7.

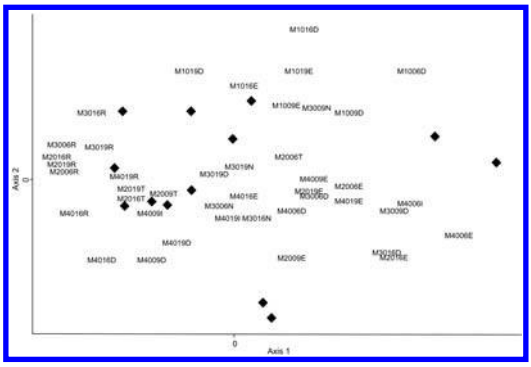

Figure 10. MDS ordination of sampling sites and habitats based on ichthyic communities. Symbols represent fish species. Abbreviations of the sampling sites are given in Figure 7. The last code refers to habitat type (D – right bank, E – left bank, T – groynes, N – riprap, R – nets and I – sand bank).

site (M1) relative to the channelized ones. This site presents, a specific benthic assemblage, characterized by different caddisflies (*Polycentropus* sp., *Plectrocnemia* sp., *Tinodes waeneri*) and stoneflies (*Leuctra fusca*) taxa. On the contrary, some Heteroptera (*e.g. Gerris lateralis* and *Micronecta* sp.) show a preference for the modified sector.

A clear seasonal separation of the sampling sites is another important aspect displayed in Figure 8.

This fact demonstrates the high capacity of recovery of the system since inter-annual differences are obscured by seasonal ones. The importance of riverbed materials in explaining the dynamics of benthic assemblages is illustrated by Figure 9. Here, we can link these changes to the winter peak flows, which cause an extensive deposition of fine sediments, especially clear in site M2. The reduced *stress* value obtained by the n-MDS ordination (0.08) demonstrates a good representation of the global variance.

In the reference site the diversity of benthic organisms was, in general, superior when compared to the channelized sites before the flood events. After this phenomenon, diversity decreased in the reference site, while the total number of individuals did not suffer strong variations. However, in the channelized sites (M2, M3 and M4), the extreme flows were probably responsible for the drastic reduction in invertebrate abundances. Nevertheless, the diversity was not substantially changed in these sites.

5.5.2 *Ichthyic communities*

A total of thirteen *taxa*, six of which were Cyprinidae, were recorded. This family, besides barbel (*Barbus bocagei*), includes three Iberian endemisms (Iberian nase – *Chondrostoma polylepis*, Portuguese roach – *Ch. macrolepidotus*, chub – . *Squalius carolitertii*), and two introduced species (goldfish – *Carassius auratus* and gudgeon – *Gobio gobio*). *Cobitis paludica* was also recorded. Aside from these, two other exotic species were recorded: eastern mosquitofish (*Gambusia holbrooki*), and the centrarchid pumpkinseed (*Lepomis gibbosus*). The migratory diadromous fish species identified were the anadromous sea lamprey (*Petromyzon marinus*), the twaite shad (*Alosa fallax*), the catadromous European eel (*Anguilla anguilla*), and the thinlip mullet (*Liza ramada*).

The influence of floods and channelization on the abundance and diversity of ichthyic communities was not conclusive. However, Figure 10 suggests that the two types of sites (channelized *versus* non-channelized) support different communities. In fact, *Ch. macrolepidotus*, *Gobio gobio* and *Squalius carolitertii* are more represented in the reference site, whereas *B. bocagei* and *Ch. polylepis* are common in both sectors (channelized/non-channelized). The other species (including the exotic ones) are restricted to the artificial segment of the Mondego. The fish populations were discriminated by the meso-habitat in each station, which is also represented in Figure 10. A lack of inter-annual differences may be concluded from this observations, demonstrating a high resilience of fish populations to extreme hydrological events.

It is also possible to see from Figure 10 that a higher number of species exhibit preferences for the meso-habitats T and N (groyne and riprap, respectively). Similarly, a higher density of the majority of species is observed precisely in these habitats.

5.6 *Discussion*

The entire new channel created in the Lower Mondego, after dredging and re-sectioning the old one, and transforming the natural banks in extensive dykes covered by riprap, affected the heterogeneity of habitats with repercussions on different fish and benthic

Copyright © 2006 Taylor & Francis Group plc, London, UK

composition, and had a detrimental effect on species diversity (Ward & Stanford, 1983; Cortes *et al*., 2002). The lack of intolerant species (with high oxygen and low levels of nutrient requirements) in artificialized sectors was replaced by benthic communities with short life cycles which can be explained by the reduction of available or suitable habitat, especially when the channel reflects hydro-geomorphic changes as pointed out by Maitland (1990) and Erskine *et al*. (1999).

Infrequent events, which are regarded as being catastrophic because of their immediate effects on ecosystems or on human activity, are capable of leaving long-lasting traces. In this respect they can affect the organization and composition of the patchwork. In spite of resulting from strong disturbances, flood "scars" generally heal quickly; major floods do not disturb the structure and functioning of the patchwork (Bravard & Gilvear, 1996). The most impressive aspect of the effects of floods on aquatic insects is not the devastation of the fauna that occurs, but rather the remarkable ability of species to recover from such severe perturbations (Ward, 1992). The floods that occurred in the winter of 2000/2001 caused substantial alterations in the fluvial dynamics. The increased transport of solid material originated a strong sedimentation of unstable fine materials, leading to a biological impoverishment and alterations in the functioning of the system. Macroinvertebrate communities underwent a substantial reduction of abundance, with larger incidence in channelized sectors, where sedimentation was higher. Nevertheless, despite the floods, macroinvertebrate communities displayed a high resilience, as obtained by Ortega *et al*. (1991) after a flood in the basin of River Segura (Spain). Macroinvertebrates respond to spatial and temporal variability by changes in the structure of their communities. They show tremendous diversity in their life history patterns, including variation in life cycle length, developmental strategies, and seasonality of the various life history stages (Greenwood & Richardot-Coulet, 1996). Such traits explain also the seasonal variations, which were very clear in the Lower Mondego, probably because in changing environments there is a dominance of short-lived species (Hershey & Lamberti, 1998). Ichthyic communities did not show clear inter-annual or seasonal differences. Moreover, the natural hydrological disturbances seemed to produce a low impact. Roux & Copp (1996) argue that the importance of hydrological variation is necessary to complete the biological cycles and that only frequent flow peaks disrupt these communities.

6 CONCLUSIONS

It is generally known that channelization of river courses leads to a decrease in microhabitats. Therefore mitigation structures providing habitat heterogeneity must be installed immediately after channelization (Brookes, 1988; Armitage, 1995).

This study evaluated the environmental impacts resulting from regularization of the Lower Mondego river, in central Portugal. It has demonstrated the impacts of human-disturbance in the vegetation establishment at the channelized segment, with the generalized increase of exotic species richness and cover, and a native displacement of herbaceous vegetation, diverging from the riparian woody species, which has shown a high resilience to intense, but discontinuous habitat alterations.

Concerning the macroinvertebrates it was observed a clear separation between the reference site and the channelized sectors. For instance, some Heteroptera showed a preference for the modified sector. The role of channelization on the abundance and diversity of the ichthyic communities was not conclusive.

The main conclusions concerning the case study are that most of the changes in the Mondego river geometry induced more homogeneous physical and hydraulic conditions and reduced life diversity. However, the construction of a set of transversal groynes and discontinuities of the bottom elevation had an opposite effect. These results are similar to findings reported in the literature, for instance Brookes (1988) and Torre (2001).

For this particular case Vieira & Ferreira (1997) and Silva-Santos *et al*. (2004) argue that the use of groynes and riprap in the Lower Mondego was environmentally positive. All these mitigation structures in channelized reaches increase the heterogeneity of available habitats for the aquatic communities and have been applied to restore streams all over Europe (Nijland & Cals, 2000).

The study also confirmed that biomonitoring over time is a precious tool for integrated river management.

Methodology and techniques for urban river rehabilitation

J.S. Rocha
Portuguese National Laboratory for Civil Engineering (LNEC), Lisbon, Portugal

ABSTRACT: The rehabilitation of urban rivers is a complex process that requires the knowledge of the adequate hydraulic techniques, and its relations with other type of interventions and constraints in the urban area and in the drainage basin. The paper describes the fundamental steps in rehabilitation of urban rivers.

For the definition of the site the three basic hydromorphological elements described in the Water Framework Directive (WFD) should be considered: the hydrological regime, the river continuity and the morphological conditions.

An extension of the strategy to recover "natural" conditions is presented: the aim is not to obtain the original conditions but rather to establish hydrological and morphological conditions that support all river functions. If this process is not scientifically sounded, the probability of achieving long-term self-sustaining river system will be compromised, as new problems will appear in the future and additional interventions will be maintained in the "new" river.

1 INTRODUCTION

The rehabilitation of urban rivers is based on the application of adequate river techniques. At same time, the use of river techniques must be in accordance with other type of interventions on urban areas.

When the river channel has not suffered significant modifications on urban areas only measures for river basin are to be used. Rarer is the case where there are no modifications in the river basin; this may happen when an urban area is situated near a large river, where only the interventions on river channel are done, and the urban area is a small percentage of the entire river basin area. In this case only measures on river channel and banks are needed. The general situation is to apply both types of measures.

This paper briefly describes the fundamental steps in rehabilitating urban rivers, according to the URBEM project activity chart: site definition, formulation, strategies and the development of technical options for urban river rehabilitation, description of consequences of urban river rehabilitation and the monitoring of rehabilitated urban river. This is a subset of the more general river rehabilitation, well documented in several works in last decade, such as FISRWG (2001) and Doll (2002). The specific case of urban river rehabilitation may be found in Tourbier *et al.* (2005).

The objective of the URBEM research project was "*to develop innovative urban watercourse rehabilitation techniques for use in future schemes*". The rehabilitation of urban rivers includes the knowledge of adequate techniques and its relations with all needed type of interventions, both before and after the implementation of techniques. The technical interventions are divided in two main groups: interventions to be practised in the drainage basin, controlling the hydrological processes, and interventions to protect, maintain and improve the hydromorphological conditions in stream channels (controlling the hydraulic processes in bed and banks).

2 SITE DEFINITION IN URBAN RIVER REHABILITATION

The site definition within the URBEM case studies has displayed both subjective and methodological approaches. In most case studies, about 70%, the sites were defined with existing knowledge, no selection method being applied, Schanze *et al*. (2005).

In the remaining case studies, the site definition is based on a selection method. But these definitions have been determined by three different specific and complementary reasons: city wide, river network based or basin wide assessments.

The site definition will be made by two different main processes, related with the main scope of the intervention, being therefore associated with the technical aspects of river rehabilitation.

One of the main processes is focussed in the river itself, although some urban aspects are necessarily included. In this process the driving forces are on the River Basin Administration or equivalent institutions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The main object is to rehabilitate the river, situated in an urban area, taking into consideration the target, i.e. a better river, and by consequence also a better urban in the adjacent area, as well as better banks and flood valleys. In this case, it is natural to find an emphasis on the river techniques. A joint work with city administration is needed.

The other main process is focused on the urban rehabilitation near an existing bad river. The main object is to rehabilitate the city, situated near a river, taking into consideration the target a better city, and by consequence also a better river passing there, with its banks and flood valleys being seen as urban zones. In this case, it is natural to find an emphasis on the urban techniques. A joint work with River Basin administration is needed.

The site definition for these two main processes is not the same, although some aspects are necessarily present in both.

When the rehabilitation of an urban river is initiated, it is necessary to define the river reach. There are not strict rules to define the site where the rehabilitation is to be implemented.

However, using the Water Framework Directive (WFD) terminology, it is possible to establish simple criteria to define the site where the rehabilitation is to be done. Considering the type and intensity of efforts to be used in the rehabilitation it is possible to differentiate the type of intervention, and consequently the site definition.

The first basic distinction is the

1 Instream river rehabilitation;
2 River basin rehabilitation (either including or not the instream).

The instream river rehabilitation is concentrated on the main channel, and on its lateral adjacent zones where the flood pass. The site definition comprises, at least, the definition of the downstream and upstream cross sections. This is relatively straightforward but only an expert in flow regimes can find the appropriate cross sections to tackle the hydraulic aspects.

The definition of the adjacent areas, equivalent to the flood prone area, is relatively more difficult, being advisable to use a step by step approach, unless previous data gives directly the right definition. An accurate definition is costly and time consuming. At a first guess a rough definition may be done with the analysis of geomorphology and geology maps, or with the help of the inhabitants, by knowing the history of past river floods, or by analysing existing flood marks.

The other more accurate definitions for the flood prone area will be done based on hydraulic modelling of present, past or future situations. The hydraulic modelling needs good river data to guarantee reliable results. The calibration and validation of hydraulic modelling will be vital because it is the only way to succeed in the proposed river rehabilitation.

For hydraulic modelling, it is necessary to define the contributing river basin. That definition is only required to determine the river discharge to be used in the computation. In some cases the river basin is entirely outside the urban area, whereas in other cases, it is precisely the opposite, i.e., all the area is in the urban area. These two limiting cases are quite different, as far as the implications to the study are concerned. The latter case may generate a chain of scenarios for the reciprocal influence of river basin and instream.

The river basin definition is relatively simple, from a conceptual point of view, it consists of determining the river basin boundaries, where the river processes are generated and transported to the river channel. Indeed, the river basin, a spatial area where complex physical, chemical and biologic processes are generated and transmitted downstream, may also be viewed as a network of small streams going from the river basin boundaries downstream to the lower cross section where the river basin is defined.

In URBEM, it was proposed that the definition of the site should include the three basic hydromorphological elements described in WFD: the hydrological regime (quantity and dynamics of water flow and connection to groundwater bodies), the river continuity and the morphological conditions (river depth and width variation, structure and substrate of the river bed and structure of the riparian zone). Therefore for the site definition it will be necessary to gather all pertinent data related with the above mentioned elements. As each element may impose different types of control and influence on the river system the site limits may not be unique. Consequently, it is not easy to obtain general and simple criteria to help find the border cross sections for the site.

The river basin definition in an urban area may be complex, the sub basins being difficult to find, and the relations between surface processes and under ground networks generating and transporting to the river channel both water and different pollutants, which are not entirely identified for all areas.

In most cases, the river basin is entirely within the urban area. The development of the urban areas creates pressures on river. The WFD also imposes "*the collection and maintenance of information on the type of the significant anthropogenic pressures to which the surface water bodies in each river basin district are liable to be subject*" (Annex II, 1.4).

3 FORMULATION OF RIVER REHABILITATION

The following three steps are recommended to formulate the urban river rehabilitation: 1) to assess the

Copyright © 2006 Taylor & Francis Group plc, London, UK

present situation, including the river basin and the river channel and bank elements; 2) to assess the previous situation, by two alternative ways – (i) the real previous river regime is obtained by gathering a data base and historical facts and documents or (ii) a previous reference situation is obtained by comparison of neighbouring unchanged river basins or by theoretical reasoning and 3) to compare both situations in order to obtain the synthesis of the modifications imposed, during all history, by the presence of urban areas in the river basin.

The identification of the modifications occurred on the river is the basis to define the interventions to be applied to the river rehabilitation.

From the knowledge of hydrological regime and the discharges for different time and space situations, it is possible to characterise the flow conditions in the river channels.

The characterisation of channel flow processes is to include the characterisation of bed and banks and the hydraulic structures. The only way to collect the required data is to survey the site. For important structures the design documents should be referred to, in which hydraulic computations may be included.

To characterise flow regimes and modification of flow regimes in urban areas, the main definitions of physical processes in rivers may help to define spatial and time-scale boundaries. The characterisation of flood plains in rivers is related to the definition of lateral boundaries. The urban drainage systems on rivers provide information on the urban systems that, to some extent, are boundaries for the river system.

The definition of spatial extension of the assessment is to take into account the relative spatial scale of the river and urban areas. In the URBEM project it is recognized that "*river width is a geometric parameter that has a strong influence on the interrelationships between the river and the city. It influences the scale of the river corridor and the waterfront and its uses, the accessibility network, the transponibility, traffic and many other factors in the urban/watercourse environment*".

Indeed, the scale and size of an urban watercourse within the urban morphology is a very important relationship. The river width has been chosen in the methodology of classification of the aesthetic values as one of the starting items for selecting the case study, due to its relevance in the urban context.

The width of a river is a good measure of the importance of a river, and is strongly correlated with many aspects of river system and river basin upstream feeding water, sediments, and other water constituents. It is possible to present an available quantification of the river characteristics based on the order of the rivers. It was observed that the order of the major part of the rehabilitated rivers is between fourth (IV) and ninth (IX) orders. That means with river basin areas and river lengths ranging from 2 km^2 to 300 km^2 and from 2 km to 50 km, Rzhanitsyn (1960).

The modifications in the river net are highly dependent on the space scale of the two areas, the river basin area and the urban area. In urban river rehabilitation, different cases can occur, and for each case different spatial extents of assessment are necessary, Rocha & Alves (2004).

Case 1 – Urban area much smaller than the river basin

The consequences for river modification, during past times, are minor except on the part of the catchment area where the urban area is settled. In this case, only a part of the river may be changed during the past.

Case 2 – Urban area covering the major part of the river basin

The urban influence on the river may be more or less important depending on the location of the urban area is located in the catchment. If the urban area is in the upstream part of the catchment, it might significantly alter the river network in the whole catchment, not only in the urban area, but also in the downstream part. If the urban area is in the downstream part of the river network the consequences to downstream will not be felt, and the urban area will receive a natural river network in the upstream border.

Case 3 – Urban area covering the entire river basin

In this case, usually the river net becomes completely artificial. Indeed, the large towns may occupy more than one river basin. The spatial extension of the river basin is practically coincident with the urban area.

The river network may be extremely disturbed in orders I and II of the stream, because the urbanisation might have destroyed the natural river network. Artificial channels for mixed sewage system and storm water system are built and they quickly drain water from non-permeable urban areas. Many streams have a very limited water flow. Since artificial piping systems and culverted streams have a lower permeability, during some flood events the roads may change into temporary streams. Consequently, the definition of boundaries, either in river network or in river basin areas, is not straightforward in heavily occupied urban areas. The careful analysis of detailed maps and field surveys are needed for a good definition of boundaries for river rehabilitation in urban areas.

In the river environment, the time scale is associated to the river size. The hydrologic processes in a river have times dependent on river basin size. For very small river basins, the significant times range from a few minutes to a few hours. It means that the rain events and associated flow discharges are running in times of order of rain event time and its multiples. For small river basins, the hydraulic events have generally times less than one day. The peaks of river discharges are sharp in a time-discharge graphic and the water level variations along time are fast.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Same processes in larger river basins have a similar variation type but now considering time values increasing from hours to days as the river basin size increases.

However, the presence of two extreme seasonal conditions, the wet period with a large amount of rain, and the dry period with absence or small amount of rain, leads to consider a second time scale for analysing the hydrologic and hydraulic processes, the seasonal variation, and also the monthly variation of hydrologic and hydraulic parameters.

The hydrologic and hydraulic processes vary also year from year. That variation will be analysed in long term time series, with a monthly or daily discrimination.

The river alluvial beds are moved by the successive river regimes along the years. For that particular analysis, it may be necessary to consider even larger time scales, being possible to arrive to centuries as a basis for the definition of river bed trends in the past, and also for the future.

The conclusion is the need to include multiple times scales to set the time boundaries of river rehabilitation. The time scales in river processes are accompanied by equivalent time scales in urban activities: from short time activities, such as emergency actions during dangerous flood events, to daily actions in the everyday life of a city, like garbage collection, cleaning of streets and of river banks; seasonal actions like flora activities; yearly actions like planning, building activities; and finally, to average and long term activities like urban plans or trends in society.

Consequently, the definition of time scales of plans and of detailed projects for river rehabilitation may be different. All time scales will be included in comprehensive river rehabilitation projects, to avoid overlooking any important subject. In small river rehabilitation projects, with some few details in river and urban parts, only one time scale can be used, as for instance in a small intervention in a cross section of a river, where there is only enough instantaneous flood discharge for the project. But, for the same example, if an alluvial river bed is present, it will be advisable to consider the time scale for long period analyses, such as a few decades trend.

If besides a physical intervention, on the hydromorphological features of an urban river, other interventions are performed on the water quality and on the ecological elements of the urban river, it will be necessary to include year time scales. The latter are to cover the daily river discharge variations along the year, or years, because both river processes are very sensitive to river discharge variations and also to the variation of climate parameters (temperature, radiation) along the year.

After the definition of spatial and time boundaries, it is possible to determine the resources for assessing and formulating river rehabilitation. For smaller space scales and longer time scales, the needed resources will be more significant. Of note is the fact that since, in general, different expertise fields are associated to different time scales, multi disciplinary teams will be used in the analysis of river problems.

In the proposed methodology the definition of success indicators and acceptability criteria will be included in the formulation of river rehabilitation.

4 STRATEGIES FOR RIVER REHABILITATION

The main technical strategies for the urban river rehabilitation, or for urban rehabilitation including a river, are the interventions at one or more levels, considering the rationale of the WFD:

- Hydromorphological;
- Water quality;
- Biological.

Also the intervention may be done in one or more of the following situations:

1. Instream river rehabilitation;
2. River basin rehabilitation;
3. Urban area rehabilitation with some or all components of passing rivers.

The strategies for urban river rehabilitation must include the appropriate isolated or combined types of interventions to rehabilitate river and urban areas together, Rocha (2005).

The fundamental question concerns the strategy for the river rehabilitation. Is the aim to renaturalise the river just as it was before the urbanisation? In Europe, this means that there is the intention to recover centuries of history. Only in rare cases this is an attainable strategy.

The most common strategy is to restore some aspects of the previous river environment. The main scope of river rehabilitation must be to obtain good combinations of interventions to restore as much as possible the "natural" conditions of the river.

The "natural" river conditions are very difficult to define. A relative broad set of conditions is possible, which turns it into a fuzzy concept. Consequently, even in a team of river experts, different strategies will be raised, and therefore, it will easy to find different parallel strategies. The combination of strategies for the river itself with other strategies of urban rehabilitation, when applicable, leads to numerous options for the rehabilitation.

Mention must be made of the fact that it is possible to consider an extension of the strategy to recover "natural" conditions: not to obtain the original conditions but rather to obtain completely new conditions where

Copyright © 2006 Taylor & Francis Group plc, London, UK

the natural forces and processes are used to "create" a river environment like the natural one. We may rather designate this river rehabilitation more as "river creation". When this process is not scientifically sound there will be problems to solve in the future, because additional interventions will be needed to maintain the "created" river. The problems may arise easily in the morphological interventions and in the ecological interventions. The corrections for the first one tend to be costly, when compared to the second one. Moreover, the interventions in the water quality are easily done and with lesser doubts in the results, although they can have higher costs when compared with the other two.

The physical constraints are yet to be identified. There are different types of physical constraints: some are associated to the river channel (like minimum or maximum admissible hydraulic parameters, singularities on the river bed, compliance with water quality standards, ecological maintenance, etc.) or to the river basin (permission on or not to carry out water transfers, maintenance or not of some land covers, etc.). Other constraints are associated with urban features (historical buildings or infrastructures, administrative subjects, social status, etc.). Some of the constraints are self explanatory, but others are only known by expertise studies. This sets the ground for debate, because these do not seem to be constraints for some in opposition to others. Again, the identification of constraints is a multidisciplinary work, and the final list of constraints is not a straightforward task, but rather an iterative task, implying some consultation outside the teams, Rocha (2004a).

In URBEM project, a minimum of 29 parameters was proposed to deal with techniques for river rehabilitation. They are divided in 23 related with WFD, 3 with social aspects and 3 with economic aspects. The 23 ecological parameters are divided into 11 for hydromorphological aspects, 8 for chemical aspects and 4 for biological aspects, Tourbier & Gerdorf (2005).

The proposed parameters generally agree with the parameters and indicators proposed in other aspects of rehabilitation interventions, such as success indicators and monitoring.

5 DEVELOPMENT OF TECHNICAL OPTIONS FOR URBAN RIVER REHABILITATION

5.1 *Identification of technical options*

The identification of technical options is mainly an expertise task to be done by a multidisciplinary team covering a large spectrum of skills. Even in the case of a small in stream intervention, a broad overview of different aspects shall be taken into consideration, namely the imposed constrains by the presence of the city, and the public participation, saw as input of data and assistance to decision-making.

The maximum of technical intervention is associated to the description of the consequences. The modelling of consequences is essentially a technical aspect.

To obtain a good set of potential options professional advice must be seek when drawing up a list, Rocha (2004).

Within an urban context there are often constraints that limit the potential for river rehabilitation. The situations that can potentially arise are so diverse that it is not possible to list all the potential constraints that have to be considered.

The following two steps are recommended to identify options for urban river rehabilitation:

1 To choose the measures to be designed for the river basin or/and river channels and banks. The measures have the effect of recovering the previous situation. The more common attitude is to mix measures in an appropriate balance, in order to minimise disturbances to the consolidated urban areas and costs.
2 To design the measures chosen to quantify the interventions, the amount and type of work, costs, duration of the intervention, and so on. The quantification of costs and the detailing of the intervention may raise important questions leading to new choices of measures or to new design for measures. Iterations are expected until a consensual design is obtained.

The assessment of deviations from an ideal state is the basis for the conceptualisation of the rehabilitation of the current urban rivers. Known the actual urban rivers and defined the goals for the interventions, a general procedure will be defined for the interventions in the stream channels, considering that other types of interventions may be simultaneously present at same time.

Measures for a drainage basin and a river site need to be combined in turn, forming "treatment trains" of measures that supplement each other to meet planning targets. The conceptualisation is followed by a pre-design and a final design for construction, in which the measures are designed to meet the particular conditions of a site.

The classical solutions are described in many Manuals and may be quantified. The quantification of the elements of the solutions is essential to determine the likely costs.

To achieve the "good ecological potential" of urban streams a new approach is required. A more natural approach needs to be taken to manage and design channel form and function. In the past, many rivers were stabilised and hardened with concrete and steel

Copyright © 2006 Taylor & Francis Group plc, London, UK

in order to accommodate navigation and to protect urban uses from flooding and erosion. River shorelines were typically designed for a single purpose. Today, there is a growing support for ecology and multiple uses as well as an interest in using "soft engineering" of shorelines at appropriate locations. Such an approach incorporates flood conveyance concerns, aquatic habitat, riparian habitat, water quality, recreation and aesthetics.

Stream bank protection designs that include vegetation satisfy these multiple objectives. Natural channel design can be well accomplished with soil-bioengineering measures that use a combination of living plant material and mechanical means to achieve specific engineering functions.

However the "soft engineering" has limitations and the classical river engineering must always be present in most cases, because some types of measures do not have alternative.

The specifications of the river engineering interventions are divided in five groups considering different aspects of the rivers.

The first group is dedicated to an important characteristic of the urban rivers: these were in the past confined by revetment of the natural riverbed and riverbanks, being in extreme cases covered by panels, which completely hid their presence.

The three following groups are based on the three main views of the rivers: cross sections (bed and banks), longitudinal profile and plan form.

Finally, in the last group some singularities are considered, most of them related with infrastructures like bridges and hydraulic works.

The identification of options will run the different aspects of the actual river status to design the future and desirable status, according to the previously defined objectives.

5.2 *Bank and bed protection*

In hard paved river beds, a layer of natural substrate can be placed on the existing lining or might completely replace the artificial material. Sand, gravel and cobble are placed into the wetted perimeter of streams that are lacking this bed load. The goal is to protect the channel bed from further degradation, to increase habitats for aquatic life forms and to provide spawning areas for some fish species. Sediments, corresponding to the natural size and shape composition are the preferred bed material.

The main interventions on river profiles are done to decrease the bed slope or to decrease only the water surface slope, maintaining the bed slope. The alternative of increasing the bed slope is much rarer, unless in very short lengths, associated to the general decrease of river bed.

The more common option is rock slope protection. This kind of protection, called riprap, consists of rock pieces placed upon the embankment. Rock, as a slope protection material, has a number of desirable features which have led to its widespread application.

Another common flexible type of armour protection is the gabion. Gabion revetments consist of rectangular wire mesh baskets filled with stone. There are two types of gabions: wall type and mattress type. In the wall type, the empty cells are positioned and filled in place for walls in a stepped fashion. Wall type revetment is not fully self adjusting but has some flexibility. When the gabion has a small height (thickness) it is designated by Reno mattress. This confers a relatively high flexibility, very important to suit to bank movements.

Point protection is performed at pockets along stream banks that pose problems. Point protection is an efficient method that can harvest fluvial processes, leading to the deposition of gravel that modifies flow to improve the hydromorphology of streams.

Their influence often extends to untreated portions downstream. Vegetated nodes have a habitat improvement function that can be combined with architectural features in urban areas.

5.3 *Training structures*

One alternative technique is a training structure (groin) or equivalent structure. Training structures, inserted in the river channel, control the direction, velocity, or depth of water flow. They control scour on banks by deflecting the currents. Some of the training structures are linked to the banks and act as protection to the bank. A groin is an elongated artificial obstruction projecting into the stream from bank to control scour by deflection of currents. There are two main types of groins: permeable and impermeable.

5.4 *Transversal barriers*

Timber logs and/or rocks creating a transversal barrier. Like other transverse structures it collects and retain gravel for spawning habitat, deepens existing resting/jumping pools, creates new pools above and/or below the structure and promote deposition of organic debris. Sills also hinder scouring of the channel bed and stabilises it. They are appropriate for degrading rivers, preventing the evolution of degradation. The result is a decrease in the river bed slope.

There is another type of transversal barriers acting mainly on the water depth, not trying to influence the river bed slope. However, they may also have some influence on river bed deposition, for the cases where these conditions occur. A set of these transverse structures creates a cascade of pools, producing, for instance, a permanent water table for all river discharges, even for the minima, in dry period. They are appropriate for mild rivers, where the river bed

Copyright © 2006 Taylor & Francis Group plc, London, UK

evolution is not a problem. The result is a decrease in the water slope for low discharges. For flood discharges they may have a minor influence, because they are submerged without inconvenience.

5.5 *Dredging*

Another type of intervention is dredging of river bed. This action may recover the flow capacity of cross section. The dredging is associated in general with an increase in river bed slope, because the dredging removes the excess of deposition, associated with a trend in decreasing slope.

The useful life of dredging depends on the sediment transport dynamics. The isolated dredging does not modify the sediment yield, and some time forward the river will return to the same bed level. However, for certain local conditions this may be an economic and justified intervention. Some care shall be put on the maintenance of plantonic habitats, and on the stability of river banks.

5.6 *Interventions in the river plan form*

It is very difficult to define the type of interventions in the river plan form, because there is a large spectrum of possibilities. The natural plan forms are controlled by complex relationships between river discharge regimes, sediment supply and geological formations. The presence of urban settlements strongly changed those interrelationships. The interventions to modify the plan forms, from the present situation to a more natural situation, are subject to reduced technical options because the rehabilitation based on geomorphologic criteria continues to be restricted by urban reality.

The rivers have natural bends, the presence of natural long righteous reaches being rare. The definition of the plan form is dependent on the form of the river valleys, and is conditioned by geologic, urban (like buildings and bridges) and hydraulic factors.

Of note is the fact there is a trend to create sinuosity only to provide a good landscape. However this approach needs to be based on valid technical criteria, unless strongly fixed banks are built and sediment supply is not intense.

5.7 *Soft interventions*

Methods of soil-bioengineering play a central role in nature like in slope stabilisation and in river rehabilitation and revitalisation. Soil bioengineering structures are based on synergies of living plants and dead materials as stones, timber or geotextiles and auxiliary objects. These structures are intended to create stable native riparian vegetation, which sufficiently protects riverbanks and improves the landscape, aesthetics and ecology, Faber (2004).

Working with living native plants in river regulation schemes has a long tradition. The utilisation of tree spurs was documented in the Roman Empire. Although none of the current technical machinery and constructions existed in the Middle Ages, durable protection of waterways was achieved with natural and living materials.

Aquatic habitats are highly dependent on the quantity and dynamics of water flow. Aquatic habitat provides cover, food, nesting and spawning sites; shelter and escape cover for fish, amphibians and other wildlife. Habitat protection and improvement refers to in-stream conditions and to riparian habitat. Both are interrelated. Vegetation on the water edges provides shade and an input of leaves that directly affects the quality of the aquatic habitats. The riparian habitat, as a transition area between terrestrial and aquatic environment, is particularly rich in life forms. In-stream habitats such as gravel riffles, deep pools, driftwood piles, sandbars, and boulder clusters are points of interest to any sport-fisherman's association, which often willingly organizes to support improvements. These measures include fish ladders, fish passage improvement and removal of migration barriers.

6 DESCRIPTION OF THE CONSEQUENCES OF URBAN RIVER REHABILITATION

To guarantee the success of the rehabilitated urban river it is necessary to characterise the hydraulics of the urban river, before and after rehabilitation, and to know the sediment transport entering in the reach. The geometric characteristics of the cross sections, the longitudinal slope and the discharges running in the reach are the basic parameters to collect and to analyse. The comparison of the flow behaviour before and after rehabilitation is the basis for describing the consequences of urban river rehabilitation.

The adequate values to be considered in the description of the consequences of technical options will be minimum discharge, possibly zero; a set of three discharges between minimum and bankfull discharge; the bankfull discharge and a few flood discharges (for instance T = 5, 10, 20, 50 and 100 return period years).

The flow depth may be computed by simple hydraulic equations, such as Manning or Strickler equation, or other empirically derived equations for computing the average flow velocity, assuming uniform and turbulent flow conditions, for simpler cases.

For estimating the shear stress, simplified equations are with the channel slope S, as an approximation of the actual energy grade J, to be used when available. It is possible to use h (flow depth) instead of R in wide flows, when the channel width exceeds the 30 fold of the perimeter.

Copyright © 2006 Taylor & Francis Group plc, London, UK

From all data available, it will be possible to compute the sediment transport capacity. It is very important to note the differences between capacity and actual sediment transport. The actual sediment transport is the lesser of two situations: the capacity if the incoming sediment load is higher or the incoming sediment load if the capacity is higher.

The sediment transport capacity may be computed by a large number of equations. This is a very specific technical work to be done by experts.

In sediment river bed there will be complex flow dynamics and erosion/deposition sequences, both being a vital part of the flow regime. On urban rehabilitated rivers, these natural processes are to be maintained to a certain extent, even in the cases of a completely artificial mobile river bed.

The computation of water levels is much more difficult on natural river beds because there are strong variations in roughness coefficients during a passage of flood wave. This will also be a job for experts on river hydraulics to guarantee successful interventions.

For lower velocities, when there is no sediment transport in the river bed, the roughness is only controlled by the grain size of the bed material. For larger discharges there is sediment transport in river bed originating bed configurations, like dunes and ripples, and the adoption of a representative of roughness is much more difficult.

The meanders are the most common plan form in rivers. The plan form of meanders can be approximate by cosine functions. The definition of the axis of a theoretical meander may be obtained by knowing the minimum curvature radius and the meander length along the axis.

The time scale has also some importance. There is the river time scale, where the seasons are a mark of the rivers. The important transport phenomena in rivers are associated with large discharges, in rainy season. On the other hand, the intervention on the river will be done during the low water period.

All computations will be done in accordance with the data available, the stage of the project and the complexity and size of intervention. The heavy computer computations are only to be used in complex and large river rehabilitation cases, simplified computing approaches being enough for most cases. Additionally, the heavy computations will be accompanied by good observation data to calibrate and validate computations. It is non sense to use heavy computations without enough data to calibrate the models.

The computations of present and future status of the urban river are the basis to describe the consequences of options. In computations the use of past experience in river behaviour and in river processes are determinant to obtain good results.

The theoretical analysis of the consequences of urban river rehabilitations will be compared with the behaviour of the river after implementing the rehabilitation. This comparison should always be done to detect deviations from the initial objective, and to define possible corrections and also to confirm the appropriateness of the theoretical analysis used.

Figure 1. The urban River Fervença (Bragança, Portugal) before rehabilitation (view from right bank).

Figure 2. The urban River Fervença (Bragança, Portugal) after rehabilitation (view from centre of river).

LNEC was involved in the analysis of the consequences of successful urban river rehabilitation in river Fervença, in Bragança, Portugal, Figures 1 and 2.

In this case it was obvious the need to verify the behaviour of the river after the rehabilitation to introduce a small additional intervention.

7 MONITORING OF REHABILITATED RIVER

The effectiveness of a project is determined by comparisons between pre- and post-development conditions, and by applying evaluation criteria through indicators of success. The monitoring costs involved are money well spent when findings are disclosed and used in order to convince the public and its representatives

Copyright © 2006 Taylor & Francis Group plc, London, UK

that the projects financed with the taxpayer's money have been a success.

In an optimal case, the lessons learned during the monitoring process are utilized in revising the intervention and the operation of controllable systems.

There are technical reasons to reinforce the need to monitor in the stream channels. Indeed, the rivers are subject to large flood events that involve strong forces in all river bed and river bank founded structures and put in motion the alluvial beds. The large mobility of the rivers imposes a careful monitoring plan.

In the urban river projects the monitoring programme will provide data to follow up the performance of the intervention measures. The appropriate parameter will be identified for each measure. The natural choice of parameters is the set of controlling parameters referred to in 4, but additional parameters may be considered necessary. The sites to monitor are related with the intervention places, some cases inside the boundaries the intervention, other cases outside the boundaries. In general, all parameters will be monitored before and after implementation. In more dynamic or sensible phenomena it is also justified to monitor during implementation.

The methods and patterns of monitoring are associated with the existing know how of each parameter observation. For some of them there are international accepted standards.

The decisions inherent to the non-compliance of pre defined objectives will also be incorporated in the monitoring programme. The decisions may be divided in regular or every day simple decisions, occasional and complex decisions, to be studied carefully when occurring, and urgent or alert decisions when critical or dangerous occurrences happen. All types of decisions may be anticipated, mainly the most dangerous one or most irreversible situations.

In WFD the monitoring has the following objectives: surveillance, operational and investigation.

The monitoring in urban river rehabilitation interventions is more related with the operational monitoring defined in WFD.

Operational monitoring shall be undertaken in order to:

- establish the status of those bodies identified as being at risk of failing to meet their environmental objectives, and
- assess any changes in the status of such bodies resulting from the programmes of measures.

In operational monitoring, enough points will be chosen in order to assess the magnitude and impact of the hydromorphological pressures.

In URBEM project the following hydromorphological controlling factors, or parameters, were proposed for the techniques of urban river rehabilitation, Table 1.

Table 1. Hydromorphological controlling factors in urban river rehabilitation techniques and monitoring frequency.

Parameter name	Descriptor	Monitoring frequency
River discharge	Q	Continuous
River slope	S	6 years
Subterranean discharge	Q_{sub}	3 months
Head loss	ΔH	6 years
River depth	H	Continuous
River width	B	6 years
Median grain size of aluvionar bed	D_{50}	6 years
Median grain size of aluvionar bank	D_{b50}	6 years
Cross sections	Z(x,y)	6 years
Sediment transport capacity of river	Q_s	6 years

Other controlling factors are: physico-chemical, biological, social and economic. The first group include the thermal conditions (T), oxygenation conditions (O), salinity (Sa), acidification status (pH), nutrient conditions (N), turbidity (T_u) and pollution by other substances (P_{ss}) all with a monitoring frequency of 3 months, plus pollution by priority substances (P_{ps}) with 1 month for monitoring frequency.

The biological controlling factors are the compositions and abundance of aquatic flora (CA_{af}) and benthic invertebrate fauna (CA_{bif}) plus composition, abundance and age structure of fish fauna (CA_{ff}) and also riparian vegetation (RV) all factors with 3 years as monitoring frequency.

The social factors are the flooded area (F_a) and the flood risk (H_fV_f), both having a 6-year monitoring frequency.

Lastly, the economic factors are the flood damage cost (FC) and the annualized maintenance cost (MC) respectively, with 6 and 3 year monitoring frequency. The maintenance of interventions will be done based on monitoring results.

For operational monitoring, the frequency of monitoring required for any parameter will be determined by Member States so as to provide sufficient data for a reliable assessment of the status of the relevant quality element. As a guideline, monitoring should take place at intervals not exceeding those shown in the Table 1 unless greater intervals would be justified on the basis of technical knowledge and expert judgement.

Frequencies will be chosen so as to achieve a level of confidence and precision. Estimates of the confidence and precision attained by the monitoring system used will be stated in the river basin management plan.

Monitoring frequencies will be selected taking into account the variability in parameters resulting from both natural and anthropogenic conditions. The times

Copyright © 2006 Taylor & Francis Group plc, London, UK

at which monitoring is undertaken will be selected so as to minimise the impact of seasonal variation on the results, and thus ensure that the results reflect changes in the water body as a result of changes due to anthropogenic pressure. Additional monitoring during different seasons of the same year will be carried out, where necessary, to achieve this objective.

The implementation of the option for urban river rehabilitation will be linked with the implementation of monitoring. Indeed, some of the monitored parameters will be obtained in advance; consequently the monitoring implementation will precede the river rehabilitation, in order to compare the present and future situation.

The time interval between first data, obtained before the river rehabilitation, and the data obtained after the completed river rehabilitation, depends on the decision process, being difficult to reach a consensus among a great number of entities involved in the decision-making process. In general, there is enough time in the decision-making process to be possible to implement in advance the monitoring program.

Monitoring reports will provide opportunity to disseminate any lessons learnt from the behaviour of rivers responding to the rehabilitation.

Besides the correct technical presentation of the results, according to the previous frequency of reporting, the presentation of monitoring results will include a classification of ecological status and ecological potential, as well as chemical status. The latter presentations are defined in WFD.

For urban river rehabilitation the same procedure may be applied, extending the classification to all significant elements of intervention, including also the hydromorphological elements and other structural and non-structural aspects of the intervention.

Indeed, most cases of urban river interventions are to be done in heavily modified and artificial water bodies, where the ecological potential classification will be represented by the lowest of the values for the biological and physico-chemical monitoring results for the relevant quality elements classified in four classes.

The same type of presentation for the compliance of WFD may be adapted and added to cover the case of urban river rehabilitation. The colour codes may be inserted in parts of the river intervention, considering not only the elements included in the WFD, but also all relevant elements specific of each intervention.

ACKNOWLEDGEMENTS

This research was partly funded by the European Commission, in the project URBEM (Urban River Basin Enhancement Methods), EVK-CT-2002-00082.

Flood management system – A newly developed instrument based on WebGIS and CMS and the improvement of basis data

A. Koch, M. Tzschirner & R. Jüpner
Institute for Water Management and Ecotechnology (IWO), Department of Water and Waste Management, University of Applied Sciences Magdeburg, Germany

ABSTRACT: The recent flood events in Germany on the River Rhine, Oder and Elbe, the responsible public authorities were forced to find new strategic ways to handle flood events more efficiently. Results of the floods showed that in spite of increasing technical flood measures, the damages are also rising. Instruments that therefore combine solutions for flood prevention and operative flood protection measures are helpful. Regarding this aim, a "Flood Management System" (FloMS) has been developed, which satisfies the duties and expectations of the responsible regional actors in case of emergency and flood prevention. FloMS consists of two main parts: the GIS and WebGIS for spatial information like flooded and flood-prone areas including flood scenarios and the Content Management System (CMS) for non spatial information. A major output of the project is the creation of different kinds of maps showing the hazards, the potential damage, special risks etc. for defined flood events. Those maps are applied for flood prevention measures and during flood events especially on a local scale. The available basis data, particularly the digital elevation model, had to be improved by additional data. Important line objects as dykes, streets and railways were acquired and implemented in order to run dyke breach simulations, which are e.g. basis for hazard maps.

1 INTRODUCTION

In the recent years, a change of paradigm in flood protection has become obvious. Thereby the "safety society" is being displaced by a risk society with the focus on flood risk management including also flood prevention.

This resulted into a rethinking within the different countries. In Germany, a law for the improvement of flood prevention was enacted in Mai 2005 to strengthen the legal framework for precaution measures of flood protection. In Europe, too, a modern flood management initiative started and even a European Flood guideline is in preparation.

The European Commission is furthermore supporting a variety of (research) projects as FLOODsite, FLOWS, IRMA, ODERREGIO and ELLA, that focus either on transnational flood prevention, integrated flood management or the development of practical instruments and tools as decision support systems. One practical instrument has been developed within ELLA for Stendal County in Saxony-Anhalt, Germany.

Stendal County with approximately 250,000 ha and 148,000 inhabitants is the biggest county in federal state of Saxony-Anhalt. It is situated in the middle part of the River Elbe watershed. In addition to the River Elbe, the Rivers Havel and Aland are important tributaries in this region (see Figure 1).

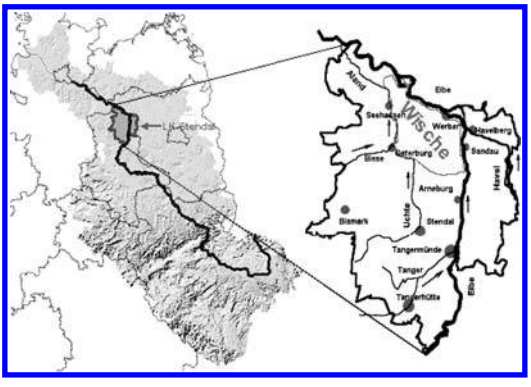

Figure 1. Overview, main towns and rivers of Stendal County in the Elbe watershed.

The terrain of Stendal County is very flat and nearly 30% of the area is former floodplain (e.g. the Wische area).

Concerning flood protection, the responsibilities are in different hands. While the state of Saxony-Anhalt is responsible for building and maintaining flood protection structures, the counties take over the emergency management in case of a flood catastrophe. Due to that the counties are responsible for planning and preparation of the emergency management. But

Copyright © 2006 Taylor & Francis Group plc, London, UK

they have also been given instruments for flood prevention by steering the flood plain management by spatial planning instruments, water management instruments as well as preparing and informing the population properly. By realizing those prevention measures the counties can contribute to reduce the potential damage caused by extreme flood events. The overall damage of the Elbe flood disaster in August 2002 was quite high in Germany. 38 people were killed and the economical damage was estimated to 11.3 billion Euros (IKSE 2004). Saxony-Anhalt had an overall damage of about two billon Euros (HWSK LSA, 2003). In Stendal County, there were luckily no victims and no dyke breaches occurred. But altogether, nearly 30,000 people had to be evacuated and thousands of emergency management forces were in action.

To improve the present flood control system and to decrease future flood damages, an integrated management instrument dealing with all aspects of flood prevention and flood defense has been developed for Stendal County. This Flood Management System (FloMS) is a pilot project for Saxony-Anhalt and has been realized by the Institute for Water Management and Ecotechnology of the University of Applied Sciences in Magdeburg since April 2003.

2 PILOT PROJECT "FLOOD MANAGEMENT SYSTEM – FLOMS"

The aim of developing the flood management system for Stendal County was the provision of all relevant data and information to the responsible authorities before and during a flood event. By the integration and presentation of existing and potential flood scenarios, the county gets an appropriate instrument to support their duties as a catastrophic authority. The system also serves as an information platform for the open public. Furthermore all flood relevant subjects such as water management, spatial planning, nature conservation, agriculture and forestry are considered in the project. Five professors representing different disciplines of the University of Applied Sciences in Magdeburg as well as two local firms are involved in this project (Jüpner, R., Tzschirner M. 2005).

2.1 *Structure/contents*

On the basis of flood scenarios, the application of FloMS is divided into two main parts, the flood prevention and the emergency management.

The flood prevention part is used during flood-free times and consists of:

– Flood plain management (Land-use planning, Natural water retention)
– Technical flood protection (dykes, retention basins etc.)

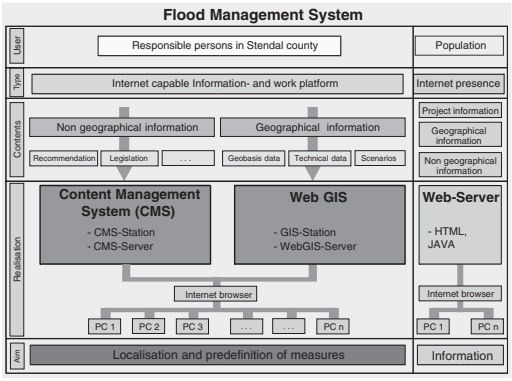

Figure 2. Technical realization of FloMS.

– Further flood prevention (risk-, building- and behavior provision).

In case of a flood event, the emergency management part is applied during:

– Routine measures for flood events up to the emergency alert and
– Disaster measures in case of the declaration of the emergency alert

The most important output data are hazard maps, hazard indication maps and dyke failure scenarios, which are the basis for preventive measures as well as for the hazard defense. Hazard maps mainly contain – according to different flood scenarios- information for emergency means as location of fire brigades, police, hospitals, collapse load of bridges, social facilities (as schools, nursing homes etc.) and special risks as location of water treatment plants, water supply and petrol stations. Hazard indication maps give an overview and depict conflict locations. They consist of information about flood-prone areas (simulated without flood protection structures for extreme flood events) and damage potential (values for different landuses).

2.2 *Technical realization*

FloMS technically consists of two major components (see Figure 2). One is a Geographical Information System (GIS), where geographical data is stored, and a WebGIS, where the data and their generated information are presented to the user via intranet/internet. The other part of FloMS stores all non spatial related data and information. This is accomplished by means of a content management system (CMS) which is based upon the open source software "MediaWiki".

The CMS (Figure 3) offers collected and structured information in different portals and gives helpful links concerning flood prevention and hazard defense. In case of an emergency alert, the web portal provides not

Copyright © 2006 Taylor & Francis Group plc, London, UK

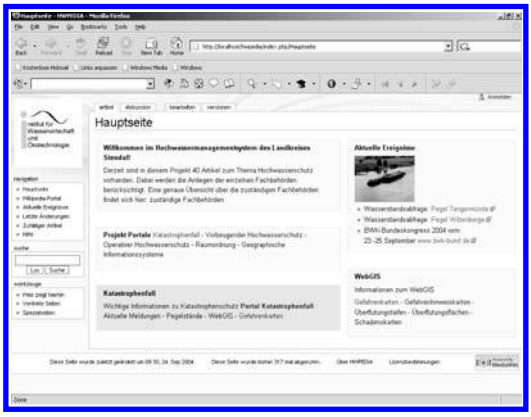

Figure 3. Homepage of the existing FloMS.

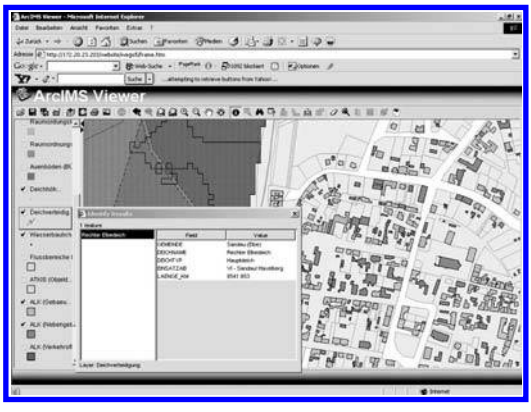

Figure 4. Representation of a scenario via WebGIS.

only emergency action plans, list of phone numbers of contact persons and action forces. It also links to the WebGIS containing maps and geographical data.

The WebGIS (Figure 4) provides different kinds of maps. These are e.g. the hazard indication maps (see section 2.1), the "dyke maps" (issued by the State Authority for Flood Protection and Water Management of Saxony-Anhalt (LHW)) and other maps with additional data containing geographical information. These maps were created with the desktop GIS and are provided to the user via WebGIS. Besides using the geographical data, the user can add its own data according to his/her special requirements of his/her work.

The current work is to improve the data basis of FloMS and to compute dyke breach scenarios as basic for hazard maps (see section 4).

At the moment, all FloMS users mainly of Stendal County but also responsible persons e.g. of the LHW are trained for using FloMS effectively.

2.3 *European project "ELLA"*

With its main focus on improving flood protection, the described interdisciplinary project FloMS became part in the European INTERREG IIIB ELLA-project "ELBE-LABE: spatial planning flood management strategies (ELLA)". ELLA which aims for the improvement of the transnational flood prevention runs from June 2003 to December 2006. Involved are 23 project partners, mostly state and regional authorities of spatial planning, water management or environmental planning, within the Elbe River Basin. Stendal County and the Ministry of Building and Traffic of Saxony-Anhalt (MBV), that is responsible authority for spatial planning, are both project partners within ELLA. The objectives of the transnational project are:

- Implementation of an integrated water management into the regional planning by agreeing upon a common transnational strategy
- Evaluation and improvements of the regional planning instruments and
- Improvement of regional and local land use plans in flood-prone areas

Finding solutions for the upstream-downstream burden that accelerates the process of improving flood prevention is another aim.

The methods being used in the project are risk analysis and their mapping, analysis and evaluation of retention measures in regional planning, agriculture and forestry.

Within ELLA, the main objectives of the pilot project "Stendal" are focused on:

- Improving the regional and local flood prevention by providing information
- Adjusting FloMS (data, information, maps) to the needs of regional and local planning authorities
- Strengthening the cooperation between water management and spatial planning and involving other actors

By realizing those and other tasks, the original project had been enlarged and extended to the end of 2006.

3 INUNDATION MAPS IN SAXONY-ANHALT

Different methods of creating inundation maps exist. Two of them (a static and a dynamic method) are being introduced in the following sections.

3.1 *Static method*

Some of the existing inundation maps had been produced by using a simple static method by intersecting the water level with the terrain. For this method the basis data is the water level and the Digital Elevation Model (DEM).

Copyright © 2006 Taylor & Francis Group plc, London, UK

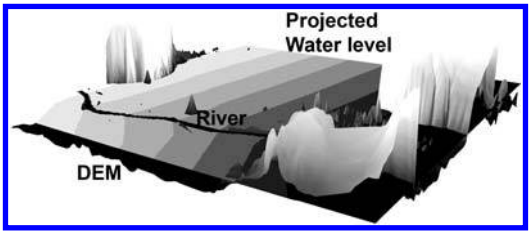

Figure 5. Intersection of the water surface and the DEM.

In GIS the water level is projected from the River into the area up to a certain buffer distance (see Figure 5). The difference between water level and terrain is calculated resulting into the water depth and the water dispersion.

This method does not consider the hydraulic fact of the subsidence of the water level and areas are being filled with water, that are naturally not reached by the water because of orographic related barriers. In general, the result obtained with this simple method is, that the inundation areas are too extended and that the water is too deep. Practical experiences during the Elbe flood in 2002 have confirmed this result.

3.2 *Dynamic method*

For the determination of the flood-prone areas different dynamic methods can be applied. In this project the ArcGIS® (company ESRI) extension FloodArea® (company Geomer) has been used. The basic data is again the water level and the DEM. In the simulation, all eight neighboring raster of one cell are considered. The discharge volume of all raster cells is calculated by using the Manning-Strickler equation, at which the flow depth during an iteration interval is taken from the difference between water level and maximum terrain elevation along the flow path [Assmann, 2003].

Because of the better consideration of the hydraulic situation, this method gives a more realistic picture for certain scenarios. In the example of Figure 6, the water depth and the inundation area are shown. With the static method (6a), a higher water level is calculated (partly more than four meter: black color) whereas the general water depth is not higher than two meter using the dynamic method (6b). Also the inundation area is lower with the dynamic method.

The aim of creating this information is to depict the worst case scenario as overtopping of dykes or failure of flood protection structures during extreme flood events. Structures as dykes were omitted in the simulation on purpose.

But the spreading of the water obtained with this dynamic method is still too wide compared to the reality. The reason is the available DEM including the natural relief and no streets, railways or dams. Those elements would naturally hinder the water flowing.

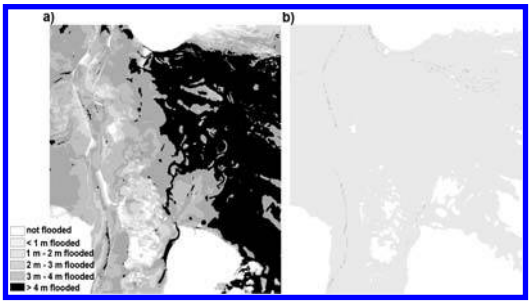

Figure 6. a) Flooded areas with static method, b) Flooded areas with dynamic method.

For local planning the data basis therefore has to be improved (see section 4.2).

3.3 *Practical application of methods*

In Saxony-Anhalt inundation maps created with the static method and followed by adjusting them to historical events exists. The maps are designed for depicting the inundation situation of the whole state of Saxony-Anhalt in a scale of 1:100,000. They give a general overview of the inundation, but they do not include water depth and water extension.

Within the ELLA project, hazard indication maps for the area of Saxony and Saxony-Anhalt have been produced using the dynamic method. They show the water depth and extension but are also on the state scale (1:100,000).

These existing maps are being applied for flood prevention on country scale. For regional and local tasks, especially for the preparation or in case of a flood event, feedbacks from the praxis showed, that the existing maps are not detailed enough for the use on the regional (1:20,000–1:50,000) or local (1:10,000–1:20,000) scale.

For this reason, maps with more detailed and differentiated information have to be created. Of a special interest are such maps that e.g. show the flooded area as a result of dyke breaches.

Out of this demand, the generation of high detailed dyke breach scenarios with a wide practical benefit was the new task. Therefore, the DEM had to be added with line objects as dykes, streets and railways on dams.

4 DYKE BREACH SCENARIOS

In comparison to the determination of the flood-prone areas on state scale, dyke breach scenarios have the advantage that they are more detailed and are on a local scale. In case of a dyke breach, usually only a small part of the water amount flows into the flood-prone

Copyright © 2006 Taylor & Francis Group plc, London, UK

areas behind the dykes, but the main discharge still remains in the river bed.

4.1 *Data basis*

4.1.1 *Water level*

The water level required for the simulation of the dyke breach scenarios is the longitudinal section of the water surface of the River Elbe with point data of 100 m. The 100 year and extreme flood event (100 years event plus 0.50 m), provided by the LHW, have been chosen for the simulation. To use the data in the ArcGIS® extension FloodArea®, the data points have to be raster with at least two pixels width. Therefore the points have been converted into a line first and second into raster.

4.1.2 *DEM*

The DEM is provided by the State Department for Surveying and Geoinformation of Saxony-Anhalt (LVermGeo). It is generated from orthophotos that are usually not older than 4 years, because one quarter of Saxony-Anhalt is renewed every year. The points extracted from the orthophotos are a raster with a clearance of 10×10 m and an elevation accuracy of ± 0.50 m. A more detailed DEM with a raster of 1×1 m and an elevation accuracy of ± 0.20 m is unfortunately only available for the River Elbe within the dyke limits. This more accurate DEM can not be used for the dyke breach scenarios, because the areas behind the dykes are of interest.

Because the available DEM does not include the required line structures, the main focus for creating the dyke breach scenarios has been the acquisition of those data and its implementation into the DEM.

4.2 *Improvement of DEM*

4.2.1 *Data sources*

For the first improvement of the DEM, the dyke structures including their elevation data for the extension of the project area has been provided by the LHW. The data is delivered in different formats, as GIS-shape- or CAD-dxf-files.

More difficult is the acquisition of the other line objects such as streets, roads and railways, because they are not compiled and stored in one hand. For the predominant part of the project area there is no surveying and mapping data of these objects. Only partly, planning data is available, but mostly not in a digital format.

Other important information for the dyke breach scenarios is the elevation of culverts or canalization. Unfortunately these data is also not available for the whole county area and therefore has to be collected by each responsible organization (organization for the maintenance of rivers of second order).

In the consequence the DEM can not be improved optimally by all required line structures.

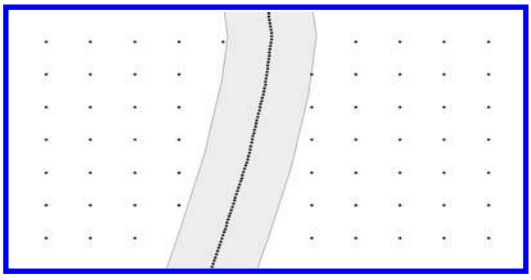

Figure 7. Grabing the elevation points from the TIN surface to the raster.

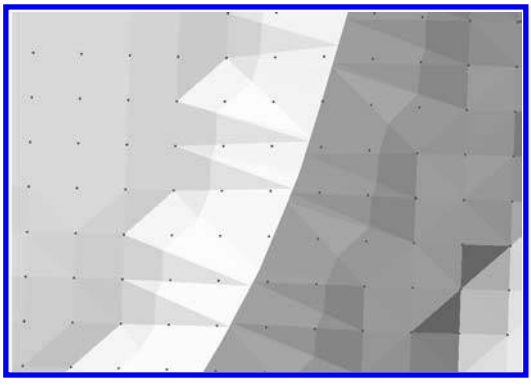

Figure 8. The dyke is integrated into the DEM, buffered with 10 m, and DEM points inside the buffer are erased.

4.2.2 *Data integration*

In order to integrate the data into the DEM, the challenge was the handling of the different structure of data within the GIS. On the one hand, the simulation software requires raster data (as the DEM), but the dyke data exists only as single points in a line without fitting in the raster of the DEM.

The conventional way is to merge the DEM raster with the single data points, buffer the dyke with 10 m (Figure 8) according to the raster width of the DEM and erase the points of the DEM inside the buffer. Then a Triangular Irregular Network (TIN) is created. The buffer is necessary to create a dyke body for the TIN.

Afterwards, the TIN has to be transformed into a raster again (Figure 7).

While relocating the elevation points of the TIN to the raster, elevation point of the dyke crest can be missed according to the raster width of 10 m (Figure 9 a) and b)). For the dyke breach simulation, the real height of the dyke crest is important. As shown in Figure 9 c) and d) the elevation of the dyke crest has to be set on a width which is wider than the clearances of the raster (in this case 10 m). In this wavy it is ensured, that at least one of the raster points is placed on top of the dyke (see Figure 10).

Copyright © 2006 Taylor & Francis Group plc, London, UK

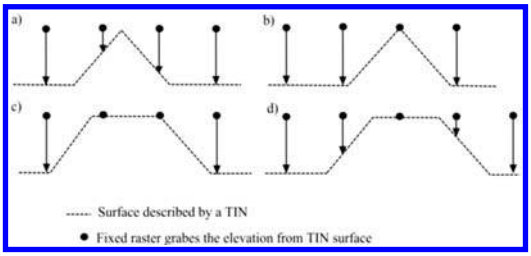

Figure 9. a) and b) not every point of the raster is located on top of the dyke, c) and d) at at least one point is on top of the dyke.

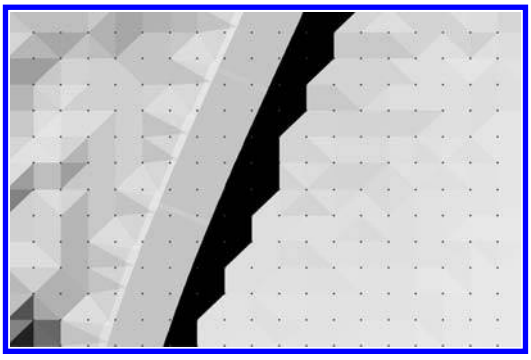

Figure 10. AT least one point is on top of the dyke by the converting from TIN to raster by the developed tool.

Because ArcGIS does not provide a tool for transforming a line into a stripe by keeping the elevation data, a new tool has been developed within this project. The tool works similar to a buffer but it additionally copies additionally the elevation to the edges of the buffer in a right angle to the axis. This process has to be done also for the other line objects.

An easy implementation of line objects into a raster model is enabled by using this helpful tool.

4.3 *Simulation*

After integrating the necessary and available surface data, the locations of simulated dyke breaches had to be defined. The localization was coordinated with the responsible persons of the LHW and Stendal County. Also the boundary conditions for the simulation were agreed on. The results were the following:

- Water level input: 100 year flood event and an extreme flood event
- Width of dyke breach: 90 m (experience values, often applied)
- Simulation time: 48 hours (most of the water is spread by then)

For the simulation the dyke was erased on a length of 90 m at the predefined locations within the DEM.

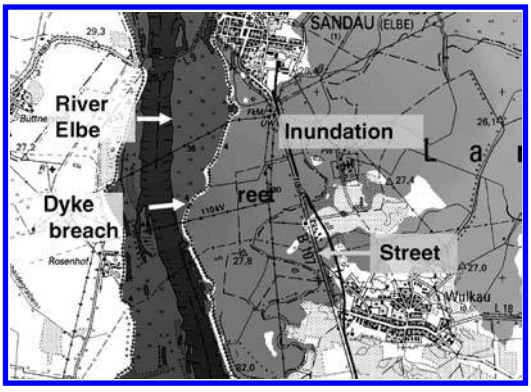

Figure 11. Simplified snap of dyke breach scenario.

Each dyke breach is simulated separately. After 6, 12, 24 and 48 hours the result of the simulation is represented in a map.

With these settings, the simulation runs about 10 days using a new desktop computer (Intel© P4 3.2 MHz, 2 GB RAM).

4.4 *Interim results of the simulation*

The result of a dyke breach scenario is a map of flood-prone areas as a consequence of a certain dyke breach that shows the water depth and extension. The result is strongly depending on the precision of the input data, especially of the DEM. In Figure 11, a snap of a dyke breach scenario can be seen as an overview. In this case, the street could not have been integrated into the DEM yet. For final calculation of dyke breach scenarios, all street elevation data have to be considered. This is elementary because the street can hinder the water spreading, depending on its elevation in relation to the water level. For this reason, proper information about the input data is also required and has to be made transparent e.g. by displaying it on the map.

In spite of the difficulties in obtaining all the required and wishful elevation data, the results are a big step forward for flood management. The maps are a very helpful tool for the authorities in the LHW and Stendal County. The dyke breach scenarios are also the basics for the hazard maps. For critical points in flood-prone areas, e.g. petrol stations, the effect due to dyke breaches can be seen and result into prevention measures.

5 SUMMARY AND OUTLOOK

The Flood Management System was developed as a instrument for optimizing the flood protection in Stendal County. It is based on the experience during the Elbe flood in 2002 and the subsequent detailed

Copyright © 2006 Taylor & Francis Group plc, London, UK

evaluation of the different emergency management activities. In January 2005 the principal establishment of the main contents and the technical solution of using a GIS, WebGIS and CMS were finished and presented. Since then FloMS has been further optimized by

- Improving the data basis by adding important data and developing practical tools for the implementation
- Simulating additional scenarios for depicting in maps with a more detailed scale for a better practical local application
- Intensifying the cooperation between persons and authorities (especially water management and spatial planning) involved in the in flood protection

During the whole project, a close communication and agreements with the responsible actors of Stendal County and state authorities e.g. LHW was maintained. Until the end of the project in the end of 2006, following further outputs are focused:

- Further acquisition of basis data as line objects, especially railway dams and new simulation of the scenarios
- Finishing the hazard maps
- Developing concepts for minimizing the damage potential in flood-prone areas

The integration of the pilot project into ELLA has been a good opportunity for further developing, expanding and adjusting the flood management system to different demands. Also, the transnational experiences in flood prevention and risk management from other riparian countries and counties could have been considered and implemented.

ACKNOWLEDGEMENTS

Stendal County, the Ministry for Building and Traffic of Saxony-Anhalt and the European Union have funded this pilot project. The authors would like to thank them as well as our colleagues Stefan Müller, Agnes Richmann and our former colleague Thilo Weichel for supporting the research within this project.

ABSTRACT: Spanish dam safety regulations recommend the estimation of a return period of 1000 years for the Design Flood and of 10,000 for the Safety Check Flood, which are obtained from Flood Frequency Analysis (FFA) or on the Probable Maximum Flood (PMF). Short gauge records afford little support for the FFA or the hypothetical PMF, which in addition to the absence of an associated probability, limits the utility of these indices for risk-based dam safety decisions. Palaeoflood hydrology was applied to the Guadalentín River, upstream of the Valdeinfierno reservoir (372 km^2), which has a spillway capacity of 550 $m^3 s^{-1}$ (design flood). Palaeoflood data and gauge station records, were combined for the FFA, using the maximum likelihood estimates of the parameters for a Gumbel distribution, providing a discharge of 2350 $m^3 s^{-1}$ for the design flood (1000-yr flood) and 3450 $m^3 s^{-1}$ for the safety check flood (10,000-yr flood). The PMF discharge is 5786 $m^3 s^{-1}$, showing an overestimation of this empirical method.

1 INTRODUCTION

Understanding the magnitude and frequency of extreme floods is critical for the design of hydraulic structures such as dams. Dams are designed, constructed and modified, when necessary, such that a catastrophic failure is prevented during a large flood. Civil engineers when designing a dam must establish the capacity of the dam and the rate at which water can be passed through the dam by means of flood gates and spillways. Dam safety components are established by two concepts: (1) the design flood and (2) the safety check flood. The design flood refers to the flood magnitude for which hydraulic design of spillways and energy dissipating structures have been designed, with a safety margin provided by the freeboard. The safety check flood represents the most extreme flood conditions that the dam structure could support without failure, including a low safety margin (worst flood scenario). Past experience indicate that overtopping represents more than 40% of dam failures, showing that extreme floods constitute an important risk for dam safety (ICOLD 1995).

According to Spanish regulations on dam safety (MOPTMA 1996), dam category depends upon the potential economic losses and human threats on downstream settlements. The Civil Protection Basic Framework on Flood Risk (MJI 1995), therefore, classifies dams into three categories: (A) High Hazard, (B) Significant Hazard, and (C) Low Hazard. A failure in a "high hazard" class of dam may cause loss of life, serious damage to residential, industrial, or commercial buildings; or damage to, or disruption of, important public utilities or transportation facilities such as major highways or railroads. The class "significant hazard" includes dam in which failure poses no threat to life but may cause significant damage to main roads, minor railroads, or cause interruption in the service of public utilities. A failure of a "low hazard" class of dam would at the most result in damage to agricultural land, farm buildings (excluding residences), or minor roads. In this flood risk Directive, the estimation of the design flood is based on probabilistic methods (statistical analysis and hydrometeorologic estimations) in which the use of historical data is highly recommended. The Spanish Committee on Large Dams (Comité Español

de Grandes Presas 1997, Penas et al. 1997) recommends the estimation of a return period of 1000 years for the design flood and of 10,000 years for the safety check flood (Table 1). The estimation of such low frequency floods are based on either probabilistic or deterministic approaches.

The deterministic method relies on the concept of the Probable Maximum Flood (PMF) or the greatest amount of precipitation theoretically possible within a region (Maximum Probable Precipitation, PMP) subsequently maximized through "moisture maximization" and other numerical methods, finally turned into runoff or flood discharge, this depending on the characteristics of the drainage basin (Berga 1998). This methodology is complex especially in large basins due to the timing of different flood hydrographs and different land use scenarios. In addition, this deterministic approach is limited due to the lack of probability value associated to the PMF, which impedes its use on the decision support for flood risk analysis.

In most European countries, the dam design determines the probability that a storm will cause the dam to overflow and consequently destroy the structure. In Spain, most of the existing dams were designed with flood gates to handle flows upto the 500-yr flood i.e. a flood that occurs on average once in five hundred years (recurrence probability of 0.002). This statistical analysis is based either on streamflow gauge records or on hydrometeorological analysis from precipitation associated with different return periods. If the reliability of flood design and safety check flood estimation is to be improved, there is a critical need to specifically extend the record of the instrumental period (systematic period) of extreme floods. This record is usually limited to only a few dozens of years and the largest floods are therefore under-rated in the data. Information on hydrological variability and extreme floods can be completed using either or both palaeoflood hydrology and/or written chronicles of historical floods. Long records of extreme floods are then applied successfully in the design of dams and flood gates, combining palaeofloods, historical and instrumental records within the statistical analysis or testing the analysis performed in the calculation of the PMF. The statistical analysis can also contribute/benefit from regionalisation to generate statistics of extremes from combining records from several sites.

Recently, a new Dam Safety Program was launched by the Spanish Government, in which different methodological approaches to dam-safety design criteria are being revised at pilot areas. In this study, a combination of methods for the estimation of the design and safety check floods have been used in the upper Guadalentín basin, SE Spain. The specific objectives of the study are to: (1) extend the instrumental flood record to past using palaeoflood and historical data; (2) combine systematic and non-systematic information on the flood frequency analysis (FFA); (3) compare the results of the FFA using palaeoflood and historical data with those obtained from hydrometeorological methods and from the PMF; (4) estimate the design flood and the safety check flood; (5) discuss the contribution of palaeoflood hydrology to dam safety issues in Spain.

2 STUDY AREA

The Guadalentín River is located in SE Spain and is a major tributary of the Segura River which flows into the Mediterranean. The study reach is located at the upper reach of the Guadalentín, at the junction of the Rambla Mayor and Caramel River (Fig. 1), and upstream of the tail of the Valdeinfierno reservoir. The Guadalentín River has a Mediterranean regime and it is known as one of the most torrential rivers in Spain. The mean monthly discharges show two maxima: (1) in spring with a twinfold peak in February–March and May–June, a (2) in fall (September to November) during which the most catastrophic floods have been produced. The gauge station is located at the Valdeinfierno dam with a drainage area of 540 km^2. This record covers the periods 1933–1949 and 1968 onwards, the largest peak discharge recorded being 178 m^3s^{-1} in 1946. It is important to note that most of the gauge record corresponds to mean daily discharges.

Palaeoflood studies were conducted at the Caramel River (El Posadero site), upstream of Valdeinfierno Reservoir. At this point the drainage basin is 311 km^2, with a mean discharge of 0.6 m^3s^{-1} and peak discharge of 178 m^3s^{-1}, as recorded at the gauge station. At the El Posadero site, the Caramel River and Rambla Mayor join at the entrance of a narrow bedrock canyon carved in Cretaceous limestones. The gorge is 15–30 m wide with bedrock walls 40 m high and a gravel bed channel. During flooding, flow is hydraulically controlled by the narrow canyon entrance, producing a hydraulic damming of the flow upstream of the constriction, which favoured the accumulation of flood deposits at the entrance sides. Palaeoflood sedimentation also occurred high along the canyon

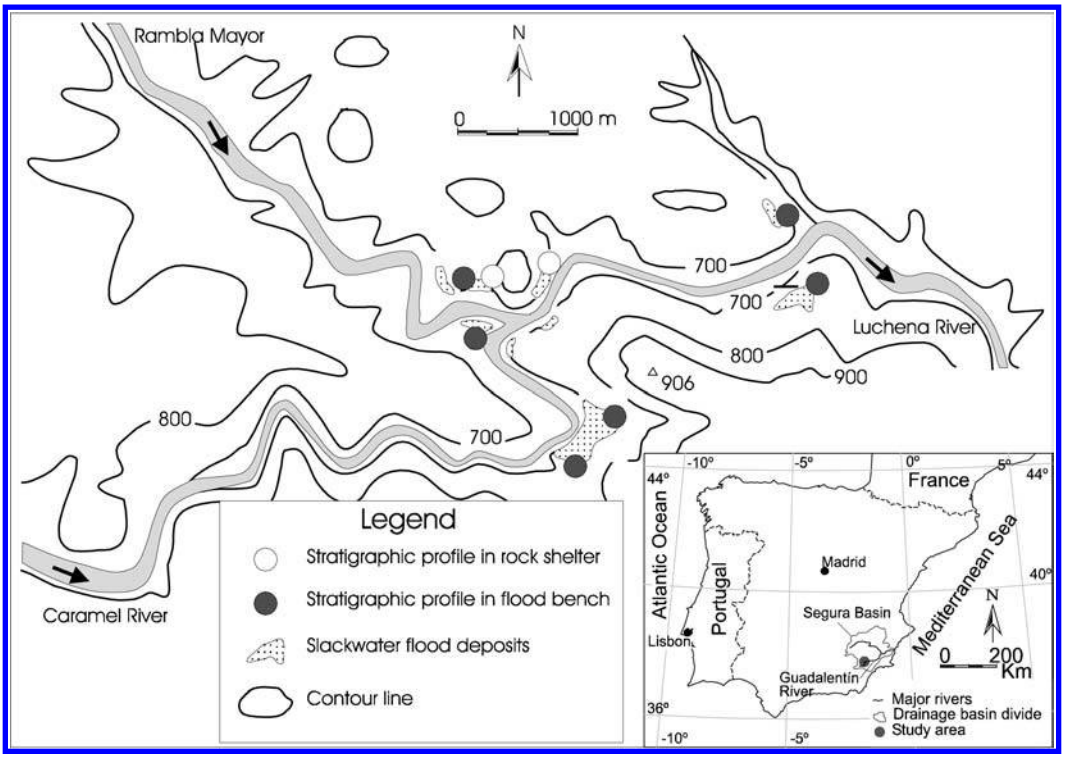

Figure 1. Location of the study area and stratigraphic profiles at the Rambla Mayor and Caramel River.

sides, bedrock caves and upstream of the canyon tributary gullies. Additional, documentary flood information of the Guadalentín at Lorca was obtained from bibliographic sources.

At the upper part of the basin, two dams where built mainly for irrigation purposes, and secondarily as flood control reservoirs. The most upstream one, Valdeinfierno, is located 5.2 km downstream of the study site, draining a catchment area of 540 km^2. The Valdeinfierno dam was built in 1806 for irrigation use and rebuilt in 1897 with a gravity structure of 51 m in height. It is 165 m in length and can hold a reservoir volume of 14 hm^3, with a spillway capacity of 673 $m^3 s^{-1}$ and a safety check flood of 850 $m^3 s^{-1}$.

The Puentes dam drains a catchment area of 1388 km^2 and has a long history of catastrophic failures that affected the city of Lorca (13 km downstream). The Puente's dam construction started in 1647, but a year later, during the construction works, a flood caused the collapse of the structure. The dam was rebuilt in 1790 but a few years later, on April 30th 1802, the failure of the dam produced a catastrophic flood that caused 608 deaths in Lorca as well as large economic losses. In 1884 the Puentes dam was rebuilt with a spillway capacity of 945 $m^3 s^{-1}$, although few years later was infilled by sediments. A new dam was built in 2000 close to the site of the former one, with a design flood of 2026 $m^3 s^{-1}$ and a safety check flood of 3626 $m^3 s^{-1}$.

3 METHODOLOGY

Palaeoflood hydrology is the reconstruction of the magnitude and frequency of recent, past, or ancient floods using geological evidence (Baker et al. 2002). The term "palaeo" has contributed to the general misconception that palaeoflood techniques are only used for estimating very old floods over geological timescales. However, most palaeoflood studies involve the study of the last 5000 years, and in this study there is a great emphasis on the last millennium. Palaeoflood hydrology is indeed defined by the fact that flood evidence is derived from lasting physical effects of floods on natural indicators, such as slackwater flood deposits, silt lines or scour lines.

During high flood stages in river canyons eddies, back-flooding and water stagnation occur at the gorge sides, producing low velocities and/or flow stagnation (slack water) that favours deposition from suspension of clay, silt and sand. These fine-grained deposits, known as slackwater flood deposits, are stage

Copyright © 2006 Taylor & Francis Group plc, London, UK

indicators of floods and can be preserved in stratigraphic sequences (Benito et al. 2003a) providing detailed and complete records of flood events that extend back several thousand of years (Baker & Kochel 1988). Slackwater flood deposits were found at three sedimentary settings: (1) forming flood benches at the sides upstream of narrow bedrock constrictions, (2) upstream of tributary valleys and (3) in rock alcoves (small caves or rock shelters formed in exposed bedrock on the valley sides) (Fig. 1). Stratigraphic and sedimentological analyses of the deposits were carried out both in the field and the laboratory, with sediment peels of the stratigraphic profiles, measuring approximately 80 cm × 50 cm in size, made in the field. Individual flood units were identified through a variety of sedimentological indicators (Baker & Kochel 1988, Benito et al. 2003b): the identification of clay layers at the top of a unit; erosion surfaces; bioturbation indicating the exposure of a sedimentary surface; angular clast layers, where local alcove or slope materials were deposited between flood events; and changes in sediment colour. As well as identifying individual flood units, sedimentary flow structures were also described in order to elucidate any changing dynamics during a particular flood event and/or infer flow velocities that can improve discharge estimation (Benito et al. 2003b).

Slackwater flood deposit chronology was determined using radiocarbon dating of charcoal collected from individual flood units. Necessary preparation and pre-treatment of the sample material for radiocarbon dating was carried out by the ^{14}C laboratory of the Department of Geography at the University of Zurich (GIUZ). The dating itself was done by AMS (accelerator mass spectrometry) with the tandem accelerator of the Institute of Particle Physics at the Swiss Federal Institute of Technology, Zurich (ETH). Calibration of the radiocarbon dates was carried out using the CalibeETH 1.5b (1991) programme of the Institute for Intermediate Energy Physics ETH Zürich, Switzerland, using the calibration curves of Kromer & Becker (1993), Linnick et al. (1986) and Stuiver & Pearson (1993).

The discharge estimations associated with the slackwater flood deposits at the Luchena River were calculated using the US Army Corps of Engineers River Analysis System computer program-HECRAS (Hydrologic Engineering Center 1995). The computation procedure is based on the solution of the one-dimensional energy equation, derived from the Bernoulli equation, for steady gradually varied flow. Palaeoflood discharge reconstruction was based on the calculation of the step-backwater profile which best matches geological evidence of the flood stage.

Twenty cross-sections about 25 to 100 metres apart were obtained from field survey along a 1800 m reach where the stratigraphical sections are located. Cross-sections and flood deposit elevations, the input data for the hydraulic models, were surveyed along both study reaches using a Trimble 4700 kinematic differential GPS, with additional data using a Sokkia total station where satellite visibility was poor. The GPS comprised two GPS receivers (a fixed base station with known co-ordinates and a rover to measure the cross-sections) with a radio link between them both to allow real time data processing.

The accuracy of the discharge estimations depends on stability of the cross-section geometry through time. In stable, bedrock-confined channels, channel geometry at maximum stage is known. In this study, the gravel bed channel is susceptible for scour and fill of the channel which reduces the accuracy of the palaeodischarge modelling. Assuming recent channel bed aggradation due to the downstream reservoir construction, the resulting values would underestimate the peak flood discharges. In the modelling, it was assumed for the calculations that flow was subcritical along the modelled reach. Manning's n values of 0.03 and 0.04 over the valley floor and margins, respectively, were assigned. A sensitivity test performed on the model shows that for a 25% variation in roughness values, an error of 4% was introduced into the discharge results. Critical flow was selected as boundary conditions at the most downstream cross-section where the channel narrows into a bedrock section where a deep pool was created.

Discharge values associated with each slackwater bench were estimated upon calculated water surface profiles matching flood unit elevations at different sites along the longitudinal profile. Rating curves relating individual flood unit elevations with flood discharges were established at each site. High water marks from the largest instrumental flood that occurred in 1973 were also fitted in the model to estimate flood discharges.

Traditional methods of flood frequency analysis (FFA) assume that the distribution of the unknown magnitudes of the largest floods is well-represented by the gauged record or can be obtained by statistical extrapolation from recorded floods (usually modest floods). The value of palaeoflood data is the potential to include physical evidence of large floods, or limits on flood magnitude, over long time periods. The basic hypothesis in the statistical modelling of palaeoflood information is that a certain threshold of water level exists and that over a specified time interval (from one year to thousands of years), all exceedances of this level have been recorded through geological palaeoflood evidence left along the river channels such as sediment deposits. It is also assumed a stationary of the long term incidence of floods. Palaeoflood data were organised in different threshold levels exceeded by flood waters over a given time period. In each threshold, individual floods are introduced as

Copyright © 2006 Taylor & Francis Group plc, London, UK

minimum, maximum, exact or range values of discharge, as well as the age dating. Data organisation on exceeded levels or thresholds reduces the potential palaeoflood discharge underestimation.

4 RESULTS

4.1 *Palaeoflood stratigraphy*

Nine stratigraphic profiles were described in a reach of 2.5 km in length. The slackwater flood deposit units varies between a few centimetres and 40 cm of fine to very fine sands and silts, with occasional clay, with gradual fining upward sequences. Massive, parallel lamination and cross-bedding are the dominant sedimentary structures.

A flood unit sequence usually culminates with climbing ripple structures overlaid by silt lamina which represents the end of the flood deposition. The oldest flood deposits were dated as 1985 ± 50 ^{14}C yrs BP (radiocarbon years before present), although the stratigraphic record contains major gaps between 2000 and 1000 BP (years before present).

The most complete section forms a flood bench on the right side of the Caramel River at the entrance of the gorge. The stratigraphic profile is ca. 7 m in thickness and provided evidence of at least 24 floods over the last 1000 years. The lower ten flood units have been dated between 1020 ± 50 and 945 ± 45 ^{14}C yrs BP, suggesting a period of frequent relatively small floods on the basis of the very fine and fine sand grain size and the thin layers. The top of this flood sequence is overlain by slope deposits which indicate a break in flood sedimentation of ca. 300 years (2-sigma age range overlaps). Overlying this are five flood layers, the lower one dated to 340 ± 45 ^{14}C yrs BP, which also have fine and very fine sand grain-size but they are generally thicker. These flood layers are capped by a 42 cm-thick colluvial layer, indicating a second break in flood sedimentation. The upper part of the section is represented by nine modern flood deposits, with a basal date of 205 ± 45 ^{14}C yrs BP, a middle date of 120 ± 45 ^{14}C yrs BP, and the upper flood layer likely left by the 1973 flood. Field evidences suggest that the 1973 flood was the largest event over the last 1000 years.

On the right side of the Rambla Mayor, also near the entrance of the gorge, a 2 m thick flood bench shows evidence of at least nine flood units with an oldest date of 190 ± 45 ^{14}C yrs BP, a middle date of 105 ± 45 ^{14}C yrs BP, and the upper deposits dated as modern. This stratigraphy is equivalent in flood unit number and chronology to the upper part of the previous stratigraphic profile.

The palaeoflood and historical flood information point out to an increase in the flood frequency and magnitude in modern times which can be attributed to climate variability accentuated by intensive deforestation and land use practices during the last 400 years.

4.2 *Discharge estimation*

Discharge values associated with each slackwater bench were estimated upon calculated water surface profiles matching the upper unit elevations at different sites along the longitudinal profile. The accuracy of the palaeodischarge estimates is reduced by the potential for scour and fill of the gravel channel bed. In the most complete stratigraphic profile, the lower 10 flood units (dated as 1020 ± 50 and 945 ± 45 ^{14}C yrs BP) are associated with minimum estimated discharges of 15 $m^3 s^{-1}$ and 580 $m^3 s^{-1}$. The second set of flood units comprising five flood units (with a basal date of 340 ± 45 ^{14}C yrs BP) is associated with minimum discharges between 580 $m^3 s^{-1}$ and 680 $m^3 s^{-1}$ (Fig. 2). In this section the third fill set (at least nine flood units) containing a dating at the lower portion of this set of 205 ± 45 ^{14}C yrs BP matched with discharge estimates between 730 $m^3 s^{-1}$ and 1033 $m^3 s^{-1}$ (Fig. 2). These discharges are minimum estimates since the water depth above the flood units are unknown, and therefore, discharge values may be considered as conservative. However, high water marks of the 1973 flood found along the study reach provided an associated discharge of 1616 $m^3 s^{-1}$, which shows that "exact" discharges may be 35% higher than the minimum estimates.

4.3 *Flood frequency analysis*

In the Valdeinfierno gauge station, the quality of the instrumental data is discontinuous, with most data corresponding to mean daily discharges. These mean daily discharges were transformed into peak discharges using nearby gauge data, but the degree of uncertainty was very high. Therefore, only peak discharges were used together with the palaeoflood data in the flood frequency analysis. The FFA was carried out with the MAX program (Stedinger et al. 1988), which computes the maximum likelihood estimates of the parameters of selected probability distributions. A critical assumption is that all the floods above specified discharge thresholds are recorded in the stratigraphy. In this study, only the floods postdating AD 1000 were used, since it was inferred that the stratigraphic record is complete for this time period. The exact date of each flood is not known, but the documentary flood record obtained in Lorca shows a great degree of agreement between the catastrophic historical floods and the number of floods recorded in the stratigraphy for specific time periods. Therefore, for practical purposes, each

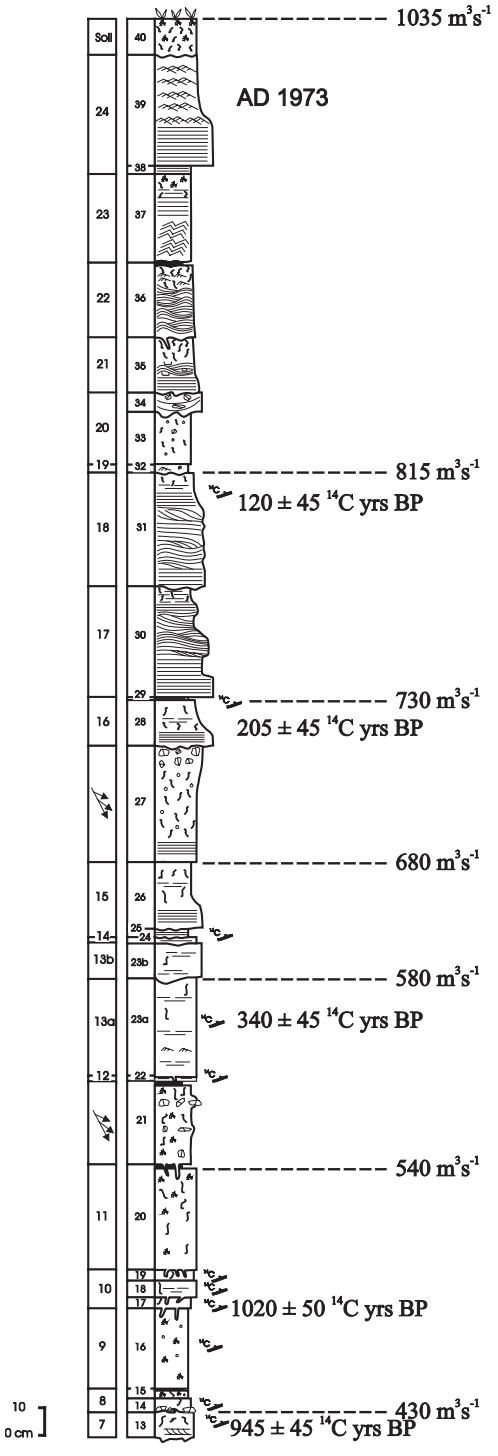

Figure 2. Stratigraphic profile, radiocarbon dates (years before present, yrs BP) and associated discharges ($m^3 s^{-1}$).

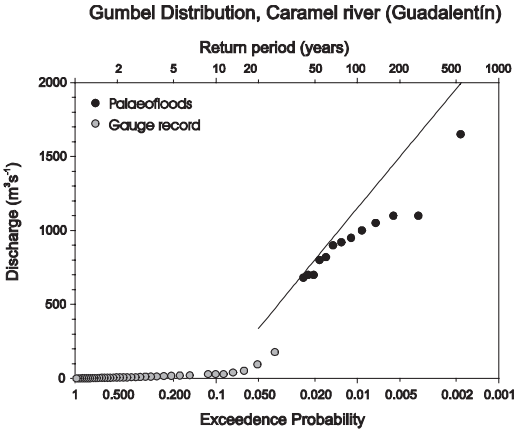

Figure 3. Gumbel distribution using gauge data (Valdeinfierno station) and palaeoflood records.

palaeoflood unit was assigned to a particular year of the historical flood record.

In this analysis, the best optimisation of the parameters was obtained using the Gumbel distribution. Plotting positions were assigned on the basis of the Weibull equation (Fig. 3). The analysis were conducted using only the last 1000 years palaeoflood record since it was noted major gaps in the previous stratigraphic record. According to this analysis the floods with return periods (T) of 100, 500, 1000, 5000 and 10,000 years correspond to discharges of 1150, 1950, 2300, 3100 and 3450 $m^3 s^{-1}$ respectively. These data are within the same order of magnitude of the rainfall-runoff analysis using a semidistributed model performed by CEDEX (Spanish Ministry of Development), in which discharges of 935, 1722, 2121, 3204 and 3727 $m^3 s^{-1}$ were calculated for the same return periods.

5 DISCUSSION

The palaeoflood data shows physical evidence of flood discharges with magnitudes almost 10 times higher than the ones recorded by the gauge station. In the studied stratigraphic profiles there is a good agreement on the number of flood units over specific time periods. A good agreement between the stratigraphic record and the documented catastrophic floods in Lorca was also found. This agreement among different data sources support the value of the palaeoflood evidence found in the study area. The potential for scour and fill of the gravely channel bed of the study reach reduces the accuracy of the palaeodischarge modelling, however, the deposits have fairly good chronological control and there is no indication of major cut and fill alluvial facies.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The FFA using palaeoflood and gauge data shows that the current design flood ($673\,m^3s^{-1}$) and the safety check flood ($850\,m^3s^{-1}$) for the Valdeinfierno dam are underestimated. The analysis using the palaeoflood data provided discharges of $2300\,m^3s^{-1}$, for the 1000-yr flood (design flood), and $3450\,m^3s^{-1}$ for the 10,000-yr flood (safety check flood). Similar conclusions can be extracted from the hydrological study performed by CEDEX in which the 1000 and 10,000-yr floods were estimated in 2121 and $3727\,m^3s^{-1}$.

Palaeoflood data can also be used for testing the analysis performed in the calculation of the PMF. The PMF has been used as a standard for hydrological analyses in dam safety for several decades (National Research Council 1985). By definition, the PMF has no return period but arbitrarily it was assigned a return period of 10,000 to 1,000,000 years at the upper and lower confidence limits for flood frequency analysis (National Research Council 1985). The PMF has been estimated for the Guadalentín River at the Valdeinfierno dam using an empirical equation based on the Meteorological World Organisation recommendations (OMM 1990), with a modification for the Spanish catchments introduced by CEDEX. According to this equation, the PMF estimated for the study reach is $5786\,m^3s^{-1}$. This value shows that the extrapolated discharges of the 10,000 year palaeoflood return period is about 60% of the calculated PMF, indicating that the calculated PMF discharges are very large overestimates. Similarly, palaeoflood studies performed for dam safety purposes by the U.S. Bureau of Reclamation, show that the upper limit for palaeoflood magnitude is up to an order of magnitude smaller than the one implied by PMF calculations (Enzel et al. 1993; Levish et al. 1996). In the USA the extrapolated discharges of the 10,000 year palaeoflood return period are between 5 to 20% of the calculated PMF (Levish et al. 1996). The value of the PMF for dam safety studies is uncertain due to the lack of physical potential of these basins to generate the calculated peak discharges. Estimated discharges from the physical evidence left by floods over periods of thousands of years provide more realistic results, which can be combined with gauge station data using appropriate statistical tools and subsequently be of great value for the planning of large scale hydrological projects (e.g. Ostenaa et al. 1994; Ostenaa & Levish 1996).

6 CONCLUSIONS

This paper illustrates that palaeodischarge estimations can be obtained from sedimentological evidence of floodwater elevations reached by past floods. These palaeoflood data are based on "real" evidence of flood stages providing advantages over the uncertainties of other methods such as the hydrometeorological models or the deterministic (PMF) estimations. In the Guadalentín River, the 2000-yr flood record from palaeofloods indicates that floods of a larger magnitude (upto $1616\,m^3s^{-1}$) than any recorded in the instrumental record ($<180\,m^3s^{-1}$) have occurred in the past. The palaeoflood discharges can be combined with the gauge record to estimate high flood quantiles (500, 1000, 5000, 10,000 year return periods with discharges of 1150, 1950, 2300, 3100 and $3450\,m^3s^{-1}$ respectively), without relying on statistical extrapolations from short instrumental records. The current design flood ($673\,m^3s^{-1}$) and the safety check flood ($850\,m^3s^{-1}$) for the Valdeinfierno dam are underestimated, and they should be modified to $2300\,m^3s^{-1}$ for the design flood and $3450\,m^3s^{-1}$ for the safety check flood. Discharges obtained from the PMF ($5786\,m^3s^{-1}$) overestimated the discharge results, and they do not provide a realistic estimation of dam safety features (dam and spillway designs).

ACKNOWLEDGEMENTS

Our palaeoflood research has been funded by the Spanish Commission of Science and Technology through the projects "Incorporation of palaeoflood and historical flood data in the calculation of dam safety – PALEOCAP" (CICYT project no. REN2001-1633-RIES), and "Infiltration on channel beds and recharge of aquifers related to floods and palaeofloods in ephemeral rivers- PALEOREC" (CICYT project no. CGL2005-01977/HID). Further funding support was provided by the Centro de Estudios Hidrográficos of the CEDEX and the European Commission projects "Systematic, Palaeoflood and Historical data for the improvement of flood Risk Estimation – SPHERE" (contract no. EVG1-CT-1999-00010) and "FloodWater recharge of alluvial Aquifers in Dryland Environments – WADE (contract no. GOCE-CT-2003-506680). The manuscript benefited from comments from an anonymous reviewer.

ABSTRACT: Two-dimensional flood inundation model and quantitative precipitation estimation(QPE) model were developed to evaluate the impact of levee failure for flood analysis. For improved areal rainfall estimation, cokriging technique was adopted to optimally merge radar reflectivity data into rain-gauges data by getting the better information of spatial variability of rainfall fields from weather radar and getting the better quantitative information from rain gauges. For the improved inundation model development, the mathematical formulation of the suggested model incorporates two-dimensional shallow water equations for flood inundation analysis.

The developed model was applied to analyze the inundation flow from the levee break of Gamcheon river during the typhoon Rusa on October 31 through September 1, 2002. To verify the simulated results, wide range field surveys have been performed including the collection of GIS database, land use condition, flooded area, and flow depths. Velocity distributions and inundation depths were presented to demonstrate the robustness of the model. Simulation results have good agreements with the observed data in terms of flood level and flooded area. Methodologies considering radar-rainfall estimation, rainfall-runoff analysis and inundation analysis in this study will contribute to the establishment of the nationwide flood disaster prevention system

1 INTRODUCTION

The climatic change of summer rainfall pattern in Korean peninsula can be summarized as the total number of rain day decreases, nevertheless, the total amount of rainfall increases, and the total number of days, whose daily rainfall amount is greater than 80 mm, increases. Floods are the most frequent natural hazards in Korea: typhoon Rusa took 213 lives and caused $5 billion worth of damage in 2002, and typhoon Memi took 117 lives and caused $4.5 billion worth of damage in 2003 (http://www.kma.go.kr). To evaluate the probable flooding damages, we need an accurate numerical model for flood and inundation analysis as well as accurate spatial rainfall estimation technique. Therefore a comprehensive approach is essential to analyze the flood and inundation effectively.

The analysis of flood wave resulting by the sudden collapse of a dam or river levee is studied continuously after development of a set of hyperbolic partial differential equations, well known as Saint-Venant equations. Katopodes and Strelkoff (1978) developed two-dimensional numerical model using characteristic curves but it is relatively complex to use. Kawata and Nakagawa (1984) and Tachi et al.(2001) represented the relationships between flood waves and obstacles in protected lowlands such as buildings, trees etc. Han et al.(1998, 2003, 2004) analyzed the characteristics of flood waves in protected low lands caused by levee breaks. In this study, a 2-D flood inundation model was developed to evaluate the impact of levee failure in a natural basin for flood analysis.

The variability of rainfall has the most critical influence on the performance of hydrologic models. Traditionally, hydrologic models have depended on rain gauge networks to provide the areal-averaged rainfall information. It will provide incorrect representation of the spatial characteristics of rainfall fields, especially in convective weather systems where rainfall amounts vary significantly over small regions. The spatial variability of rainfall in mountainous regions is very large because of orographic influences (Li et al., 1995). Korea is mountainous and marked by deep, narrow valleys. A complex system of mountain ranges and spurs extends across the country. Therefore accurate spatial rainfall information is essential to analyze the rainfall runoff process appropriately. Therefore

Copyright © 2006 Taylor & Francis Group plc, London, UK

accurate spatial rainfall information is essential to analyze the rainfall runoff process appropriately. In this study, we introduced an ordinary cokriging technique which optimally merges radar reflectivity data into rain-gauges data (Krajewski, 1987).

The purpose of this study is to develop an integrated model of the advanced spatial rainfall estimation technique and flood inundation analysis to simulate two-dimensional surface flow during floods.

2 MODEL DESCRIPTION

In this study, two-dimensional flood inundation analysis model was developed to evaluate the impact of levee failure in a natural basin for flood analysis. The mathematical formulation of the suggested model incorporates 2-dimensional shallow water equations for flood inundation analysis. The two-dimensional unsteady shallow water equations consist as follows:

$$\frac{\partial h}{\partial t}+\frac{\partial q_x}{\partial x}+\frac{\partial q_y}{\partial y}=0 \tag{1}$$

$$\frac{\partial Q_x}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q_x^2}{A_x}\right)+\frac{\partial}{\partial y}\left(\frac{Q_xQ_y}{A_y}\right)+gA_x\left[S_{fx}+\frac{\partial H}{\partial x}\right]=0 \tag{2}$$

$$\frac{\partial Q_y}{\partial t}+\frac{\partial}{\partial y}\left(\frac{Q_y^2}{A_y}\right)+\frac{\partial}{\partial x}\left(\frac{Q_yQ_x}{A_x}\right)+gA_y\left[S_{fy}+\frac{\partial H}{\partial y}\right]=0 \tag{3}$$

where Q_x, Q_y are the flow rates in the x- and y-directions, respectively; q_x, q_y are flow rates per unit width in the x- and y-directions; A_x, A_y are the cross sectional areas; s_{fx}, s_{fy} are the friction slopes in the x- and y-directions; g is gravitational acceleration, h is water depth; and H is water surface elevation.

The developed model consisted of unstructured mesh basis to analyze complex flow problems associated with complicated topography and boundary of protected lowlands. Figure 1 shows a sample element of unstructured mesh. Where c denotes the center element in computation; 1, 2, 3, 4 are adjacent elements number; G_i is coordinate of centroid of mass for each element; a_i is area of each element; n_i is coordinate of corner points of center element; L_{ij} is distance between centroid of element i and boundary with element j; and SL_i is length of i-side.

The two-dimensional unsteady shallow water equations for unstructured meshes are can be written as

$$\frac{\partial q_i}{\partial i}+\frac{\partial h}{\partial t}=0 \tag{4}$$

$$\frac{\partial Q_i}{\partial t}+\frac{\partial}{\partial i}\left(\frac{Q_i^2}{A_i}\right)+gA_i\left[S_{fi}+\frac{\partial H}{\partial i}\right]=0 \tag{5}$$

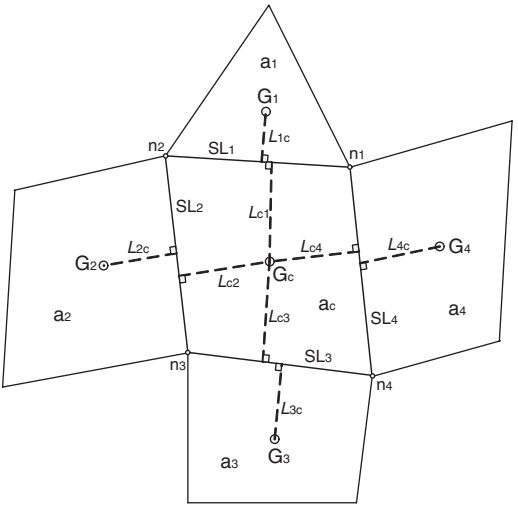

Figure 1. Sample element for two-dimensional flood analysis.

where Q_i is the flow rates in the i-direction; q_i is flow rates per unit width in the i-direction; A_i is the cross sectional area; s_{fi} is the friction slope in the i-direction; g is gravitational acceleration; h is water depth; and H is water surface elevation.

The friction slope, S_{fi}, can be written as follows using Manning's formula

$$S_{fi}=\frac{n_i^2|Q_i|Q_i}{\varphi^2A_i^2R_i^{4/3}} \tag{6}$$

where n_i is Manning's roughness coefficient; ψ is 1 for SI units and 1.49 for US Customary units; $R_i=(A_i/P_i)$ is hydraulic radii, P_i denotes the perimeter for i-direction. Equation 5 can be written as

$$M_i+\left\{S_{fi}+\frac{\partial H}{\partial i}\right\}=0 \qquad \text{where} \quad Mi=\left(\frac{\partial Q_i}{\partial t}+\frac{\partial}{\partial i}\left(\frac{Q_i^2}{A_i}\right)\right)/gA_i \tag{7}$$

Arial and directional components of unstructured element are computed by Equations (8) and (9).

$$\theta_k=\tan^{-1}\left(\frac{y_k}{x_k}\right) \tag{8}$$

$$\frac{1}{2}\sum_{k=1}^{n}\det\begin{vmatrix}x_k & x_{k+1}\\ y_k & y_{k+1}\end{vmatrix}=0 \tag{9}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

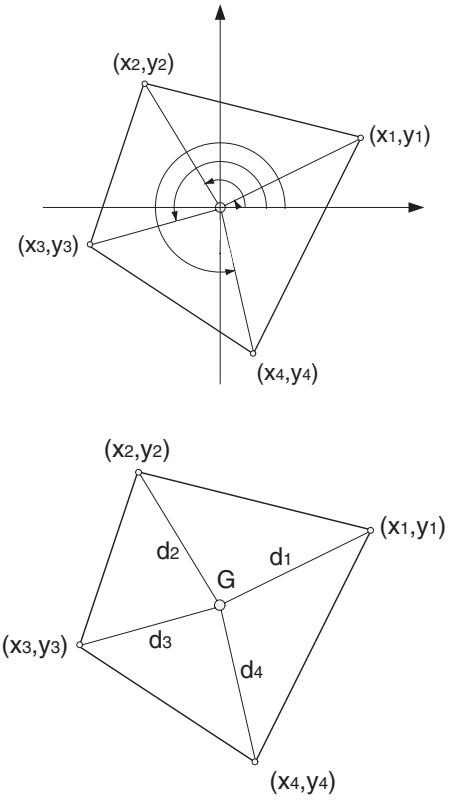

Figure 2. Schematic of arial and directional components of unstructured element.

The elevation of centroid was estimated using inverse distance method.

$$z_G = \frac{\sum_{r=1}^{n} d_r z_r}{\sum_{r=1}^{n} z_r} \tag{10}$$

where z_r is elevation of corner points; $d_r = \{(x_r - x_G)^2 + (y_r - y_G)^2\}^{1/2}$

Optimal time step, Δt is estimated using Courant-Friedrichs-Lewy (CFL) stability condition. The differences in flow rates Q and water depth h were estimated respectively as

$$\Delta Q_c^j = -\left\{ \sum_{i=1}^{3 \text{ or } 4} q \,|\, \Gamma_i \cdot \delta_i \right\} \tag{11}$$

$$\Delta h_c^j = \frac{\Delta Q_c^j \cdot \Delta t}{a_c} \tag{12}$$

where δ_i is length of i-side.

At time step $j+1$, the water surface elevation H of element c can be estimated as

$$H_c^{j+1} = H_c^j + \Delta h_c^j \tag{13}$$

The model is able to compute maximum stage and peak discharge efficiently in channel and protected lowland.

3 RAINFALL ESTIMATION USING GEOSTATISTICAL APPROACH

Based on the assumption that rain gauge networks give us the accurate rainfall quantity at a point and weather radar gives us accurate spatial distribution of rainfall fields, a geostatistical approach is employed to describe the spatial structure of rainfall fields. Geostatistical estimation techniques such as kriging give us unbiased linear estimations with minimum error variance. A linear estimator for rainfall estimation can be written as

$$\hat{P}_0 = \sum_{i=1}^{N_G} \alpha_i P_i + \sum_{j=1}^{N_R} \beta_j M_j \tag{14}$$

where M is radar reflectivity data, P is rain gauge data. N_G is the number of rainfall gauges, and N_R is the number of radar bins. Now we have two sets of coefficients: those that multiply the rainfall measurements and those that multiply the radar reflectivity measurements. The two sets of coefficients have different units.

The estimation problem is reduced to estimating the coefficients of α's and β's. The estimation error, defined as the difference between the estimate and the actual value of P_0 is

$$\hat{P}_0 - P_0 = \sum_{i=1}^{N_G} \alpha_i P_i + \sum_{j=1}^{N_R} \beta_j M_j - P_0. \tag{15}$$

The coefficients must be such that the variance of the estimation error is as small as possible. The coefficients can be determined by minimizing the Equation (16)

$$E[(\hat{P}_0 - P_0)^2] = E\left(\sum_{i=1}^{N_G} \alpha_i (P_i - G) + \sum_{j=1}^{N_R} \beta_j (M_j - S_j) - (P_0 - G) \right)^2 \tag{16}$$

Figure 3 represents the schematic diagram of the computation processes of the spatial rainfall data including quality control process of rain gauge and radar reflectivity data, computation of multi resolution constant altitude plan position indicator (CAPPI), and merging filtered radar reflectivity data into rain gauge data ordinary cokriging.

4 RESULTS AND DISCUSSION

The model was applied to analyze the inundation flow from the levee break of the Gamcheon river during the typhoon Rusa on October 31 through September 1, 2002. Rusa was the most violent typhoon to hit South Korea since 1959. During the typhoon Rusa, 213 people were dead and 33 people were missing. The total damage estimates were more than 5 billion US$. The rainfall field estimated using rain gage data and radar reflectivity data by cokriging was able to describe the spatial structure of rainfall fields more accurately than that using only rain gage data. Results show that rainfall fields estimated by ordinary cokriging give the improved results than that of traditional approach. Figure 5 represents topography and watershed characteristics of the Gamcheon basin. The watershed

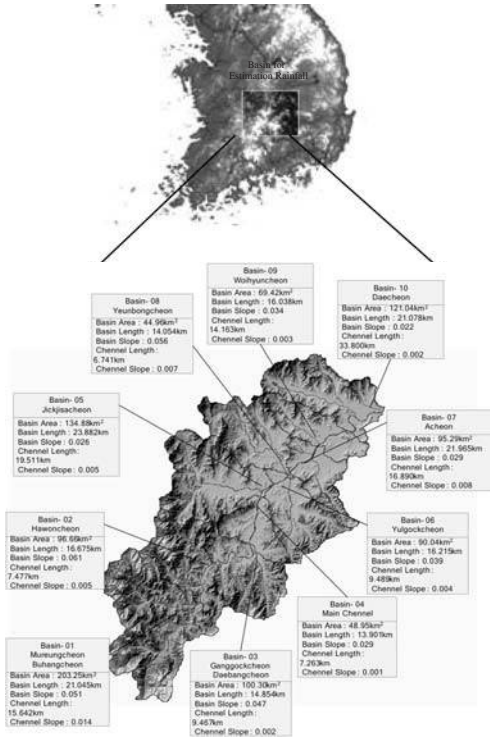

Figure 5. Topography and watershed characteristics of the Gamcheon basin.

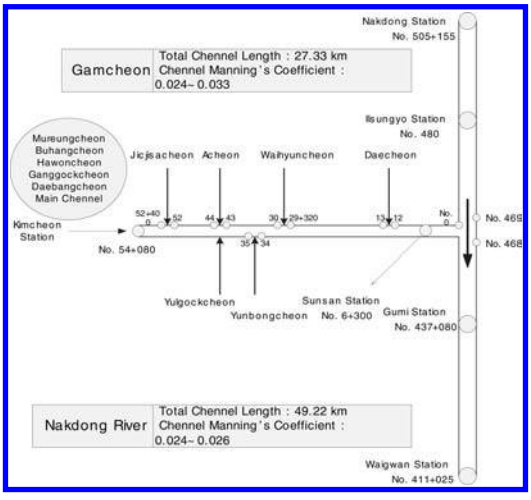

Figure 6. Schematic diagram describing characteristics of channel networks in Gamcheon river system.

was subdivided to ten small watersheds as shown in the Figure 5. Figure 6 shows the schematic diagram describing characteristics of channel networks in the Gamcheon river system. The Muskingum and

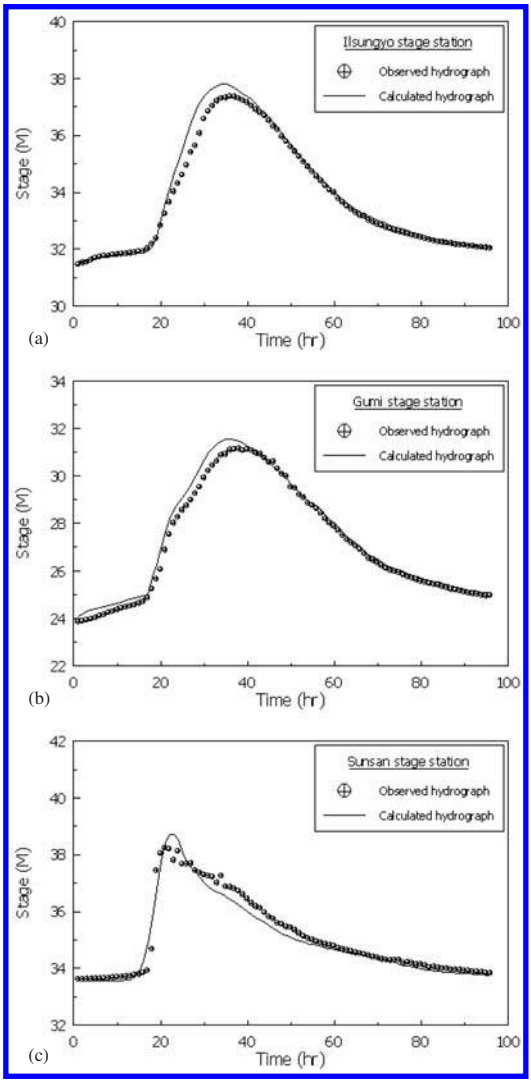

Figure 7. Observed and calculated stages at (a) Ilsungyo, (b) Gumi, and (c) Sunsan.

Clark methods were used for the flood routing. To verify the simulated results, wide range field surveys have been performed including the collection of NGIS(National Geographic Information System) database, land use condition, flooded area, and flow depths. Figure 7 shows the observed and calculated stages at Ilsungyo, Gumi, and Sunsan stations respectively. Sunsan station is located at the downstream of the Gamcheon river, Ilsungyo and Gumi stations are located up- and down-stream of the Gamcheon river inflow along the Nakdong river respectively. Results show good agreement between the simulated and observed data. Velocity distributions and inundation

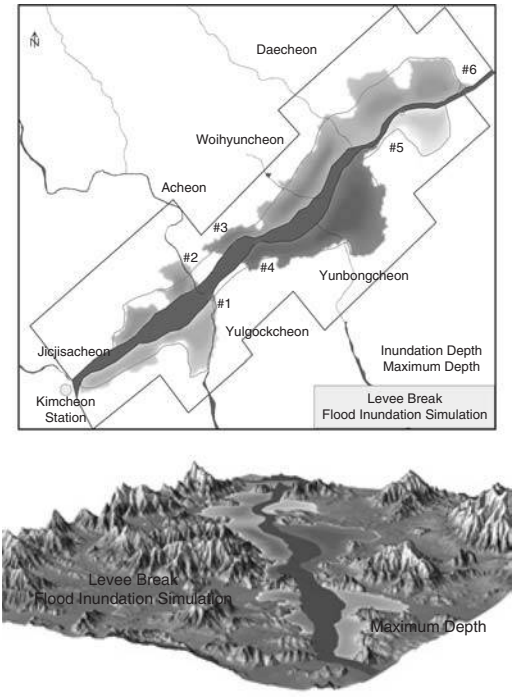

Figure 8. Observed flooded area (solid line) and the simulated flooded area (shaded area).

depths for different time were presented. Model results have good agreements with the observed data in terms of flood level and flooded area. Figure 8 represents the observed flooded area (solid line) and the simulated flooded area (shaded area). Overall results show good agreements with observed data and demonstrate the robustness of the model. The developed model will contribute to the establishment of the national integrated flood disaster prevention system and the river or protect lowland management system.

ACKNOWLEDGEMENTS

This study was supported by the 2003 Core Construction Technology Development Project(03-SANHAKYOUN-C03-01) through the Urban Flood Disaster Management Research Center in KICTTEP of MOCT, KOREA.

A management system to optimize reservoir control in the case of floods

R. Pohl & A. Bornschein
Dresden University of Technology, Germany

ABSTRACT: Many multipurpose reservoirs are situated in the low mountain range of Germany. Most of them are necessary for drinking water supply and flood protection as well. Other utilizations are recreation, water power and the downstream low water regulation during dry seasons. The operation rules of the reservoirs have to be optimized to meet the different requirements of use. One tool within this framework is a management system for river basins including all reservoirs and their specific operation rules affecting the downstream reaches. As an optimization objective for instance the minimization of inundation risks can be defined. In this case the risk can be defined as hydraulic and hydrologic safety of the reservoir itself and the risk due to inundation and damaging in the downstream regions. Considering the European Water Framework Directive the ecological aspect of reservoir management is one more point in the optimization process. To establish a pilot project the software TALSIM will be applied to river catchments in the ore mountains (Saxony).

1 INTRODUCTION

In the last few years some big flood events occurred in the catchments of the rivers Elbe, Danube and Odra in Germany (Figure 1). Heavy damages occurred. Thus 21 people were killed and substantial parts of the infrastructure were destroyed during the 2002 flood.

The total loss in Germany was estimated to be 11.9 billion €. These floods have dramatically called attention to limits and deficits of flood risk management in the affected areas. It became obviously that there was a need to develop and implement improved instruments of flood risk management by the integration of different professional disciplines and experts in different fields.

The German Federal Ministry of Education and Research (BMBF) funded the national research program RIMAX (risk management of extreme flood events). The program has duration of 3 years (www.rimax-hochwasser.de). It focuses on flood events with a return period greater than 100 years and with high damage potential.

The program consists of three major subjects:

– Integrated concepts of flood risk management
– Technical flood protection

Figure 1. River Elbe with flooded open air cinema in Dresden during the 2002 flood event (photograph: Bornschein).

– General issues (e.g. Education, Networking, Flood awareness and Risk communication)

The general issues should warrant the knowledge transfer into practice and education as well as the national and Europe-wide network of research activities. The research program stresses on implementation, which means, that the funded projects have to collaborate with responsible organizations at different political levels.

The research program includes more than 30 research projects with partners from universities, engineering consultants, governmental organizations and dam authorities. The first projects started in summer 2005. There is a wide range of research themes such as ground water management in urban areas in the case of extreme floods, reservoir and polder management, geo-textiles, stability of dikes and levees, flood retention in river networks, flood prediction and management, flood impacts on water supply, risk management and risk prediction using historical flood data information.

2 OBJECTIVES OF THE PROJECT

The presented project is a joint project between the Institute of Hydraulic Engineering and Applied Hydromechanics of the University of Technology Dresden and the Institute of Hydraulic Engineering and Water Management of the University of Technology Darmstadt, both are situated in Germany.

The research work of the project is focused on the improving of tools to analyze, evaluate and to manage flood risks. The future aim is to integrate the flood risk management including the reservoir operation strategies into the river catchments management.

In the end the flood risk of a certain flood event should be reduced in terms of both the failure probability of the dams and the consequences (damages, costs, impacts etc.) in the downstream areas. This means that an optimization has to be carried out to find the reservoir operation rules with the lowest environmental impact and the highest structure safety (dams, weirs, levees). Two strategies are possible: On the one hand a risk management system can be established due to pre-calculations of possible flood events including the consideration of retention in reservoirs and polders. On the other hand a just in time calculation can help to achieve better operation rules during a flood event.

In a catchments area the reservoirs and dams, the structures in the downstream regions like weirs, dikes and levees, the urban areas, industries and agricultural might be at risk. Furthermore the preservation and the improvement of the ecological system in the river basin, in the reservoirs and the river network are very important requirements of the risk management system.

3 INPUT DATA

The system which comes out of the research project has to include the calculation of the discharge in the whole catchments area (precipitation-runoff-calculation), retention calculation of the reservoirs and the computation of wave propagation downstream the dams with the determination of inundation areas. Furthermore the damages occur due to the flooding have to be calculated.

This needs a wide range of input data which are described in the following paragraphs.

3.1 *Digitalized morphological data*

A digitalized morphological data set is the basis for the whole system. It determines the river morphology, the geographical data set for precipitation run off calculation and provides the information of land use and soil properties as well as the location of buildings and bridges (Figure 2).

The profiles of river cross section are often determined by terrestrial surveying. Additionally laser scan data or digital topographical maps are used for the whole watershed and the floodplains.

3.2 *Precipitation and discharge*

To model the areal precipitation for the whole watershed, the polygon method will be used.

This method is used because of the non uniform measurement station spacing. To determine the areas belonging to each station, lines are drawn between adjacent stations on the map. The perpendicular bisectors of these lines form a pattern of polygons with one station inside each polygon (see Figure 3). These are the areas in which the measured precipitation of each station will be used to calculate a certain event for the whole watershed.

Figure 2. Morphological data set with vegetation and buildings from laser scan (confluence of the rivers Wilde Weißeritz and Rote Weißeritz at the town of Freital; data: LTV 2005).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Furthermore data are needed to estimate the maximum possible precipitation (DVWK 1997 and DWD 1997), the discharge of a flood event with a certain reoccurrence (LfUG 1993) and the soil-moisture at a certain event.

To validate the calculated discharge from precipitation-runoff-analysis gauge data will be needed. Considering bigger flood events where the discharge measurement didn't work it is also possible to validate the discharge by use of hydraulic water level calculation and comparison with measured water levels along the river banks or at bridges and buildings.

3.3 *Operation strategies and rules for dams, reservoirs and polders*

The operation rules of a controlled reservoir determine the future reservoir water level and the outflow hydrograph depending on the inflow hydrograph, the initial reservoir water level, the actual season and the precipitation forecast. These operation rules depend on reservoir purposes like flood protection, water supply, low water regulation, fishing and recreation benefits.

There are different common operation strategies for reservoir storages and release decisions like the following:

- Determination of a minimal and maximal outflow discharge; the minimal outflow discharge often depends on ecological reasons; the maximal outflow discharge could be determined by the inbank capacity in a downstream river reach.
- For flood control purposes free reservoir storage has to provide enough volume to keep a flood of a certain reoccurrence within the reservoir. This could mean to discharge more water downstream in anticipation of a flood event.
- Water supply for drinking water or industrial water demands a defined release discharge to meet the needs.
- Controlled outflow to balance the downstream flow (reservoir storage management plan).
- Low water regulation (to ensure a critical water level for commercial navigation, thinning of wastewater inflow, fulfilment of a water supply demand downstream).
- The reservoir outflow depends on the reservoir inflow.
- Release decisions depending on other states of the system (actual water level in other reservoirs in the same or in other catchments areas, actual discharge in a special river reach, the snow height in the catchments area, actual precipitation, actual soil moisture and others).

All release decisions may vary with respect to the time. The outflow discharge is limited by the gate opening and or the spillway capacity (Figure 4).

In the case of a multipurpose reservoir there are often competing purposes. One example could be flood protection and water supply. Flood protection needs an initially large empty flood control storage resulting in a low water level. Water supply needs a high water level because of required supply safety and the need of water extraction in different water levels to guarantee the water quality.

But in the case of an extreme flood event it is difficult to control the outflow. In Figure 5 the inflow, outflow and storage hydrographs of the Malter reservoir in Saxony are shown during the flood event in August 2002. The volume of the whole flood wave was 11 times bigger than the flood detention storage of the reservoir and almost triple of the total storage

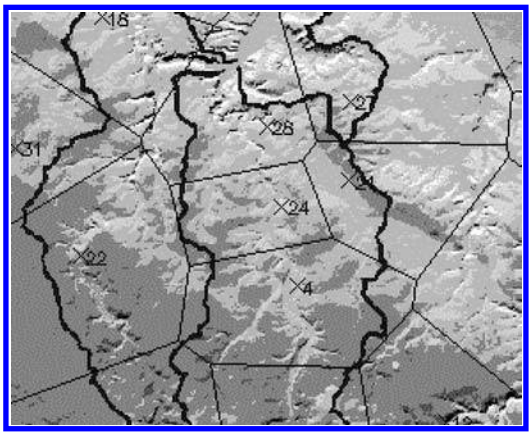

Figure 3. Polygon method to calculate the areal precipitation distribution in the catchments area of the Weißeritz river (x = the location of a precipitation station; – = border of the related areas).

Figure 4. The intake of the spillway of the Malter dam on 13th August 2002.

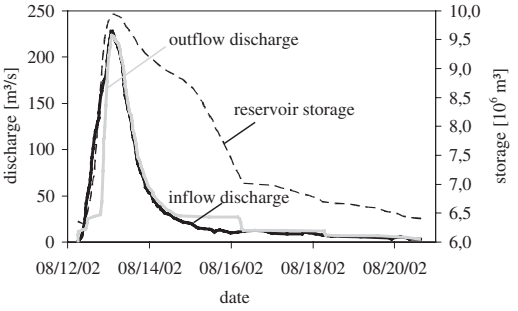

Figure 5. Inflow and outflow hydrographs as well as reservoir capacity of the Malter reservoir during the flood in August 2002 (LfUG 2002).

volume of the reservoir. The inflow and outflow peak are almost the same.

Polders often have more simple operation rules. In the case of an uncontrolled polder the inflow begins when the water level in the river exceeds a certain level. If there is a gated inflow structure the filling of the polder can be delayed until the flood peak arrives.

4 OPTIMIZATION CRITERIA

The optimization process is mainly based on a multi-criterion matrix which includes different types of optimization criteria.

4.1 *Freeboard and overtopping of dam*

The new German standard (DIN 19700) gives two design cases for dams. Furthermore the hydraulic safety of the dams has to be considered (Pohl & Horlacher 1996 and Pohl 1999). In the risk management the failure frequency of gates and valves at dams has to take into consideration (Pohl 2000 and Martin & Pohl 2002).

If the water level in a reservoir or in the river reaches a certain level the dam or levee could be overtopped. Because of the possibly unstoppable erosion process due to overtopping and the following completely destruction this must be avoided at all costs (Aigner et. al. 2002 and Bornschein & Pohl 2003). So the level of the dam crest or the top of a levee or dike is a very strong criterion for maximum water level.

4.2 *Stability of dams and levees*

There are different stability criteria for each type of hydraulic structure like dams, dikes, levees, weirs. They are e.g. described in dam or levee standards and guidelines. Typical failure modes are sliding, overturning, erosion due to piping or overtopping.

The difference in water level outside and inside a levee has an influence on seepage and can reduce levee stability.

Just before overtopping extraordinary water surface elevation can reduce the stability of a dam. In general safety coefficients below 1 indicate insufficient stability and therefore a severe failure risk.

4.3 *Inundation damages*

The inundation of industrial and urban areas or forests and farmland results in different types of damages which are:

- Asset damages (economic, public and private)
- Production downtimes (during and after the flood event)
- Casualties
- Damage to cultural buildings or sites with considerable ideal losses
- Ecological impacts

Some of these damages were recorded or can be expressed monetarily. An advanced description of possible damage due to high water levels is a stage-damage-function. This is a summary statement of direct economic cost of flood water inundation for a specific river reach (US Army 1996). This function depends on the land use and the kind of structures within the considered area (residential structures, non-residential structures).

There is a wide range of different stage-damage-functions. Therefore the above mentioned RIMAX program includes also research groups dealing with damage functions.

But some damages can be described only qualitatively. Therefore an evaluation system with qualitative description has to be used. A very simple example is the classification of damages into groups as high, mean, low and none.

4.4 *Ecological impacts*

The operation of dams, the installation of weirs as well as the set up of dikes and levees change the landscape and have ecological impacts.

A qualitative calculation of this impact is very difficult or often impossible. One has to distinguish between the ecological impacts in mean level and low level times and in the case of a flood event.

In times of a low water level the water temperature and oxygen content have often negative impacts on protozoa, fishes and plants. The reservoir operation rules could help to avoid critical states in the stream.

But also a flood itself has negative ecological impacts although a flood is a natural phenomenon. Too frequent and too long inundation of floodplains or polders can hurt the flora and fauna. Since the velocity is high fishes may floating away during a flood event.

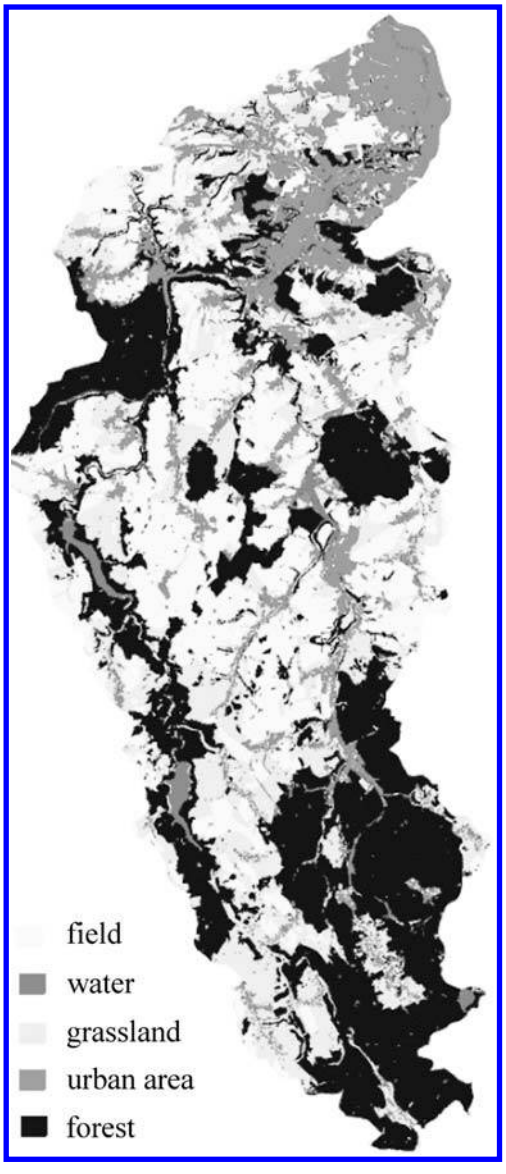

Figure 6. Land use in the Weißeritz watershed (LTV 2005).

5 CALCULATION PROCEDURE

To find out the optimum operation strategy several calculation steps have to be included in a calculation procedure. The separate computation steps that have to be repeated many times can be described as follow:

1 Precipitation-runoff-calculation in the whole watershed using TALSIM. The result is the discharge hydrograph in each river reach (Q(t)).
2 Determination of stage-discharge-relation at each cross section using a water level calculation for different flood scenarios.
3 Determination of a relation between a certain water level and the possible damage at a certain river reach
   – allocation of a flooded area to a certain water level at each cross section
   – selection of the appropriate stage-damage-function depending on the major land use in the flooded area
   – addition of all damages related to a water level at each cross section
4 determination of the relation between the amount of damage and the river discharge using the results from step 2 and 3
5 determination of a multi-criteria objective function for optimization purposes including monetary and non-monetary criteria
6 search of this operation strategy with the lowest damage for all possible flood events or the most of them.

To check the different operation strategies it is necessary to use artificial flood events with a reoccurrence period of about 20 to 100 years and beyond and the series of historical flood events if recorded.

5.1 *Precipitation-runoff analysis using TALSIM*

The TALSIM software has been developed to solve water management problems including reservoirs at Darmstadt University, chair of hydrology and SYDRO-Consultants. Water management systems like a multi reservoir system or a river basin can be modelled.

The description of the water management system needs different artificial system elements. A system element yields a certain output under certain defined input conditions. Different system elements have been connected to create the whole water management system.

The following elements are available: single discharger, reservoir, customer, transport element (= river reach), branch and single catchments area. An element is described by characteristics and parameters. Characteristics can be determinate clearly like a cross section shape of a river reach. Parameters need a calibration and validation process like the roughness parameter of the river bed. A special element uses different methods to transform the input data into the output data.

The level of discretization of the water management system depends on possible cost and effort as well as how detailed the output is needed.

To calculate the precipitation-runoff process three models are implemented. The most simple is to define

Copyright © 2006 Taylor & Francis Group plc, London, UK

a fixed discharge coefficient for each single catchment area depending on land use, altitude and subsoil properties.

More advanced is the widely used soil-conservation service method (SCS-method) or curve number method considering soil texture, land use and soil moisture. The Curve number and the total precipitation of the last 21 days are necessary for input.

The highest effort needs a complex soil moisture and ground water calculation. This model needs a wide range of detailed measured data and is only recommended for smaller catchments areas.

TALSIM is not a hydrodynamic model. The flood routing and water retention in a river network are approximated using the conceptual model of *Kalinin-Miljukov.*

5.2 *Water level calculation and determination of inundation area*

To connect the damages due to the inundation with the precipitation-runoff-model a one-dimensional hydrodynamic model has been introduced into the calculation.

A possible hydrodynamic model is HEC-RAS developed by the Hydrologic Engineering Center of the US Army Corps of Engineers (USA). It solves the one-dimensional shallow water equation and can be used for both steady state and dynamic water level calculation. Backwater effects of bridges and weirs as well as more complex cross sections can be considered.

The water level from the hydrodynamic model together with the digital morphological data set let to the inundated area due to a certain river discharge.

5.3 *Polder*

There is no special element or tool to describe a controlled polder within TALSIM. Therefore a combination of different elements has to be established.

The polder itself is represented by the element "Reservoir". A water-level-storage-relation must be known as input. The distribution of the flow at the inflow cross section of the polder can be modelled using the element "branching" with a threshold model (Figure 7). If the discharge reaches a critical value the inflow into the polder begins.

To determine the actual characteristics of inflow structure it is possible to set "selectivity" for it. Another possibility is to set a variable threshold $Q_{crit.}$

The outflow from the polder can be included in an element "river reach". The definition of a weir or an operation rule is necessary at this cross section.

5.4 *Model calibration*

Previous flood events among them the 2002 event in Saxony are used to calibrate the model. First the

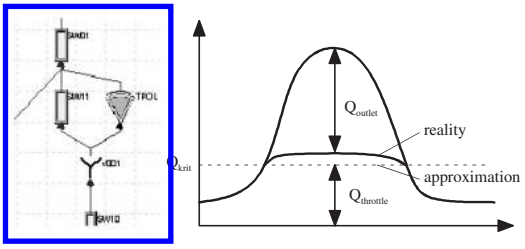

Figure 7. System elements of TALSIM describing a polder with rectangles = river reaches and triangle = reservoir (left) and the principle of the threshold model for the polder inflow (right).

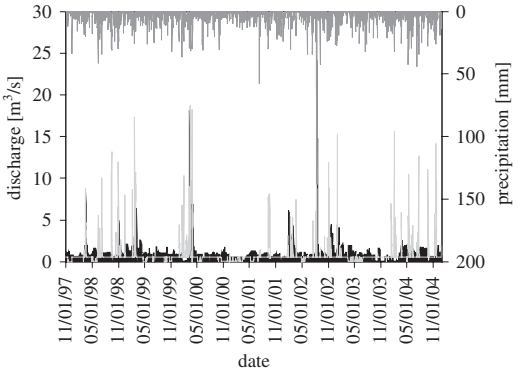

Figure 8. Measured (–) and simulated (–) water level at the gauge Lehnmühle UP together with precipitation data (–) of the station Fichtelberg.

modelling of the precipitation-runoff-relation has to be verified. Figure 8 shows the precipitation measured at the rain gauge Fichtelberg versus the measured and calculated discharge at the gauge Lehnmühle in the period from November 1997 to November 2004.

At the moment the agreement is not sufficient due to the assumption that the measured precipitation at one rain gauge is equal to the areal precipitation of the whole catchments area of the discharge gauge, which is about 60 km^2. Therefore further data and calibration are needed.

Another calibration is necessary for the hydrodynamic model and calculation of the water level. Water level and discharge measurements are required. The water level of the extreme 2002 flood event is available. More data of this quality would be desirable. This event represents a reoccurrence interval of about 500 years for the Weißeritz watershed (LfUG 2004).

6 CASE STUDY

To evaluate the effectiveness and usability of the calculation model two case studies will be carried out. The Weißeritz case study will be presented shortly.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Catchments area, river length and altitude of the Weißeritz River (LfUG 2004).

Catchments area	Area [km^2]	River length [km]	Altitude max. [m a.s.l.]	Altitude min. [m a.s.l.]
Wilde Weißeritz	163	52.9	735	185
Rote Weißeritz	154	35.4	765	185
Weißeritz	67	14.2	185	110
Total	384	102.5		

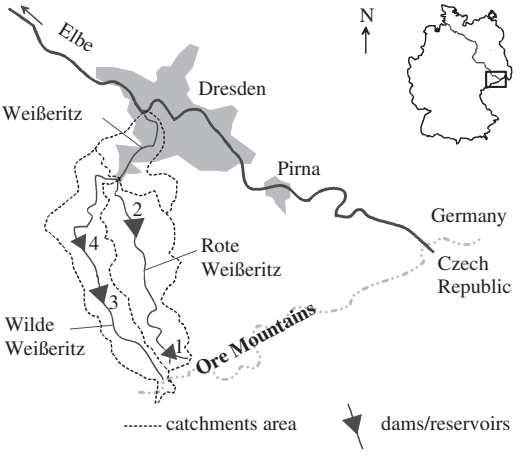

Figure 9. Catchment areas of the three Weißeritz rivers with existing dams (the numbers of the dams refers to table 2).

Table 2. Dams in the Weißeritz catchments.

Catchments area	No. of the dam	Name of the dam or Storage system	Storage [10^6 m^3]
Rote Weißeritz	1	Altenberg	1.036
	2	Malter	9.2
Wilde Weißeritz	3	Lehnmühle	23.53
	4	Klingenberg	17.49

Three rivers belong to the Weißeritz watershed. The Rote (red) Weißeritz River and the Wilde (wild) Weißeritz River have their sources in the Ore Mountains (Figure 9). The Weißeritz River (also named Vereinigte (united) Weißeritz River) originates due to the confluence of these two rivers at the town of Freital (figure 2). The Weißeritz River runs into the Elbe River at Dresden.

There are four reservoirs situated in the Weißeritz watershed all directly connected with the natural river system (Figure 9 and Table 2). The Rote Weißeritz River begins at the Altenberg reservoir. Furthermore

Figure 10. The Klingenberg gravity dam in the Weißeritz catchment area (photograph: LTV).

the Malter dam is situated at the Rote Weißeritz River. This is a multipurpose reservoir for flood retention, water supply and recreation.

There are the Klingenberg dam (Figure 10) and the Lehnmühle dam in the catchment area of the Wilden Weißeritz River. The main purpose of these two reservoirs is the drinking water supply for the town of Freital and the city of Dresden. Another purpose is flood control.

There are 21 precipitation stations within and near the Weißeritz watershed.

7 FIRST RESULTS

First calculations were made to check the reliability and the results of a reservoir or polder retention model. In the case of reservoirs and polders it was very important to find the right point in time to open the outlets (dams) or inlets (polder). As already expected the results were sensitive to the reliability of the forecast of the discharge hydrograph.

As an example a polder with a reservoir surface of $A_p = 2\,km^2$ was taken into consideration. The mean discharge in the river (in the frame of this example the Elbe river, also a federal navigation waterway) was set to the mean discharge $MQ = 400\,m^3/s$ whereas the peak flow was $Q = 4500\,m^3/s$. The time to peak was set to 48 h. It was assumed that the river was 250 m wide and the longitudinal bottom slope was $I = 0.0003$. The elevation of the river bed was 102.0 m a.s.l. The *Strickler* coefficient of the river bed was $k_{st} = 36\,m^{1/3}/s$ ($n = 0.0277\,s/m^{1/3}$).

The polder bottom was set to 105 m a.s.l. and the inflow of the polder had a fixed overflow crest at a level of 105.2 m a.s.l. There were two dike gates each 20 m wide. If the water level reached 108.0 m a.s.l. the 1st of two dike gates was opened. When opening the 2nd dike gate the water level had to be at 109.5 m a.s.l. The dike crest is set to 110.5 m a.s.l and for the crest width 1414 m was chosen.

The calculation uses a time step of $dh = 0.08\,h$. If the dike gates are opened in perfect matter just before the discharge reaches its maximum the peak reduction is more than $300\,m^3/s$, it is about 7% (Figure 11).

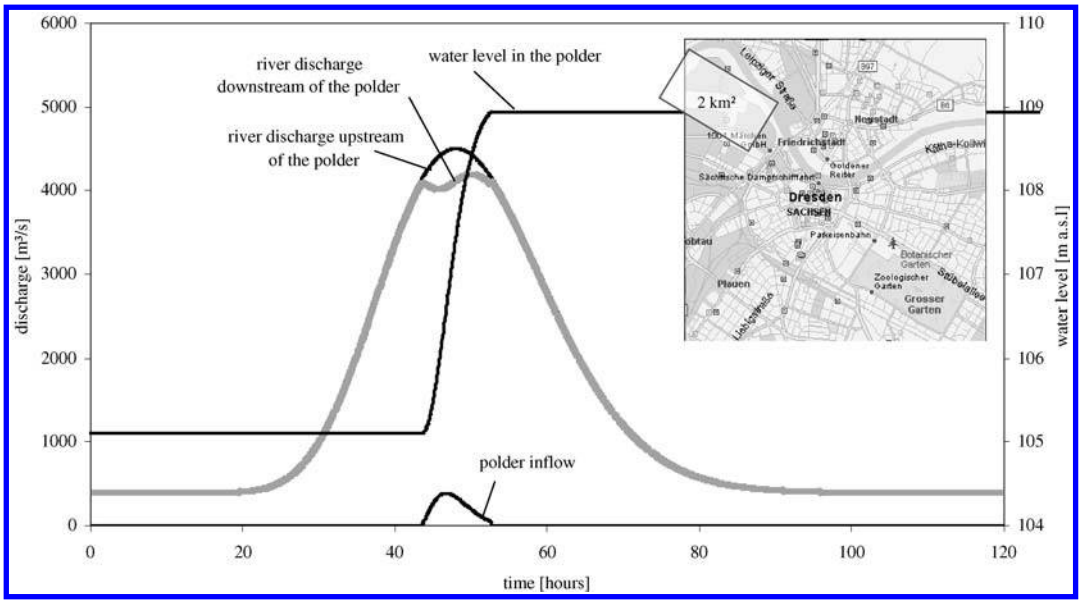

Figure 11. Example for controlled polder flooding with sufficient reduction of peak discharge.

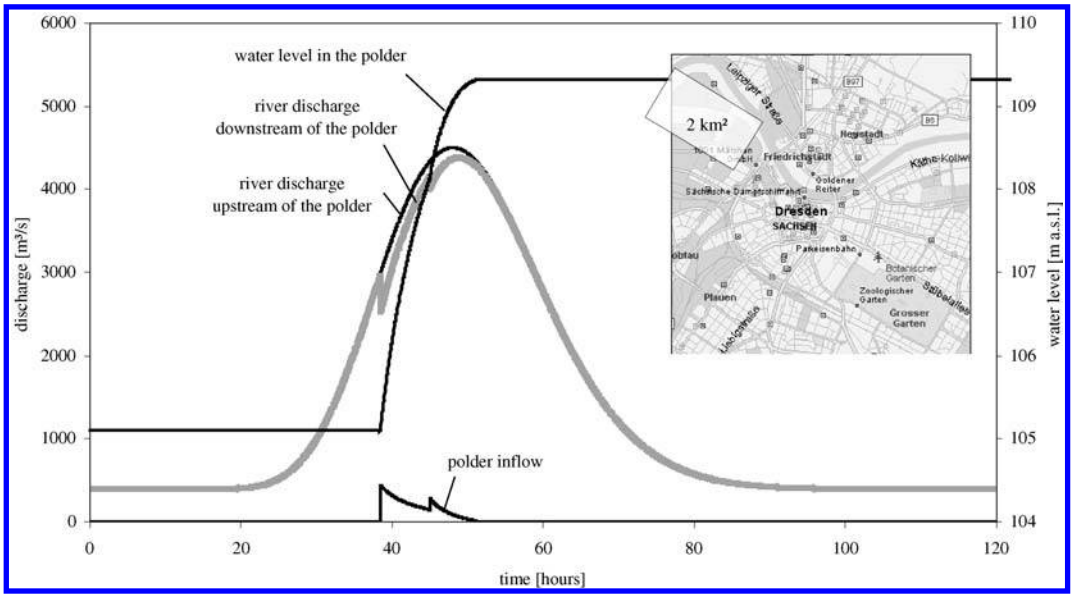

Figure 12. Insufficient peak discharge reduction due to inexact prediction of river flow discharge.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Due to inexact forecast and an early opening of the inlets the retention effect could be completely lost. In Figure 12 the discharge hydrograph is shown. The polder was flooded to early and the peak discharge reduction is less than 3%.

It is obvious that the peak discharge reduction ability of a reservoir or a polder is very sensitive on opening time of the inflow gates and this decision needs a very good runoff forecast.

Flood damage reduction studies often recommended polders or the rebuilding of dikes more far away from the river to reduce the risk of inundation. But only controlled polders with controlled inflow gates have significant peak discharge reduction ability.

8 CONCLUSIONS AND FURTHER INVESTIGATIONS

A calculation procedure for the optimization of reservoir operation rules considering inundation damages as well as ecological impacts is presented.

The optimization of reservoir operation strategies needs a computation model and a multi criteria function.

A computation model can be established using available software and data describing the catchment areas and the reservoirs. The further issue is to connect these different models in an efficient way.

The description of optimization criteria is more complicated. It needs the combined consideration of monetary and non-monetary damages due to flood events. We have to remark a lack of data about the most of the non-monetary damages so that additional research has to be done.

Using results of mathematical modeling of debris flows for optimization of a river channel form to convey debris flows and floods

R. Fazarinc
Water Engineering Ltd., Ljubljana, Slovenia

B. Majes & M. Mikoš
Faculty of Civil and Geodetic Engineering, University of Ljubljana, Ljubljana, Slovenia

ABSTRACT: This paper is about how the final channel form of the Predelica Torrent and the Koritnica River was designed and optimized in order to convey future torrential floods and possible future debris flows of different magnitudes and densities, generated from the Stože slope in W Slovenia. For this purpose two mathematical non-commercial models have been used, a 1-D model DEBRIS1D in the narrow canyon of the Predelica Torrent, and a 2-D model PCFLOW2D in the Koritnica valley. A sensitivity analysis on rheologic parameters (dynamic viscosity, yield shear stress, pseudo Manning roughness coefficient) was performed with the PCFLOW2D model. Furthermore, the influence of the size of the computational numerical grid (2×2 m, 4×4 m) and the selected boundary conditions (dry vs. wet debris flow) on the numerical results was determined. The calibrated 2-D model was used for the final design of the river channel geometry, and to optimize the proposed widening of the local narrow in the Predelica Torrent.

1 INTRODUCTION

On November 17, 2000, the Stože debris flow devastated the Koritnica River valley, a typical narrow alpine valley in W Slovenia. It was the largest event of this kind in the last century in Slovenia. More than 1 million m^3 of debris material flowed as a wet debris flow from the Stože landslide area through a narrow channel of the Predelica Torrent for 4 km to the village of Log pod Mangartom and further downstream along the Koritnica River (Fig. 1).

The debris flow reached the village in a few minutes, killed 7 people in their homes, destroyed or damaged 29 residential or farm buildings and devastated nearly 15 ha of agricultural land. As the main triggering factor, prolonged rainfall of 1638.4 mm in 46 days prior to the event with the return period well above 100 years (Table 1) was recognized by a hydrologic analysis (Mikoš et al. 2004b).

If the Stože debris flow magnitude is compared to other case studies documented in the Alps (van Steijn 1996), it can be put into the group of "very high-magnitude" events. Even though its return period cannot be estimated from historical data, one can roughly estimate it to be well above 100 years.

The maximum flow velocity of the debris flow was estimated to be well over 10 m/s in the steep and narrow channel of the Predelica Torrent, and between 3 and 5 m/s in the more open valley of the Koritnica River.

Figure 1. Debris flow deposits in Log pod Mangartom on November 22, 2000. The Predelica Torrent flows from above into the Koritnica River, coming with clear emerald green water from the right (photo: authors, November 2000).

These estimated values were confirmed using one 1-D (non-commercial DEBRIS1D) and two 2-D mathematical models for debris flows (commercially available FLO-2D, non-commercial PCFLOW2D) (Četina et al. 2006). The hazard zones in the valley were determined using the before mentioned 2-D mathematical models for debris flows and different scenarios for further land sliding in the Stože area. For debris-flow hazard assessment a combination of a 1-D model (routing from source areas along steep and/or narrow

Table 1. Measured rainfall depths (mm) at the rainfall gauging station in Log pod Mangartom compared with the statistical values given for different recurrence intervals for this gauging station.

Measured values (Autumn 2000)	
Rainfall depth [mm]	Period
174.0	12.10.2000 (1 Day)
481.6	11.11. – 17.11.2000 (7 Days)
1042.7	18.10. – 17.11.2000 (1 Month)
1638.4	03.10. – 17.11.2000 (46 Days)
1666.4	18.09. – 17.11.2000 (2 Months)

Statistical values (reference period 1961–1990)				
Reccurence interval	Duration			
	1 Day	7 Days	1 Month	2 Months
2 years	170	359	496	756
5 years	226	453	684	1018
10 years	263	515	808	1192
25 years	309	594	966	1411
50 years	344	652	1082	1574
100 years	378	710	1198	1735

channels) and a 2-D model (deposition areas: fans or valley floors) is frequently used (Lenzi et al. 2003; Bertolo & Wieczorek 2005; Mikoš et al. 2006).

During the debris-flow event, around 400,000 m^3 of debris material were deposited along the debris flow pathway upstream the valley, and nearly 700,000 m^3 were deposited in the valley itself, locally with a thickness up to 10 m. Early in 2001, an outline scheme for temporary river engineering measures was designed in order to stimulate natural river erosion processes.

This scheme has proved to be highly effective, because in 5 years more than half of the debris-flow deposit was eroded from the valley by natural river erosion processes (Fig. 2; Mikoš & Fazarinc 2005). As a basis for this scheme, the results of the hydrologic analysis (Mikoš et al. 2004b), analysis of grain-size distribution of debris-flow deposits (Fig. 3), preliminary evaluation of cross-sectional sediment transport capacities (Mikoš et al. 2004a), and 2-D mathematical modelling of debris flows were used (Četina et al. 2006).

This paper discusses the sensitivity analysis of the PCFLOW2D mathematical model, which was validated using the data from the 2000 Stože debris flow, and the way it was applied for optimization of the river channel geometry. Furthermore, the results of the PCFLOW2D model were used to map debris-flow hazard zones according to the 3 classes of debris-flow intensity (Petraschek & Kienholz 2003) in order to plan future land use in the area (Četina et al. 2006).

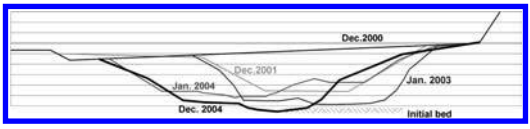

Figure 2. The time evolution of a typical cross section of the Koritnica River after the debris flow event in November 2000. The vertical step is 1 m.

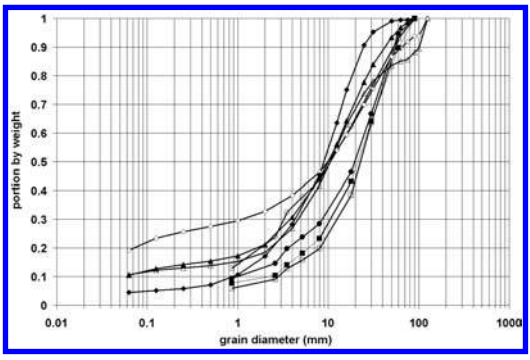

Figure 3. Grain size distribution of debris flow deposits in Log pod Mangartom.

2 DESCRIPTION AND CALIBRATION OF THE 2-D MODEL

2.1 *Description of the PCFLOW2D model*

In the DEBRIF1D and the PCFLOW2D models the same formulation is used for the resistance slope S_f, adapted from O'Brien & Julien (1993):

$$S_f = \frac{\tau_y}{\gamma_m h} + \frac{K\eta V}{8\gamma_m h^2} + \frac{n^2 V^2}{h^{4/3}} + S_e + S_b \quad (1)$$

in which τ_y = the yield shear stress of a sediment-water mixture; γ_m = the specific weight of a sediment-water mixture; h = the flow depth; K = the non-dimensional friction parameter of the laminar flow ($K = 24$ for smooth wide rectangular channels but increases with roughness and irregular cross-section geometry; Julien & O'Brien 1997; FLO-2D 2006); η = dynamic viscosity of the mixture; V = flow velocity; n = "pseudo Manning" roughness coefficient; S_e = resistance slope due to eddy losses at sharp channel expansions, equal to the difference of the values of kinetic terms in two subsequent cross-sections (Rajar 1978); S_b = resistance slope due to bends, which was calculated by a simple equation, known from steady state river hydraulics (Rajar 1978):

$$S_b = 2\frac{B_b}{r_b}\frac{V^2}{2g} \quad (2)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

in which B_b = water surface width in the bend; r_b = radius of curvature; V = flow velocity; g = acceleration due to gravity.

Using the Cartesian coordinate system, the continuity (Equation 3) and momentum equations (Equations 4 and 5), which describe the two-dimensional, incompressible unsteady depth-averaged debris flow, are written in the following form (Četina 2000):

$$\frac{\partial h}{\partial t}+\frac{\partial (hu)}{\partial x}+\frac{\partial (hv)}{\partial y}=0 \tag{3}$$

$$\frac{\partial (hu)}{\partial t}+\frac{\partial (hu^2)}{\partial x}+\frac{\partial (huv)}{\partial y}= -gh\frac{\partial h}{\partial x}-gh\frac{\partial z_b}{\partial x}-ghS_{fx}+\frac{\partial}{\partial x}(hv_{ef}\frac{\partial u}{\partial x})+\frac{\partial}{\partial y}(hv_{ef}\frac{\partial u}{\partial y}) \tag{4}$$

$$\frac{\partial (hv)}{\partial t}+\frac{\partial (huv)}{\partial x}+\frac{\partial (hv^2)}{\partial y}= -gh\frac{\partial h}{\partial y}-gh\frac{\partial z_b}{\partial y}-ghS_{fy}+\frac{\partial}{\partial x}(hv_{ef}\frac{\partial v}{\partial x})+\frac{\partial}{\partial y}(hv_{ef}\frac{\partial v}{\partial y}) \tag{5}$$

where t = time, h = water depth, u and v = depth-averaged velocity components in the x and y directions, z_b = bottom level, g = gravity constant and v_{ef} = effective viscosity. The terms S_{fx} and S_{fy} express energy line slopes, analogous to Equation 1.

The set of coupled partial differential equations (Equations 3 to 5) is solved by the Finite Volume Method proposed by Patankar (1980). This robust numerical algorithm is also used in the 2D-UFM model (Pianese & Barbiero 2003), but not in the FLO-2D model that uses the Finite Difference Method (FLO-2D 2006). A fully implicit scheme is used in the PCFLOW2D for time integration, providing a stable and accurate solution even at relatively high Courant numbers (up to about 10). It is possible to simulate both subcritical and supercritical flow (Četina & Rajar 1994, Četina et al. 1996).

2.2 *Calibration of the PCFLOW2D model*

The value of non-dimensional friction parameter K was always taken as 2285, a value that has been used effectively for most urban studies (FLO-2D 2006) and that lies in the range for sparse vegetation (K = 1000–4000; Woolhiser 1975; see Table 8 in FLO-2D Users' Manual; FLO-2D 2006). Similar value of $K = 2480$ was used when modelling the 1998 Sarno debris flows using the FLO-2D (Aleotti & Polloni 2003).

The boundary conditions at the upstream boundary were hydrographs $Q(t)$ determined from the DEBRIS1D simulations. An assumption of uniform velocity distribution at the inflow cross section was also applied, as more detailed information from upstream 1D computations was not available.

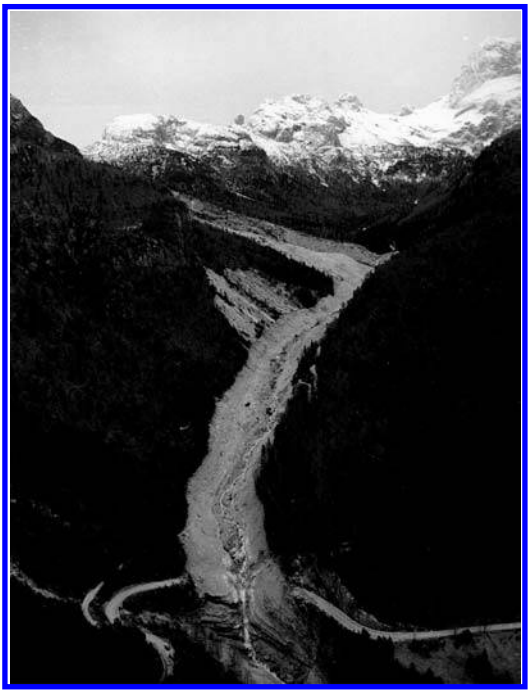

Figure 4. The flowpath of the Stože debris-flow from the source area along the channel of the Mangart torrent across the main road Bovec (Slovenia) – Tarvisio (Italy). The clearly visible erosional scar was used for the calibration of the DEBRIS1D model (photo: authors, November 2000).

At the downstream end two types of boundary conditions were used: (a) Critical flow: at all downstream control volumes where there was an outflow from the computational domain, critical velocities depending on the instantaneous water depth were prescribed in the direction perpendicular to the outflow boundary; (b) Uniform conditions at the downstream end, where zero gradients of water depths and velocities perpendicular to the outflow boundary were prescribed.

The boundary condition (b) gave more realistic results but it caused some stability problems. Condition (a) was more robust without causing stability problems but the results just upstream of the outflow boundary were a little less accurate, although the results were not essentially different.

For the calibration of the DEBRIS1D and PCFLOW-2D models the measured maximum levels (Fig. 4) and inundation limits along the whole computational domain were taken into account (Fazarinc 2002), because no other direct debris-flow measurements were available. In cases with more frequent events, a large range of different debris-flow monitoring devices and methods are available (Itakura et al. 2005).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 2. Selected combinations of dynamic viscosity and yield shear stress for fixed pseudo Manning roughness coefficient $n = 0.05\ \mathrm{s.m^{-1/3}}$ with case numbers.

	μ[Pa.s]					
τ_y [N/m^2]	0	10	20	50	100	1000
0	2 & 3	14	8		9	
20	7	1	11	18	6	17
50		19				
100	10	15	12		5	
10,000		16				4

Calibration was made by determining the proper values of the three rheological parameters in Equation 1, expressing flow resistance: (1) yield shear stress τ_y; (2) viscosity η; (3) pseudo Manning roughness coefficient n. In the literature the values of these parameters may be found to vary over a very wide range, differing by several orders of magnitude, especially the first two. In the calibration process three methods for determination of these values were used: (a) values available in the literature; (b) results of geo-mechanical laboratory experiments: $\gamma_m = 18.75\ \mathrm{kN/m^3}$, $\gamma_s = 22\ \mathrm{kN/m^3}$ (Majes et al. 2002), and (c) values obtained by a trial-and-error procedure starting with values suggested in the literature. Method (c) was taken as the most relevant, even in the case of non-agreement with the other 2 methods.

Two rheological parameters were used with values obtained from back-calculations when applying DEBRIS1D, and geo-mechanical laboratory measurements (yield stress $\tau_y = 20\ \mathrm{Pa}$, and viscosity $\eta = 10\ \mathrm{Pa.s}$). The value of the pseudo Manning coefficient n was calibrated, and a uniform value $n = 0.05\ \mathrm{s.m^{-1/3}}$ was used overall. A numerical grid of $2 \times 2\ \mathrm{m}$ was used, and buildings were taken into account in the numerical grid as "dry" grid cells. Usually no field data are available on debris-flow front velocities, thus calibration of the pseudo Manning coefficient is done using the inundation boundaries.

A comparison of maximum inundation levels, computed by the calibrated PCFLOW2D model and those observed in the field, shows a good correlation.

3 SENSITIVITY ANALYSIS

3.1 *Sensitivity analysis on rheological parameters*

Sensitivity analysis of the PCFLOW2D model was performed using the original geometry prior to the debris-flow event in November 2000 by changing all three rheologic parameters: dynamic viscosity μ, yield shear strength τ_y and pseudo Manning roughness coefficient n (19 sensitivity cases in Table 2).

For all sensitivity cases the boundary condition at the upstream boundary was taken into account as determined by the DEBRIS1D model: volume $V = 740{,}000\ \mathrm{m^3}$ and the hydrograph $Q(t)$ with the maximum discharge $Q = 5684\ \mathrm{m^3/s}$. The computed maximum discharge fits between the semi-theoretical equation satisfying the Froude similarity (Rickenmann 1997): $Q = 0.1\ V^{0.833} = 7746\ \mathrm{m^3/s}$ and the empirical equation for the relationship between the peak discharge Q_p and the debris-flow volume V for granular debris flows in Japan (Mizuyama et al. 1992): $Q_p = 0.135\ V^{0.780} = 5109\ \mathrm{m^3/s}$.

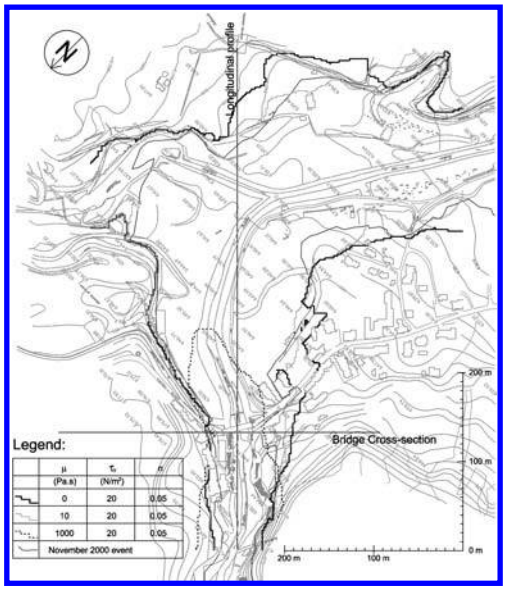

Figure 5. The sensitivity of the PCFLOW2D model on rheological parameters as computed for 3 sensitivity cases #1, #7 and #17 (see Table 2) to show the influence of dynamic viscosity μ to the envelope of debris flows.

3.1.1 *The influence of dynamic viscosity μ*

The sensitivity analysis has shown moderate to high influence of dynamic sensitivity on hydraulic parameters of debris flows. The influence of dynamic viscosity was determined at a constant (validated) value of yield shear stress. The results are given in Figures 5–7.

The differences between cases are moderate: with increasing viscosity, flow-depths rise in the upper part and decrease in the lower part of the domain. The differences in the flow-depths at the upper boundary are for realistic values of viscosity $\mu \leq 100\ \mathrm{Pa.s}$ between 1 m and 3 m on average. The largest differences can be observed along the Predelica Torrent (narrow section, followed by a sudden widening of the domain). In the other part of the domain, along the Koritnica River, these differences zeroed out, or, as in the lower part, flow depths at higher viscosities were even smaller than those computed with relatively small values of viscosity. These increased flow depths

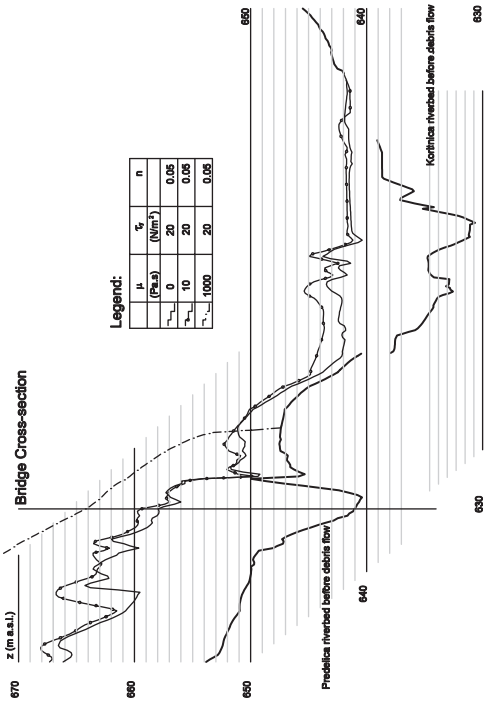

Figure 6. The sensitivity of the PCFLOW2D model on rheological parameters as computed for 3 sensitivity cases #1, #7 and #17 (see Table 2) to show the influence of dynamic viscosity μ to the envelope of debris flows – shown in the longitudinal profile along the Predelica Torrent. The distortion of the vertical to horizontal scale is 10 : 1.

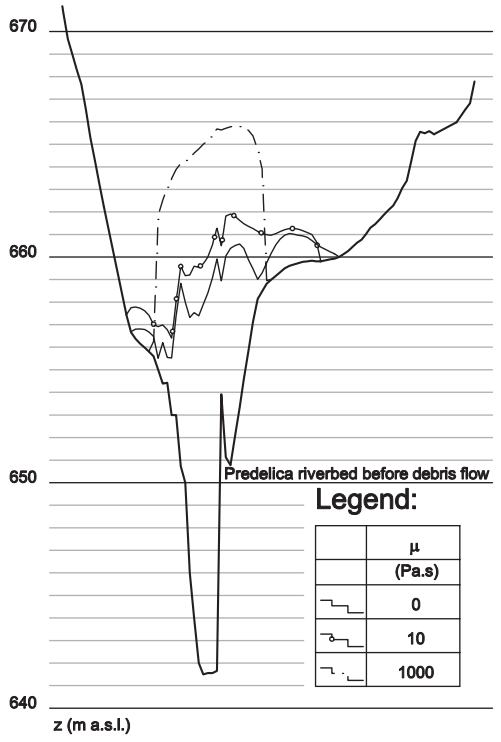

Figure 7. The sensitivity of the PCFLOW2D model on rheological parameters as computed for three sensitivity cases #1, #7 and #17 (see Table 2 for details) to show the influence of dynamic viscosity μ to the envelope of debris flows – shown in the cross section of the temporary bridge (see Figure 6 for the location of this cross section). The distortion of the vertical to horizontal scale is 10:1.

Table 3. The influence of dynamic viscosity on travel time through domain t and the maximum discharge at outflow Q_{out} for fixed calibrated yield shear stress $\tau_y = 20$ Pa and for fixed calibrated Manning roughness coefficient $n = 0.05$ s.m$^{-1/3}$.

μ[Pa.s]	0	10	20	50	100	1000
t(s)	96	103	112	120	170	∞
Q_{out} (m^3/s)	3374	2973	2436	1433	686	0

can be explained by the more pronounced flow afflux at sudden geometrical changes at large viscosity values. Large viscosity increases the energy gradient (due to larger energy losses) and so the flow depths in the lower part of the domain are smaller than those for low viscosity values.

With very high viscosity (case #17, $\mu = 1000$ Pa.s) the debris-flow stops around the bridge at Gorenji Log (the upper part of Log pod Mangartom village). However, this situation is unrealistic, because such a dry debris flow triggered at the Stože slope would not be able to reach Gorenji Log. At low viscosity (case #7, $\mu = 0$ Pa.s) the results are identical to those for water flow without any rheologic characteristics (case #2, $\tau_y = 0$ Pa). Increasing viscosity decreases the debris-flow front velocity and thus also the travel time of the debris-flow front through the domain and the maximum discharge at the outflow (Table 3).

The hazard situation in Gorenji Log (the computational domain), where debris-flow velocities and impacts forces are highest, is favorable when the debris flow is as wet as possible or with low clay content (smaller viscosity). On the other hand, less viscous debris flows travel much faster, and the attenuation of the front is less pronounced thus raising the hazard in Spodnji Log (the lower part of Log pod Mangartom village).

3.1.2 *The influence of yield shear stress* τ_y

Similarly to viscosity analysis, the influence of yield shear stress was determined at a constant but validated value of dynamic viscosity. At very high yield shear stress $\tau_y = 10{,}000$ N/m^2 flow depths are higher in the upper part of the domain (Gorenji Log) and lower

Table 4. Selected combinations of dynamic viscosity and yield shear stress for two pseudo Manning roughness coefficients with case numbers.

n [s.m$^{-1/3}$]	0.03			0.07		
μ [Pa.s]	0	10	100	0	10	100
τ_y[N/m^2]						
0	20	21	22	29	30	31
20	23	24	25	32	33	34
100	26	27	28	35	36	37

in the lower part of the domain (Spodnji Log) when compared to low (ordinary) yield shear stress values between 0 and 100 N/m^2. For such low values, identical results are obtained, and yield shear stress has no important influence on debris flow. Much larger influence may be given to dynamic viscosity than to yield shear stress. When both rheological parameters are set to zero ($\tau_y = 0$ Pa, $\mu =$ Pa.s), the average flow depths decrease between 0 and 2 m.

For values of yield shear stress between 0 and 100 N/m^2, the maximum discharge of the outflow hydrograph stays nearly the same (decreases from 2981 to 2954 m^3/s). A noticeable decrease in maximum discharge to 1055 m^3/s is caused by high yield shear stress $\tau_y = 10{,}000$ N/m^2.

The travel time of the debris-flow front through the domain was in all sensitivity cases practically constant (103 s), and so yield shear stress had no influence on debris-flow front velocity.

The influence of yield shear stress on hydraulic parameters of debris flows is low during the travel phase. This is not true during the triggering and especially the deposition phase of a debris flow, when the influence of yield shear stress is of high importance. This was confirmed during the calibration using the DEBRIS1D model (Četina et al. 2006).

3.1.3 *The influence of pseudo Manning roughness coefficient n*

The pseudo Manning roughness coefficient covers two influences, namely that of dispersivity caused by collisions of particles in the debris flow front, and that of roughness and channel form. Three values of pseudo Manning roughness coefficient were analyzed: $n = 0.05$ s.m$^{-1/3}$ (case #60), $n = 0.03$ s.m$^{-1/3}$ (low dispersivity and favorable channel form, as with hydraulics of Newtonian fluids), and $n = 0.07$ s.m$^{-1/3}$ (high dispersivity and natural torrential channels). Additional sensitivity cases for changed pseudo Manning values are given in Table 4.

The influence of the pseudo Manning coefficient is largest in the upper part of the domain (narrow channel, sudden confinement, high flow velocities), where the kinematic-inertial flow regime is clearly predominating. The differences in flow depths are between 2 and 4 m in the reaches with very irregular channel geometry, and much smaller (practically negligible) in the reaches with regular channel geometry. Another flow regime type is the macroviscous regime where viscosity starts to be the dominating parameter.

The influence of the pseudo Manning coefficient on debris-flow front velocity is determined by the time it travels through the domain: by increasing n from 0.03 s.m$^{-1/3}$ to 0.05 s.m$^{-1/3}$ or 0.07 s.m$^{-1/3}$, the time of travel increases from 86 s to 103 s or 104 s. The debris flow travels slightly faster at smaller roughness or at lower dispersivity. The maximum discharge at the outflow slightly decreases from 3037 m^3/s to 2973 m^3/s when n changes from 0.03 s.m$^{-1/3}$ to 0.05 s.m$^{-1/3}$.

When analyzing the influence of the pseudo Manning coefficient, one may conclude that the optimized channel form for conveying debris flows would have rather smooth and uniform cross sections, thus reducing the danger of flow impoundments. On the other hand such a solution increases the flow velocities and impact forces on structures. Lowering of n values can also be achieved by extracting large particles from a debris-flow mass by flow breakers or separating grills.

For this specific case study, the effect of the pseudo Manning coefficient on hydraulic parameters of debris flows is moderate. It might well have been much larger at higher channel slopes and less regular channel geometries.

3.2 *The influence of the numeric grid size*

The influence of the numeric grid size was studied by comparing the results of simulations using two sizes: 2 × 2 m and 4 × 4 m. The rheological parameters were the same as in the basic case ($\tau_y = 20$ N/m^2, $\mu = 10$ Pa.s, $n = 0.03$ s.m$^{-1/3}$) and the geometry was selected to be the same as it was prior to the November 2000 event.

The differences between both simulations were within 1 m, with more pronounced details with the 2 × 2 m grid. The main cause for this was the more detailed geometry than that with the 4 × 4 m grid and the size of the phenomenon in nature, being better described by the 2 × 2 m grid. A less dense grid also attenuated the local extreme flow depths. Also in the case of a muddy debris-flow in the Wartschenbach (Austria), a 2 × 2 m grid was found to be clearly the better choice over a 5 × 5 m grid (Laigle et al. 2003). In some cases (Lenzi et al. 2003) also a 1 × 1 m grid was applied. Though, many study cases applied much larger grids: 20 × 20 m grid (Aleotti & Polloni, 2003), 25 × 25 m grid (García et al. 2003), or 30 m DTM (Bertolo & Wieczorek, 2005).

The maximum discharges at inflow $Q_{in} = 5684$ m^3/s decreased at outflow to $Q_{out} = 2973$ m^3/s with the

Copyright © 2006 Taylor & Francis Group plc, London, UK

2×2 m grid, and to $Q_{out} = 2860$ m^3/s with the 4×4 m grid, respectively. This difference is mainly restricted to the maximum discharge. Other values of the hydrograph were quite similar. Also, the travel time of the debris-flow front through the domain was practically the same for both grid sizes.

For this case study the influence of the numerical grid size on hydraulic parameters of debris flows was low.

3.3 *The influence of the outflow boundary condition*

In some cases, due to instabilities, the domain was prolonged for less than 100 m and then the critical flow conditions were selected. Normally, uniform conditions at the downstream end were considered as the better solution when compared to the critical flow conditions.

4 OPTIMIZATION OF THE CHANNEL GEOMETRY

One of the key issues of debris-flow modeling was the optimization of the proposed river engineering measures. The basic starting point for the new channel design was to find a combination that would be ecologically acceptable, financially feasible and would yield the selected level of safety for the village and infrastructure in the case of new debris flows triggered on the Stože slope. The main question when optimizing the geometry of new channels was how to ensure flood safety to a 100-year flood (77 m^3/s for the Predelica Torrent, 211 m^3/s for the Koritnica River) and how to form new channels in 5 to 12 m thick debris-flow deposits to effectively convey possible future debris flows.

Early in 2001, a preliminary design of final river engineering measures in the Predelica Torrent and the Koritnica River was prepared. The channels were designed in cross sections and in the longitudinal profile in such a way that the optimal hydraulic conductivity was secured without the need to excavate all the debris flow deposits. The fastest solution would be if all the debris deposits would be mechanically removed and transported to dumping sites. However, there is not enough room for dumping such a volume of material.

The computed debris-flow levels without the widening of the narrow section of the Predelica Torrent are similar to those obtained for the geometry prior to the event and for the boundary conditions when calibrating the model and performing the sensitivity analysis (volume $V = 740{,}000$ m^3 and the hydrograph $Q(t)$ with the maximum discharge $Q = 5684$ m^3/s).

In 2001 proposed mitigation measures between the Stože slope and the village of Log pod Mangartom (two earthen dams, two reinforced concrete debris-flow breakers) were later reduced to only one debris-flow breaker (erected early in 2005), thus a new boundary condition was selected for the optimization of the channel geometry. Therefore, for all optimization cases the new boundary condition at the upstream boundary was taken into account as determined by the DEBRIS1D model, namely the debris-flow volume $V = 910{,}000$ m^3 and the hydrograph $Q(t)$ with the maximum discharge $Q = 7090$ m^3/s. Also this maximum discharge fits between the semi-theoretical equation satisfying the Froude similarity: $Q_p = 0.1\ V^{0.833} = 0.1\ 910{,}000^{0.833} = 9202$ m^3/s and the empirical equation for granular debris flows in Japan: $Q_p = 0.135\ V^{0.780} = 0.135\ 910{,}000^{0.780} = 6003$ m^3/s.

Figure 8. Downstream view on the debris-flow breaker, made of reinforced concrete, 11.5 m high, erected early in 2005 some 150 m upstream of the temporary bridge in Gorenji Log at the upstream end of the narrow in the Predelica Torrent.

The 2-D modeling proved that Gorenji Log is not safe by lowering the riverbed to the initial level (excavating debris-flow deposits) only. Therefore, additional modeling was done, taking into account the following proposed measures around the bottle neck in the Predelica Torrent (cross section of the temporary bridge across the Predelica Torrent in Gorenji Log):

a) Deflecting wall on its right hand side to prevent riverbank overtopping.
b) Widening of the narrow section from the existing 24–28 m to uniform 33 m, 40 m, and 48 m, respectively, to lower debris-flow levels.

The widening and smoothing of the natural rock walls of the narrow reach upstream of the temporary bridge would lower the pseudo Manning coefficient. This measure would support the influence of the debris-flow breaker (see Fig. 8), erected 150 m upstream of the bridge at the upstream end of the narrow. A breaker would separate the coarse and fine fractions within a debris flow, decrease kinetic energy of the flow front and thus change its rheologic parameters.

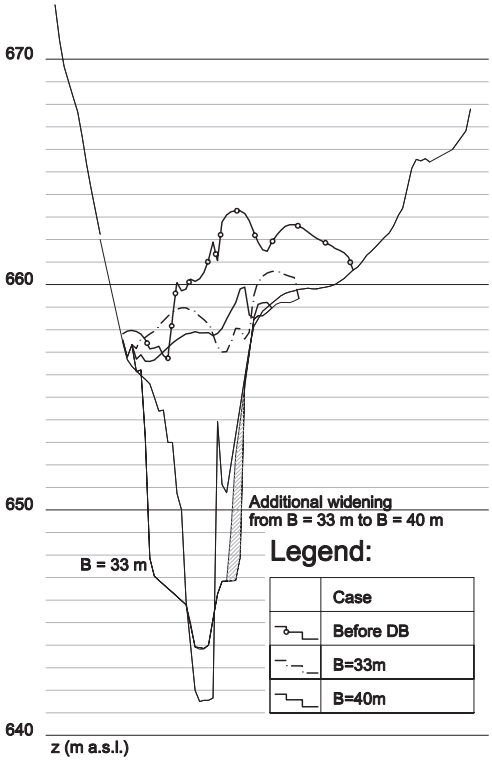

Figure 9. The optimization of the channel geometry using the results of the PCFLOW2D model as computed for three optimization cases #1, #3 (B = 33 m), and #3 (B = 40 m) to show the influence of the widening of the narrow to the envelope of debris flows – shown in the cross section of the temporary bridge (see Figure 6 for the location of this cross section). The distortion of the vertical to horizontal scale is 10:1.

Several channel geometries were taken into consideration when modeling their influence. The three most important optimization cases were:

1 Situation prior to the November 2000 event.
2 Situation immediately after the November 2000 event.
3 The proposed final situation according to the preliminary design of the river channels with the proposed widenings of the narrow (uniform width 33 m, 40 m, and 48 m) in the Predelica Torrent.

As the optimal solution for widening of the critical cross section of the Predelica Torrent through the temporary bridge in Gorenji Log, its widening to 40 m was selected. Due to the mass momentum there was an obvious rise of the maximum debris-flow table along the right bank. This rise was maximal at the maximum selected width of the narrow, i.e. at 48 m. Hence, the maximal possible widening of the cross section to the uniform 48 m did not prove to be optimal.

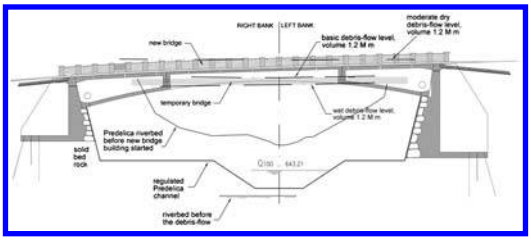

Figure 10. Cross-sectional upstream view of the new concrete bridge in Gorenji Log (see Figure 11 for the location of the bridge). The debris-flow levels computed for different debris-flow wetness are also indicated. The actual construction of the bridge is shown on Fig. 13.

In the reach upstream of the bridge the computed debris-flow levels decreased with increasing width of the narrow (Fig. 9). With all three selected widenings of the narrow, no overtopping of debris flows across the right-hand bank could be expected. Additionally, the proposed widenings eliminated the need to erect a deflecting wall along the right bank to prevent overtopping; such a wall was proposed by some experts immediately after the disaster.

Our goal was to design the new concrete bridge (Fig. 10) higher than the computed maximum debris-flow table to avoid its destruction. However, due to restrictions in space (especially the existing buildings to be preserved) this was not achieved for all cases. The moderately dry debris flow having relatively low flow velocities and thus higher levels would overtop the bridge construction.

The results of the channel geometry optimization were taken into account when preparing the final river engineering plan (Fig. 11).

Immediately downstream of the bridge, the envelopes for all three proposed widenings are quite similar. The reason lies in the similarly regulated channel geometry. A smaller debris-flow level rise can be observed downstream of the bridge. A sudden widening downstream of the bridge leading to an afflux can be nominated as a possible cause. Therefore, the maximal possible widening of the narrow is not to be considered as the optimal solution, even though it might optically seem as if it was.

The widening of the narrow upstream of the bridge should be in accordance with the width of the cross section next to the bridge. A local narrow to make the new concrete bridge shorter would cause the local rise of the debris-flow level and could cause overtopping. As a consequence of this, the optimal widening of the narrow in the reach of the bridge in Gorenji Log was determined to be around 40 m. This width should be kept also for some 40 to 50 m downstream of the bridge in order to avoid the local afflux of debris flows.

Early in 2006, we proceeded with the implementation of the optimized final river engineering plan

by erecting the new concrete bridge in Gorenji Log (Figs 12–13).

5 CONCLUSIONS

The PCFLOW2D model, a 2-D mathematical model, was successfully calibrated using field data from the November 2000 debris flow from the Stože slope in W

Figure 13. Ongoing construction works of a new concrete bridge in Gorenji Log (photo: authors, May 2006). The cross section of this bridge is given in Fig. 10.

Slovenia. The rheological parameters in the calibrated model were as follows: dynamic viscosity $\eta = 10$ Pa.s, yield shear stress $\tau_y = 20$ Pa, and the pseudo Manning roughness coefficient $n = 0.05$ s.m$^{-1/3}$. A computational grid 2×2 m was applied.

A sensitivity analysis of the PCFLOW2D model on rheological parameter has shown moderate to high influence of dynamic sensitivity on hydraulic parameters of debris flows. The influence of yield shear stress on hydraulic parameters of debris flows remained low during the travel phase of debris flows – this is not true during the triggering and especially during the deposition phase of a debris flow, when the influence of yield shear stress is of high importance. In this case study the influence of the pseudo Manning roughness coefficient and the computational grid on hydraulic parameters of debris flow was low and moderate. It might well have been much larger at higher channel slopes and less regular channel geometries. The most important parameter was definitely the geometry itself.

The mathematical modeling of debris flows using the DEBRIS1D and the PCFLOW2D models has proved that the proposed river engineering scheme with the longitudinal profile 2 to 3 m above the original river bed and with the widened cross sections will give even better flow conditions when compared with the situation prior to the November 2000 debris-flow event.

A step-wise mitigation of the Stože debris-flow devastation in the Koritnica river valley is under way after the initial immediate relief actions performed in winter 2000/2001. Combining field observations and laboratory experimental results with the results of mathematical modeling of possible future debris flows enabled the preparation of a sound river engineering plan. This plan has so far respected natural river erosion processes by stimulating sediment transport (washing away of debris-flow deposits instead of their mechanical removal to dumping sites) in the first

Copyright © 2006 Taylor & Francis Group plc, London, UK

years after the debris flow. When completed, the plan will assure relatively natural outlook of this alpine river flowing in the Triglav national park.

Climate change, sediment delivery and flood risk explored using two-dimensional inundation modelling

S.N. Lane, R.J. Hardy & D. Yu

V. Tayefi & S.C. Reid
Formerly, School of Geography, University of Leeds, Leeds

ABSTRACT: Much concern has been expressed about the potential impacts of changing climate upon future flood risk. However, there has been much less attention given to the ways in which changes in catchment function in general, and sediment delivery in particular, might themselves impact upon flood risk. This includes the effects of climate change upon sediment delivery and hence upon changes in river channel conveyance and hence flood risk. In this paper, we present the results of two types of modeling. The first presents predictions of future sediment delivery rates under future climate changes (estimated for the 2050s and 2080s) in order to provide first order estimates of rates of channel aggradation in an upland river with a gravelly bed. The second couples measured channel geometry changes, over short timescales, to flood events with 1 in 0.5 year and 1 in 2 year return periods, for both the present, and for future climates (the 2050s and 2080s). This coupling is achieved through a coupled 1D-2D model, with a full solution of the 1D St.Venant equations for the channel and a 2D diffusion wave treatment on the floodplain. Our results show that, for the system and flood return periods studied, sedimentation rates are the primary control upon the frequency of overbank flows and the magnitude of flood inundation extent. However, these interact non-linearly with future climate changes to increase future flood risk dramatically. This leads us to make three important observations: (1) we must consider what happens when historical flood events are modelled contemporary geometrical surveys in aggrading systems, as this is likely to yield unrealistically low friction parameters during the parameterization process; (2) we must factor the indirect impacts of future climate change upon sediment delivery into estimates of future flood risk; and (3) we must think about how river management activities impact upon the sedimentation process and make sure that the mechanisms by which a channel maintains conveyance when subject to sediment delivery are not undermined by river management activities.

1 INTRODUCTION

1.1 *Climate change and flood risk*

The magnitude, frequency and extent of floodplain inundation will be a direct function of the hydrological response of a catchment. As future climates may be responsible for increases in the magnitude of peak flows (e.g. Middelkoop et al., 2001, Milley et al., 2002) and given recent major flooding events across Europe, future climate change is likely to be a contributing factor to more frequent flood events (Hunt, 2002).

1.2 *The impacts of changing conveyance*

The magnitude of a peak flow is not the only control on flood risk: a flood begins when main channel water levels are sufficient to exceed local bank height, which is a function of channel conveyance. Conveyance is a function of three primary properties: (1) the elevation and shape of river channel cross-sections; (2) the slope of the energy line; and (3) surface roughness properties. Thus, channel conveyance acts as a crucial connection between climate change impacts upon river flows and the onset and magnitude of flood inundation. Traditionally, changing conveyance due to aggradation or degradation has not been factored into flood risk assessment. This may reflect a traditional view of sediment delivery as some kind of local (in time and space) disturbance to an equilibrium channel morphology, where cross-sectional areas adjust to some characteristic bankfull flow. When sediment is delivered, it is thought to be just a matter of time before channel capacity re-establishes itself through transport of that sediment downstream through the river system. However, this overlooks extensive geomorphological evidence of alluviation, potentially rapidly over short

Copyright © 2006 Taylor & Francis Group plc, London, UK

time periods (e.g. Macklin & Lewin, 2003), including aggradation. For example, Harvey (2002) reports that the long-term response of a major input of sediment to Bowderdale and Langdale Becks in the Howgill Fells was partial stabilisation of associated sedimentation zones and not downstream progradation.

Concurrently, there is a growing recognition that reductions in channel conveyance due to sedimentation could be contributing to flood risk (e.g. James, 1999, Stover & Montgomery, 2001, Korup et al., 2004, Pinter & Heine, 2005). We have no knowledge as to how such changes might compare with future climate changes in relation to future flood risk.

1.3 *Climate change and sediment delivery*

There is a second reason to be concerned about the potential impacts of changing conveyance upon flood risk. This is due to the possibility that climate change may impact on sediment delivery in a way that exacerbates in-channel sedimentation. Increased sediment delivery from hillslopes and channel banks to river systems may follow from climate related changes in precipitation. If this delivery leads to in-channel sedimentation it could further exacerbate flood risk (e.g. Stover & Montgomery, 2001). Given that climate change is likely to have a major impact upon the distribution, frequency and magnitude of rainfall patterns (Brooks et al., 1993, 2004), these changes could have major impacts upon coarse sediment generation in upland environments (Buma & Dehn, 1998).

1.4 *Aims*

Given the potential importance of conveyance changes due to sedimentation for future flood risk, and the potential climate changes upon sedimentation, this paper aims to understand, for a gravel-bed river in an upland temperate environment, the possible relative contributions of climate change, sedimentation and sediment delivery upon future flood risk. The approach we adopt is based upon simulation modeling, using a hillslope failure model to estimate coarse sediment delivery rates (Reid et al., in press, a) and a coupled 1D-2D hydraulic model to assess the effects of in-channel sedimentation (Tayefi et al., in press).

2 METHODOLOGY

2.1 *Study site*

Our study site is in a temperate upland environment in the north of England (Fig. 1). In terms of catchment characteristics, this is a good study site as it has shown to be representative of the upper reaches of a number of rivers in the region in terms of probable geomorphological changes during the Holocene

Figure 1. The location of the study site, including the catchment (top diagram) and reach of river studied (bottom diagram). Diagram from Lane et al. (in press, a).

period (Coulthard et al., 2005). These are largely characterised by the reduction of valley gradient and the widening of valley floodplain width, both of which lead to aggradation and rapid downstream fining of surface sediment. In choosing this site, we are therefore focusing upon those rivers associated with coarse sediment (in the gravel fraction and coarser) and a climatic regime that is strongly influenced by the North Atlantic Oscillation, with weather that is strongly influenced by North Atlantic pressure systems when the index is positive and partly influenced by continental originating air masses when the index is negative. Generally, this results in a humid climate, with (relatively) warm winters and (relatively) cool summers.

The study site has been the subject of intensive investigation since July 2000, as a result of a problem of gravel sedimentation, in terms of both catchment hydrology and sediment delivery and river channel response and flood risk. The catchment comprises a mixture of limestone and gritstone, some of which is

Copyright © 2006 Taylor & Francis Group plc, London, UK

covered by thick post-glacial drift material. Almost all of the hillslopes and moorland surfaces are covered with a thin layer of peaty soils. Tributaries (locally known as Gills) extend steeply up the hillslopes and onto the moorland, are commonly dissected into drift material, and this has been observed to be a major source of delivered sediment (Reid et al., in press, a). Some of the moorland has been drained by shallow open drains, although these are now not routinely maintained, and some have been subject to attempts to block them.

The river flows out of a confined, bedrock reach at Hubberholme (Fig. 1), where the valley gradient reduces, the valley widens, and the river becomes alluvial, with well developed floodplain systems. The study reach for the flood risk analysis extends from Hubberholme to Starbotton (Fig. 1) and is predominantly sinuous, although straighter reaches are interspersed between intensely meandering reaches. At Starbotton, a major landslide blocks the valley and measurements suggest that not much sediment passes downstream beyond Starbotton (Reid et al, in press, b). The floodplain land use is a mixture of managed hey meadow (of conservation value). The river was subject to extensive management in the 1980s (Hey & Winterbottom, 1990) as a result of flooding between 20 and 30 times per year on average. Some of this engineering activity was reversed in the late 1990s and 2000s as a result of a perceived failure of the 1980s scheme.

2.2 *Coarse sediment delivery modeling: SEDMAP*

The approach to modelling is explained in full in Reid et al. (in press) and only a summary is provided here. SEDMAP is based on a modified form of SHALSTAB (Montgomery & Dietrich, 1994, Montgomery et al., 1998), leading to determination of failure likelihood (slope stability) without and with a soil and root cohesion treatment. In SHALSTAB, slopes and channel banks can fail at full or partial saturation. In practice, failed material may then be transferred to the drainage network whether or not there is hydrological connection between the failure site and the network. However, in SEDMAP, we follow the theoretical analysis of Legros (2002). Legros shows that water at the bed of a failed material may significantly increase the associated transfer distance, so increasing its connectivity with the drainage network. Thus, we modify SHALSTAB to require hydrological connection into the location for failed sediment to be delivered to the drainage network. Our method provides discrete predictions of failed sediment areas and, with assumptions regarding soil depth, failed sediment volumes. Reid et al. (in press, b) assessed the model by comparing measured failure locations to modeled failure locations and obtained a good level of agreement. They also used coarse sediment sensors to compare when the model predicted sediment delivery to when it was observed and, again, the agreement was good. Provisional estimates suggest that the ratio of coarse sediment to fine sediment in the mix of failed sediment is about 11% and we use this to compare delivered sediment rates to surveyed river bed level changes.

We drive the model using a modified form of TOPMODEL, which is a continuous simulation hydrological model. This is modified from the Beven and Kirkby (1979) formulation to include a treatment that allows for saturated parts of the landscape to be disconnected from the drainage network (Lane et al., 2004). In the study site, we observed negligible sediment storage within the tributaries and the main stem of the river above Hubberholme (Fig. 1) and, with the coarse:fine sediment ratio, this allows us to convert estimates of sediment delivery from the catchment to estimates of coarse sediment delivery to the river channel between Hubberholme and Starbotton.

The model was applied using measured rainfall data from a nearby gauge to provide a baseline set of data (representative of the 1960–1990 period). These rainfall data were then scaled using UKCIP (2002) climate predictions for the region to provide rainfall estimates for the 2050s and 2080s. These provide monthly rainfall estimates which were downscaled using a range of downscaling approaches (see Reid et al., in review). The topographic data required by the model were supplied at 2.0 m resolution from a specially flow Lidar survey.

2.3 *Channel response to coarse sediment delivery*

The sediment delivery method gave us a first approximation of mean coarse sediment delivery rates. In order to assess these rates, and also to provide us with an understanding of the spatial structure of sediment deposition along the 6 km reach and cross-section data for the coupled 1D-2D hydraulic model, we have been surveying a series of 60 cross-sections (average spacing 100 m) in March and December of each year, since 2001. These surveys were based upon instrumented cross-sections, located and recovered using Real-time Kinematic GPS.

2.4 *Modelling floodplain inundation*

Tayefi et al. (in press) reviewed three options for modelling upland floodplain inundation with complex topographic and topological structure: (1) lateral extension of cross-sections across the floodplain; (2) representation of the floodplain as a series of connected storage cells; and (3) a coupled one-dimensional model of the main channel and two-dimensional diffusion wave model of the floodplain. The latter was based on methods reported in Yu and Lane (2006a, 2006b) and Lane (2005) in which we

Copyright © 2006 Taylor & Francis Group plc, London, UK

explicitly represent floodplain topography and topology rather than representing its effects implicitly through upscaling of a roughness parameter. On the basis of comparisons of measured and modeled inundation extent for an event on the 4th February 2004, Tayefi et al. found a significantly better level of agreement with the coupled 1D-2D model than with either the extended section or storage cell approaches. Thus, we use the coupled 1D-2D approach in this paper (see Lane et al., in press, for a full review). The main channel flow was modelled using HEC-RAS, which allows description of the river channel as a series of discrete cross sections perpendicular to the flow direction. Water surface elevation and other hydraulic characteristics of flow were calculated at each cross section and all hydraulic structures defined in the domain (e.g. lateral weirs). These were coupled with a weir equation and used as the boundary conditions for the floodplain inundation model, which uses the depth-averaged mass conservation equations and a simplification of the shallow water momentum equations, based upon ignoring the spatial and temporal acceleration terms and adopting a Manning friction equation (Bradbrook et al., 2004, Yu & Lane, 2006a, 2006b). The floodplain was discretised to an 8 m resolution, following Yu and Lane (2006a, 2006b). Fluxes between cells were set to zero where cells fell adjacent to impervious boundaries. Flow exchanges between the main river and floodplain were calculated based on water levels in the adjacent cells and some form of boundary condition, in this case a weir equation.

The model required a number of boundary conditions. First, the channel cross-section surveys provided the geometrical boundary conditions. In this paper, we compare the geometrical boundary conditions for two dates: December 2002; and March 2004. Second, the model required floodplain topography and this was based upon remotely-sensed Lidar data, filtered for trees and hedgerows (assumed to be pervious to flow at the scale of model application, but compare with Cobby et al., 2003) using automated image processing techniques. These data were supported by Ordnance Survey Landline data on field and other boundaries, held in the same co-ordinate system as that used for both the cross-section and LiDAR data surveys. These data needed additional field based classification into whether or not the boundaries were pervious, and over what spatial extent. Third, we needed flow and stage conditions. We specified measured water levels at the upstream end of the reach, which were converted to flows by using the Flood Estimation handbook Rainfall-Runoff model. This allowed us to model two events: one with a 1: 0.5 year event and one with a 2 year event. We were also able to use the rainfall-runoff model with the UKCIP (2002) predictions to generate estimates of future flows for the 2050s and 2080s. At the downstream end of the reach, we specified a reach slope and a normal depth condition, but extended the sections downstream so that this boundary condition had no impact upon results in the area of interest.

3 RESULTS

The results are structured into two sections. First, we describe how coarse sediment delivery is estimated to change in response to different downscaled climate changes for the 2050s and 2080s. Second, we present results from the coupled 1D-2D floodplain flow model and assess how predictions of inundation duration and areal extent change in response to both measured geometrical changes and future climate change impacts upon flow magnitude.

3.1 *Coarse sediment delivery under climate scenarios*

Under the baseline scenarios we estimate an average of 70.4 sediment generating events per year, although only 0.8 events per year affect more than 0.1% of the catchment area. Most events are highly localized to the channel margins. These events delivered an annual average of 24,300 cubic meters of sediment, which is equivalent to an average annual bed level rise for the 6 km study reach of about 10 cm.

Figure 2 shows predicted changes with respect to baseline under the three types of climate downscaling: (1) magnitude refers to proportionate application of the predicted precipitation changes, applied to each rain day in the data; (2) frequency refers to delivering forecast increases in rainfall through an increase in the number of days on which rainfall events occur; and (3) variability refers to keeping the number of rain days constant and adding the predicted increase in rainfall to only those days on which rainfall occurs, in proportion to the magnitude of the rainfall that occurs. For the 2050s, the average number of events increases by around 10%, regardless of downscaling scenario used. However, there is a marked difference in the predicted failure volume, with much more sediment produced under the magnitude and variability scenarios. This is because of the different nature of the downscalings. Under the frequency scenario, the additional days of rainfall result in an increase in the number of very small failures, largely channel marginal ones. Under the magnitude and variability scenarios, the increase in rainfall predicted for the 2050s occurs primarily as an increase in the size of existing events, more so for the variability scenario. This emphasizes the need to distinguish between different types of climate change impacts. If climate change impacts primarily increase the level of catchment wetness (i.e. the frequency scenario) this is likely to result in a smaller increase in

Copyright © 2006 Taylor & Francis Group plc, London, UK

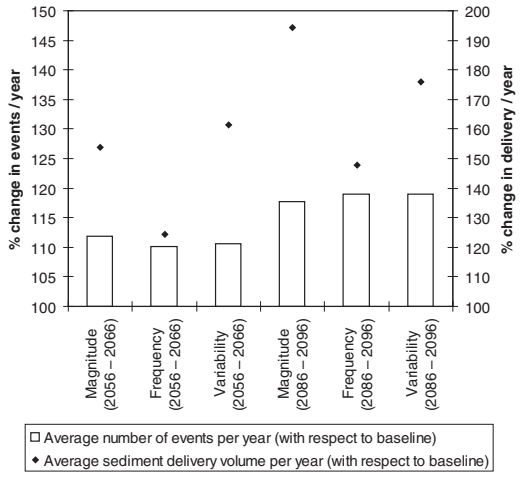

Figure 2. Predictions of coarse sediment delivery rates expressed as a percentage of the baseline estimates.

coarse sediment delivery than if the impacts result in an increase in the intensity of storm events, as in the variability (and to a lesser extent, the magnitude) scenarios. Indeed, the coarse sediment sensor results (Reid et al., in press, a) show that coarse sediment delivery in this environment is particularly sensitive to short-lived intense storm events, and not antecedent wetness.

These patterns are amplified for the 2080s. Again, the number of failure events does not vary significantly between downscaling methods, at just below a 20% increase. However, the sediment volume delivery per year increases by between 50 and 100%, according to the downscaling scenario used. These are quite dramatic increases and emphasise that the impacts of climate change upon coarse sediment delivery could be very significant for this kind of upland environment. Annual average aggradation rates are forecast to rise between 12 and 15 cm per year for the 2050s and 16 and 20 cm per year for the 2080s which, when compared with average annual aggradation rates of 10 cm per year at present are quite dramatic rises.

3.2 *Flood inundation model results*

Figure 3 shows the results from the flood inundation model, run with the December 2002 geometry and a 1 in 0.5 year flood event. The river flow is from right to left and predictions are superimposed on a digital elevation model of the reach. The upper part of the reach also illustrates the floodplain structure in terms of walls etc. Each image has a computational time step of 10 units and the 20 time-steps shown correspond to about 2 hours of simulation

It is clear from Figure 3 that the nature of flood inundation in this system is complex. Inundation begins early at a number of locations down the river, notably associated with floodplain low points. The total inundated area expands quite rapidly between 40 and 70 time steps and then slows quite significantly. The images show that the structure of the floodplain has a major effect upon the time-space patterns of inundation, with the walls, largely impervious to flows except where there are gates, having a major impact on inundation.

The prime reason for using this model was to compare the effects of short term changes in aggradation with longer term changes in climate. If we focus on the short term changes in aggradation, and compare the flood characteristics of the 1 in 0.5 year and 1 in 2 year events for the December 2002 and March 2004 measured cross-sections, the results are quite striking. This 16 month period has a reduction in bankfull discharge of 6.2% during which there was a measured average aggradation along the reach of 0.12 m. For the 1 in 0.5 year event, the average duration during which flows exceeded bankfull increased by 9.5%. The result was a 5.7% increase in inundated area. For the 1 in 2 year event, the increase in inundated area was 7.1%.

We then ran the 2002 geometry with flows estimated for the climate change scenarios for the 2050s and the 2080s. The inundation area increased by 12.2% by the 2050s and 21.6% by the 2080s for the 1 in 0.5 year event.

Finally, we ran the 2004 geometry with the 2050s and 2080s. This increased in inundated area over the baseline flows and 2002 geometry of 38.2% for the 2050s and 52.1% for the 2080s. This emphasizes the non-linear nature of the interaction between geometrical changes and changes in flow due to climate.

4 DISCUSSION

The main finding that emerges from the above results is that relatively short duration channel configuration changes, in this case over a 16 month period, can lead to substantial changes in inundated areas for 1 in 0.5 and 1 in 2 year floods, in an upland environment associated with coarse sediment transfer. For the 1 in 0.5 year event, the increase in inundated area was almost one half of the increase in inundated area estimated as resulting from simulated climate change to the 2050s. The non-linear nature of the onset of floodplain inundation (i.e. associated with the onset of overbank flow) meant that when these geometrical changes were combined with forecast climate changes, the increases in inundated area were amplified over the increases associated with each change in isolation. In other words, in this case study, in-channel sedimentation increases the sensitivity of flood inundation to future climate changes.

Following from these findings, a number of important research questions and river management issues

Copyright © 2006 Taylor & Francis Group plc, London, UK

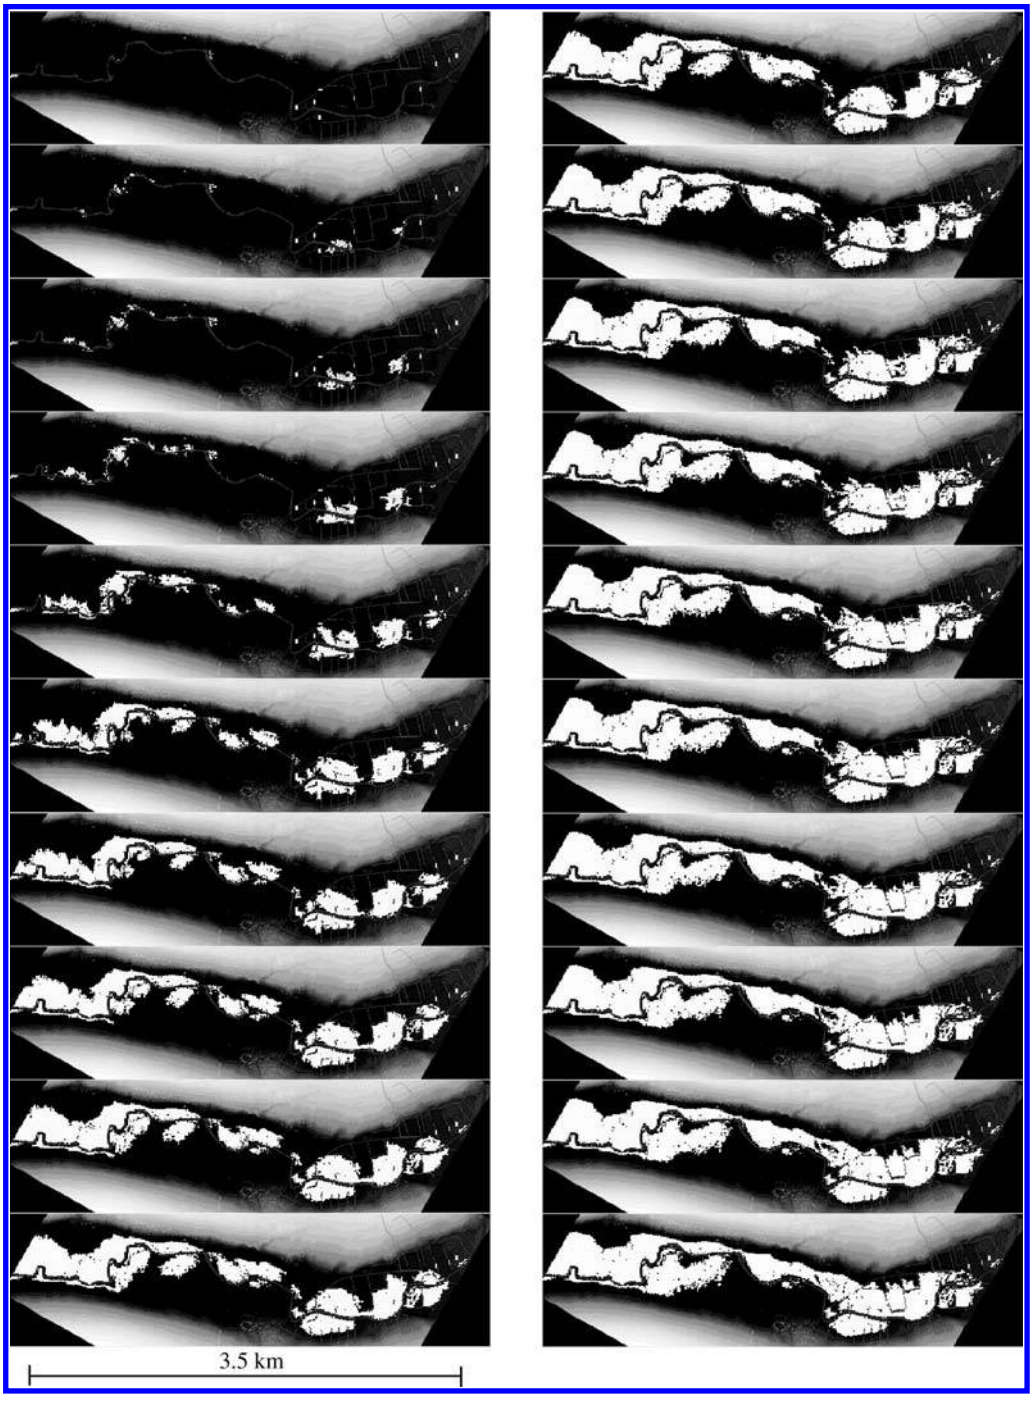

Figure 3. Model predictions of inundation for the 1 in 0.5 year event with the 2002 geometry. Each image is shown every 10 computational time steps and a total of 2 hours is simulated. The flow is from right to left.

emerge. First, much attention is currently being given to detecting climate change signals in time-series of river flows. The evidence is not conclusive (e.g. Robson, 2002). However, this emphasis on flow is misleading as it does not necessarily provide any indication of the impacts of climate change upon flood risk. The kinds of geomorphological changes described here do not impact on flows, but they do impact upon the return periods and magnitudes of floodplain inundation, such that there could be a major increase in the magnitude and frequency of inundation events in any river, or river reach, that is aggradational, with no change in the magnitude and frequency of imposed flows.

Second, the sediment delivery model shows that the effects of climate change upon coarse sediment delivery may, in some situations, lead to a very significant increase in future flood risk. This is an indirect impact, independent of changes in river flow, although the latter may be important in controlling the spatial patterns of sediment transfer and hence the nature of any future river bed aggradation. Current cross-section surveys suggest annual average aggradation rates of about 10 cm per year, which are similar to the baseline simulations from the coarse sediment delivery model. We know that UK upland rivers can go through distinct cycles of alluviation in response to both short and long-term climatic fluctuations (e.g. Macklin et al., 1992). At present, upland landscapes are thought to be more sensitive to climatic fluctuations as a result of historical land use change (Macklin & Lewin, 2003). For instance, Coulthard and Macklin (2001) used modelling to show a severely non-linear interaction between climate change and deforestation in a similar upland river catchment.

The sediment delivery model results suggest increases in annual average aggradation rates of between 50 and 100%, which would be sufficient to make the annual aggradation rate equivalent to climate change impacts on flows to the 2050s. It appears that the indirect impacts of the climate change signal upon sediment delivery will act so as to reinforce the importance of short-term aggradation upon the magnitude and frequency of floodplain inundation, and that short-term variability in aggradation rates may be superimposed on top of a longer-term, aggradational trend. Hence, the changing flood risk identified here will be strongly impacted upon by climate change, not only because of the direct impacts of climate upon the magnitude and frequency of high flow events, but also because of the indirect effects of changing climate upon coarse sediment delivery which in turn will impact upon coarse sediment delivery and hence aggradation rates. There has been much debate over the extent to which land management impacts on catchment hydrology might be contributing to changing flood magnitude and frequency (see review in O'Connell et al., 2005). There has been much less acknowledgement of the extent to which land management practices have sensitised river basins to climate change (Coulthard et al., 2002, Macklin & Lewin, 2003) and in so doing are indirectly exacerbating flood magnitude and frequency. This case study emphasises the need to broaden the current focus of debate on the impacts of climate change upon river flows to include a much stronger engagement with catchment sediment delivery processes and how these interact with climate change.

There are three important practical issues that arise from these findings. The first is concerned with practical aspects of flood risk mapping. Commonly, flood risk mapping is based upon specially-commissioned geometrical surveys, application to one-dimensional hydraulic models, and model calibration based upon adjustment of model parameters, notably channel friction (commonly Manning's n), to predict the water level recorded in historical events. If there has been bed aggradation since that historical event, then a lower value of n will be required to reproduce that event than if the historical flood had been combined with historical geometrical survey. Thus, when modelling future events, this type of calibrated model will under-estimate water levels, and hence inundated area, inundation depth and flood risk, as a result of having a calibrated value of n that is too low. The converse would occur in systems that are degradational. Where this approach is being used in aggradational systems, it is highly likely that we are under-estimating future flood risk.

The second issue relates to river management in response to sediment aggradation problems. On the basis of observations, including the cross-section surveys, that began in July 2000, as well as the historical analyses of other data available for the area, it is possible to identify a distinct style of in-channel sedimentation and lateral channel adjustment, in response to the deposition of coarse sediment (Lane et al., in press). Most of the sedimentation occurs in distinct zones, commonly where the channel is weakly or strongly sinuous. This deposition is asymmetrical, commonly localized on point bars, attached to either meander bends or the inside edge of weakly sinuous reaches. Concurrent with this deposition is the erosion of mixed fine and coarse material from channel banks on the channel margin opposite the zone of deposition, and this is central to maintaining bankfull capacity. We can hypothesise that this transfer of coarse sediment to storage, through channel migration, should be an integral contribution to the observed rapid downstream fining, as well as a mechanism that leads to long-term valley fill. Given this response to in-channel sedimentation, it is important to consider the range of river management options available. The 1980s river management scheme chose to manage sedimentation through a combination of a gravel trap (to allow more

Copyright © 2006 Taylor & Francis Group plc, London, UK

manageable removal of sediment) and river channel realignment to increase sediment throughput, coupled to bank protection measures. Aside from the problem that enhancing sediment throughput will simply deliver sediment more readily to downstream locations, river bank stabilization is a particular problem in relation to flood risk. It prevents the *erosion* that is necessary to maintain channel bankfull capacity in response to river bed aggradation. There is still a general view in some river management communities that bank erosion (as opposed to artificially enhanced bank erosion, such as due to stock poaching) is a problem that has to be prevented, rather than a natural geomorphological response to high rates of sediment delivery. Consultant reports from the late 1990s for the reach of river considered in this paper advocated focusing management on stretches where eroding banks should be stabilised (e.g. RKL Arup, 1999a, 1999b). This assumes that a channel can be engineered to be robust, to transfer sediment through it and so to absorb changes in sediment supply with only minor adjustment in its form. However, channel morphology and stability in fact reflect the net sediment budget (e.g. Hooke, 2003), which in turn reflects: (i) the net erosion and deposition observed; and (ii) the supply and connectivity of sediment from the hillslopes and upstream reaches. Where river management restricts: (a) lateral movement of the river; and (b) transfer of sediment into floodplain storage; the channel bed becomes responsive (e.g. Schumm, 1979, Harvey, 2001, Hooke, 2003); and one response is aggradation. This will reduce channel conveyance and lead to the kinds of impacts described above in relation to flood risk. Thus, in addition to naturally high rates of sediment delivery, this kind of river management exacerbates flood risk. The Holocene record (e.g. Macklin & Lewin, 2003) tells us that these systems can experience large increases in sediment delivery over relatively short time periods and it is this historical record that emphasises the need to incorporate changes in conveyance due to sediment aggradation more explicitly into flood risk assessment and river management.

The third management question then becomes what should be done to manage river systems undergoing high rates of sediment delivery and consequent bank erosion and increased flood risk, if bank erosion is not an acceptable situation? The only option that recognizes the natural function of such river systems, aside from active dredging of sediment which may be unacceptable for ecological reasons, is to reduce the rate of sediment delivery to the system. The simulations from the coarse sediment delivery show that just four out of twelve tributaries were responsible for over 80% of delivered coarse sediment and that less than 1% of the area of each sub-catchment was delivering sediment. We simulated the effects of localized tree planting using native woodland through changing the root cohesion term in the sediment delivery model and found that this resulted in almost an 85% reduction in coarse sediment delivery rates. This is substantial, and provides a very different approach to managing the problems caused by coarse sediment aggradation in upland river systems.

5 CONCLUSION

This paper has shown the importance of considering the effects of coarse sediment delivery and the associated bed aggradation in the case study of a temperate upland environment. Whilst based on a case-study, it has some very important implications for climate change studies, flood risk assessment and river management more generally. In this study, for a flood with a 1 in 0.5 year event, short-term bed aggradation (over a 16 month period) was shown to result in about half the inundated area increase that results from applying climate changes estimated for the 2050s to the same event. Consideration of the joint impacts of climate change and bed aggradation emphasised the non-linear nature of system response, and the possibly severe and synergistic effects that come from combined direct effects of climate change and sediment delivery. Such effects are likely to be exacerbated further as a result of the impacts of climate change upon coarse sediment deliver and our modeling results suggested serious increases in aggradation rates to the 2050s and the 2080s.

When couched in conventional flood frequency terms, these changes do not result in a change in the return period of extreme flow events, but rather a reduction in the return period of the flow events that lead to floodplain inundation. Thus, analyses that focus upon the changing magnitude and frequency of flow events will overlook a key influence upon the return period and magnitude of flood inundation events.

Our analysis suggests that if more attention to to be placed on coarse sediment aggradation and its impact upon flood risk, then this needs to adopt a different approach to river management. Rather than managing the sediment once it is in the river system, more attention needs to be given to managing the sediment delivery process through reducing sediment source impacts. Our coarse sediment delivery modeling provides a framework for reducing delivery rates in a way that is, ultimately, much more sustainable.

Finally, whilst this research is based upon an upland case study, the observations will apply to flood risk issues in any upland or piedmont system, where there is coarse sediment delivery and accumulation, but also where active river management precludes the possibility of coarse sediment transfer into floodplain storage. Research by Pinter and Heine (2005) shows that river engineering on a river with a sand and silt-bed may also

Copyright © 2006 Taylor & Francis Group plc, London, UK

lead to systematic increases in stage for a given flow, and this may make these kinds of issues of relevance in other river systems.

Consideration of protection works in hazard assessment – A case study

W. Gostner
Patscheider & Partner Engineers, Mals, Italy

B. Mazzorana
Public Water Authority, Province of South Tyrol, Italy

ABSTRACT: The paper describes an approach that makes it possible to consider protection works in hazard assessment properly. With the help of event trees the probability of flood events is combined with the failure probability of protection works. Probability of flood events is studied with classical methods of hydrology. Failure probability of protection works is examined by means of a semi-probabilistic approach respectively by expert judgement. Hydraulic modelling of different flood scenarios allows to compare hazard zones with and without consideration of protection works.

1 INTRODUCTION

Hazard assessment plays a key role in management of natural dangers such as floods, debris flows, snow avalanches, rock fall, etc. In order to plan and realize sustainable measures, communities and authorities recognize that, first of all, a thorough investigation of natural dangers is required. Exact knowledge of the hazard potential forms the base for efficient land use planning, reliable design of protection works and useful emergency concepts.

Therefore in recent years hazard mapping has become an important tool in hazard assessment. Different methodologies reflecting the needs of the area where they have been developed exist.

On the other hand, usually where financial and administrative conditions allowed it, structural protection works of different kinds have been realized in the past in order to reduce the hazard potential of natural dangers.

However, in hazard mapping most of the adopted procedures don't consider the impact of protection measures yet. In the present paper an approach is described which makes it possible to quantitatively judge the effectiveness of protection works in hazard zone mapping.

The approach has been developed by means of a case study that deals with an alpine torrent where clear water floods and debris flow event occurred in the past and that has been trained by different structural measures.

First of all there is a brief description of the studied torrent in order to point out clearly its main characteristics and the potential hazards related to it. Then an introduction into the method of hazard mapping is made. Further on stays the explanation of the developed method and at the end of the paper the application to the present case is described.

2 THE UPPER EISACK TORRENT

2.1 *General characteristics of the watershed*

The upper Eisack lies in the north of Italy closed to the border to Austria. Shortly after its origin it reaches the village of Brenner which is situated to the relatively small debris fan. It therefore represents the potentially endangered area. At this point the watershed of the torrent covers an area of 3,24 km^2 (Fig. 1).

The highest elevation of the watershed is at an altitude of 2.166 m a.s.l., whereas the mean elevation of the village of Brenner is at 1.370 m a.s.l. The main reach of the torrent has a length of 2,6 km. The main reach has a longitudinal slope of 23,5% in the upper

Figure 1. Watershed of the upper Eisack torrent.

Figure 2. The flooded village of Brenner in 1956.

Figure 3. Check dam series with damaged check dams.

part, of 14% in the central part and of 38% in the lower part. The mean slope of the debris fan is around 8%.

The lower part of the watershed is covered by conifers, whereas the upper and central part are mainly characterized by pastureland.

In terms of geology the principal rock formation of the watershed are metamorphic stones such as lime schist and lime phylitte. The main debris sources are to be found, rather untypical for an alpine torrent, along the central part of the main reach. In the upper part of the watershed, where in alpine torrents sediment delivery usually takes place, no significant debris sources exist.

2.2 *History of events and protection works*

Besides of smaller flood events in recent history one catastrophic event is known. In 1956 on August 20th after heavy rains in the central part of the torrent large erosion processes took place. A debris flow developed and the village of Brenner was flooded. Registered precipitation states that the rainfalls in the period between August 16th and August 20th were the heaviest within the last 80 years.

After this event several protection works took place. In the central part of the torrent a series of 45 masonry check dams was built, immediately upstream of the village a debris retention basin with a volume of around 1400 m^3 was realized and through the village the torrent got an artificial trapezoidal flow profile.

However, site surveys have revealed that at present around one third of the check dams is damaged and no longer in a perfect state (Fig. 3). Among other things, this circumstance has been one of the main motivations to carry out the present study: the consideration of protection works in hazard assessment is of utmost importance to understand their effectiveness.

2.3 *Available debris volume*

The available debris volume that can by mobilized in an event is one of the key factors when dealing with debris flows in alpine torrents. Assuming that the erosion depth in an event can amount up to 20% of the river bed width, as observed in the past (Lehmann 1993), and that in the same event the side banks can be eroded in a triangular shaped manner, the available debris volume within the erodible part can be estimated at 28,800 m^3.

This estimation is confirmed through empirical relationships, as f.i. proposed by D'Agostino (1996), Takei (1984) or Rickenmann & Zimmermann (1993). This formulae give volumes of 25,000–35,000 m^3.

2.4 *Hazard features of the torrent*

The investigation of the watershed allows the following conclusions:

- The upper Eisack is a torrent where debris flow events and clear water floods with bed load transport can take place. The debris sources are to be found in the central reach of the torrent, having a potential volume of around 30,000 m^3.
- Due to the realization of the check dam series debris flow activity has been reduced to a minimum, i.e. debris flow events only can take place in the case of failure of several check dams.
- As the watershed has a rather small extension, in case of floods the mobilized sediment is likely delimited by the transport capacity of the clear water discharge.
- The maximum sediment concentration in a debris flow is probably low, due to the moderate slope of 14% in the erosion reach.

3 PROCEDURE OF HAZARD ZONE MAPPING

Usually, in hazard assessment different hazard degrees are defined, distinguished by different colors. The differentiation of the hazard zones is obtained by combining the probability of catastrophic events with their intensity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

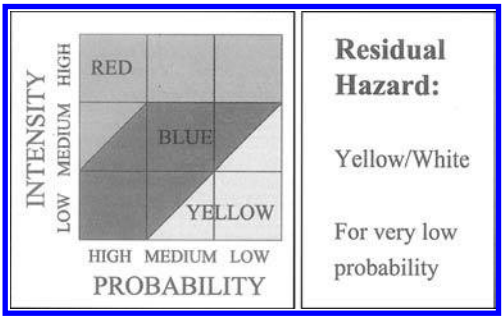

Figure 4. Matrix for determination of hazard degree.

Table 1. Criteria for intensity of mountain hazards.

Process	Low intensity	Medium intensity	High intensity
Rockfall	$E < 30$ kJ	30 kJ $< E < 300$ kJ	$E > 300$ kJ
Landslide	$Vs < 2$ cm/year	Vs: dm/year	$Vs >$ dm/year
Debris flow	—	$D < 1$ m or $v < 1$ m/s	$D > 1$ m and $v > 1$ m/s
Static flooding	$h < 0.5$ m	$0.5 < h < 2$ m	$h > 2$ m
Dynamic flooding	$q < 0.5$ m^2/s	$0.5 < q < 2$ m^2/s	$q > 2$ m^2/s
Bank erosion	$t < 0.5$ m	$0.5 < t < 2$ m	$t > 2$ m
Avalanche	$P < 3$ kN/m^2	$3 < P < 30$ kN/m^2	$P > 30$ kN/m^2

E = kinetic energy, Vs = mean annual velocity of landslide, D = thickness of debris front, v = flow velocity, h = flow depth, q = specific discharge, t = extent of lateral erosion, P = avalanche pressure exerted on an obstacle.

Figure 4 shows the matrix that has been applied in the present study. It was presented by FOWM (1997) and it distinguishes four degrees of hazard zones: high danger where life is endangered in- and outside of buildings and heavy damages can be expected (red zone), medium danger where human life is at risk only outside of buildings (blue zone), and low danger without danger of life (yellow zone). Finally, a residual hazard zone where probability of occurrence is very low is determined.

The intensity of an event may be characterized by different parameters depending on the type of the event. When dealing with mountain hazards, the criteria shown in Table 1 are used (after Petraschek & Kienholz 2003).

The probability of an event is directly related to its return period. The method of FOWM (1997) defines return periods of 30, 100 and 300 years as events with low, medium and high probability respectively.

Knowing the events with the defined return periods, their probability of occurrence can be calculated. Table 2 illustrates the probability of occurrence of the events, related to the period of one year.

Table 2. Relation between probability and return period.

Probability	Return period (Years)	Probability
High	30	0.033
Medium	100	0.01
Low	300	0.0033

4 THE ROLE OF PROTECTION WORKS

4.1 *General considerations*

Structural protection works are active measures with the aim to reduce the intensity respectively probability of an event. Thus, hazard mapping becomes substantially more reliable if the role of protection works is considered in a proper manner. The elaboration of scenarios should be integrated directly within the frame of the analysis (Romang et al. 2000).

Methods used in classical risk analysis f.i. concerning the safety of nuclear power plants or of large dams have been used for the development of the approach described in the present paper.

4.2 *Event trees*

A risk analysis is sustained by a logical tree whose function is to decompose the problem into its parts in a logical structure such as (Salmon & Hartford 1995):

1 Identification of initiating events;
2 Lay out of all possible combinations and sequences of following events;
3 Consideration of the outcome of each sequence along the branches.

Among the different types of logical trees the most appropriate to apply in natural hazard assessment are event trees. Their principal concepts are described in the following.

The probability of the occurrence of an event is given by the product of the probability of the primary process w_0 and the relative probabilities of the consecutive processes

$$w = w_0 w_1 w_2 \ldots\ldots w_n \quad (1)$$

where n is the number of consecutive processes. For the relative probabilities one has to consider that the probability that a process does not occur is

$$w_{ni} = 1 - w_{ij} \quad (2)$$

where w_i is the relative probability of the process i. Accordingly, the sum of the probabilities from all the events that share the same primary process is equal to the probability of the primary process (Beffa 2000). Figure 5 shows an abstraction of an event tree for extreme precipitation induced failure.

Copyright © 2006 Taylor & Francis Group plc, London, UK

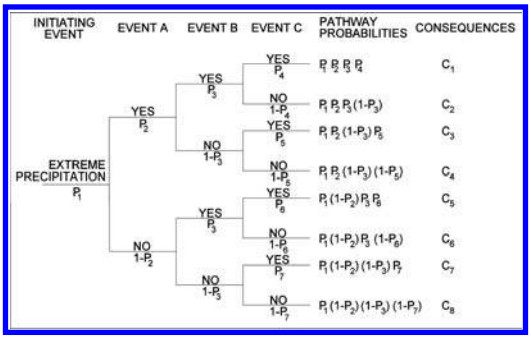

Figure 5. Exemplification of an event tree (after Darbre, 2000).

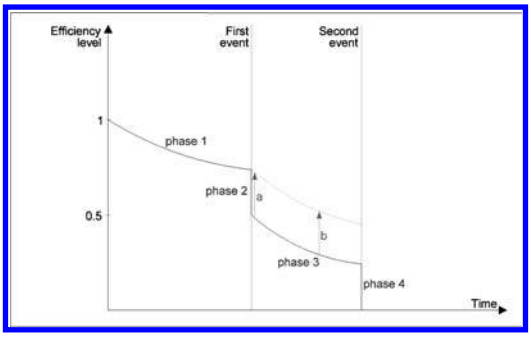

Figure 6. Component reliability during its working period.

In the present case the primary process is given by a flood event with a certain probability respectively return period, whereas the consecutive processes are defined by the reaction of the system, especially of the protection works.

4.3 *Probability determination of structural collapse*

4.3.1 *General considerations*

Figure 5 demonstrates that a given event causes several reactions with different probabilities. The response of protection works on a flood event might be either the perfect functioning without any damage at the structure, the partially functioning with some damages or the collapse of the structure.

Moreover, the efficiency of the same protection structure can vary in course of time as follows (Fig. 6):

- Phase 1: efficiency decrease of endogenous type, due to progressive deterioration of the materials and the permanent loadings on the structure;
- phase 2: during an extreme event the efficiency may decrease abruptly in time;
- phase 3: after the extreme event the decreasing of the efficiency is analogous to that in phase 1, but faster.

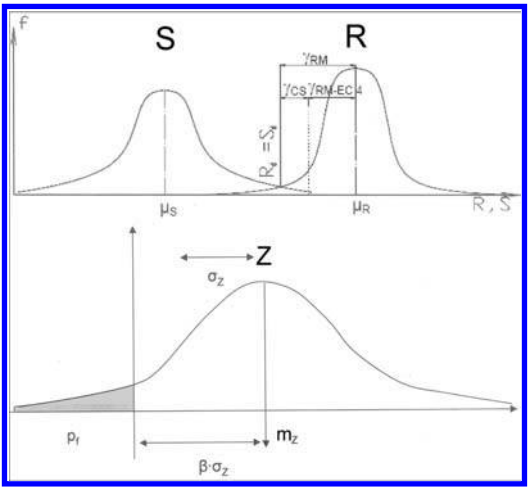

Figure 7. Distribution of S and R.

- phase 4: this represents the final collapse of the structure.

However, in the present study only two cases are considered: the perfect functioning of the structure respectively the collapse of the structure.

Thus, the key task in the next step is to quantify the collapse probability of the protection works. Once the collapse probability is known, the probability of non collapse can be determined using Equation 2.

Two different approaches have been utilized. The first is based on the semi-probabilistic concept established in the Eurocodes for the correct dimensioning of supporting structures. The second takes advantage of the precious experience of technicians involved over many years in the planning, realization and maintenance of river protection works.

4.3.2 *Semi-probabilistic approach*

The Eurocodes consider the fact that structures aren't either safe or non safe. Indeed, a structure has a certain failure probability depending on different variables, i.e. external or internal actions and material resistance.

The semi-probabilistic approach starts from the assumption that actions S and resistance R are aleatory variables with a normal distribution around their mean value m_S and m_R respectively. Consequently, the difference $Z = R - S$ that determines the failure probability has again a normal distribution (Fig. 7).

The failure probability can also be described by the so-called index of reliability

$$\beta = \frac{m_z}{\sigma_z} \tag{3}$$

where β is the index of reliability, m_z the mean value and σ_z the standard deviation of Z. In order to increase the factor β respectively to decrease the failure

Copyright © 2006 Taylor & Francis Group plc, London, UK

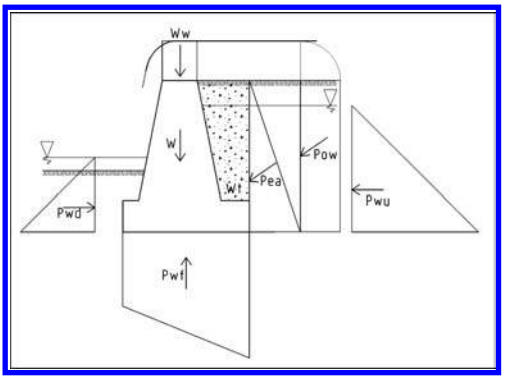

Figure 8. Forces acting on a check dam.

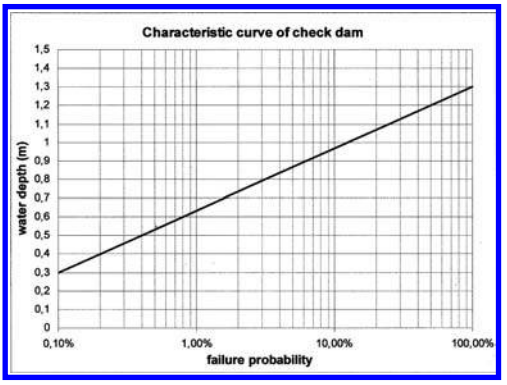

Figure 9. Correlation between water depth over check dam and failure probability for the check dams on the Eisack torrent.

probability partial safety factors are introduced which allow to increase the action respectively to decrease the resistance of the material.

In civil engineering the partial safety factors are defined with the background that a failure probability of $1 \cdot 10^{-6}$ for a single structure is acceptable. However, in Geotechnics a failure probability of $1 \cdot 10^{-3}$ for sustaining structures is accepted (Meyerhof 1995). Therefore, if the partial safety factors proposed in Eurocode 7 – Geotechnical design (1997) for the USL (ultimate state limit) are applied in the dimensioning procedure, a sustaining structure will have a failure probability of $1 \cdot 10^{-3}$. On the other hand, if the partial safety factors are set to an overall value of 1, the failure probability of the structure will be equal to 1.

Coming back to the present case, the failure probability of check dams has to be analyzed. The actions on a check dam can be subdivided into active earth pressure P_{ea}, hydrostatic pressure upstream P_{wu}, pressure due to the water or sediment-water-mixture overflowing the check dam P_{ow}, hydrostatic pressure downstream P_{wd}, water pressure beneath the foundation P_{wf}, own weight W, weight of the upstream earth fill W_e and weight of the overflowing water respectively water-sediment-mixture W_w (Fig. 8). The passive earth pressure downstream is not taken into account, as there are substantial uncertainties concerning its entity.

The structure has to be verified regarding its safety for translation and rotation, the bearing capacity of the soil and the safety for siphoning. To actions and resistance usually an unequivocal, clearly defined value can be assigned. Only the depth of the overflowing water depends on the discharge, in other words on the return period. For a given structure two water depths can be searched: utilizing the partial safety factors as proposed by the Eurocode and searching the water depth at which all the verifications are fulfilled, is the case which corresponds to a failure probability of $1 \cdot 10^{-3}$.

On the other hand, if the partial safety factors are set to an overall value of 1, at the corresponding water depth the failure probability is equal to 1.

Furthermore, assuming a logarithmic behaviour, a function can be defined that correlates the water depth and the failure probability of the structure.

As the check dams on the Eisack torrent are similar in terms of geometry and construction, a single function, valid for the whole check dam series, has been worked out (Fig. 9).

The semi-probabilistic approach offers the advantage that it is certainly based on a scientific and well recognized background, as the Eurocodes have adopted it in different subjects. The major disadvantage consists in the fact that the methodology presumes a perfect structure, i.e. a structure immediately after completion with an efficiency level of 1 (Fig. 6). For a slightly or heavily damaged structure assumptions based on subjective judgement have to be made. From that point of view the empirical approach proposed in the next chapter seems to be more consistent.

4.3.3 *Empirical approach – Expert judgement*

Key personnel in public water authorities has many years of experience in planning, realizing and maintaining of protection structures. The idea of the proposed approach is to gather this experience in order to judge the failure probability of a structure in a best possible manner.

Thus, an expert questioning finalized to the deeper understanding has been organized and structured as follows:

In the first step, the estimation step, the experts get a detailed photographical documentation of the check dams as well as the available project documents (basin characteristics, assumed peak flow for the dimensioning of the structure, available information about past sediment transport or debris flow events). Then the experts fill out a prepared evaluation form.

After having evaluated the single damage or defect types, the experts estimate the failure probability of the considered structure, assuming an impact event of

Copyright © 2006 Taylor & Francis Group plc, London, UK

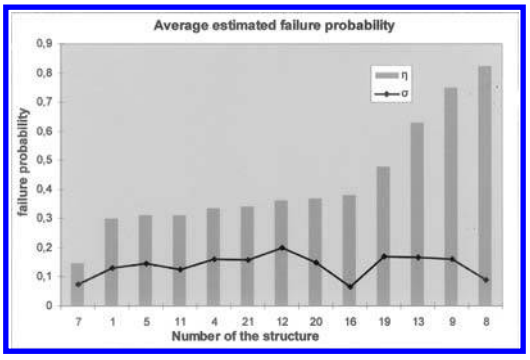

Figure 10. Average values and standard deviations of the estimations.

a reference return period of 100 years (a horizontal line in the cross section indicates the flow height related to this return period).

In addition the experts evaluate the relative importance of each detected defect type by assigning a specific percentage that reflects the relative weight of the severity of the detected damage type in the estimation process.

In the second step, the data analysis step, the damage or defect types are grouped into two larger damage categories:

1 External damage categories: defined as any action due to groundwater flow, weir overfall, water and earth pressure that change the external configuration of the considered structure.
2 Structure related damage categories: defined either as equilibrium changes or any sort of deformations and degradations of the structure.

Through a multiple correlation between the average value of the sums of the assigned ratings to the external damage factors and the average value of the sums of the assigned ratings to the structure related damage factors with the average failure probability estimated by the experts a failure probability indicator can be proposed:

$$Z = 0.03 \cdot \Sigma X_i + 0.02 \cdot \Sigma Y_i \quad (4)$$

where Z is the estimated failure probability, ΣX_i is the sum of the assigned ratings for the detected external damage factors, ΣY_i is the sum of the assigned ratings for the detected structure related damage factors.

Figure 10 shows the failure probability estimations of the experts. The standard deviations of the failure probability estimations do not seem to depend on the average failure probability estimations. Furthermore, the figures indicate that the expert's relative weight assignments to the two categories are surprisingly homogeneous.

As already mentioned above the failure probability indications are related to a well defined input event intensity. In order to derive useful failure probability indications also for higher intensity input events and therefore for events of lower occurrence probability or higher return period in this work an extrapolation procedure based on the two parameter Weibull distribution has been adopted.

The assumption is that the shape parameter γ depends on the structure material, so for a given value of the parameter γ and for a given failure probability estimation for a 100 years return period input event, the location parameter of the Weibull distribution is found by a secant iteration method.

The so fixed parameters of the Weibull distribution permit the determination of other return periods.

Concluding, both of the proposed approaches can be utilized for the development of event trees. However, in the present paper the semi-probabilistic approach is presented.

5 APPLICATION TO THE PRESENT CASE

5.1 *Adopted methodology*

The adopted methodology consists in a modular and gradual structure. The procedure can be interpreted as the modelling of a process chain where the different processes have to be considered as a cause-effect-relation. Parameters that can not be defined exactly must be assumed for the modelling of each process. Therefore it was necessary to conduct a sensitivity analysis in each step of the study in order to test the reaction of the system on the variation of the different assumptions. Herewith possible events can be constrained and plausible scenarios defined. The following steps have been worked out:

– Generation of clear water hydrographs. Analysis begins with a rainfall-runoff-model. Precipitation data based on the local meteorological conditions are combined with the hydrological characteristics of the watershed to define clear water hydrographs at different points of interest.
– Elaboration of flood scenarios. Event trees are developed that permit to consider existing protection works properly in order to define flood scenarios which take into account the wholeness of the real conditions. In this step different transport formulae for bed load transport and debris flow are used.
– Numerical modelling of the urbanized area. A two-dimensional numerical model is used. Clear water floods and debris flows are analyzed in order to define the hazard zones.

5.2 *Generation of clear water hydrographs*

In the watershed of the upper Eisack torrent no rainfall gauges are installed, thus no direct measurements of

Copyright © 2006 Taylor & Francis Group plc, London, UK

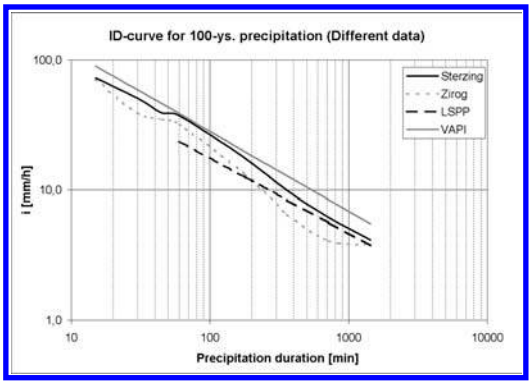

Figure 11. Comparison of intensities for precipitations with a return period of 100 years.

precipitations are available. Therefore, statistical evaluation of precipitation data recorded at gauges near the watershed as well as regionalized analytical functions proposed by Villi (1994) in the context of the project VAPI (Valutazione delle Piene in Italia) were used (Figure 11).

Extensive sensitivity analysis led to the following basic observations for the assumption of rainfall scenarios:

1 Data from the rain gauge in Sterzing, distant from the upper Eisack torrent around 20 km, can be used as precipitation data.
2 Floods in the upper Eisack torrent are caused by precipitation with short duration and high intensity, i.e. storms triggered by convective air circulation. Therefore, rainfall events with a duration of 60 minutes are considered.
3 In order to simulate the variation in rainfall intensity throughout the storm, hyetographs according to the alternating block method are used. This method, described in Chow et al. (1988) is a simple way of developing a design hyetograph from an IDF-curve. In this way, it is possible to incorporate the observation that generally 90% of the precipitation falls within a third of the duration of the whole storm.

In order to compute clear water hydrographs at different points of interest, the watershed is subdivided in several subbasins. The formation of the clear water hydrographs, based on the chosen rainfall scenarios, is modelled with the software HEC-HMS. The software includes several components which, based on different optional methods provide the possibility to model runoff volumes, runoff hydrographs and the routing of the hydrograph through the channel.

In Figure 12 hydrographs obtained with the rainfall-runoff model for different return periods are shown at the entrance into the village of Brenner.

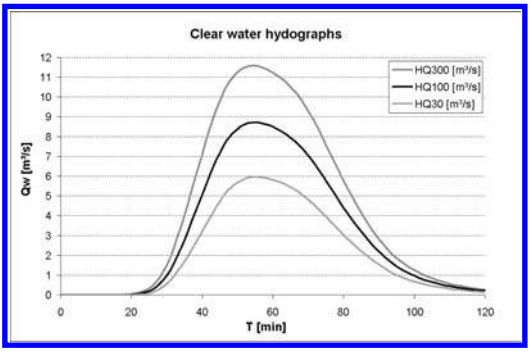

Figure 12. Clear water hydrographs at the entrance into the village.

Table 3. Basic assumption for the development of event trees.

Return period (Years)	Q_{max} (m^3/s)	H_w (m)	P_f	V (m^3)
30	3.05	0.60	$8 \cdot 10^{-3}$	7.800
100	4.44	0.78	$2{,}8 \cdot 10^{-2}$	9.800
300	5.89	0.94	$8{,}3 \cdot 10^{-2}$	11.800

5.3 *Elaboration of flood scenarios*

Development of event trees is based on the basic assumptions summarized in Table 3 and described explicitly in the following.

– Maximum discharges Q_{max} in the part of the check dam series are 3.05, 4.44 and 5.89 m^3/s for the flood events with return periods of 30, 100 and 300 years.
– The water depth over the check dam H_w can be calculated with the Poleni formula

$$Q = \frac{2}{3}\mu b\sqrt{2g}\,h^{3/2} \quad (5)$$

where Q is the discharge, μ the weir coefficient that can be set equal to 0.489, b is the width of the check dam and h is the flow depth. For the considered return periods the water depths are 0.60, 0.78 and 0.94 m.
– The failure probability P_f which is directly related to the water depth (Figure 9) amounts at $8 \cdot 10^{-3}$ for a 30-ys flood, $2{,}8 \cdot 10^{-2}$ for a 100-ys flood and $8{,}3 \cdot 10^{-2}$ for a 300-ys event.
– Concerning the maximum sediment load, the assumption is made that it is distributed equally on the check dam series. Consequently, having estimated a total sediment potential of 30,000 m^3 behind each check dam a volume of 670 m^3 can be mobilized.
– Moreover, a debris flow can only develop if a certain amount of sediment is mobilized. In other

Copyright © 2006 Taylor & Francis Group plc, London, UK

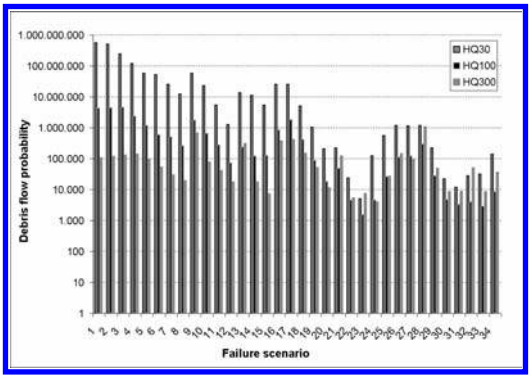

Figure 13. Return periods of debris flow events for the different scenarios.

Table 4. Debris flow probability P_{DF} for the considered flood events.

Return period (Years)	P_{DF} (%)
30	1.4
100	25.6
300	48.4

words, if the mobilized volume is not enough for a debris flow, the flood has the characteristics of a clear water flood with bed load transport or of a hyperconcentrated flow. The modelling of different scenarios, as described in chapter 5.4.2, allows to set the threshold V for a debris flow at 7800 m^3 for a 30-ys flood, at 9800 m^3 for a 100-ys. flood and 11,800 m^3 for a 300-ys. flood. Therefore, at least 11 check dams have to collapse in order to mobilize enough sediment for the development of a debris flow.

Based on this assumptions event trees are elaborated. The probability of the failure of 11 check dams is calculated by defining the scenarios that might physically occur. Considering that the check dam series is composed of 45 dams and supposing that the structures are failing from upstream to downstream, one after each other, 34 (45–11) scenarios can be defined. Scenario no. 12 f.i. stands for the rupture of check dam no. 12 and its 10 following check dams.

At each check dam the event tree is divided in two branches, where one represents the failure probability of the check dam and the other the probability of withstanding the load. According to Equation 2 the sum of the two branches gives the value of 1.

Further on, the probability for the development of a debris flow corresponds, as shown in Equation 1, to the product of the failure probabilities of 11 single check dams.

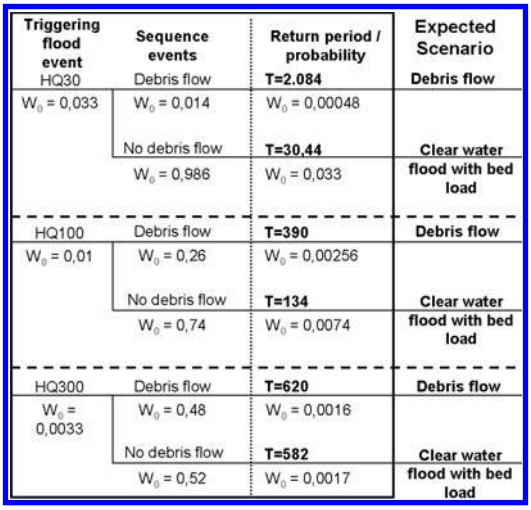

Figure 14. Event tree for flood events in the upper Eisack.

Finally, the overall probability that a debris flow occurs is represented by the sum of the 34 scenarios for a debris flow event.

Worth mentioning are the assumptions concerning damaged check dams. In the present case it is presumed that the failure probability of a moderate damaged check dam is five times higher than that of a check dam in perfect state, whereas for a heavily damaged check dam a 10 times higher probability is assumed.

Furthermore, in the failure case of a check dam the water depth on the downstream check dam is increased due to the mobilized sediment. Consequently, the failure probability is increasing successively along the check dams.

Figure 13 shows the return periods for the occurrence of debris flows for each of the considered scenarios. The figure points out the weak points of the system. Scenario no. 23 and no. 25 have the lowest return periods. This can be explained by the fact that downstream of check dam no. 23 several structures are heavily damaged. Hence, refurbishment measures have to start first in that zone.

The sum of the single scenarios gives the overall probability for a debris flow (Table 4).

Based on this calculations the event tree for the global system behaviour can be built (Figure 14). This event tree summarizes the event trees developed for the single scenarios described above. The figure states that a debris flow event in the upper Eisack torrent at the moment has a return period of at least 390 years, precisely for a 100-ys flood. Thus, a debris flow event at the upper Eisack torrent has still a very low return period.

On the other hand, a comparative analysis shows that for a check dam series without any damage the return period for a debris flow event is around

Copyright © 2006 Taylor & Francis Group plc, London, UK

5100 years. This proves that proper maintenance of protection works is of primary importance for their efficiency.

Due to the above considerations hazard mapping in the village of Brenner requires the following scenarios:

- modelling of 30-ys, 100-ys and 300-ys flood with bed load,
- modelling of a debris flow event in order to delimitate the residual hazard zone.

5.4 *Numerical modelling in the urbanized area*

5.4.1 *Clear water floods with bed load*

When modelling clear water floods, consideration of bed load is crucial as the debris retention basin situated immediately upstream of the village doesn't have a large volume.

The sediment transport capacity can be calculated by the formula proposed by Smart & Jäggi (1983). Assuming that enough sediment is available and thus the flood hydrograph can fully exploit its transport capacity, a total bed load of 1240 m^3 for a 30-ys flood, 1860 m^3 for a 100-ys flood and 2510 m^3 for a 300-ys. flood has been calculated.

5.4.2 *Debris flows hydrographs*

A debris flow hydrograph is developed based on a 100-ys flood event. It is assumed that maximum solid concentration at the front of the debris flow is not larger than 50%, due to the relatively moderate slope in the debris flow initiation zone.

The debris flow hydrograph is elaborated based on an approach proposed by Gostner et al. (2003) that utilizes for the debris flow front a criterion after Takahashi (1991) and for the debris flow body a transport formula presented by Tognacca et al. (2000).

Figure 15 shows the debris flow hydrograph at the entrance into the village. It can be noticed that lateral tributaries, joining the main reach after the debris flow initiation zone, reduce the maximum solid concentration to a value of 40%. Therefore the behaviour of the debris flow after the front has passed might also be of Newtonian type.

5.4.3 *Modelling of the urbanized area*

For the investigation of the flood and deposition processes in the village, the numerical model FLO-2D (O'Brien 2001) is used. FLO-2D is a two-dimensional flood routing model and allows the use of both clear water hydrographs and debris flows.

The input data of the model are a DEM, eventually the geometry of the channel, the incoming hydrograph and the rugosity of the grid elements.

In order to have both satisfactory accuracy and a reasonable calculation time for the model a grid size of 4 m for the floodplain is used and the trapezoidal

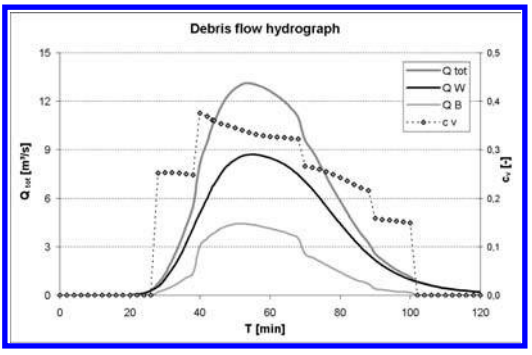

Figure 15. Debris flow hydrograph at the entrance in the village.

channel downstream of the debris retention basin is modelled one-dimensionally.

As the solid concentration of the debris flow after the front is relatively low as well as assumptions regarding the rheological parameters of the debris flow are quite speculatory, it seems justified that the debris flow is modelled as a Newtonian fluid. However, an increased rugosity, compared with the clear water floods, has to be adopted.

The model FLO-2D doesn't allow changes in topography throughout an event, therefore the debris retention basin situated upstream of the village has to be considered in a qualitative manner:

- Concerning clear water floods, due to the reduced transport capacity of the flood, the bed load is depositing in the debris retention basin. When the maximum discharge is reached, around 50% of the bed load has settled down and the topography has changed accordingly.
- For the debris flow a simplified way is adopted: it is assumed that as long as the retention basin is not completely filled up, the debris flow solids are retained and only clear water flows out of the basin. Once the basin is full the characteristics of the surge are no longer affected by the basin. The modified geometry of the filled retention basin is taken into account properly.

5.5 *Hazard mapping*

If protection works are taken into account, almost the whole flooded zone lies within a yellow zone due to inundations provoked by a 300-ys. flood with bed load.

On the contrary, if protection works were not considered properly, big part of the village would be in a blue hazard zone, as the 100-ys. flood would provoke a debris flow with the same return period.

However, the elaboration of event trees has clearly proven that at present a debris flow event has a return period >300 years.

Copyright © 2006 Taylor & Francis Group plc, London, UK

5.6 *Recommendations for measures*

The study allows to propose the following measures:

- At present the return period of a debris flow is >300 years. Nevertheless, the event trees have shown some weak points in the system. If the deterioration of the check dams continues, hazard potential in the village of Brenner can increase significantly. First of all, the check dams downstream of check dam no. 23 should be replaced.
- Enlarging the debris retention basin it is possible to prevent inundations of the village even for a 300-ys. event.

Both the refurbishment of the check dams and the enlargement of the debris retention basin contribute to reduce significantly the hazard potential in the village of Brenner. A zone with residual risk will always remain, when ever with a very low probability of occurring.

6 CONCLUSIONS

An approach that permits to consider in a proper manner protection works in hazard mapping has been described in this study.

The approach has been developed by means of a case study where a check dam series and a debris retention basin have been taken into account in hazard mapping for the village of Brenner.

With the help of event trees the return period of different flood scenarios can be properly investigated. The key step therein consists in relating the probability of flood events with the failure probability of the protection structures.

Failure probability can be either estimated by a semi-probabilistic approach or by an expert hearing. In the present study the semi-probabilistic approach has been presented in detail. However, in the semi-probabilistic approach a structure in a perfect state is implicitly presumed and damaged structures have to be considered by engineering judgement. Therefore an expert hearing might be the more consistent way for further developments.

ABSTRACT: The Water of Leith is a steep mountain stream which has been heavily modified in the past to facilitate intensive urban development of an alluvial floodplain at the lower end. An extreme flood in 1929 resulted in major channel breakout of floodwaters and extensive floodplain inundation. A 1999 review of the flood hazard for the stream identified serious channel capacity and other deficiencies at several locations across the floodplain. Following this review, a comprehensive scheme was developed to address these deficiencies. This paper provides a brief overview of the catchment and the flood hazard issues associated with the stream, and describes three innovative aspects of the scheme developed to improve flood security.

1 DESCRIPTION OF WATER OF LEITH CATCHMENT

The Water of Leith is a steep mountain stream which falls about 600 m over a distance of 10.6 km before discharging into the Otago Harbour (see Figure 1). The Leith and its major tributary, Lindsay Creek, drain a catchment of approximately 42 km2. The catchment extends up to a maximum elevation of 740 m and is mostly covered in a mix of native forest, regenerating scrub, plantation forest and pasture with tussock grasslands above 600 m. However the lower part of the catchment consists of an intensely developed urban floodplain at the north end of Dunedin City.

The middle part of the catchment features a very narrow gorge with steep vee-shaped and actively eroding ravines branching laterally off it. The gorge widens out at the lower end and urban development has extended upstream from the floodplain onto flat areas adjacent to the stream. In the lower part of the catchment, the stream flows across the floodplain for a distance of approximately 3 km before reaching the harbour. Lindsay Creek joins the Water of Leith approximately 2.1 km upstream of the harbour outlet.

Although it is predominantly a boulder and cobble bed stream in the lower gorge and lower part of the catchment, the Water of Leith has been heavily modified to facilitate urban development of both areas.

Figure 1. April 2006 flood event in the Water of Leith immediately downstream of a sharp ninety degree bend through the University of Otago Campus (view looking downstream).

Channel modifications in the lower gorge include concrete-lined banks and concrete walls in places, several grade control weirs and two coarse sediment traps. In the upper part of the urban floodplain, a concrete supercritical flow channel has been constructed which was originally intended to extend to the outlet although it has never been completed. Over the lower part of the urban floodplain through the University

Copyright © 2006 Taylor & Francis Group plc, London, UK

of Otago Campus, the stream features concrete-lined banks and a coble bed with regularly spaced grade control weirs. There is also a gauging station weir on the stream and a number of road and pedestrian bridges which cross it, including an historic one. The original stream outlet has also been extended seawards by about 0.7 km with an artificial concrete-lined double channel system through an old harbour reclamation.

2 FLOOD HISTORY

The Leith Catchment experienced a devastating flood in 1929 which inundated an extensive part of Dunedin City. This flood was estimated at the time to have had a peak discharge of as much as 400 m3/s but recent re-evaluation of the rainfall and slope / area gauging data measured during the event has put the magnitude of the peak discharge in the order of 220 m^3/s.

The 1929 flood followed one only six years earlier in 1923 which also resulted in extensive inundation of the urban floodplain. However anecdotal evidence from this event indicates that it was smaller than the 1929 one. Another flood in 1877 is considered to have been of a similar magnitude to the 1929 one although there are no data for it. At that time the extent of floodplain development was very limited.

The stream flow below the Lindsay Creek confluence has been gauged since 1963. The largest flood since the historic 1929 one has been the February 1991 event with a peak discharge of 114 m^3/s. Figure 1 shows a photograph of a slightly smaller flood event in April 2006 in the heavily modified natural channel through the University of Otago Campus.

3 KEY FLOOD HAZARD FACTORS

Although only limited damage and disruption occurred during the 1991 flood event, there was a concern that another flood of similar magnitude to the 1929 one could occur with major breakouts occurring through the University of Otago Campus. Such breakouts would potentially cause severe damage across the floodplain as far south as the city's central business district (the floodplain is much more intensively developed than in 1929 and the likely inundation zone includes significant facilities such as part of the main hospital). The February 1991 flood event was only just contained at a very sharp ninety degree bend through the University Campus which induced a standing wave pattern with waves estimated to be up to 1.3 m high (Figure 2). The expansion of flood flows from the modified stream channel to the artificial concrete-lined double channel system 200 m downstream of this sharp bend was also observed to be very inefficient, producing an uneven distribution of flow between the two channels (Figure 3).

Figure 2. Flow round a sharp ninety degree bend through the University of Otago Campus during the February 1991 flood event (view looking upstream).

Figure 3. Flow entering the artificial double channel system from the modified natural channel upstream of the Forth Street Bridge during the February 1991 flood event (view looking upstream).

Other significant issues include the limited flow capacity of many bridges, the lack of any energy dissipation facility at the end of the supercritical flow channel in the upper part of the urban floodplain reach, the potential for large amounts of sediment and woody debris to be flushed out of the actively eroding ravines off the main stem of the Water of Leith in the middle part of the catchment, the performance of the existing boulder traps and scouring of the stream bed through the heavily modified urban floodplain reach.

4 PRELIMINARY INVESTIGATION OF FLOOD HAZARDS AND CHANNEL CAPACITY ENHANCEMENT MEASURES

Following the transfer of responsibility for catchment management from the Dunedin City Council

Copyright © 2006 Taylor & Francis Group plc, London, UK

to the Otago Regional Council in 1995, the Otago Regional Council commenced a study of flood hazards in the Water of Leith catchment. This culminated in the publication of the Water of Leith Flood Hazard Report (Otago Regional Council, 1999) in 1999 and the Lindsay Creek Flood Hazard Report (Otago Regional Council, 2001) in 2001. In the case of the Water of Leith, serious channel capacity deficiencies were identified in parts of the partially urbanized lower section of the gorge in the middle catchment and in the lower part of the urban floodplain reach downstream of the exit from the supercritical flow channel.

In mid 2003, the Otago Regional Council commissioned Opus International Consultants to embark on a major programme of investigations to develop a comprehensive flood scheme for the water of Leith and Lindsay Creek to enable the 1% annual exceedance probability (AEP) flood to be satisfactorily passed with freeboard. These investigations initially involved a thorough review of the flood hydrology taking account of the estimated magnitude of the historic 1929 flood. Subsequently several MIKE11 one-dimensional computational hydraulic models of separate parts of the Water of Leith and Lindsay Creek were constructed and calibrated against observed flood data. These models were used to evaluate reaches of both stream channels with restricted flood capacity and then to investigate possible in-channel or out-of-channel works to achieve the required flood capacity. The possible modification of two water supply dams to provide flood detention and the feasibility of other in-channel detention pond options were also investigated. The potential for erosion of the stream bed and banks at the downstream end of the supercritical flow channel where no stilling basin structure exits was examined. Debris traps to capture large woody debris flushed out of the upper and middle parts of the Water of Leith catchment and the Lindsay Creek catchment were also designed (these have since been constructed).

This paper focuses on three innovative aspects of the overall flood scheme concept developed for the Water of Leith:

- the design of a woody debris trap for the lower urbanized part of the gorge in the middle catchment
- the design of channel enhancements for the sharp ninety degree bend through the University of Otago Campus
- the design of a more efficient channel expansion from the modified natural channel to the artificial concrete-lined double channel system.

5 FLOOD HYDROLOGY REVIEW

The flood hydrology review involved careful re-examination of all flow gauging data, application of corrections to some of the gauging data to account for both the angle of skew of the gauging transect to the channel centreline and the location of the transect on a stream bend, revision of the stage / discharge rating curves for the gauging station, revision of the streamflow record from 1962 to 2002 on the basis of the revised rating curves and a flood frequency analysis of the annual flood maxima series. The latter analysis incorporated the estimated magnitude of the historic 1929 flood. The results of the flood frequency analysis are summarised in Table 1 with the magnitude of the 1% AEP flood estimated to be 171 m^3/s.

Table 1. Estimated flood magnitudes for the Water of Leith based on a Log Pearson 3 distribution.

Return period (years)	AEP (%)	Flood discharge (m^3/s)
Mean annual		34
10	10	84
50	2	142
100	1	171
200	0.5	202
500	0.2	247

6 DESIGN OF WOODY DEBRIS TRAP FOR LOWER GORGE

As part of the flood scheme, a debris trap was proposed to be constructed on the Water of Leith in the lower urbanized gorge section of the middle catchment. It was intended that this debris trap would capture large woody debris transported under extreme flood conditions from the heavily forested parts of the upper and middle catchments. This would prevent such debris from getting snagged on any of the bridges in the lower catchment and which could otherwise result in breakout of floodwaters onto the floodplain.

A coarse sediment trap already existed in an old abandoned quarry about 0.8 km downstream. However, this boulder trap (which consists of a steel grille across the stream) rapidly gets clogged with smaller scale vegetative debris and then overtops, behaving effectively as a sharp crested weir.

The proposed site for the woody debris trap was located where the channel followed a gradual right hand turn, widening out to form a boulder beach area on the left with the main (low flow) channel then experiencing a gradual left hand turn down to the confluence with a small tributary stream. This is shown in Figure 4 with the direction of flow being from top to bottom. The boulder beach area is a natural deposition area for both boulders and woody debris due to centrifugal force effects.

Based on a literature search, a concept was developed for the woody debris trap of a line of vertical

Copyright © 2006 Taylor & Francis Group plc, London, UK

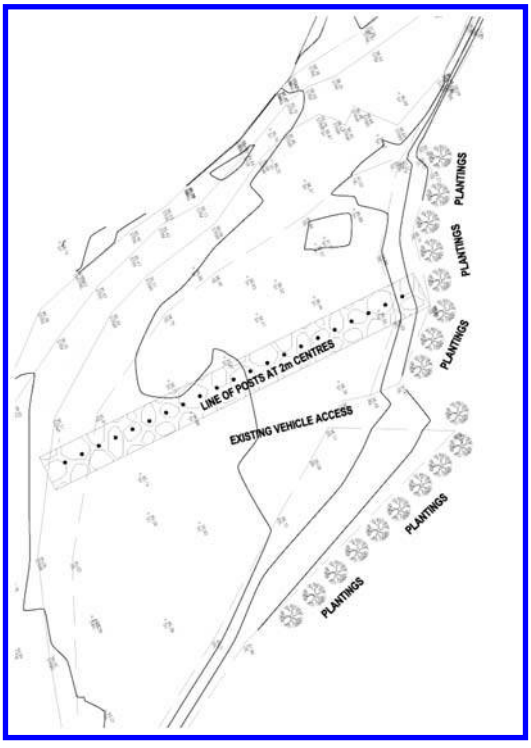

Figure 4. Layout of the woody debris trap designed and constructed in the lower gorge section of the Water of Leith (flow from top to bottom).

poles angled at forty-five degrees to the direction of flow across the boulder beach area (Figure 4). This was based on some examples of similar traps constructed in the German Bavarian Alps with a downstream pointing vee-shaped row of poles across the flanks and a row of poles perpendicular to the direction of flow across the main channel (Wallerstein and Thorne, 1995). These examples had been extensively tested in physical hydraulic models and had also been shown to work effectively in practice. In the case of the proposed water of Leith debris trap, the chosen configuration consisted of only one half of the vee-shaped row of poles with the row stopping short of the low flow channel to leave this unrestricted for recreational purposes (Figure 4).

The design process for the debris trap included both MIKE11 one-dimensional model simulations of the backwater effect of a partially blocked trap and detailed MIKE21 two-dimensional model simulations of the flow pattern across the boulder beach area to assist with orientation of the row of poles forming the trap.

The debris trap was constructed in late 2005. It was first exposed to a large flood event in April 2006. Figure 5 shows of a photograph of the trap near the

Figure 5. Woody debris trap in operation during the April 2006 flood event (view looking upstream).

Figure 6. Woody debris trap after the April 2006 flood event (view looking downstream).

peak of the flood with evidence of a significant amount of woody debris captured. Figure 6 shows another photograph of the trap after the flood event. In addition to the woody debris captured, a significant quantity of boulders was deposited in front of the row of poles forming the trap with some boulders estimated to be as large as 800 mm in diameter. The volume of boulder material deposited was significantly less than the volume of sediment material captured by the boulder trap 0.8 km further downstream. The woody debris trap was considered to have performed very effectively in its first major test.

7 DESIGN OF CHANNEL CAPACITY ENHANCEMENTS FOR SHARP NINETY DEGREE BEND

The heavily modified stream channel for the Water of Leith through the University of Otago Campus

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 7. Geometry of the sharp ninety degree bend through the University of Otago Campus.

with near vertical concrete banks and closely spaced grade control weirs incorporates a sharp ninety degree bend with a radius to width ratio in the order of 6. The University's Information Technology Services (ITS) Building spans the stream channel near the downstream end of the bend with a line of columns supporting the building along the edge of the existing inside bank.

Figure 7 shows the geometry of the bend. The existing channel is about 11.5 m wide and has a bed slope of 1.2%. The grade control weirs have a shallow trapezoidal shape although they are partially covered by a gravel beach on the inside of the bend. The cobbles on the pools between the weirs have a median diameter of 200–300 mm.

MIKE11 model simulations of flood flows through the University Campus reach identified the outside of the sharp bend as the most critical location for channel breakout of floodwaters in the event of an extreme flood. Although the MIKE11 model of the Water of Leith below the exit from the supercritical flow channel was used to help determine a general concept for enhancing channel capacity round the bend (principally channel widening with lowering of grade control weirs and raising outside wall), it was considered prudent to establish a more detailed design concept for the recommended measures using a physical hydraulic model. Such an approach would elucidate the complex flow behaviour round the bend including the interaction between flood flows, the grade control weirs and the cobble-lined bed.

A 1:50 scale physical model of the bend was constructed in the Fluid Mechanics Laboratory of the University of Auckland's Department of Civil and Environmental Engineering. The model covered a 340 m long reach of the stream channel through the University of Otago Campus which extended approximately 100 m upstream of the start and 100 m downstream of the end of the sharp bend. The model was initially constructed as a fixed bed model with projecting grade control weirs above the bed surface. Following testing of various channel capacity enhancement measures in the fixed bed model, the model was converted to a mobile bed to test the final modified channel configuration with an erodible bed. The prototype bed material was represented by 3.35–6.7 mm size fine gravel in the model.

The fixed bed model was initially calibrated for the existing channel geometry against estimated flood levels for the February 1991 flood event (Figures 2 and 3). Measured surface wave heights of 1 m in prototype terms measured at the location of the University's ITS Building were comparable with wave heights from photographs of the actual flood event as indicated by Figure 8. The model was then tested for the 1% and 0.5% AEP floods of magnitude 171 and 202 m^3/s respectively.

Subsequently the fixed bed model was modified to represent the following bend configurations:

(a) the existing channel geometry with the grade control weirs lowered
(b) the existing channel widened from 11.5 m to 16 m with the grade control weirs lowered
(c) the widened fixed bed between the grade control weirs converted to a mobile bed with the grade control weirs lowered.

The effect of incorporating a mobile bed in the model was very dramatic. Even with the maximum amount of channel widening applied (within the constraints of the University's ITS Building spanning the stream), the mobile bed was highly erodible with scour holes more than 3 m deep forming upstream of each grade control weir on the outside of the bend for the 1% AEP flood (site investigations have since revealed the existence of a hard cemented boulder layer about 2 m below the surface of stream bed which would limit the depth of prototype scour in practice).

The erodible bed also induced a significant increase in super-elevated flood levels (up to 1 m) round the outside of the bend compared to those for the corresponding fixed bed case as seen in Figure 9 for the 1% AEP flood case. The magnitude of the surface wave

Copyright © 2006 Taylor & Francis Group plc, London, UK

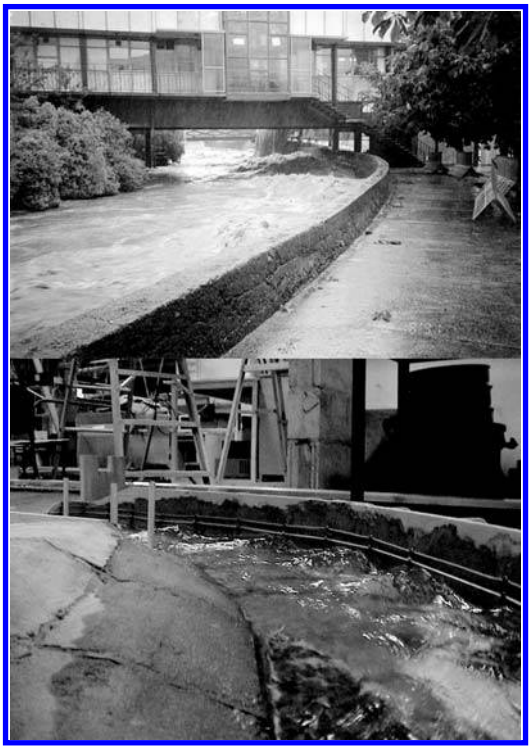

Figure 8. Comparison of prototype and model surface waves round the outside of the sharp ninety degree bend through the University of Otago Campus (top view – prototype, bottom view – model).

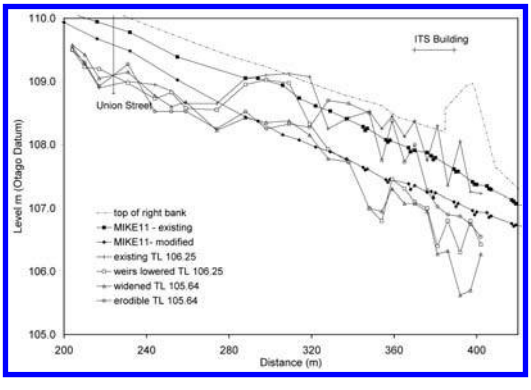

Figure 9. Comparison of flood levels measured in the model round the outside of the sharp ninety degree bend for the 1% AEP flood.

heights round the outside of the bend also increased with the erodible bed case. The magnitude of flow velocities round the outside of the bend were typically of the order of 3.5–4 m/s in prototype terms for the erodible bed case which was considerably lower than for the fixed bed situation (flow velocities were as high as 6–6.5 m/s for the latter case).

The magnitude of both surface wave heights and flow velocities round the outside of the bend increased with increasing flood discharge for both the fixed bed and erodible bed cases.

The results of the model tests were used to refine the general concept for the channel capacity enhancement round the bend. Broadly this consists of:

- widening the channel from 11.5 m to 16 m to provide the maximum possible waterway width
- incorporating a low level footpath on the inside of the bend to improve public access to the stream and assist with meeting the University's objectives for pedestrian routes through the Campus
- modifying the grade control weirs by cutting down the shallow trapezoidal shape on the outside of the bend
- raising the height of the wall on the outside of the bend to provide the required amount of freeboard

It was originally proposed to modify the structural support system for the University's ITS Building to allow channel widening, However recent site investigations have indicated that the existing columns are founded deeper than originally thought and it might be possible to retain the columns in their present position with some additional foundation support.

The treatment of the prototype erodible bed round the bend has yet to be finalised. Two options exist: either partially armour the bed with rock riprap material during construction of the proposed channel modifications, or increase the outside wall height, allow bed scouring to occur in the interim and place rock riprap material in the future when required.

8 DESIGN OF EFFICIENT EXPANSION FROM MODIFIED NATURAL CHANNEL TO ARTIFICIAL CHANNEL SYSTEM

The geometry of the transition from the heavily modified natural channel to the artificial double channel system downstream of the sharp ninety degree bend through the University Campus is quite complex (Figure 10). The transition lies between the Clyde Street and Forth Street Bridges. The channel slope reduces from 1.2% to 0.46% at a point just upstream of the Clyde Street Bridge and from 0.46% to 0.13% below the Forth Street Bridge (which marks the start of the double channel system). The modified natural channel down to the Forth Street Bridge has near-vertical concrete banks and a cobble-lined bed with closely spaced grade control weirs. There is a side-spill weir just upstream of the Forth Street Bridge to allow floodwaters to spill from the main channel into the left overflow channel. The weir is aligned with the

Copyright © 2006 Taylor & Francis Group plc, London, UK

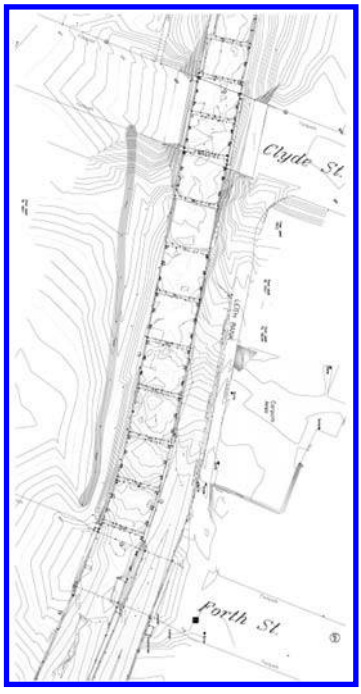

Figure 10. Geometry of the expansion from the modified natural channel and the artificial double channel system between the Clyde Street and Forth Street Bridges (flow from top to bottom).

central pier of the Forth Street Bridge. A high dividing wall between the main and overflow channels continues downstream of the Forth Street Bridge as an extension of the central pier.

Figure 3 demonstrates that the geometry of the Clyde Street to Forth Street channel expansion does not allow for an efficient distribution of flow between each component of the double channel system under flood conditions.

It is not possible to satisfactorily simulate the complex flow behaviour in the Clyde Street to Forth Street channel expansion of the Water of Leith with either a one-dimensional or two-dimensional computational hydraulic model. For this reason it was recommended that a physical hydraulic model of the Clyde Street to Forth Street channel expansion be constructed and tested to establish a detailed design concept.

A 1:65.78 scale model of the channel expansion based on an initial concept of widening the modified natural channel upstream of the Clyde Street Bridge on the left bank, incorporating a new gradual left bank expansion wall downstream of this bridge and extending laterally the existing grade control weirs was constructed in the Hydraulics Laboratory of Opus International Consultants' Central Laboratories. This particular length scale was chosen so that the combined width of the main channel and overflow channel at the downstream boundary of the model just matched the width of the laboratory flume in which the model was set up. Figure 10 shows that there is a slight change in alignment of the prototype expansion between the two bridges. In order to fit the model into the laboratory flume it was necessary to ignore this change in alignment (the effects of this were considered to be very minor). The model covered a reach extending upstream of the Clyde Street Bridge (so that it overlapped with the bend model) and 100 m downstream of the Forth Street Bridge where the main and overflow channels of the double channel system attain their full width.

The model was originally configured as a fixed bed model to represent the initial modification concept for the channel expansion. However it was found that the backwater profile predicted by the model for the 1% AEP flood was markedly different from that predicted by an approximate MIKE11 model of the modified channel expansion. Consequently the model was set up as a mobile bed model (with 4.2 mm gravel chip used to represent the 200–400 mm size prototype bed material) and temporarily reconfigured to simulate the existing channel geometry.

The model was run in this temporary configuration for the February 1991 flood event. It was found for this flood event that the mobile bed was highly erodible with scour holes forming on the bed in front of each grade control weir and corresponding standing waves forming on the water surface. Any eroded bed material that reached the fixed bed of the double channel system was rapidly flushed downstream. Although it is normal practice to run a mobile bed setup in a model over a long period of time to establish an equilibrium bed profile, a slightly different approach was adopted to try and expedite the test programme. The pool levels were progressively lowered over a series of runs to achieve an approximate match between the simulated water surface profile in the model and the flood level data for the February 1991 event estimated from photographs taken just prior to the peak. The amount of pool "scour" required to achieve a good match between the model water surface profile and the observed flood level data was found to very large. This was consistent with the results of the mobile bed tests on the bend model with the widened channel configuration where extremely large scour depths on the outside of the bend were observed, albeit for a widened channel geometry rather the existing channel geometry.

Having achieved an adequate understanding of bed behaviour under flood conditions in the existing channel situation, the initial modification concept for the channel expansion was restored in the model and tested with a mobile bed. In contrast to the existing channel situation, it was found that the mobile bed was

Figure 11. Surface wave action in the model of the modified channel expansion between the Clyde Street and Forth Street Bridges for the 1% AEP flood (view looking upstream).

no longer erodible under 1% AEP flood conditions. However it has to be acknowledged that the model setup in the flume ignored the scouring effect of the highly asymmetric flow distribution round the upstream sharp bend which the bend physical model had identified.

Figure 11 shows a view of the wave action in the model configured to represent the initial modification concept for the channel expansion. The occurrence of a standing wave on the surface in front of each grade control weir is still evident even though the degree of projection of the weir crest above bed level is much less that for the scoured bed condition of the existing channel geometry.

The model was further modified to represent an alternative channel modification concept which retained the essential channel widening component of the initial concept but which incorporated a low level path along the left bank downstream of the sharp bend to enhance the public amenity value of the stream and to provide an alternative pedestrian route through the University Campus. The low level path terminated immediately downstream of the Clyde Street Bridge at the start of the channel expansion. It was accepted that this path would be inundated on average 1–2 times per year and more frequently under the Clyde Street Bridge but these occasions would provide only temporary disruption. One advantage of this alternative concept over the initial concept was that it would not be necessary to laterally extend the grade control weirs over the reach between the sharp bend and the Forth Street Bridge.

Testing of the alternative channel modification concept in the model generally confirmed the suitability of the concept although it also helped identify useful

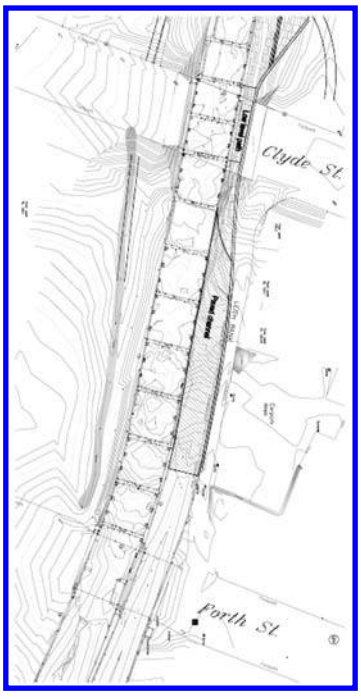

Figure 12. Final recommended layout for the modified channel expansion between the Clyde Street and Forth Street Bridges.

refinements. The cobble-lined bed with this alternative channel geometry showed slight evidence of movement in the case of the 0.5% and 0.2% AEP floods.

Figure 12 shows the final geometry recommended for the Clyde Street to Forth Street channel expansion. Key components of this geometry include:

- widening of the channel on the left bank upstream of the Clyde Street Bridge
- a shaped contraction past the left abutment of the Clyde Street Bridge
- a shaped left bank expansion wall downstream of the Clyde Street Bridge
- lowering the crest of the side-spill weir to just above the top of the transverse grade control weirs
- a continuous left bank low level path just above the top of the grade control weirs with an alternating sequence of steep and flat sections to promote energy dissipation of flood flows through the formation of weak hydraulic jumps
- extension of the paved left overflow channel upstream to the Clyde Street Bridge
- filling in with suitable cobble and boulder material the deeper scour holes in the pools between the grade control weirs upstream of the Forth Street Bridge.

9 CONCLUSIONS

The combination of a steep mountain stream and a heavily modified channel across an intensively developed floodplain provide a challenging environment in which to design and construct improved flood security measures. This paper has described three innovative aspects of a comprehensive flood scheme in such a setting for the Water of Leith at the north end of Dunedin City, New Zealand. A woody debris trap was designed and constructed and, in its first major test, performed exceptionally well. Channel capacity enhancement measures round a sharp ninety degree bend (which is presently the most critical location for flood breakout) in the heavily modified natural channel were designed with the aid of a mobile bed physical hydraulic model. A more efficient channel expansion from the modified natural channel to an artificial double channel system was also designed with the aid of another mobile bed physical hydraulic model. Both the bend and channel expansion enhancements incorporate features to improve the public amenity value of the stream.

ABSTRACT: The plane distribution of water flows and sediment deposition and erosion at Chongqing reach are studied with a 2-D numerical model, especially the backflows at the confluence of the Jialingjiang River flowing into the Yangtze River, and the backflows owing to irregular local banks. According to the water flows and sediment conditions the amount of sediment deposition and distribution for the period of 2003～2032 are calculated. Deposition mainly occurs on the meandering reaches with uneven bank lines, backwater areas, and wide and shallow reaches as well. The bank lines will become more straight and smoother due to sediment deposition near the banks.

1 INTRODUCTION

Three Gorges Project constructed on the Yangtze River, which is called "Gold Watercourse" is of multiple benefits of flood control, power generation and navigation. Experience gained from the existing hydro projects in China shows that in the backwater area of reservoirs the problems related sediment will gradually aggravate with time (Dou et al, 1988). The sediment problems of the Three Gorges Project affects the development and prosperity of Chongqing Harbor, which has a great importance on the development of national economy in the southwest areas of China. During the construction of Three Gorges Project, Chongqing City became the municipality directly under the Central Government of China, and its municipal construction has been rapidly performing. In recent years, the municipal construction has changed the bank line of Chongqing reach: Chaotiamen bank line has extended 50～100 m toward the river channel, the bank line of left bank upstream the Chongqing Yangtze River Bridge has extended 100～200 m toward the river, and those of other reaches have changed to some extent. The influence of the modification of the bank lines on flood prevention and navigation has attracted concern of people and researchers.

Yangtze River is the largest river in China, with abundant water and large drainage areas, and there are many tributaries flowing into the river. Discharges of tributaries have a great influence on water flow and sediment motion in the Yangtze River, especially those with large drainage areas, abundant water and sediment. The river and tributaries are of different flood periods, their water levels affect with each other, the flow velocity and sediment carrying capacity decrease as a result of the reservoir operation, so as to make large quantity of sediment deposit and to result in shoals near the mouths of the tributaries, directly affecting navigation of the stream and tributaries.

Applications of 1D mathematical models to sediment transport simulation were reported as early as in the 1960s (Dou, 1963; Lin et al., 1981; Chang, 1982; Han, 1987; Holly and Rahuel, 1990). These models have been used to calculate long term sediment deposition and erosion for fluvial river channels. In the past few decades, 2D and 3D mathematical models for sediment transport have been developed to predict river regime and riverbed deformation due to engineering projects (Dou et al., 1987; van Rijn, 1987; Li, 1989; Shimizu et al., 1990; Spasojevic and Holly, 1990; Olsen, 1999; Zhou, 1997; Lu, 1998; Lu et al., 2002, 2004; Wu et al., 2000). The numerical models assume either an equilibrium or a non-equilibrium state of sediment transport. The models for suspended load transport mostly assume non-equilibrium sediment transport. The state of bed load transport (equilibrium or non-equilibrium) is essentially a key issue in the modeling of local sediment deposition and riverbed erosion. The existing 2D sediment mathematical models mostly highlight simulation of water

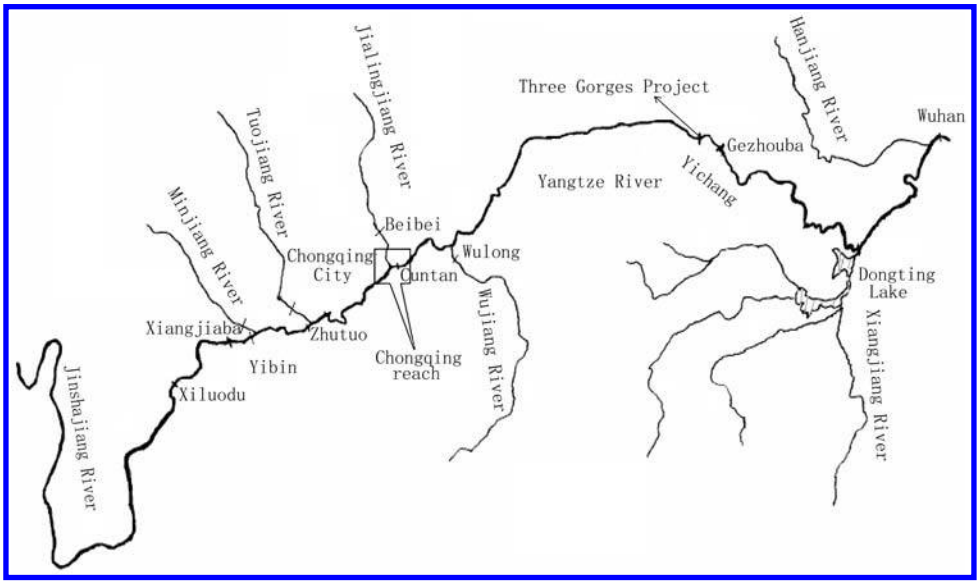

Figure 1. Sketch of middle and upstream Yangtze River.

flows and sediment in a single river. The 2D sediment mathematical model in the boundary fitting orthogonal curvilinear coordinate system developed by the authors overcomes the difficulty of complex boundary between the river and its tributaries (Lu, 1998). It is employed to simulate water flow motion and riverbed deformation of the 44 km-long Chongqing reach (Qiezixi—Tongluoxia) located about 25 km upstream of a tributary of Yangtze River, Jialingjiang River (Fig. 1).

2 CHONGQING REACH AND ITS WATER FLOWS AND SEDIMENT CHARACTERISTICS

Chongqing reach is located in the wide river reaches with hills in the upstream of Yangtze River. From the plane configuration, the present reach is meandering, especially the channel of the Yangtze River is continuously meandering, and the ratio of lengths between the meandering reach and straight transition reach is 1:1. The Jialingjiang River, from north to south, flows into the Yangtze River on the left bank at Chaotianmen, as shown in Figure 2. The channel is narrow, usually only 1000 m in flood season and 600 m in low-water periods, some reaches are 2000 m in flood season and 250 m in low flow season. The banks are steep and usually made up of bedrock, with huge rocks protruding towards the river. The bank line is not smooth, but it is stable. The riverbed consists of gravel and sand, with the median diameter being about 60 mm. There are some bedrocks surfacing out at part of the

Figure 2. Chongqing reach and its computational domain.

reach, resulting in stone reefs. From the longitudinal section, the riverbed is uneven with deep pools and shallow ridges, showing a shape of indention. The afflux of Jianglingjiang River makes Chongqing reach be of estuarine characteristics. The above-mentioned results in the complexity of water flows and sediment motion of Chongqing reach. Cuntan station, a hydrological station on Chongqing reach, has a catchment area of 866559 km^2, and Beibei station on Jialingjiang River has a catchment area of 157900 km^2, occupying 18.2% of the catchment area of Cuntan station. About 75% of the total annual runoff for the stations Cuntan and Beibie mainly occurs during the flood period. 18.6% of the amount of runoffs of Cuntan station is

Grain size (mm)	0.025∼0.05	0.05∼0.10	0.10∼0.15	0.15∼0.20	0.20∼0.25	0.25∼0.50	0.50∼1.00
Percentage (%)	10.50	13.00	31.50	26.00	11.00	6.00	2.00

from Jialingjiang River, and it is nearly of the same percentage during the flood and low-water periods. Perennial mean sediment load by suspended load of Jialingjiang River is 148000000 t, about 1/3 of sediment load of Cuntan station (Dou et al, 1988). During the low-water period, the percentage of sediment load from Jialingjiang River is larger, reaching 41.7%. The median diameter of suspended load at Cuntan station is 0.0275 mm, and that of the Beibei station is close to that of Cuntan station.

Perennial mean transport of gravel bed load at Cuntan station is 277000 t/y, and the median diameter is 51 mm (Table 1), with the maximum being 202 mm. the size distribution of sand bed load is given in Table 2. Generally, the narrow and deep reaches are of coarse riverbed material, and the wide and shallow ones has fine material; the main stream carries coarse material, and the beach area is of fine material.

3 MODEL VERIFICATION

In this paper, verification and calculation of water flows and sediment deposition and erosion are performed to Chongqing reach in the upstream of Yangtze River. It is about 43.6 km in length, the upper boundary is Qiezixi (687.6 km away from Yichang), and the lower boundary is Tongluoxia (644 km away from Yichang) and Jialingjiang.

3.1 *Generation of computational domain and orthogonal curvilinear grid mesh*

The computational domain includes the reach from Qiezixie (inlet) to Tongluoxia on Yangtze River and the reach from Jinkou (about 25 km away from the afflux) to the afflux on Jialingjiang River. Its river regime is shown in Fig. 2. A grid system of 407×63 is arranged, among which, 248×31 nodes are arranged for the reach from Qiezixi to the afflux, 248×31 nodes for Jialingjiang River, and 159×63 nodes for the reach from the afflux to Tongluoxia. The resulting orthogonal curvilinear grid mesh is shown in Fig. 2. The nodes have intersection angles of 88°∼92° except for some nodes close to the banks. The spacing between each two nodes is 80∼120 m along the longitudinal direction and 10∼40 m along the lateral direction.

3.2 *Verification of water levels*

On March 8, September 22 and November 22, 1986, the discharges at Cuntan station are 3170 m^3/s, 22600 m^3/s and 6400 m^3/s, respectively, as for at Beibei station, they are 447 m^3/s, 1710 m^3/s and 716 m^3/s, respectively. Differences between the calculated and measured instantaneous water levels are all smaller than 0.1 m except individual water levels (Lu, 2001).

3.3 *Verification of velocity distribution and simulation of flow fields*

When the discharge of Jialingjiang River is 716 m^3/s or 1710 m^3/s, the calculated and measured values of velocities for Section Wen-O III are in good agreement (Lu, 2001). When the discharge at Cuntan station is 6400 m^3/s or 22600 m^3/s, the calculated distribution of velocities along the river width for Cuntan section are also in good agreement with the measured ones (Lu, 2001). Distribution of velocities of Cuntan section fully shows the controlling action of river topography, that is, large velocity in deep channels and small one in beach areas.

It is simulated that with the increase of discharges, water flows gradually submerge beach areas and backflows are caused by local topography. Especially when the discharge of Jialingjiang River is small (1710 m^3/s), the confluence ratio is small ($R = 0.076$) and the discharge of Cuntan station is 22600 m^3/s, it is simulated that the river of Yangtze River has an effect on its tributary, Jialingjiang River, resulting in that the estuarial water flows of the latter become tranquil flows, with the velocity being only 0.2∼0.4 m/s; while when the confluence ratio is 0.45, $Q_{Jia} = 4860\ m^3/s$, $Q_{Cun} = 11350\ m^3/s$, water flows from Jialingjiang River directly flow towards the right bank on Yangtze River and large area of backflow at the left bank is thus formed, about 400 m in length and about 300 m in width (Fig. 3); when the confluence ratio is much larger ($R = 0.72$), $Q_{Jia} = 10500\ m^3/s$, $Q_{Cun} = 14500\ m^3/s$, the

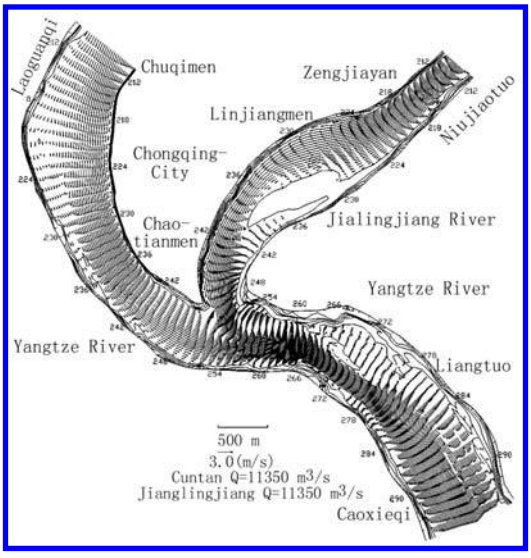

Figure 3. Flow fields at the afflux when $Q_{Cun} = 11350\ m^3/s$, $Q_{Jia} = 4860\ m^3/s$ and $R = 0.45$.

velocity of water flows from Jialingjiang River directly flowing toward the right bank is up to 5 m/s, and the backflow area is 600 m in length and 400 m in width (Lu, 2001).

3.4 *Verification of sediment concentration and its gradation distribution*

Based on the measured sediment concentration and gradation in Jialingjiang River and Jiulongtan on Yangtze River on September 22 and November 22, 1986, sediment concentration fields for various grain sizes are calculated. The calculated values of mean sediment concentration along the river width for Section Wen-O III on Jialingjiang River and Cuntan station on Yangtze River are in good agreement with the measured ones, and their gradation is close to the measured one (Lu, 1998; Lu, 2001).

3.5 *Verification of riverbed deposition and erosion*

A period from the middle of January to the middle of November 1986 is selected for verification of riverbed deposition and erosion, and there are 88 time intervals, with the time step of 3∼4 days on average, that is, 5∼6 days during non-flood season and 1∼2 days during flood season. Calculation of sediment concentration of suspended load is conducted for 6 groups of grain sizes, and percentage of various grain sizes employs the annual mean value. Table 3 gives the percentage and settling velocities of various grain sizes on the inlets of Yangtze River and Jialingjiang River. Calculation of sediment transport of bed load is conducted

Table 3. Sediment concentration and settling velocities of suspended load.

Grain size (mm)	0.005	0.0169	0.0368	0.0736	0.169	0.368
Ps (%)						
Yangtze River	23.6	20.9	25.9	17.6	8.0	4.0
Jialingjiang River	17.7	19.9	28.9	24.1	7.0	2.4
Settling velocity (mm/s)	0.016	0.180	0.855	3.39	16.40	51.10

for 7 groups of grain sizes (Table 1), with the grain size being 1∼200 mm, among which, as for the pebble bed load with grain size of 10∼200 mm, the empirical equation by Nanjing Hydraulic Research Institute based on the measured data is employed (Dou, 1988), that is,

$$g_b = 8.0\times10^{-12} mQ^{2.60} \quad (1)$$

where m is the efficiency coefficient of instruments; $m = 11.6$. Because there is no measured data of pebble bed load on Jialingjiang, during calculation sediment transport rate by use of discharge ratio of the river is estimated for Jialingjiang River. As for the gravelly bed load of 1∼10 mm, it is calculated by the percentage of 3% of pebble bed load, and the sandy bed load smaller than 1 mm is taken into account during calculation of deposition and erosion of suspended load. The initial gradation of riverbed material is based on Table 1, and change of components of riverbed material is also considered, that is, the narrow and deep reaches are of coarse riverbed material, and the wide and shallow ones are of fine material; the riveris of coarse material, and the beach area is of fine material.

3.5.1 *Jinshaqi reach in the estuary of Jialingjiang River*

During January∼June of 1986, though there is large discharge from the upper boundary from April to June and the confluence ratio is larger than 0.2, with the maximum being 0.7, water flows in Yangtze River have no effect on Jialingjiang River, however, water flows in Jialingjiang River have certain effect on Yangtze River. As for Jinshaqi reach, there is little deposition; during July∼September, that is, the flood period for Yangtze River, the confluence ratio gradually decreases, and it is usually about 0.10 and the maximum sediment concentration of Jialingjiang River is 2.6 kg/m^3, with the mean value being smaller than that during April∼June, affected by water flows of Yangtze River, velocity and sediment carrying capacity decrease, resulting in large amount of deposition on Jinshaqi reach, up to 370000 m^3 and mainly on

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 4. Verification of deposition and erosion for various reaches (10^4 m^3).

Rivers and reaches		Distance (km)	Amount of deposition from Mar. to Sept. 1986		Amount of erosion from Sept. to Nov. 1986		Scour rate (%)	
			Calculated	Measured	Calculated	Measured	Calculated	Measured
Yangtze River	Jiulongtan	669∼674	187.4	181.7	−97.0	−115.2	51.8	63.4
Jialingjiang River	Jinshaqi	0∼3	37.7	37.8	−20.9	−25.3	55.4	66.9
	Shimen	10∼12	20.0	23.1	−11.5	−11.6	57.5	50.2

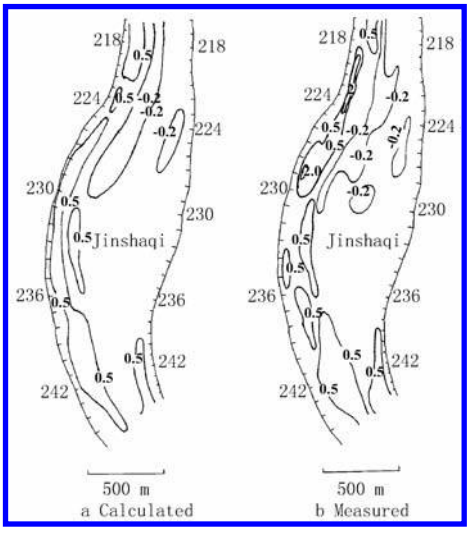

Figure 4. Deposition and erosion at Jinshaqi reach on Jialingjiang River from Mar. to Sept. 1986

its right channel; after October, that is, the ebbing period for Yangtze River, effect of Yangtze River on Jialingjiang River gradually decreases, the confluence ratio increases and the discharge from Jialingjiang River is nearly clear water with the sediment concentration being only 0.01 kg/m^3, the deposited sediment on Jinshaqi reach during the flood period are started to erode, till the middle of November, about 200000 m^3 is washed away by water flows. Table 4 gives a comparison between the calculated and measured amount of deposition and erosion. Figure 4 shows a comparison between the calculated and measured locations during March∼September. It is seen that the calculated amount of deposition and erosion and corresponding locations are close to the measured ones.

3.5.2 *Shimen reach on Jialingjiang River*

Shimen reach is located 10∼12 km upstream Jialingjiang River. The width of the widest and shallowest reach is about 2 times that of the deep channel in the upstream, and the velocity and sediment carrying capacity of the wide reach is fairly smaller than those of the deep channel reach, resulting in that during the flood period large quantity of sediment carried by water flows deposit in the wide reach, and during the ebb period, water flows return and the velocity increases, the deposited sediment during the flood period is eroded, and the riverbed basically recover the topography during the low-water period. The calculated distribution of locations during March∼September 1986 (Lu, 2001) and the calculated amount of deposition and erosion during March∼September and September∼November 1986 are close to the measured ones (Table 4).

3.5.3 *Jiulongtan reach on Yangtze River*

Jiulongtan reach is located 669∼674 km upstream Yichang. During the flood period sediment deposition is mainly resulted from rapid widening of the reach, decrease of velocity and sediment carrying capacity. The calculated distribution of locations during March∼September 1986 (Lu, 2001) and the calculated amount of deposition and erosion during March∼September and September∼November 1986 for Jiulongtan are also close to the measured ones (Table 4).

4 CALCULATION OF DEPOSITION AT CHONGQING REACH AFTER THE IMPOUNDMENT OF THREE GORGES PROJECT (2003∼2032)

4.1 *Calculation conditions*

According to the data of 1D mathematical models by Yangtze River Scientific Research Institute, that is, discharge, sediment concentration as well as its gradation of Qiezixi section (inlet) on Yangtze River during 2003∼2032 and water level hydrograph of Tongtianba (Shengjitang) (outlet), the deposition process of the present reach is calculated. Among which, discharge of Jialingjiang River is obtained by subtraction of discharge of Qiezixi section from that of Cuntan; sediment concentration process of Jialingjiang River is obtained by relationship (Lu, 2001) between sediment transport rate and discharge at Beibei station

on Jialingjiang River during 1961∼1970; gradation of sediment concentration employs the perennial mean gradation at Beibei station.

During June 2003∼June 2007, Three Gorges Project employs the impoundment scheme of 135 m; During July 2007∼July 2009 the impoundment scheme of 156 m is employed; After August 2009 the impoundment scheme of 175 m is employed. During 2003∼July 2009, the study reach is basically in a natural state, and its riverbed will show evolution characteristics of natural riverbed. After August 2009, owing to the effect of backwater, the study reach will be located in the fluctuating backwater area, water levels will increase, and velocity and sediment carrying capacity will decrease, resulting in sediment deposition.

4.2 *Amount of deposition at Chongqing reach before change of bank line and its comparison with the test results of long model of Nanjing Hydraulic Research Institute*

In order to check the precision of the present model to simulate sediment deposition after the construction of Three Gorges Reservoir, amount of deposition at Chongqing reach before change of bank line should be compared with the test results of long models. As for the long model of Nanjing Hydraulic Research Institute for fluctuating backwater areas of Three Gorges Project, tests on sediment deposition for 80 years were once performed to the impoundment scheme of 175 m (Dou, 1988), they were demonstration tests for water levels of Three Gorges Project. For the impoundment scheme of 175 m, the level of 156 m is employed for the first 10 years and after that, the level of 175 m is employed. During model tests, considering that at the level of 156 m the study reach is basically not affected by backwater, thus its corresponding discharge hydrograph was not simulated, therefore, the test results of the 28th year in the research report are equivalent to the amount of deposition of 18th year after the impoundment of 175 m. Table 5 gives the Amount of deposition at Chongqing reach of 18th year after the impoundment of 175 m calculated with the topography of 1986 being the initial one and its comparison with the test results of long model of Nanjing Hydraulic Research Institute. It is seen from the table that as for the 26 km-reach from Lijiatuo to Tongtianba, the amount of deposition calculated by mathematical models is 46587000 m^3, that by physical model tests is 41559000 m^3, with the difference being only 5028000 m^3. Except individual reaches, differences of the amount of deposition for various reaches and Jialingjiang River between mathematical and physical model tests are small.

4.3 *Amount of deposition at Chongqing reach after change of bank line*

4.3.1 *Amount of deposition*

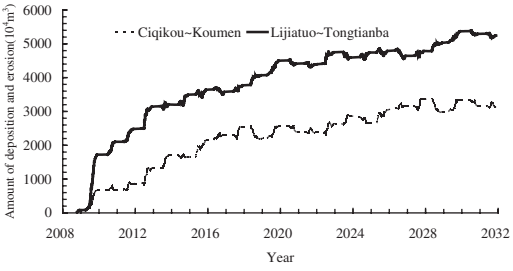

Figure 5. Change of amount of deposition and erosion at Chongqing reach with time.

and 2032, respectively. Figure 5 shows the change of the amount of deposition at Lijiatuo-Tongtianba reach with time. It is seen that untill the completion of the impoundment in 2032, there will be a deposition of 69112000 m^3 at Qiezixi-Tongtianba reach. The spatial distribution of this deposition is as follows: 16654000 m^3 for Qiezixi-Lijiatuo reach, 1176000 m^3 for Lijiatuo-Jiulongtan reach, 9614000 m^3 for Jiulongtan-Huangsha reach, 14129000 m^3 for Huangsha-Chuqimen reach, 1948000 m^3 for Chuqimen-Chaotianmen reach, 16554000 m^3 for Chaotiamen-Cuntan reach, and 9037000 m^3 for Cuntan-Tongtianba. The law of change of amount of deposition with time is as follows: during October~November after the flood period Three Gorges Reservoir begins to impound, when the water level gradually rises to 175 m from 145 m, the water level of the study reach increases, velocity and sediment carrying capacity decrease, resulting in sediment deposition. Before the flood period, the water level decreases to 145 m, the water level of the study reach is of little rise, thus the riverbed of the main channel of the study reach is slightly eroded. Therefore, the process of amount of deposition has an alternative deposition and erosion within a year, showing an increasing tendency in general. Deposition mainly occurs during the period from October to May of the next year, and erosion occurs during June~September, and it fully shows the function of Three Gorges Reservoir, that is, to store clear water and release eddy water, so as to ensure the effective capacity of Three Gorges Project.

Table 7 gives the amount of deposition at Jinkou-mouth reach on Jialingjiang River after the impoundment till 2022 and 2032, respectively. Fig. 5 shows the change of the amount of deposition at Ciqikou-mouth reach with time. It is seen that the deposition law of tributaries is basically the same as that of the trunk stream, that is, there is an increasing tendency in general and it is slightly eroded during the flood period. Till the impoundment in 2032, there is amount of deposition of 56115000 m^3 at Jinkou-mouth reach, among which, 24728000 m^3 for Jinkou-Ciqikou reach, 20210000 m^3 for Ciqikou-Niujiaotuo reach and 11197000 m^3 for Niujiaotuo-mouth reach.

4.3.2 *Location of deposition*

The calculated riverbed topographies are shown in Figs. 6a, 6b, 6c and 6d for Lijiatuo-Chuqimen reach, Chuqimen-Yuduchuanchang reach, Duchuanchang-Tongtianba reach and Ciqikou-Zengjiayan reach in 2032. It is seen that the deposition mainly occurs on the

5 CONCLUSIONS

This paper studies the plane distribution of water flows and sediment deposition and erosion at Chongqing reach, especially the backflows at the confluence of the two rivers, that is, Yangtze River and Jialingjiang River,

Copyright © 2006 Taylor & Francis Group plc, London, UK

and those owing to irregular local banks. The calculated water levels, distribution of velocities, sediment concentration and its gradation, amount of deposition and erosion as well as its locations of Jiulongtan on Yangtze River and Shimen and Jinshaqi on the Jialingjiang River are in good agreement with the measured data.

According to the water flows and sediment conditions, the amount of sediment deposition and locations during 2003 ~ 2032 are calculated. At the end of the 30th year of impoundment of the reservoir the amount of deposition in the 38.6 km-long Qiezixi-Tongtianba reach will be 69.112 million m^3 whereas in the 25 km-long Jinkou-mouth reach will be 56.135 million m^3. Deposition mainly occurs on the meandering reaches with uneven bank lines, backwater areas as well as wide and shallow reaches. The bank lines will become more straight and smoother.

A preliminary study on the local abrupt descent of downstream water level near the Three Georges Dam

Zhaohua Sun, Yitian Li & Ming Li

Changjiang Waterway Engineering Bureau, Wuhan, China

ABSTRACT: The Yangtze River transforms from gravel bed channel into sand bed channel in the reach of Yichang to Shashi, which is close to the Three Georges Dam and undergone the immediate clear water erosion after impoundment. Prediction of how water level and long profile will response to the dam in dry season has draw wide concerns, for their likely influence on navigation condition. Based on historical data collection and analysis, it is found that the water level drop in this reach is controlled not only by channel erosion but also by pivotal reach segment with special geological and morphological features. Because of its control function, an abrupt descent of water level is formed, that will become even higher gradient slope in future.

1 INTRODUCTION

The Yangtze River, with a total length of more than 6300 km, is divided into upper and middle reaches at Yichang, where the river exits from the upper rock-confined valley into the Jingjiang fluvial plain. In the downstream reach near Yichang, the river transform from confined gravel bed channel into alluvial sand bed channel. After the construction of the Three Georges Project (TGP) at Yichang, dam effects would take places in this section more immediate than other reaches. As channel incision and water level drop is common on other regulated rivers, how fast would the post-dam channel adjustment occur in this reach and to what extent the water level would drop have draw much concerns. Numerical models have indicated that water level decrement would amount to about 0.5 m (5000 m^3/s) in dry season at Yichang after 5 years clear water erosion (Changjiang River Scientific Research Institute, 2002), but the actual process is even unnoticeable in the past three years. With channel degradation shifts to downstream sand bed reaches, will the upstream water level be affected and get into obvious periods of decreasing? Whether the streamwise uneven scour depth would result in abrupt descent of water level at some locations? At present, these are questions very cared by engineers, especially in waterway management near the dam.

In numerous catchments throughout the world human intervention has strongly altered natural river dynamics. The response of flow processes and channel morphology to engineering and regulation of alluvial streams have been studied widely both on gravel channels and sand bed channels, for hazard mitigation, infrastructure stability and environmental conservation, but few on navigation (Kondolf, 1997; Surian & Rinaldi, 2003). The middle and upper reaches of the Yangtze River differing in geology, channel geomorphology and bed composition, as the transitional section between them, dam effect issues surrounding the immediate downstream of the TGP will inevitably be complex. Documented historical data of changes that have occurred in response to human impacts is helpful for prediction of the future evolution of the river. This paper examines the gauged information in this reach in the past few decades and investigates the relationships between low flow hydraulic features and channel adjustment, based on which, some predictive description about the future evolution is given.

2 STUDY AREA

2.1 *Regional setting*

The upper Yangtze is deeply incised into rocky canyons with high slope. At the exit of the Three Gorges, the TGP (dam impoundment in 2003) and Gezhouba Project (dam impoundment in 1981) were constructed. In the middle Yangtze, the slope decreases dramatically. Downstream from Shashi, a typical meandering river pattern is formed (Fig. 1). In the 1960s and the 1970s, a set of cutoff projects were used to manage

Copyright © 2006 Taylor & Francis Group plc, London, UK

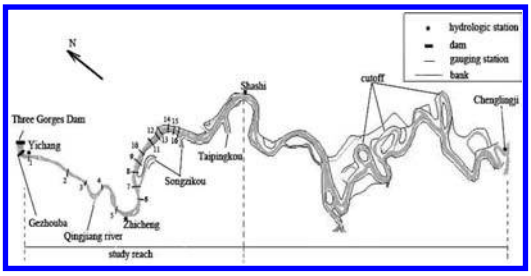

Figure 1. Location of the study reach.

the fluvial environment and the course of the river was shortened by approximately 78 km. The study reach from Yichang to Shashi is about 140 km long with confined channel boundary and low sinuosity in planform. A little tributary named Qingjiang joins the main stream about 39 km downstream Yichang, but its runoff only amounts to less than 5% of the Yangtze's at Zhicheng. At Songzikou (74 km from Yichang) and Taipingkou (138 km from Yichang), there are diversions linking the Yangtze River with Dongting Lake, but they are usually dry in low flow season.

In this reach, the low flow water level is of navigational interests for two reasons. One is related to the threshold water depth in the downstream ship-lock entrance of the Gezhouba Project. If the water level of Yichang dropped too much to make the water depth less than the designed 4.0 m depth at lock entrance, ships would not be able to get through. Another reason is about the slope gradient at some location. After the TGP enclosure, more ships are reported to have difficulty in upstream navigate in certain location in dry season, so engineers wondered if water level has descended abruptly in that reach, which is causing a high gradient.

2.2 *Historical events*

Both human disturbance and extreme hydrologic event have impacts on the channel adjustment history in this reach, including dam construction, river cutoff projects, gravel mining, sediment excavate and major floods:

(1) Two cutoff projects were implemented at Zhongzhouzi and Shangchewan in the 1960s and another natural-cutoff occurred in 1972 at Shatanzi. Although these changes were not taken place in the study reach, but they aroused backward erosion and water level had been changed in upstream reaches.
(2) From 1971, for the purpose of the Gezhouba Dam construction intense gravel mining and sediment excavate had taken place in neighborhood of Yichang. Records show that $14.55 \times 10^6 m^3$ sediment had been mined from 1972 to 1981. Affected by this, average channel degradation between Yichang and Qingjiang River confluence was amount to 0.91 m.
(3) The Gezhouba Dam is a run-of-river project and it locked the Yangtze River in 1981. After impoundment, the dam released water had taken $22.40 \times 10^6 m^3$ sediment away from 1981 to 1986. Integrating with gravel mining, average bed degradation upstream of the Qingjiang River confluence is about 0.4 m to 0.5 m in this period.
(4) In the extreme flood of 1998, about $53.42 \times 10^6 m^3$ sediment was flushed out of the Gezhouba reservoir. The downstream reach undergone obvious deposition. Top elevation of some bars in Yichang reach was increased by 5 m and the deposition depth averaged to 1.85 m in the reach of more than 30 km long.
(5) After the TGP closure in Jun 2003, water level behind the dam was increased from about 60 m to 135 m above mean sea level. Down stream channel degradation is still ongoing.

Those events affect different segments of the whole reach and their impacts often compound with one another. In order to roughly separate the effects of those impacts, the past few decades is divided into several consecutive periods: 1961–1970, 1971–1980, 1981–1987, 1987–1998, 1998–2003 and 2003–2005.

3 DATA COLLECTION AND METHODS

The Yangtze River Water Resource Committee (YRWRC) has set gauging stations along the Yangtze River from the 1950s. Three major gauging stations were chosen for this study at Yichang, Zhicheng and Shashi, representing the upper, middle and lower part of this reach. Among them, water level gauging data is available from the 1950s and daily mean discharge can be obtained at Yichang(1950–2005) and Shishi (data before 1990 not available). The focus of this paper in on low flow, so that only data in January to March is collected. In this period, the discharge of Zhicheng and Shashi can be calculated by adding the discharge of Qingjiang into Yichang. In addition to the hydrologic data gauging by YRWRC, the Changjiang Waterway Engineering Bureau (CWEB) has set 16 water gauges in this reach to survey the water level change after 2003. Their distance from Yichang are 0 km, 20 km, 27 km, 43 km, 57 km, 71 km, 76 km, 80 km, 83 km, 87 km, 92 km, 98 km, 103 km, 106 km, 109 km and 112 km (Fig. 1). From those gauging sites, simultaneous water level along the reach can be obtained. It will give convenience to the present study for detailed understand of the slope in each segment. The water level from different sources or in different periods may have the different base level; these factors are all considered and taken into account.

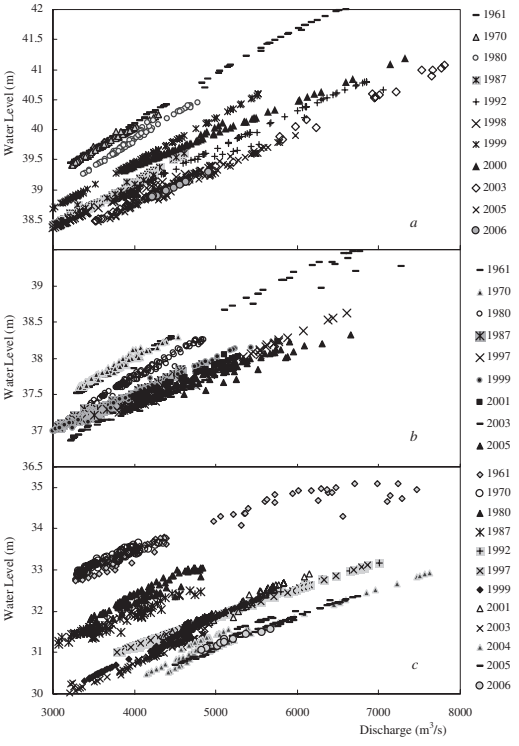

Figure 2. Stage-discharge relation of different station; *a*.Yichang, *b*.Zhicheng *c*.Shashi.

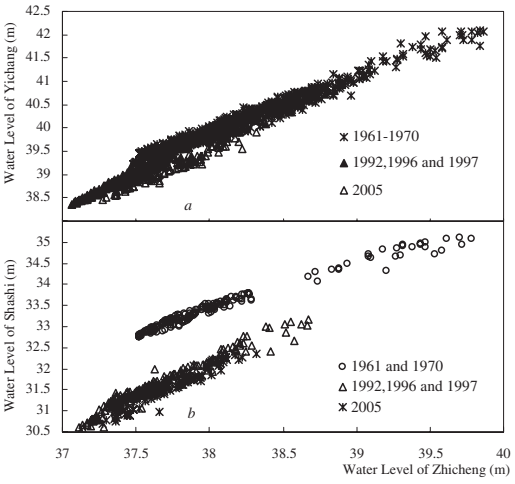

Figure 3. Correlation of water level between stations; *a*. Yichang-Zhicheng, *b*. Shashi-Zhicheng.

In the study reported here, records of discharge and water level in this reach were collected to examine the spatial and temporal changes of water level. The exploration is performed by three means:①For each gauging station, the stage-discharge relations of different periods are plotted (Fig. 2). Because only the first three months of every year is investigated, the discharge variation is limited in a certain scope. By this way, the changing process of low flow water level of different parts of the reach can be indicated.②On the basis of one site study, the relationships between different sites were depicted for different periods. As Zhicheng located in the middle of the other two stations, the value of daily water level is plotted in manners of Shashi-Zhicheng and Yichang-Zhicheng (Fig. 3). Because interval between those stations is not a very long distance and the flow isclose to a quasi-steady state in dry season, the inter-station discharge difference can be ignored. The daily water level has the foundation to be compared, so the result will be credible.③From the data of the 16 water gauges, some characteristics of water surface profile can be plotted. In order to eliminate the influence of unsteady flow, only data series of those times is chosen when the discharge and water level at Yichang keep steady for several days. The above hydrological analysis work will figured out the water level changing in history, which is helpful for present state assessment.

From the 1980s, the YRWRC has implemented long distance channel morphology survey for several times. Morphology information available for this study is from survey of 1980 and 2002. From the channel morphology map of 1980 and 2002, 103 and 294 cross sections were taken from Yichang to Shashi respectively from the two maps. Because the two sets of morphology data spanned a long period of 22 years, it will provide evidence of channel adjustment if there were any those changes. Besides the direct morphological comparison, the data can also serve as boundary condition for 1D numerical hydrodynamic model, with which a quantitative analysis can be given about the flow character in different periods. The CWEB also has carried out some geology and geomorphology survey in recent years, but their work only covered some segment in this reach. Anyhow, those data will provide supplementary information for this study.

4 RESULT AND DISCUSSION

4.1 *Hydrological data analysis*

From the stage-discharge relation plotted in Figure 2, the corresponding consequence of the major historical events can be clearly figured out.

(1) Yichang: Before 1970, the water level at Yichang was quite stable. This can be referred as undisturbed state. From 1970 to 1987, the water level had dropped by 0.2 m, which might caused by the intense gravel mining in this period. The largest extent of water level decrement happened between

Copyright © 2006 Taylor & Francis Group plc, London, UK

1980 and 1987, with the value of 0.8 m (4500 m^3/s). It is the period when the Gezhouba Dam finished construction. After 1987, the water level changing is not obvious until 1998. It seems that the water level adjustment was getting into another stable state. After the flood in 1998, the water level at Yichang elevated for the deposition caused by sediment from the reservoir. Although the flood interrupted the descending process, the water level quickly changed to the state before the flood. By 2003, the water level dropped to the position little lower than 1998. Even after the TGP construction, it showed no more decline trend.

(2) Zhicheng: Before 1970, the water level is under a natural stable state. In the period of 1971–1980 and 1981–1987, it experienced continued decreasing. But from 1987 until 2001, the water level remained another quasi-equilibrium. This state is kept even after 2003. The post-dam water level is unnoticeable. In general, the total changing of water level at this station is about 0.6 m (4500 m^3/s), which is less than that of Yichang.

(3) Shashi: This station is adjacent to the river cut-off project accomplished in the 1960s and early 1970. In the 1970s, the water level dropped about 0.8 m (4500 m^3/s) for the impact of downstream river cutoffs. Between 1980 and 1987, the water level continued to decrease but with lower speed, unlike that at Yichang. After 1987, the decreasing speed got increase. To 1992, the water level finished a descent of 0.6 m (4500 m^3/s). It seems that the Gezhouba's influence on this station had taken effects. After then, the water level became stable, which can be indicated by the points of 1992–2001. Unlike the trend of Yichang and Zhichen, obvious water level decline taken place at Shashi right after 2003, the TGP dam closure. But it appeared that the drop main occurred in 2003, the subsequent two year showing no clear change. Because this station is in sand bed reach, the total water level drop is much larger than the other two.

The water level change at the three stations shows both similarity and difference. From the historical data, we can find that the distribution of stage-discharge points show stable appearance before and after rapid changes in the 1970s and 1980s. Those periods can be picked out to set up the inter-station relation. The period of 1961–1970 is chosen to represent the undisturbed natural condition; 1992–1998 can be chosen to indicate the equilibrium after early human disturbance; 2005 represents the post-dam condition. The relations show that the water level has both dropped at Yichang and Shashi corresponding to the same Zhicheng level from the 1960s (Fig. 3). The Yichang-Zhicheng relation changed little from the 1960s while Shashi-Zhicheng changed obviously. The good relation between Yichang and Zhicheng indicated that the middle and upper part of this reach must dominate by some same factors. Those relations can also be revealed in the changing corresponding to historical events in Figure 2.

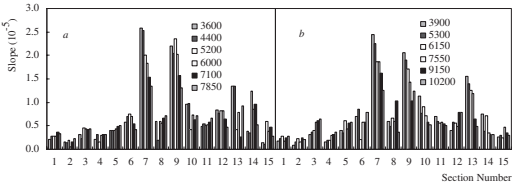

Figure 4. Local slop of water surface at different discharges, the number on x-axis indicates the section between every two gauging sites; *a*. in year 2003, *b*. in year 2005.

Gauging data of long profile is absent before 2003. The data from the water gauges set by CWEB gives information of recent years' low flow profile. Some selected data is depicted in Figure 4. The slop along this reach is quite uneven, with high gradient in the middle reach. In sections 7–9, the reach length occupies 1/11 of the whole, but the energy loss almost accounts for one third of the whole energy dissipation. An interesting phenomenon is: in the high gradient section the slope becomes steeper with discharge decreasing, but this is not the case in low-gradient sections. In fluvial rivers, low flows profile is to some degree control by channel morphology. The characters indicated by Figure 4 implied that channel morphology of certain sections may play an important role in upstream water level maintaining. This may also be the reason for the modes of water level changing at different stations, as Figure 2 and Figure 3 demonstrate.

4.2 *Morphological change and its impact*

Some geological survey discovered that there is underlying gravel layers buried beneath uneven depth of alluvial deposition in most part of the study reach. The sketch of top elevation of the gravel layer is depicted in Figure 5 with channel profile of 1980 and 2002. It shows that the alluvial layer depth is deeper in the upper and lower reach than the middle reach. According to this, some early research predicated that water lowering would take place in upper reach during the TGP post-dam erosion process (Changjiang River Scientific Research Institute, 2002). Comparing with the channel profile of 1980, bed elevation only obviously lowered in few locations until 2002, although the top of underlying gravel layer is not reached. In the middle part (70 km to 100 km), channel profile is almost not changed. Survey data of CWEB from 1999 to 2005 coincide with this trend.

By 1D numerical hydrodynamic model, low flow process is simulated under the 1980 and 2002 condition. The model is calibrated with the gauged discharge and water level series at Yichang, Zhicheng and Shashi

Copyright © 2006 Taylor & Francis Group plc, London, UK

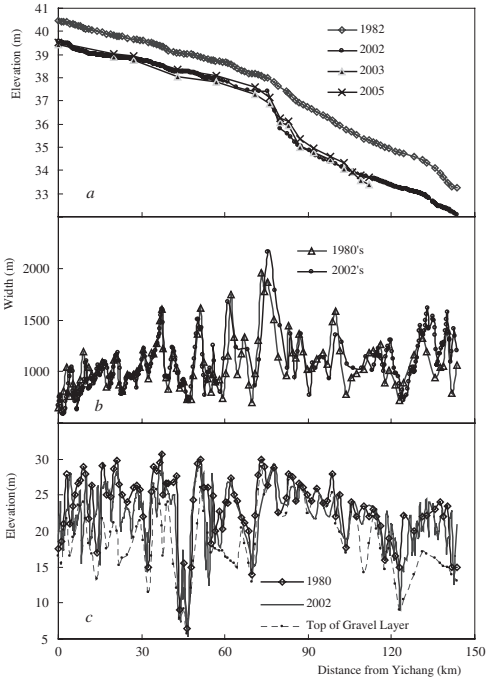

Figure 5. Channel width and profile in different periods; *a*. low flow profile of 5000 m^3/s, *b*. water surface width of 5000 m^3/s, *c*. channel profiles.

in 1982, 2002 respectively. Given the same discharge of 5000 m^3/s, the water profile and surface width is calculated (Fig. 5). It is obvious that water level had drop notably between 1982 and 2002 but the width only increased a little in the lower part. The magnitude of water level drop is much higher in the lower part reach and a tuning point is formed at the location about 75 km from Yichang. Around this location, an abrupt water level descent appeared. It is also the place where the top elevation of the underlying gravel layer is high. Below this reach segment, channel changes from wide to narrow and channel profile begins to decline. This reach segment can be named as pivotal segment. It should be pointed out that the roughness coefficient in 2002 is much larger than that in 1982. This may result from the channel erosion process from the 1980s.

The water gauges of CWEB provide low flow profiles from 2003. The gauged data in 2003 and 2005 (5000 m^3/s) is plotted with the calculation results. Though the TGP began to trap sediment after 2003, low flow profile changed little till 2005.

4.3 *Discussion*

In this reach, water level change is affect by channel erosion, downstream influence and channel geomorphology. From historical data analysis, their roles and correlations can be revealed. Water level lowering in the upper reach before 1987 and in the lower reach before 1992 is absolutely consequence of channel erosion. But water level lowering of Shashi to some extent attributes to downstream erosion, which can be seen as downstream influence. Water level of Zhicheng is affected both by Yichang and Shashi. Although the Yichang-Zhicheng relation is quite good, but water level of Zhicheng lowered much in 1970–1980 when Yichang's dropped little. This must be affected by water level drop of Shashi in the same period. After 1987, this trend was not continued, which implied that when water level had dropped to some degree the control function of channel morphology began to take effect. This means the water level descent at Shashi would no longer have impact on the upstream reach of the pivotal segment, including Yichang and Shashi.

After 1987, water level of Yichang kept a relative stable state disregard the flood of 1998. One the one hand it maybe the function of the pivotal segment, on the other hand it may indicate that bed armoring was gradually formed in Yichang reach, because channel profile of 2002 shows the underlying gravel layer is still not reached. Whatever the reason, the water level at Yichang is unlikely to drop large extent after the TGP construction, so is Zhicheng.

After the TGP dam closure, channel erosion has certain taken place in the reach near Shashi and its downstream. The obvious water level drop from 2003 to 2004 at Shashi provides evidence for this process. Considering the deep alluvium of the Jingjiang reach, the relative stable state of water level after 2004 can not be taken for equilibrium. With erosion going on, the downstream water level drop will cause the high gradient section even higher.

5 CONCLUSION

Channel adjustments on human disturbed rivers have straightforward impacts on low flow water level, which will possibly affect waterway condition. On the basis of more than 40 years long database, the following main conclusions can be drawn from the analyses that have been presented.

(1) Because of the particular geologic surroundings of the study reach, magnitude and rate of water level lowering is not only controlled by channel erosion but also by pivotal reach segment, where a high gradient local slop is formed.
(2) After the water level dropped to a certain extent, upstream reach from the pivotal segment is no longer obviously affected by the downstream reach erosion and water level drop. Whether this relation will be remained after the TGP dam closure is still need more research.

Copyright © 2006 Taylor & Francis Group plc, London, UK

(3) Water levels at Yichang and Zhicheng has good correlation and they are unlikely to decrease with dam effects of the TGP, while the abrupt descent around the pivotal segment will drive the local slop gradient even higher.

ABSTRACT: Human activities, especially dam construction and river training projects are changing the river environment and stream habitat in the Yangtze River in China. As a consequence, aquatic organisms, especially, rare species and fishes with economic value are affected. Therefore, it is necessary to study the changing characteristics of the river that affect the aquatic community habitat, such as substrate, water depth, water temperature, velocity, water quality, etc. There are four species of carps in the Yangtze River that have the most importance to the fresh water fishery in China. They are the black carp (Mylopharyngodon piceus), the grass carp (Ctenop haryngodon idellus), the silver carp (Hypoph thal michthys molitrix) and the big-head carp (Aristichyths nobilis), which are the four major Chinese carp Species. A model is developed in this paper of the habitat Suitability Indices for the four major Chinese carp Species. Based on research on the main eco-factors influencing growth and reproduction, 10 main aquatic eco-factors are analyzed, including water temperature; velocity; water depth; dissolved oxygen; un-iomized ammonia; vegetative cover; and amount of pools, backwaters, and marshes. The Suitability Index (*SI*) curves of the ten eco-factors for these species are obtained. The stream habitat for the carp species is assessed with the model, which integrates these eco-factors. The model is validated by application to 15 groups of data.

1 INTRODUCTION

In recent years, human activities and exploitation of rivers have altered flow patterns and aquatic habitat. Large dams alter flow regimes, retain sediment and nutrients, interrupt fish migration, cause changes in water quality and temperature, and destroy riparian habitats (Ligon et al. 1995, McCully 1996). As a consequence, the quality of riverine ecosystems across the globe is declining and at the same time the pressure on water resources is further increasing. There is a general need for tools to analyze, assess and quantify the impacts of human activities on physical processes and ecological functions in such systems to help finding better solutions for adaptive management of watersheds (Schneider & Jorde 2006).

Habitat evaluations of rivers and streams have become important tools for estimation of the amount of habitat that is available for a given species within a study reach as a function of flow. One of the most common one-dimensional techniques is the Physical Habitat Simulation System (PHABSIM). PHABSIM uses the methodology known as the Instream Flow Incremental Methodology (IFIM) and is one of the most widely used tools for assessing flow management practices (Bovee et al. 1986). New applications of PHABSIM are also including 2D hydrodynamics (Katopodis 2003). Recently, two-dimensional models (RIVER 2D and SMS) have been developed for detailed hydraulic analysis of spatially explicit habitat units at the microhabitat scale (Steffler & Waddle 2002). Scientists chose RIVER 2D because of the ease with which the model reaches a steady-state solution without compromising accuracy. The aquatic habitat simulation models (AHSMs) generally have physical and biological modeling components and compare measured or simulated physical parameters at a location with habitat suitability criteria. (Schneider & Jorde 2006) A more general critique is that AHSMs have widely been used to determine instream flow regulations simply based on instream physical habitat and neglecting the need to address wider ecosystem related aspects such as channel maintenance flows, overbank flows, the lateral connectivity with the floodplain or with smaller tributaries, etc. (Hudson et al. 2003). The computer model CASiMiR (Computer

Copyright © 2006 Taylor & Francis Group plc, London, UK

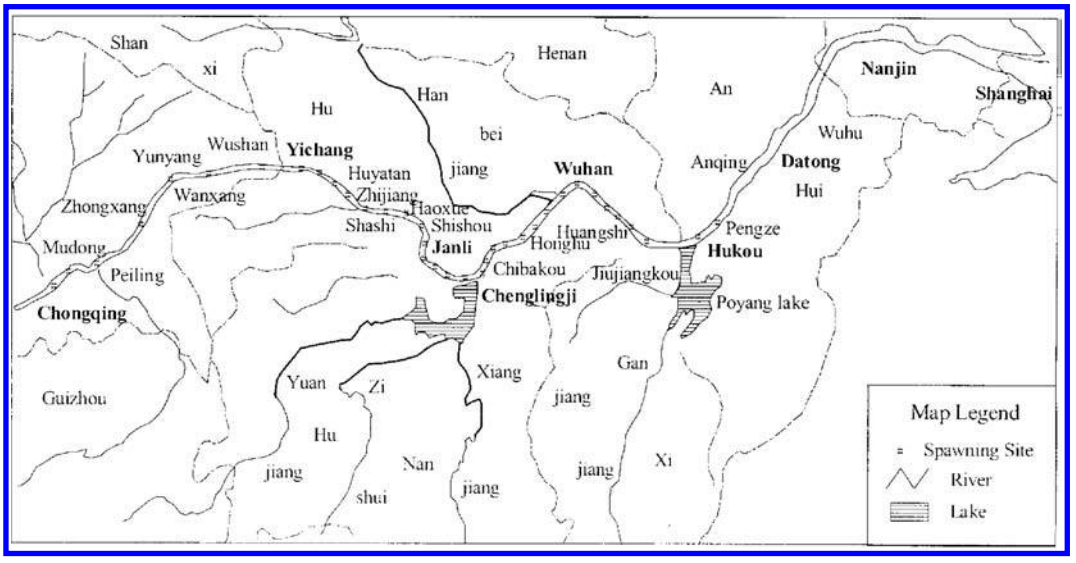

Figure 1. The spawning site of the four major Chinese carp species in the Yangtze River.

Aided Simulation Model for Instream Flow Requirements) was developed at the University of Stuttgart's Institute for Hydraulic Engineering. It is a surface water habitat model, in which – among other things – fish habitat can be investigated (Schneider 2001, Jorde 1996). The model uses additional information for the regulation of hydraulic parameters. This enables the assessment of, for example, water depth, flow velocity, or sediment transport as conditions are modified.

There is still a lack of understanding of the habitat process and none of the models are mature enough for assessment of habitat of all different species. The basic principle guiding habitat-modeling is that the majority of water organisms have specific demands for the suitability of their environment. Selection of the indicator fish species in the studied stream habitat is important. There are four Chinese carp species, i.e. the black carp (Mylopharyngodon piceus), the grass carp (Ctenop haryngodon idellus), the silver carp (Hypoph thal michthys molitrix), and the big-head carp (Aristichyths nobilis) in the Yangtze River, which are the main species of economic value to the fresh water fishery in the river. The four carps reproduce in the Yangtze River and grow in the riparian lakes, such as the Tongting and Poyang Lakes. These carps live in lakes with different environment but their spawning sites of the carps in the river have the similar environmental conditions. A model is developed in this paper of the habitat suitability indices for the four major Chinese carp. Based on the research of the main eco-factors influencing the growth and reproduction in the Yangtze River, 10 main aquatic eco-factors are analyzed, including water temperature; velocity; water depth; dissolved oxygen; un-iomized ammonia; vegetative cover; and amount of pools, backwaters, and marshes. The stream habitat for the carp species is assessed with the model, which integrates these eco-factors.

2 HABITAT OF CARP SPECIES IN THE YANGTZE RIVER

The 6300-km long Yangtze River is the largest and longest river in China and the third in the world in length. It flows from west to east and pours into the East China Sea at Shanghai. The Yangtze River has a watershed area of 1.80 million km^2. In China, the river is called the Changjiang, with special names for different stretches. From the source to Yichang (the Three-Gorges Dam) is the upper reach, from Yichang to Hukou (Poyang Lake mouth) is the middle reach, from Hukou to Datong is the lower reach and below Datong is the estuary (Wang & Lee, 2004).

The middle reach of the Yangtze River is 898 km long, has a drainage area of about 680,000 km^2, and is the main reproduction area of the carp. A 393 km long reach from Yichang to Chenglingji is one of the most important habitats of the four carp species. There are 12 spawning sites for the carp species in this reach (Fig. 1), with 43% of the total egg production in the Yangtze River. From 1970s, increasing human activities in the river basin has affected the reproduction of fish in the river and the amount of the four major Chinese carp species decreased sharply. Especially during 1997–2003 when the construction of Three Gorges Dam, resulted in the clearing of 8 spawning areas in the reservoir. Thus the flux of fries through Jianli during the spawning season reduced quickly.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The impoundment of the reservoir delays the spawning season of the carp of the some of the spawning sites downstream of the reservoir, and decreases the amount of fry at each site. Some sites can not provide the carp with adequate spawning conditions.

3 HABITAT SUITABILITY INDEX MODEL

Carp habitat quality analysis is based on basic components consisting of food, water quality, and reproduction requirements. Variables which have been shown to affect growth, survival, abundance, or other measures of well-being of carp are placed in the appropriate component.

Ten aquatic eco-factors, which mainly influence the habitat of the four major Chinese carp species, are selected for the modeling as follows: (1) Percentage of vegetative cover in shallow areas during spring and summer (V_1); (2) Percentage of pools, backwaters, and marsh areas during average summer flow (V_2); (3) Average water temperatures for adults (V_3, °C); (4) *DO* concentrations for juvenile and adult carp (V_4, mg/L); (5) Water-level fluctuation during spawning season (V_5, m); (6) Average water temperature during spawning within specified areas (V_6, °C); (7) Average water temperature during hatching within specified areas (V_7, °C); (8) Flow velocity during hatching within specified areas (V_8, m/s); (9) Minimum *DO* concentrations within specified areas during hatching (V_9, mg/l); and (10) NH_3-N concentrations (V_{10}, mg/l).

The suitable ranges of the 10 main eco-factors for carp are determined using the research results of biological scientists. The Suitability Index (*SI*) curves of each eco-factor for these species are developed based on those results. By analyzing these eco-factors, a habitat assessment model is developed, which combines these factors and can be used for assessing habitat changes due to human activities or hydraulic processes.

3.1 *Suitability index curve*

The suitability index (*SI*) curve is a curve that quantifies the physical habitat such as water temperature, flow velocity, and *DO* concentration. The habitat suitability ranges from unsuitable (0) to optimal habitat suitability (1). The intermediate values represent the suitability range based on a specified hydraulic variable.

The habitat suitability model is divided into three parts: food component, water-quality component and reproduction component.

Food component: Percentage of vegetative cover (V_1) is included because areas with abundant vegetation provide habitat for various food organisms. In addition, the amount of vegetation reflects the general productivity of the habitat, and carp are opportunistic feeders on vegetation and detritus, as well as animal matter. Percent pools, backwaters, and marsh areas (V_2) is included because this variable quantifies the amount of area available for production of food for the species.

Water quality component: Water temperature (V_3) and *DO* (V_4) affect growth, survival, and feeding. NH_3-N (V_{10}) is included because too much NH_3-N may be harmful for survival and reproduction.

Reproduction component: Percentage of vegetative cover (V_1) is important because the preferred spawning substrate is vegetation. Percentage pools, backwaters, and marsh areas (V_2) are included because these variables quantify the amount of spawning habitat. The water depth is not a key factor affecting the reproduction, but the water level range (V_5) is important, because higher levels of depth change may cause a higher rate of spawning. Flow velocity during hatching (V_8) is included because carp fry should have a certain velocity to prevent them from depositing. Temperature (V_6, V_7) and dissolved oxygen (V_9) are important water-quality variables which can affect embryo survival and development.

By summarizing the research of the fisheries biologists, the factors *SI* for the four major Chinese carp species in the Yangtze River were developed. The data sources are listed in Table 1, and the *SI* curves are shown in Figure 2.

3.2 *Habitat suitability function*

Edwards (1982) developed an *HSI* model for carp in the USA. The authors modified the model by considering the features of the Chinese carp and the Yangtze River.

Habitat Suitability Index:

$$HSI = (C_F C_{WQ} C_R)^{1/3} \tag{1}$$

In which C_F represents the food component given by

$$C_F = (V_1 V_2)^{1/2} \tag{2}$$

C_{WQ} represents the water quality component given by

$$C_{WQ} = \frac{V_3 + V_4 + V_{10}}{2} \tag{3}$$

C_R represents the reproduction component given by

$$C_R = (V_5 V_6 V_7 V_8 V_9)^{1/5} \tag{4}$$

The values of V_1–V_{10} are determined from Figure 2.

Table 1. Eco-factors for the four major Chinese carp species.

Variables	Eco-factors	Research results of biologists
V_1	Percentage of vegetative cover in shallow areas during spring and summer	In both riverine and lacustrine habitats, carp prefer enriched, well-vegetated waters with a mud or silt substrate (McCrimmon 1968). Adults spend summer and early autumn in shallow areas of dense vegetation (May & Gloss 1979).
V_2	Percentage of pools, backwaters, and marsh areas	The carp prefer areas of slow current. In the Missouri River, common carp occurred in pools and chutes ($\leq$60 cm/s) and in the main channel borders (60–120 cm/s) (Schmulbach et al. 1975), but were most abundant in marshes and backwaters ($\leq$20 cm/s) (Kallemeyn & Novotny 1977). Deep pools with abundant cover, including logs, brush, and other objects, provide feeding and resting areas in swift rivers (Pflieger 1975). Although occasionally found in high gradient streams, carp is more common in low to moderate gradient streams. In high gradient streams, carp occur in warm backwaters and in organically polluted sections (Sigler 1958, Pflieger 1975).
V_3	Temperature (Adult)	A range of 20–32°C is suitable for growth under laboratory conditions and optimum in 25–32°C. The carp will die when temperatures are $<$0.5°C and $>$40°C (Zhang & Fan 2004). The growth rate decreases when the temperature is $<$15°C (Yang 1996). The carp begins feeding when temperature is over 5°C, increasing with temperature, and is greatest for temperatures between 25–30°C (Xiong 2003). Under laboratory conditions, feeding and growth increase for temperatures between 22–30°C, are optimum at 30°C (Cui. et al. 1995).
V_4	*DO* (Juvenile and adult)	The four major Chinese carp species feed more and grow faster along with higher *DO* concentrations, they will die when *DO* is $<$0.5 mg/l (Zhang & Fan 2004). Adults are very tolerant of low *DO* concentrations, a condition common in warm, fertile waters (Sigler 1955, McCrimmon 1968). Adults will also feed in the oxygen-depleted hypolimnion ($<$2 mg/l *DO*) (Hover 1976). Adults can gulp surface air when the *DO* is $\leq$0.5 mg/l (Yashouv 1956). Respiration is elevated at 3–5 mg/l *DO* (T $\sim$ 13–23°C) (Itazawa 1971, Davis 1975). The *DO* should remain at least 6–7 mg/l for good growth (Huet 1970).
V_5	Water level fluctuation	Rising of water level makes the carp spawn, and spawning ceases when water level falls (Yih & Liang 1964). Most carp spawn when water level rises, the wider the rise rang, the bigger the flux of fry. On 9–21 May, 1997, the water level at Jianli rose 3.17 m, and flow increased 6550 m^3/s caused the first fry flux; and 6–15 June, 1997, water level rose 3.47 m, and flow increased 10,300 m^3/s, caused the second fry flux (The Technology Report of Fish Resources and Environment Monitoring, 2004).
V_6	Temperature (Spawning)	Spawning begins when temperature $>$18°C (Yang 1996). The four major Chinese carp species in the Yangtze River stop spawning when temperature $<$18°C, the optimum is 21–24°C, the top temperature in Yichang reach during laying season is 27°C, the carps still spawning (Li 2001). The species generally will not spawn in waters with an average temperature $<$18°C, and optimum in the range of 21–24°C (The Technology Report of Fish Resources and Environment Monitoring, 2004). The spawning temperature for black carp is 22–30°C and the optimum temperature is 25 $\sim$ 28°C (Large fresh water fish species in China- black carp, 2006).
V_7	Temperature (Hatching)	Embryos are tolerant water temperatures between 18 and 30°C, the optimum is 22–28°C, fetation ceases or abnormality results when temperature is $<$17°C or $>$30°C (Wang 2003).
V_8	Flow velocity (Spawning and hatching)	Preferred spawning areas have a flow velocity of 0.2–0.9 m/s. A velocity increase of 0.25–0.50 m/s is better for spawning (Yih & Liang 1964). The eggs and fries will not sink when velocity $>$0.2 m/s (Cao et al. 1987). The eggs begin sinking as water velocity is $<$0.27 m/s, and most of the eggs sink if the velocity is $<$0.18–0.25 m/s, and all eggs deposit if the velocity is $\leq$0.1 m/s (H. Y. Tang, & Z. T. Yu, et al. 1996).
V_9	DO (Hatching)	Fetation needs a *DO* concentration in the range of 5–8 mg/l, and should not be $<$4 mg/l, if $<$2 mg/l, the eggs will die by suffocation (Wang 2003). Eggs are tolerant of fluctuating *DO* concentrations, and some may survive short exposures to *DO* concentrations as low as 1.2 mg/l (at T = 25°C). The percentage of hatching increases with increasing *DO* concentrations. At 3 mg/l *DO*, 40% of the embryos hatched; at 6 mg/l, 65% hatched; and at 9 mg/l, 92% hatched (Kaur & Toot 1978).
V_{10}	NH_3-N(Adult and juvenile)	Experiments show that grass carp enjoy an uniform growth rate in a NH_3-N range between 0.042 and 0.240 mg/l, and also an uniform growth rate for a concentrations between 0.306 and 0.414 mg/l, but there are notable growth differences when concentration is below or above 0.240 mg/l. thus, ammonia toxicity affects are present for concentrations $>$0.240 mg/l (Zhu et al. 1995). The 24 h LC_{50} (50% lethal concentration) of silver carp and big-head carp is 0.46 mg/l and 0.91 mg/l, respectively (Lei & Jin 1979). Experiments show that the 96 h LC_{50} of 1.73 cm, 2.62 cm, and 7.07 cm grass carp is 0.469 mg/l, 1.325 mg/l, 1.386 mg/l, respectively (Zhou 1986).

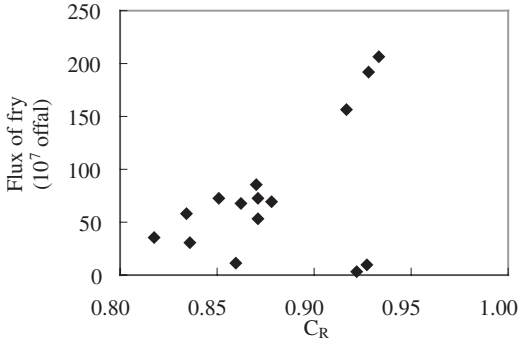

Figure 3. Relation between flux of carp fry and the calculated habitat suitability index for reproduction (C_R) at Jianli.

4 VALIDATION

The reproduction component is validated using 15 groups of sample data during 1997–2003 at Jianli station. The reproduction suitability index is validated by the flux of fry. The results are listed in Table 2.

Figure 3 shows the relation between the calculated *HSI* and flux of carp fry. The flux of carp fry increases with the index *HSI*. It seems that the flux of fry increases linearly with *HSI* as *HSI* is larger than 0.8.

5 CONCLUSIONS

Human activities change the river and ecological environment, reduce aquatic biodiversity, and influence aquatic organisms. Habitat evaluations of rivers and streams have become important tools for estimation of the amount of habitat that is available for a given species within a study reach as a function of flow.

In this paper, the main species of economic value for fresh water fishery in the Yangtze River-four Chinese carp are studied. Ten aquatic eco-factors, which mainly influence the habitat of four major Chinese carp, are selected for the modeling. The suitable ranges of 10 main eco-factors for carp are determined and the Suitability Index (SI) curves of each eco-factor for these species are developed. By analyzing these eco-factors, a habitat assessment model is developed, which combines these factors and can be used for assessing habitat changes due to human activities or hydraulic processes. The validation result shows that the relation between calculate HSI for reproduction and adult carp fry flux is evident.

Influence of flow and sediment inputs on channel sediment delivery ratio: An example of the Yichang – Hankou Reach, Yangtze River, China

J.X. Xu
Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China

ABSTRACT: The channel sediment delivery ratio (*SDR*) of the Yichang – Wuhan reach in the middle Yangtze River has been determined using the concept of sediment budget at channel-reach scale, based on which the variation in *SDR* from 1956–1997 has been studied in response to the variation in sediment load and flow inputs. The *SDR* showed a increasing overall trend, but its variation can be divided into 4 stages: (1) increased rapidly from 1955 to 1962; (2) still increased from 1963 to 1975, but the rate of increase became slower; (3) rapidly decreased from 1976 to 1979; and (4) increased rapidly from 1980 to 1997. Some indices describing flow and sediment load characteristics have been related to the *SDR*, and then a multiple regression equation has been established between *SDR* and these influencing factors. The multiple regression equation indicates that channel sediment delivery ratio of the Yichang-Hankou# river reach increases with the increases in river flow and the ratio of the sediment diverted from the three outfalls, and decreases with the increases in the suspended load at Yichang station, the ratio of the flow diverted from the three outfalls and the flood discharge at Yichang station.

1 INTRODUCTION

Erosion, transport and deposition are basic processes in a fluvial system (Schumm, 1977). The relation of the three processes or three components can be generalized by the concept of sediment budget (Dietrich & Dunne, 1978; Trimble, 1981), namely, for a given fluvial system, the sediment yield equals the sum of erosion amount from all sources minus the sum of sediment deposition or storage within the system. Because a fluvial system may be divided into two sub-systems, hillslope system and river channel system, sediment delivery can also be differentiated into two coupled components. Thus, sediment budget can be established for these two sub-systems separately, and so can be the sediment delivery ratio. Under this consideration, Xu has established the channel sediment budget for the channel of lower Yellow River (Xu, 2002) and studied the channel sediment delivery ratio (Xu, 2003). Much study has been made for the sediment transport and deposition in the middle reaches of theYangtze River (Li & Ni, 1998; Li et al., 2000a; Li et al., 2000b; Xu, 2005), but channel sediment delivery ratio has not yet been involved. The present study will deal with channel sediment delivery ratio in response to the variations in flow and sediment load imposed by the upper drainage basin.

2 OUTLINES OF THE STUDIED RIVER REACH, DATA SOURCE AND METHOD

Yichang, above which the drainage area of the Yangtze River is 100.5 million km^2, is the dividing point between the upper and middle reaches of the Yangtze River (Fig. 1) and controls the river flow and sediment load from the upper to the middle Yangtze River. The mean annual water discharge is 13883 m^3/s at Yichang station, and suspended sediment load is 500.94 million tons, respectively. Below Yichang, the river leaves mountainous areas and enters a vast alluvial plain known as the Middle and Lower Yangtze River Plain. The Yichang-Wuhan reach may be divided into four sub-reaches according to channel morphology: (1) The sub-reach from Yichang to Zhicheng is a single channel, locally confined by terraces and bedrock hills. In this sub-reach, the transition from a gravel bed to a sand bed occurs. (2) The sub-reach from Zhicheng to Ouchikou, known as upper Jingjiang, 168 km in length, is a meandering channel, with some alluvial islands appearing occasionally. (3) The sub-reach from Ouchikou to Chenglingji, known as lower Jingjing, 170 km in length, is a typical meandering channel. Natural bend neck-cutoffs occurred frequently. (4) The sub-reach from Chenglingji to Wuhan has an "island" channel pattern, namely, some stable mid-channel

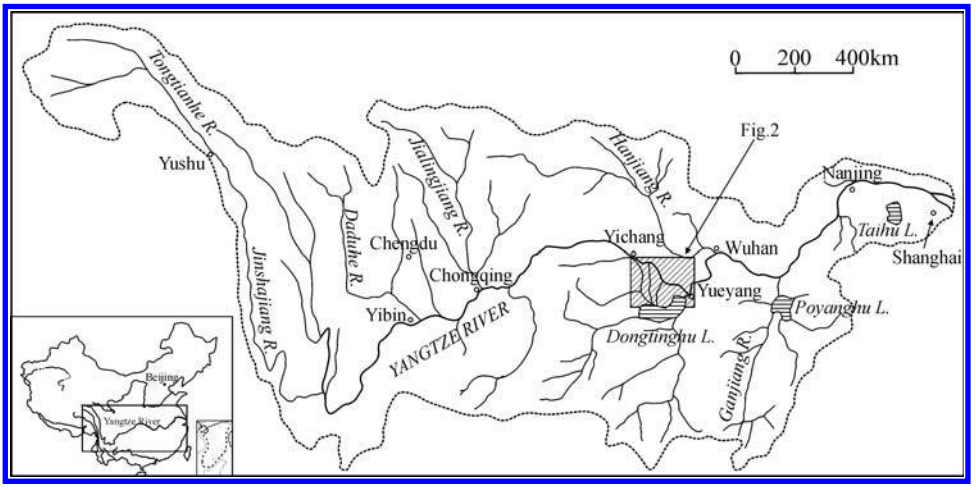

Figure 1. A diagram of the studied river reach.

alluvial islands are well developed, the surface height of which is roughly the same as floodplain, separating the channel to a multi-thread one.

The Lower Jingjiang is characterized by frequent occurrence of natural bend neck-cutoffs in history. In 1967 and 1969, two bend neck-cutoffs were induced by man, at Zhongzhouzi and Shangchewan, to improve the navigation channel. In 1972, a natural cutoff occurred at Shatanzi. Due to these three cutoffs, the length of the river was reduced by 78 km, and the channel sinuosity of the lower Jingjiang decreased from 3.0 to 2.0. These cutoffs significantly increased the local channel slope, and therefore enhanced the river's sediment carrying ability, resulting in degradation below the point at which the cutoff occurred. The lowering of bed due to scour may cause backward erosion upstream from the cutoff point, also resulting in bed degradation. The increased sediment load due to upstream degradation may cause sediment deposition downstream the scoured reach. Thus, the occurrence of cutoffs induced strong channel adjustment, which may have some influence on channel sediment budget in the Yichang-Wuhan reach.

Due to the coupling between the Yangtze River and the Dongtinghu Lake (Fig. 2), the channel sediment budget of the Yichang-Wuhan reach is complicated. Between the mainstem of the upper and lower Jingjiang reaches and the Dongtinghu Lake, a channel network of distributaries developed in history, and thus the mainstem of Jingjiang, the distributary channels and the Dongtinghu Lake constitute a coupled system, known as "river-lake coupled system". This system has a great influence on channel sediment budget. Part of the sediment load from the upper Yangtze River is diverted through the distributaries to the Dongtinghu Lake and deposited there, significantly reducing the sediment load of the main stem downstream. High artificial levees were built along both banks of the Jingjiang River in history, for flood protection. To release the flood of the main stem to the distributaries in case an abnormal flood occurs, some "gaps" were left on the levee. In history, there were many such "gaps", but by 1954, only four remained, known as "Four outfalls" in Chinese, known as Songzhi, Taiping, Ouchi and Tiaoxian. In 1959, a sluice gate was built at Tiaoxian, and in 1970, the sluice gate was closed, and since then only 3 outfalls were left. There is a waterway linking the Dongtinghu Lake and the Yangtze River. The water of the Lake, including the water from the rivers emptying to the lake and from the three outfalls, may flow to the Yangtze River main stem though this waterway which is gauged at Chenglingji hydro-metric station. The Hanjiang River, a major tributary of the Yangtze River, joins the main stem near Hankou. The flow and sediment load of the Hanjiang to the Yangtze main stem is measured at Xiantao station. As long-term data are not available at Xiantao station, the flow and sediment loads measured at Huangzhuang station are used to represent the loads to the Yangtze main stem. Hankou station just in Wuhan on the Yangtze is the end of the Yichang-Wuhan reach, and the flow and sediment loads measured at this station are the outputs of flow and sediment load of the studied reach. Additionally, another tributary, the Qingjiang River joins the main stem near Yidu. The flow and sediment load from the Qingjiang River to the Yangtze River account for only 1.7% and 0.4% of the loads of the Yangtze measured at Yichang station (Li and Ni, 1998), and thus,

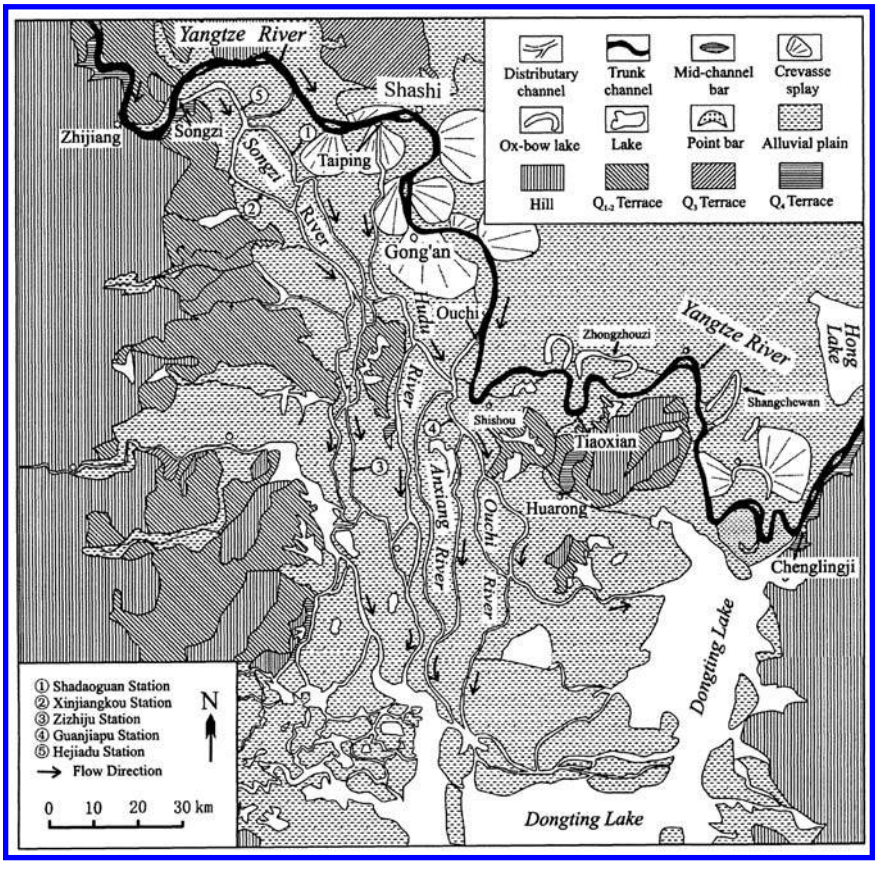

Figure 2. The relationship between the Yangtze River and the Dongtinghu Lake.

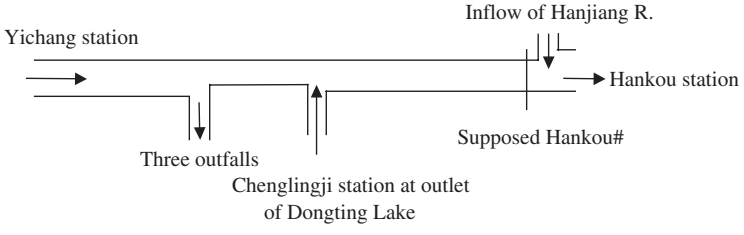

Figure 3.

they are not taken into account. The sediment input and output for the Yichang-Wuhan reach are generalized as Fig. 3.

In terms of sediment budget concept, the following can be written for the Yichang-Hankou# reach:

The sediment storage of the Yichang-Wuhan reach = Σsediment input – Σ sediment output, or

$$S_{Y\text{-}H}=(Q_{s,Yichang}+Q_{s,Chenglingji}+Q_{s,Huangzhuang})-(Q_{s,3outfalls}+Q_{s,Hankou}) \quad (1)$$

where S_{Y-H} is the sediment storage in the Yichang-Wuhan reach, $Q_{s,Yichang}$ is annual suspended sediment load at Yichang station, representing the sediment input to the studied river reach from the upstream drainage basin of the upper Yangtze River. $Q_{s,Hankou}$ is annual suspended sediment load at Hankou station, representing the sediment load output from the studied river reach. $Q_{s,Chenglingji}$ is annual suspended sediment load at Chenglingji station, representing sediment load from the Dongtinghu Lake to the Yangtze

Copyright © 2006 Taylor & Francis Group plc, London, UK

River. $Q_{s,Huangzhuang}$ is mean annual suspended load at Huangzhuang station, representing the sediment inflow from the Hanjiang River to the river reach. $Q_{s,3outfalls}$ is the sum of annual suspended loads measured at the three outfalls, i.e., Songzhikou, Taipingkou, and Ouchikou, representing the sediment load outflow from the Yangtze main stem to the Dongtinghu Lake. The unit for all the variables is 10^4 t/yr.

As the confluence between the Hanjiang and Yangtze Rivers is just above Hankou station, the sediment load inflow from the Hanjiang River immediately flows out of the studied river reach and therefore basically has no influence on sediment deposition in the studied river reach. Thus, for simplicity, we introduce a supposed control point just above the Hanjiang-Yangtze confluence, which is called Hankou#, as the end of the Yichang-Wuhan reach. After doing so, the sediment load from the Hanjiang River may be excluded when considering the channel sediment storage in the Yichang-Hankou# reach. The sediment load ($Q^{s,Hankou\#}$) at Hankou# can be calculated as the sediment load at Hankou station on the Yangtze River minus that at Huangzhuang station on the Hanjiang River. Thus, the sediment storage of the Yichang-Hankou# reach can be written as follows:

$$S_{Y\text{-}H\#} = \Sigma \text{ sediment input} - \Sigma \text{ sediment output} = (Q_{s,Yichang} + Q_{s,Chenglingji} - Q_{s,3outfalls}) - (Q_{s,Hankou} - Qs,Huangzhuang) \quad (2)$$

And therefore, the channel sediment delivery ratio ($SDR_{Y-H\#}$) of the Yichang-Hankou# reach can be expressed as

$$SDR_{Y\text{-}H\#} = (\Sigma \text{ sediment output})/ \Sigma \text{ sediment input} = Q_{s,Hankou} - Q_{s,Huangzhuang})/(Q_{s,Yichang} + Q_{s,Chenglingji} - Q_{s,3outfalls}) \quad (3)$$

The annual sediment delivery ratio of the Yichang-Hankou# river reach has been calculated using Equation (3). All the data involved are from the relevant hydro-metric stations, as mentioned above. It should be pointed out that the sediment budget established in this study is only for suspended sediment load, with bed-load ignored, because no bed-load data are available, as is the case for most rivers in the world. The studied river reach has sand-bed, and thus bed-load transport rate is rather low, compared with suspended load. According to some incomplete measurements made at Yichang station, the ratio of bed-load to suspended load is only 1%–2% (Institute of Geography, Chinese Academy of Sciences and Yangtze River Institute of Water Conservancy and Hydro-power Research, 1985). Thus, ignoring bed load does not make much difference.

After annual sediment deposition is determined, it is further related to the variables of river flow and sediment load of the studied river reach using empirical statistical approaches, to elucidate the response of sediment deposition to the changing river flow and sediment load input.

The indices of flow and sediment load that are used in the present study are as follows: (1) Annual river flow ($Q_{w,Yichang}$) and suspended load ($Q_{s,Yichang}$) and mean suspended sediment concentration ($C_{mean,\ Yichang}$) at Yichang station; (2) Annual flow ($Q_{w,3outfalls}$) and suspended load ($Q_{s,3outfalls}$) flowing to the Dongtinghu Lake through the three distributaries, represented by the sum of river flow or suspended load at the stations on Eastern Songzhihe, Western Songzhihe, Huduhe, Anxianghe and Ouchihe Rivers; the mean suspended sediment concentration ($C_{mean,3outfalls}$) of the distributed river flow is also used, calculated as $C_{mean,3outfalls} = Q_{s,3outfalls}/Q_{w,3outfalls}$. (4) Annual river flow ($Q_{w,Chenglingji}$) and suspended load ($Q_{s,Chenglingji}$) and mean suspended sediment concentration ($C_{mean,Chenglingji}$) at Chenglingji station, representing the features of the water and sediment flowing from the Dongtinghu Lake to the Yangtze main stem.

3 RESULTS

3.1 *Temporal variations in the components of channel sediment budget and sediment delivery ratio*

As pointed out earlier, the components of channel sediment budget for the Yichang-Hankou# reach include sediment input at Yichang station ($Q_{s,Yichang}$), the sediment load outflow from the Yangtze main stem to the Dongtinghu Lake ($Q_{s,3outfalls}$), the sediment input from the Dongting Lake at Chenglingji station ($Q_{s,Chenglingji}$), and sediment output at the end of the reach, Hankou# ($Q_{s,Hankou\#}$). The temporal variations of the 4 variables have been shown in Fig. 4.

Fig. 4a shows that the temporal variation in annual suspended load at Yichang station may be divided into two stages. From 1951 to 1979, although there were some fluctuations, no overall trend can be seen. However, from 1980 to 1997, a clear decreasing trend appeared. This decreasing trend may be related to two factors. The implementation of soil and water conservation measures and the building of large numbers of reservoirs and checkdams since the 1980s reduced the sediment supply to the Yangtze River. The Gezhouba Reservoir, located above Yichang and used for water storage since 1983, also reduced the sediment input of the studied river reach.

The sediment diversion through distributaries expressed by $Q_{s,3outfalls}$ showed a clear decreasing trend. The sediment outflow at Hangkou# ($Q_{s,Hankou\#}$) showed an increase with time and reached a peak around 1980, followed by a decline. The increase in

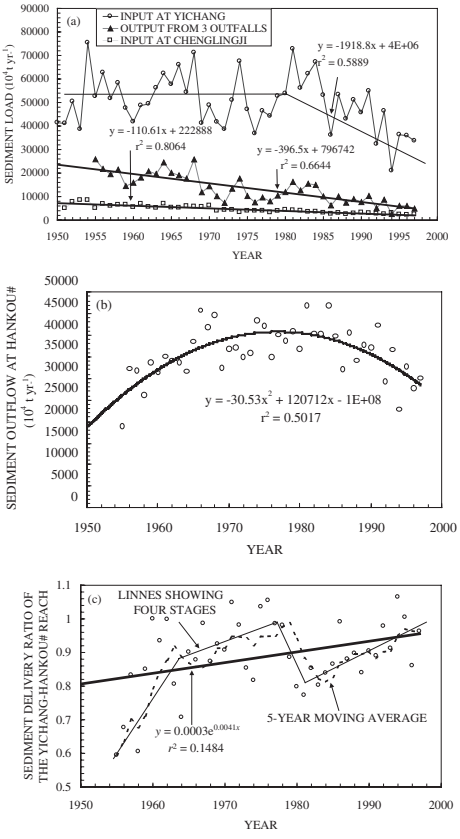

Figure 4. Temporal variations in four components of the channel sediment budget of the Yichang- Hankou# reach.

(a) Inflow sediment at Yichang station ($Q_{s,Yichang}$), outflow sediment through "three outfalls" ($Q_{s,3outfalls}$) and inflow sediment from the Dongting lake ($Q_{s,Chenglingji}$)
(b) Sediment outflow at Hankou#
(c) Sediment delivery ratio of the Yichang-Hankou# reach.

sediment outflow during the period 1955–1979 may be related with the increase in $Q_{s,3outfalls}$, which led to a relative increase in the "net" input of sediment, and also with the man-made bend neck-cutoffs, which enhanced the sediment carrying ability of the river and thus, more sediment could be transported to the end of the river reach. The increase in $Q_{s,Hankou\#}$ after 1980 result from the decrease in the sediment input at Yichang station.

The temporal variation in channel sediment delivery ratio ($SDR_{Y-H\#}$) of the Yichang-hankou# reach has been plotted in Fig. 4c. As an overall tendency, $SDR_{Y-H\#}$ increased with time T, and the correlation coefficient between $SDR_{Y-H\#}$ and T is 0.385, significant at a level of $p < 0.01$. However, the 5-year moving average indicates that the variation in $SDR_{Y-H\#}$ can be divided into 4 stages. From 1955–1962, it increased

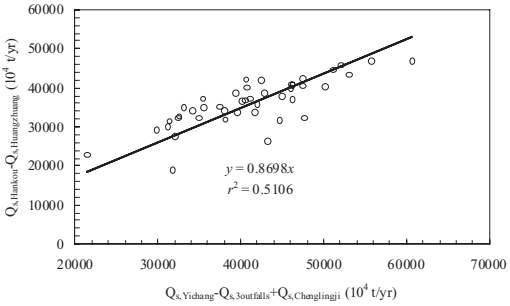

Figure 5. The relationship between the annual input ($Q_{s,Yichang} + Q_{s,3outfalls} + Q_{s,Chenglingji}$) and output ($Q_{s,Hankou} - Q_{s,Huangzhuang}$) sediment of the the Yichang-Hankou# river reach.

rapidly. From 1963–1975, it also increased, but the rate of increase decreased. From 1976–1979, it declined rapidly, but from 1980–1997, it increased rapidly. The relationship between sediment input and output of the Yichang-Hankou# reach is shown in Fig. 5, where the regression equation is given as: Annual sediment output $= 0.8698 \times$ Annual sediment input.

3.2 *Sediment delivery ratio of the Yichang-Hankou# reach as influenced by sediment load and river flow conditions*

As the sediment input and output of the studied river reach were different in the periods before and after 1980, and so was the sediment delivery ratio. Thus, the period 1955–1997 was divided into two stages, 1955–1979 and 1980–1997, in the following study.

3.2.1 *Influence of flow conditions*

The flow conditions include the annual flow at Yichang station ($Q_{w,Yichang}$), the annual outflow through "three outfalls" ($Q_{w,3outfalls}$) and its ratio ($R_{w,div}$) to the total flow at Yichang, and the annual flood discharge ($Q_{max,Yichang}$) at Yichang. The $SDR_{Y-H\#}$ has been plotted against $Q_{w,Yichang}$, $Q_{w,3outfalls}$ and $Q_{max,Yichang}$ in Fig. 6, where the periods 1955–1979 and 1980–1997 are distinguished by different symbols. The figure shows that in all the four plots the correlation for the period 1980–1997 is much closer than that for the period 1955–1979. This can be related to the human impacts, especially to the man-made bend neck-cutoffs in the lower Jingjiang River in 1967 and 1969. Afterwards, the river length was reduced by 78 km, and the channel sinuosity decreased from 3.0 to 2.0 (Lu, 1996). The resultant strong scour lowered the elevation of river bed of the Yangtze main stem near the "three outfalls", which means a relative rise of the river bed of the distributaries. As a result, less floodwater could flow out of the main stem to the Dongtinghu

Copyright © 2006 Taylor & Francis Group plc, London, UK

Lake. The yearly lowest water stage at Shashi station was used as an index to reflect the elevation of river bed (Xu, 2005). From 1950 to 1967, although there were some fluctuations, no trend of declining in the yearly lowest water stage at Shashi station can be seen. Afterwards, it declined rapidly. It became stable again around 1980. Obviously, it is the man-made bend neck-cutoffs in 1967 and 1969 that resulted in strong scour, and therefore the lowering of water stage (Xu, 2005).

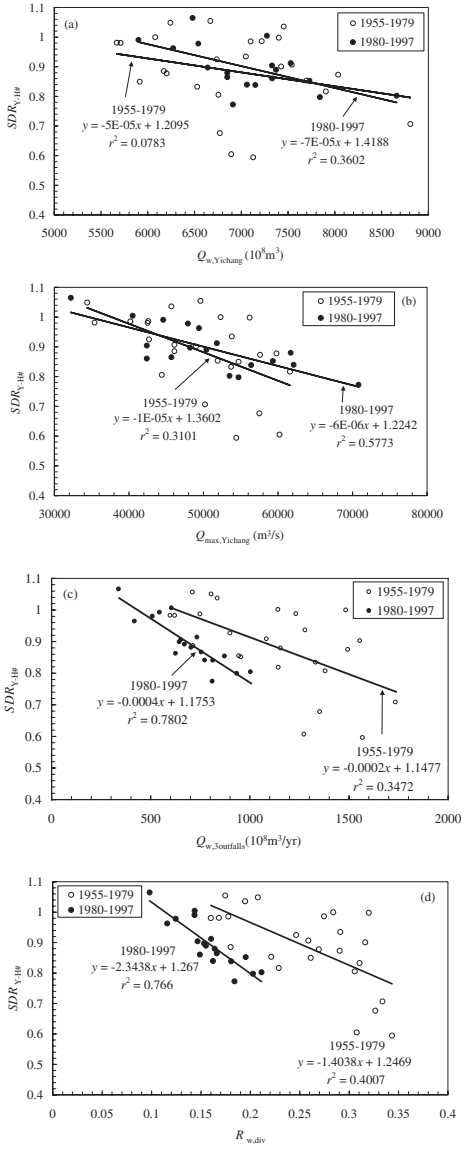

Figure 6. The relationships of sediment delivery ratio ($SDR_{Y-H\#}$) of the Yichang-Hankou# river reach with annual river flow ($Q_{w,Yichang}$) (a) and flood discharge ($Q_{max,Yichang}$) (b) at Yichang station and the water diversion ($Q_{w,3outfalls}$) (c) from the 3 outfalls and its ration ($R_{w,div}$) (d) to the river flow at Yichang station.

Fig. 6a shows that the correlation coefficient between $SDR_{Y-H\#}$ and $Q_{w,Yichang}$ is much higher than that between $SDR_{Y-H\#}$ and $Q_{max,Yichang}$. For the period 1980–1997, the $SDR_{Y-H\#} - Q_{max,Yichang}$ squared correlation coefficient (r^2) is 0.5773, much larger than the critical r^2 at $p < 0.01$, 0.1546. The r^2 of $SDR_{Y-H\#}$ with $Q_{w,3outfalls}$ and $R_{w,div}$ are even higher, which are 0.7802 and 0.7660 for the period 1980–1997. Thus, the influence of outflow from the three outfalls on channel sediment deliver ratio is larger than those of flood and annual water discharges. This is because the $R_{w,div}$ has a marked decreasing trend (Fig. 7). A decrease in outflow from the three outfalls means a equal increase in the flow in the main stem below the three outfalls, a factor that would result in an increase in sediment carrying ability. In general, sediment carrying ability of the river is proportional with the square of water discharge (Q) (Qian et al., 1987). If the increase in Q is ΔQ, then the sediment transport rate related with Q and ΔQ are aQ^2 and $a(\Delta Q)^2$, respectively, given the state of equilibrium in sediment transport. Here a is a constant. After the increase of ΔQ in water discharge, the discharge becomes $(Q + \Delta Q)$, and the sediment that the river can carry becomes $a(Q + \Delta Q)^2 = aQ^2 + a(\Delta Q)^2 + 2a(Q\,\Delta\,{}^*Q)$, which is larger than the sum of sediment transport related with Q and ΔQ, $aQ^2 + a(\Delta Q)^2$. This implies that if the sediment transport equilibrium exists previously, the sediment carrying ability after the increase in water discharge would exceed the supplied sediment load. Thus, scour may occur. Obviously, this factor may increase the river's sediment delivery ratio, and therefore results in the negative correlation of $SDR_{Y-H\#}$ with $Q_{w,3outfalls}$ and $R_{w,div}$ (Fig. 6c and 6d). In this study, $R_{w,div}$ and $R_{s,div}$ are defined as the ratio of water and sediment outflow from the 3 outfalls to those at Yichang station, respectively.

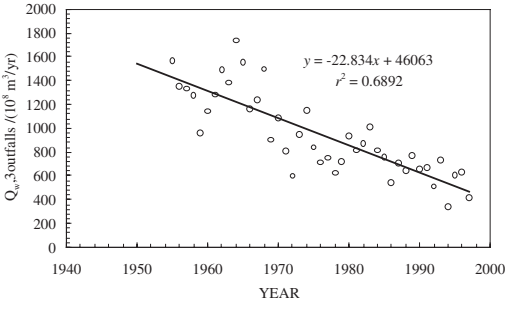

Figure 7. Water diversion ($Q_{w,3outfalls}$) from the 3 outfalls varying with time.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The negative correlation between $SDR_{Y-H\#}$ and $Q_{w,Yichang}$ (Fig. 6b) can be explained by strong sediment deposition induced by overbank flows when large floods occur. As considerable amount of sediment is deposited in floodplain, the sediment transported downstream decreases, leading to a decrease in $SDR_{Y-H\#}$.

3.2.2 *Influence of sediment load*

The annual channel sediment delivery ratio of the Yichang-hankou# reach is positively correlated with annual suspended load at Yichang station (Fig. 8), and the r^2 for the period 1980–1997 is as high as 0.7730.

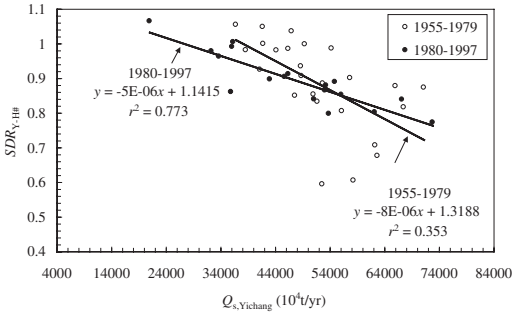

Figure 8. Relationship between sediment delivery ratio ($SDR_{Y-H\#}$) of the Yichang-Hankou# reach and annual sediment load ($Q_{rms,Yichang}$) at Yichang station.

3.3 *Multiple regression analysis*

To establish the relationship between the variation in annual channel sediment delivery ratio ($SDR_{Y-H\#}$) in the Yichang-Hankou# reach and the river's flow and sediment conditions, a multiple regression analysis has been performed. The influencing variables include annual river flow ($Q_{w,Yichang}$ in $10^8 m^3$/yr), annual suspended load ($Q_{s,Yichang}$ in $10^4 t^3$/yr) and annual maximum water discharge ($Q_{max,Yichang}$ in m^3/s) and the ratio ($R_{w,div}$) of annual river flow diverted through the three outfalls to the annual river flow at Yichang station, and the ratio ($R_{s,div}$) of annual suspended load diverted through the three outfalls to the annual suspended load at Yichang station. The multiple regression equations are established for the period 1955–1997 in general, and for the period 1980–1997 in particular. As pointed out earlier, the channel conditions for the periods 1955–1979 and 1980–1997 are different. In the former period, the strong adjustment following the three bend neck-cutoffs that occurred in 1967, 1968 and 1972 was underway, but before the beginning of the latter period, it may be thought that the quasi-equilibrium had been re-established. Thus, the relationship for the period 1980–1997 can be used to represent the situation of the channel at quasi-equilibrium.

The correlation matrix among $SDR_{Y-H\#}$ and all the influencing variables has been calculated for the periods 1955–1979 (Table 1) and 1980–1997 (Table 2). The multiple regression equations have been established for the periods 1955–1979 and 1980–1997,

Table 1. The correlation matrix among $SDR_{Y-H\#}$ and $Q_{w,Yichang}$, $Q_{s,Yichang}$, $Q_{max,Yichang}$, $R_{w,div}$ and $R_{s,div}$ (1955–1997).

	$Q_{w,Yichang}$	$Q_{s,Yichang}$	$R_{w,div}$	$R_{s,div}$	$Q_{max,Yichang}$	$SDR_{Y-H\#}$
$Q_{w,Yichang}$	1.00	0.70	0.40	0.38	0.49	−0.43

$Q_{max,Yichang}$	0.57	0.81	0.66	0.68	1.00	−0.76
$SDR_{Y-H\#}$	−0.80	−0.88	−0.88	−0.84	−0.76	1.00

Copyright © 2006 Taylor & Francis Group plc, London, UK

respectively. The regression equation based on data from the period 1980–1997 is as follows:

$$SDR_{\text{Y-H\#}} = 1.1863 + 2.5521\times10^{-6}Q_{\text{w,Yicahng}} - 3.5568\times10^{-6}Q_{\text{s,Yichang}} - 3.4159R_{w,\text{div}} + 2.5050R_{\text{s,div}} - 1.1049\times10^{-6}Q_{\text{max,Yichnag}} \quad (4)$$

For the above equation, number of samples $N = 18$, multiple correlation coefficient $R = 0.9394$, the result of F-test is $F = 18.034$, with the probability of significance $p = 0.00003$, and the standard error of estimate is $SE = 0.0321$. The multiple regression equation indicates that channel sediment delivery ratio of the Yichang-Hankou# river reach increases with the increases in river flow and the ratio of the sediment diverted from the three outfalls, and decreases with the increases in the suspended load at Yichang station, the ratio of the flow diverted from the three outfalls and the flood discharge at Yichang station.

Based on data from 1955–1997, the multiple regression equation has been established as follows:

$$SDR_{\text{Y-H\#}} = 1.2824 + 1.2364\times10^{-5}Q_{\text{w,Yichang}} - 3.3434\times10^{-6}Q_{\text{s,Yichang}} - 0.3910R_{w,\text{div}} - 3.8817\times10^{-6}Q_{\text{max,Yichang}} \quad (5)$$

The units for the variables are shown in Table 2. For the above equation, number of samples $N = 43$, multiple correlation coefficient $R = 0.7010$, the result of F-test is $F = 9.18$, with the probability of significance $p = 0.00003$, and the standard error of estimate is $SE = 0.0825$.

It should be pointed out that in the above equation, $R_{\text{w,div}}$ was not selected, because the two variables expressing water and sediment diversion through the three outfalls, $R_{\text{w,div}}$ and $R_{\text{s,div}}$, are closely correlated, the effect of one can be represented by an other. Thus, only $R_{\text{w,div}}$ was selected. Table 1 shows that all the correlation coefficients between $SDR_{\text{Y-H\#}}$ and influencing variables are not high, but the correlation coefficients between $R_{\text{w,div}}$ and $R_{\text{s,div}}$ is very high. If both $R_{\text{w,div}}$ and $R_{\text{s,div}}$ are selected to enter the equation, the quality of the equation would be much lower.

4 CONCLUSIONS

The channel sediment delivery ratio (*SDR*) of the Yichang – Wuhan reach in the middle Yangtze River has been determined using the concept of sediment budget at channel-reach scale, based on which the variation in *SDR* from 1956–1997 has been studied in response to the variation in sediment load and flow inputs. The *SDR* showed a increasing overall trend, but its variation can be divided into 4 stages: (1) increased rapidly from 1955 to 1962; (2) still increased from 1963 to 1975, but the rate of increase became slower; (3) rapidly decreased from 1976 to 1979; and (4) increased rapidly from 1980 to 1997. Some indices describing flow and sediment load characteristics have been related to the *SDR*, and then a multiple regression equation has been established between *SDR* and these influencing factors. The multiple regression equation indicates that channel sediment delivery ratio of the Yichang-Hankou# river reach increases with the increases in river flow and the ratio of the sediment diverted from the three outfalls, and decreases with the increases in the suspended load at Yichang station, the ratio of the flow diverted from the three outfalls and the flood discharge at Yichang station.

Restore water levels in the river channel downstream of the Three Gorges Reservoir: A numerical simulation

G. Zhou, H. Wang, D.D. Jia & X.J. Shao
Dept. of Hydraulic Engineering, Tsinghua University, Beijing, China

ABSTRACT: Among the many physical processes triggered by the impoundment of the Three Gorges Reservoir, the degradation of river channel downstream of the project will develop very quickly in the next few decades. This paper presents results of a numerical study on the effectiveness of proposed measures to reduce bed scour and to maintain water stage during dry seasons, by placing a layer of articulated concrete mattresses on the river bed at several selected locations in a reach 63 km long of the Yangtze River.

1 INTRODUCTION

The Three Gorges Reservoir (TGR) has substantially reduced sediment supply to the downstream river channels since its impoundment in June 2003. Comparison of observed sediment transport rates before and after the impoundment of the Reservoir indicates a significant drop in sediment transport after the impoundment (Figure 1). Numerical simulation results (IWHR & YSRI, 1990, as cited in Lu et al 1997) predicted that, in the first 30 years after its impoundment, the siltation of TGR would cause a 70% reduction in both the average concentration and the total amount of sediment transport downstream of the project, as shown in Table 1. The sediment concentration at the outlet of the reservoir would not recover and restore to its original level until 100 years later, when the reservoir siltation process achieves an equilibrium.

The river bed scour downstream of the Gezhouba Shiplock, located 2 km upstream of the Yichang Station, would be most severe in the next few decades due to the impoundment and siltation of TGR. Lowered water stages at Yichang Station caused by channel degradation could pose a great problem for the navigation traffic trying to get through the Gezhouba shiplocks. The present water level at Gezhouba is already 1 meter lower than the designed operational level, because of the bed scour after the completion of the Gezhouba Dam in 1983 (Lu Yongjun et al 2002). When the operation of TGR introducing another round of bed scour and water stage reduction, the navigation condition at the shiplocks would be worsened and normal traffic could be interrupted more frequently during the dry seasons. Water level drop will also affect the aquatic environments and ecosystem processes in the alluvial channels. In such a case, river training works are usually applied to prevent or stop scour and restore water stages.

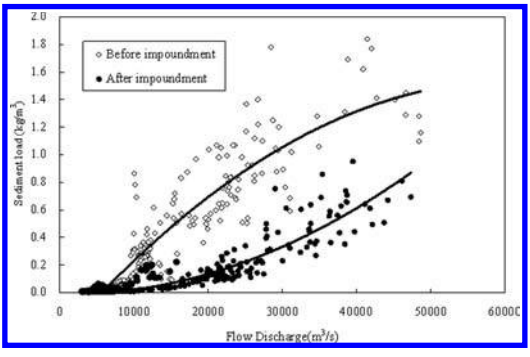

Figure 1. Measured sediment load ~ flow discharge relation at Yichang Station before and after Three Gorges Reservoir impoundment.

The purpose of this study is to evaluate the effectiveness of the proposed engineering measures to maintain water level on this section of the Yangtze River channel. A 2-D numerical simulation model for flow and sediment tansport is used for the calculation.

2 STUDY AREA

This numerical simulation applies a 2-D model to calculate water flow and sediment transport in a channel

section from Yichang Station to Zhicheng Station, with a total length of 63 km (Fig. 2).

In this hilly area, planform of the channel section is mostly straight with a few river bends and major sand bars, as the Yangtze River runs out of the mountainous area into the Great Jiang-han Plain. Within the next few decades, the operation of the Three Gorges Reservoir will dominate the seasonal variation of water stages of the river reach between the City of Yichang and the downstream Zhicheng Station, and will impose a long-term impact on the navigation conditions at Gezhouba Shiplock. Detailed processes of bed degradation caused by such an impact can be predicted using numerical simulations that take into

account the reduction of sediment supply due to the siltation of the TGR. Effectiveness of proposed measures, e.g., increase of bed roughness through bottom pavement methods, can also be estimated and optimized for maintaining water stages during dry seasons ($Q_{min} = 3000\ m^3/s$). Such measures should not create problems for flood control during flood seasons ($Q_{max} = 76000\ m^3/s$).

3 MATHEMATIC MODELS

3.1 *Governing equations for water flow*

Wind-induced surface stresses are ignored in the mathematical model for water flow, and the depth integrated conservation equations can be written as follows:

$$\frac{\partial Z}{\partial t}+\frac{1}{J}\left[\frac{\partial(h_2 q)}{\partial \xi}+\frac{\partial(h_1 p)}{\partial \eta}\right]=0 \tag{1}$$

$$\frac{\partial q}{\partial t}+\beta\left(\frac{1}{J}\frac{\partial(h_2 qU)}{\partial \xi}+\frac{1}{J}\frac{\partial(h_1 pU)}{\partial \eta}-\frac{pV}{J}\frac{\partial h_2}{\partial \xi}+\frac{qV}{J}\frac{\partial h_1}{\partial \eta}\right)$$
$$-fp+\frac{gH}{h_1}\frac{\partial Z}{\partial \xi}+\frac{qg|\vec{q}|}{(CH)^2}=\frac{\nu_e H}{h_1}\frac{\partial E}{\partial \xi}-\frac{\nu_e H}{h_2}\frac{\partial F}{\partial \eta} \tag{2}$$

$$\frac{\partial p}{\partial t}+\beta\left(\frac{1}{J}\frac{\partial(h_2 qV)}{\partial \xi}+\frac{1}{J}\frac{\partial(h_1 pV)}{\partial \eta}+\frac{pU}{J}\frac{\partial h_2}{\partial \xi}-\frac{qU}{J}\frac{\partial h_1}{\partial \eta}\right)$$
$$+fq+\frac{gH}{h_2}\frac{\partial Z}{\partial \eta}+\frac{pg|\vec{q}|}{(CH)^2}=\frac{\nu_e H}{h_2}\frac{\partial E}{\partial \eta}+\frac{\nu_e H}{h_1}\frac{\partial F}{\partial \xi} \tag{3}$$

$$E=\frac{1}{J}\left[\frac{\partial(h_2 U)}{\partial \xi}+\frac{\partial(h_1 V)}{\partial \eta}\right],\quad F=\frac{1}{J}\left[\frac{\partial(h_2 V)}{\partial \xi}-\frac{\partial(h_1 U)}{\partial \eta}\right] \tag{4}$$

$$h_1=\sqrt{\left(\frac{\partial x}{\partial \xi}\right)^2+\left(\frac{\partial y}{\partial \xi}\right)^2},\quad h_2=\sqrt{\left(\frac{\partial x}{\partial \eta}\right)^2+\left(\frac{\partial y}{\partial \eta}\right)^2} \tag{5}$$

where ξ, η are orthogonal curvilinear horizontal coordinates, respectively; h_1, h_2 are Lame coefficients in the ξ, η directions, respectively; U, V are depth-averaged velocity components in the ξ, η directions, respectively; the unit discharge vector is $\rightharpoonup_q = (q, p) = (UH, VH)$, where $q = UH$, $p = VH$; Z is water level relative to the reference plane; H is total depth; β is the correction factor for non-uniformity of the vertical velocity profile, $\beta = 1.016$; f is Coriolis parameter; g is gravitational acceleration; C is Chezy coefficient; ν_e is depth mean effective vortex viscosity; $J = h_1 h_2$ is the Jacobian of ordinates transformation.

A staggered grid system is applied in the model, with Z, C and ν_e located at the center of each grid cell, q, p, U and V at the center of the grid boundary, respectively (Fig. 3). The numerical model uses a finite difference method in the orthogonal curvilinear coordinate system. The finite difference equations corresponding to the differential equations are expressed in an alternating direction implicit form. All the discretization procedures use a second-order central difference

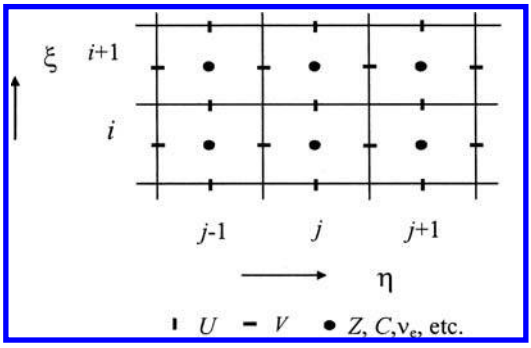

Figure 3. The staggered grid system.

scheme, except the time differentials of water level in the continuity equation which use a forward difference scheme. For the advective accelerations in the momentum equations, a combination of the first-order upwind scheme and second-order central difference is applied.

The computational domain has a total of 385 × 29 grids in an orthogonal curvilinear coordinate system (Fig. 4).

In the longitudinal direction, the grid steps vary within a range of 100 m∼200 m, with an average value of 150 m. In the lateral direction the grid size varies from 24 m to 40 m, with a mean value of 32 m.

Measured contour of the channel section dated October 1998 was used in this study as the initial bed topography, as shown in Figure 5. Observed daily discharges and water stages in the year 1999 at Yichang Station and Zhicheng Station were applied as the boundary condition.

From the above we note that sin $\theta = (x + y)z$ or:

$$K_t=\left(1-\frac{R^2\tau}{c_a+\nu\tan\delta}\right)^4 k_1 \tag{6}$$

where c_a = interface adhesion; δ = friction angle at interface; and k_1 = shear stiffness number.

3.2 *Governing equations for sediment transport*

The governing equations for sediment transport included the 2-D unsaturated suspended load transport equation and the transport equation for bed load. A total of 16 size groups of the non-uniform bed material were considered. The transport equations for suspended load are:

$$\frac{\partial(HS_k)}{\partial t}+\frac{1}{J}\left[\frac{\partial(HS_k Uh_2)}{\partial \xi}+\frac{\partial(HS_k Vh_1)}{\partial \eta}\right]-\frac{1}{J}\left[\frac{\partial}{\partial \xi}\left(H\varepsilon_\xi\frac{h_2}{h_1}\frac{\partial S_k}{\partial \xi}\right)\right.$$
$$\left.+\frac{\partial}{\partial \eta}\left(H\varepsilon_\eta\frac{h_1}{h_2}\frac{\partial S_k}{\partial \eta}\right)\right]+\alpha_k\omega_k(S_k-S_{*k})=0 \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

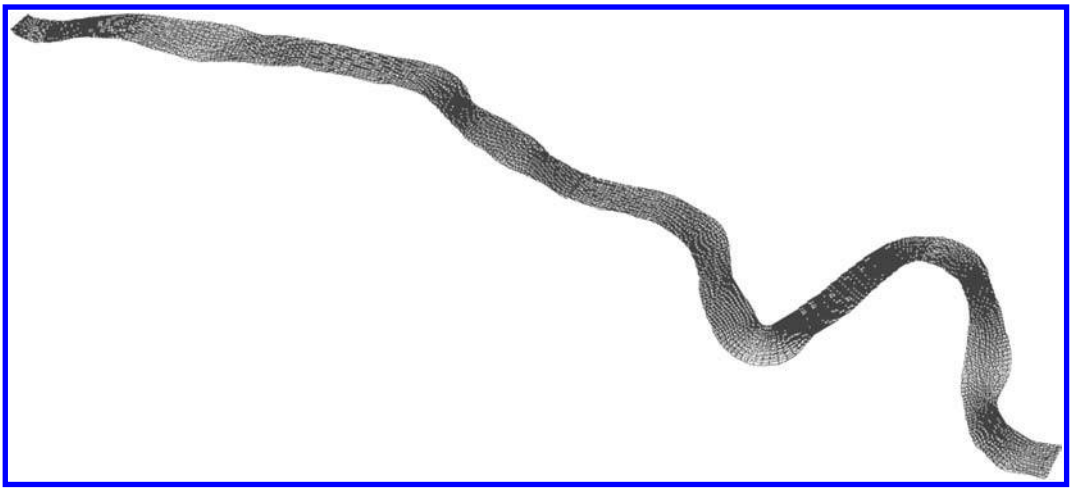

Figure 4. Grid system in an orthogonal curvilinear coordinate.

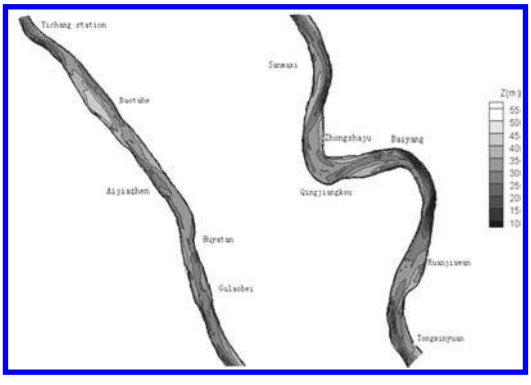

Figure 5. Measured topography of the river reach.

$$\varepsilon_\xi = \frac{\left(k_t U^2 + k_t V^2\right) H\sqrt{g}}{\sqrt{U^2 + V^2}\,C} \tag{8}$$

$$\varepsilon_\eta = \frac{\left(k_t U^2 + k_t V^2\right) H\sqrt{g}}{\sqrt{U^2 + V^2}\,C} \tag{9}$$

Bed degradation due to suspended load transport is evaluated using the following

$$\rho_s \frac{\partial Z_{bsk}}{\partial t} = \alpha_k \omega_k \left(S_k - S_{*k}\right) \tag{10}$$

Bed degradation due to bed load transport is calculated using the following

$$\rho_b \frac{\partial Z_{bgk}}{\partial t} = \frac{1}{J}\left[\frac{\partial}{\partial \xi}\left(g_{b\xi k} h_2\right) + \frac{\partial}{\partial \eta}\left(g_{b\eta k} h_1\right)\right] \tag{11}$$

where subscript k indicates the size group; S_k, S_{*k} are depth-averaged sediment concentration and carrying capacity of size group k (in kg/m^3), respectively; ε_x, ε_y are longitudinal and transverse diffusion coefficients, respectively; k_t, k_l are longitudinal and transverse components of the depth-averaged diffusion coefficient, respectively; ω_k is fall velocity of size group k (m/s); α_k is the saturation-restoration coefficient for size group k, assumed as constants in this study, i.e., $\alpha_k = 1.0$ for sour process ($S_k < S_{*k}$) and $\alpha_k = 0.25$ for siltation process ($S_k > S_{*k}$); ρ_s, ρ_b are dried bulk density of suspended-load and bed-load, respectively; Z_{bsk}, Z_{bgk} are deposition depth resulted from suspended-load and bed-load transports, respectively; $g_{b\xi k}$, $g_{b\eta k}$ are unit-width bedload transport rates of size group k in the ξ and η directions, respectively. The bedload transport rates were evaluated using an empirical formula that uses the depth averaged velocity as the driving variable.

The fall velocity of sediment particles is calculated using the following formula developed by Zhang Ruijin (1961), which is similar to the Rubey formula for settling velocity, except that the coefficients were calibrated differently:

$$\omega = \left[\left(13.95\frac{\nu}{D}\right)^2 + 1.09\frac{\gamma_s - \gamma}{\gamma} gD\right]^{1/2} - 13.95\frac{\nu}{D} \tag{12}$$

The river channel in the study area has a cobble-and-sand bed, and the following method (*Li* 1987) is applied to evaluate the carrying capacity S_*, which calculate the transport rate of a particular size group k out of the non-uniform bed materials:

$$S_{*k} = P_k S_*(\omega) \tag{13}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

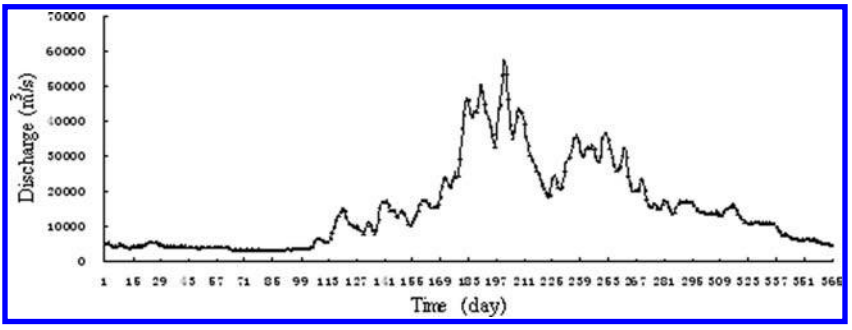

Figure 6. Measured daily-averaged discharges at Yichang Station (1999 data).

in which

$$S_*(\omega) = K\left(\frac{U^3}{gh\varpi}\right)^m$$

$$\varpi = \left(\sum_{l=1}^{n} p_{sl}\omega_l^m\right)^{1/m}$$

$$P_k = a_k P_{bk} \Big/ \sum_{k=1}^{N} a_k P_{bk}$$

$$a_k = (1-\Lambda_k)\left(1-e^{-R_k}\right)\Big/\omega_k$$

$$\Lambda_k = \omega_k \Big/ \left[u_* e^{-\omega_k^2/2u_*^2} + \omega_k \psi\left(\omega_k/u_*\right)\right]$$

$$\psi(\xi) = \int_{-\infty}^{\xi} e^{-t^2/2}dt \Big/ \sqrt{2\pi}\,, \quad R_k = \frac{6\omega_l}{\chi u_*}$$

where $S_*(\omega)$ is the total carrying capacity (expressed as suspended load concentration) for the non-uniform bed-material; K, m are constants to be calibrated; P_k is the share of carrying capacity for size group k in total carrying capacity; p_{sl} , ω_l are the fraction of size group l in the incoming suspended load and its corresponding fall velocity, respectively;P_{bk} is the fraction of size group k in the bed material.

4 MODEL CALIBRATION

In the present paper, the numerical model for flow of water was calibrated first. The sediment transport model was calibrated after all the parameters in the flow simulation model were determined.

4.1 *Calibration of the Flow Simulation Model*

Daily-averaged discharges observed in 1999 at Yichang Station were applied as the upper boundary conditions of the study area, as shown in Figure 6. Daily water stages at Zhicheng Station observed in 1999 were applied as the lower boundary conditions, as shown in Figure 7. In this study, river bed roughness were evaluated from observed

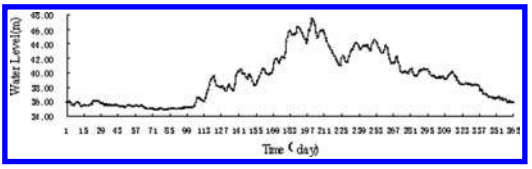

Figure 7. Measured daily-averaged water stages at Zhicheng Station (1999 data).

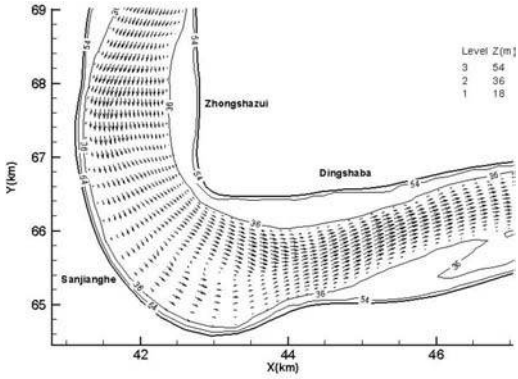
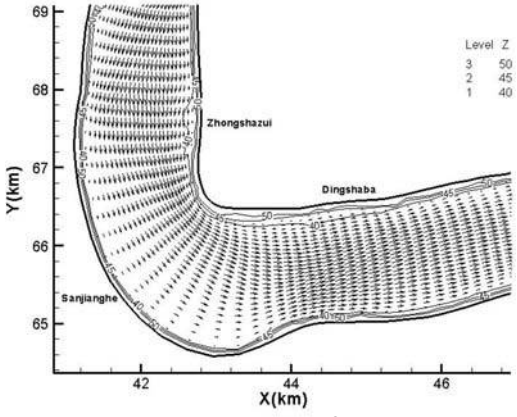
stage-discharge relations. The time interval in the numerical calculation was 6 seconds.

Flow patterns for various discharges in different seasons ($Q = 3140\ m^3/s$, $21000\ m^3/s$, $50000\ m^3/s$) at a 90 degree river bend are shown in Figure 8.



It can be seen from the simulated patterns that flow patterns during dry seasons are quite different from that in flood seasons. Both the inundated areas and the direction of velocity vectors will change significantly when discharge varies. Figure 9 shows calculated water surface profile. Comparison of observed and calculated water stages at Yichang Station is shown in Figure 10, which suggests results from simulations agree with measurements.

4.2 *Calibration of the Sediment Transport Model*



The sediment transport model was calibrated using observed data of bed contours, river cross-sections, sediment concentrations and water stages. Topographical measurements for this reach taken in October 1998 and November 1999 were used to obtain the observed volume of scour or deposition. The daily averaged hydrological data collected in the year 1999 were used as initial and boundary conditions for the simulation model to reproduce the observe scour or deposition in this river reach.

The 63 km long channel is divided into 4 sections (Fig. 2). Volume of scour and deposition for each section during 1999 were calculated and compared with observations. Table 2 lists the observed and calculated amounts of deposition and scour, which suggest

Calculated (10^4 m^3)	−3025.34	−356.434	+647.3009	+1462.45

Note: The "−" signs indicate bed scour; "+" signs indicate deposition.

that: 1) in the upstream part of the study area bed scour occurred and in the downstream part deposition occurred; 2) the model calculation is capable of simulating the sediment transport pattern in this type of river channel with complicated sour and deposition processes. Scour volume of section 2 was overestimated due to the lack of measured size distribution for bed materials, which should be used as initial conditions. Obviously the local armoring process was more complex than what was predicted.

5 SIMULATION OF LONG-TERM CHANNEL DEGRADATION

The simulation model was applied to predict degradation processes of a 20-year period beginning at the impoundment of the TGR in June 2003. The upper boundary conditions of water discharge and sediment supply from the Reservoir were provided by the same numerical simulation model that produced the results listed in Table 1. The observed long-term average

water stage ~ discharge relations at Zhicheng Station were used for the lower boundary conditions in this simulation.

Figure 11 shows the distribution of predictions of accumulated depth of scour and deposition in the study reach 20 years after the TGR impoundment. Calculation results expressed as the total volume of scour and deposition in each river sections are listed in Table 3, which indicates that the entire area will be subject to a net scour of about 90 million m^3 in the next two decades.

During the first 10 years, channel degradation will develop very rapidly and the total volume of net scour will reach 88 million m^3 at the end of the first decade. In the next 10 years, the scour would virtually stop and the river channel would be stabilized, due to the armoring process.

There is little possibility that the river channel in this hilly area would migrate laterally, because of the geological conditions that impose restraints on the channel planform. The scour will mainly occur in the main channel while deposition will occur on the floodplain along the river.

Model predictions of the armoring process are shown in Figure 12, from which it can be seen that the armoring process will be more obvious in the upstream part of the study reach, e.g., the first section in Fig. 2, where the median size will increase from $D_{50} = 0.34$ mm to $D_{50} = 3.4$ mm and becomes stabilized in 5 years' time after impoundment.

In contrast, smaller increases median sizes were predicted for the downstream sections. Close to the lower boundary, the size of bed materials became finer than before.

The long-term scour would result in water level drops from the 2003 water level along the entire study reach, with a maximum of 1.26 m at the Yichang Station, as shown in Figure 13. Such a systematic and

Copyright © 2006 Taylor & Francis Group plc, London, UK

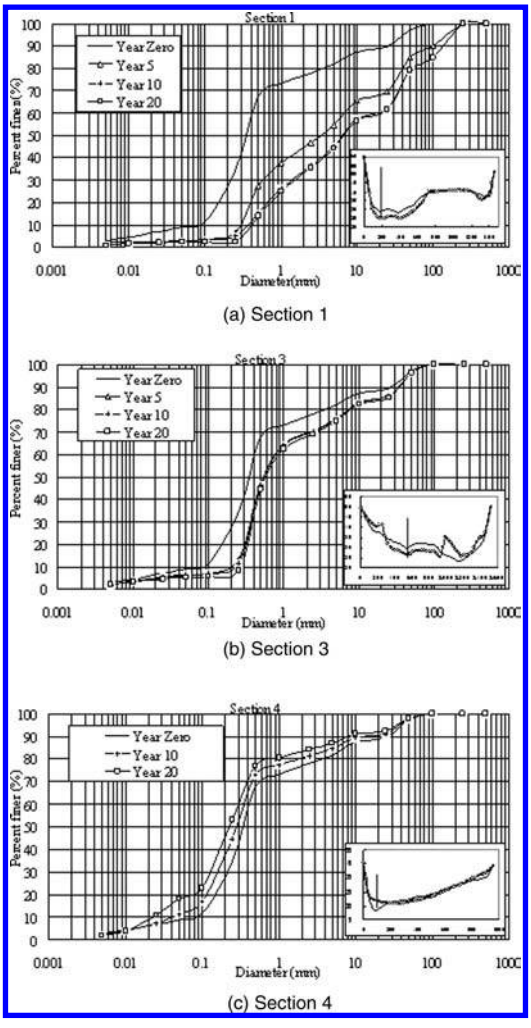

Figure 12. Predicted armoring process at various locations along the channel.

long-term water level drop will not only create difficulties for the operation of the Gezhouba Shiplock but also will have negative impacts on the environment and ecology in this area.

6 RESTORE THE WATER LEVEL BY BED PAVEMENT

The proposed measures to prevent bed scour and to restore water level include laying a layer of articulated concrete mattresses or stone ripraps on the river bed, at several selected sections between Yichang Station and Zhizheng Station. In this numerical simulation, the water level rises due to such measures were estimated for the selected five locations between Yichang and Zhicheng, as locations A to D shown in Figure 14.

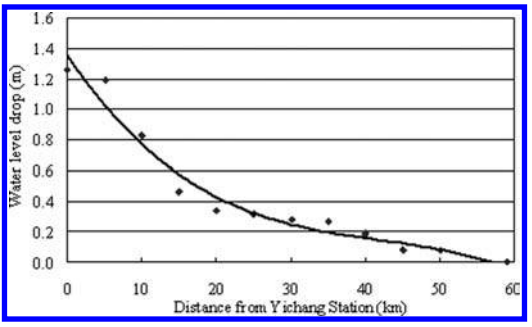

Figure 13. Predicted water level drop at Yichang Station due to channel degradation.

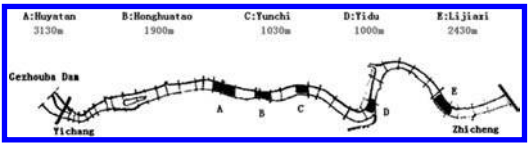

Figure 14. The length and location of selected sections for bed pavements.

Table 4. Predicted water level recovery (ΔWL) after bed pavements (for $Q = 5000\ m^3/s$).

Series Number	Controlled reaches	Thickness (m)	ΔWL of Yichang(m)		
			1.00*n*	1.35*n*	1.48*n*
s8-1	A+B+C	0.5	0.05	0.13	0.16
s8-2	A+B+C	1.0	0.08	0.17	0.21
s9-1	A+B+C+D	0.5	0.06	0.15	0.02
s9-2	A+B+C+D	1.0	0.11	0.20	0.26
s10-1	A+B+C+D+E	0.5	0.07	0.26	0.32
s10-2	A+B+C+D+E	1.0	0.15	0.3	0.38

The pavements will be constructed for a portion of the river bed which could be submerged when the discharge is $5010\ m^3/s$. Such pavements can raise the river bed elevation by 0.5 m to 1.0 m, and the local roughness of the channel will also increase by a certain magnitude. The predicted effects of various pavement schemes, listed in Table 4, are obtained by assuming various magnitudes of roughness increase, expressed as increases in the Chezy coefficient, *n*.

Let roughness height K_s be equal to D_{50}, and assume that the K_s will be increased from 5.7 mm to 78 mm after pavements are completed, the Chezy coefficient *n* are found to have increased by 35%. If stone ripraps of larger sizes are used for pavements, e.g., K_s becomes 150 mm, the Chezy coefficient *n* will be increased by a magnitude of 48%. For various *n* values, the water level rise was calculated accordingly. The simulation results are based on the assumption that the paved areas of the river bed will no long be subject to further scour.

7 CONCLUSIONS

This study presents results from a 2-D water flow and sediment transport model, which is developed to calculate the transport of graded sediments downstream of the Three Gorges Reservoir. The model is validated using field observations from the study area on the Yangtze River.

Long-term river channel degradation processes were calculated for the study area, which is a 63 km long reach downstream of Yichang. Simulation results suggest that during the first 20 years after the impoundment of TGR, the accumulated total amount of bed scour will be 89 million m^3 (which only includes those areas of the bed that could be inundated by a discharge of $Q = 10000\ m^3/s$). River bed scour at such a scale will cause a water level drop of 1.26 m at Yichang Station, from the present stage for the discharge of 5000 m^3/s. This would create difficulties for the operation of the Gezhouba Shiplock and would have negative impacts on the environment and ecology in this area.

The effectiveness of bed pavement measures has been evaluated by numerical calculations. It was found out that such measures could prevent the development of bed scour and restore water stages to a certain extent. Calculation results indicate that the water stage at Yichang can be raised by up to 0.38 m for the discharge of 5000 m^3/s, if pavement measures are applied at all the 5 selected locations. However, the numerical simulations were based on assumed increases of roughness coefficient, *n*, due to bed pavements. Such assumptions require confirmation or modification through experiments or field observations in the future.

The evolution analysis of Fengcheng reach under the changing conditions

L. Chen, J. He, Z.G. Wang & W.S. Xu
Key Laboratory of Water Resources and Hydropower Engineering, Key Lab. of the Water and Sediment Sciences of Ministry of Education, Wuhan University, Wuhan, China

ABSTRACT: Impoundment of upstream reservoir, construction of Ganjiang highway bridge and actualization of navigation regulation project changed the incoming water & sediment condition and boundary condition of Fengcheng reach and consequently brought to the reformation process which caused adjustment of local river regime. Based on flied data and model experiment, river evolution and reformation process tendency in Fengcheng reach under changing conditions was analyzed. Furthermore interaction between reformation process and changing conditions was interpreted as well as the influence to navigation and near-shore project. It is concluded that after change of the condition general scour occurs. Left branch downstream highway bridge has gradually declined while mid branch has developed to be the main channel. Evolution tendency presents as shoal line recession in Sha-shoal and thalweg swing rightwards in mid bending part and thalweg deepen and widen in mid branch. The reformation will influence navigation condition and near-shore project in a long run.

1 INTRODUCTION

River evolution is affected by three essential factors, incoming water & sediment condition, channel boundary condition and downstream erosion base level. When these mutual interacting factors reach to a homeostasis, channel keeps stable, yet when factors changed, a new reformation process occurs.

Fengcheng Reach (shown in Figure 1) locates downstream of Ganjiang River in Jiangxi province. Fengcheng highway bridge and the controlling node Leigongnao divide this reach into three parts: upper straight part, mid bending part and lower branching part. Western mountain (peak height-60 m) alternates with mesa in the left bank, and west levee connects discontinuously. Gandong Levee lies on the right side of the reach with flood control standard of 50-year frequency.

The channel is relatively narrow in upper straight part and mid bending part, while in lower branching part channel broadens gradually at 2000 m downstream Shishang. Side bar Peng-shoal and Dong-shoal locates at the left side of upper straight part, and side bar Sha-shoal locates at the right side of the mid bending part of the reach. There are two central sand-bars lying in the middle of the lower branching part. Left Xin-bar has lower height with narrow surface and divides flow into left and mid branch in low water period. Right Zhong-bar has higher height with nearly 1000 m broad surface and divides flow into middle and right branch which join together 3500 m downstream in middle and high water period.

The riverbed of this reach is composed by gravel and coarse sand while 7∼8 m height below is anti-scouring grit stone. Riverbed particle median diameter is 5∼19 mm, in which diameter lager than 1 mm occupies 70%∼90%, maximum particle diameter is from 40∼20 mm and minimum is over 0.2 mm. Side bars is consisted mainly by sand with median diameter of 0.43∼2.7 mm, and particle with diameter lager than 1 mm occupies 8%∼20%.

The mean annual discharge in Fengcheng reach is 1890 m^3/s and the mean annual runoff is $596.4 \times 108\ m^3$ (as much as the Yellow River). The mean annual sediment runoff (refers to suspended load) is only 912×104 t.

Either river bed or banks of this reach has fine stability. And with less incoming sediment, the river regime in Fengcheng reach presented to be stable in natural condition and annual variation of scouring and silting was small before 1990.

In the early 1990s, the construction of Gangjiang highway bridge, water intake & drainage project of Fengcheng thermal power plant and navigation channel dredging project in Xin-bar middle branch have changed the boundary condition of Fengcheng Reach. On the other hand, the impoundment of Wanan reservoir upstream has changed the incoming water & sediment conditions. Annual runoff distribution tended to be even. Trimestral runoff of April, May and June occupies 40.87% of the annual runoff while it had occupied 51.18% before. Changes in sediment transportation also occurred: the annual average sediment runoff was 464.36×104 t from 1993 to 2003, only half

Copyright © 2006 Taylor & Francis Group plc, London, UK

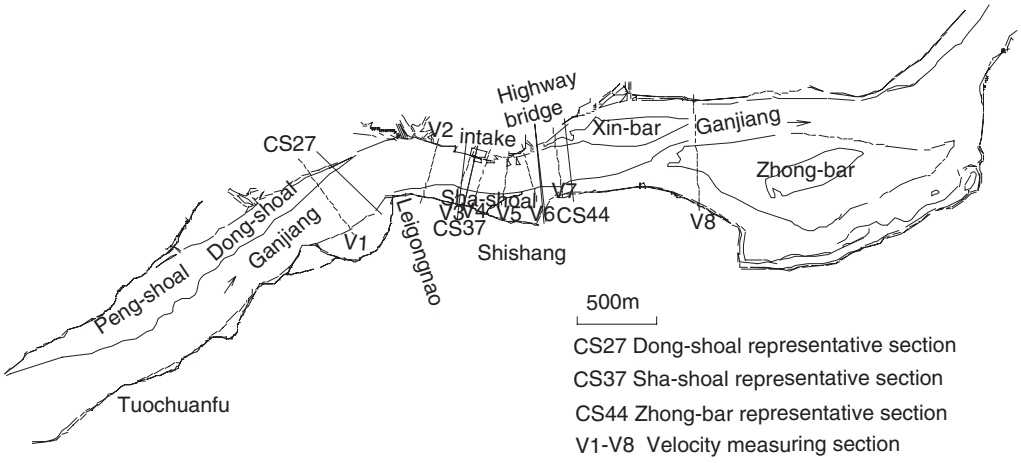

Figure 1. Planform in Fengcheng reach.

of the amount before 1990, trimestral sediment runoff of April, May and June decreased from 66.59% to 57.63% of annual sediment runoff. All these variations have induced the reformation process in Fengcheng reach and probably brought to the adjustment of local river regime. Based on the field data and physical model, the prediction of evolution tendency under the changing conditions in Fengcheng reach is analyzed.

2 RECENT EVOLUTION

2.1 *In upper straight part*

Thalweg varied in a relatively small range in upper straight part before and after the change of boundary conditions. The thalweg kept in the left side upstream, and transferred to the right in the vicinity of Tuochuanfu. In upper straight part below Tuochuanfu, the thalweg cling to the right bank. Side bar Peng-shoal and Dong-shoal is basically stable, and the range of sliting and scouring there was rather small.

2.2 *In mid bending part*

Flow was deflected to the opposite side by controlling node Leigongnao, thalweg correspondingly transferred to the left bank. In mid bending part, the thalweg kept to the concave side of the bend and swung in a small range. Hereinto, the thalweg moved leftwards for about 30 m from 1985 to 1992, and kept on moving leftwards for about 30 m from 1992 to 1997. From 1997 to 2003, the thalweg swung back to the right. Till 2003, the thalweg had almost moved back to the location where it lay in 1985.

The Sha-shoal head was in a state of erosion from 1985 to 2003. And the bed level variation at intake section in the middle Sha-shoal is shown in Figure 2.

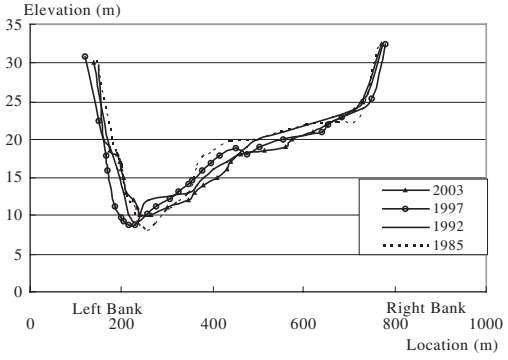

Figure 2. Bed level variation at intake section.

As Figure 2 shows, section morphology was stable in intake section from 1985 to 2003, the thalweg height only changed in a small range. The height of the deepest point in section thalweg ranged from 7.94 m∼10.0 m. Meanwhile the height variation in Sha-shoal was about 3.5 m, which exceeded the variation range (=2.06 m) in thalweg. From 1985 to 2003, the thalweg swung rightwards together with the downcut of Sha-shoal and the deposition in the thalweg.

2.3 *In lower branching part*

Before 1992, the thalweg entered into the left branch smoothly along the left bank of Xin-bar, and stretching in the left branch afterward. After 1992, the Xin-bar head extended forwards for about 5∼7 m, it invaded into the left branch and blocked the flow movement in left branch. Sediments deposited at left side of Xin-bar, and Xin-bar tended to spread leftwards. Meanwhile, the Xin-bar tail also had a leftward deflection and blocked the flow movement in left branch furthermore.

Copyright © 2006 Taylor & Francis Group plc, London, UK

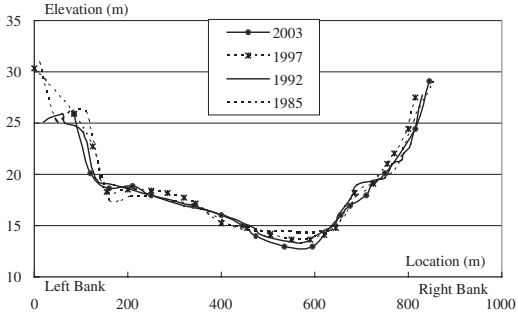

Figure 3. Bed level variation at Xin-bar head section.

The bed level variation of the typical section at Xin-bar head is shown in Figure 3. It is found that, the gradual deposition occurs at 160 m from initial point, and height of which rises beyond 18.0 m. The left branch declined gradually while the middle branch developed rapidly.

The thalweg kept to the left bank from Xin-bar tail to Zhong-bar tail and transited to the right bank at Zhong-bar tail, the thalweg changed little in this part and swung rightwards for about 90 m from 1985 to 2003. The regulation works on Zhong-bar including three spur dikes was advantageous for river regime in Zhong-bar.

2.4 *Variation of downstream erosion base level*

Figure 4 shows the variation of the relation between discharge in Zhangshu (23 km upstream Fengcheng reach) and water level in Fengcheng from 1993.

It is figured out in Figure 4 that the gauge-discharge curve varies in a certain extent: when discharge is 2000 m^3/s, variation amplitude of water level is 0.59 m; when discharge is 4000 m^3/s, variation amplitude is 0.42 m; when discharge is 8000 m^3/s, variation amplitude is 0.65 m; when discharge is 10000 m^3/s, variation amplitude is 0.39 m. From 1993 to 2003, the variation of water level is relatively large. Although it does not present as holistic descend, the water level in 2000~2003 is lower than it is in the early 1990s'. Erosion caused by artificial sand excavation and reduce of incoming sediment have lowered the bed level downstream, consequently decreased the downstream erosion base level.

3 PREDICTION OF EVOLUTION TENDENCY BY MODEL EXPERIMENT

3.1 *Model design*

In order to make clear about river evolution in different hydraulic condition as well as do an evolution tendency prediction of this reach, a moveable-bed physical model has been established.

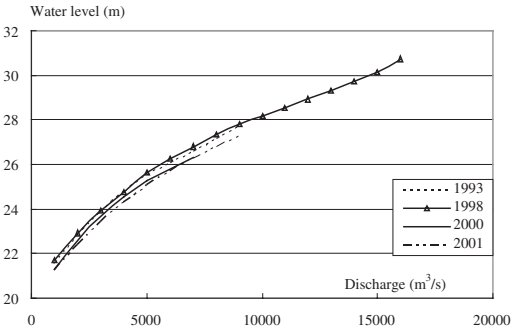

Figure 4. Relation curve between discharge in Zhangshu and water level in Fengcheng.

The reach which the model simulated is from Tuochuanfu to Fengcheng stage gauging station with a length of 13.5 km. Considering about the length, width and depth of the simulating reach, physical model has been defined to be distorted with horizontal scale of 250, vertical scale of 100 and distortion ratio of 2.5. The model has simulated bed load and suspended load. The main similarity scales have been chosen as follows:

(1) Settling velocity scale and model sand size scale

In distorted physical model, flow convection & gravity deposition ratio similarity and turbulent diffusion & gravity deposition ratio similarity cannot be satisfied at one time. The turbulent diffusion & gravity deposition ratio similarity has been chosen to ascertain the settling velocity scale

$$\lambda_\omega = \lambda_u \left(\frac{\lambda_H}{\lambda_L} \right)^{\frac{1}{2}} \quad (1)$$

where λ_u refers to settling velocity scale; λ_H refers to horizontal scale; λ_L refers to vertical scale.

Meanwhile model sand size scale formula that satisfied the suspended load sediment movement similarity can be induced as

$$\lambda_d = \frac{\lambda_\omega^{\ 2}}{\lambda_{\frac{\gamma_s - \gamma}{\gamma}} \lambda_\xi} \quad (2)$$

Thereinto:

$$\xi = \sqrt{\left(\frac{13.95 \frac{\nu}{d}}{\sqrt{\frac{\rho_s - \rho}{\rho} gd}} \right)^2 + 1.09} - \frac{13.95 \frac{\nu}{d}}{\sqrt{\frac{\rho_s - \rho}{\rho} gd}}$$

(2) Incipient velocity scale

Model and prototype incipient velocity have been calculated respectively according to the incipient velocity

Copyright © 2006 Taylor & Francis Group plc, London, UK

formula

$$u_c = 1.14\sqrt{\frac{\gamma_s - \gamma}{\gamma} gd}\left(\frac{h}{d}\right)^{\frac{1}{6}} \quad (3)$$

where γ_s and γ refer to the unit weight of sediment and h, d refer to water depth and grain diameter.

The suspended load incipient velocity scale has been calculated as

$$\lambda_{uc} = u_{cp} / u_{cm} \quad (4)$$

where u_{cp}, u_{cm} refer to incipient velocity of prototype and model.

(3) Sediment concentration scale

Based on the imbalanced sediment transportation formula

$$\frac{d_s}{d_x} = -\frac{\alpha\omega}{q}(s - s_*) \quad (5)$$

and Zhang Rui-jin's sediment transport capacity formula

$$S_* = \frac{\rho_s}{8c_1\frac{\rho_s - \rho}{\rho}}(f - f_s)\frac{u^3}{gR\omega} \quad (6)$$

sediment concentration scale formula can be induced as

$$\lambda_s = \lambda_{s_*}$$
$$\lambda_s = \frac{\lambda_{\rho_s}}{\lambda_{\frac{\rho_s - \rho}{\rho}}\eta^{1/2}} \quad (7)$$

where η refers to variability.

(4) Riverbed reformation time scale

Based on sediment balance equation

$$\frac{\partial q_s}{\partial x} + \rho'\frac{\partial Z_0}{\partial t} = 0 \quad (8)$$

and concentration scale which has been mentioned above, riverbed reformation time scale can be derived as follows

$$\lambda_{t_s} = \frac{\lambda_l \lambda_{\rho'}}{\lambda_u \lambda_s} \quad (9)$$

where λ_L, $\lambda_{\rho'}$, λ_u, λ_s respectively refer to vertical scale, sediment dry density scale, velocity scale and sediment concentration scale.

More detailed similarity is shown in Table 1.

Table 1. Scale of similitude statement.

Similarity	Scale		Remark
Geometric similarity	Horizontal scale Vertical scale	250 100	
Current movement similarity	Velocity scale Roughness scale Discharge scale	10 1.36 250000	
Suspended load sediment movement similarity	Settling scale Incipient scale Size scale Sediment concentration scale	6.3 10 0.437~0.548 0.048	Plastic sand density 1.05 t/m^3
Sandiness bed load sediment movement similarity	Incipient scale Size scale Riverbed Reformation Time scale	10 11 160	Coal density 1.39 t/m^3

Table 2. Flow profile verification results.

Discharge	Measuring section	Z_p(m)	Z_m(m)	Difference (m)
665 m^3/s	V1	19.05	19.03	−0.02
	V2	19	18.99	−0.01
	V3	18.95	18.94	−0.01
	V4	18.92	18.93	0.01
555 m^3/s	V5	18.7	18.7	0
	V6	18.69	18.68	−0.01
	V7	18.6	18.62	0.02
	V8	18.5	18.52	0.02
2020 m^3/s	V3	21.33	21.3	−0.03

Z_p – water level in prototype, Z_m – water level in model.

3.2 *Model verification*

Verification test including flow profile verification, velocity distribution verification and riverbed scouring/erosion verification has been conducted to verify resistance similarity, current movement similarity and riverbed reformation similarity respectively.

In flow profile verification, water level has been measured in 8 measuring sections (V1–V8 have been figured out in Figure 1) under different discharges (665 m^3/s, 555 m^3/s and 2020 m^3/s). The result is shown in Table 2 that model flow profile was accord with observed prototype data, the max difference between prototype and model water level was less than ±0.03 m.

In velocity distribution verification, the section mean velocity in vertical has been measured and verified in 8 measuring sections (V1–V8 have been figured out in Figure 1) under different discharges. The result shows that the velocity distribution was consistent with observed prototype data, the max difference

Copyright © 2006 Taylor & Francis Group plc, London, UK

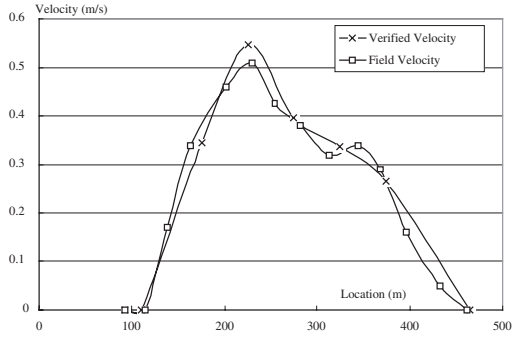

Figure 5. Velocity distribution in V5 ($Q = 665\ m^3/s$).

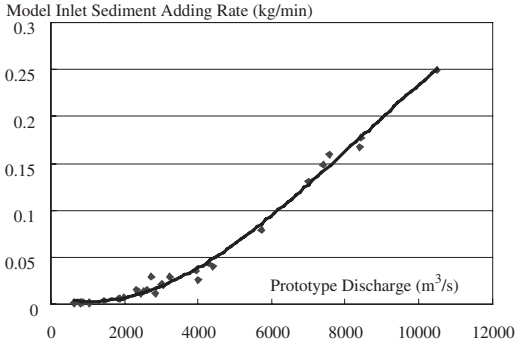

Figure 6. Relationship between sediment adding rate at model inlet and prototype discharge.

between prototype and model section mean velocity in vertical was less than 0.1 m/s. Figure 5 shows the velocity verification in V5 ($Q = 665\ m^3/s$).

In riverbed scouring/erosion verification, Dec 1997 1:5000 terrain field data has been chosen as initial terrain while Dec 2003 1:5000 terrain field data as terminate terrain. The discharge process of Zhangshu gauging station (23 km upstream Fengcheng reach) has been adopted as intake discharge. The generalized discharge hydrograph from Jan 1998 to Dec 2003 and intake sediment adding rate shown as Figure 6 have been adopted as controlling condition.

The verification test result shows that the thalweg tendency, scouring/erosion position as well as scouring/erosion amounts were basically consistent with terrain field data. Comparison between verification terrain and prototype terrain in CS44 is shown in Figure 7. It is indicated that the chosen of distortion ratio, sediment discharge scale and riverbed reformation time scale were suited and reasonable.

The verification test indicates that the model has satisfied resistance similarity, current movement similarity, suspended load sediment movement similarity, bed load sediment movement similarity and riverbed deformation similarity etc.

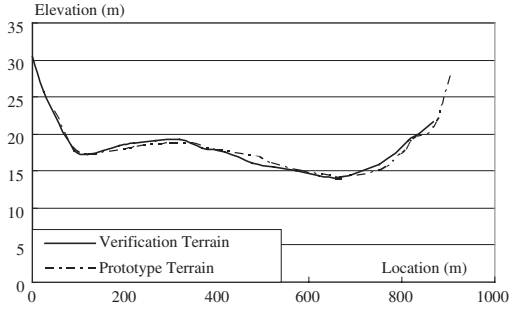

Figure 7. Comparison between verification terrain and prototype terrain in CS44.

Table 3. Eigen values of representative years.

Year	W ($10^8\ m^3$)	W_S (10^4 t)	Q (m^3/s)	S (kg/m^3)	Remark
1994	786.7	994	2494	0.126	High-flow year
1998	827	588	2622	0.071	High-flow year
1996	534	555	1693	0.104	Moderate-flow year
1999	587	292	1861	0.05	Moderate-flow year
2003	446.5	189	1416	0.042	Low-flow year

W – Annual Runoff, W_S – Annual sediment runoff, Q – Annual mean discharge, S – Annual Average Sediment concentration.

3.3 *Evolution tendency prediction*

Based on the data of Zhangshu gauging station, 5 representative years have been selected as typical water & sediment condition of the model test. The eigen values of these representative years are shown in Table 3.

The model experiment has indicated that under the representative water & sediment conditions, different part of Fengcheng Reach has different evolution trend.

In upper straight part, both silting and scouring were comparatively small in different representative years. But there was still slight deposition in Peng-shoal and Dong-shoal in flood season. The deposition was more obvious after moderate-flow year than after high-flow year. As Figure 8 shows that the max deposition thickness in Dong-shoal in flood season of 1998 is 10 cm while in flood season of 1999 the max deposition thickness reaches to 97 cm.

In mid bending part, the influence in Sha-shoal and Zhong-bar left side were rather small after low-flow year and moderate-flow year, while they presented to be scouring after high-flow year. As Figure 9 shows that comparing to the moderate-flow year, the 17 m

Copyright © 2006 Taylor & Francis Group plc, London, UK

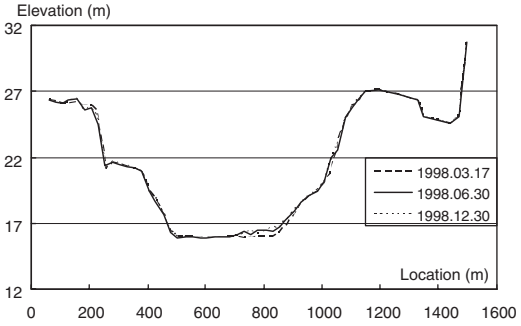

Figure 8(a). The silting/scouring variation of CS27 (Dong-shoal) in 1998 (high-flow year).

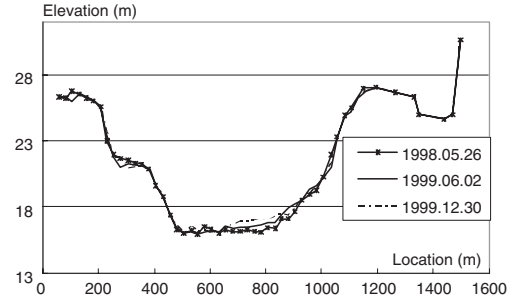

Figure 8(b). The Silting/Scouring Variation of CS27 (Dong-shoal) in 1999 (moderate-flow year).

contour line recedes back for 11.2 m after high-flow year, at the same time the section deepest point swings right for about 10 m. Scouring still occurred in Sha-shoal and Zhong-bar left side during the flood season in moderate-flow year, but the scouring extent was not that obvious than in high-flow year. The 17 m contour line at Sha-shoal receded back for 7.85 m in flood season of 1999 (moderate-flow year) while it is 11.5 m in 1998 (high-flow year).

In lower branching part, as the left branch was mostly blocked, the change of the hydraulic condition had little influence at left branch. While in the middle branch, the main channel was scoured down cutting and leftwards. It is figured out in Figure 10 that the deepest point downcut for 30 cm and moves rightwards for 25 m after high-flow year.

In upper straight part, the thalweg and main stream cling to the left bank upstream Leigongnao, the velocity near Peng-shoal and Dong-shoal at the left bank is not that small, so the deposition could not stay long there. Peng-shoal and Dong-shoal would keep stable and have little chance to extend sideward and lengthways.

In mid bending part, as the thalweg and main stream downstream had switched from left branch to mid branch, flow straightened especially in flood season.

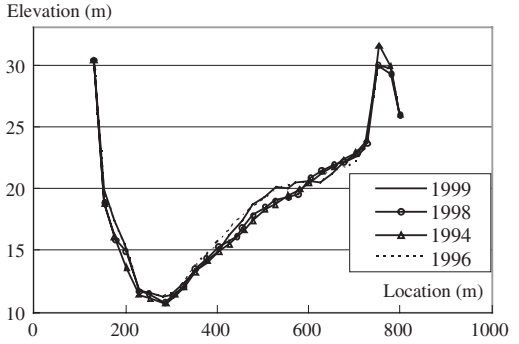

Figure 9. The silting/scouring variation of CS37 (Sha-shoal) between years.

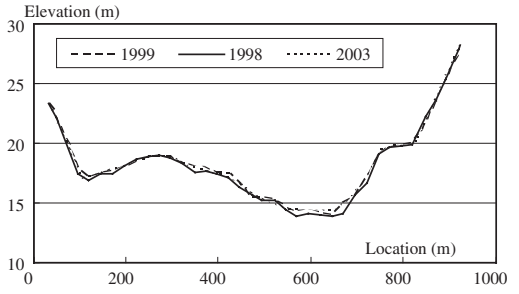

Figure 10. The silting/scouring variation of CS44 (Zhong-bar) between years.

On the other hand, the bed composition is thick with the particle median diameter of 5～19 mm while composition of side bar is relatively thin with the particle median diameter of 0.43～2.7 mm which is easy to be scoured. So Sha-shoal and Zhong-bar left side have a trend of scouring in flood season and the thalweg tends to swing rightward.

In lower branching part, the left branch tends to decline. The thalweg and the mainstream will settle in the mid branch whether in low-water or in flood condition. The downcut and swinging rightwards will continue in mid branch, and the mid branch has a trend of deepen and widen.

4 REFORMATION PROCESS IN CHANGING CONDITIONS

4.1 *Change of the influencing condition*

(1) The impoundment of Wan-an reservoir upstream in 1992 has changed the incoming water & sediment conditions. After the impoundment, the incoming sediment reduces as half as it was before impoundment, and the incoming flow and sediment distribution tend to be even.

Copyright © 2006 Taylor & Francis Group plc, London, UK

(2) The Gangjiang highway bridge which lies upstream of the branching part was built in 1992. The piers' vertical axes directed to the middle branch and had a relatively large deflection angle with the left branch. The navigation channel dredging project in the late 1990s lowers the thalweg elevation of mid branch.
(3) As the erosion and the sand excavation downstream of the Fengcheng reach, the downstream erosion base level has decreased.

4.2 *Analysis of the reformation process in changing conditions*

With the relatively thick bed composition, fine bank control and less sediment runoff, the river regime of Fengcheng reach keeps stable in natural condition. Along with the impoundment of Wan-an reservoir, Fengcheng reach was scoured by the unsaturated runoff. By diversion effect of the highway bridge, the unsaturated runoff was led to the mid branch, and brought to the erosion in mid branch and the deposition at the inlet of the left branch. The main stream and the thalweg successively transferred to the mid branch from the left branch. The subsequent navigation channel dredging lowers the thalweg elevation of the mid branch and further promoted the development of the mid branch and the decline of the left branch. The mid branch had totally replaced left branch to be the main channel. The deflection of the main stream may cause the local scouring in riverbed and bank on the right side of the transitional reach to the branching part. As the particle composition of the side bar is thinner than that of the riverbed, the local scouring will present to be the shoreline recession of Sha-shoal and the left side of Zhong-bar. The thalweg in mid bending part tends to swing right rather than downcut. In addition, as it is too narrow as a main channel, the mid branch has the requirement of deepen and widen rightward.

4.3 *Influence on navigation condition and near-shore project*

(1) After the construction of the highway bridge, the navigation condition became worse because the piers axes had a large inclination with the left branch which was the former navigation channel. As the mid channel developed to be the main channel, the navigation channel shifted to the mid branch, the inclination between piers axes and navigation channel greatly decreased, navigation condition had improved a lot. On one hand, the trends that the shoal line of Sha-shoal scouring backwards and the thalweg swinging rightwards may make the navigation channel more smooth and straight. On the other hand, the decrease of downstream erosion base level may possibly bring to the flow depth inadequate in navigation channel.
(2) The water intake of Fengcheng thermal power plant lies in the mid bending part where the thalweg clings to the left bank at present, so the intake can operate normally now. But with the adjustment of the local river regime, the thalweg here has a trend of swinging rightwards and the left side near water intake has a trend of deposition. It is disadvantageous to the operation of the water intake.

Although the adjustment of local river regime is rather slow at present, countermeasures should be studied.

5 CONCLUSION AND SUGGESTION

(1) The river regime of Fengcheng reach keeps stable in natural condition. After the change of the incoming water & sediment condition and boundary condition, the local river regime adjustment has occurred. The left branch gradually declined while the mid branch developed to be the main channel. At present, the main stream and the thalweg settle in the mid branch at all discharge range.
(2) The reformation process gradually turns peace. There will not be large scale evolution variation in Fengcheng reach while adjustment in local river regime still exists. The evolution tendency presents as shoal line recession in Sha-shoal and thalweg swinging rightwards in mid bending part and thalweg deepen and widen rightwards in mid branch.
(3) The adjustment of local river regime may have influence on navigation condition and near-shore project. Although these adjustments evolve rather slowly at present, countermeasures should be studied.

Impacts of the Three Gorges Project on flood in the middle reach of Yangtze River

Yitian Li, Yun Liu, Zhaohua Sun & Jinyun Deng
State Key Laboratory of Water Resource and Hydropower Engineering Science, Wuhan University, Wuhan, China

ABSTRACT: In the Yangtze River basin, the most severe flood disaster mainly occurred in the middle reach, especially in the Jingjiang reach and Dongting Lake Area, which just locate downstream the Three Georges Project (TGP). In these areas, the bed erosion due to the construction of the TGP will make the flood control issues more complicated. This paper provides a short background on the present flood situation and details in methodology and analysis in order to provide a reasonable prediction of flood evolution in future. Conclusions are drawn regarding the effective use of gauged historical data and mathematical model. After the dam operation, although channel degradation takes place immediately in the near-dam reach, water level changed little around Chenglingji station, which locates at the outlet of the Dongting Lake. Based on these conclusions, some measures are presented to alleviate the probably flood deterioration.

1 INTRODUCTION

The area of the middle reach of Yangtze River, in immediately downstream of the Three Georges Project (TGP) is 6.8×10^5 km^2. The main stream, tributaries and lakes connect with each other to form a complex river network (Fig. 1). The middle Yangtze River is the region with the most severe flood disasters in the whole basin, especially in the Jingjiang reach and Dongting Lake area. The flood level in the Jingjiang reach is higher than the ground elevation because of the deposition of sediment, and the discharge often exceed the maximal flood discharge that the channel can pass. In recent years, the phenomenon of 'low discharge with high water level' has occurred frequently (Fig. 2), which show the flood disaster situation of the Jingjiang reach and Dongting Lake Area is worse and worse.

At Songzikou, Taipingkou, and Ouchikou, there are diversions linking the Yangtze River with Dongting Lake, but they are usually dry in low flow season. Besides the three diversions, four tributaries join Dongting Lake in the south. The outlet of the lake joins the main stream of the Yangtze River at Chenglingji station. The area and the volume of the Dongting Lake are rapidly reduced because of the deposition of sediment in the lake, and the water delivered into the Dongting Lake is reduced because of the shrinking of the three diversions. Although the reduction of sediment transportation from the main stream to the lake area may reduce the deposition in the Dongting Lake, the high flood stage in recent years show that the flood situation hasn't been alleviated. After dam impoundment, although the TGP has large storage capacity to regulate flood, its volume for flood prevention is still relatively insufficient. Thus, flood detention area is still needed in addition to the reservoir operation.

Because the sediment trap of the TGP Dam reduce the downstream sediment discharge, channel degradation is inevitable. It will induce the change of the relationship between the Yangtze River and the Dongting Lake, which will bring a new problem of flood prevention. Present researches mainly focus on single aspect, the main stream or the Dongting Lake. Few consider two as a whole, which make it difficult to have a comprehensive understanding of impacts of the TGP on flood in the middle reach of Yangtze River.

In this paper, According to the characteristics of flood disaster in the middle reach of Yangtze River, causes of flood disaster are analyzed. A flood regulation model and a 1-D numerical model of flow and sediment transport are set up to predict the change of flood in the middle of Yangtze River in the early period after the TGP's operation. Finally, flood control measures are put forward.

2 CAUSES OF FLOOD DISASTER IN THE MIDDLE REACH OF YANGTZE

2.1 *The flood characteristics*

The flood of Yangtze River is caused by rainstorm. The great spatial-temporal differences of floods and rainstorms result from the geographical and climatic difference in different regions. Normally, the rainstorms

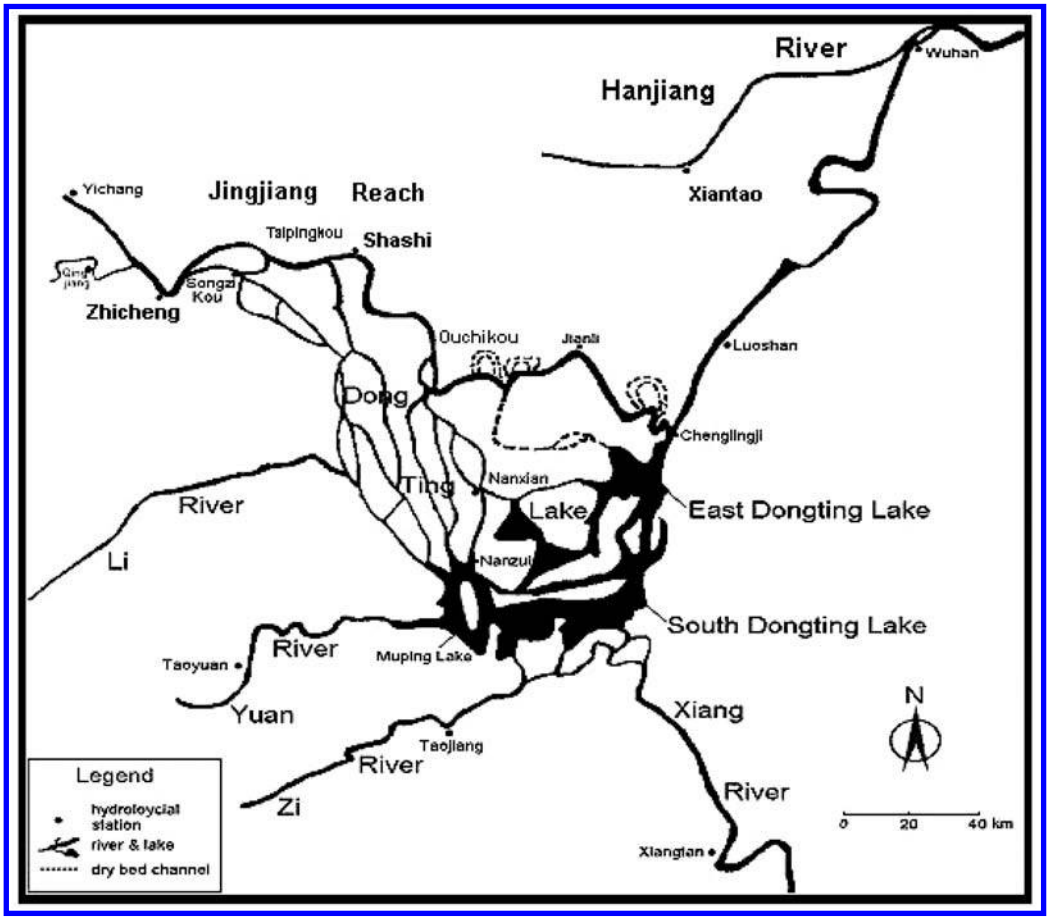

Figure 1. The study area in the middle Yangtze River.

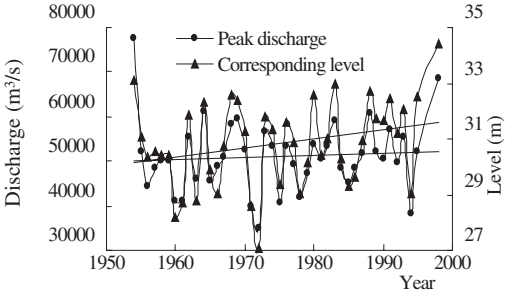

Figure 2. Annual peak discharge and corresponding water level at Luoshan station.

move from the south to the north and from the lower reach to the upper reach.

In normal condition, the floods of different region are not encountered. So the large flood disaster is not caused. If the weather, rainfall and its movement are abnormal, the probabilities of flood encounter of different regions increase and regional or basin level flood will occur.

The river network and regime of water level and discharge are all extremely complicated in the middle reach of Yangtze River, and the source and composition of the floods have great changes as the regional difference of rainstorm every year. The composition of annual volume of floods upstream from Luoshan station is displayed in Table 1. The drainage area upstream from Yichang station is 77.7% of that of Luoshan station, so that flood from Yichang is the main source of the floods. The reach from Yichang to Luoshan, including the Qingjiang River and the tributaries of the Dongting Lake have the regions of rainstorm, so the flood volume during flood season is large. The control area of the four tributaries of the Dongting Lake is 16.1% of the control area of Hankou station, which is the important compositive part of the flood.

Table 1. Composition of average annual flood volume near Chenglingji station (1951–1983).

Period	15d		30d	
Item	Flood volume (10^8m^3)	Percent	Flood volume (10^8m^3)	Percent
Zhicheng	489.1	72.8	860.8	73.2
Xiangtan	48.04	7.15	85.9	7.3
Taojiang	19.05	2.84	32.5	2.8
Taoyuan	73.32	10.92	126.3	10.8
Sanjiangkou	22.37	3.33	36.8	3.1
Four tributaries	162.79	24.23	281.5	24
Region	13.45	2.0	33.1	2.8
Luoshan	611.75	100	1175.5	100

(Xiangtan (Xiang River), Taojiang (Zi River), Taoyuan (Yuan River), Sanjiangkou (Li River), four tributaries (Xiang, Zi, Yuan, Li River), Zhicheng (Yangtze River), Luoshan (YangtzeRiver)).

Table 2. Flood passing capacity of the reach in the middle reach of Yangtze (m^3/s).

Reach	Flood passing capacity
Shashi	5000
Jianli	46000
Chenglingji	60000
Hankou	71600
Hukou	83400

The characteristics of the floods are that they have high peaks and large volume of water and keep in a long time. But large volume of water conflict with the flood passing capacity of the channel (Table 2), which is the main reason of the flood disaster in the middle reach of Yangtze River.

2.2 *Variation of sediment transport*

The sediments of Yangtze River, especially bedloads, mainly come from the upstream from Yichang station. When sediment transportation amount of Yichang, the four tributaries of the Dongting lake and Hankou (the outlet in this region) have only a few changes (the effect of Hanjiang River is not treated), the average annual deposition quantity is about 1.8×10^8t. Although the change of the deposition quantity is little, the places of the deposition are transferring. With the reduction of the deposition of the Dongting Lake, the quantity of the deposition of the reach from Luoshan to Hankou is increasing, and the speed of the reduction and the increase is approximate same (Fig. 3).

Because of the deposition, the three outlet tributaries shrink gradually and the diversions ratio of

Table 3. The change of average discharge under conditions of the different water levels at Qilishan station.

Level Period	32 m	30 m	25 m	20 m
1963∼1966	36833	19184	10439	4212
1981∼1985	26462	16168	9488	3663
1960s–1980s	10371	3016	951	549
1980s/1960s	72%	84%	91%	87%

Wusong elevation system, unit of discharge: m^3/s.

sediment is reduced so that the function of the trap sediment of the Dongting Lake is weakened (Li et al, 2004). The reduction of deposition in the Dongting Lake loses the long-range balance of sediment transportation in the middle reach of Yangtze River so that new places of deposition are formed, or the slope of the riverbed downstream from Chenglingji station is adjusted to enhance the ability of sediment transportation.

The main stream of the Yangtze River and the Dongting Lake are interactional, and the sediment transportation rapidly drives up the water level near Chenglingji station, which blocks the water outflow of the Dongting Lake. Generally, slope during flood season of the Dongting Lake is relatively smooth, and the water level of the Dongting Lake is close to that near Chenglingji station, however, the raising of the water level near Chenglingji station makes more water volume kept in the Dongting Lake, which causes the raising of the water level of the whole lake (Li et al, 2000; Li et al, 2001a,b). Table 3 shows that the discharge through Chenglingj station is reduced at the same stage.

3 TENDENCY OF FLOOD DISASTER IN THE MIDDLE REACH OF YANGTZE

3.1 *The methodology of studies*

3.1.1 *The flood regulation model*

In the Jingjiang reach and Dongting Lake Area of the middle reach of Yangtze, with many river systems and

Copyright © 2006 Taylor & Francis Group plc, London, UK

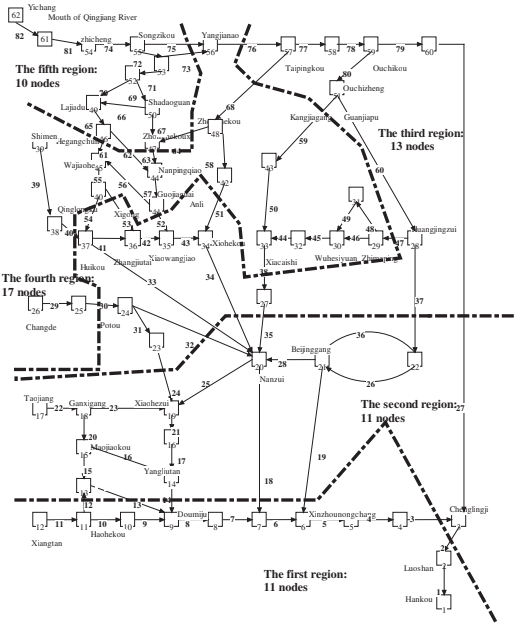

Figure 4. The outline picture of river networks in the middle reach of Yangtze and flood division areas.

complex river networks and many separate flood division areas, it's difficult to simulate stream movement by hydraulic model of single channel. So, hydraulic model of river networks is most suitable to simulate flood propagation. However, under conditions of special relation between the Yangtze River and the Dongting Lake, with complex river networks, big matrixes are formed so that it's difficult to compute. Moreover, stage-discharge relationships are complex so that it's difficult to ascertain the condition of the lower boundary. At present, Some models of flood regulation with the Yangtze River and the Dongting lake in the middle reach of Yangtze are set up, which is mostly made up of river networks. However, these models divide the whole areas into many little areas, which loses the integrity of the relationship of the Yangtze River and the Dongting lake in the middle reach of Yangtze, and loses the conservation of the water volume and the momentum, and depresses the computational speed and precision.

Hydrological model has a good precision to forecast the water level. It may provide the condition of the lower boundary. By using the junctions group method for unsteady flow in multiply connected networks (Li, 1997). A model that combines hydrological model with hydraulic model is set up (Fig. 4), which can be properly applied for the flood regulation in the middle reach of Yangtze. Its calculation speed and accuracy are improved.

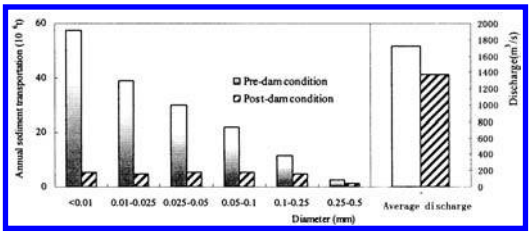

Figure 5. Annual sediment transportation capacity of each grain group size of different periods downstream from the Danjiangkou reservoir.

3.1.2 *Erosion and deposition model downstream from the reservoir*

The TGP has been put to use. In a long time, the long reach downstream from the TGP will be eroded because of the trapping sediment function of the reservoir. Current researches are very much on the erosion change downstream from the TGP. Some literatures (Han & He, 1995; Han & Yang, 2000; Wang & Han, 1997) analyzed the evolvement of the reach from Yichang to Chenglingji by the 1D steady suspended load model with a slight erosion or deposition, including the erosion and the descent of the water level on the main stream of the Yangtze River. However, many reservoirs throughout the world show the phenomenon that the upper reach is eroded and the lower reach is deposited in the early period after the reservoir's operation. It is disadvantageous to the flood prevention. For example, after the reservoir in the Spey River in Scotland operated 50 years, some of lower reaches are deposited to drive up the riverbed. Although the reservoir may adjust flood process, flood disasters are more than ones before building the reservoir (David. 2004). Thus erosion simulation downstream from the TGP need study, and it is necessary to build an erosion model downstream from the reservoir in order to estimate the erosion impacting on flood prevention in the early period after the TGP's operation.

The change process of erosion and sediment transportation capacity from the Danjiangkou Reservoirs (Fig. 5) indicate that through the riverbed erosion and sediment concentration recovery process, sediment transportation capacity of each grain group size after the reservoir's operation can't exceed it s original level before the reservoir's operation (Li et al, 2003), which is common erosion law downstream from the reservoir.

In order to forecast the erosion process downstream from the TGP in the early period after the TGP's operation, The 1D unsteady mathematical model for total sediment transport (suspended load and bed load), including the main stream of Yangtze and the Dongting lake downstream from the TGP is established, which is suitable to simulate sediment concentration recovery process downstream from the reservoirs.

Table 4. The regulating result of the TGP for the 1% exceedance floods.

Typical flood	Maximal flood volume near Chenglingji station ($10^8 m^3$)		Reduction of the water level without the TGP and with the TGP (m)	
	Without the TGP	With the TGP	Shashi	Chenglingji
1954	313.7	279.8	0.89	1.77
1995	268.6	263.4	0.19	1.84
1998	338.1	273.4	1.01	1.87

3.2 *Regulating capacity of the TGP for floods of the middle Yangtze*

3.2.1 *The regulation mode of the TGP*

The flood prevention emphases of the TGP are the Jingjiang reach. According to the design operation scheme, the highest limit of the regulation is to control the water level at Shashi station on 45.00 m. There are two regulation modes of the TGP: the compensation regulation mode aimed at the Jingjiang area to control the water level at Shashi station and the compensation regulation mode aimed at the Chenglingji area to keep Jingjiang reach safe as well as to reduce the flood diversion near the Chenglingji station.

For the floods in the upper Yangtze River, the first mode can adjust the discharge at Zhicheng station in order to ensure the water level at Shashi station under 45.00 m; for the floods in the whole Yangtze River and in the middle reach of Yangtze, the second mode can adjust the discharge at Chenglingji station by using the TGP effectively.

3.2.2 *The regulating capacity of the TGP*

The flood regulation model is put into use to simulate different criteria floods, with and without the TGP. The upper boundary conditions are 1% design floods including the basin-wide flood in 1954 , the tributary flood in the middle Yangtze in 1995 and the flood in the upper Yangtze River in 1998. The computational results are analyzed.

As shown in Table 4, for the 1% floods in 1954 and in 1998, the function of flood regulation is obvious because of operating the TGP, and Jingjiang spreading area is not used; for the 1% flood in 1995, the function of the TGP is less, and the flood spreading areas of the Dongting Lake and the Honghu are used.

The TGP has a function of reducing the water level of the Dongting Lake and the main stream. The bigger the flood proportion of the main stream is, the more obvious the function of the reservoir is. It reflects that the probability that the flood encounters in the middle reach of Yangtze is reduced and the beginning time of the peak water level of main stations is earlier than before the TGP. For the main stream, the effect on the upper water level reduction is more obvious; but the influence period is very short. The closer it is to the lower reach, the less reduction of water level is, and the influence period is longer. The range of water level reduction relates with the compositive proportion of the flood. For the Dongting Lake, the water level reduction of the three outlet diversions in the Yangtze River is obvious. And there are no influences on the upper reaches of four tributaries of the Dongting Lake.

3.3 *The erosion process of the lower reach in the early period after the TGP's operation*

The input data of the model is supported by the computational result (1960–1970) of Yangtze River Scientific Research Institute (YRSRI). The flow & sediment process downstream the TGP is the upstream boundary condition of the simulation reach from Yichang to Hankou. The flow & sediment process of the tributaries, Qingjiang River and Hanjiang River, corresponds to the typical year. The stage-discharge relationships at Hankou station are the lower control condition of the water level. According to the gauged data, the long-term stage-discharge relationships at Hankou station keep steady. Moreover, in the early period after the TGP's operation, the stage-discharge relationships changes little too, so it is feasible to take the relationships as the downstream boundary. As a result the stage-discharge relationships between 1981 and 1993 at Hankou station are adopted. The computational erosion result is analyzed.

3.3.1 *The erosion process*

In the first twentieth year, the riverbed erosion from Yichang to Shashi will have finished, and the riverbed erosion from Shashi to Jianli will not come to the end. Furthermore, the upper erosion near the TGP will cause a slight deposition in the reach from Jianli to Chenglingji at the beginning, and the riverbed erosion of that reach will start in the fifth year (Fig. 6). Table 5 lists average depth of the reach erosion from Yichang to Chenglingji. From the tenth year, the deposition tendency from Chenglingji to Hankou starts to decrease, and the riverbed starts erosion. By the end of the 20 years, the succeeded erosion volume will been close to the deposition in the first ten years.

Table 6 compares the erosion and deposition computational results of our model, the YRSRI model (2002) and the model of China Institute of Water Resources and Hydro-Power Research (CIWRHPR) in the first twentieth year after operating the TGP. The table shows that our computational erosion quantity in the whole reach is relatively smaller than previous study. The sediment budget from Chenglingji to Hankou keeps balance.

The terrain of the model in this paper is that of 1981, but the terrains of the YRSRI model and the

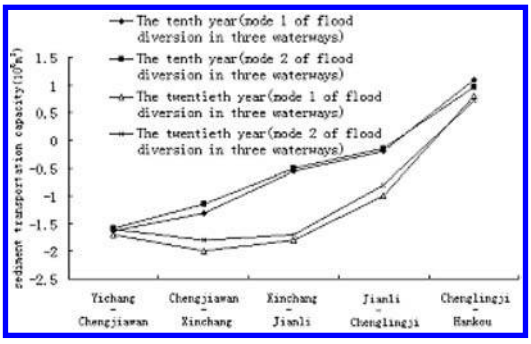

Figure 6. The comparison of erosion and deposition of riverbeds in different mode of flood diversion in three waterways in the tenth, twentieth year after the TGP's operation. (Mode 1 of flood diversion in three waterways is that the diversions ratio of flow and sediment in three waterways changes with reduction of the water level of the main stream because of erosion, and Mode 2 is that it keeps invariable when three waterways and the main stream are synchronously eroded.)

Table 5. Average depth of the erosion between the Yichang reach and the Chenglingji reach in the twentieth year after the TGP's operation (m).

Item	Yichang-Shashi	Shashi-Jianli	Jianli-Chenglingji
The width of rivers	1300	1525	1500
Average depth of the erosion	1.09	1.6	0.75

Table 6. The comparison of the quantity of erosion and deposition in the twentieth year after the TGP's operation (10^8 m^3).

Reach Model	Yichang-Chenglingji	Chenglingji-Hankou	Yichang-Hankou
YRSRI	−14.68	−2.87	−17.55
CIWRHPR	−14.22	−3.2	−17.42
This article	−6.57	0.83	−5.74

CIWRHPR model are that of 1993. If the quantity of erosion and deposition from 1981 to 1993 is deductible, the erosion result computing by this model is less 8.11×10^8 m^3 than that of YRSRI, and is less 7.65×10^8 m^3 than that of CIWRHPR.

3.3.2 *The reduction of the water level*

The erosion and deposition of the long reach downstream from the TGP and its influence on flood

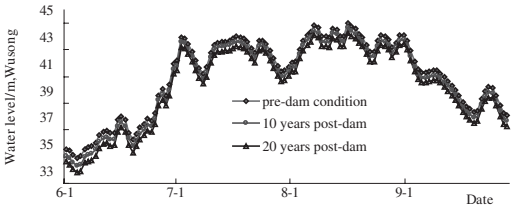

Figure 7. Computational water level process at Shashi station in 1998 under conditions of different terrains.

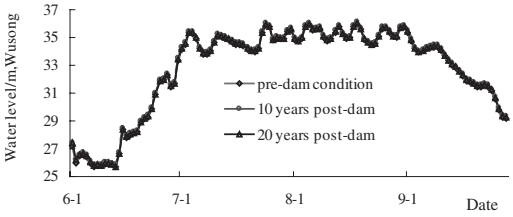

Figure 8. Computational water level process at Chenglingji station in 1998 under conditions of different terrains.

prevention have cause more attention (Han & He, 1995). According to the analysis of this paper, the channel erosion process after dam closure is not as rapid as previous prediction. So the change of flood prevention in the middle reach of the Yangtze River needs more examination (Han & He, 1995,1997; Wang & Han, 1997).

In order to estimate the influence of the erosion and deposition in the main stream on flood prevention, according to the riverbed terrain from Yichang to Hankou, computing by this model, in the tenth and twentieth year after the TGP, there is no erosion and deposition on the three outlet diversions of the Yangtze River. The flood water level processes in different period are computed. The gauged discharge processes of the tributaries and the main stream from June to September in 1998 is adopted. The flood water level processes at present, the tenth year after the TGP's operation and the twentieth year after the TGP's operation are computed.

Figures 7 and 8 show the flow process at Shashi and Chenglingji. As the figure indicates, because the lower Jingjiang reach is eroded, the water level at Shashi station reduces obviously. The low water level reduces more than the flood water level. Because of some indistinct change happening in the reach from Chenglingji to Hankou, the water level at Chenglingji station does not change obviously unlike people thought to reduce generally. Table 7 lists the water level change in the upper Jingjiang reach, the lower Jingjiang reach, the outlet of the Dongting Lake and inner stations of the west Dongting Lake. According to the table, although

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 7. The highest water level in 1996 and in 1998 (Wusong elevation system, m).

	Terrain without the TGP		The tenth terrain with the TGP		The twentieth terrain with the TGP	
The station	1996	1998	1996	1998	1996	1998
Chenglingji	35.44	35.98	35.56	36.1	35.48	36.02
Jianli	36.80	38.16	36.78	38.08	36.71	38.03
Shashi	42.85	45.02	42.48	44.65	42.14	44.31
Nanzui	37.08	37.44	37.11	37.45	37.03	37.35
Xiaohezui		36.97		37.04		36.95

the lower Jingjiang reach is eroded heavily, the reduction of the water level at Jianli station is little because of the backwater near Chenglingji station, and the reduction of the low water level at Shashi station is more; because of big influence of the water discharge of the three outlet diversions and the influence of the water level at Chenglingji station, the water level change of the west Dongting Lake is not obvious. Table 5 shows that the flood water level in 1996 has the same law, which is irrespective to the compositive proportion of incoming water.

The integrated function of the TGP is that the stress on flood prevention of the upper Jingjiang reach is alleviated, but the situation of flood prevention near Chenglingji has little change. Of course, those are the qualitative analysis, the quantity relating to the combination of the flood and the computational precision of the erosion of the lower reach.

3.3.3 *The analysis of the rationality of the computational result*

Sediment concentration recovery process in the lower reach after the TGP operation should has the same law with downstream from other reservoirs, which is that sediment transportation capacity of each grain group size downstream dams can't exceed its original level before the reservoir's operation.

Figure 9 presents the sediment content recovery process at Luoshan and Hankou station after the TGP's operation. The figure shows that the sediment transportation capacity of all the stations of the model of this article, the gauged data in 2003 and the gauged data in 2004 don't exceed their average levels before the reservoir's operation. However, according to the computational result of YRSRI and CIWRHPR, the computational reach has erosion of large volume at the beginning. The reason is that the sediment transportation capacity of grain group size more than 0.1 mm is greatly increased. In the early 30 years after the TGP's operation, the annual sediment transportation capacity of grain group size bigger than 0.1 mm increases 3.6 times than before the reservoir's operation.

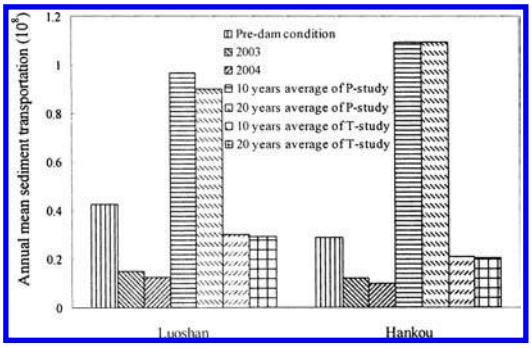

Figure 9. Sediment transportation capacity of grain size more than 0.1 mm. (P-study represents the result of previous study and T-study represent the result of study in this paper.)

4 MITIGATION MEASURES OF FLOOD DISASTER IN THE MIDDLE REACH OF YANGTZE

Flood disasters are caused by many factors including nature and human activity. Natural factors, such as rainfall and geography, belong to objective fact. The factors of human activity are such as keeping the water and soil, building the bank, repairing the channel and so on.

In the Yangtze River basin, flood & sediment problem influences the whole basin. So flood disasters should be cured through thinking about strategy and measures from the point of whole basin. After running the TGP, riverbed erosion downstream from the reservoir will impact on flood prevention. According to the character of flood & sediment disaster, corresponding disaster mitigation measures are put forward.

(1) Improving the regulation mode of the TGP and constructing reservoirs in the upper Yangtze River.

During the course of preliminary designing the regulation mode of the TGP, the compensation regulation mode of the TGP aimed at the Jingjiang area is studied emphatically. In addition, the compensation regulation mode of the TGP aimed at the Chenglingji area is also studied. Under the condition of keeping the Jingjiang reach safe, we may adjust the regulation mode to properly reduce the compensation discharge to the Chenglingji area, and to reduce the flood diversion near Chenglingji station, and to improve the flood control effect of the TGP on ordinary flood.

The floods in the Yangtze River characterize high peak, large discharge. Constructing reservoirs in the upper Yangtze River can make the flood detention capacity in the upper Yangtze River increase. And it is a long-term measure to cut the peak discharge that those reservoirs cooperate with the TGP

Copyright © 2006 Taylor & Francis Group plc, London, UK

to controls the floods in the Yangtze River. As a result, the loss of flood diversion will decrease. The joint regulation of reservoirs in the upper Yangtze River and the TGP will improve the flood control ability in the middle and lower reaches of the Yangtze River.

(2) Increasing clear water with less sediment diversion from the Yangtze River to the Dongting Lake and improving the relation between the Yangtze River and the Dongting Lake.

The result of this paper and current results indicate that the Jingjiang reach will have plenty of erosion in the early period after the TGP's operation, and the Lower Jingjiang River will also erode continuously at the end of 20 years after the operation of the TGP. Quantity of water from the Yangtze River into the Lake through the three outlet divisions will reduce largely, and the outlet pathways will shrink so that erosion of the lower Jingjiang reach will be more drastic.

Enlarging the division of the three outlets by dredging pathways and building gate can increase clean water with less sediment diverted from the Yangtze River to the Dongting Lake. On the one hand, the discharge in the Jingjiang reach will reduce largely so that the danger of caving bank causing by large erosion reduces; river bed shape is prevented from changing and the sediment entering the reach from Chenglingji to Hankou decreases. On the other hand, the three outlet divisions will be scoured and the end reach of Li River and Yuan River, the branches of the Dongting Lake, will be scoured too. Then, when the Dongting Lake joins the Jingjiang River, Chenglingji which is the outlet of the Dongting Lake will be scoured. And the benchmark level of the outlet of the Dongting Lake will depress so the whole level of the Dongting Lake will depress and the flood carrying capacity of the Yangtze River and the Dongting Lake will increase.

(3) Assistant structural and nonstructural measures.

In the middle reach of the Yangtze River, all kinds of flood control measures are supplemented each other. Although they have remarkable effect on dealing with big floods in the past, they have many shortages need to be improved.

After running the TGP, the conditions of flow & sediment downstream from the TGP change, and the river shape of local reach will adjust. Former danger projection section may come to change and the stability of the bank slope and retaining wall projects may be influenced. So project measures, such as revetment dikes, bank protection, should be adopted.

Nonstructural measures are also adopted, such as monitoring channels change in future, predicting floods, flood alarm, and so on. At present, it is the most important task to monitor and analyze change of the channel in the middle reach of the Yangtze River in order to bring forward the corresponding measure.

5 CONCLUSION

In this paper, causes of flood disaster are analyzed based on the change of sediment transportation in the middle reach of the Yangtze River; the tendency of flood disaster is estimated, and disaster mitigation measures are put forward from the point of whole basin.

(1) Main reasons of flood disaster in the middle reach of the Yangtze River are that encounters of local flood are complicated; high peak and large amount of water conflict with the flood passing carrying capacity of the channel; and sediment transfer causes the change of the water level.

(2) The flood regulation model is put into use to simulate different criteria floods with and without the TGP. For the basin-wide floods in the whole Yangtze River, the flood regulation of the TGP has obvious function. For the floods in the middle reach of the Yangtze River, the function of the TGP will decrease.

In the early 20 years after the TGP's operation, the reach from Yichang to Chenglingji will be eroded. But little changes take place in the reach from Chenglingji to Hankou.

The influence of the erosion of the main stream downstream from the TGP in the first decade and in the second decade after the TGP's operation on the flood process is compared. The influence to the upper Jingjiang reach is more than that of the lower Jingjiang reach and the water level at Chenglingji station does not change. But the total change isn't obvious. So after the TGP's operation, the situation of flood prevention in the upper Jingjiang reach is alleviated, and the situation near Chenglingji reach changes little.

(3) After the impounding of the TGP, riverbed erosion downstream from the reservoir will impact on flood prevention. Disaster mitigation measures are put forward, such as improving the regulation mode of the TGP, constructing reservoirs in the upper Yangtze River, increasing clean water with less sediment diversion from the Yangtze River to the Dongting Lake, strengthening flood control project, strengthening dike protection and monitoring channel change in future.
