Figure 7. Estimated Froude number in the left central street.

water depth measurements with the velocity measurements, an estimate of the local Froude number can be obtained. This is illustrated in Figure 7, and confirms the change from supercritical to subcritical flow in the upstream part of the urban district. At the exit of the urban district, the flow accelerates and is supercritical.

3.3 *The single crossroad*

This test case is a kind of "zoom" on the previous situation. Indeed, in the previous aligned case, complex interactions appeared at each crossroad between the rapid flow in the longitudinal streets and the slow flow in the transversal direction. However, the scale of this first series of experiments did not allow detailed measurements of those interactions.

When the dam-break wave hits the main street of the system, a hydraulic jump forms and the flow is divided in three parts: a main flow through the central street, and lateral flow on both sides of the channel. Those latter waves will later enter the crossroad through the lateral streets and merge with the main axial flow.

Copyright © 2006 Taylor & Francis Group plc, London, UK

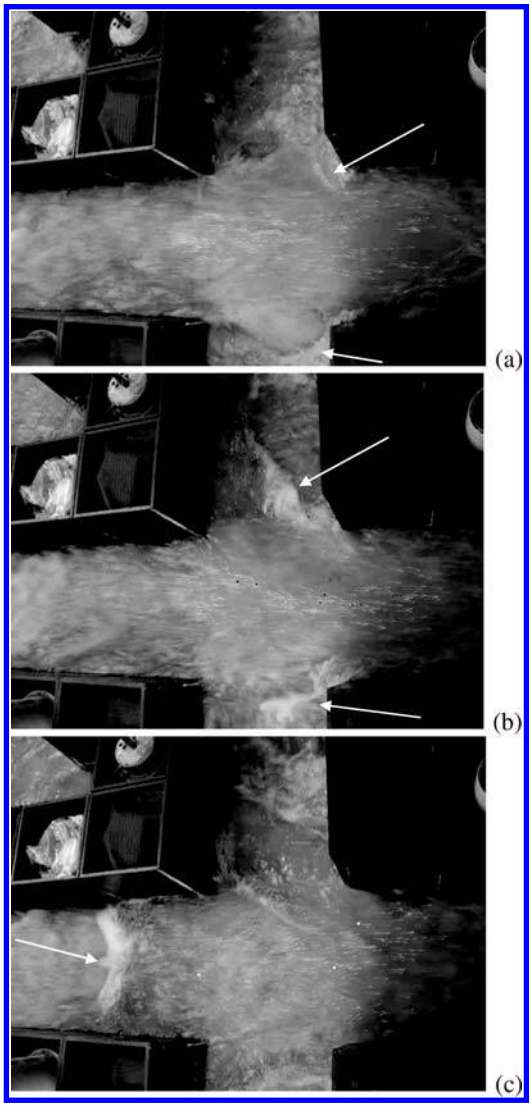

Figure 8. Formation and evolution of the hydraulic jump in the single crossroad (a) $t = 4.5$ s, (b) $t = 5$ s, (c) $t = 7$ s.

The formation and evolution of the hydraulic jump in the crossroad are illustrated in Figure 8 by means of pictures of the flow combined with velocity vectors issued from the digital imaging measurements. When the slow flow from the lateral streets comes up with the rapid main flow in the central street (Fig. 8a), hydraulic jumps form in the lateral streets (Fig. 8b, marked by arrows) and re-circulating flows can be observed. As the flow in the lateral streets increases, the hydraulic jumps are pushed towards the crossroad and merge, then starts to recede in the upstream direction in the central street (Fig. 8c, marked by an arrow).

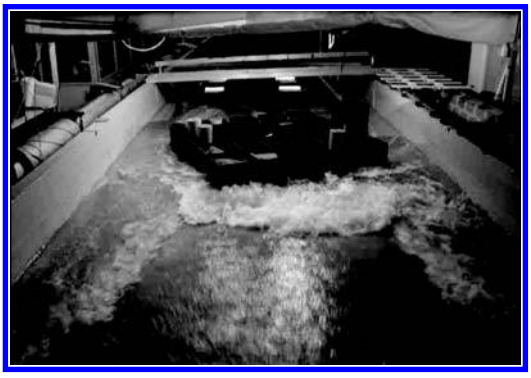

Figure 9. Upstream hydraulic jump in the skew case.

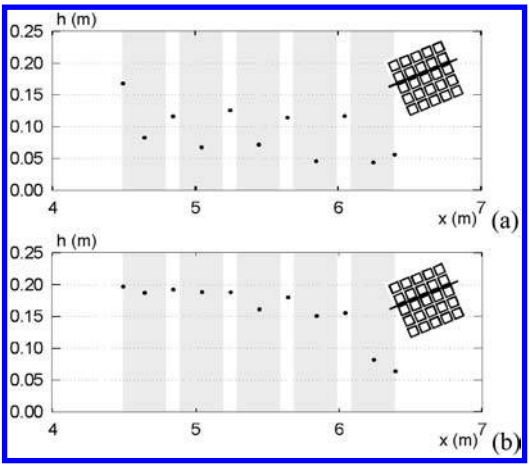

Figure 10. Water profile through the urban district in the skew case: (a) $t = 4$ s and (b) $t = 9$ s.

3.4 *Not aligned (skew) square city*

In this test case, the square urban district is now rotated by an angle of 22.5° and the streets are thus no more aligned with the main flow direction.

Like in the aligned case, a hydraulic jump forms upstream from the buildings (Fig. 9). As the flow enters the urban district through the front side and through the left side, the hydraulic jump is not symmetric as in the previous case.

Complex interactions occur at each crossroad and the urban district is progressively filled with water. Figure 10a shows the measured water depths after 4 s. The experimental data in Figure 10a show a much more important scatter than in the aligned case (Fig. 4). This highlights the complexity of the flow in this case, where the interactions at the crossroads lead to more local reflections in the streets during the first times of inundation of the urban district. After 9 s, when the urban district is completely flooded (Fig. 10b), the flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

stabilises towards a profile similar to the one obtained in the aligned case, i.e. a progressive decrease of the water depth along the urban district. The main difference relies in the absence of any hydraulic jump inside the urban district, as was observed in the aligned case.

Due to difficulties of lightening the scene but also mainly due to imperfect distribution of tracers in the skew streets with the available devices, data obtained with the digital imaging technique were found not be completely usable at this stage. Only water level results will thus be presented in this paper.

4 NUMERICAL MODEL

Fast transient free-surface flows are usually simulated using the two-dimensional shallow-water equations. Those equations are solved using a shock-capturing finite-volume scheme, which means that the scheme is able to represent discontinuities such as hydraulic jumps. The scheme is briefly presented here. More details can be found in Soares-Frazão and Zech (2002).

4.1 *Two-dimensional shallow-water equations*

In two-dimensional conservative vector form, the Saint-Venant shallow-water equations stating mass and momentum conservation read (Abbott, 1979)

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{U})}{\partial x} + \frac{\partial \mathbf{G}(\mathbf{U})}{\partial y} = \mathbf{S} \qquad (1a)$$

with the variables defined as

$$\mathbf{U} = \begin{pmatrix} h \\ uh \\ vh \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} uh \\ u^2h + gh^2/2 \\ uvh \end{pmatrix} \qquad (1b,c)$$

$$\mathbf{G} = \begin{pmatrix} vh \\ uvh \\ v^2h + gh^2/2 \end{pmatrix}, \quad \mathbf{S} = \begin{pmatrix} 0 \\ gh\left(S_{0x} - S_{fx}\right) \\ gh\left(S_{0y} - S_{fy}\right) \end{pmatrix} \qquad (1d,e)$$

In equation 1, h is the water depth, uh and vh the unit discharge in the x- and y-direction respectively, S_{0x} and S_{0y} the bed slope in the x- and y-direction respectively and S_{fx} and S_{fy} the components of the friction slope, computed using Manning's formula and considering that friction only applies for the channel bed.

4.2 *Finite-volume scheme*

The finite-volume scheme is built upon an integral form of equation 1, yielding the generalised expression for non-Cartesian grids (Toro, 1997):

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n - \frac{\Delta t}{\Omega_i} \sum_{j=1}^{nb} \mathbf{T}_j^{-1} \mathbf{F}_j^* \left(\bar{\mathbf{U}}_j\right) L_j + \mathbf{S}_i \, \Delta t \qquad (2)$$

where Ω_i is the cell-base area, L_j the j-interface length and nb the number of cell interfaces (3 for triangular cells). The vectors $\bar{\mathbf{U}}$ and $\mathbf{F}(\mathbf{U})$ express $\mathbf{U}$ and $\mathbf{F}$ in terms of normal and tangential velocity components, u_n and v_t, attached to the considered interface, using a transformation matrix $\mathbf{T}$, where n_x and n_y are the components of the outwards unit vector normal to the interface:

$$\bar{\mathbf{U}} = \mathbf{T}\,\mathbf{U} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & n_x & n_y \\ 0 & -n_y & n_x \end{pmatrix} \begin{pmatrix} h \\ uh \\ vh \end{pmatrix} = \begin{pmatrix} h \\ u_n h \\ v_t h \end{pmatrix} \qquad (3)$$

The flux normal to the interface becomes:

$$\mathbf{F}\left(\bar{\mathbf{U}}\right) = \begin{pmatrix} u_n h \\ u_n^2 h + gh^2/2 \\ u_n v_t h \end{pmatrix} \qquad (4)$$

The problem is thus solved by computing the mass and momentum fluxes in the direction normal to each interface, and then combining those fluxes to obtain the mass and momentum balance over each cell.

The normal fluxes are computed using Roe's scheme adapted to the shallow water equations (Alcrudo & Garcia-Navarro, 1993), taking into account the wave propagation celerity of the system.

4.3 *Discretisation of the urban district*

An unstructured triangular mesh is used to discretise the computational domain, with a higher density of triangles around the urban area to increase the results accuracy (Fig. 11).

The buildings are impervious blocks, and their limits are represented as impervious boundary conditions in the model (closed walls).

In this way, wave reflections against the buildings are accounted for in a way conform to the physics. The mesh used for each urban district layout is shown in Figure 10: 53591 elements in the aligned case, 15649 elements for the single crossroad and 14667 elements in the skew case.

5 COMPARISON WITH THE EXPERIMENTS

For each configuration of the urban district, the water level and velocity predictions by the numerical model will be compared respectively to the water level measured by means of the water level gauges and to the velocity measured by means of the digital imaging technique.

Copyright © 2006 Taylor & Francis Group plc, London, UK

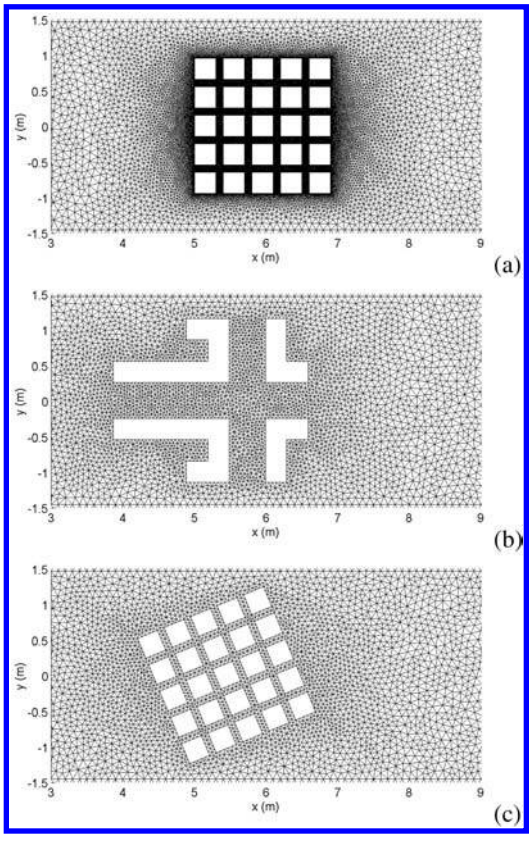

Figure 11. Computational mesh for (a) the aligned case, (b) the single crossroad and (c) the skew case.

The velocity data will be used either under the form of a surface-velocity field showing the magnitude and direction, or under the form of velocity magnitude, for example to compare the velocity in a particular street of the urban district.

From the water level evolution in time measured at each gauging point, data is extracted at a given time to form a water profile. To account for the important variability of the water level in time that can be observed in the experimental data sampled at a rate of 200 measurements per second, an averaged is performed over a time step of 0.05 s. This means that the water level at time t is represented by the averaged measured water level over the period $[t - 0.025\ \text{s};\ t + 0.025\ \text{s}]$.

A similar averaging procedure is used for the velocity measurements issued from the digital imaging technique. To obtain an equivalent "point" measurement of the velocity at a position (x, y), data is averaged in space over a square box of 0.05 m around (x, y) and in time over a time step of 0.1 s.

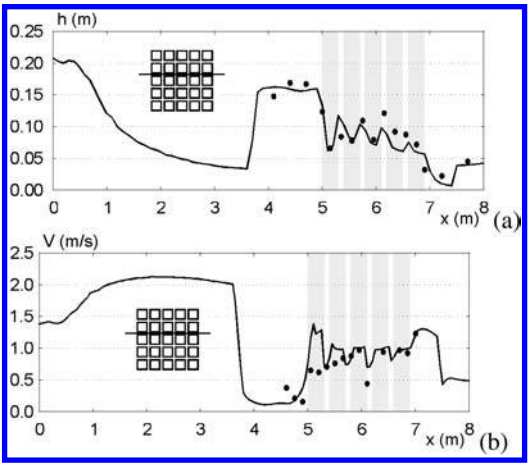

Figure 12. Water level (a) and velocity profiles (b) in a central street at $t = 6$ s. Comparison between experimental data (points) and numerical results (continuous line).

5.1 *The aligned case*

As shown in Figure 11, the mesh used to represent the urban district is quite refined, such that there is an average of 10 triangles over the width of each street. This level of refinement allows the resolution of details of the flow, including two-dimensional features in the street and in the crossroads. However, the corresponding computational time is important.

Simulations were also undertaken using a coarser mesh of 14341 elements, with only 2 triangles over the width of each street. Using such a mesh implicitly indicates that the flow in the streets is considered as being mainly one-dimensional. It appeared that this coarse mesh was insufficient to accurately represent the water profile (Deswijsen & Duthoit, 2005).

Longitudinal flow profiles in a street close to centre of the urban district are shown in Figures 12 and 13. The exact location of the profile is indicated. Figure 12 shows results after 6 s with the water level profile in Figure 12a and the velocity profile in Figure 12b. Similar results at time $t = 8$ s are shown in Figure 13.

The numerical model reproduces well the observed flow features. Especially, the hydraulic jump at entrance of the urban district is well reproduced. This was not the case when using a coarse mesh with only 2 triangles over the width of the streets: the hydraulic jump was completely missed, as illustrated in Figure 14.

However, the agreement is better for the water level than for the velocity, which tend to be overestimated in the numerical model. This might be due to momentum exchanges and losses in the crossroads that are not properly taken into account by the numerical model. Indeed, the flow is complex at the streets interactions, as illustrated in Figure 8 for the single crossroad: the

Copyright © 2006 Taylor & Francis Group plc, London, UK

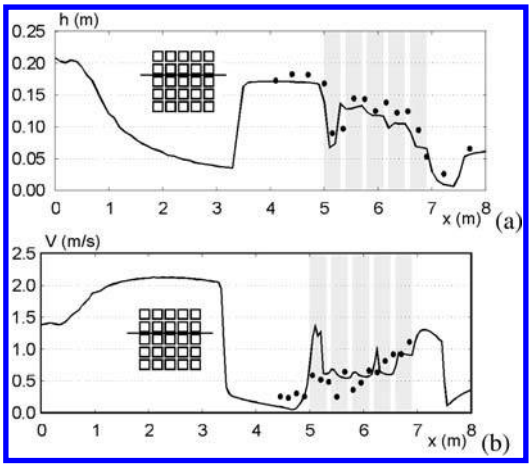

Figure 13. Water level (a) and velocity profiles (b) in a central street at $t = 8$ s. Comparison between experimental data (points) and numerical results (continuous line).

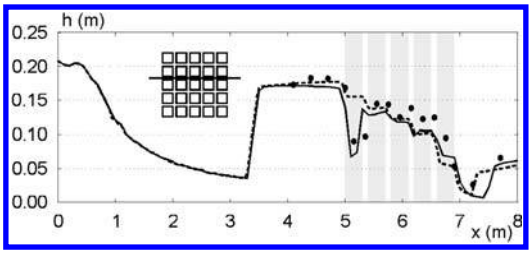

Figure 14. Water level in a central street at $t = 8$ s. Comparison between experimental data (points) and numerical results (continuous line for the fine mesh, dotted line for the coarse mesh).

hydrostatic pressure assumption of the model does probably not hold there, and three-dimensional effects including re-circulation in the vertical plane occur.

Moreover, it must be recalled that the velocity is measured at the surface, which is certainly not representative of the depth-averaged velocity in the case of a complex velocity profile in re-circulation areas.

5.2 *The single crossroad*

As already mentioned, this case can be considered as a zoom on the previous test case, with the aim of better describing the flow in the crossroads. The computational mesh of 15649 elements is such that the main street is discretised with 10 triangles on the width, corresponding to the mesh refinement used in the previous case.

5.2.1 *Water and velocity profiles*

Experimental and computed water level and velocity profiles at $t = 9$ s are shown in Figure 15. The hydraulic

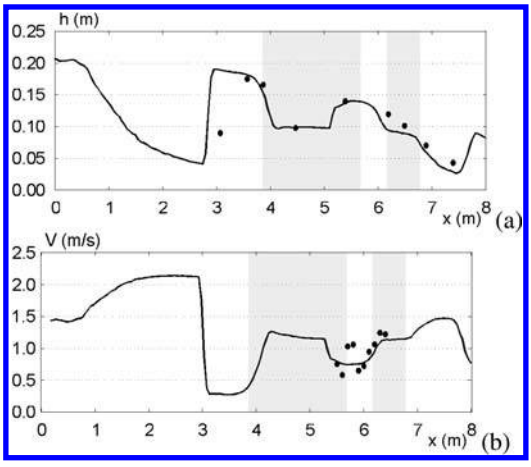

Figure 15. Water level (a) and velocity (b) profiles in the main street at $t = 9$ s. Comparison between experimental data (points) and numerical results (continuous line).

jump at the entrance of the main street can be clearly identified. This jump propagates in the upstream direction. The overall agreement of the computations with the measurements is good. The velocity reduction in the crossroad is well predicted.

5.2.2 *Velocity field and water surface*

The computed water depth and velocity field in the crossroad are shown at different times in Figure 16, corresponding to the three stages of the formation of the hydraulic jump illustrated in Figure 8. The grey-scale map used in the water surface plots is such that dark regions correspond to a high water depths (around 0.15 m), and clear regions to shallow water depths (around 0.02 m).

Comparing Figure 19 and Figure 8, it can be observed that the complex flow features are well reproduced by the numerical model. The shape of the hydraulic jump growing from the lateral streets is well reproduced.

5.3 *The skew urban district*

In this case, the square urban district is rotated by an angle of 22.5° and is thus no more aligned with the flow direction. However, the streets can still be considered as "longitudinal" and "transversal" (Fig. 2c).

The computational mesh used in this case is similar to the coarse mesh used in the aligned case, with only 2 triangles over the width of the streets. Again, like for the experiments, more in-depth analysis is in progress to obtain a complete characterisation of the flow in this skew case. However, the preliminary analysis with the coarse mesh and only water level data already provides interesting information, presented in the next section.

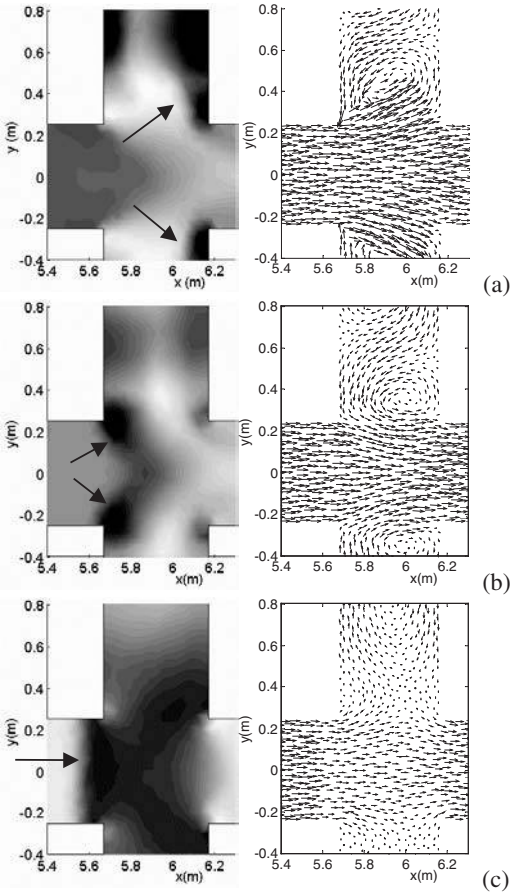

Figure 16. Computed water depth and velocity field at times (a) $t = 4.5$ s, (b) $t = 5$ s, (c) $t = 7$ s.

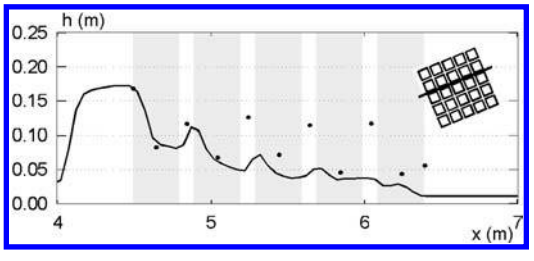

Figure 17. Water level profile in a longitudinal street at $t = 4$ s. Comparison between experimental data (points) and numerical results (continuous line).

5.3.1 *Water level profiles*

Water level profiles are illustrated for the fast transient period of the flow in Figure 17 ($t = 4$ s) and after stabilisation of the flow in Figure 18 ($t = 9$ s).

The overall agreement of the computed results with the experimental data is good. The progressive decrease of the water depth along the urban district is well reproduced, although the water depth is slightly underestimated in the numerical model. This is expected to be improved by refining the mesh in the streets, like in the aligned case.

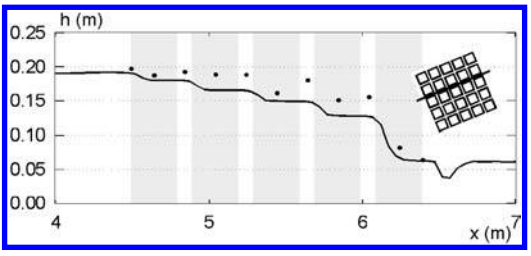

Figure 18. Water level profile in a longitudinal street at $t = 9$ s. Comparison between experimental data (points) and numerical results (continuous line).

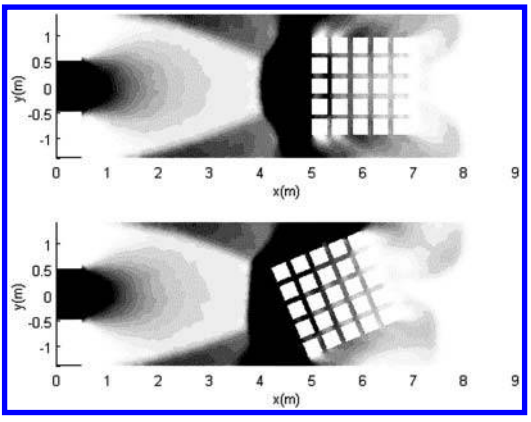

Figure 19. Computed map of the water depth at $t = 3$ s for (a) the aligned case and (b) the skew case.

5.3.2 *Comparison with the aligned case*

As it was shown in the previous sections that the numerical model is able to reproduce well the main features of the observed flow, only numerical results will be used here to highlight the particular features linked to the orientation of the urban district.

In the initial stage of the inundation of the urban district, the distribution of water in the streets logically depends on their orientation. This is illustrated in Figure 19, comparing computed results after 3 s in the aligned and skew case. The upstream hydraulic jump is also influenced by the orientation of the urban district.

After 10 s, when the flow reaches a quasi steady state, i.e. when the urban district is filled with water, the water level maps tend to be closer to each other (Fig. 20). This trend is confirmed by the longitudinal profiles in Figure 21.

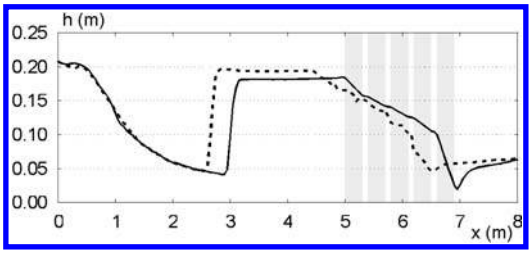

Figure 21. Computed water profile at $t = 10$ s for the aligned case (continuous line) and the skew case (dotted line).

6 CONCLUSIONS

Three dam-break flow experiments in idealised urban districts have been presented. The first one concerned an aligned configuration, for which the analysis could be deepened by investigating the flow behaviour in a single crossroad. Then, by rotating the urban district, some ideas of the influence of the orientation of the streets could be given.

A two-dimensional finite-volume scheme is used to solve the shallow-water equations describing this type of flow. It was successfully validated against the experimental measurements, which allows its use in further analysis of different flow configurations close to the ones studied here.

A particularly interesting conclusion arises from the observation that after the complete inundation of the urban district, the flow profile is not much dependent on the orientation of the streets. This observation introduces the idea of considering the urban district like a porous media inducing mass storage and momentum losses, regardless of its exact shape and orientation. This assumption of course has to be further investigated.

Some tentative developments were undertaken to include this concept of "urban porosity" in the shallow-water equations (Guinot & Soares-Frazão, 2006). They now have to be validated against this new experimental data set.

Evolution of mixing layers in turbulent flow over submersed vegetation: Field experiments and measurement study

A. Sukhodolov & T. Sukhodolova
Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

ABSTRACT: Submersed plants interact with river flow and create complex flow patterns that absorb wakes behind stands and internal boundary layers developing over plant canopies on the general pattern of the open-channel flow. Recent laboratory investigations suggested the usage of mixing layer analogy for flow inside and on the upper edge of canopies. This field study explores applicability of mixing layer analogy in a natural stream. A series of field experiments was completed in a lowland river. In these experiments detailed measurements of flow characteristics were made over a patch of *Sagittaria Sagittifolia* implanted in a certain order on the river reach. Density of canopies varied among the experimental runs. Analysis of obtained data confirmed efficiency of mixing layer analogy and provided insight into spatial evolution of mixing layers in the natural stream. The results are compared to the canonical and shallow mixing layers and discrepancies between those layers are discussed.

1 INTRODUCTION

Aquatic vegetation exposed to flowing waters in fluvial systems experiences physical forces imposed by flow and alters the surrounding flow via resistance forces. These interactions affect transport and mixing processes in natural streams and hence are of great importance for ecology of river ecosystems. Until recently the effect of vegetation on flow has been of primary interest only in respect to complex roughness characteristics imposed by vegetation on the river channel. Customary logarithmic law stemming from perturbed boundary layer approximation was used as an analytical framework for flows over vegetative canopies (Kouwen & Unny 1973; Murota et al. 1984; Stephan & Gutknecht 2002). However, recent laboratory studies with scaled model vegetation (Ghisalberti & Nepf 2002) have indicated that flow within and just above a canopy behaves more like a mixing layer rather than a boundary layer.

A free mixing layer belongs to the family of free-turbulence flows that also includes free wakes and free jets. The qualifier *free* stresses the fact that these turbulent flows are maintained by internal velocity gradients and their evolution is independent of solid boundaries (Monin & Yaglom 1971; Brown & Roshko 1974). Canonical free mixing layers evolve in coflowing liquids of different densities or flows of different mean velocities, for instance downstream a splitter plate, Figure 1.

The available quantitative methods describing evolution of free shear flows are based on similarity

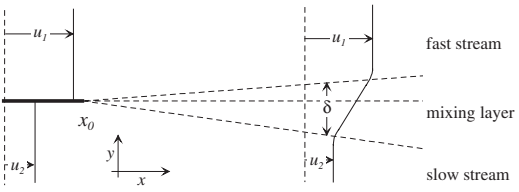

Figure 1. A sketch of evolution of a canonical free mixing layer downstream a splitter plate (after Tukker 1997).

hypotheses that impose scaling relationships (Monin & Yaglom 1971) $L(x) \sim x^m$ and $U(x) \sim x^{-n}$, where L and U are characteristic length and velocity scales of turbulence, m and n are the scaling exponents. In canonical free mixing layer the characteristic length scale is the width of layer δ and characteristic velocity scale is velocity difference $\Delta u = u_1 - u_2$. The scaling exponents in mixing layer take values of 1 and 0, respectively (Brown & Roshko 1974)

$$\frac{\partial \delta}{\partial x} = \alpha \lambda \tag{1}$$

$$\lambda = \frac{\Delta u}{u_1 + u_2} = \frac{\Delta u}{2u_c} \tag{2}$$

where α is spreading coefficient which value for canonical mixing layers was determined experimentally, $\alpha = 0.18$, λ is velocity ratio, and u_c is the mean velocity. Mean velocity profile in mixing layers has

Copyright © 2006 Taylor & Francis Group plc, London, UK

been shown to comply with hyperbolic tangential distribution (Michalke 1965)

$$\frac{u}{u_s} = 1 + \tanh\left(\frac{2y}{L}\right) \tag{3}$$

where $u_s = \Delta u/2, L = \gamma\delta$ is characteristic length scale, and γ is a coefficient. Canonical mixing layer model assumes well defined flow upstream of the layer origin and equations (1)–(3) are supposed to be valid at distances relatively far from the origin.

Conditions similar to those of the canonical flow can be attained in the atmospheric flows over terrestrial vegetation, for instance over woods of considerable area (Raupach et al. 1996). However in rivers macrophytes form patches variable in size and locality with well defined margins and spatially separated by areas of free flowing water (Sand-Jensen & Pedersen 1999; Sukhodolov & Sukhodolova 2005). Therefore in natural streams the areas over which spatially uniform mixing layers develop may be relatively small and the flow is thus permanently evolving. For that reason the knowledge on spatial dynamics of mixing layers in natural streams with submersed vegetation is particularly valuable.

Another important difference between terrestrial and freshwater vegetation is flexibility and buoyancy of the later. These properties of submersed plants make the characteristics of submersed canopies dependable upon the bulk characteristics of the flow – mean velocities and depth. The relationships between elastic deformations and buoyancy of plant species, and flows drag and lift are extremely complex and generally unknown – what makes prediction of deflected canopy height and projected area of plants uncertain.

Because of difficulties to carry out detailed field studies of mixing layers over submersed vegetation in natural stream the research was hitherto carried out in the laboratory facilities with a simulated vegetation (Ghisalberti & Nepf 2002). Some preliminary data about velocity and turbulence intensity distributions over the patches of macrophytes were obtained by Sand-Jensen & Pedersen (1999). Their pioneering study presents an excellent qualitative picture but unfortunately lacks the quantitative analysis and is insufficient in detail for examining the evolution of mixing layers.

The goals of the present study were: (1) to investigate the dynamics of the flow over submersed vegetation in a natural stream; (2) to explore the applicability of mixing layer analogy and spatial evolution of mixing layers over macrophytes patches; (3) to examine complex relationships between density of plant canopies, flow velocity and deflected height of canopies. To achieve these goals a field-scale experimental study has been carried out in a straight reach of a lowland river. The design of the study included an original methodic combining field measuring study traditional for natural conditions with an experimentation aimed at exploring wider range of governing flow variables characteristic of laboratory investigations. Therefore the study besides the focus of its own program provides a valuable link between contemporary field and laboratory methods. This paper presents the first results of the study and concentrate on the details of experimental procedures, analysis of spatial patterns of mean velocity and Reynolds stresses distributions, attempts to generalize the findings, and also briefly discusses further research on this study.

2 FIELD EXPERIMENTS

2.1 *Experimental river reach*

Field experiments were performed in the lowland river Spree near the village Freienbrink, 10 km east of Berlin, Germany. In the study reach the channel is straight with stone armored banks and with a bed covered by sands of about 1 mm in diameter. Detailed information about river reach morphology, morphodynamic processes and seasonal dynamics of submersed vegetation cover on the reach is provided by previous investigations (Sukhodolova et al. 2004; Sukhodolov & Sukhodolova 2005). The study was completed in July 2005. Hydraulic and morphometric characteristic of the bulk river flow and experimental conditions are presented in Table 1.

Table 1. Bulk characteristic of the flow during field measurements.

Run	Q, m^3/s	U, m/s	H, m	h, m	S, $\times 10^5$	ρ, kg/m^3	Fr,	Re, $\times 10^{-5}$	$\sqrt{gHS}$, cm/s

2.2 *Experimental program*

The main purpose of the experimental program was to obtain the spatial patterns of flow characteristics over a patch of submersible plants. Experimentation was attained by means of control provided on the properties of the vegetation patch – its composition, location, and density of the canopy. Measurements of instantaneous velocities were taken on the verticals distributed along the longitudinal axis of the patch. Experimental run typically consisted of ten vertical profiles and a stationary point. After completion of each particular experimental run the canopy density was progressively reduced by factor of four preserving uniformity and the pattern of plants distribution and a next run was commenced.

The patch of rectangular shape 4×8 m in dimesion was created artificially in the central part of the river reach. It was composed of uniformly distributed submerged macrophytes *Sagittaria Sagittifolia*. The plants of approximately the same dimensions (leaves length 1.6 m, number of leaves 12, and the diameter near the root of 20 mm) were gathered over the river reach and manually implanted, Figure 2. The aluminum rods of 20 cm in length were fixed by wires at roots of individual plants before implanting. The rods were completely buried into the riverbed together with roots of the plants enabling firm plantation in the river flow. Positioning of plants was assisted with the aluminum guides spanned by marks on 20 cm intervals. The plants were distributed uniformly on a chess board pattern, Figure 3. A week later after macrophytes implanting, the control observation indicated that plants accommodated completely to the new locations and produced fresh rhizomes.

2.3 *Measuring systems and equipment*

The acoustic Doppler velocimeter (ADV) was used to measure velocities in this study. The device is capable of remotely sensed three-component sampling of velocities at frequency of 25 Hz. To mount ADV probes customary manufactured mounting equipment was employed. This equipment consists of an adjustable T-shaped platform designed for accurate positioning and easy traversing of velocimeters probes along the flow, Figure 4. During measurements 3 synchronized ADV probes were operated by a portable computer set on a floatable platform equipped with a shelter for an operator, Figure 4. The ADV probes (5-cm distance from the tip to the sampling volume, on 1-m cable) were attached to the ends of 2-m long aluminum rods positioned in the vertical directions by elevating nodes. A pair of orthogonal cylindrical bubble levels was used to align the rods along vertical axis. The third ADV probe was set upside down on the riverbed at a stationary location in the upstream part of the vegetation patch, Figure 5. The T-shaped platform was firmly secured to the riverbed by 6 taglines. Vegetation naturally grown around the artificial patch was preserved and this way provided conditions typical for surrounding flow environment over natural vegetation patches, Figure 5.

Surveys of riverbed morphology and measurements of free surface slope were performed with a laser total station Elta R55. Local river depth was measured with standard hydrometrical wading rods. Bed material was collected manually with a handy sampler.

To measure the deflected height of the vegetative canopy *in-situ* a purposely developed underwater video system UVS-RAY was employed in this study. The system consists of a digital camera Olimpus

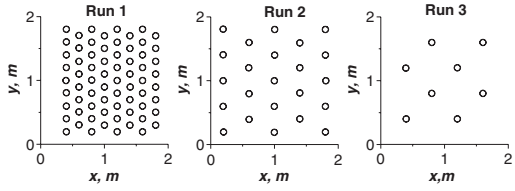

Figure 3. Patterns of spatial distributions of plants in the field experiments.

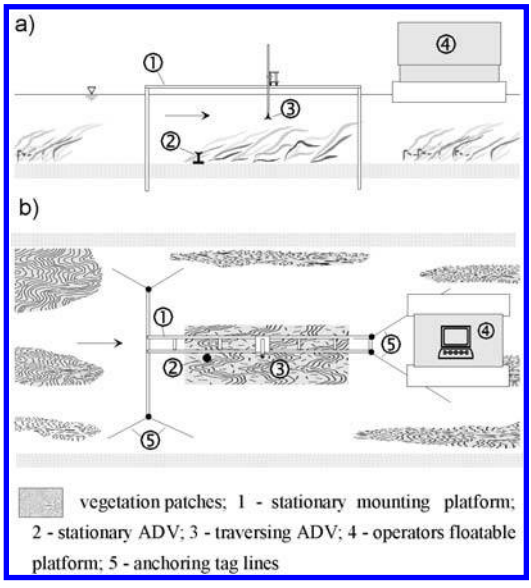

Figure 5. Schematic view of the experimental setup.

C-5060 with a wide angle lens converter WCON-07 mounted in an underwater housing IKELITE and an underwater lighting system Werner Videolight 100. The camera was installed on a platform aligned with a wire screen. The mesh of the screen (10 cm) provides a reference coordinates enabling further processing of the obtained digital video records. Two examples of underwater pictures taken with UVS-RAY are shown in Figure 6.

2.4 *Measurements*

Instantaneous 3-D velocities were measured at seven points uniformly distributed over each vertical profile. Records were taken at 25 Hz sampling rate and over 300 s sampling periods for each point. To prevent crossing of ADV sampling volume by plant leaves the plants adjacent to probes were removed. As laboratory studies indicate (Ghisalberty & Nepf 2002; Ikeda & Kanazawa 1996) that removal of up to four plants had produced no significant effect on the flow.

Video recording of the underwater canopy was performed for each experimental run after velocity measurements. Video records were taken over 50 second for each of five frames juxtaposed longitudinally on the right hand side of the experimental vegetative patch. At the last frame (downstream edge of the canopy, Figure 6b) video recording was taken synchronously with ADV records during 300 s periods.

Water surface levels and the slope of free surface of the flow were measured prior and after velocity measurements on each vertical. Fluctuations of water level were within 3–5 mm which was negligible small in comparison with the mean depth of the flow. The

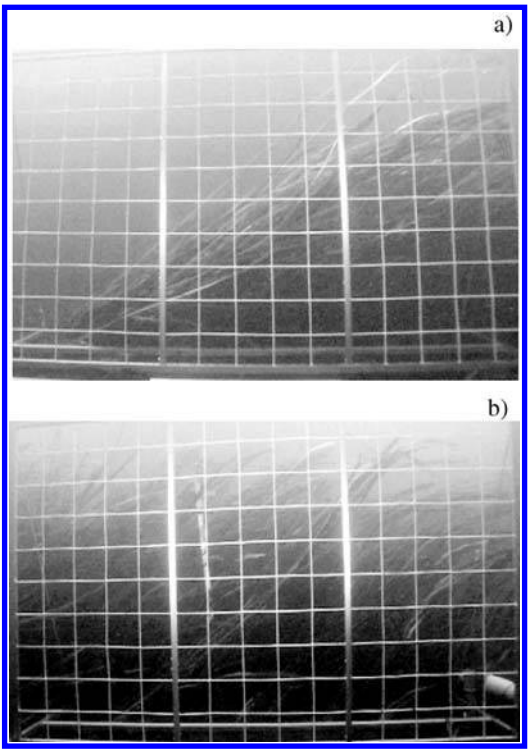

Figure 6. Side view of the experimental patch of macrophytes, Run 1, (a) – upstream edge and (b) downstream edge.

plants removed in the course of reduction of the canopy density were collected, dried and later weighted to determine a biomass density of the canopy.

2.5 *Data processing*

Time series of velocity measurements were processed with a versatile commercial software package ExploreV 1.5, Nortek AS, Norway. The software provides interactive graphical environment enabling fast and comprehensive data treatment. It allows editing, clipping, filtering of row data, stationarity, spectral, cross-spectral and other advanced methods of analysis including the data processing on a spatial grid.

With the use of ExploreV measured time series were inspected visually to identify possible problems, such as spikes, trends or abrupt discontinuities in the time series. Frequency distributions of the velocity data were also examined to identify outliers. Examination of these distributions is especially valuable for determining errors associated with large spikes resulting from interruption of the acoustic signal by large pieces of debris moving through the sampling volume. Spikes always generated velocity values more than 3 standard deviations from the mean (3σ). These spikes were removed and replaced with values generated by linear

Copyright © 2006 Taylor & Francis Group plc, London, UK

interpolation between adjacent data using a 3σ filter in the time series option of ExploreV. In all cases this post-processing procedure did not greatly affect the values of means, producing changes of only few mm/s.

Video records were converted into a sequence of digital images in the format JPEG with the specialized software DVD Create. JPEG images were imported into GRAPHER 6 software and the boundaries between free flow and macrophytes were digitalized. The physical coordinates of the boundaries were computed using calibration screen marks (Figure 6) and averaged over the sequence of the frames to obtain double time-spatial averages of variable canopy boundaries.

3 RESULTS AND ANALYSIS

3.1 *Mean velocities*

Distribution of measured mean flow velocities over the vegetative stand of plants is shown in Figure 7. Density of the vegetative canopy is decreasing on this plot from (a) to (c), plot 7d corresponds to a zero density. The boundaries of the layers of the flow are depicted in accordance with a definitional scheme of the canonical mixing layers (Figure 1).

The data in Figure 7a obviously indicate a flow pattern resembling at first glance the canonical mixing layer, Figure 1. However, there are noticeable distinctions between these mixing layers. First, in the canonical mixing layer velocity difference Δu is constant along the whole lengths of the flow domain while measurements indicate systematic growths of Δu in the streamwise direction. The second difference is the direction of mixing. In the canonical flow faster stream accelerates the slower flow and therefore the mixing layer appears progressively transversely distorted toward the slower flow. Figure 1 indicate the opposite – the domain occupied by the faster flow progressively decreases toward free surface of the flow. With the decrease of vegetation density the lower boundary of the layer is decreasing and at lowest density the mixing layer hits the riverbed. Obviously that at low density of vegetation the flow behaves much like perturbed boundary layer rather than mixing layer.

3.2 *Reynolds stresses*

Measured spatial patterns of the principal component of the Reynolds stresses tensor $-\overline{u'w'}$ are shown in Figure 8. Dashed lines on this plot are also marking the boundaries of the mixing layers. However for Reynolds stresses the boundaries were determined differently. Intersects of zero or nearly zero values of Reynolds stresses with vertical axis were considered to represent the boundaries of the layers. Comparison with the flow without vegetation indicates the applicability of this approach. Although principal features of the mixing layers conjectured from velocity distributions apply to those inferred from Reynolds stresses, there were some quantitative differences. In general, Reynolds stresses display somewhat broader layers than velocity distributions. The difference can be accounted for the fact that Reynolds stresses manifest subtle mechanisms that are smeared in velocity gradients.

Measured distributions of the Reynolds stresses also indicate that at far downstream distances of the mixing layer origin the maximum of Reynolds stresses practically coincide with the upper margin of the vegetative canopy, Figure 8. This observation supports an analytical treatment of the overlaying flow as a perturbed boundary layer.

3.3 *Velocity difference*

A principal feature of the canonical mixing layers is that they display constant velocity difference along the whole flow domain. This feature of course is not expected to hold in shear flows developing in vegetative canopies and therefore the behavior of the velocity difference is important for understanding the evolution of the flow. The velocity differences normalized by mean velocity of the layer u_c are shown in Figure 9.

Two types of changes in the velocity difference can be observed in Figure 9. In runs 1 and 2 the velocity difference increases at the beginning of the mixing layers and then, at distances larger than 3 m from the upstream margin of the vegetative patch, the differences stabilize and remain practically constant over the downstream part of the patch. When the density of plants is low (experimental run 3) the velocity difference decreases at downstream distances close to origin and then gently increases at far downstream, Figure 9.

3.4 *Mixing layer widths*

Mixing layers widths determined for certain verticals from velocity and Reynolds stresses distributions are summarized in Figure 10. Figure 10a shows mixing layers widths δ_v obtained from velocities (Figure 7), and Figure 10b the values δ_s from Reynolds stresses (Figure 8). For comparison Figure 10 represents spatial dynamics in the canonic mixing layer with a constant velocity difference and spreading coefficient $\alpha = 0.18$, reported in many literature sources (Brown & Roshko 1974; Tukker 1997). Dashed lines in Figure 10 indicate the spatial dynamics in the far field of the boundary layer $\delta \sim x/\ln x$ (Tennekes & Lumley 1972).

It can be seen from Figure 10 that measured mixing layer widths agree with equation (1) quite closely at distances shorter than 4 m and systematically deviate at far downstream. The departure from (1) obviously depends on the density of vegetative cover and the experimental data exhibit convergence to the behavior typical for the boundary layers. Such convergence should be naturally expected as with the decreasing

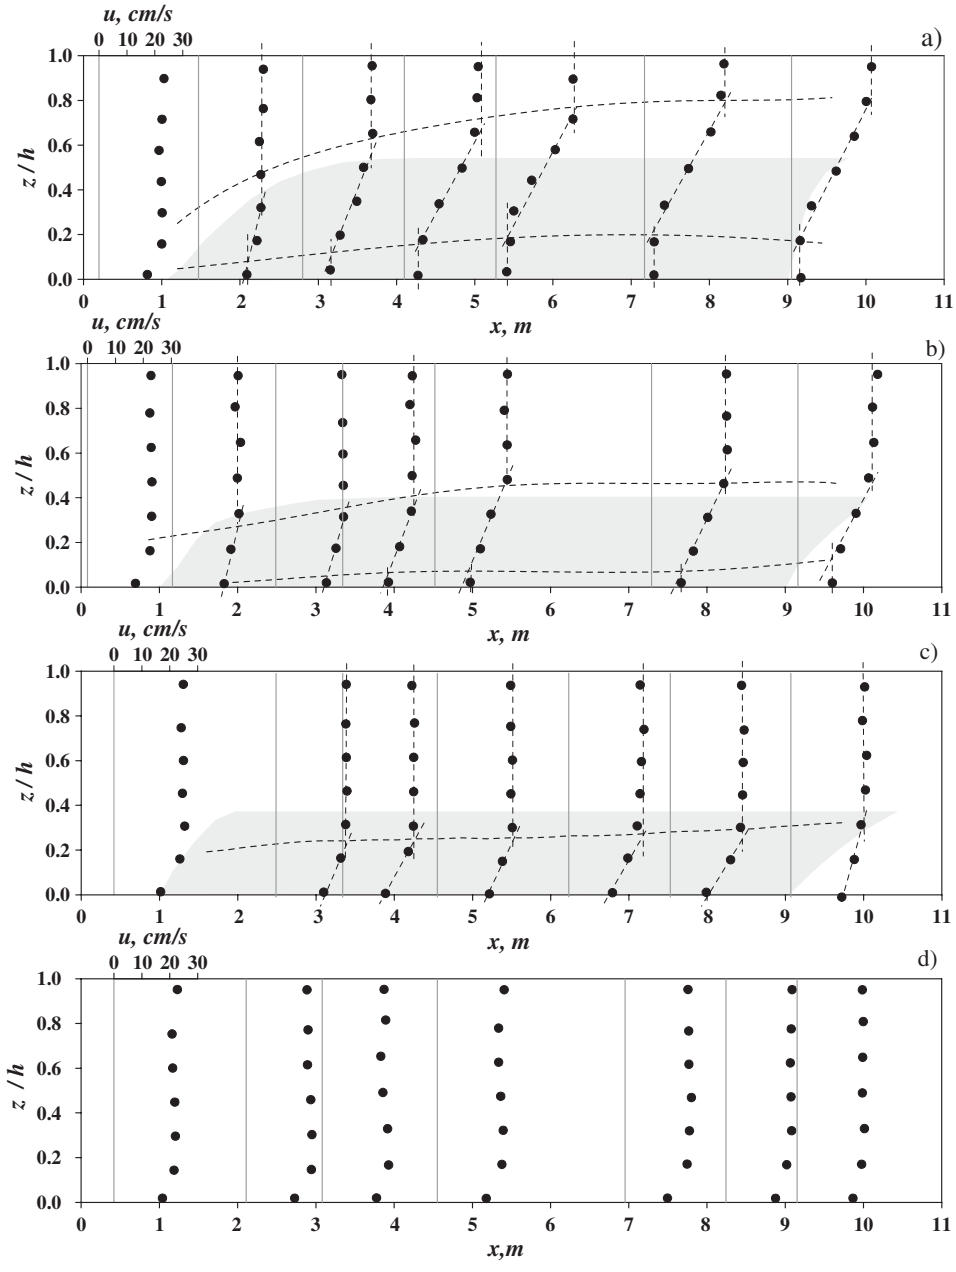

Figure 7. Vertical profiles of mean streamwise velocity as a function of position over the experimental vegetative patch: a) run 1; b) run 2; c) run 3, and d) run 4 (dashed lines mark the boundaries of the flow layers).

density of vegetation the lower boundary of the mixing layer converges to the riverbed.

3.5 *Vertical velocity distribution*

The data on mixing layer widths were used to normalize measured mean streamwise velocities in accordance with equation (3). The vertical positions of measuring points were centered in respect to the mixing layer centerline z_c and scaled with the local width of the mixing layer. Velocity deviations from mean inside the mixing layer were normalized with velocity difference across the flow, Figure 11.

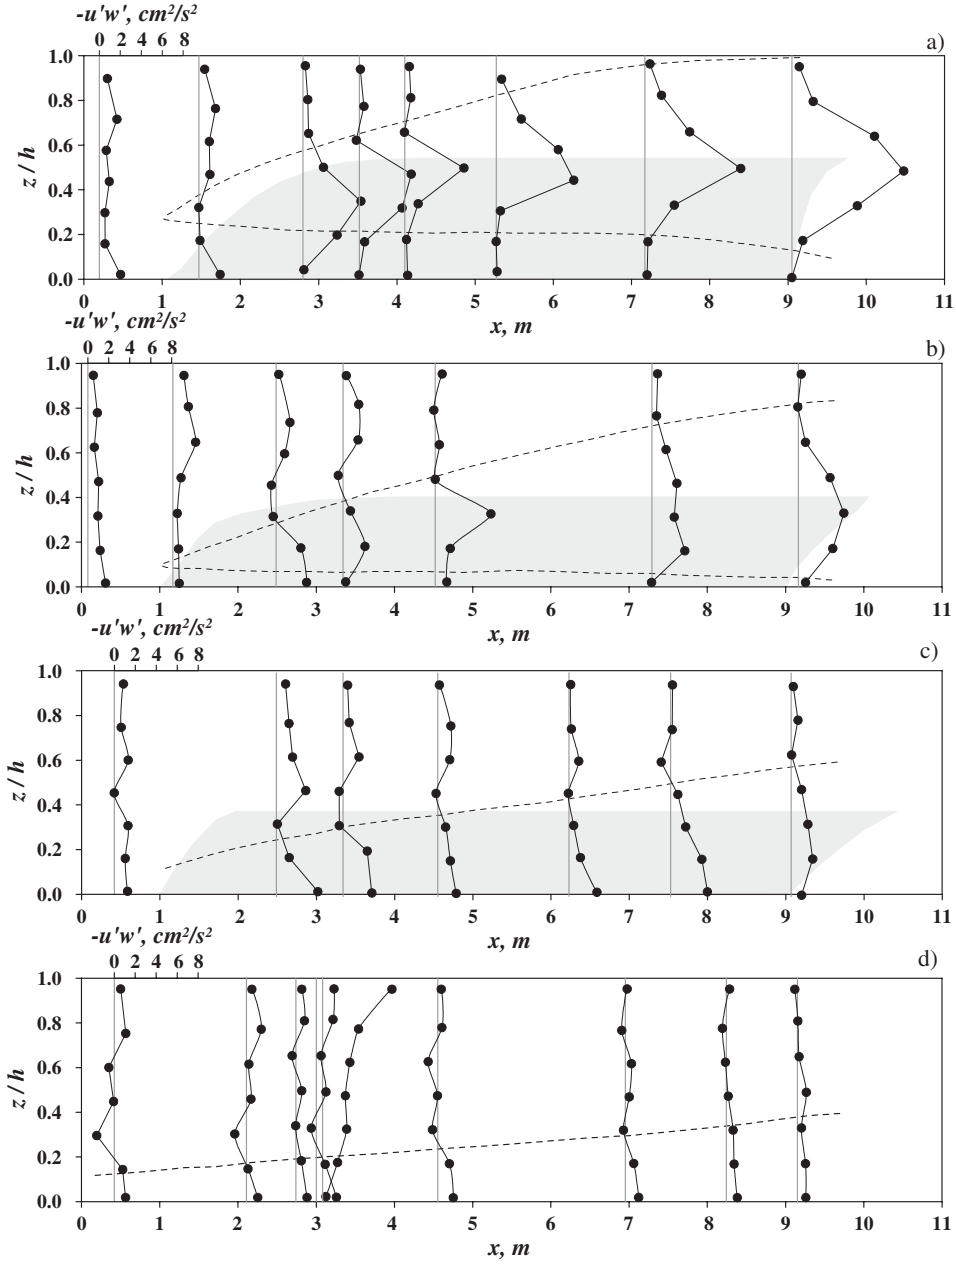

Figure 8. Vertical profiles of Reynolds stresses as a function of position over the experiemntal vegetative patch: a) run 1; b) run 2; c) run 3, and d) run 4 (dashed lines mark the boundaries of the flow layers).

Normalized data indicate a collapse at a certain curve characteristic for mixing layers, Figure 11. Comparison of this pattern with the universal dimensionless profile indicates a reasonable agreement for runs 1 and 2, Figure 11a,b. In run 3 the data systematically deviated from equation (3). Vertical velocity distribution measured in far downstream of the vegetative patch indicate only minor scatter around (3) while in the near field of the patch origin the scatter was significantly larger. This scatter is most probably attributed

Copyright © 2006 Taylor & Francis Group plc, London, UK

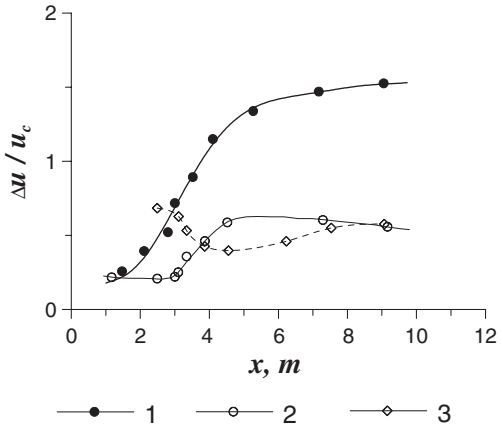

Figure 9. Downstream variation of velocity difference across mixing layers (numbers indicate experimental runs).

to the stochastic instability of field conditions of measurements rather then physically explainable flow behavior.

3.6 *Effect of vegetation density*

In previous sections it was clearly shown that flow characteristics and also reconfiguration abilities of vegetation depend on the vegetation density. To quantify the effect of vegetation a simple dimensionless analysis suggests

$$\frac{\Delta u}{u_c} = f_1\left(\frac{\rho}{\rho_0}\right), \text{ and} \tag{4}$$

$$\frac{h_l}{h} = f_2\left(\frac{\rho}{\rho_0}\right) \tag{5}$$

where h_l is average height of the macrophytes in a patch, ρ_0 is density of water. At first approximation empirical functions f_1 and f_2 can be obtained using a standard least square method, Figure 12. The following relations were established

$$\frac{\Delta u}{u_c} = 0.44\exp\left(0.87\frac{\rho}{\rho_0}\times 10^4\right) \tag{6}$$

$$\frac{h_l}{h} = 0.35\exp\left(0.33\frac{\rho}{\rho_0}\times 10^4\right) \tag{7}$$

Both velocity difference and the average height of macrophytes in a patch decay exponentially with the decrease of vegetation density. Although the applicability of least squares method to a data set of only few points may seem unreasonable, we think that derived equations are valuable because they are still today the only relations representing basic parameters for natural conditions.

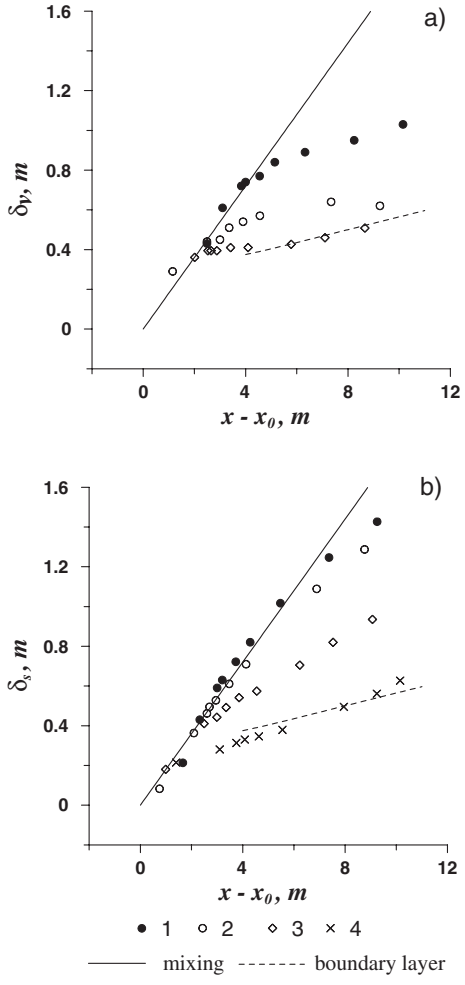

Figure 10. Downstream evolution of the mixing layers.

4 DISCUSSION AND CONCLUSIONS

This field-scale experimental study was performed to investigate spatial evolution of the mixing layers in a river with submersed vegetation. In this study the patch of natural uniformly distributed submersed plants was placed in the experimental river reach, and a series of accurate measurements of instantaneous velocities provided the spatial distributions of basic characteristics of turbulence. Obtained experimental data were compared with the evolutionary models of the canonical mixing layers. Variation of vegetation density in the experimental program provided possibility for investigating the effect of vegetation density on evolution of the flow over submersed vegetation. The study has revealed noticeable similarities and principal differences between canonical mixing layers and

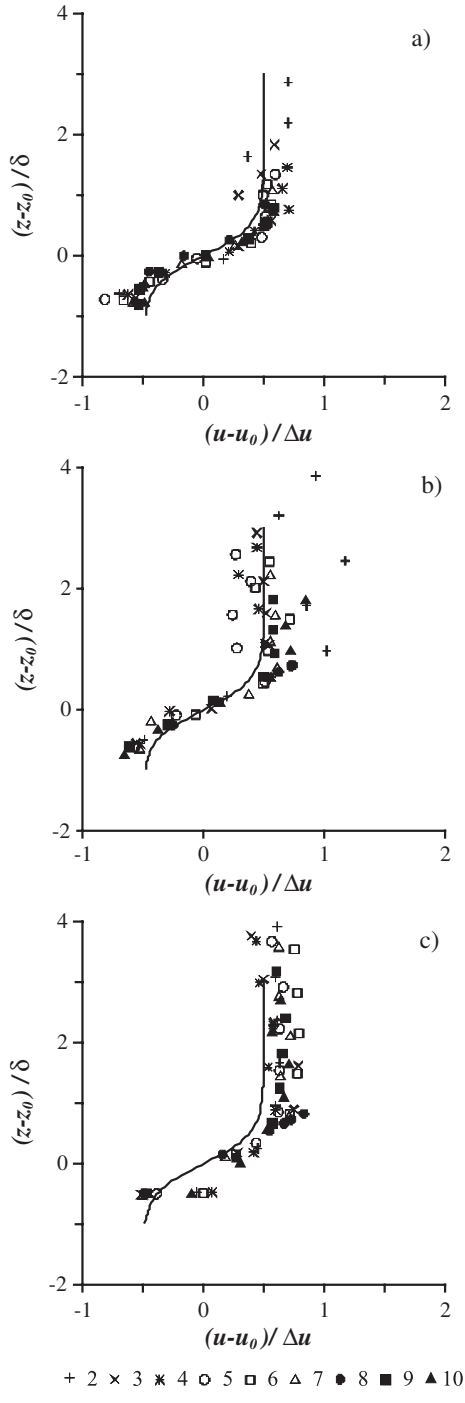

Figure 11. Vertical distribution of mean streamwise velocity component: a) run 1; b) run 2; and c) run 3.

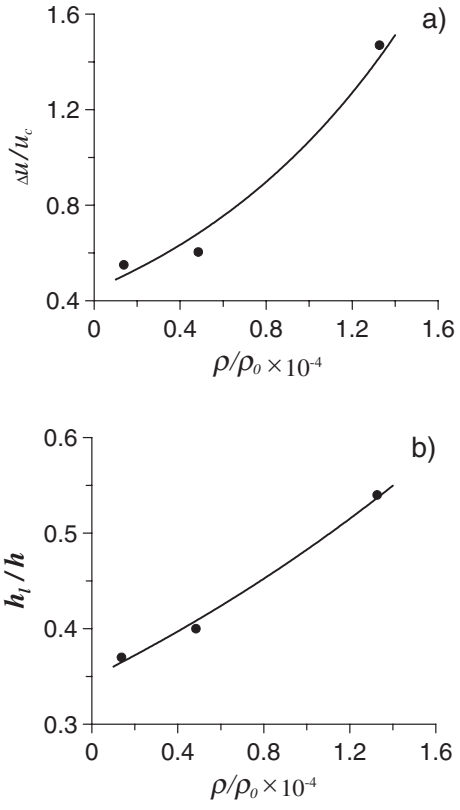

Figure 12. Velocity difference (a) and average height of vegetation in a patch as the functions of vegetation density.

the flow over submersed vegetation. A principal difference between the canonical mixing layer and the flow over submersed vegetation in a river is the evolution of the velocity field. In contrast to the canonical mixing layer with a constant velocity difference between the mixing flows, the flow over submersed vegetation maintains the velocity difference along a certain distance at near field of the vegetative patch origin. As the upper boundary of the flow reaches the free surface of the flow the mixing layer attains nearly constant velocity difference. The width of the developed mixing layer over submersed vegetation is thus controlled by two vertical length scales – the local river depth, and the penetration depth which strongly depends on the density of the vegetation cover.

As the velocity difference is variable, this experimental observation invalidates the applicability of the model (1), and (2). Adequate representation of the mixing layer will require formulation of dynamical relation for spreading coefficient as a function of spatial distance and density of vegetative cover. Similar solutions were applied in the models of shallow mixing

Copyright © 2006 Taylor & Francis Group plc, London, UK

layers where velocity difference was decreasing with the distance (Tukker 1997).

Vertical distribution of the streamwise mean velocity component in the form of hyperbolic tangent equation (3) was compared to the normalized measured velocity distributions. In general this comparison revealed applicability of equation (3) to describe velocity distributions in natural streams with vegetation. However, the results of the study also suggest that density of vegetative canopies should be also taken into consideration.

The conclusions of the study summarize as follows. The flows developing over submersed vegetative patches in natural streams behaves differently than in the canonical free turbulent mixing layers and mixing layers in shallow open-channel flows. At the same time these flows are shown to attain some self-similarity as the vertical velocity profiles can be scaled with the reasonable accuracy to reveal self-similar solution in the form of hyperbolic tangent function. This function was shown to describe satisfactory the velocity profiles in the canonical mixing layers, in the shallow mixing layers in open-channel flows, and in the developed laboratory flows over model submersed vegetation. In this study we propose simple empirical formulae relating main parameters of the flow and the average height of submerged plants in the patches to the dimensionless macrophytes density. Further studies required to explore the applicability of mixing layer model to describe flow over natural vegetative patches with non-uniform distribution of plants.

Although from a formal point of view, the flow in natural streams cannot be considered as free flow because its spatial evolution is limited by the free-surface of the river, this flow behaves as free flow over substantial domain and thus the term *mixing layer* should be preserved for classification purposes. However, certain specification for the term is required and by our opinion it should be qualified as a free-surface limited vertical mixing layer.

ACKNOWLEDGEMENTS

The authors acknowledge the help of Rüdiger Biskupek and Henrik Zwadlo in the construction of field equipment. Heinz Bungartz is thanked for assistance with organization of the field campaigns. Anna Sukhodolova and Mischael Thiele provided logistics support during measurements and Ruslan Andronov helped with underwater video recording. A new 1D-numerical model for flexible vegetated channels

D. Velasco, A. Bateman & V. Medina
Hydraulic, Maritime and Environmental Engineering Department, Technical University of Catalonia (GITS-UPC), ETSCCPB, Av/ Gran Capitan s/n, Barcelona, Spain

ABSTRACT: This paper suggests a simple new numerical scheme for calculating the vertical velocity profile, turbulent shear stress distribution and canopy deflection for flow in vegetated channels. The scheme is derived from the simplified, steady Reynolds equation (momentum balance) and its vertical integration. This study includes an experiment that compares and calibrates the numerical model to flume data. Fourteen runs were performed in a laboratory flume, of which nine involved natural grass (cultivated barley) and five involved plastic plants (PVC). Turbulent diffusion coefficient, mixing length, and a resistance equation (drag coefficient *Cd* vs. Reynolds number) were the input parameters for the numerical model. Parameters with physical meaning were calibrated. This scheme offers a low computation time and good estimation of plant deflection and velocity and stress profiles.

1 INTRODUCTION

When we study fluvial hydrosystems, we must not focus only on the various isolated elements involved in the process (water, sediment, vegetation and fauna). Rather, we must deepen our knowledge of their common relationships. We aim to study the effect of flexible vegetation on flow. The presence of flexible canopy (grass, bushes and reeds) in the riverbed and along the banks changes flow resistance and, in consequence, river hydrodynamics. Many authors (Kouwen, 1969 and Nepf, 1999) have experimented with plastic and natural canopy in their laboratories to obtain empirical relationships. The complexity of physical model studies and the popularization of numerical schemes in hydraulics have led to the development of applications focused on flow through vegetation. Three different lines of numerical research have been followed. First, well-known 3D turbulent schemes have been applied to special geometric boundaries to simulate obstruction due to vegetation. López and García (2001) and Fischer-Antze (2001) adjusted the two-equation κ-ε closure model to flow through vertical rigid cylinders. These simulations are quite well adjusted. Cui and Neary (2002) compared the numerical results of Reynolds-averaged Navier-Stokes (RANS) and large eddy simulation (LES) in order to reproduce the particular anisotropy generated in flow through rigid, submerged cylinders. Finally, Choi and Kang (2004) used Reynolds stress modeling (RSM) to improve mean and turbulent field results. High-accuracy numerical schemes will be developed in the future, but the high computational cost is still a disadvantage in terms of their practical application to large-scale hydraulic problems. A second group of researchers (Klopstra, 1997 and Carollo, 2002) has developed analytical expressions for adjusting velocity profiles $U(z)$ in very specific conditions, but the input parameters involved in the problem are hard to estimate. The third line of research is very interesting because it considers the flexural properties of vegetation and calculates the reduction in relative depth h/k due to stem bending. Kutija and Hong (1996) developed this line of research based on very simple turbulent models applied to the 1D Reynolds momentum equation. They calculated deflected plant height k using a function that reproduces the elastic behavior of a vertical beam or cantilever loaded by drag forces. Unfortunately, no data was available to verify the model with flexible vegetation, and the only data used in the calibration were from Tsujimoto's test with rigid cylinders.

This paper tries to improve this third line of research. We develop a new integrated momentum balance scheme for calculating the velocity and turbulent stress profile that includes a mechanical stem-deflection subroutine. We then verify and calibrate the results with our experimental data, which were measured in a flume covered with flexible vegetation.

2 GOVERNING EQUATIONS

The numerical model is based on integrated momentum conservation equations, Eqs. (1) to (4), which are obtained from the vertical integration of the Reynolds x-equation. Let us now recognize and separate four different zones in the flow. The resulting equations are written as Eqs. (1) to (4):

$$0 = \underbrace{\rho.g.So.(h-z)}_{\tau_G(z)} + \tau_{xz}(z) \qquad \text{ZONE 1. external region, } h > z > k$$

$$0 = \rho.g.So.(h-z) + \tau_{xz}(z) + \tau_{Cd}(z) \qquad \text{ZONE 2. internal region, } k \geq z > p$$

$$0 = \rho.g.So.(h-z) + \tau_{Cd}(z) \qquad \text{ZONE 3. shearless region, } p \geq z > \delta_o$$

$$0 = \rho.g.So.(h-z) - \nu.\frac{\partial U(z)}{\partial z} + \tau_{Cd}(z) \qquad \text{ZONE 4. laminar region, } \delta_o \geq z$$

(1),(2),(3),(4)

Zone 1, the "external region", corresponds to heights z from h to k, above the canopy, and thus has no drag forces. Integral Eq. (1) shows how the gravity shear term is uniquely balanced to turbulent shear stress τ_{xz}. Maximum turbulent stress is located, then, at $z = k$. Zone 2, the "internal region", is located below $z = k$. It is characterized by the presence of canopy. The vertical integration of drag forces f_{cd} from the top of canopy k to height z is the amount of shear stress that is absorbed by the plant (τ_{cd}). This vegetative stress is defined in Eq. (5), where C_d = drag coefficient, B = plant width and a = stem spacing. From Eq. (2), we can deduce that gravity shear stress is balanced by both vegetative and turbulent stress. Hence, turbulent stress τ_{xz} is reduced at $z < k$ and, if τ_{cd} is equal to gravity shear τ_G, then turbulent stress τ_{xz} disappears (see Fig. 1). This means that the momentum absorption capability of the canopy is greater than the hydraulic gravity shear. Zone 3 is delimited by height $z = p$, which is called the penetration depth (Nepf, 1999). This zone is called the "shearless region" because the turbulent stress τ_{xz} is negligible (Eq. (3)). In this region, there is no vertical momentum exchange, but turbulence is completely developed; the flow is governed by drag forces that balance the gravity shear completely.

$$\tau_{Cd}(z) = \int_z^k f_{cd}(z)dz = \int_z^k \frac{1}{2}.\rho.C_d(z).\frac{B(z)}{a^2}.U^2(z).dz \qquad (5)$$

The vertical computational domain is uniformly discretized with a Δz step, as shown in Fig. 2, and all of the variables are calculated at these nodes. Water depth (h), undeflected plant height (h') and deflected plant height (k) are denoted as *ih, ihp* and *ik* indexes respectively. Finite-difference approximations (forward differences) are used in the explicit method when vertical velocity U profiles are computed, and first order integral methods (Simpson's rule) are applied in integral operations. Because the scheme is explicit, the number of nodes must be considerable.

Two different boundary conditions must be set in the computational domain: 1) $\tau_{xz} = 0$ at the water surface ($z = h$), and 2) $\partial\tau_{xz}/\partial z = 0$ in the shearless region ($0 < z < p$). The application of the former to the Reynolds equation in the x direction leads to an expression that can be used to explicitly estimate velocity U. Thus, at the very first node of calculation, and for the entire shearless zone ($z_i < p$), velocity U_o is determined by

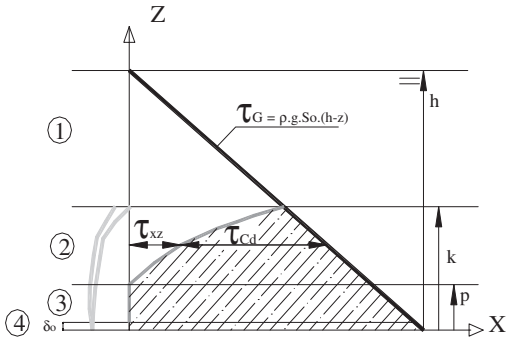

Figure 1. Shear balance scheme for high vegetative momentum absorption capability.

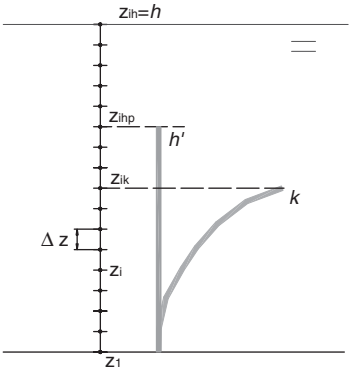

Figure 2. Vertical discretization scheme.

$$U_o = \left(\frac{2.g.So.a^2}{C_{d,o}.B_o}\right)^{1/2} \qquad (6)$$

where drag coefficient $C_{d,o}$ and plant width B_o correspond to node 1. This velocity boundary condition is critical because the general method is based on the hypothesis that the shearless region (Zone 3 in Fig. 1) is developed.

In order to relate Reynolds turbulent stresses to velocity gradients, we used Von Karman's turbulent mixing-length theory. This one-equation turbulence closure reflects momentum diffusion in a very simple way and could be considered a low-accuracy method. However, for the purposes of this work, the results are quite good as a first approach to the problem of

Copyright © 2006 Taylor & Francis Group plc, London, UK

turbulence. The turbulence mixing-length equation is expressed as follows:

$$\tau_{xz} = \rho l^2 . \left|\frac{\partial U}{\partial z}\right| . \frac{\partial U}{\partial z} \tag{7}$$

where ρ = water density and l = mixing length. Various theories on vertical profiles of mixing length $l(z)$, with and without vegetation, are found in the literature. We finally adopted Eq. (8) to estimate the variation of mixing length l as a function of depth. The integral scale L is analogous to the popular mixing-length l of the Von Karman turbulence closure equation because both concepts reflect a characteristic eddy scale. The diffusion mechanism is therefore not very different. We analyzed the vertical distribution of integral scale L from experimental profiles and concluded that, despite the dispersion of the estimated data, a linear tendency above $z = p$ was estimated. Eq. (8) describes the proposed distribution of mixing-length l:

$$\begin{cases} l(z) = l_o + \kappa' . (z - p) & \text{for } z > p \\ l(z) = l_o & \text{for } z \le p \end{cases} \tag{8}$$

where l_o is the mixing length in the shearless zone and κ' is a diffusion coefficient. Numerical parameters l_o (bed mixing length) and κ' (diffusion coefficient) are unknown and must be calibrated, but the advantage is that both of them have a particular physical meaning.

The intrinsic effects of secondary currents and the turbulent anisotropy of flow over vegetated covers are introduced in the model by a simple preliminary approach. The experimental data show the effective reduction of the energy slope ($So_{max\ shear}$), so we propose using a secondary current factor α_{sc}, defined as $\alpha_{sc} = S_{o,max\ shear}/S_o$, where S_o=channel slope (in uniform flow conditions). The value of α_{sc} is always less than one. As a turbulent parameter, it must also be calibrated.

Finally, the drag stress term τ_{cd} in the governing equations (2) and (3) is estimated using Eq. (5). The numerical integral is expressed as Eq. (9):

$$\tau_{Cd}(z_i) = \frac{\rho}{2.a^2} . \int_{z_i}^{z_{ik}} C_{d,j} . B_j . U_j^{\,2} . dz \tag{9}$$

where C_{dj}, B_j and U_j are the drag coefficient, plant width and velocity respectively at node j.

Special care must be taken in the estimation of drag coefficients C_{dj} because they are closely related to the resistance to flow over vegetated covers. The value of C_d is very sensitive to changes in the flow turbulence regime, which is governed by the obstacle or stem Reynolds number $Re_d (= U.B/\nu)$, where ν = water kinematic viscosity. Therefore, a resistance

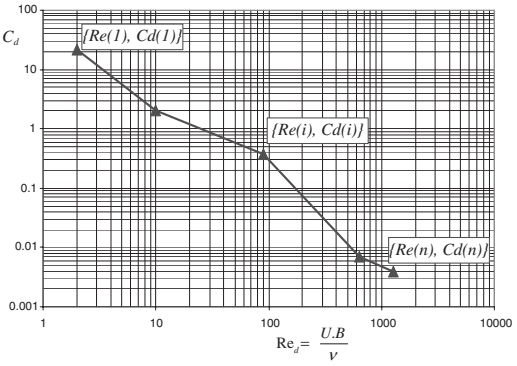

Figure 3. Estimation of the Cd(Red) law as a linear approximation between a series of discrete points {Red(i), Cd(i)} in a log-log graph.

function of the type $C_d(Re_d)$ is added to the model to take this important factor into account and Re_d is calculated at every computational node i as Eq. (10):

$$Re_{d,i} = \frac{U_i . B_i}{\nu} \tag{10}$$

Unfortunately, the classical resistance laws $C_d(Re_d)$ of 2D rigid bodies that have been widely studied in the past are not applicable to the heterogeneous shape of stems and leaves. New relationships must be researched. In order to further the fitting-optimization procedure, the estimation of the $C_d(Re_d)$ law was introduced as a linear approximation between a series of discrete points {Re_d (i), C_d (i)}, for i = 1,n, in a log-log graph. Fig. 3 shows the proposed resistance law as a function of a series of n = 5 points.

The numerical estimation of drag coefficient C_d at node i is based on the previous calculation of $Re_{d,i}$ by Eq. (10) and the application of the linear discrete function $C_{di,} = \Psi_n(Re_{d,i})$. This C_{di} value is included as drag in Eq. (9).

3 DESCRIPTION OF THE NUMERICAL PROCEDURE

3.1 *General iterative scheme*

This numerical model aims to create an iterative succession of well-balanced flow solutions that can generate the final stabilization or convergence of the deflected plant height k. Fig. 4 shows the computational flowchart. At each iteration i, the deflected plant height k^i is calculated and, as a consequence of the geometric change, a new flow solution $U^i(z), \tau^i_{xz}(z)$ is obtained. At this point, the plant deformation is recalculated using the aforementioned flow conditions and a new deflected plant height k^{i+1} is incorporated at iteration $i + 1$. The computation finishes when

Copyright © 2006 Taylor & Francis Group plc, London, UK

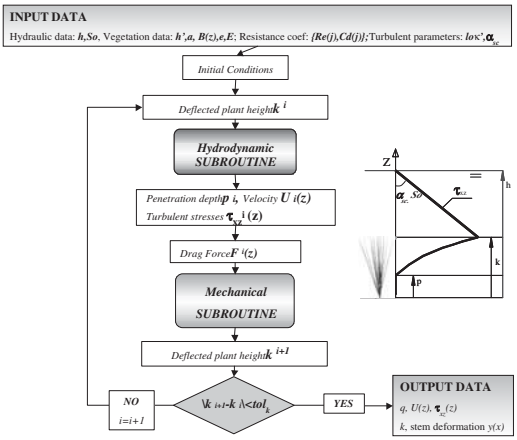

Figure 4. General flowchart.

a convergence in $\{k^i\}$ is a set ($\backslash k^{i+1} - k^i \backslash < tol_k$). The flow solution is then considered dynamically and mechanically balanced.

The input data consists of hydraulic variables: water depth h, energy slope So and the vegetation's geomechanical properties (undeflected plant height h', plant spacing a, vertical distribution of plant width $B(z)$, thickness of stems e, stiffness modulus E, the resistance law $\{Re(j),Cd(j)\}$ and three turbulence parameters [bed mixing-length lo, diffusion coefficient κ' and secondary currents factor α_{sc}]). The results of the model (output data) are unit discharge q, velocity $U(z)$, Reynolds stresses $\tau_{xz}(z)$, deflected plant height k and stem deformation $y(x)$.

The model can estimate the unit discharge q given an initial water depth h and an energy slope So, which is equivalent to solving the flow resistance equation for any kind of vegetation. Friction factors (the Darcy-Weisbach f or the Manning n) can easily be deduced from the hydraulic results.

The general scheme is very simple in its conception, but the most important and critical part is the creation of adequate modules to calculate velocity profiles and stem deformation. The hydrodynamic subroutine calculates flow profiles $\{U^i(z),\tau_{xz}(z)\}$ for a particular plant height k and the mechanical subroutine estimates the deflected plant height k as a function of drag forces $F(z)$. The next section briefly explains the numerical methods used in these two subroutines.

3.2 *Description of the hydrodynamic subroutine*

The numerical strategy used to estimate well-balanced velocity profiles is based on a predictor-corrector technique for Reynolds stresses τ_{xz}. and a minimization function. Fig. 5 shows a flowchart and a schematic diagram with predicted τ_{xz} and corrected τ_{xz} profiles.

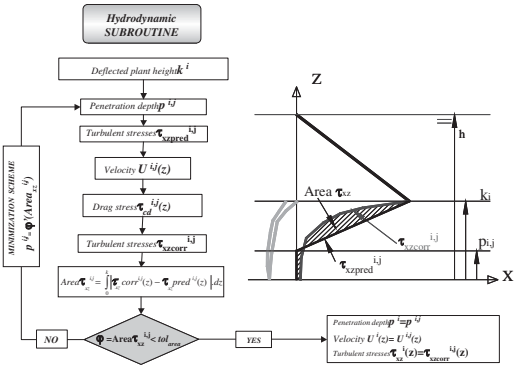

Figure 5. Flowchart of the hydrodynamic subroutine.

Based on a constant deflected plant height k^i (the input of this subroutine), a penetration depth $p^{i,j}$ is proposed and a linear distribution of turbulent stresses $\tau_{xz,pred}{}^{i,j}(z)$ is then predicted (as seen in Fig. 5). Eqs. (6) and (7) are then used to calculate the velocity profile $U^{i,j}(z)$ and Eq. (9) is used to estimate drag stresses $\tau_{cd}{}^{i,j}(z)$. Then, the corrected $\tau_{xz,corr}{}^{i,j}(z)$ profile is balanced using Eqs. (1), (2) and (3). The area between the predicted and corrected stress profiles is then calculated using Eq. (11).

The value of $Area\tau_{xz}{}^{i,j}$ is then related to the penetration depth $p^{i,j}$, and a positive function is defined as $\varphi(p) = Area\tau_{xz}(p)$. Under this scheme, the minimization of function φ implies a well-balanced solution in the $\tau_{xz,corr}(z)$ and $U(z)$ profiles. An iterative, first-order minimization method is applied to $\varphi(p)$ and the solution (penetration depth p^i, velocity $U^i(z)$ and stresses $\tau_{xz}{}^i(z)$) is sent to the main program. The accuracy of the solution basically depends on the definition of function $\varphi(p)$ (existence and uniqueness of an absolute minimum). The analysis of this function shows that the search method's behavior and efficiency are sufficient.

$$Area\,\tau_{xz}{}^{i,j} = \int_0^k \left|\tau_{xz,corr}{}^{i,j}(z) - \tau_{xz,pred}{}^{i,j}(z)\right| dz \qquad (11)$$

3.3 *Description of the mechanical subroutine*

This subroutine consists of a numerical code that reproduces load-deformation processes in a stem. Each canopy element is modeled as a vertical, isolated beam or cantilever in order to simplify the structural problem. The forces on the stem are imported from the hydrodynamic subroutine and are applied to every calculation node in order to obtain an approximation $y(x)$ of stem deformation. Classical, analytical expressions of deformation on beams are not valid here, because they are only derived for small deformation conditions. Natural canopy elements bend easily in river floods.

Copyright © 2006 Taylor & Francis Group plc, London, UK

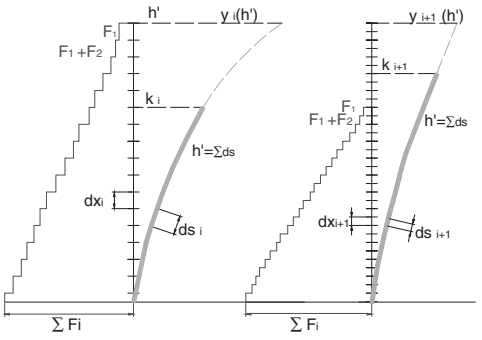

Figure 6. Numerical discretization and iteration process for the mechanical subroutine (large deformations).

Brushes and aquatic species also bend easily in normal flows. The deformation of the top of the canopy is often of the same order as the deflected plant height ($y(h') \cong k$). In the simulation, large deformations are required to adequately estimate the vertical deflected plant height k.

A discretization of the beam elasticity equation is applied in the stem (x is adopted as the vertical, longitudinal direction of the stem) and an explicit forward finite-difference scheme is computed to solve the transversal deformation profile y(x), as in Eq. (12):

$$\frac{\partial^2 y}{\partial x^2} = -\frac{Mf}{E.I} \tag{12}$$

where $y =$ transversal deformation, $Mf =$ moment (N.m), $E =$ stiffness modulus (N/m^2) and $I =$ cross area inertial modulus (m^4). The large deformation hypothesis conserves total stem length h'. The vertical load distribution (drag forces) must then be redistributed to reach equilibrium. A general iterative scheme is established in $\{y_i(x), k_i\}$ to converge to the deflected plant height k. The deformation profile $y_i(x)$ is calculated from Eq. (12) and the total stem length is measured along the deformed stem to define the deflected plant height k_i. New nodes are defined according to k_i. A new distribution of forces F is used. Then, $y_{i+1}(x)$ and k_{i+1} are calculated. Fig. 6 presents a diagram of the iterative procedure. The convergence into the solution is fast enough (less than 15 iterations, in general). In calculating large deformations, the additional bending due to second-order moments in the beam must be taken into account. New moments Mf' appear in the beam due to non-orthogonality between loads F and the longitudinal direction of the deformed beam(s). This effect is introduced as follows: 1) first-order moments Mf are used and a deformed profile $y(x)$ is obtained; 2) secondary moments Mf' are calculated from derivatives $y'(x)$ and vertical distances; and 3) a new calculation of the beam is performed for the total moments $Mf + Mf'$. The final result is a decrease from the first-order calculations in the deflected plant height k and an increase in the bending curvature (observed in real elastic materials). Fig. 7 demonstrates the importance of including secondary moments in order to more accurately reproduce the bending of elastic stems.

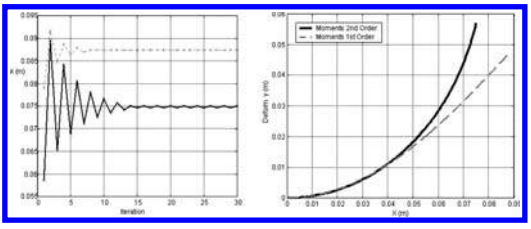

Figure 7. Comparison of computational stem deformation with (solid line) and without (dashed line) the calculation of secondary moments.

4 MODEL VERIFICATION

In this study, we were able to calibrate and verify the model in an accurate, controlled way due to a previous experimental study. Our own data was vitally important. Although the tests were limited in number (a greater variety of plant density and shapes would be desirable), we obtained detailed measurements.

To calibrate the mechanical subroutine, we performed load-deformation tests in the laboratory under strictly controlled conditions. We tested PVC cylinders with well-known geomechanical properties to check that the large deformation hypothesis and numerical algorithm were acceptable. We directly measured or estimated the geomechanical properties of the canopy (both PVC palms and natural barley stems), including length, average width and thickness, stiffness modulus E and inertial modulus I. These properties were introduced as input data in the mechanical model. The results were quite good for all load steps. Although the bending-stem curvatures were hard to reproduce (due to the heterogeneity of real stem properties), we assumed the discrepancies and finally accepted the model. Limitations were present for larger deformations ($k/h' < 0.6$). The adjustment between the measured and calculated deformation profiles presented the lowest accuracy (Fig. 8). The error on k was 12%.

The numerical results of the integrated model were compared to experimental data in order to verify the accuracy of the method. Fig. 9 shows two examples. First, the experimental data obtained by Tsujimoto (1990) was adjusted for flow through rigid cylinders. Run A11 involved vertical cylinders 4.59 cm tall and 1.5 mm in diameter, arranged in a staggered pattern with 2 cm spacing. The second run in Fig. 9 used data from our tests (barley cover). The flexible barley stems were 18 cm tall. The spacing between

Copyright © 2006 Taylor & Francis Group plc, London, UK

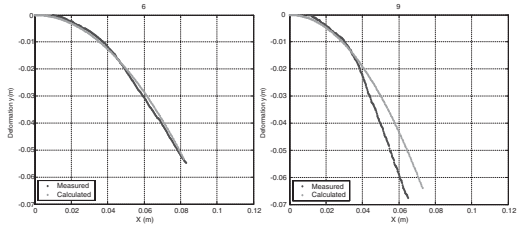

Figure 8. Comparison between measured and calculated deformations of a barley stem (length h′ = 0.125 m) for increasing loads.

stems was $a = 6.7$ mm and the submergence ratio was h/k = 1.83. The vertical distribution of plant width $B(z)$ was defined as a constant for cylinders and was variable for barley (calculated from a frontal image). The drag coefficients $C_d(z)$ were set as a unique value for cylinders ($C_d = 1.5$). For barley, the experimental values of $C_d(z)$ obtained from the barley test were used in the numerical model.

Computational input parameters such as mixing length lo, momentum diffusion constant κ', and the secondary current factor α_{sc} were adjusted for each run. For Tsujimoto's run they were $lo = 2.5$ mm, $\kappa' = 0.17$ and $\alpha_{sc} = 1.0$. For the barley run with TN-h′ = 0.18 m, the parameters were $lo = 10$ mm, $\kappa' = 0.08$ and $\alpha_{sc} = 0.78$. Fig. 9 shows very good agreement between the measured and calculated velocity profiles, and the velocity profile curvatures were reproduced quite well.

Calibrating the general model involved a significant amount of work. A particular set of general computational parameters needed to be found to fit all different tests. The list of unknown parameters included drag coefficient points, $\{Re(j), Cd(j)\}$, j = 1,5, mixing length lo, momentum diffusion constant κ', and the secondary current factor α_{sc}. A multi-parameter optimization technique was applied to fourteen runs with vegetation (T3 and TN runs) in which the canopy was deflected and totally submerged. The measured data used in the optimization routine was the unit discharge q_{mea} (m^3/m/s) and the velocity profiles $U_{mea}(z)$. Some discrepancies were obtained between the measured unit discharge q_{mea} and the vertical integral of $U_{mea}(z)$ due to 3D flow characteristics. Both measurements were integrated in the optimization function. This function Φ was defined as a quadratic function of the difference between the calculated output data and the measured data. A first-order, intelligent-conjugate-gradients technique was used to find the minimum of Φ. Table 1 shows the optimal adjusted parameters.

These parameters are consistent with the physical measurements, but some comments must be made about the resistance law. The values of adjusted $Re(j)$ and $Cd(j)$ are shifted with respect to measured data, as shown in Fig. 10. Adjusted drag coefficients C_d are lower than measured C_d. This shift is probably due to a numerical diffusion in the model.

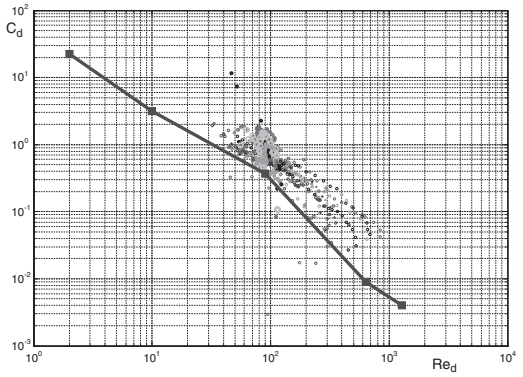

Figure 10. Optimally adjusted resistance law (Cd vs. Red) compared to experimental data (circles).

experimental data to computed data. Velocity $U(z)$ and Reynolds turbulent stress $\tau_{xz}(z)$ profiles are presented. In general, velocities and shear are both well adjusted. Very good agreement is observed for the penetration depth p, and the shearless zone is well defined in terms of velocity and shear. Velocity U_o in this zone is calculated as a uniform profile and agreement with measured U_o is sufficient. We therefore conclude that the proposed velocity boundary condition (Eq. (6)) is efficient. In Zone 2 (internal zone $p < z < k$), the calculated stress τ_{xz} shows some deviation from the measured data, but vegetative momentum absorption seems to be accomplished. The top of the canopy in the figure (circle) corresponds to the peak of calculated stress ($\tau_{xz,max}$) and approximately agrees with the peak of measured τ_{xz}. In the external zone ($z > k$), the slope of calculated τ_{xz} does not fit the data. However, the effects of secondary currents are simulated, which is a major goal of the numerical model and the calibration study. The calculated velocity $U(z)$ reproduces the gradients in the internal zone quite well, but there is some discrepancy close to the free surface.

Figure 12 shows the calculated *Re* and C_d vertical profiles and compares them to the experimentally measured profiles. The obstacle Reynolds number shows good agreement both for natural and artificial plants (plant shape controls *Re* distribution). However, as mentioned above, the numerical drag coefficients are lower than the experimental C_d. This effect is very important in the artificial plants (T3 runs), as shown in the figure.

Lower drag coefficients should translate into a reduction in drag stresses (see Eq. (9)). However, the final balance of momentum is well adjusted. This discrepancy should be reviewed in the future by verifying the adjusted parameters through new tests with a range of vegetation configurations (the influence of spacing a) and submergence ratios. The next step in the results analysis is mass conservation. In Fig. 13, the

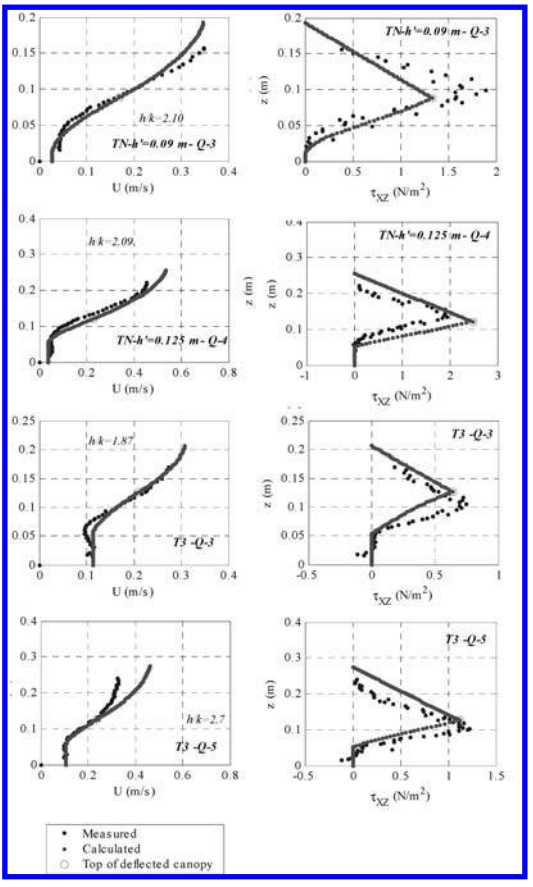

Figure 11. Comparison between calculated and measured U(z) and τ_{xz}(z) profiles.

water discharge (an output of the numerical model) is compared to the experimental discharge. For all fourteen tests, the comparison between the calculated unit discharge q_{calc} (m^2/s) and the measured q_{mea} shows a certain dispersion. The average estimation error is 14.8%, but the experimental error between q_{mea} and the vertical integral of experimental $U_{mea}(z)$ was set at 10%. We conclude that the data on discharge q is not much more accurate than typical laboratory work

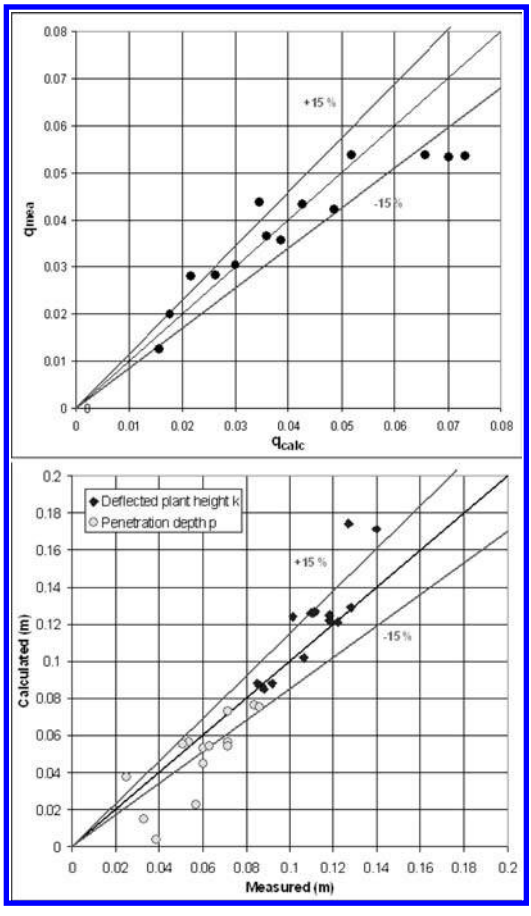

Figure 13. Numerical results for unit discharge q (top) and deflected plant height k and penetration depth p (bottom).

involving vegetation covers. Figure 13 also shows the results for deflected plant height k and penetration depth p. Some dispersion of data is detected, but the estimations are generally in an error range of 15%. More experiments are needed to check that the calculated deflected plant is adjusted to reality (especially in large deformation conditions, $h'/k > 0.6$).

6 LIMITATIONS OF THE MODEL

The integrated vegetation model is very useful for reproducing vegetative covers in both emergent and submerged plant conditions. Due to its low computational cost, this model can easily be incorporated into any general 1D or 2D hydraulic code to estimate friction factors in riverbeds and floodplains. However, the numerical code has certain limitations. The governing equations are only defined for the existence of a shearless zone, so vegetation must be able to absorb the total gravity shear τ_G. This model is therefore recommended for high-to-medium plant density (high A_o/a ratio). The model should be modified for flooding scenarios in which the canopy is totally prone, friction factors are low and an effective shear stress is acting on the river bed. Furthermore, the model introduces real convective currents in the flow through canopy (α_{sc} factor) but it is still hard to evaluate for different flow conditions. Finally, a more intense experimental campaign is needed to verify the proposed drag coefficient law $C_d(Re_d)$ for new plant shapes and configurations.

7 SUMMARY AND CONCLUSIONS

This paper presents an experimental and numerical study that provides deeper knowledge of resistance to flow through flexible vegetation. A numerical model was computed to simulate vertical velocity profiles and plant deflection. The scheme was derived from the simplified, steady Reynolds equation, which was vertically integrated above and along the deflected plant height k. A mechanical module was computed to estimate large elastic deformation in stems. Mixing-length theory was used in a turbulence closure equation for the hydrodynamic subroutine. We proposed an iterative convergence scheme for plant deformation k as a function of balanced drag forces. Finally, the well-balanced vertical velocity profile $U(z)$ was calculated using a simple, explicit finite-difference scheme.

In the experimental chapter, two different experimental flumes were used. Both natural (barley) and artificial (PVC strips) vegetative covers were fixed on the channel bed. Vertical velocity profiles U and turbulent shear stress τ_{xz} (obtained using ADV measurement techniques) provided valuable experimental data on every flow and vegetative configuration. Fourteen experimental runs were performed to verify and calibrate the numerical model. Turbulent diffusion coefficients, mixing length and a resistance equation (drag coefficient C_d vs. Re_d) were the input parameters of the model. Parameters with physical meaning were calibrated. A multi-parameter minimization algorithm was used to adjust the computed profiles to the experimental data. Finally, the parameters were estimated. In theory, these computational parameters should be universal and independent of vegetation shape and configuration. In practice, the uniqueness of this set of general parameters should be verified in the future using different species of vegetation.

This integrated model offers a low computation cost and a reasonable estimation of plant deflection, velocity and stresses. Vertical profiles are obviously less accurate than any 3D-turbulent scheme. However, the approximation errors are quite small and would therefore be easily dealt with in a general floodplain

calculation. This quick model is therefore very suitable and fast enough to be included in a future general 1D or 2D hydraulic model as a resistance function for vegetation.

ACKNOWLEDGMENTS

This research was supported by a *UPC per la recerca* grant (Technical University of Catalonia) and projects REN2000-1013/HID and BTE2002-0375. We are especially grateful to Prof. J.M. Redondo, who was very helpful in the initial phase of the experimental work.

NOTATION

The following symbols are used in this paper:

a	= Spacing between plants
A_o	= Frontal area of plant
b	= Channel width
B	= Average plant width
C_d	= Drag coefficient
E	= Stiffness modulus
h	= Water depth
h'	= Undeflected plant height
I	= Second-order geometrical momentum
k	= Deflected plant height
l	= Mixing length
L	= Integral scale
M	= Density of vegetation (plants/m^2)
Mf	= Moment
p	= Penetration depth
q	= Unit discharge ($= Q/b$)
Q	= Discharge
Re	= Reynolds number ($= U.h/\nu$)
Re_d	= Obstacle Reynolds number ($= U.B/\nu$)
R_h	= Hydraulic radius
S_f	= Energy slope
$S_{omax\ shear}$	= Experimental energy slope obtained from the τ_{xz}, vertical profile
S_o	= Geometric slope
U, V, W	= Longitudinal, transversal and vertical mean velocities respectively
u', v', w'	= Longitudinal, transversal and vertical velocity fluctuations respectively
u^*	= Shear velocity
α_{sc}	= Secondary current factor
γ	= Specific weight of water
κ	= Von Karman universal diffusion constant
κ'	= Diffusion coefficient
ν	= Kinematic viscosity
ρ	= Water density
$\tau_{xz}, \tau_{xy}, \tau_{yz}$	= Reynolds stresses
τ_{cd}	= Vegetative drag stress
τ_*	= Bed shear stress

Steady 1D water surface model of natural rivers with vegetated floodplain: An application to the Lower Biebrza

D. Świątek, J. Kubrak, J. Chormański
Warsaw Agricultural University, Warsaw, Poland

ABSTRACT: A steady 1D flow model for water surface calculation, based on the energy equation, was developed for natural rivers with vegetated floodplains. The friction slope was determined by the friction law of Darcy-Weisbach. The total Darcy-Weisbach friction factor for each cross section was calculated according to type of vegetation and flow interaction between main channel and vegetated areas. The model was applied to the Biebrza River, situated in the north-eastern part of Poland, flowing through the last extensive, fairly undisturbed river-marginal peatland in Europe. A 41 km long reach of the Lower Biebrza River, which basin covers 350 km^2, was selected for the study. The floodplains are covered by mosaic pattern vegetation. There are reeds, sedges, grasses, bushes as well as trees and scrubs. Three steady flow cases were computed. Two of them, when water levels are low, were compared to measured data. The absolute roughness values in the main channel were calibrated by the measurement in conditions where the water levels were less than bankfull levels. In the next case, when water was on the floodplains, the Digital Elevation Model of the floodplain constructed with the use of GIS techniques was coupled with calculated water level for spatial flood extent in the valley. Result was verified with the help of the processed Landsat satellite image. Water levels produced by the model correlated well with the measured data and the processed satellite image. Elaborated model can be also useful for water surface assessment in lowland rivers with floodplains and vegetation.

1 INTRODUCTION

Many studies were carried out in the past to investigate the hydraulic impact of natural roughnesses such as bank and flood plain vegetation or bed roughnesses of different textures on the overall flow field (see e.g. Rouve 1987, Kubrak & Nachlik 2003). The flow processes in channels with local flood berm vegetation between main channel and flood plains are very complex. The ability to model water level between the instream and floodplain is fundamental for assessing the quality of aquatic habitat for riverine biota, particularly floodplain vegetation and waterbirds. Precise hydraulic modelling of these relationships is difficult because of the lack of appropriately scaled information to describe floodplain topography and surface roughness. Non-uniform flow occurring in a lowland river with gradual changes in its free surface elevation is termed gradually varied.

Existing methods for water level calculation are, to varying degrees, unreliable for compound channel hydraulics. Therefore, more accurate methods are needed for calculation of water levels in these channels. The steady gradually-varied flow model was used for estimation of water profiles in the reach of the Biebrza River.

2 NUMERICAL MODEL DEVELOPMENT

2.1 *The steady flow model*

The water profile in steady gradually-varied flow was calculated using the standard step method. This method is characterized by dividing the river with compound cross sections into short reaches and carrying the computation step by step from one end of the reach to the other. Problem is formulated as follows: For a given discharge the river stage H_2 is known at one section (2) downstream and it is required to calculate the stage H_1 at the adjacent section (1) upstream. At both sections a plan of the waterway is available, from which values of cross section area, wetted perimeter, mean velocity, perimeter of vegetation, etc., may be determined for any given stage.

The equation for H_1 calculation is conduced from equating the total heads at two end sections:

$$\alpha_1 \frac{V_1^2}{2g} + H_1 = \alpha_2 \frac{V_2^2}{2g} + H_2 + \frac{1}{2}(J_1 + J_2)\Delta L \quad (1)$$

where H_1, H_2 = water surface elevation at the two end sections; J_1, J_2 = friction slopes at the two end sections, V_1, V_2 = mean velocities; and α_1, α_2 = energy

Copyright © 2006 Taylor & Francis Group plc, London, UK

coefficients at the two end sections; ΔL = length of the river reach.

For a trial value of unknown stage H_1 the values V_1, α_1, J_1 were calculated. The same values were calculated at section 2 by given stage H_2. The test of trial process is whether this value of H_1 is equal to the one previously calculated; if not, a further trial value must be taken.

The discharge of steady flow in the river was expressed as the product of the velocity and the water area. For the mean velocity calculation Darcy-Weisbach formula was used. Velocities, friction factors and the components of discharge in the main channel and on the floodplains were calculated using momentum transfer between the main channel and the floodplains were included in the model using Pasche method (Pasche 1984).

2.2 *Determination of friction factors*

Physically, the composite roughness along the wetted perimeter of the compound cross section modifies the velocity distribution across the cross section. A detailed examination on the effects of varying wall roughness and cross sectional geometry would require three-dimensional analysis of the flow. Pasche (1984) proposed the one-dimensional analysis of steady flow in compound cross section of the lowland river based on the Darcy-Weisbach formula.

According to observed velocity distribution the compound cross section is divided into sections with vertical interfaces into the main channel and neighbouring floodplains. The heights of these interfaces are taken into consideration at calculation of wetted perimeter of the main channel. Mean velocity of the flow in each section is calculated according to the Darcy-Weisbach equation, which results from the momentum balance in part of cross section:

$$v = \sqrt{\frac{8gRJ}{\lambda}} \tag{2}$$

where λ = average dimensionless friction factor of flow in given part of section, g = gravitational acceleration [m/s^2], J = hydraulic slope [-], R = hydraulic radius [m].

For the velocity calculation in each section proper evaluation of the friction factor λ is necessary. The resistance of flow in parts of channel sections overgrown by vegetation depends on both vegetation and bed roughness. The friction factor for this area, according to the concept issued by Einstein and Banks (Indlekofer 1981), is the following sum:

$$\lambda = \lambda_s + \lambda_v \tag{3}$$

where λ = average friction factor in part of cross-section [-], λ_s = friction factor caused by channel bed roughness [-], λ_v = friction factor for submerged vegetation [-].

The resistance of flow caused by the roughness of the scarp and the channel bed is calculated from the formula given by Colebrook-White:

$$\frac{1}{\sqrt{\lambda_s}} = -2.03 \log\left(\frac{2.51}{Re\sqrt{\lambda_s}} + \frac{k_s}{14.84\,R}\right) \tag{4}$$

where λ_s = friction factor of not overgrown part of channel [-], k_s = bed roughness of channel [m], Re = the Reynolds number for part of cross-section.

As it results from the Colebrook-White law, the friction factors of flow depend on the Reynolds number and on relative roughness k_s/R. The influence of the Reynolds number on friction factors decreases along the increase of its value and of relative roughness of channel sides. In natural channels the relative roughness is also considerable that the influence of the Reynolds number may be neglected without any harm to the precision of calculations. Therefore Rickert (1988) recommends to apply the equation (4) for practical calculations in the following form:

$$\frac{1}{\sqrt{\lambda_s}} = -2.03 \log\left(\frac{k_s}{14.84\,R}\right) \tag{5}$$

The friction factor of scarps and of channel bed with k_s roughness is then calculated from transformed formula (5).

The friction factors for high vegetation λ_v were the object of investigations by Kaiser (1984), Lindner (1982) and Pasche (1984). For areas with trees the λ_v factor is calculated on the basis of resistances caused by submerged vegetation and is related to the area of the whole floodplain:

$$\lambda_v = \frac{4h_p d_p}{a_x a_y} C_{WR} \cos\alpha \tag{6}$$

where h_p = height of submerged part of trees [m], d_p = trees diameter [m], α = the angle of slope of the bed in transverse direction to direction of flow, C_{WR} = dimensionless drag coefficient for submerged part of the trees.

The drag coefficient C_{WR} depends on the ratio of the V_i flowing velocity to the average velocity V_v of the flow going through tree-overgrown areas, and the height of waves formed on the surface of the water flowing around the trees:

$$C_{WR} = \left(1.1 + 2.3\frac{d_p}{a_y}\right)\left(\frac{V_i}{V_v}\right)^2 + 2\left(\frac{1}{1 - d_p/a_y} - 1\right) \tag{7}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

Pasche (1984) gave an empirical formula on the relative velocity of water flowing against the tree, and Rickert reduced it to the following form:

$$\left(\frac{V_i}{V_v}\right)^2 = 0.6 + 0.5log\left(\frac{a_x}{a_y}\right) \quad (8)$$

where a_x, a_y = distance between plants along the flow and transversal.

The way of calculation of flow intensity in the floodplain with trees is exemplified below. Calculation of the flow rate in a floodplain requires definition of the width of this area. For this aim we need calculation of the length a_{NL} and the width a_{NB} of the Karmann path of the round-the-tree flow.

$$a_{NL} = 128.87 C_{W\infty} d_p \left(1 + \frac{g\, a_{NL} J}{V_T^2/2}\right)^{-2.143} \quad (9)$$

$$a_{NB} = 0.24\, a_{NL}^{0.59} (C_{W\infty} d_p)^{0.41} \quad (10)$$

where a_{NL}, a_{NB} = the length and the width of the Karmann path formed at a single plant submerged [m].

The drag coefficient $C_{W\infty}$ is determined for a single tree at ideal two-dimensional flow. Its variability for different forms of the turbulent flow was given by Lindner (1982) in the equations:

$$C_{W\infty} = 3.07 Re_p^{-0.1680} \quad \text{for} \quad Re_p = \frac{V_v d_p}{\nu} < 800 \quad (11)$$

$$C_{W\infty} = 1.0 \quad \text{for} \quad 800 \le Re_p \le 8000 \quad (12)$$

$$C_{W\infty} = 1.2 \quad \text{for} \quad 8000 < Re_p < 10^5 \quad (13)$$

where Re_p = the Reynolds number for a single plant [-], ν = viscosity of water [m^2/s].

The calculations are conducted at the assumption of the V_T value, and of $V_T > V_v$, due to the occurrence of velocity V_T in the formula (9) for cross-section interfaces. Then the coefficient of overgrowing is calculated:

$$\Omega = \left(0.07 \frac{a_{NL}}{a_x}\right)^{3.29} + \left(\frac{a_{NB}}{a_y}\right)^{0.95} \quad (14)$$

The dimensionless velocity in interfaces is calculated from the formula:

$$C_T = -3.27 log\, \Omega + 2.85 \quad (15)$$

The width of the area of main channel flow influence on flows in floodplains is calculated from the formula:

$$b_m = \frac{h_T}{\lambda_v (0.068 e^{0.56 C_T} - 0.056)} \quad (16)$$

where h_T = depth of interfaces between main channel and floodplain [m]; c_T = dimensionless velocity in interfaces.

At calculation of the discharge in the main channel, the interface of the floodplain from the main channel is treated as the rough wall with roughness of channel k_T and friction factor λ_T. In reality these resistances are made by intensive cyclical impulses of mass and momentum in transverse direction to the main flow, as well as by associated high turbulence strains and whirls on the surface of water in round-the-tree flows. The roughness in the interfaces is calculated from the formula:

$$k_T = 0.854\, R_{hy,T}\, \Omega \left(1.7 \frac{2b_m}{b_k}\right)^{1.07} \quad (17)$$

where $R_{hy,T}$ = hydraulic radius concerning the resistance by the interface [m]; b_m = width of the zone of influence of the area with trees on the area without trees [m]; b_k = main channel width [m].

The occurrence of different roughness and friction factors in the main channel requires calculation of the average friction factor and the distribution of the hydraulic radius of the main channel according to the concept by Einstein assuming the equality of average velocity in every sub-domain of the main channel:

$$R_{hy,i} = \frac{\lambda_i}{\lambda} R_{hy,F} \quad (18)$$

where λ_i = friction factor of part-section with hydraulic radius; R_i, $R_{hy,F}$ = hydraulic radius of the main channel calculated with account of the length of interfaces h_T.

The calculation of the hydraulic radius for different roughness in cross-sections is conducted using the iterative method. The hydraulic radius in the interface $R_{hy,T}$ is calculated from the formula (18), then the equivalent height of roughness in the interface k_T from the formula (17) and the friction factor λ_T from the formula (5) for k_T.

The average friction factor in the whole main channel λ is calculated with consideration to the friction factors in the flow bed λ_s and λ_T in the interface cross-section:

$$\lambda = \frac{2\lambda_T h_T + \lambda_s l_s}{2h_T + l_s} \quad (19)$$

The average velocity of main channel flow is calculated from the Darcy – Weisbach formula (2), and the velocity V_T in the interface between the main channel and its floodplain from the formula:

$$V_T = C_T \sqrt{\frac{\lambda_v}{8}} V_F \quad (20)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The velocity V_T calculated from the equation (20) is usually different from the one assumed at the beginning of a_{NL} calculation (9); therefore the wholeness of calculations should be repeated, accepting the calculated value V_T according to formula (20) as the next approximation.

2.3 *Pre-processing programs*

The pre-processing programs were developed to create an input of complex data to steady state simulation. The first program is a graphical interface, which inserts measured coordinate points of cross-sections to the data and assigns vegetation parameters to segments of cross-sections. A computed channel is divided into components with different resistance parameters on the floodplains and in the part of the main channel.

The second program enables to the input of boundary conditions and distances between cross-sections along a main-channel and floodplains. It is capable of interpolating the cross-sections geometry with a selected space step.

The vegetation parameters are transferred to interpolated cross-sections from downstream part for each line segment between two adjacent measured cross-sections. Vegetation components ranges or resistance parameters for any interpolated cross-section may be changed by using a graphical editor.

3 APPLICATION: THE LOWER BIEBRZA

3.1 *Research area*

The elaborated model was applied to a 41 km long reach in the Lower Biebrza Basin, between two gauges: Osowiec in upstream and Burzyn in downstream. The Lower Biebrza Basin is a river-marginal peatland, located in the north-eastern Poland. The flood phenomenon occurs regularly in this river system and is not constrained by any man-made structures. The Biebrza Lower Basin forms a natural valley with numerous oxbows, organic saturated soils and natural vegetation, which generates problems during field measurements and consequently makes a process of calibration and verification of numerical model very difficult.

3.2 *Topographical data*

The Digital Elevation Model (DEM) of the Lower Basin was elaborated with GIS techniques as a representation of the floodplain morphology. The DEM was generated by the ArcInfo TOPOGRIDTOOL procedure during an interpolation process. This interpolation method is based upon the ANUDEM program developed by Hutchinson (1996) specifically designed for the creation of a hydrologically correct DEM.

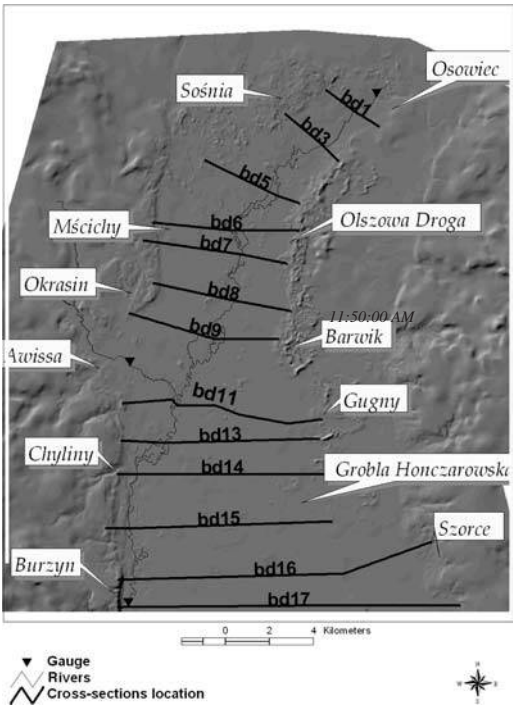

Figure 1. DEM of the Lower Biebrza Basin and cross sections location.

Wise (2000), evaluated the TOPOGRID routine as one of the best available algorithms for DEM generation. The main data source for the model generation was a set of contour lines in the digital form, with an accuracy of 1:25,000 scale topographic maps. Additionally, the point elevation data was digitized from the topographic maps and measured in the field. In order to improve the interpolation process and obtaining the DEM which correspond to numerical model, the valley cross-sections were included in data source. The DEM was created with cell resolution of 25 m (Figure 1). Next, interpolation errors were identified and corrected. Then, three valley cross-sections were measured in selected location which included different types of valley for the purpose of model verification. The survey compared with DEM gave the root mean square error (RMSE) of 0.35 m. According to the verification results, it is concluded that, the constructed DEM seems to be good enough for spatial mapping of flood.

3.3 *Hydraulic data*

Cross-sections, in the number of 13 (Figure 1, Table 1), were established at the distance of 2–6 km from each other along the river, from Osowiec downstream to Burzyn, to for describe the geometry of the river channel and valley geometry.

Table 1. Distance between the measured cross-sections.

Cross-section name	Distance along the river [km]	Distance between cross-sections [km]		
		Left floodplain	Channel	Right floodplain
BD1	0.00			
BD3	2.38	2.17	2.38	2.04
BD5	7.36	2.98	4.98	3.35
BD6	11.61	1.59	4.25	2.45
BD7	14.37	1.32	2.76	1.03
BD8	17.44	2.10	3.07	2.04
BD9	19.98	1.85	2.54	1.83
BD11	26.73	3.12	6.75	3.60
BD13	29.94	1.69	3.21	1.80
BD14	33.23	1.40	3.29	1.56
BD15	36.12	2.44	2.89	2.50
BD16	38.87	2.34	2.75	2.34
BD17	41.23	1.27	2.36	1.27

The river bed elevations were measured by manual sounding, the neighbourhood of river banks was leveled and points situated in floodplain were calculated from Digital Elevation Model and topographic maps for each cross section. Close to the river, the cross sections were measured in the field by coupling the traditional leveling survey with Differential GPS (DGPS) techniques. Then, the reference points – one for each cross section – were measured by the DGPS technique with post-processing differential correction, using 12 channel L1 single-frequency GPS receiver MX 9400N Leica receivers. The DGPS was found as a very useful and time saving method for coordinates and altitude measurements, and were often the only possible method in such a remote area with dense vegetation, numerous oxbows, and limited number of reference points (Chormański et al. 2000). At these points the levelling was done giving the shape of the valley close to the river on both sides of the river channel. The measured part of cross-sections varied from 50 to 500 meters depending on the height and the density of floodplain vegetation. Then, the cross-sections were extended to the edge of the valley by capturing elevation every 100 meters from DEM and topographic maps (Chormański et al. 2002) (Figure 1).

The water level of the Biebrza River was measured between Osowiec and Burzyn by use of dual frequency GPS (L1/L2) TOPCON Legacy E GPS receivers with RTK DGPS techniques. The water level was measured from a motorboat each 200–400 m. This technique provides us with horizontal accuracy of ±1–2 cm and vertical accuracy of 2–3 cm (Chormanski et al. 2003).

3.4 *Floodplain vegetation data*

The vegetation parameters of Biebrza floodplains used in calculations were determined on the basis of vegetation inventory in the Lower Biebrza Basin, vegetation map and PHARE aerial photos. Every part of a cross-section has one bottom roughness parameter. Water flow resistance in flowing round high vegetation such as bushes or trees is calculated on the basis of supplementary average vegetation diameter d_p and supplementary distances between plants in direction of water flow a_x, and transversal to it a_y. Resistances of totally flooded vegetation are characterized by roughness height of flexible and stiff vegetation k_s determined on the basis of vegetation map, shape of particular vegetation types and parameters suggested by Ritterbach (1991) for different types of vegetation. The vegetation types and parameters of Biebrza floodplains are presented in Table 2.

Table 2. Vegetation hydraulic parameters (k_s, a_x, a_y).

Name of plant	k_s [m]	d_p [m]	a_x [m]	a_y [m]
Meadow	0.3–0.4			
field under cultivation	0.2–0.3			
tall sedge communities	0.4–0.5			
reed rushes	1–1.2			
Glycerietum maximae rushes	1–1.2			
Phalaridetum arundinaceae rushes	1–1.2			
willow shrubs	0.3	0.045	0.16	0.16
alder swamp forest	0.8–1.6	0.175	1.54	1.5

3.5 *Simulation results*

Three steady flow cases were computed and compared to measured data. Two of them were calculated for conditions when water level is less than bankfull. They were refered to discharges $Q_a = 8.8\,m^3/s$ and $Q_b = 12.9\,m^3/s$ at Burzyn gauge, where an over bank discharge is $40.1\,m^3/s$. The next case was a flood event with discharge $Q_c = 168\,m^3/s$. Because for the flood condition the water level was measured only in a lower part of valley, the Digital Elevation Model of the floodplain constructed with GIS techniques was coupled with calculated water level for spatial flood extent and a result was verified with the help of the processed Landsat satellite image. In the computation the discharge at the cross-section BD1 was used as the upper boundary condition and the water level at the Burzyn gauge (BD17) determined the lower boundary condition. Because an average distance between measured cross-sections is about 3.4 km the interpolated cross-sections were added with a space step 0.5 km.

There is a significant difference in discharge rates between the upper (BD1 cross-section) and the lower

part of a river (BD17 cross-section). This is mainly due to the lateral inflow from a subcatchment during the flood event. The lateral discharge inflow, Q_{Wissa}, from the Wissa tributary was added 14.5 km upstream of Burzyn. Next, the uniform lateral inflow $Q_{in} = Q_{BD17} - Q_{BD1}$ was imposed along the river section (Table 3).

This solution is obviously a rough approximation of the actual situation, as it does not account for the spatial variation of the lateral inflow. A more realistic approach to this issue needs to be elaborated in further study. The roughness values in the main channel were calibrated by the measurement of a water level at the discharge rate 8.8 m^3/s and by the use of formulas (3), (5). The Table 4 presents the calibrated roughness values for the main channel. The rough recognition of geometry of an analysed strongly meandering reach, where an average distance between measured cross-sections is 3.4 km, is a reason of a very high value of roughness factors for some cross-sections.

The calculated water levels from the simulation are presented in Figure 2 and Figure 3. In order to objectively evaluate the model performance, the most commonly employed error measure, such as the root mean square error (*RMSE*) was computed for each

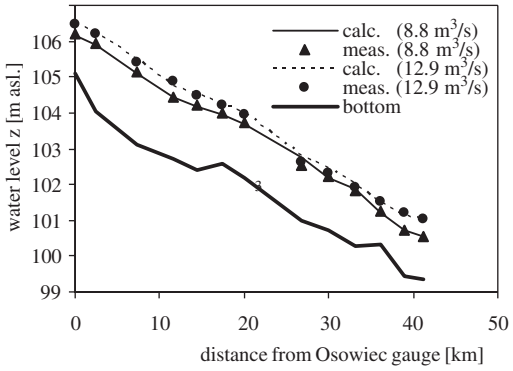

Figure 2. Calculated and measured water levels for low discharges.

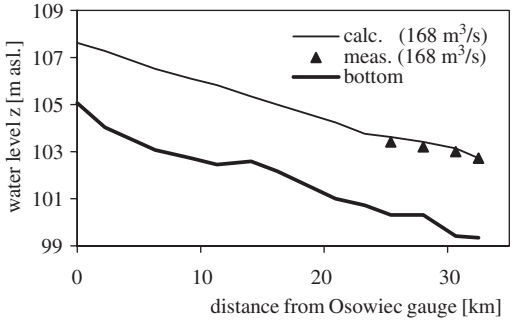

Figure 3. Calculated and measured water levels for a flood event (Q = 168 m^3/s).

Table 5. The RMSE for calculated steady state for different discharges.

Q_{Burzyn} [m^3/s]	RMSE [m]
8.8	0.07
12.9	0.09

case and summarized in Table 5. The *RMSE* can be defined as:

$$RMSE = \sqrt{\frac{\sum_{i}^{N}\left(W_{m_i} - W_{p_i}\right)^2}{N}} \qquad (21)$$

where W_m = the measured water level; W_p = the computed water level; and N = the number of cross-sections.

The RMSE is varied from 0.07 m for the low discharge rate to 0.19 m for the flood condition.

Although the main channel roughness heights were calibrated at the lowest discharge rate, the error at high over bank water level is acceptable.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The second calibration of the main channel roughness factor for data of water level during flood event, should improve the model accuracy. Unfortunately, there were collected water level data partly in the lower part of the valley and they are not enough to an appropriate calibration at a high discharge rate.

The Digital Elevation Model was coupled with calculated water level for spatial flood extent in the valley. Calculated water stages by hydraulic model in cross-sections were interpolated into water surface elevation model and next mapped in whole floodplain by analyzing of the difference between water level and DEM in GIS software ArcView GIS. Result was verified with help of the processed Landsat satellite image.

The image was geometrically corrected, and next, processed by use of selected ratios and transformations: moisture ratio 7/5, NDVI and PC1 (Chormanski 2003). The moisture ratio 7/5 is a simple division of two middle infrared bands: TM7 by TM5. The second, the Normalized Difference Vegetation Index (NDVI), is computed by dividing the difference of the near-IR (TM4) and visible red (TM3) by the sum of them. The PC1 is a first component of the principal component analysis (PCA). Finally, the supervised classification by maximum likelihood method was performed on these new developed image bands. The high classification accuracy equal to 93% was obtained during verification on the basis of 796 points with known cover type, for the March 2002 flood (Chormanski 2003). Next, result was reclassified for flooded, inundated by snowmelt and groundwater seepage and dry classes. Identification of inundated and flooded classes is done based on observed vegetation types. It was assumed that areas flooded by river water correspond to distinguished classes as follows: deep open water, shallow open water, inundated tall sedges and reeds, inundated alder forest, inundated meadow. Consequently, flooding caused inundation is determined, but somewhere these could be found far a way from the river channel as isolated areas (e.g. a class of shallow open water on areas where vegetation was cut). Then, a number of inundation areas, which are isolated from the flooded area were eliminated from flooding results. Water levels produced by model correlated well with measured data and processed satellite image.

The processed image was used for verification of the spatial extent of maximum river flood generated by hydraulic model. Comparison of the inundated area generated by hydraulic model coupled with DEM with one obtained by remote sensing method shows very good correctness (Figure 4). The flooded area calculated by model is equal to 76.36 sq km and flooded area determined by remote sensing is equal to 66.42 sq km, which give as difference of 13%. This difference comes partly from DEM quality, which is not perfect when we cannot generate it based on direct measurements and use topographic maps instead. They come partly from

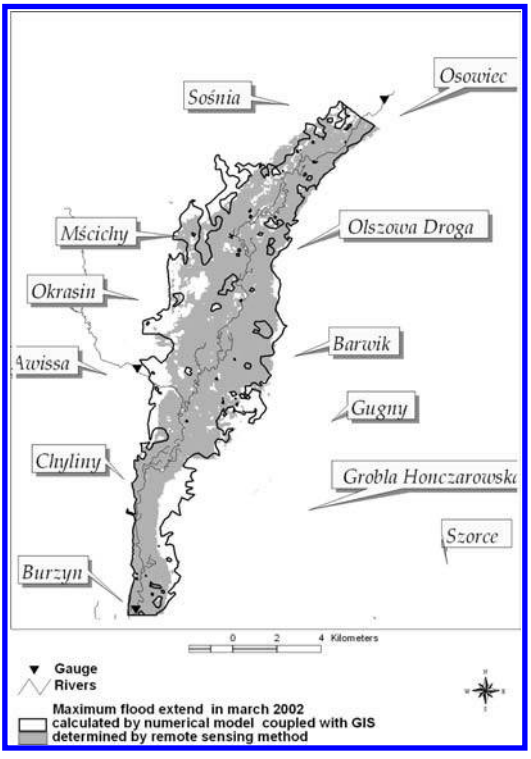

Figure 4. Comparison of the maximum flood extend in march 2002 calculated by model and obtained from Remote sensing analysis.

simplification of the classification procedure used for such a satellite image processing.

The lower Biebrza River is strongly meandering (Table 1, Figure 1) and when water is on the floodplains a reach length is significantly shorter than total river distance when water is below a bankfull level. The weighted reach length L is calculated from a following expression:

$$L = \frac{L_{lf} Q_{lf} + L_{ch} Q_{ch} + L_{rf} Q_{rf}}{Q_{lf} + Q_{ch} + Q_{rf}} \tag{22}$$

where L_{lf}, L_{ch}, L_{rf} = reach length between two adjacent cross-section in the left floodplain, main channel and right floodplain, respectively; Q_{lf}, Q_{ch}, Q_{rf} = arithmetic average of the discharge rate between two adjacent cross-section in the left floodplain, main channel and right floodplain, respectively

The Figure 3 shows, that at a discharge rate 168 m^3/s, the river length was a 78% of a total reach length.

The variation of friction factors of a main channel for different discharges is presented in Figure 5. It decreases at a high discharge and a range of a variation depends on channel dimensions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The components of the discharge on the floodplains and the main channel are shown in the Figure 6, giving an overview of water conveying. The high variation of distribution of total discharge to floodplains and main channel along a river as well as in eachcross-section are caused by significant differences in cross-sectional areas, water depths and type of vegetation.

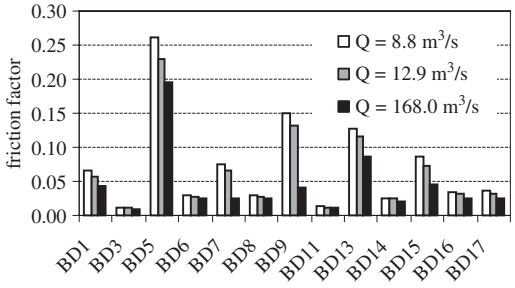

Figure 5. Variation of friction factors for different discharges.

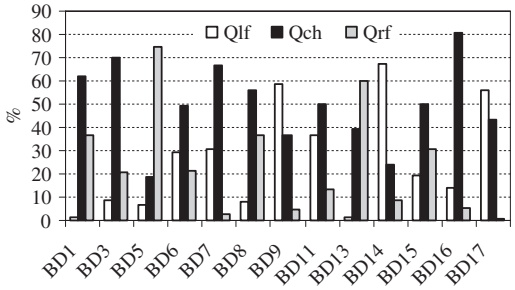

Figure 6. Percentages of discharge rate on the floodplains and in the main channel.

The discharges, velocities, water depths and areas in cross-section BD14 (Figure 7 and Table 6) were analysed as an example.

There are following seven types of vegetation below water level 103.12 m: 1 – alder swamp forest, 2 – tall sedge communities, 3 – meadow, 4 – tall sedge communities, 5 – main channel vegetation, 6 – Glyceretum maximae rushes, 7 – meadow. The depths of the imaginary boundaries are 0.24 m (area 2 – area 1), 1.19 m and 0.85 m for main channel and left and right floodplains respectively (Figure 7). The flow velocity in the interface between the alder swamp forest and the sedge community is 0.05 m/s. The left floodplain conveyed up to 67%, the main channel 24% and the right floodplain 9% of total discharge. The velocity is varying from 1.56×10^{-2} m/s to 1.42×10^{-1} m/s and

Table 6. Computed water widths B, areas A, water depths h and discharges Q for each parts of cross-section BD14.

Area number	B [m]	A [m^2]	h [m]	Q [m^3/s]
1	328	50.7	0.15	0.8
2	1420	724	0.51	50.4
3	392	279	0.71	32.0
4	120	143	1.19	20.4
5	33.6	81.1	2.41	37.3
6	27.8	20.4	0.73	2.2
7	446	167	0.37	11.5

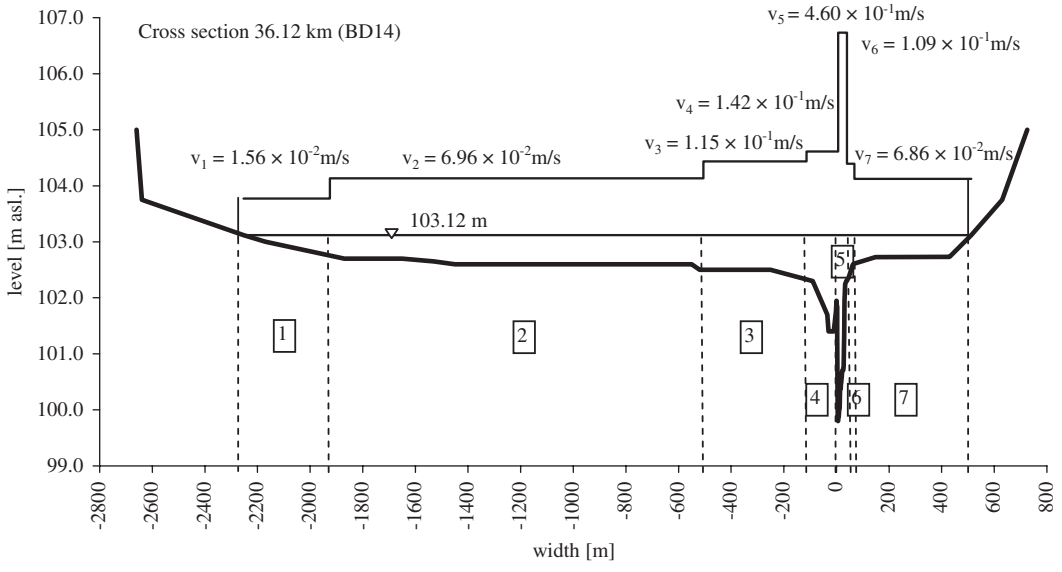

Figure 7. The vegetation division of the cross-section BD14 and computed velocities.

Copyright © 2006 Taylor & Francis Group plc, London, UK

from 6.86×10^{-2} m/s to 1.09×10^{-1} m/s on the left and right floodplains respectively.

The main channel velocity (4.6×10^{-1} m/s) is significantly higher than over banks velocities, but the channel area is only 9% and 43% of left and right floodplains areas. The field monitoring has confirmed that the left floodplain in this cross-section is conveyed a flow in a distance over 2 km from a river bank during very high discharges.

4 CONCLUSIONS

The developed model enables a solution for steady flow problems for natural rivers with floodplains and different vegetation. It may be used as a tool to estimate new water surface level for renaturalized rivers, especially for flood condition, as well as to ensure suitable conditions for habitat diversity in projects of environmental flood management.

The model was used to a reach of the Lower Biebrza. The results showed a good reproduction of recorded water levels. Analysis of the spatial extend of flood calculated by model coupling with GIS shows good correlation with inundation detected by remote sensing, although significant part of inundation in Lower Basin is cased by snowmelt and groundwater seepage. Contrary to the traditional approach, where floodplains are considered as storage areas, the proposed model computes velocities, discharges and friction factors for each specified part dependently on type of vegetation on floodplains and in the main channel. The floodplains convey a significant part of a total discharge rate.

The Lower Biebrza case shows that for strongly meandering lowland rivers, which feature varying cross-sections and an irregular longitudinal profile, the field data such as geometry of sections should be measured at short distances along a river.

ABSTRACT: Vegetation altering hydrodynamic conditions of an open channel flow controls the exchanges of sediment, nutrients and contaminants. In this paper the local flow characteristics in a straight flume with grass-like vegetation bed is studied. A 2D-ADV is used to measure the local flow velocities, for different vegetation concentrations by varying the discharge and the flume slope. The influence of both vegetation concentration and depth/vegetation height ratio on the measured velocity and turbulence intensity profiles is analyzed. All measured velocity distributions are S-shaped and exhibit a three zones profiles with an inflection point at a water depth quasi-equal to the bent vegetation height. The analysis of turbulence intensity distributions highlights that the peak value of turbulence intensity occurs at the same water depth of the inflection point. A theoretical velocity profile allowing to describe the flow both inside and above the vegetation and based on the classical Prandtl's mixing length approach is presented.

1 INTRODUCTION

Vegetation affects fluvial processes and is a key in current river management and river hydraulics.

The main difficulty to analyze the effects of vegetation on hydrodynamic characteristics of flow is that vegetation is flexible in varying degrees and it oscillates in the flow changing position. Thus, in vegetated channels, a large variation in depth of flow and in hydraulic roughness have to be encountered. In general, large-scale roughness conditions may occur when depth of flow is less than or equal to vegetation height; small-scale roughness conditions migth occur when flow depth is greater than vegetation height. But, because of temporal changing of roughness due to natural vegetative growth, tillage practices and dynamic response of vegetation to the flow, the hydrodynamic conditions could change continuously. In other words, flow in a vegetated channel is essentially a movable boundary problem since roughness elements are deformed by the flow within the channel.

In accordance with Palmer (1945) essentially three flow conditions could be experienced by vegetation: 1) low flow, with the flow passing through stems without bending and submerging them (erect vegetation position); 2) intermediate flow, with complete submergence of the vegetation, that is bent and flattened towards the bed (waving position); 3) high flow, forcing vegetation to a prone or nearly prone position.

Velocity profiles measured by Eastgate (1969) over Kikuyu grass bed showed that local mean longitudinal velocity, u, varies in proportion to the logarithm of the distance, y, from the channel bed. Kouwen et al. (1969) presented velocity profiles observed in a laboratory flume in which artificial flexible vegetation (strips of styrene) was fixed and found that the logarithm velocity profile adequately represents flow conditions above a flexible plastic cover.

The analysis of Gourlay (1970) established that for slopes less than 0.05 three layers can be distinguished in the experimental velocity profiles: 1) a layer of virtually constant low velocity within the grass near the bed in which the velocity can be assumed proportional to the shear velocity u^*; 2) a layer of rapidly increasing velocity within the upper part of the vegetation elements; 3) a layer of less rapidly increasing velocity above the grass. For slopes greater than 0.05 the layers 2) and 3) merged together and the profiles presented a two layer appearance.

Thus, indicating with k_v the bent vegetation height, the velocity distribution above flexible roughness can

Copyright © 2006 Taylor & Francis Group plc, London, UK

be defined by the following logarithm law (Kouwen et al. 1969):

$$\frac{u}{u^*} = \frac{u_{kv}}{u^*} + \frac{1}{k} ln\left(\frac{y}{k_v}\right) \quad (1)$$

in which k = the von Karman's constant and u_{kv} = the longitudinal flow velocity at distance k_v from the bed (slip velocity).

From a theoretical point of view, the logarithmic velocity profile (1) is applicable above a reference distance from the bed which would be the level where the bottom layer of constant velocity matches with the shear layer above it. This reference level could be either within the vegetated layer or at the top of the vegetation depending on the flow regime (erect, waving, prone). Because of measurement difficulties, reliable measurements of flow velocity through the vegetated boundary region are somewhat limited. For practical applications Kouwen & Unny (1973) suggested a reference level equal to the vegetation height.

Temple (1986) suggested a two layers velocity distribution: for y values less than bent vegetation height k_v, the velocity through the vegetation is assumed constant and is only dependent on vegetation characteristics and energy slope; for $y > k_v$, the velocity profile is dependent on momentum transfer in the form of the turbulent shear. In this last case, Temple (1986) obtained a generalized velocity profile using the Prandtl's mixing length approach and assuming a mixing length proportional to $y - k_v$.

Ikeda & Kanazawa (1996) carried out experiments in an open channel flow with artificial filaments on the bed. The analyses of the vertical distributions of longitudinal velocity component, measured using a two component Laser Doppler Velocimeter, allowed to highlight some peculiar aspects on flow velocity behavior. The Authors observed that the temporally averaged velocity profile has an inflection near the top of the vegetation layer. Furthermore, both the longitudinal component of the turbulence intensity and the shear stress have the maximum value at the top of the vegetation layer and decrease toward the free surface and the bottom.

Many theoretical and experimental investigations have been performed in order to analyze also the turbulence structure of open-channel flow (Nezu & Rodi 1986; Lemmin & Rolland 1997, Shvidchenko & Pender 2001).

Referring to a two-dimensional uniform flow and a small-scale roughness condition, the turbulence structure has been analyzed considering three different regions (Nezu & Nakagawa 1993): 1) the near to the bed region and for $y^+ = yu^*/\nu < 50$ (in which ν = the kinematic viscosity) where the production of turbulent energy exceeds its dissipation rate; 2) the near to the free surface region, i.e. for $y/h \geq 0.6$ (in which h is the flow depth) where the energy dissipation exceeds the turbulent energy production; 3) the intermediate region where the turbulence energy is transported from the bed toward the free surface and an equilibrium between the energy production and its dissipation exists.

The attention of many researches has been devoted to the study of the turbulence structure in the inner region, where the so-called bursting phenomena evolve (Kline et al. 1967, Corino & Brodkey 1969, Jackson 1976; Cantwell 1981). They consist in coherent and organized motions whose growth and breakdown occur periodically.

Experimental investigations (Grass 1971) revealed that a sequence of bursts appears both in smooth and in rough beds. For an hydraulically smooth regime, bursting occurs because of the viscous sublayer instability; in rough turbulent regime bursts are generated inside the cavities between the elements forming the bed roughness. The instantaneous vertical velocity profiles associated with a complete bursting sequence (lift-up, oscillation, ejection and sweep motion), show an inflection point, due to the vortex ejection, where the vertical distribution of the turbulence intensity shows a maximum.

Recently, Shvidchenko & Pender (2001) observed the turbulent structure of the flow in a gravel bed channel. The experiments were conducted by using a visualization technique and measuring the flow velocity by an Acoustic Doppler Velocimeter (ADV). On the basis of their measurements, the authors confirmed the formation of an ordered sequence of long-term large-scale vortices moving downstream with the same velocity as the mean flow and producing a motion of fluid toward both the bed (sweep) and the free surface (ejections), involving the whole flow depth. The longitudinal turbulence intensity decreases progressively as the distance from the bed increases, with the exception of the thin layer close to the wall, where the viscous effects exceeded the turbulent fluctuations (Nezu & Nakagawa 1993).

Very few studies analyze the turbulence structure in vegetated channels and, presently, there are no models readily available for predicting the distribution of turbulence intensity.

Experimental runs carried out in a laboratory flume with flexible bottom vegetation (Kutija & Hong 1996; Ikeda & Kanazawa 1996), investigated some peculiar characteristics of flow turbulence structure. The measurements carried out by Ikeda & Kanazawa (1996) revealed also in this case the generation of periodic organized vortices whose center is located slightly above the top of the vegetation layer. The intermittent motion of these coherent structures has been, in turn, considered responsible of the flexible vegetation oscillation. The form of the vortex was elliptical with the long axis inclined downwards toward the front.

The analysis of collected measures highlighted that at the bent vegetation heigth, where velocity profile has an inflection point, the flow becomes unstable, rolling up into discrete vortices and the turbulence intensity assumes the highest value.

In this paper velocity measurements, obtained by a two-dimensional (2D) Acoustic Doppler Velocimeter (ADV) in a rectangular laboratory flume with a bottom grass vegetation, are used to establish the influence of the vegetation concentration and the depth/vegetation height ratio on the velocity profile and turbulence intensity profile.

The velocity measurements are used to test a new velocity profile reproducing the typical shape of the velocity distribution and having a single equation to represent the flow conditions both inside and above the vegetation.

2 EXPERIMENTAL APPARATUS

The experimental runs were carried out in a rectangular straight laboratory channel of Dipartimento di Ingegneria Idraulica ed Applicazioni Ambientali at the University of Palermo. The flume had a sloping bed and was 0.60 m wide and 14,4 m long (Figure 1). The channel banks were of transparent glass.

In a reach of the channel (measurement reach), located at 7.9 m from the entrance channel section and 3 m long, the bed was covered by a turf layer The turf layer was produced sowing a soil layer having a thickness of 5 cm, and then the obtained vegetated plot was installed into the measuring reach. The grass bed was a mixture of stable *Loietto* (50%), *Festuca rubra* (40%) and *Poa pratensis* (10%).

Three values of the vegetation concentration, δ(280, 377, 440 stems/dm^2) were used for the experimental runs. The concentration, estimated as the number of stems per unit area, was measured in a reference area 0.6 m wide and 1.0 m long as explained in a previous work (Carollo et al. 2002). The visual bent vegetation height, k_v, (i.e. the vegetation heigth in presence of flow observed through the transparent walls) and the non-submerged vegetation height (i.e. the vegetation height in absence of flow), H_v, were estimated as the mean of three measurements by three decimal rules fixed to flume wall.

The turf layer was jointed with the flume bed by two plane chutes (50 cm long and 5 cm height) that bounded the experimental reach. The reference level was set coincident with the upper soil surface where the plants were rooted, at 5 cm above the flume bed.

The water depth h was measured by an hydrometer in four cross-sections (the first was at 90 cm downstream from the beginning of turf reach and the following three cross-sections had a relative distance of 40 cm), in order to verify the occurrence of quasi-uniform flow conditions in the middle part of experimental reach.

16	27.2	0.2	189.2	3.5	337	3.1

Sixteen runs were carried out in order to analyze the influence of the depth/vegetation height ratio h/k_v and of the stem concentration δ on velocity and turbulence intensity profiles. For a given stem concentration, the influence of depth/vegetation height ratio was examined by varying the discharge and the flume slope s.

For each run, Table 1 lists water depth h, flume slope s, discharge Q, non-submerged vegetation height H_v, stem concentration δ and bent vegetation height k_v.

For all runs, the vegetation was submerged. Runs 1–14 were carried out with a vegetation which was always prone; while for runs 15 and 16 ($H_v = 5.9$ and 3.5 cm) the vegetation was cut (original vegetation height equal to 10 cm) for obtaining more rigid stems having a quasi-erect configuration.

The local flow velocities were measured by using a 2D, side-looking probe, Acoustic Doppler velocimeter (ADV) (Kraus et al. 1994) in five verticals of a cross-section located in the middle of the measuring reach. The measurements positions were located at a distance of the wall equal to 4 cm, 7 cm, 14 cm, 22 cm and 30 cm (axial vertical).

The 2D-ADV acoustic sensor was connected to a signal conditioning module. It was mounted on a rigid stem 40 cm long and was composed of one transmitting transducer and two receiving transducers. The three transducers were in the same plane and aligned along the x axis set coincident with the main flow direction. The intersection of the receiving and the transmitting beams defined the barycentre of the sampling volume (0.25 cm^3) localized at 5 cm from the axis of the acoustic sensor along the transverse direction. The accuracy of measures was greater than ±0,25% or ±0,25 cm/s (Carollo et al. 2002).

Eighty velocity and turbulence intensity distributions were measured. For each measurement point, the turbulence intensity u' was calculated by the following relationship:

$$u' = \sqrt{\frac{\sum_{i=1}^{N}(u_i - u)^2}{N}}, \quad (2)$$

in which u_i = the local instantaneous longitudinal flow velocity, N = the number of samplings.

For each measurement point the maximum sampling rate of 25 Hz was used. The number of samplings was set equal to the minimum value required to determine a constant local mean velocity u. The tests, carried out for different values of δ, h and y, showed that 700 local velocity samplings were sufficient to obtain a stable estimate of u.

3 ANALYSIS OF EXPERIMENTAL DISTRIBUTIONS

3.1 *Flow velocity profiles*

The measured longitudinal flow velocities have been normalized by the shear velocity u^* and plotted against the relative water depth $Y = y/h$. The shear velocity has been estimated by Clauser method (Kironoto & Graf 1995). As an example, in Figure 2 a velocity profile measured in the axial vertical during run 8 is shown.

The analysis of the eighty measured velocity distributions highlighted that for each velocity profile three zones, marked by two relative depths Y_1 and Y_2, can be identified (Figure 2):

1. zone I, obtained for relative depth values $Y < Y_1 < k_v/h$, is characterized by very small flow velocities.

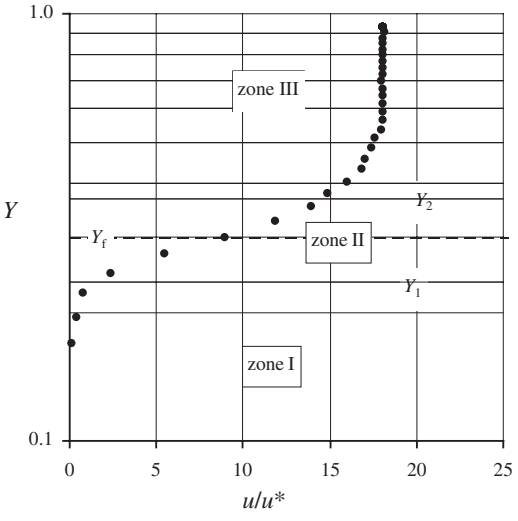

Figure 2. Localization of three different zones into measured velocity profile.

In contrast to the findings of Gourlay (1970), for $Y < Y_1$, the measured flow velocities do not assume a constant value, but show an increasing vertical velocity gradient;

2. zone II is obtained for $Y_1 \leq Y \leq Y_2$. Here the logarithm velocity profile can be fitted to the measured velocities;
3. zone III, for distances $Y > Y_2$. This zone is characterized by positive vertical velocity gradients which are progressively decreasing until to become null near the free surface, where the measured velocity distribution follows a vertical profile.

In the zone I the velocity profile has the concavity turned toward the bottom and tends asymptotically to the vertical axis. In the zone II the velocity values rapidly increase, and the velocity gradient along the vertical assumes its maximum value. In other words, even if a logarithm velocity profile can be fitted, the shape of the experimental velocity distribution clearly shows that an inflection point, located at a distance from the bed equal to y_f, occurs in the zone II ($Y_f = y_f/h < Y_2$).

Within the zone III the part of the velocity profile below the free stream zone shows a concavity turned toward the free surface. This confirms that the inflection point is located inside the zone II.

Carollo et al. (2002) suggested to estimate Y_1 and Y_2 by the following equations:

$$Y_1 = 0.865\frac{k_v}{h} \quad (3a)$$

$$Y_2 = 0.15 + 0.865\frac{k_v}{h} \quad (3b)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

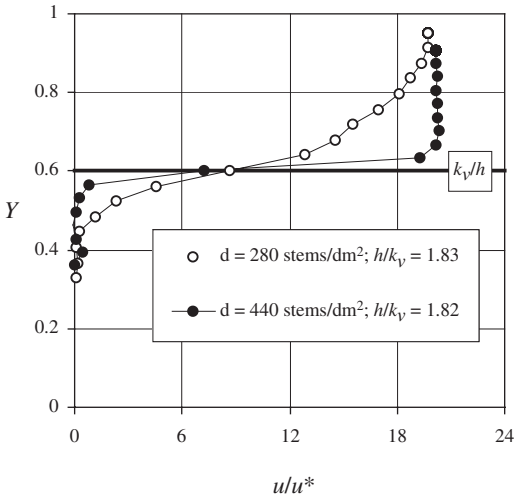

Figure 3. Velocity profiles for different values of vegetation concentration.

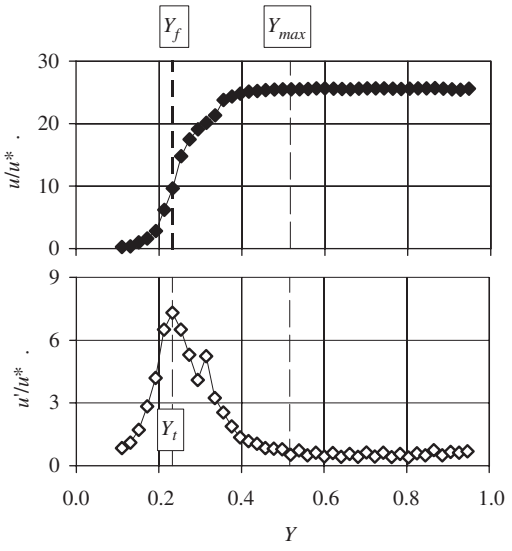

Figure 4. Comparison between a measured turbulence intensity distribution and the corresponding velocity profile.

that satisfy the boundary conditions for $k_v/h \rightarrow 0 Y_1 = 0$ (in absence of vegetation the zone I does not exist) and $Y_2 = 0.15$ (in absence of vegetation the superior limit of the logarithm profile, Y_2, coincides with the superior limit of the "inner region").

According to the eqs. (3) the location of the logarithm distribution zone (zone II) strongly depends on the non-dimensional vegetation height k_v/h, but the thickness of this velocity distribution zone, equal to $0.15\,h$, does not depend on vegetation height.

Since the measured velocity profiles showed that the depths Y_1 and Y_2 do not vary with the stem concentration δ, the location of the three velocity distribution zones does not depend on δ.

The experimental runs showed that for decreasing values of the stem concentration, the flow velocity increases inside the vegetation and decreases above it (Figure 3), and the thickness of the vertical velocity profile in zone III decreases. Thus, decreasing the stem concentration decreases the curvature of the velocity profile both inside and above the vegetation.

3.2 *Turbulence intensity distribution*

In order to analyze the distribution of the turbulence intensity, the values of u', estimated at each measurement point according by (q), have been normalized by the shear velocity u^* and plotted against Y.

The distributions of the normalized turbulence intensity have been compared with the distributions of the local mean velocity. As an example the comparison of the distributions measured in the axial vertical of run 13 is reported in Figure 4.

Some peculiar characteristics of the vertical profile of both turbulence intensity and velocity are highlighted in this figure:

1. the turbulence intensity profile shows a peak value at a relative water depth Y_t corresponding to the relative depth Y_f: for $Y < Y_t$ the turbulence intensity increases rapidly; for $Y > Y_t$ the turbulence intensity decreases until $Y = Y_{max}$, being Y_{max} the relative water depth in which the maximum value of velocity is reached; then, i.e. for $Y > Y_{max}$, the turbulence intensity assumes a constant low value;
2. approaching the free surface the decrease in vertical velocity gradient coincides with the decrease in turbulence intensity. Furthermore when the vertical velocity gradient is close to zero the turbulence intensity becomes constant. For $Y < Y_t$ the turbulence intensity increases with Y, as well as the vertical velocity gradient.

During the experiments a strong oscillation of stems was observed. The vegetation stems were bent with different inflection degrees and oscillated in the flow changing position and producing a variation of the bent vegetation height. In accordance with Ikeda & Kanazawa (1996), it has been observed that the motion of the flexible vegetation is strongly related to the high velocity gradient and to the inflection of the velocity profile occurring at the top of vegetation layer. The flow instability causes a vortex generation and the generated vortices move downstream just above the vegetated layer producing the wavy motion of the flexible stems, known as monami (Ghisalberti & Nepf, 2002).

Copyright © 2006 Taylor & Francis Group plc, London, UK

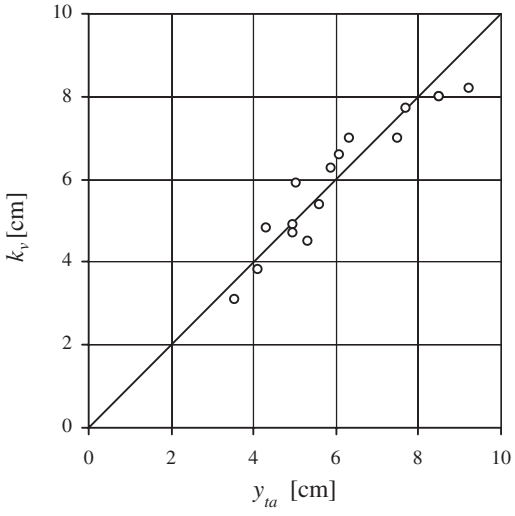

Figure 5. Comparison between mean depth at which maximum turbulence intensity is located and visual vegetation height.

The cyclic presence and absence of vegetation stems in the region where monami appears determines a strong variability on instantaneous longitudinal velocities. This variability produces a peak value of the normalized turbulence intensity u'_{max}/u^*. Therefore, the peak value of u'_{max}/u^* appears at the same distance from the bed where the number of changes (presence–absence of vegetation stems) is maximum.

These observations support the idea that the relative water depth Y_t, where the peak of turbulence intensity occurs, can be considered as a local estimate of the relative distance of the top of the bent vegetation layer from the bed.

In Figure 5 the bent vegetation height k_v is compared with the average y_{ta} of the depths y_t corresponding to the five measurement verticals. In spite of the dispersion due to measurement discontinuity (intervals of 5 mm along the water depth were used) and to the errors due to the visual estimation, the pairs (y_{ta}, k_v) place around the bisector line. Thus, the maximum turbulence intensity is located approximately at the depth of the top of the bent vegetation.

Figure 6 shows, for all measurement verticals, the comparison between the pairs (Y_t, Y_1), (Y_t, Y_2) and corresponding eqs. (3), in which k_v/h has been replaced with Y_t. It is evident that the top of vegetation is located into zone II of velocity profile.

For a given vegetation concentration ($\delta = 280$ stems/dm^2), Figure 7 shows the trend of the normalized turbulence intensity for different relative vegetation roughness k_v/h. Figure 7 clearly highlights that the normalized turbulence intensity presents a peak

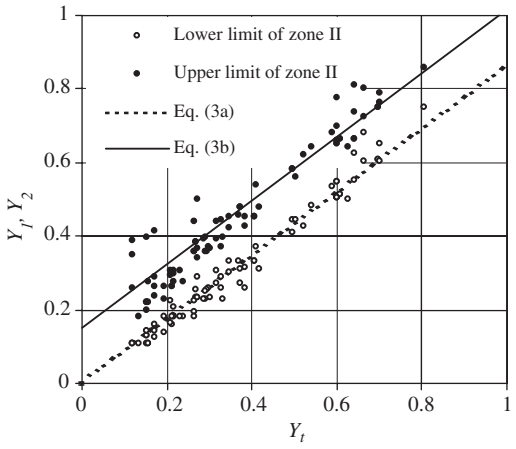

Figure 6. Comparison between pairs (Y_t, Y_1) and eq. (3a) and between pairs (Y_t, Y_2) and eq. (3b).

value for $Y = Y_t$. This trend of the normalized turbulence intensity is very similar to that observed in non-vegetated bed channels (Grass 1971); but the peak value, u'_{max}/u^*, is higher than that one ($u'_{max}/u^* < 3.6$) obtained in non-vegetated beds (Blinco & Partheniades 1971; Wang et al. 1993; Nezu & Nakagawa 1993). Furthermore, it seems clear from Figure 7 that the relative vegetation roughness (k_v/h), strongly affects the turbulence intensity distribution. Taking into account that the relative depth Y_t increases with the relative roughness, the whole turbulence intensity profile is shifted toward the free surface.

For a given k_v/h, vegetation concentration increasing induces a reduction of turbulence intensity. Analogous result was found in gravel bed channels (Carollo et al. 2005) where the turbulence intensity is damped by boulder concentration increasing.

3.3 *Proposed analytical velocity profile*

On the basis of the experimental observations discussed in previous sections, the following velocity profile equation has been derived (Carollo et al. 2002):

$$\frac{u}{u^*} = b_o + b_1 \arctan\left(\frac{Y - a_1}{a_2}\right) \tag{4}$$

The relationship (4) has been theoretically deduced applying the mixing length approach and a new expression of the mixing length l:

$$l = \left[k_1 (y - k_v)^2 + l_0\right]\sqrt{\frac{\tau}{\tau_{max}}} \tag{5}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

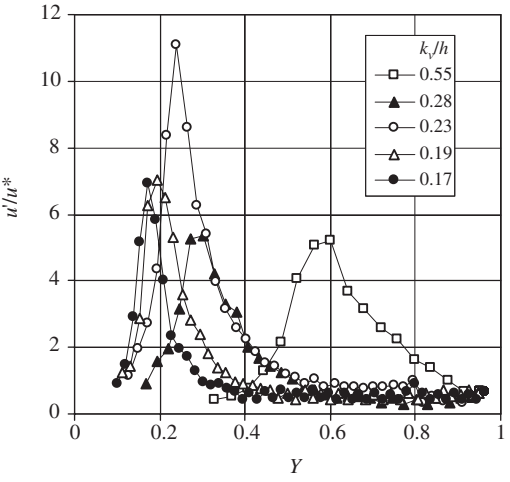

Figure 7. Turbulence intensity distributions measured in the axial vertical and corresponding to different values of the relative roughness.

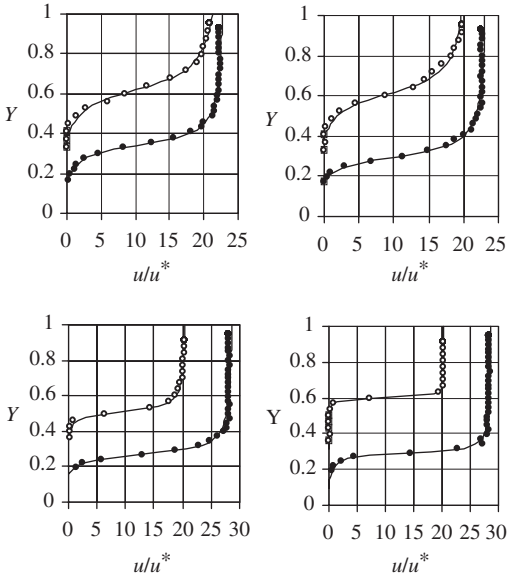

Figure 8. Examples of fitting of eq. (4) to measured profiles.

where k_l = numerical constant, τ_{max} = the maximum shear stress which is located at $y = k_v$, l_0 = the mixing length at $y = k_v$.

The coefficients a_1 and b_0 of eq. (5) have a physical meaning since they represent the coordinates Y and u/u^*, respectively, of the inflection point while b_1 and a_2 are parameters linked to the coefficients k_l, l_o and τ_{max} of eq. (6) (Carollo et al. 2002). The parameters a_1, a_2, b_0, b_1,have also a geometrical meaning: a_1 and b_0 produce respectively the vertical and the horizontal translation of the profile, a_2 modifies its steepness, and b_1 determines the distance between the two vertical asymptotes.

The velocity profile (5) is an analytical function characterized by two vertical asymptotes:

– when $Y \to +\infty$: then $u/u^* \to b_0 + b_1\pi/2$;
– when $Y \to -\infty$: then $u/u^* \to b_0 - b_1\pi/2$.

Substantially, the u/u^* values calculated by eq. (5) for $Y = 1$ and $Y = 0$ are quasi-equal to the asymptotes for $Y \to +\infty$: and $Y \to -\infty$, respectively. The velocity profile (4) reaches the maximum velocity u_{max} at $Y = 1$.

The eq. (5) fits very well to the empirical velocity profiles both near the bed and the free surface, as Figure 8 shows for some distributions chosen as examples. Furthermore, eq. (5) locates almost exactly the position of its inflection point ($a_1 = Y_f$) at Y_t (Figure 9).

3.4 *Relative turbulence intensity distribution*

The experimental turbulence intensity profile can also be analyzed using the ratio u'/u named relative turbulence intensity (Laufer 1951; Blinco & Partheniades 1971; Nezu & Nakagawa 1993).

Excluding a zone very near the bed ($Y < 0.003$ for the smooth bed) in which viscous effects are dominant, Blinco & Partheniades (1971) showed that for a given roughness condition the relative turbulence intensity decreases with the relative depth. Increasing of roughness (from smooth to rough bed) produces an increase of the relative turbulence intensity values.

As an example, Figure 10 shows the pairs $(Y, u'/u)$ corresponding to four experimental runs. Along the relative turbulence intensity profiles three regions, marked by two relative water depths $Y_1' < Y_t$ and $Y_2' > Y_t$, can be identified:

1) for $Y_1' < Y < Y_2'$ the relative turbulence intensity exponentially decreases with the distance from the bed;
2) for $Y < Y_1'$, i.e. for water depth close to the bed, both the flow velocities and the turbulence intensity values are very small and their ratio can increase or decrease with the bottom distance depending on which variable (u or u') is prevalent;
3) for $Y > Y_2'$ the variability of the relative turbulence intensity is not appreciable and for $Y > Y_{max} u'/u$ takes a constant value.

This behavior of the relative turbulence intensity can be explained analyzing both the instantaneous turbulence distribution and the flow velocity profile. In fact, the experimental runs showed that for $Y > Y_2'$ the measured values of both the turbulence intensity u'

Copyright © 2006 Taylor & Francis Group plc, London, UK

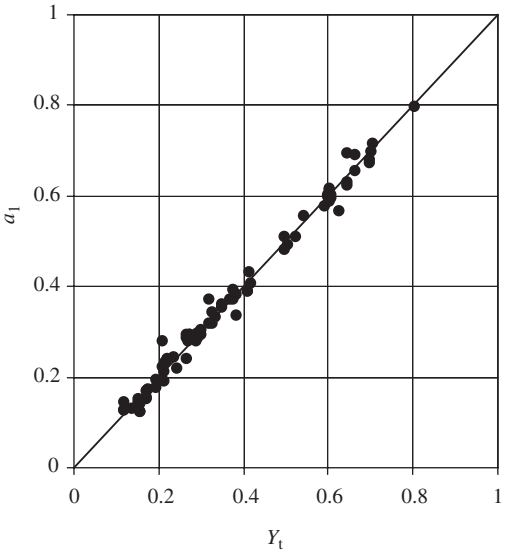

Figure 9. Comparison between relative depths Y_t, and the relative depth a_1 at which the inflection point of theoretical profile (5) is located.

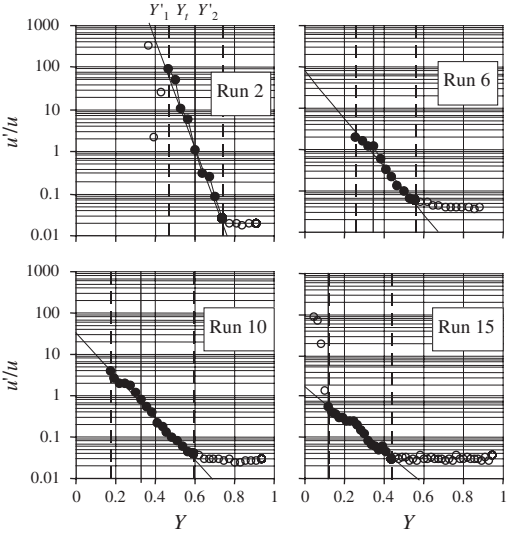

Figure 10. Relative turbulence intensity profiles measured in four experimental runs.

and the local flow velocity u are quasi-constant and that those values become constant for $Y = Y_{max}$.

In the range $Y'_1 < Y < Y'_2$ two different trends of u' and u with Y determine the same exponential-type trend of the relative turbulence intensity profile: for $Y_t < Y < Y'_2$ both the decrease in u' and the increase in u with Y determine a decreasing ratio u'/u; for

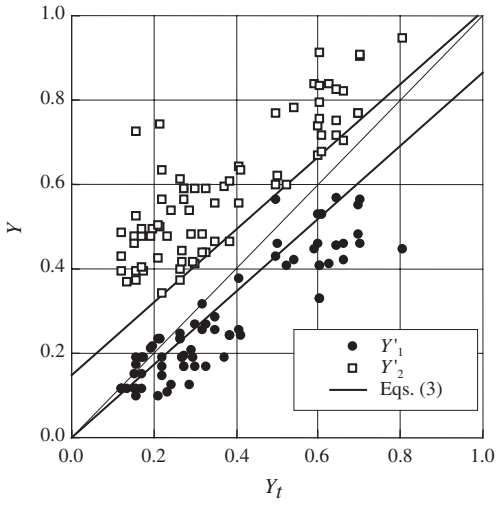

Figure 11. Localization of three different zones into measured velocity profile.

$Y'_1 < Y < Y_t$ both u' and u increase with Y but the ratio u'/u follows the same exponential trend established in the range $Y_t < Y < Y'_2$.

Thus, in contrast to the turbulence intensity distribution u'/u^*, no angular discontinuity can be observed at the top of the vegetation layer, i.e. at $Y = Y_t$.

The behavior of the relative turbulence intensity profile observed in the range $Y'_1 < Y < Y'_2$ is very similar to that observed by Blinco & Partheniades (1971), who found a decrease in u'/u above the viscous sub-layer both in smooth and in rough bed.

The analysis of all measured relative turbulence intensity profiles showed that at $Y = Y_t$ the relative intensity u'/u assumes values ranging from 0.3 to 1; when $Y = Y'_2$ the value of u'/u ranges from 0.02 to 0.06. These extreme values are very similar to those observed by Blinco & Partheniades (1971) near the bed ($u'/u = 0.4$–0.6) and near the free surface ($u'/u = 0.05$). Close to the bed (for $Y < Y'_1$) the relative turbulence intensity u'/u moves away from the exponential decreasing trend; this result can be justified, according to Blinco & Partheniades (1971), taking into account that the viscous effects become dominant.

In Figure 11 the relative depths Y'_1 and Y'_2 are plotted versus Y_t, assumed, as aforesaid, as a measure of the relative local bent vegetation height. The relative depth values Y'_2 fall beyond the bisector line while the relative depths Y'_1 fall below this line. This result confirms that the top of the vegetation layer falls inside the region $Y'_1 = Y = Y'_2$. According to Figure 11, the values of the relative depths Y'_1 and Y'_2 increase with the relative roughness k_v/h, so that when $k_v = 0$, i.e. without bed vegetation, $Y'_1 = 0$ and the reference plane coincides

Copyright © 2006 Taylor & Francis Group plc, London, UK

with the bed; if the vegetation becomes emergent it means that $k_v/h = 1$ and, thus, $Y_2' = 1$.

The eqs. (3) are also represented in Figure 11, clearly demonstrating that $Y_1' \leq Y_1$ and $Y_2' \geq Y_2$; in other words the region $Y_1' = Y = Y_2'$ of the relative turbulence intensity profile, contains the zone II of the velocity profile (Figure 2).

4 CONCLUSION

The flow velocity measurements carried out in a straight flume with grass-like vegetation bed highlighted that all measured velocity distributions are S-shaped. Three zones can be identified along the velocity profiles: zone I, inside the vegetation, characterized by very small velocities; zone II in which the logarithm velocity profile can be fitted to the measured velocities; zone III characterized by positive vertical velocity gradients, progressively decreasing until to become null near the free surface. Inside zone II an inflection point at a water depth quasi-equal to the bent vegetation height occurs. The localization of zone II (logarithm zone) is influenced by the depth/vegetation height ratio, but no relevant influence of the stem concentration has been observed. The stem concentration affects the shape of the velocity profile: decreasing the stem concentration the flow velocity increases inside the vegetation and decreases above it.

The analysis turbulent intensity distributions show a peak value at a relative water depth Y_t. The comparison, for each measurement vertical, with the corresponding measured velocity profiles has clearly shown that the inflection point occurs at a relative water depth coincident with Y_t.

These observations support the idea that the relative water depth where the peak of turbulence intensity occurs could be considered as a local estimate of the relative distance of the top of the bent vegetation layer from the bed.

On the basis of the aforementioned characteristics a new velocity profile has been presented. It has been theoretically deduced applying the mixing length approach and a new expression of the mixing length. The proposed velocity profile fits very well the experimental data both near the bed and near the free surface and allows to locate correctly the position of the flex point.

Finally, the analysis of the relative turbulence intensity distributions have shown that in contrast to the turbulence intensity distributions, no angular discontinuity can be observed at the top of the vegetation layer, i.e. at the relative water depth Y_t. Furthermore, in accordance with the experimental results obtained by Blinco & Partheniades (1971) above the viscous sub-layer both in smooth and in rough bed, these distributions show a decrease in relative turbulence intensity inside a region, delimited by two relative water depths Y_1' and Y_2', containing the zone II of the velocity profile.

This peculiar trend of the relative intensity distributions stimulates to keep up the work toward the verification of the experimental observations presented in this paper for different kind of vegetation concentration and stiffness characteristics.

ABSTRACT: A 2D lattice Boltzmann model (LBM) is proposed for describing the turbulent shallow water flow in a vegetated channel. The flow turbulence is taken into account by means of the standard Smagorinsky subgrid-scale model. The drag stress exerted by the flow on the vegetation as well as the frictional effects of the channel bed and walls are included in the LBM main equation. The simulated results are compared to the experimental cross-stream profiles of flow velocity obtained when considering a flume with alternate vegetation zones in which a meandering flow pattern is developed. In addition, a study about the influence of the distance between these vegetated areas on the flow turbulent structures is also reported.

1 INTRODUCTION

Many field and laboratory experiments have been devoted to describe the interaction among flow, sediment transport and riparian vegetation. The effect of both the emergent or submerged and rigid or flexible vegetation on the flow velocity and turbulent structure has been analyzed among others by Nepf (1999), Nezu & Onitsuka (2001), López & García (2001), Wilson & Horritt (2002), Righetti & Armanini (2002), Bennett et al. (2002) and Bennett (2004). Some works have studied the drag coefficient of vegetation (e.g. Fathi-Maghadam & Kouwen, 1997; Wu et al., 1999; James et al., 2004; Lee et al., 2004; Armanini et al., 2005). López & García (1998) explored the sediment transport in vegetated channels and Tsujimoto (1999) measured the efficiency of the vegetation trapping and sorting sediments.

The complex interactions between flow, sediment and vegetation have been simulated with different models. Among others, Wu & Wang (2004) and Wu et al. (2005) proposed a depth-averaged two-dimensional k-ε model for describing the flow in vegetated open channels combining it with a sediment transport model. López & García (2001) used vertical two-dimensional models to characterize turbulent flow with vegetation effect. Su & Li (2002) developed a large eddy simulation (LES) model to simulate the hydrodynamic behavior of turbulent flow in an open channel with a domain of vegetation. Choi & Kang (2004) applied the Reynolds stress model to open channel flows with vegetation.

In order to complement the models previously mentioned, new alternatives are always opportune. The lattice model approach (e.g. Succi, 2001) is a numerical tool developed to simulate fluid dynamics that has recently raised great interest. The kinematic viscosity is easily fitted and the fluid-solid interactions are implemented in a simple way. In addition, the LES method is straightforwardly included in that model producing a code that can be parallelized.

The objective of this work is to verify whether the lattice model approach is suitable to reproduce the flow patterns in the presence of alternate vegetated zones. With this aim, a lattice model is proposed including the effects of the channel bed and walls friction as well as the drag exerted by the stream on the vegetation. The model is calibrated using the experimental

results reported by Bennett et al. (2002). After that, the influence of the distance between vegetated zones on the flow turbulent structures is analyzed.

2 THE LATTICE MODEL

The lattice model is a numerical approach developed to simulate fluid dynamics (e.g. Chen & Doolen, 1998; Wolf-Gladrow, 2000 §5). In that model, the reality is transformed into a regular lattice where particles move and interact with each other following simple rules. The lattice model used in this work is the known as BGK. Chen et al. (1992) and Qian et al. (1992) firstly presented it in an independent way. This model is based on a simplification of the lattice Boltzmann model, using the relaxation time parameter proposed by Bathnagar, Groos & Krook (1954) in the context of collisions of gas molecules. To honor the latter authors the model was named lattice BGK.

2.1 *The lattice BGK model equation*

In this approach the fluid particles move in a regular lattice in which each node is linked to its neighbors following a vicinity model that is chosen depending on the complexity of the phenomenon to be simulated. To calculate the fluid velocity field in two dimensions the vicinity model *d2q9* is used (Fig. 1), with $d=2$ meaning the number of dimensions and $q=9$ the number of particles considered. In this case there are eight moving particles and one at rest. The interactions of the particles keep up the mass and momentum (Rothman & Zaleski, 1997 §6.1; Chopard & Droz, 1998 §3.5).

The probability of finding a particle in a link i that connects a node with one of its neighbors, is represented by the independent variable f_i which varies continuously between 0 and 1 according to the hypothesis of Boltzmann molecular chaos. The main mesoscopic equation of the lattice BGK model for a node $\mathbf{r}$ at time t is (e.g. Succi, 2001 §5.1):

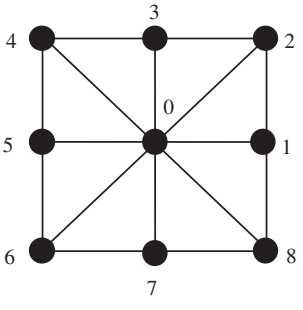

Figure 1. The vicinity model *d2q9* used in simulations done with the proposed lattice BGK model; d and q denote the number of dimensions and particles (eight moving and one at rest), respectively.

$$f_i(\mathbf{r}+\mathbf{c}_i,t+1) = \frac{1}{\eta} f_i^{eq}(\mathbf{r},t) + \left(1-\frac{1}{\eta}\right) f_i(\mathbf{r},t) + \frac{1}{c_s^2} t_i c_{i\alpha} F_\alpha(\mathbf{r},t) \quad (1)$$

where t is the time. $\mathbf{c}_i$ is the velocity of a particle in the link i and f_i^{eq} is the local equilibrium function. The relaxation time parameter, η, represents the difference between f_i and f_i^{eq} while t_i are weighting factors associated with the lattice directions. The parameter c_s is selected according to the vicinity model chosen and F_α is the component of the external stress in the α direction. Equation (1) reproduces a hydrodynamic behavior if f_i^{eq} is expressed as:

$$f_i^{eq} = \rho t_i \left[1+\frac{c_{i\alpha}u_\alpha}{c_s^2}+\frac{1}{2}\left(\frac{c_{i\alpha}u_\alpha}{c_s^2}\right)^2-\frac{u_\alpha u_\alpha}{2c_s^2}\right], \; i\in[1,8]$$
$$f_0^{eq} = \rho t_0\left(1-\frac{u_\alpha u_\alpha}{2c_s^2}\right), \quad i=0 \quad (2)$$

where $\rho(\mathbf{r},t)$ and $\mathbf{u}(\mathbf{r},t)$ stand for the fluid density and velocity, respectively. In Equation (2), the Einstein's summation convention has been adopted (i.e. $u_\alpha u_\alpha = \sum_\alpha u_\alpha u_\alpha$) and k_α is the component of any vector $\mathbf{k}$ in the α dimension.

The fluid density and velocity are deduced from f_i in the following way:

$$\rho(\mathbf{r},t) = \sum_{i=0}^{q-1} f_i(\mathbf{r},t)$$
$$\mathbf{u}(\mathbf{r},t) = \frac{\sum_{i=0}^{q-1} f_i(\mathbf{r},t)\mathbf{c}_i}{\rho(\mathbf{r},t)} \quad (3)$$

The relaxation time parameter allows the identification of the kinematic viscosity, υ

$$\upsilon = c_s^2\left(\eta-\frac{1}{2}\right) \quad (4)$$

In the case of the simulation of turbulent flows is possible to use the LES method combined with the lattice model as Hou et al. (1996) suggested. In this situation, a spatially-dependent kinematic viscosity $\overline{\upsilon}$, also known as effective viscosity, made up of the original viscosity υ and an eddy viscosity υ_t has to be considered:

$$\overline{\upsilon} = \upsilon + \upsilon_t \quad (5)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

The eddy viscosity has been used in many approaches like the Smagorinsky eddy viscosity model (Smagorinsky, 1963; Pope, 2000 §13.4; Succi, 2001 §9.5), where υ_t is defined as

$$\upsilon_t = C_{smg}^2 |S| \tag{6}$$

where $|S|$ is the magnitude of the strain-rate tensor $S_{\alpha\beta}$, with the spatial components α and β and the external parameter C_{smg} called the Smagorinsky constant. The spatially-dependent relaxation time, $\overline{\eta}$, is related to the original and eddy relaxation times, η and η_t, respectively, from (4) as:

$$\overline{\eta} = \frac{\overline{\upsilon}}{c_s^2} + \frac{1}{2} = \frac{\upsilon + \upsilon_t}{c_s^2} + \frac{1}{2} = \eta + \frac{\upsilon_t}{c_s^2} = \eta + \eta_t \tag{7}$$

After some operations the expression for $\overline{\eta}$ is derived:

$$\overline{\eta} = \frac{1}{2}\left(\eta + \sqrt{\eta^2 + 2C_{smg}^2 \frac{C_2}{C_4}\frac{\sqrt{Q}}{\rho c_s^2}}\right) \tag{8}$$

where Q is the scalar product of the non-equilibrium momentum flux tensor, $Q = \Pi_{\alpha\beta}\Pi_{\alpha\beta}$, with

$$\Pi_{\alpha\beta} = \sum_i c_{i\alpha} c_{i\beta} \left(f_i - f_i^{eq}\right) \tag{9}$$

Finally, η is replaced by $\overline{\eta}$ in (1). To simulate a turbulent flow with the lattice BGK and Smagorinsky models it is necessary to fit empirically C_{smg}, usually between 0.1 and 0.4, depending on the configuration of the flow. This is the main drawback of the use of the Smagorinsky subgrid scale stress model.

2.2 *The external stress in the lattice BGK model*

The external stress can be easily included in the lattice BGK model equation (e.g. Zhou, 2002a; 2002b). In the model proposed for describing the flow in an open and vegetated straight channel, the external stress consists of the bed and wall shear stresses due to friction, τ_b and τ_w, respectively, and the drag exerted on vegetation, D_f. For the spatial direction α, F can be expressed as

$$F_\alpha(\mathbf{r},t) = -\left[\tau_{b\alpha}(\mathbf{r},t) + \tau_{w\alpha}(\mathbf{r},t) + D_{f\alpha}(\mathbf{r},t)\right] \tag{10}$$

The shear stress due to bed friction is included in the lattice BGK model by means of the expression (11) (e.g. Julien, 1994 §6.2)

$$\tau_{b\alpha} = C_b(1-\chi_b)u_\alpha\sqrt{u_\beta u_\beta} \tag{11}$$

Where χ_b is the fraction of bed occupied by the vegetation in the zones where it is placed. For the vegetated area shown in Fig. 2, χ_b is derived from

$$\chi_b = 2N\phi^2/\vartheta^2 \tag{12}$$

with N as the number of vegetation elements, ϕ as the diameter of each vegetation element and ϑ as the diameter of the semi-circular vegetated area. Otherwise, $\chi_b = 0$. C_b is a non-dimensional bed friction coefficient that is calculated from

$$C_b = \frac{g n_b^2}{h^{1/3}} \tag{13}$$

where g is the acceleration of gravity, n_b is the roughness coefficient of Manning at the bed and h is the flow depth that is equal to the vegetation height, h_v, in case of emergent vegetation.

The shear stress in the channel walls is considered as (e.g. Zhou, 2001)

$$\tau_{w\alpha} = C_w(1-\chi_w)u_\alpha\sqrt{u_\beta u_\beta} \tag{14}$$

where C_w is a non-dimensional friction coefficient calculated from (13) replacing n_b by the Manning's roughness coefficient at the walls, n_w. In this work $n_b = n_w$ is assumed. χ_w is the fraction of the channel wall area covered by the vegetation elements in the zone where they are placed. For the vegetated area shown in Fig. 2, $\chi_w = \phi/b_v$, with ϕ as the diameter of each vegetation element. Otherwise, $\chi_w = 0$.

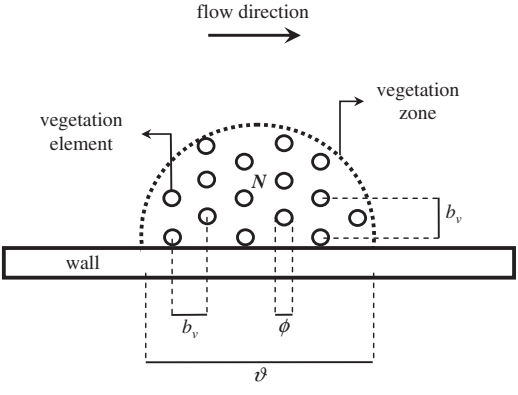

Figure 2. Scheme used for explaining the calculation of the projected area of the vegetation in the streamwise direction, A_v. The vegetated zone is a semi-circle with a diameter ϑ containing N similar emergent vegetation elements (open circles) in a staggered arrangement with a diameter ϕ separated between them by a distance b_v.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Finally, the drag stress exerted by the flow on vegetation is (e.g. Shao, 2000 §5.2)

$$D_{f\alpha} = \frac{1}{2} C_d A_v u_\alpha \sqrt{u_\beta u_\beta} \tag{15}$$

with C_d as a non-dimensional drag coefficient related to the flow and vegetation characteristics (e.g. Alonso, 2004). A_v represents the relationship between the projected area of the vegetation elements in the streamwise direction, A_{nv}, and the area of the vegetated zone where they are placed, A_{vz}, both projected in the streamwise direction such that

$$A_v = \frac{A_{nv}}{A_{vz}} \tag{16}$$

For the scheme shown in Fig. 2, it can be obtained that $A_{nv} = N\phi\mu h$ with μ being a non-dimensional shape factor of vegetation related to its irregularity and flexibility and $A_{vz} = h\vartheta/2$, resulting $A_v = 2N\phi\mu/\vartheta$.

2.3 *Boundary conditions*

In the lattice BGK model simulations done in this work, the flow is determined assigning the spatially averaged velocity u_0 at the inlet of the computational domain in such a way that if α is the flow direction and β its normal, $u_\alpha = u_0$ and $u_\beta = 0$. Periodic boundary conditions are applied at the outlet.

Because of considering the shear stress in channel walls, the boundary condition applied at these places has to be different from the common bounce-back rule used in lattice BGK models for simulating solids. As Zhou (2001) observed, there is a large velocity gradient near a solid boundary for turbulent flows due to wall friction. This can not be correctly simulated with no-slip boundary condition. Although there are other alternatives for dealing with this kind of boundaries such as diffuse reflection (e.g. Sofonea & Sekerka, 2005), the semi-slip boundary condition proposed by Zhou (2001) is adopted. It consists of a combination of the shear stress (14) with the specular reflection. That boundary condition has been implemented according to Zhang et al. (2002) at the places marked as channel wall in the computational domain.

3 LABORATORY EXPERIMENTS PERFORMED BY BENNETT ET AL. (2002)

The experiments on the flow in the presence of alternate emergent vegetation zones done by Bennett et al. (2002) were conducted using a tilting recirculating flume of $L = 16.5$ m in length and $w = 0.6$ m in width. Its scheme is shown in Fig. 3. The flow discharge, P, was kept constant at $0.0042\ \mathrm{m^3 s^{-1}}$. Flow depths were measured over a longitudinal section excluding the vegetation zones and these data were used to calculate the spatially averaged flow depth h and velocity u_0.

A total of six alternate vegetation zones were placed along the length flume spaced a distance $\lambda = 4.8$ m each other, λ was the so-called meander wavelength (Fig. 3). The shape of the vegetated areas was semicircular with a diameter of $\vartheta = 0.6$ m. The emergent vegetation was simulated by Bennett et al. (2002) using wooden dowels of $\phi = 3.2 \times 10^{-3}$ m in diameter and 70×10^{-3} m in height. For a determined vegetation density, VD, a number of dowels, N, were placed perpendicularly to the plywood flume floor in a staggered

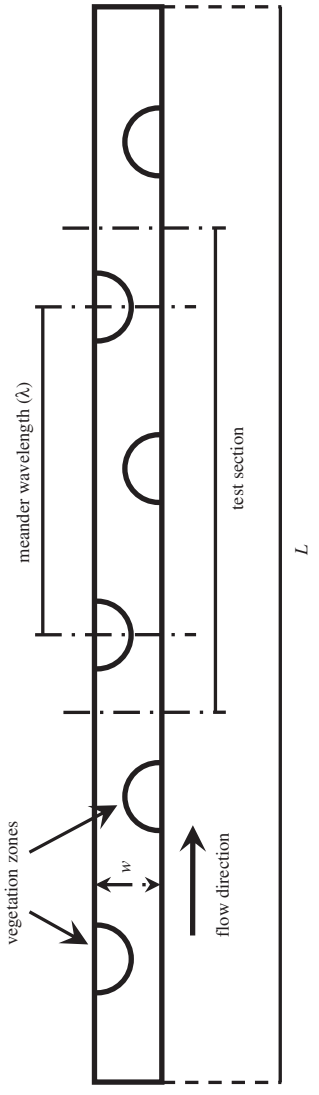

Figure 3. Scheme of the experimental channel used by Bennett et al. (2002) to study the turbulent flow structures provoked by emergent vegetation placed in alternate zones.

Copyright © 2006 Taylor & Francis Group plc, London, UK

arrangement with spacing b_v to maximize the flow resistance (Fig. 2). The definition of vegetation density (17), expressed in m^{-1}, adopted by Bennett et al. (2002) was the proposed by López & García (1997) as the ratio between the sum of the frontal areas of the vegetation divided by the volume of fluid (depth water over an area encompassing one meander wavelength λ)

$$VD = \frac{N\phi h}{w\lambda h} \tag{17}$$

Bennett et al. (2002) used the Particle Image Velocimetry (PIV) to characterize the surface flow field for the test area marked in Fig. 3. The experimental results in some cross sections of the flume, obtained by Bennett and co-workers with $VD = 2.739\,m^{-1}$ ($u_0 = 0.196\,m\,s^{-1}$, $h = 0.036\,m$), were reported in Wu & Wang (2004).

4 RESULTS

The experimental results of Bennett et al. (2002) were taken into account to calibrate the proposed lattice model. A computational domain of 516×20 square cells was used with the scale factors $\Delta r = 0.03\,m$ and $\Delta t = 0.011302\,s$, for the length and time, respectively. The relaxation parameter $\eta = 0.50004$ and $C_{smago} = 0.2$ were taken. The parameters C_b and C_w were calculated from (13) considering $n_b = n_w = 0.015\,m^{-1/3}s$. The value of the Manning's roughness coefficient was not reported by Bennett (2001) and Bennett et al. (2002). The value adopted here for the flume plywood corresponds to the suggested by Chow (1959) for laminated wood. Regarding to the vegetated zones, χ_b, χ_w and A_v were deduced from the experimental arrangement of the simulated vegetation elements described by Bennett et al. (2002). The shape factor was assumed $\mu = 1$. The drag coefficient C_d had to be obtained from calibration by comparing the simulated and the surface flow velocities measured by Bennett et al. (2002) and reported in Wu & Wang (2004). Table 1 summarizes the values of the parameters used for simulating the effects of the considered vegetation density.

Figure 4 shows the time-averaged surface flow pattern over 100 samples each one taken every 1000

Table 1. Values of the parameters used in the lattice BGK model for the simulation of the experimental results described by Bennett et al. (2002) for the vegetation density $VD = 2.739\,m^{-1}$.

$C_b = C_w$	χ_b	χ_w	C_d	A_v
0.00709	0.09973	0.355	3.15	37.397

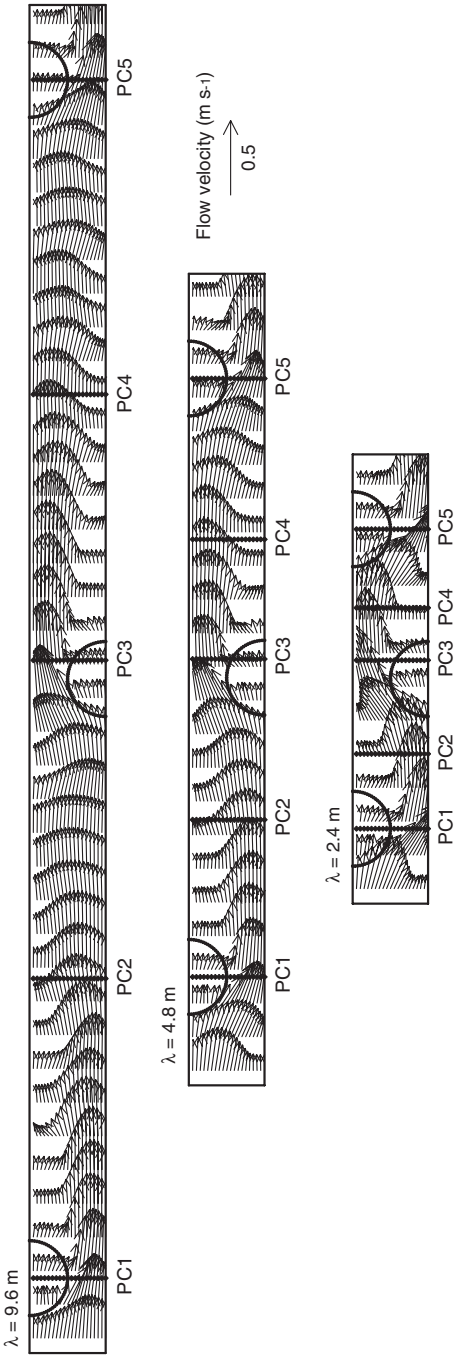

Figure 4. Time-averaged surface flow patterns simulated with the proposed lattice BGK model for the test section (Fig. 3) considering different values of meander wavelength (λ). The vegetation zones are represented by semi-circles. The vertical lines *PCi*, $i \in [1,5]$ mark the places where the time-averaged surface flow velocities were considered.

Copyright © 2006 Taylor & Francis Group plc, London, UK

time-steps considering several values of λ. The simulated effect of the vegetation for $\lambda = 4.8$ m was similar to the described by Bennett et al. (2002). The flow was influenced by the emergent vegetation. It decelerated in the leeward of the vegetation zones and accelerated in the opposite regions. In the same way that Bennett et al. (2002) reported, the flow was diverted away from the vegetation zone toward the other bank until it encountered the next vegetation zone downstream where it diverted again toward the opposite bank.

In the case of $\lambda = 2.4$ m the flow keeps the same pattern described before but, as is shown in Fig. 4, it is greatly perturbed due to the nearness of the vegetated zones. When $\lambda = 9.6$ m, the variation in the time-averaged surface velocity is lower compared to the two previous cases with decelerated areas of $\approx \lambda/4$ in distance downstream the vegetation obstacles.

Some of the effects of vegetation on turbulent flow structure are shown in Fig. 5 when different values of λ are considered. They correspond to the snapshots obtained after 75×10^3 time steps (≈ 14 minutes of real time) of simulation. For the case of $\lambda = 4.8$ m, the turbulent structures reproduced by the lattice model are comparable to those described by Bennett (2004). The flow decelerated upstream, within and downstream near the vegetation areas while it accelerated around the vegetated zones apices. Bennett (2004) also described a mixing layer created downstream of the vegetation zone and associated with small-scale and large scale vortices. Both of them are clearly visible in the flow pattern simulated with the proposed model. The small-scale vortices were located near and downstream of the vegetation zone apex, while the large-scale vortices were placed further. The direction of rotation was toward the vegetation zone and their shape was elliptical being in agreement with the description done by Bennett (2004). As can be appreciated in Fig. 5, the small-scale vortices appear for all the values of λ. However, the large-scale vortices only are reproduced in the cases of $\lambda = 4.8$ and 9.6 m, being fully developed in the last case. For $\lambda = 2.4$ m, the proximity of the vegetated zones avoid the presence of these turbulent structures.

In the test area cross sections denoted by *PCi*, $i \in$ [1,5] in Fig. 4, the time-averaged surface flow velocity was considered. Figure 6 shows the experimental data taken using PIV by Bennett et al. (2002), reported in Wu & Wang (2004), and the results obtained with the proposed lattice BGK model for $\lambda = 4.8$ m. As can be appreciated, the simulated results were in good agreement with the measurements. The surface velocities reproduced by the model when $\lambda = 9.6$ m are similar to those obtained for $\lambda = 4.8$ m in the corresponding cross sections. However, the differences are notable in the case of $\lambda = 2.4$ m. This fact is a consequence of the strong influence of the vegetated zones on the flow in this case.

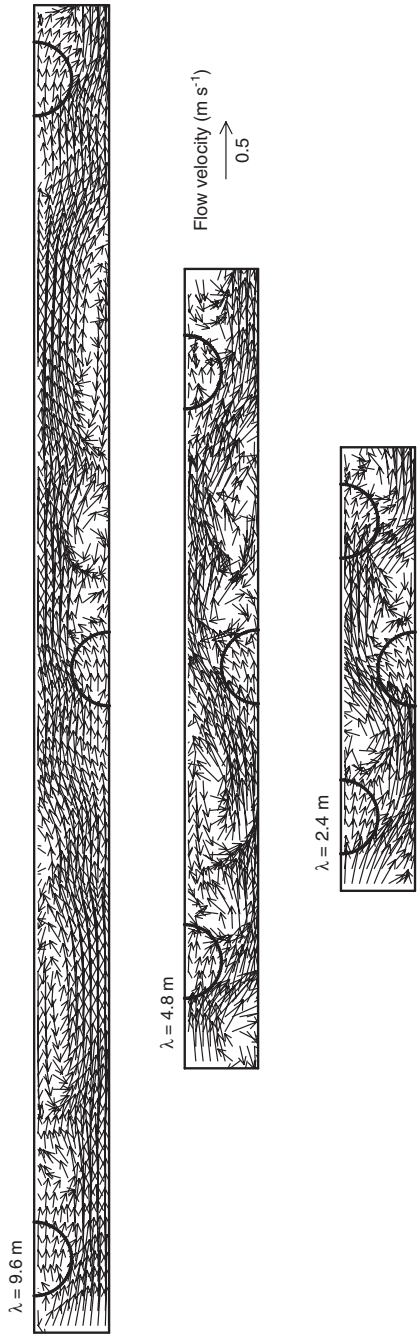

Figure 5. Flow pattern snapshots obtained from the lattice BGK model simulations in the test section of Fig. 3 after 75×10^4 time steps (≈ 14 minutes of real time) considering different values of meander wavelength (λ). The simulated turbulent flow structures agree with those described by Bennett (2004) for $\lambda = 4.8$ m.

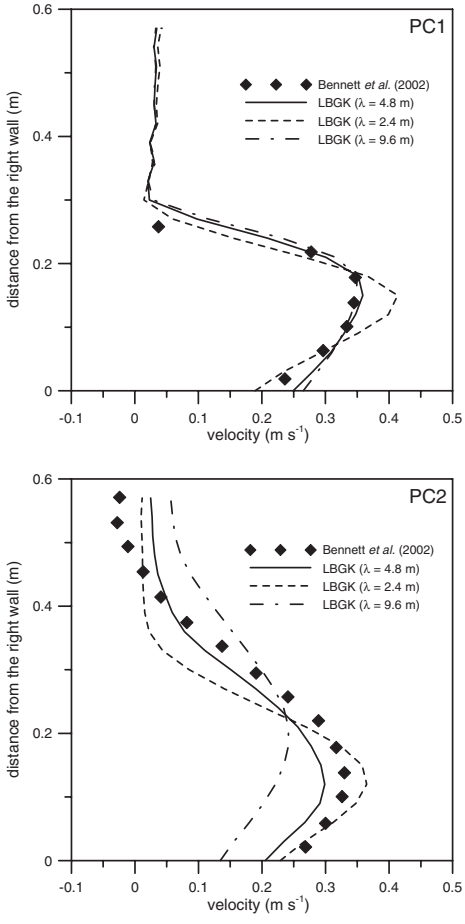

Figure 6. Experimental surface flow velocities (symbols) measured by Bennett et al. (2002) and reported in Wu & Wang (2004) for $\lambda = 4.8$ m and the results (solid lines) simulated with the lattice model in the sections PC1 and PC2 marked in Fig. 3. The dash and dash-dot lines correspond to the simulations done for $\lambda = 2.4$ and $\lambda = 9.6$ m, respectively.

5 CONCLUSIONS

The proposed lattice BGK model has shown to be a suitable alternative for describing the water flow in presence of emergent vegetation arranged in alternate zones along an experimental flume. The simulated time-averaged flow pattern and the surface flow velocities agree with the experimental results obtained by Bennett et al. (2002). The effects of vegetation on the turbulent flow structure reproduced by the lattice model, including accelerated and decelerated zones and small-scale and large-scale vortices, are similar to those described by Bennett (2004). In addition, the model simulates in an acceptable way the influence

of the distance between vegetated zones on the open channel flow.

The main advantageous features of the numerical model introduced in this work are: (a) the Smagorinsky subgrid scale stress model for simulating the flow turbulence can be straightforwardly included; (b) a simple slip boundary condition is used for the treatment of solid walls overcoming the drawbacks of applying at these locations the standard non-slip boundary condition in turbulent flows; (c) the frictional effects of the channel bed and walls and the drag exerted on the vegetation are added in the lattice model as external stresses, permitting to consider the vegetation density influence on the flow in an easy way.

The above mentioned characteristics make the lattice BGK model a promising tool for being applied to simulate different river restoration techniques.

ABSTRACT: The hydraulic resistance of vegetation can play a major role in the hydrodynamics of rivers with extensive natural floodplains. Vegetation penetrates the flow field and thereby causes drag that, in addition to the flow resistance at the bed level, causes energy losses and slows down the flow. Here, these flow processes are studied in an idealized form by treating vegetation as cylindrical roughness elements with homogeneous geometrical dimensions. Based on scaling considerations of the forces involved, depth-averaged flow velocities within the resistance layer and in the free flowing layer above the roughness elements are estimated. This yields a new description of the overall average flow field, which is entirely determined by measurable geometrical boundaries. We tested the new relation against laboratory flume experiments and found very good agreement ($R^2 = 0.98$). The new description even showed realistic results when the depth of flow is of similar size as the height of the roughness elements themselves. This result demonstrates its superiority over commonly used wall-roughness methods.

1 INTRODUCTION

Submerged vegetation directly influences the discharge capacity in rivers, floodplains or irrigation channels. As a result, the hydraulic resistance of vegetation has been extensively studied in the past decades (for overview see Green 2005). While the hydraulic resistance of solid boundaries with small scale irregularities is quite well understood, situations in which resistance elements are of similar sizes as flow depths still pose large problems (e.g. Smart et al. 2002, Stone and Shen 2002). Especially near the roughness tops, the general form of the most representative velocity profile is still a matter of debate (e.g. Nikora et al. 2004). In case of vegetation, this is further complicated by the natural variability in plant dimensions or streamlining effects.

Laboratory flume studies with natural vegetation have resulted in several empirical flow resistance equations (e.g. Huntington et al. 1992, Copeland 2000). A drawback of these resistance relations is that it is not possible to attribute the relative importance of different flow processes to overall energy losses. General application is therefore difficult, especially in situations that differ much from the original experiments.

More general insight into the hydraulic resistance of vegetation can be achieved by ruling out effects that are due to streamlining effects of leaves and natural variability. Natural vegetation is then replaced by an idealized form: rigid cylindrical stems. Examples hereof can be found in flume studies (e.g. Meijer and van Velzen 1998 or Stone and Shen 2002) and detailed numerical flow models (e.g. Uittenbogaard 2003, Neary 2003). While numerical flow models have shown to represent flow characteristics realistically, the computational effort makes them of limited use for large-scale river applications. Therefore, more simplified solutions are desired that describe the mean flow field in terms of the cylinder characteristics and flow depth.

Stephan and Gutknecht (2002) suggest that the mean deflected plant height is a suitable measure for vegetation resistance. However, Klopstra et al. (1997) claim that a roughness height analogy underestimates vegetative resistance and developed a method that takes into account drag due to individual stems (cylinders) and turbulent mixing. Through depth-integration of the vertical velocity profile an analytical expression for the mean velocity was derived. Unfortunately, the expression is still quite complex and the necessary turbulence closure parameter is poorly understood. Consequently, there are still difficulties in its practical application.

In the current work, flow over vegetation is described by an average-velocity model where distinct flow characteristics are attributed to two separate flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

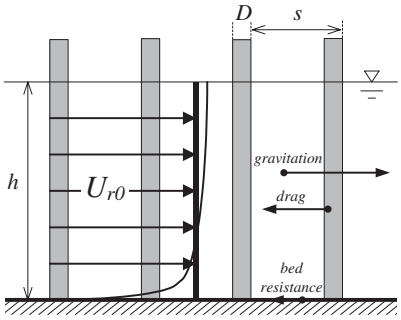

Figure 1. The depth-averaged velocity U_{r0} is the result of the balance between the gravitational force (i.e. gravity-driven flow, because of channel with bed slope i), the drag force and the bed resistance. The individual stems have a diameter D [m] and a separation s [m] ($s = 1/\sqrt{m}$, m = surface density [m^{-2}]).

layers. These two regions will be referred to as the surface layer and the resistance layer (see also Figure 2). General scaling assumptions are made, which avoid the necessity of integration over depth and the associated complications of depth-dependence of turbulence intensities. Even though specifics of natural vegetation are neglected, its accurate description of flow through an array of cylindrical stems gives confidence in applications that involve vegetative hydraulic resistance.

2 FLOW THROUGH VEGETATION

When a flow field is penetrated by vegetation, turbulent vortices are created in the wake behind the protruding stems (e.g. Akilli and Rockwell 2002). Consequently, in addition to the resistance at the bed, drag effects around the individual plant stems cause the flow to slow down. By replacing the vegetation with a homogeneous field of identical cylindrical stems, the water movement is represented by a bulk force balance (e.g. Baptist 2005):

$$\underbrace{\rho g h i}_{\text{gravitation}} = \underbrace{\tfrac{1}{2}\rho C_D m D h U_{r0}^2}_{\text{stem drag}} + \underbrace{\rho f U_{r0}^2}_{\text{bed resistance}} \qquad (1)$$

where the individual stems, with diameter D [m] and bed surface density m [m^{-2}], exceed the flow depth h [m] (see Figure 1). Furthermore, C_D [-] is the drag coefficient, i [-] the slope of the channel, and f [-] is the bed resistance function. The separation between individual cylinders s is entirely determined by their bed surface density m:

$$s = \frac{1}{\sqrt{m}} \qquad (2)$$

Also, the stem diameter D and the stem surface density m can be combined to give a new length scale. Together with the drag coefficient we introduce b, the *drag length*:

$$b = \frac{1}{C_D m D} \qquad (3)$$

By using (3), the average velocity U_{r0} [m/s] may be written as:

$$U_{r0} = U_{r0}^* \sqrt{\frac{1}{1 + \frac{2b}{h} f}} \qquad (4)$$

where U_{r0}^* is the average flow velocity in the resistance layer if no bed resistance effects were present (i.e. when $f = 0$).

$$U_{r0}^* = \sqrt{2bgi} \qquad (5)$$

The average flow velocity U_{r0} can now be determined if the bed resistance function f is specified. For turbulent flows, several functions for f exist (see e.g. Yen 2002). A commonly used relation for turbulent rough flow was proposed by Strickler (1923), here given in a dimensionally homogeneous form:

$$\sqrt{f} = \frac{\sqrt{ghi}}{U} = \tfrac{1}{8}\left(\frac{k_S}{h}\right)^{1/6} \qquad (6)$$

where Strickler's roughness height k_S [m] reflects the size of the irregularities on the bed and U the associated depth-averaged velocity. Considering that k_S is usually much smaller than the flow depth h, the contribution of bed resistance is often negligible in the force balance (1) and, consequently, the average velocity in the resistance layer U_{r0} is practically equal to U_{r0}^*.

Kadlec (1990) warns of the possibility that within the resistance layer flow velocities could reduce to yield a laminar flow field. In that case, the resistance function f is inversely proportional to the Reynolds number (see e.g. Yen 2002).

3 SUBMERGED VEGETATION

3.1 *The resistance layer*

Whenever cylindrical elements become submerged, the flow in the surface layer has a higher average velocity because in this layer no drag due to the stems is experienced. The energy losses in the surface layer are then entirely due to a shear stress near the top of the resistance layer, which balances the gravitational force that drives the flow. Subsequently, the shear stress between surface and resistance layer (i.e. the *interface*

Copyright © 2006 Taylor & Francis Group plc, London, UK

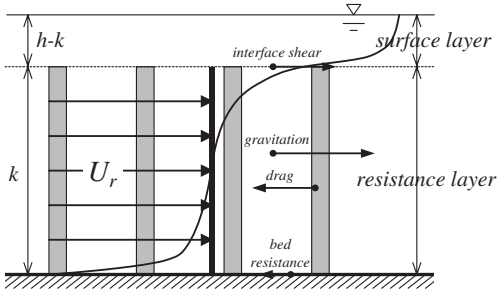

Figure 2. The depth-averaged velocity U_r in the layer occupied by the cylindrical stems (i.e. in the *resistance layer*) in the case that the stems are submerged.

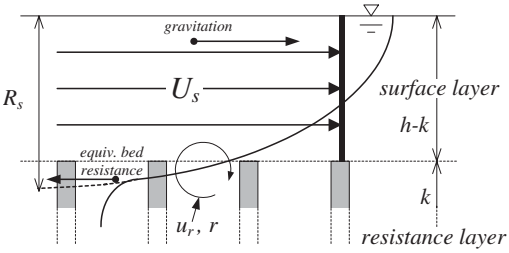

Figure 3. The depth-averaged velocity in the surface layer U_s. Two hydraulic radii are also shown: R_s reflects the depth of the surface layer with respect to an artificial rough bed and r (the *spacing hydraulic radius*) reflects the roughness height of the artificial rough bed.

shear) also causes the flow in the top of the resistance layer to speed up (see Figure 2). With an extra component due to the surface layer, the force balance (1) modifies to:

$$\underbrace{\rho g(h-k)i}_{\text{interface shear}} + \rho g k i = \frac{\rho k {U_r}^2}{2b} + \rho f {U_r}^2 \qquad (7)$$

The two contributions on the left-hand-side of (7) are due to the gravitational force that acts on the surface and in the resistance layer, respectively. The drag force acts over a depth k, as opposed to the total flow depth h in case of (1), where the cylindrical stems were not submerged. As a result, the average velocity in the resistance layer U_r becomes:

$$\frac{U_r}{U_{r0}} = \sqrt{\frac{h}{k}} \quad (h \geq k) \qquad (8)$$

where U_{r0} is the average velocity in the resistance layer if no free flowing layer above the cylindrical stems were present (equation (4)). Inserting the bed resistance function f as given in (6) into (7), yields for U_{r0}:

$$U_{r0} = U^*_{r0} \sqrt{\frac{1}{1 + \frac{b}{32k}\left(\frac{k_S}{h}\right)^{1/3}}} \qquad (9)$$

In earlier works, results similar to the square root law in (8) have been found. Smart et al. (2002) point out that with increasing relative roughness, a conceptual drag coefficient model would lead to a square-root law of the flow resistance. Baptist et al. (2006) used dimensionally aware genetic programming (Keijzer and Babovic 2000) and also found a square root dependence with respect to the relative flow depth h/k.

3.2 *The surface layer*

Based on physical principles and scaling assumptions, the well-known Strickler equation (6) can be derived for the case of rough channel flow (see Gioia and Bombardelli 2002). The main principles behind the derivation are: (i) a simple force balance; (ii) scaling of turbulent velocity fluctuations to the average flow velocity; and (iii) the concept of a constant energy dissipation rate when large turbulent flow patterns (i.e. eddies) break up into smaller ones (known as *Kolmogorov scaling*). Here we will follow the same line of reasoning to describe depth-averaged flow over submerged rigid cylinders (i.e. for the surface layer; see Figure 3).

3.2.1 *Shear stress in the surface layer*

In steady flow over a rough bed, the shear stress at the top of the bed τ_k balances the gravitational pull on the water volume above the bed. In analogy, for the surface layer this gives an expression for the shear stress (R_s is the hydraulic radius of the surface layer):

$$\tau_k = \rho g R_s i \qquad (10)$$

Furthermore, from the Reynolds averaged Navier-Stokes equation it follows that the (Reynolds) shear stress at any location in a (2D) flow field is determined by the magnitude of fluctuations in the velocity field (e.g. Pope 2000):

$$\tau_{xz} = \rho \overline{v_x v_z} \qquad (11)$$

where v_z and v_x are velocity fluctuations perpendicular and parallel to the direction of the average flow field. The overbar denotes time-averaging of these fluctuations. Gioia and Bombardelli (2002) argue that for the shear stress near the bed, v_x is associated with the characteristic velocity in the surface layer and that the perpendicular component is related to turbulent eddies that dominate between the roughness elements. The average velocity in the surface layer is U_s and the velocity associated with the dominating eddies near the artificial rough bed is denoted by u_r. Following

Copyright © 2006 Taylor & Francis Group plc, London, UK

Gioia and Bombardelli the shear stress at the artificial bed (i.e near the top of the resistance layer, see Figure 3) scales as:

$$\tau_{xz} \propto \rho U_s u_r \tag{12}$$

Together with the force balance (10) this yields:

$$\rho g R_s i \propto \rho U_s u_r \tag{13}$$

To find a relation for the average velocity in the surface layer U_s an independent expression for u_r needs to be found. For that purpose, energy considerations of the turbulent flow field are used.

3.2.2 *Turbulent energy and Kolmogorov scaling*

In the Kolmogorov view on turbulent flow, turbulent energy is created through external forcing at the largest scale of the system (energy containing range) and is dissipated to successively smaller scales until eventually viscosity damps the smallest flow patterns (viscous dissipation). The rate of dissipation of turbulent kinetic energy per unit mass is denoted by ε [m^2/s^3] and, at large scales, is independent of molecular viscosity. For the energy input at the largest scale (the energy containing scale), a scaling expression for ε is composed of representative geometrical parameters (hydraulic radius R_s) and the representative flow velocity (U_s), based on dimensional analysis (e.g. Pope 2000).

$$\varepsilon \propto \frac{U_s^3}{R_s} \tag{14}$$

Furthermore, if we assume that:

- the turbulence intensity at the artificial rough bed is a result of the energy cascade to smaller scales;
- eddies of size r and velocity u_r dominate the flow field near the artificial rough bed;

then the dissipation rate should also scale as:

$$\varepsilon \propto \frac{u_r^3}{r} \tag{15}$$

Now ε is related to the characteristic velocity u_r and the spacing hydraulic radius r that bounds the extent of the dominant local eddies. The characteristic velocity in the resistance layer can be related to the average velocity in the surface layer as (using (14) and (15)):

$$u_r \propto U_s \left(\frac{r}{R_s}\right)^{1/3} \tag{16}$$

Expression (16) can now be inserted into relation (13). This yields a scaling expression for the average velocity in the surface layer:

$$U_s \propto \left(\frac{R_s}{r}\right)^{1/6} \sqrt{g R_s i} \tag{17}$$

Note that relation (17) reduces to the Manning/Strickler equation (Manning 1889, Strickler 1923) if the total relative flow depth is large (R_s large) and the spacing hydraulic radius is small (r becomes an equivalent roughness height). Also, using expression (16) and (17) a scaling equation for the characteristic velocity at the top of the resistance layer (u_r) can be established:

$$u_r \propto \left(\frac{r}{R_s}\right)^{1/6} \sqrt{g R_s i} \tag{18}$$

To specify the hydraulic radii R_s and r in terms of geometrical quantities, we will analyze the two scaling expressions (17) and (18) for their behaviour in certain limiting cases (*asymptotic analysis*).

3.2.3 *Asymptotic behaviour of hydraulic radii*

Scaling the average velocity in the surface layer U_s (17) to the velocity U_{r0} (9) yields the dimensionless velocity function:

$$\frac{U_s}{U_{r0}} \propto \sqrt{1 + \frac{b}{32k}\left(\frac{k_S}{h}\right)^{1/3}} \frac{R_s^{2/3}}{(2b)^{1/2} r^{1/6}} \tag{19}$$

For most practical cases the bed resistance can be neglected ($k_S << h$). Therefore, (19) reduces to:

$$\frac{U_s}{U_{r0}} \approx \frac{U_s}{U_{r0}^*} \propto \frac{R_s^{2/3}}{(2b)^{1/2} r^{1/6}} \tag{20}$$

We now assume that both U_s and u_r scale to the relative depth of the surface layer $(h-k)/\ell$, where ℓ is an unknown scaling length to be determined empirically. By making U_s and u_r dimensionless through division with U_{r0} we define the following power law asymptotics:

$$\frac{U_s}{U_{r0}} \propto \left(\frac{h-k}{\ell}\right)^{\gamma} \tag{21}$$

$$\frac{u_r}{U_{r0}} \propto \left(\frac{h-k}{\ell}\right)^{\eta} \tag{22}$$

The power law expressions (21) and (22), with constant γ and η, express *complete similarity* between the considered dimensionless velocities and the relative flow depths of the surface layer (as opposed to *incomplete similarity* when γ and η are variable, see Barenblatt 1996). According to (21) and (22) U_s and u_r allow different rates of convergence, but both eventually vanish when the surface layer disappears. The latter observation immediately limits the validity of the assumptions that lead to (21) and (22): the average flow velocity in the surface layer should always be larger than the flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

velocity in the resistance layer (U_{r0}), even if the surface layer is extremely shallow. Essentially, power laws (21) and (22) no longer give realistic results when values below unity are found (i.e. when the depth of the surface layer, $h-k$, becomes smaller than ℓ). Nevertheless, we continue with (21) and (22), realizing their limitations, and later on evaluate implications for practical application.

Solving for R_s and r by combining (21) and (22) with (17) and (18) yields:

$$R_s \propto 2b\left(\frac{h-k}{\ell}\right)^{\eta+\gamma} \tag{23}$$

$$r \propto 2b\left(\frac{h-k}{\ell}\right)^{4\eta-2\gamma} \tag{24}$$

Next, the two unknowns in the power law η and γ are determined by investigating the expected behaviour in the case that the water depth becomes much larger than the roughness height. Experimental observations (e.g. Manning 1889, Strickler 1923) have shown that when the depth of flow is much larger than the roughness height, then the flow hydraulic radius can be replaced by the flow depth h. For these conditions, the spacing hydraulic radius r as it appears in relation (17) reflects a roughness height and is independent of depth. Thus:

- If $h >> r$ then $R_s \sim h$
- If $h >> r$ then $r \sim$ constant

A priori it is not quite clear which parameter, or combination of parameters, r should scale to when h becomes much larger than k, but as long as r is not dependent on the depth h then the power law for r in (24) should vanish:

$$h^{4\eta-2\gamma} \sim 1 \Rightarrow 4\eta - 2\gamma = 0 \tag{25}$$

The hydraulic radius in the surface layer scales with h; therefore the power law in (23) should behave as:

$$h^{\eta+\gamma} \sim h \Rightarrow \eta + \gamma = 1 \tag{26}$$

Solving for η and γ by combining expression (25) and (26) yields $\eta = 1/3$ and $\gamma = 2/3$. As a result, the power law expressions for R_s and r become:

$$R_s \propto 2b\left(\frac{h-k}{\ell}\right) \tag{27}$$

$$r \propto 2b = \frac{2}{mDC_D} = \frac{2s^2}{C_D D} \tag{28}$$

It was mentioned earlier that r reflects the extent of the largest eddies near the artificial bed. This means that when the separation between roughness elements s is equal to the dynamic diameter of the cylinders (i.e. $C_D D$) then the largest eddies are bounded by s. However, when the diameter of the elements are significantly smaller than the spacing between elements, then (28) shows that r exceeds s. In effect, relation (28) tells us that whenever the spacing between elements is large as compared to the size of the elements themselves, then the eddies are not confined to the space in between the roughness elements.

Expressions (27) and (28) are inserted into the scaling expressions for the average velocity in the surface layer (19), and we arrive at:

$$\frac{U_s}{U_{r0}} \propto \left(\frac{h-k}{\ell}\right)^{2/3} \tag{29}$$

This is the new scaling expression for the average velocity in the surface layer. Basic assumptions that lead to this result were (i) similarity between velocities and relative flow depths (power laws (21) and (22)) and (ii) correspondence with Manning's equation at large flow depths. A specification of the unknown scaling length ℓ in terms of measurable geometric parameters follows from comparison with laboratory experiments.

4 COMPARISON TO DATA FROM FLUME EXPERIMENTS

4.1 *Average velocities in the two flow layers*

The experimental data used in this section is adopted from laboratory flow studies as performed at the *De Voorst* WL|Delft Hydraulics facility in 1996 (Meijer and van Velzen 1998, Meijer 1998, also reported in Baptist 2005). Based on four flow experiments without artificial vegetation, the roughness height k_S of the flume bed was determined to be $k_S = 2.3 \pm 0.6$ mm. In the results presented here, this value for k_S is used for computing U_{r0} (equation 9).

Further data from these studies comprise 48 flow experiments with homogeneously distributed cylindrical stems that all have the same diameter D of 8 mm. Flow depths h and cylinder heights k were varied between the experimental runs (three values for k were used: 0.45, 0.9 and 1.5 [m]). Half of the experiments were carried out with a surface density of $m = 256$ cylindrical stems per square meter, and the other half with a surface density of $m = 64$ [m^{-2}]. Flow velocities were measured at different depths 0.10 [m] apart. Using linear interpolation the average flow depth for the surface and the resistance layer were estimated separately. From the measured average velocities in the resistance layer, local Reynolds numbers were calculated ($Re \sim 3 \cdot 10^4 - 4 \cdot 10^4$) and, subsequently, the drag coefficients C_D for the circular cylinders. Standard works on fluid mechanics report that in such a flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

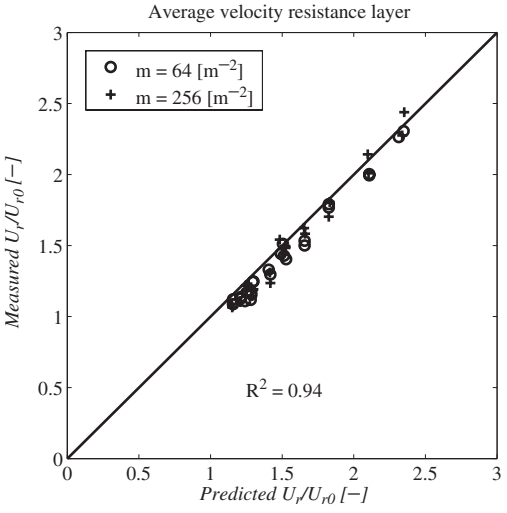

Figure 4. The proposed scaling relation for the depth-averaged velocity U_r in the resistance layer (relation (8), on horizontal axis) as compared to results from laboratory flume experiments (m = number of cylindrical stems per m^{-2} on the bed surface).

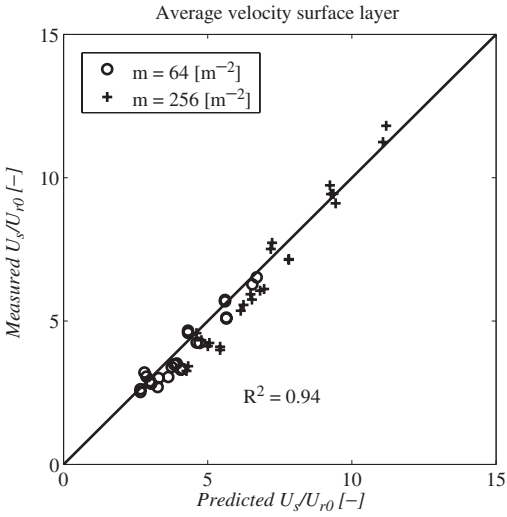

Figure 5. The depth-averaged velocity U_s in the surface layer; the proposed relation (30) (on horizontal axis) vs. measured flow velocities.

regime the drag coefficient remains fairly constant with a value of nearly 1 (e.g. Schlichting 1979).

Figure 4 shows the measured average velocities in the resistance layer as compared to the predictions of relation (8). Although for slow flows the velocities are slightly overestimated, by using relation (8) overall agreement with data is very good ($R^2 = 0.94$).

For the specification of the unknown scaling length ℓ in relation (29), several combinations of available length scales were attempted (D, s, b and combinations of these). It turns out that for $\ell = s$ the proposed scaling law gives best agreement with laboratory data (see Figure 5). The correlation coefficient is again $R^2 = 0.94$, in which we have chosen the coefficient of proportionality equal to unity. Apparently, the spacing between the roughness elements is a suitable measure of the extent to which the flow in the surface layer influences the flow field in the resistance layer. Based on this finding, it seems natural to assume that ℓ may never exceed the height of the cylinders k. By imposing a limit of height k on the scaling length ℓ, we propose the following scaling expression for the average velocity in the surface layer:

$$\frac{U_s}{U_{r0}} = \left(\frac{h-k}{\min(s,k)}\right)^{2/3} \tag{30}$$

In section 3.2.3 it was argued that expression (29), or (30), is no longer valid when the flow depth $(h-k)$ is close to or smaller than the scaling length ℓ (i.e. $\ell = \min(s,k)$). However, in the considered experimental data the flow depth $(h-k)$ goes down to less than three times ℓ, and still expression (30) performs well (see Figure 5).

4.2 *A two-layer scaling model for the entire flow depth*

The average flow velocity for the entire flow depth U_T can be found by adding the weighted average flow velocities of the resistance and the surface layer (U_r and U_s, respectively):

$$\frac{U_T}{U_{r0}} = \frac{k}{h}\frac{U_r}{U_{r0}} + \frac{h-k}{h}\frac{U_s}{U_{r0}} \tag{31}$$

By making use of scaling relations (8) and (30), the expression for the average velocity over the entire flow depth (31) becomes:

$$\frac{U_T}{U_{r0}} = \sqrt{\frac{k}{h}} + \frac{h-k}{h}\left(\frac{h-k}{\min(s,k)}\right)^{2/3} \tag{32}$$

In the previous section the validity of (30) was addressed for cases when the depth of the surface layer $(h-k)$ becomes small. Significant errors in (30) are expected when $(h-k)$ becomes close to or smaller than ℓ. However, relation (31) shows that in such cases the average velocity in the surface layer (U_s) only contributes little to the *overall* average velocity (U_T). Therefore, errors in (30) due to shallowness of the surface layer only have a minor impact on the total depth-averaged velocity U_T.

Copyright © 2006 Taylor & Francis Group plc, London, UK

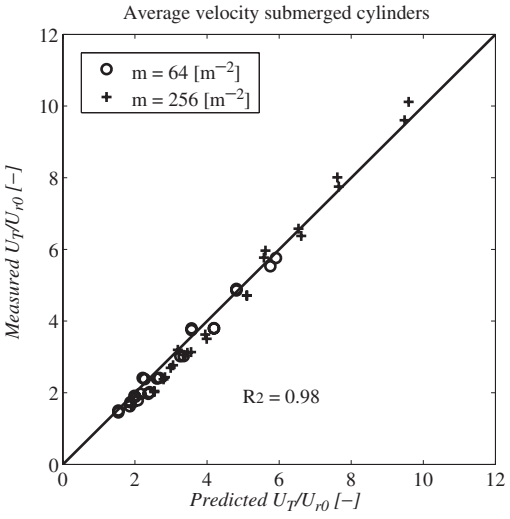

Figure 6. The depth-averaged velocity U_T over the entire flow depth (relation (32), on horizontal axis) vs. measured average velocities.

In Figure 6, the predictions of relation (32) are shown in comparison to the measured average flow velocities (interpolation between flow velocities measured at different depths). The combined performance of the velocity scaling expressions (8) and (30) is even better than found before, yielding a correlation coefficient of $R^2 = 0.98$.

5 CONCLUSIONS

For open channel flow over rough surfaces, several suitable relations exist that relate the average flow velocity to a roughness height that reflects the resistance of the bed. However, when the bed is covered with large roughness elements such as vegetation, or cylindrical elements, these methods are theoretically no longer valid. In this paper, a two-layer scaling model is proposed that treats the flow field above and in between the roughness elements separately, and, when combined, gives a description of the depth-averaged velocity of the entire flow field. When comparing the newly derived description to results from flume experiments, very good agreement is found (correlation coefficient $R^2 = 0.98$). The scaling length ℓ, that completes the velocity relation in the surface layer, is found to be well represented by the spacing between the cylindrical stems. It is expected that this is no longer the case when the height of the cylinders is smaller than the distance between them. Further investigations with different geometrical properties of the cylinders, and different spatial distributions, should be carried out to substantiate this claim.

The difficulty of describing flow over vegetation is primarily due to flow characteristics near the top of the vegetation, as reflected in the scaling length ℓ that is necessary to describe the flow in the surface layer. The flow field in between the resistance elements is satisfactorily described by drag forces. However, for the surface layer energy losses are due to the turbulent patterns, for which in a bulk flow description a representative closure parameter is required. In the used experimental data set, vegetation was represented by homogeneously distributed identical rigid stems, and the turbulent length scale was adequately described by one geometrical length scale from *within* the resistance layer. Future work will be focussed on the characteristics of such a scaling length when geometric variability between the resistance elements exist. Eventually, the aim is to describe flow over natural vegetation, which involves further complications as stem flexibility, or leaves and side branches that individual plants may have.

Turbulent structure and dispersive properties in vegetated canopy open-channel flows

I. Nezu, M.Sanjou & T. Okamoto
Dept. of Civil Eng., Kyoto University, Kyoto, Japan

ABSTRACT: It is very important in river environment as well as in hydraulic engineering to investigate the hydrodynamic properties in vegetated canopy rivers, in which velocity distributions are largely changed in not only vertical but also spanwise directions. In particular, it is necessary to reveal such dispersive properties of velocity components, since the velocity dispersion has significant relations with turbulent transport and generation of turbulence due to the vegetation wakes. Therefore, in this study, turbulence measurements were conducted intensively in the vegetated open-channel flows by using two-component laser Doppler anemometer (LDA), and consequently, the turbulent structure and dispersive effects were revealed experimentally.

1 INTRODUCTION

A large amount of aquatic plants are observed in actual rivers and they have significant effects on hydrodynamic characteristics such as the velocity distributions, turbulence and coherent structure, as well as mass and momentum exchanges between the vegetated and non-vegetated zones. Of particular significance is that the importance of river vegetation has recently been recognized not only for water management but also for river environment, and it is therefore needed to reveal a coherent property of turbulence which has a vital influence on scalar transports, such as dissolved oxygen, chemical materials and suspended sediment in water.

In particular, open-channel flows with submerged vegetation may somewhat be similar to air flows over the forest and crop fields. Some meteorologists have studied intensively these canopy flows by field measurements and laboratory experiments. For example, Raupach *et. al* (1979, 1981) have tried to measure the canopy roughness flows in a wind tunnel by using hot-wire anemometers, and revealed the roughness effects on the velocity profiles and turbulence characteristics. Shaw *et. al* (1990) have conducted the field measurements with a sonic anemometer and pressure sensor in canopy flows of deciduous forest, and they showed a strong linear relationship between the deviations of velocity and pressure. Meyers & Baldocchi(1991) have also measured canopy flows in pine forest, and examined turbulent kinetic energy (TKE) budget, shear stress and vertical profiles of high order moments. These results have revealed that the turbulent energy is generated more largely by the velocity shear than by the vegetation wake except for around vegetation edge. Raupach *et. al* (1991) have compared their experimental data of wind tunnel canopies with some field data measured by the other researchers, and showed the relation between the velocity profiles and vegetation density. Furthermore, they have investigated a large-scale coherent structure by using two-point velocity correlation function and conditional analysis. Finnigan (2000) has reviewed the aerodynamic characteristics and turbulence in plant canopies on the basis of the recently measured and calculated data, and as the results, an interesting analogy between the canopy flow and the plane mixing layer was proposed. There are also some numerical studies on forest canopy flows. Dwyer *et al.* (1997) have calculated the TKE budget in air shear layers above and within a forest by LES. The noticeable advantage of such a numerical simulation is that the pressure transport term is evaluated directly, whereas it is very difficult to measure it experimentally. They predicted numerically the vertical profiles of the pressure diffusion transport and other terms in TKE.

As mentioned above, there are a lot of knowledge and valuable data in air flows over and within the vegetation canopies. In contrast, the vegetated rivers and open-channel flows have recently been investigated. For example, Neph *et al*. (2000) have conducted some turbulence measurements in vegetated open-channel flows with both of a laser Doppler anemometer (LDA) and an acoustic Doppler velocimetry(ADV). They highlighted a relation between the water depth and turbulence structure, and pointed out that the generation of wake turbulence is strongly associated with the relative water depth. Poggi *et al*. (2004) have also

Copyright © 2006 Taylor & Francis Group plc, London, UK

measured the vegetated open-channel flows by using LDA. They classified the whole flow depth region into three layers, i.e., the first is the lower layer in which sweep and ejection events are dominant, the second is the middle layer in which K-H waves are generated by the inflectional instability and the third is the upper layer which is similar to the boundary layer. They showed the relation between the energy cascade of spectrum and the vegetation density.

Although the friction law and resistance of vegetation have in the past decades been investigated intensively, a lot of uncertainties remain concerning the coherent structure, dispersive effects and turbulent energy transport properties. Therefore, we highlighted these important topics in the present study, and conducted accurate turbulence measurements with LDA in vegetated canopy open-channel flows in order to investigate dispersive properties and turbulence structure by varying the vegetation density.

2 EXPERIMENTAL PROCEDURES

2.1 *Measurement system*

Figure 1 shows the experimental setup and the coordinate system. The experiments were conducted in a 10 m long and 40 cm wide tilting flume. The elements of vegetation model were composed of non-flexible strip plates. These vegetation elements were attached vertically on the flume bed, as seen in Fig. 1. The size of this element is 50 mm height, 8 mm width and 1 mm thick, as shown in Fig. 2. H is the water depth and h is the vegetation height. B_v and L_v are the neighboring vegetation spacings in the spanwise and streamwise directions, respectively. x, y and z are the streamwise, vertical and spanwise coordinates. The vertical origin, $y = 0$, is chosen as the channel bed. The time-averaged velocity components in each directions are defined as U, V and W and the turbulent fluctuations are defined as u, v and w, respectively.

In order to measure two components of instantaneous velocity, i.e., $\tilde{u} \equiv U + u$ and $\tilde{v} \equiv V + v$, within and above the canopy vegetations, two-component fiber-optic LDA (DANTEC) system was used as shown in Fig. 1. This probe was located at 7 m downstream from the channel entrance. The four laser beams of 2W Ar-ion laser were projected into within the canopy layer as well as over the canopy vegetation. We could successfully measure the velocity profiles in the whole flow region from the bottom-bed to the water surface, including within the canopy vegetation, because the laser beams were not blocked by any vegetation strips.

2.2 *Hydraulic condition*

Table 1 shows the hydrodynamic conditions. Three kinds of experiments were conducted, i.e., case A, B and C, in which only the vegetation density λ was varied. U_m is the bulk mean velocity, $Re \equiv U_m H/\nu$ is the Reynolds number, $Fr \equiv U_m/\sqrt{gH}$ is the Froude number and U_* is the friction velocity.

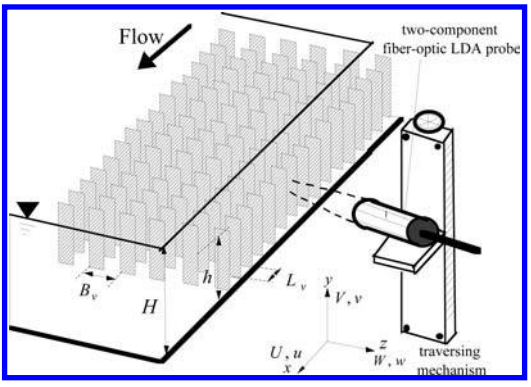

Figure 1. Experimental setup and coordinate system.

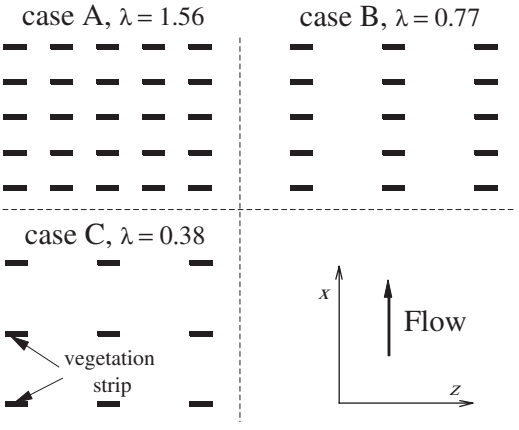

Figure 2. Allocation patterns of vegetations (top-view).

Table 1. Hydrodynamic conditions.

Case	λ	U_m(cm/s)	H (cm)	h (cm)	Re	Fr	U_* (cm/s)
A	1.56						2.8
B	0.77	12.0	15.0	5.0	18000	0.10	2.5
C	0.38						2.3

The combinations of B_v and L_v were selected as three patterns to examine the effects of the vegetation density as shown in Fig.2. The vegetation density λ is defined as follows:

$$\lambda \equiv \sum_i A_i / S \tag{1}$$

A_i is the frontal square of the vegetation strip and S is the referred bed area of $40 \times 40\,cm^2$. In this study, the

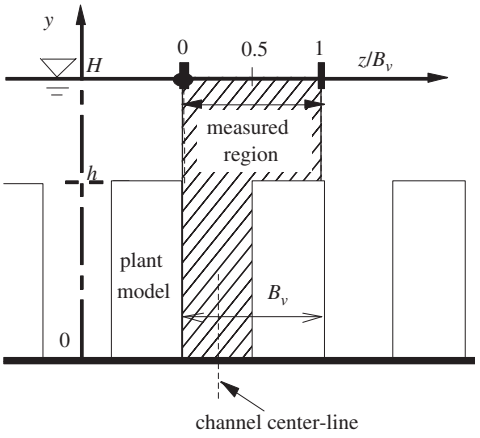

Figure 3. Measured region within and above vegetations (case A).

largest vegetation density is $\lambda = 1.56$(caseA), the middle density is $\lambda = 0.77$(caseB) and the sparsest density is $\lambda = 0.38$(caseC). In order to examine the lateral variations of velocity components and their dispersive properties, LDA measurements were conducted along eight vertical traversing lines between the neighboring plants, $0 \le z/B_v \le 1.0$, as shown in Fig. 3.

To reveal the effects of vegetation on turbulent structure, it is of essential importance to consider the horizontal space averaging in the time-averaging N-S equations (RANS), as pointed out by Raupach *et al.* (1991) and Finnigan(2000). A hydrodynamic value Φ is defined as follows:

$$\Phi \equiv \langle \Phi \rangle + \Phi'' \tag{2}$$

in which the angle bracket $\langle\rangle$ denotes the horizontal space averaging, and the double prime denotes the deviation from the space-averaged quantity.

3 RESULTS AND DISCUSSIONS

3.1 *Lateral profiles of streamwise velocity*

Figures 4(a) and (b) show the spanwise distributions of streamwise mean velocity $U(z)$ at several elevations within and above canopy for the different vegetation densities of $\lambda = 0.38$ and 1.56, respectively. The velocity is normalized by the space-averaged velocity $\langle U(y) \rangle$. It is found clearly that the streamwise velocity is varied significantly in the spanwise direction within the canopy, i.e., $y/h \le 1$, due to the local deceleration behind the vegetation, i.e., we call the "vegetation wake area". This trend is more remarkable in the denser vegetation. In contrast, over the canopy ($y/h > 1$), the lateral variations become smaller with an increase of

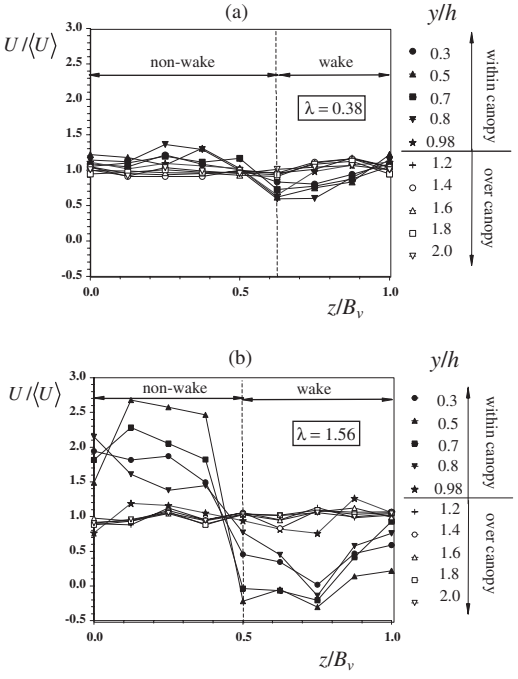

Figure 4. Lateral profiles of the streamwise velocity.

y/h, because the local effects of vegetations become negligibly small. From this viewpoint, it is suggested strongly that the velocity profiles may have a universal function over the canopy in a wide range of vegetation density as mentioned later.

3.2 *Space-averaged velocity profiles*

Figure 5 shows the vertical profiles of space-averaged streamwise velocity $\langle U(y) \rangle$, which is normalized by the vegetation-edge velocity $U_h \equiv \langle U(h) \rangle$. This figure reveals that the typical drag effects of vegetation decelerate the streamwise velocity more largely in the canopy layer of $y/h \le 1$ as the vegetation density becomes larger. Consequently, a significant inflectional point appears near the canopy edge$y/h = 1$, the feature of which is consistent with that of plant canopy flows, as reviewed by Finnigan(2000). Furthermore, a second peak, i.e., the counter-gradient velocity profile, is observed near the bottom-bed, which may be caused by three-dimensional dynamics of wakes.

In order to evaluate the inflectional velocity strength reasonably, the shear length scale L_s is defined as

$$L_S \equiv \frac{U(h)}{(\partial U / \partial y)_{y=h}} \tag{3}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

in the same manner as used by Raupach *et al.* (1996). They pointed out that L_s has a significant relation with the wave length of coherent eddies observed in mixing layers and canopy flows. Figure 6 shows the relation between L_s and λ, in which previous field plant data of Raupach *et al.* (1996) are also plotted for a comparison. L_s is in good correlation with vegetation density, and it is found obviously that the present flume value of L_s become smaller with an increase of λ, which is consistent with plant data reviewed by Raupach *et al.* (1996).

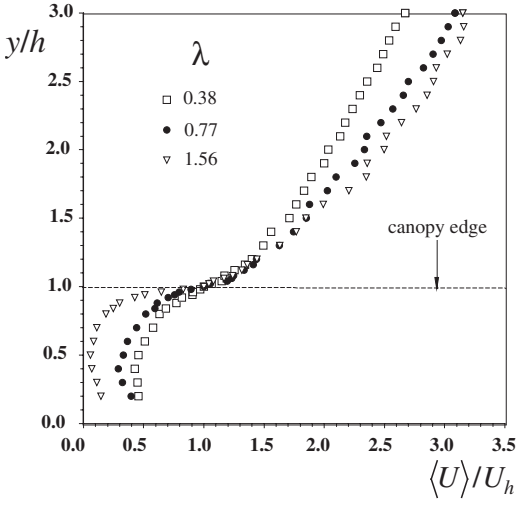

Figure 5. Vertical profiles of the horizontal averaged streamwise velocity.

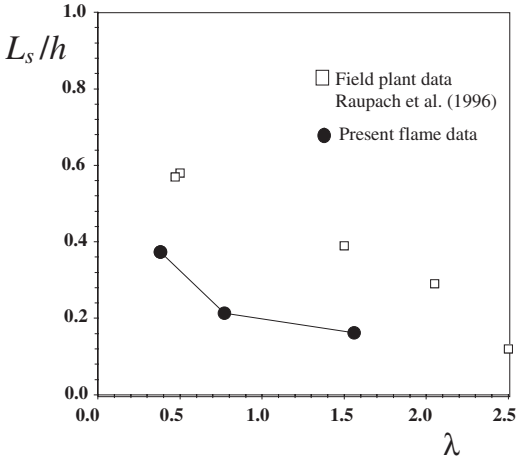

Figure 6. Relation between the shear length-scale and vegetation density.

3.3 *Reynolds stress and friction velocity*

Figure 7 compares the vertical profiles of horizontal averaged Reynolds stress, $-\langle\overline{uv}\rangle/U_*^2$, in the different vegetation density of $\lambda = 0.38, 0.77$ and 1.56. The friction velocity U_* was evaluated here as the peak value of the Reynolds stress, which is consistent with the method of plant canopy flows as reviewed by Finnigan (2000). The following theoretical equation derived from 2-D equation of motion is also included in Fig. 7.

$$-\left\langle\overline{uv}\right\rangle/U_*^2 = 1-(y-h)/(H-h) \tag{4}$$

It should be noticed that there are almost no differences among the vegetation densities over the canopy region of $y/h > 1$ and also that the normalized Reynolds stress coincides well with Eq. (4). In contrast, within the canopy, $y/h \leq 1$, the values of $-\langle\overline{uv}\rangle/U_*^2$ decrease toward the flume bed, irrespective of vegetation density. This trend is the most remarkable in the densest case due to the vegetation effect. The friction velocity U_* evaluated from Eq. (4) is also indicated in also Table 1. The results suggest that the bed friction becomes larger with an increase of the vegetation density.

3.4 *Logarithmic law*

We found that vegetations have much more significant effects on the space-averaged velocity and Reynolds stress within the canopy rther than over the canopy. Therefore, a universal formula may be applied to the velocity profiles over the canopy. Previous studies of

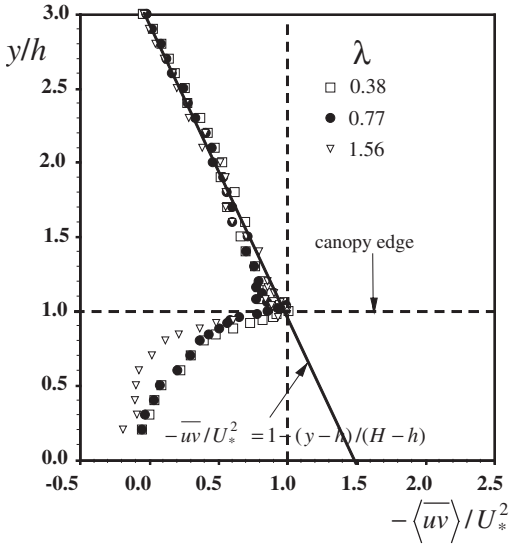

Figure 7. Distribution of the horizontal averaged Reynolds stress.

Copyright © 2006 Taylor & Francis Group plc, London, UK

plant flows have suggested the following log-law in the inner layer roughness wall and vegetation boundaries, e.g., see Jackson (1981)

$$\langle U\rangle/U_* = \frac{1}{\kappa}\ln\left(\frac{y-d}{y_o}\right) \tag{5}$$

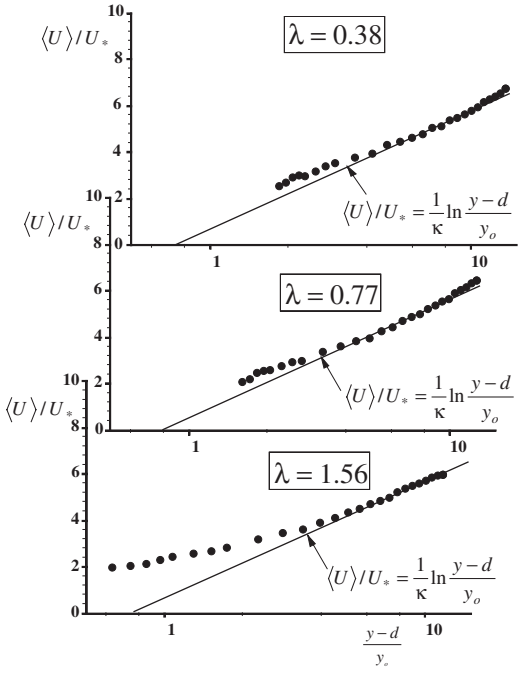

Figure 8. Horizontally averaged streamwise velocity normalized by the friction velocity.

in which d and y_o are the displacement thickness and roughness height, respectively. The von Karman constant κ was used as the standard value in the open-channel flows, i.e., $\kappa = 0.412$. Figure 8 shows the space-averaged velocity profiles over the vegetation canopies, in which the logarithmic law of (5) is also included. The measured values are in good agreement with the log-law for all vegetation densities. Figure 9 shows the relation between d and λ, which includes the field data and the wind-tunnel data obtained by previous researchers shown in Table 2. The detailed information is available in Raupach *et al*. (1996). It is found that d becomes slightly larger as the vegetation density is denser, and this property is also observed in a wide range of vegetation types. Figure 10 shows the relation between y_o and λ. Although the various data

are somewhat scattered, the present values are in the same order as the wind-tunnel (WT) ones, in which the strip-type vegetations were also used.

3.5 *Conditional analysis*

It is inferred from the inflectional profiles of velocity shown in Figure 5 as well as the Reynolds stress profiles shown in Figure 7 that coherent eddies are generated by the velocity shear near the vegetation edge, and consequently, they cause large momentum exchanges between the low-speed flow within the canopy and the high-speed flow over the canopy. In order to evaluate these properties quantitavely, the quadrant conditional analysis was conducted for the instantaneous Reynolds stress $-u(t)v(t)$. The quadrant Reynolds stress RS_i is defined as follows:

$$RS_i = \left(\overline{uv}\right)^{-1} \lim_{T\to\infty} \frac{1}{T} \int_0^T uvI_i\,dt \quad (i=1,2,3,4) \qquad (6)$$

If (u, v) exists in a quadrant i, then $I_i = 1$, otherwise $I_i = 0$. Each quadrant of (u, v) corresponds to the following coherent events:

$i=1$ $(u>0, v>0)$: outward interaction
$i=2$ $(u<0, v>0)$: ejection
$i=3$ $(u<0, v<0)$: inward interaction
$i=4$ $(u>0, v<0)$: sweep

Figure 11 indicates the vertical profiles of RS_i in the non-wake region between the neighboring elements ($z/B_v = 0.25$ in the case A, $z/B_v = 0.375$ in the cases B and C). It is found that RS_2 is larger than RS_4 near the free-surface and thus, the ejection event is pronounced in the same manner as observed in boundary layers. In contrast, RS_4 is much larger than RS_2 within the canopy, and the sweep event is more dominant.

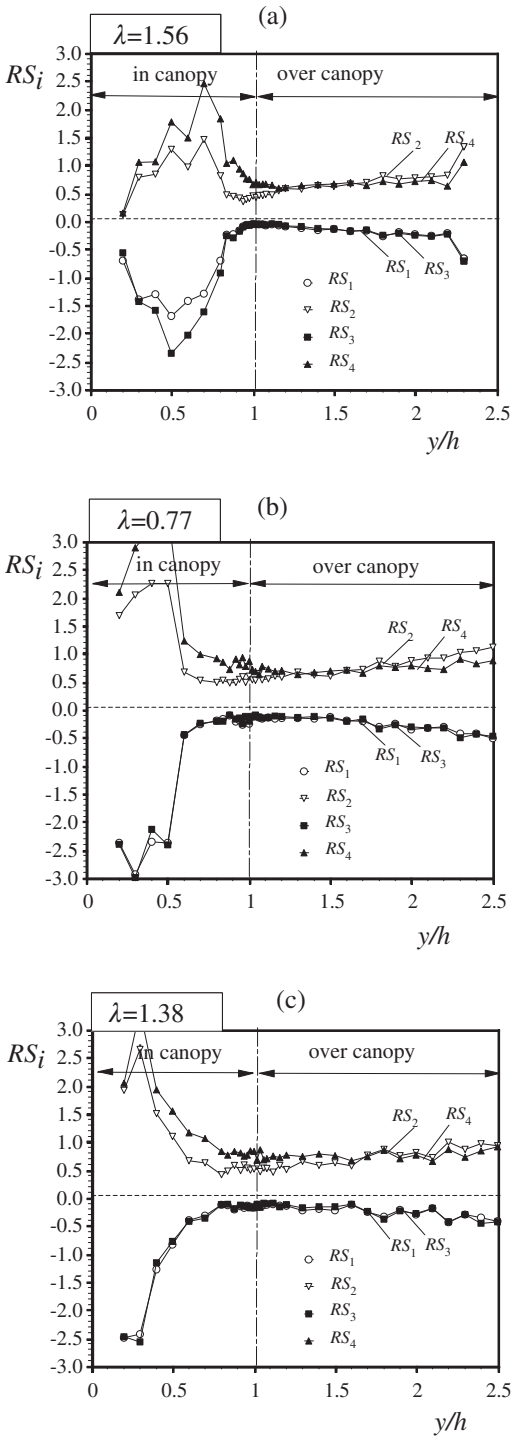

Figure 11. Distribution of the conditional Reynolds stress (non-wake region).

Copyright © 2006 Taylor & Francis Group plc, London, UK

It should be noticed that the coherent sweep motion transports the high-speed fluid from the outer canopy toward the inner canopy region. Of particular significance is that RS_2 and RS_4 attain the peak value closer to the bottom-bed with a decrease of the vegetation density λ, and it suggests strongly that the high-speed sweep motion is more inrushed toward the channel-bed in sparser canopy flows.

3.6 *Distributions of third-order moments*

The sweep and ejection events are related with skewness which is the third-order moments, because the skewness means the deviation from the Gaussian (the skewness is zero), as pointed out by Nakagawa & Nezu (1977). The skewness factors of $u(t)$ and $v(t)$ are defined as follows:

$$S_u \equiv \overline{u^3}/u'^3, \quad S_v \equiv \overline{v^3}/v'^3 \tag{7}$$

Figure 12 shows the variations of S_u and S_v, $\Delta RS \equiv (RS_4 - RS_2)$ which means the difference of sweeps to ejections. S_u and S_v are close to zero over the canopy, whereas these values vary largely within the canopy. Of particular significance is that S_u has a large positive peak and S_v has a large negative peak within the canopy. These results suggest that coherent motions are generated predominantly near the just edge and within the canopies. The values of ΔRS are positive ones within the canopy, and the distribution of ΔRS is similar to that of S_u. From these findings, it is considered that the coherent events such as sweeps and ejections are related significantly with the third-order moments.

3.7 *Spectral analysis*

Figure 13 shows some examples of the power frequency spectrum $F_u(f)$ of the streamwise fluctuations $u(t)$ in the within-canopy layers ($y/h \leq 1$) and the over-canopy layers ($y/h > 1$), in which each figure is shifted up by 10^3 to avoid confusions, and the spectrum is normalized by the frequency f and the turbulent intensity. In the over-canopy layers, the spectral distributions obey the Kolmogoroff's $-5/3$ power law (the spectral gradient in Figure 13 is not $-5/3$ but $-2/3$ due to the multiplying by f.) in the inertial subrange ($1 < f < 10$ Hz). However, within the canopy, the spectral distribution fits to the $-5/3$ power law in a narrower range($1 < f < 5$ Hz), and the spectrum increases in the high frequency range of $f > 10$ Hz. This suggests that there may be a turbulence energy supply caused by the wake eddies generated behind the vegetation elements. This property is more remarkable nearer the bottom bed, whereas the spectral profile nearer the free surface is closer to that of boundary layers since the

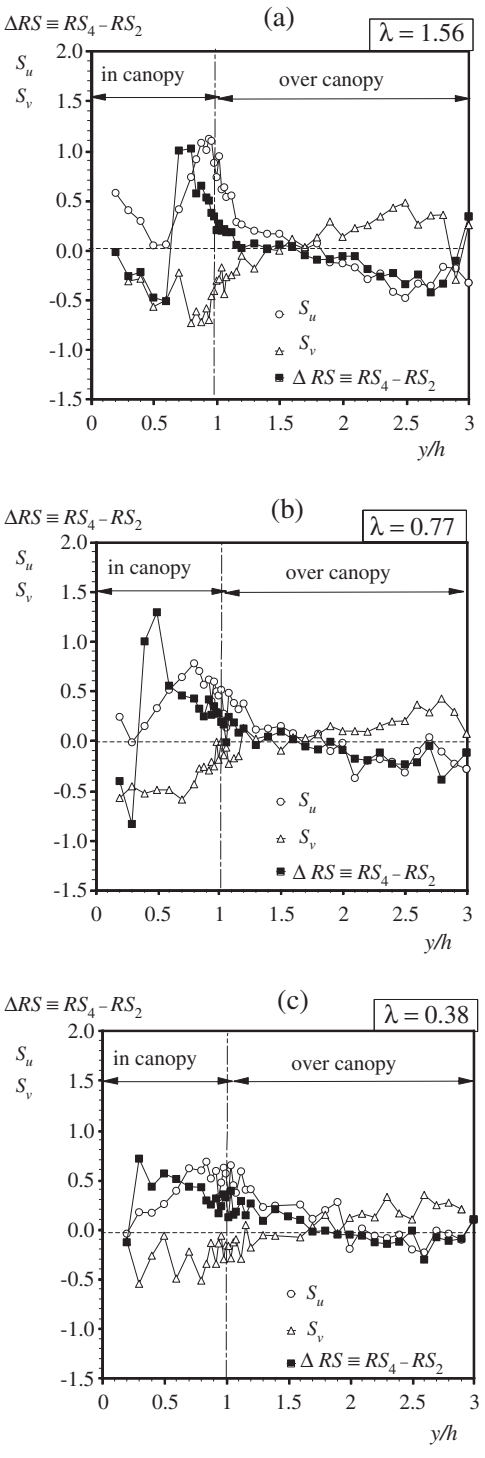

Figure 12. Skewness factors of u and v, and the difference of RS_i (non-wake region).

Copyright © 2006 Taylor & Francis Group plc, London, UK

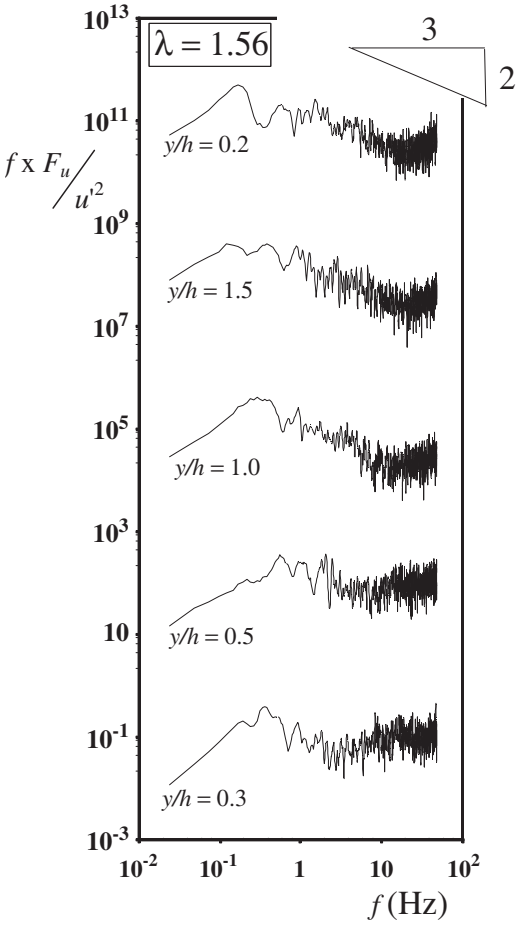

Figure 13. Spectrum distribution ($\lambda = 1.56$ and $z/B_v = 0.25$).

effects of coherent motions are smaller farther from the vegetation layer.

3.8 *TKE budget*

It is found from the present study that the lateral variations of turbulence characteristics are very small over the vegetation canopy, whereas, they are, however, varied largely within the canopy. It is therefore suggested strongly that there are significant dispersive influences due to space-averaging of Eq. (2) in vegetated open-channel flows. In this section, we highlight the despersive effects on the generation of turbulent energy. The turbulent kinetic energy (TKE) is given by

$$k \equiv \frac{1}{2}(u'^2 + v'^2 + w'^2) \tag{8}$$

Since the spanwise velocity component $w(t)$ was not measured in the present study, k was approximately given by:

$$k \cong \frac{1}{2}(u'^2 + 2v'^2) \tag{9}$$

The horizontally averaged TKE equation is reduced to

$$\frac{\partial k}{\partial t} = \langle G_s \rangle + G_w + \langle T_t \rangle + T_d + \langle T_p \rangle + \langle T_v \rangle - \langle \varepsilon \rangle \tag{10}$$

as pointed out by Raupach *et al.* (1996). Each term in the right-hand side of (10) means the sink and source of the turbulent kinetic energy, and it is given by, respectively,

$$\text{(shear generation)} \quad \langle G_s \rangle = -\langle \overline{uv} \rangle \frac{\partial \langle U \rangle}{\partial y} \tag{11}$$

$$\text{(wake generation)} \quad G_w = \left\langle \overline{u_i u_j}'' \frac{\partial U_i''}{\partial x_j} \right\rangle \tag{12}$$

$$\text{(turbulence transport)} \quad \langle T_t \rangle = -\frac{\partial}{\partial y}\langle \overline{vk} \rangle \tag{13}$$

$$\text{(dispersive transport)} \quad T_d = -\frac{\partial}{\partial y}\langle V''k'' \rangle \tag{14}$$

$$\text{(pressure transport)} \quad \langle T_p \rangle = -\frac{\partial}{\partial y}\langle \overline{vp} \rangle \tag{15}$$

$$\text{(viscous diffusion)} \quad \langle T_v \rangle = -\nu \frac{\partial^2}{\partial y^2}\langle k \rangle \tag{16}$$

The first and second terms in the right-hand side of (10) imply the turbulence generation rate. $\langle G_s \rangle$ is the horizontally averaged shear generation caused by the velocity gradient $\partial U/\partial y$, which is generally dominant near the wall region in boundary layers and open-channel flows. On the other hand, G_w is the wake generation which implies the energy transport from the mean flow toward turbulence field by the wakes behind the vegetation elements. Of particular significance is that G_w is introduced by the space-averaging operation of (2), and its term does not appear at all in the standard TKE (local) equation of (10). To avoid differential errors when the measured data are used in (11), Raupach *et al* (1986) have given the following approximate equation.

$$G_w \cong -\langle U \rangle \frac{\partial \langle \overline{uv} \rangle}{\partial y} \tag{17}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

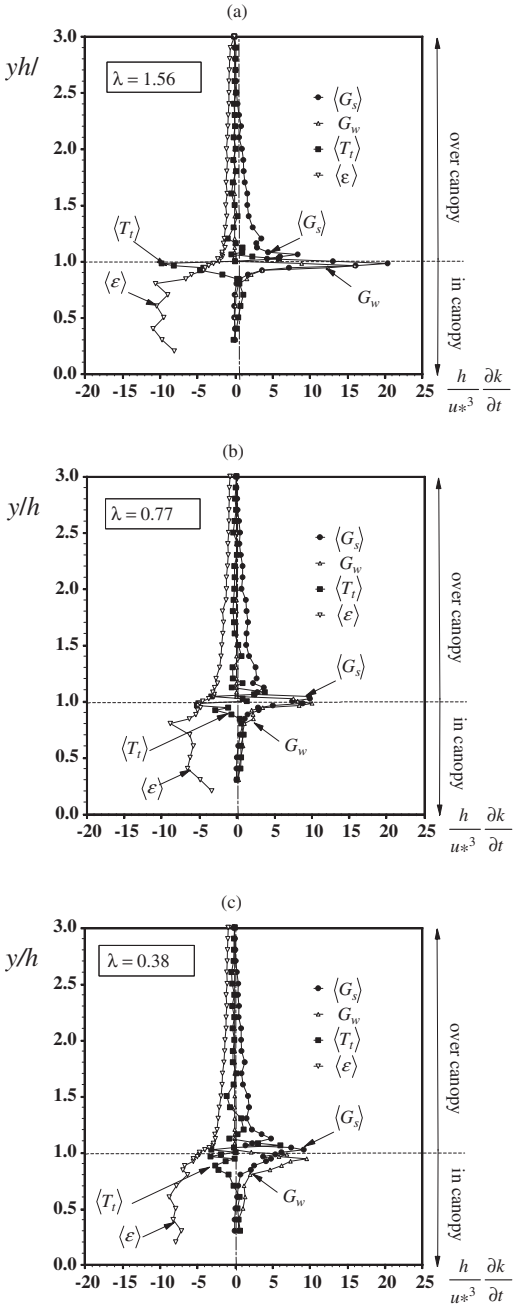

Figure 14. Turbulent kinetic energy budget.

$\langle T_t \rangle$, T_d, $\langle T_p \rangle$, $\langle T_v \rangle$ and $\langle \varepsilon \rangle$ imply the 'turbulence transport', the 'dispersive transport', the 'pressure transport', the 'viscous diffusion' and the 'space-averaged energy dissipation'. The local dissipation of ε was evaluated by applying the Kolmogoroff's $-5/3$ power law to the sectrum distributions in the whole depth region ($0 < y < H$). Unfortunately, $\langle T_p \rangle$ could not be evaluated directly because the pressure was not measured in the present study. T_d and $\langle T_v \rangle$ were assumed to be negligibly small.

Figure 14 shows the vertical distributions of $\langle G_s \rangle$, G_w, $\langle T_t \rangle$ and $\langle \varepsilon \rangle$. $\langle G_s \rangle$ has a peak value near the vegetation edge and this corresponds to the Reynolds stress profiles shown in Fig. 7. It is also found that G_w decreases toward the vegetation bed. Of particular significance is that G_w is comparable with or larger rather than the shear generation $\langle G_s \rangle$. This suggests that the wake generation plays an important role on the turbulence generation within the canopy.

$\langle T_t \rangle$ has negative values near the edge within the canopy. This implies that the significant energy loss is caused by strong downward sweeps which transport high-speed momentum toward the inner vegetation layer. As the results, we can observe a positive distribution of $\langle T_t \rangle$ around the middle canopy layer ($y/h \cong 0.5$). Since these fluctuations are much dissipated into heat, $\langle \varepsilon \rangle$ becomes more dominant within the canopy layer.

4 CONCLUSIONS

The hydrodynamic properties and dispersive effects were investigated in the vegetated open-channel flows on the basis of LDA measurements in the whole depth region from the bottom-bed to the free surface. In particular, it was found that the vegetation density correlates strongly with the turbulent structure. The main findings obtained in the present study are as follows:

1) The mean velocity profile has an inflectional point near the vegetation edge, which causes the significant shear instability. The measured shear length-scale decreases with an increase of the vegetation density.
2) The mean velocity profile is affected by the vegetation within the canopy, and it is decelerated largely with an increase of the vegetation density. On the other hand, it obeys the universal formula, i.e., the log-law over the canopy in which the plant elements do not greatly affect the fluid.
3) It is found from the skewness distributions that there are noticeable coherent structures within the canopy, and the significant momentum exchange occurs between the within-canopy and the over-canopy. The conditional quadrant analysis revealed that the sweep event is greater than the ejection event near the canopy edge.
4) The spectrum obeys the Kolmogoroff's $-5/3$ power law in the inertial subrange within and above the canopy. However, it should be noticed that the high-frequency spectrum becomes larger as compared

Copyright © 2006 Taylor & Francis Group plc, London, UK

with the low-frequency one within the canopy vegetation. This may be caused by the wake turbulence behind the vegetation elements.

5) The TKE budget was examined in order to reveal the dispersive contributions of turbulence due to vegetations. Of particular significance is that the turbulent fluctuations are generated strongly near the vegetation edge and the wake generation is comparable or larger than the shear generation. Furthermore, it is demonstrated significantly that the coherent motion such as sweeps transports the turbulent energy into the canopy layer.

ACKNOWLEDGEMENTS

The financial support to the present study was awarded from the government [Grand-in-Aid for Scientific Research (B) No.15360265; Representative: I. Nezu], and it is hereby acknowledged.

Influence of aquatic plants on the flow resistance and the hydraulic capacity of vegetated rivers

L. De Doncker, P. Troch & R. Verhoeven
Hydraulics Laboratory, Ghent University, Belgium

K. Bal & P. Meire
Ecosystem Management Research Group, University of Antwerp, Belgium

ABSTRACT: Vegetation growth drastically influences water levels and flow patterns in lowland rivers. Rise of the water level can have consequences for the surrounding areas and varying velocity patterns can influence the morphology of the river. The universities of Ghent and Antwerp are carrying out research in the river Aa, the Grote Kaliebeek and the Desselse Nete (Antwerp, Belgium) in order to better understand the natural phenomena involved and to come to a more accurate determination of the different parameters. Field measurements are carried out to collect data on discharge, stage and amount and variation of aquatic weed growth. The variation of the friction factor (Manning coefficient), influenced by the varying amount of vegetation, is determined as a function of time and distance. Following a seasonal cycle, flow resistance increases with plant growth in spring, reaches a maximum in early summer and then decreases slowly to the minimum in winter. Knowledge of the variation of the biomass in the time will lead to appropriate use of roughness coefficients in modelling surface flow in rivers.

1 INTRODUCTION

1.1 *Scope*

Vegetation growth influences water levels and flow patterns in lowland rivers. The mowing of vegetation in order to meet the requirements of protecting riparians against summer floods is directly opposing the need for a sound environment and a well balanced ecosystem. Studies aiming at finding a solution for both these problems by limited but well-considered mowing and at the same time guaranteeing safe evacuation of floods should lead to a better river ecosystem management.

The universities of Ghent (UG) and Antwerp (UA) are conducting scientific research in de river Aa in Belgium.

This fundamental study on exchange processes in river ecosystems is multidisciplinary. The overall research aim is to study the diverse physical and biological processes in margins and inundation areas of water courses and their interactions with regard to the exchange of water, dissolved compounds and particulate matter. In a first phase, the influence of the vegetation on the flow resistance in the stretch will be investigated, using both field measurements and hydraulic surface water modelling.

1.2 *Importance of the roughness coefficient*

Knowledge of the movement of water is essential as water flow is the driving factor for all other water related processes. Measurements of discharge and water level give an idea of the actual situation, but hydraulic modelling allows to represent parameter influence and future prospects. Hydraulic modelling becomes more and more important with respect to water resources management, strategic planning and crises management.

A hydraulic model tries to provide reliable information on some aspects of the real situation. The numerical model is used to simulate the actual behaviour of the river, but it is also an important tool to produce a forecast of possible floodings, peak discharges, low water levels, etc. in the future. For that, a representative model is necessary. The topography of the river and river banks is determined, discharges and water levels are registered. A parameter of main importance is the roughness of the river channel and the banks. This roughness cannot be measured. It can be determined by empirical formulas (e.g. Cohan) which include the bed material, presence of vegetation in the river, meandering, etc. However, the large variability of the coefficients leaves too many degrees

Copyright © 2006 Taylor & Francis Group plc, London, UK

of freedom to allow an accurate determination of the roughness coefficient. Another methodology is to use pictures which represent a comparable situation or to use graphs and tables (Hydrologic Engineering Center, US Army Corps of Engineers 2004).

As this approach also does not guarantee accurate values for the Manning coefficient, a calculation of the roughness starting from measurements is recommended. The assumptions made are: first, the bottom slope and the cross sections are supposed to be constant, so sediment transport and transformation of the channel bed are not included. Further, the friction factor or roughness coefficient (expressed by the Manning coefficient n) is set as a constant value in the channel and at the banks. The flow is regarded in a 1-dimensional way, with uniform velocity over the cross section. The Manning coefficient n can be calculated in two ways: first, when uniform flow is supposed, the energy slope is equal to the bottom slope and n is obtained from the Manning equation. Further, when the Bresse equation is used, also here steady state flow is assumed and the roughness coefficient n is calculated from the energy slope.

Several measurement campaigns allow to determine the variation of the roughness coefficient (friction factor or Manning coefficient n [$m^{-1/3}s$]) as a function of time, type and density of vegetation, hydraulic parameters, etc. and to evaluate flow pattern changes in the vicinity of vegetation patches. During these measurement campaigns, velocity and discharge measurements are performed in multiple cross-sections in presence of and after careful local removal of vegetation in the measurement section. Removing the vegetation allows for determining species and vegetation density as well as for studying the influence of plants on flow distribution and patterns.

1.3 *Calculation of the Manning coefficient*

The most widely used expression to analyse open channel flow is the Manning equation, which was named after the Irish engineer Robert Manning in 1891 (Dyhouse et al. 2003). The formula is commonly used to express the roughness, particularly with respect to vegetated channels. The expression is based on the Chezy equation (first found relationship to calculate velocity in a channel) and close to the resistance equation proposed by Ganguillet and Kutter in 1869 (Dyhouse et al. 2003), which was a first try to introduce the roughness of the channel, all of them using the assumption of uniform flow (Dyhouse et al. 2003). The Manning equation [metric units] is:

$$n[m^{-1/3}s] = \frac{S_f^{1/2}R^{2/3}}{U} = \frac{S_f^{1/2}A^{5/3}}{QP^{2/3}} \quad (1)$$

where U [m/s] is the mean channel velocity, R[m] is the hydraulic radius, S_f [-] is the slope of the energy grade line and n [$m^{-1/3}s$] Manning's roughness coefficient.

In this study, the Manning coefficient is calculated according to three different approaches, in the following mentioned as 'Approach 1', 'Approach 2' and 'Approach 3'. 'Approach 1' calculates the roughness coefficient directly using Manning's equation (Eq. 1). Second way (Approach 2) of calculating the Manning coefficient is by using the numerical model HEC-RAS solving the complete Saint-Venant equations (in steady state conditions, which correspond with Bresses equation). Fitting allows to determine the roughness value. 'Approach 3' is similar to 'Approach 2' but is using a simplified geometry (constant cross-section and bottom slope) to evaluate the accurateness of the model.

1.4 *The river Aa*

The catchment basin of the river Aa is situated in the region of Antwerp in Belgium and is hydrographically part of the Nete basin. More than 40% of the water in the Nete basin is carried by the river Aa. The river Aa flows into the Kleine Nete near the city of Grobbendonk. The well of the river Aa is found near the communities of Merksplas and Turnhout. It passes through Turnhout, Gierle, Gielen, Poederlee and Vorselaar, it has a total length of 36.8 km and a drainage area of about 23,700 ha. The study area is focused on the downstream part of the Aa, on a reach controlled by 2 weirs over a distance of 1.4 km.

As a comparison, also measurements in the Grote Kaliebeek and the Desselse Nete, in the same region as the river Aa, are carried out.

1.5 *Research*

This paper discusses the influence of aquatic plants on the flow resistance and the hydraulic capacity of the river Aa. First of all, the study area is introduced, then the measurement of flow characteristics and the results of the measurement campaigns are presented. In particular, research on the importance of the roughness factor, expressed by the Manning coefficient, is carried out. The interaction of vegetation and Manning coefficient is shown. Finally, results of other rivers in the neighbourhood of the river Aa are presented.

2 MEASUREMENTS OF FLOW CHARACTERISTICS

2.1 *Hydraulic measurements*

The discharge measurements are carried out by UG. Two teams have determined the discharges from a bridge and from a boat. First of all, the flow is measured at the up- and downstream end of the stretch of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

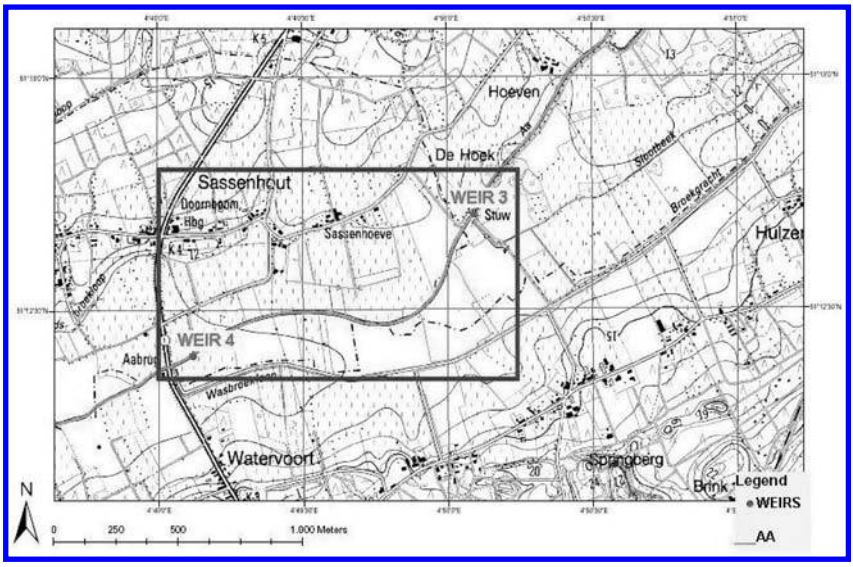

Figure 1. Study area of the river Aa, Poederlee, province of Antwerp, Belgium.

river Aa. In the sections also the biomass is determined by UA.

Two systems are used for measuring the velocity of the water. First of all, flow measurements have been carried out using hydrometric propellers (Type: OTT, C31 Universal Current Meter). This instrument is designed for flow metering in combination with a cable suspended from a bridge or boat. The rotation rate of the calibrated propeller is proportional to water velocity. The velocity is determined with a counter unit by counting the time for a present number of revolutions of the propeller. Knowing the dimensions of the river channel and the measured velocities, the flow is calculated using the principal of integration of the velocities over the cross section (2):

$$Q[m^3/s] \quad = \quad \sum U * \Delta A \qquad (2)$$

with Q = discharge [m^3/s], U = velocity [m/s], Δ A = part of the wetted cross section to which U is attributed [m^2].

The sections are divided into several vertical parts. For each of these verticals (for example, each half a meter), the velocity of the water is measured on different depths, so that the velocity profile is known over the entire water column. The result of the measurements is an overview of velocities over the section. Integration of the values over the wetted area gives an average velocity over the cross section.

When the amount of vegetation is substantial, use of the propellers is difficult. Then, an electromagnetic instrument (type: OTT, Nautilus C2000/SENSA Z300 and Valeport, Type 801) is applied to measure the velocities. Advantage of these devices is that they can be used in vegetated rivers. There are no moving parts which can interfere with the macrophytes, the device is wear-resistant and maintenance free.

Measurements are not carried out according standards as these suppose a Prandtl Von Karman velocity profile, which is not seen in vegetated rivers.

Next to the velocity measurements to calculate the discharge, also the water levels are registered.

2.2 *Measurement campaigns*

To collect accurate and relevant data for calibrating the model, hydraulic measurements are carried out. Monthly, the discharge was measured upstream and downstream the selected stretch of the river Aa. Also water levels are registered to calculate the energy slope and to check the influence of the aquatic plant growth on the water stage.

The studied stretch of the river Aa is situated between two weirs. A gauge is fixed upstream and downstream the stretch. During the measurements, the water level is read off the gauge regularly, with an accuracy of 0.5 cm. The water height is measured while carrying out the discharge measurements in particular sections. Also, the water level upstream and downstream the weir is registered continuously by the Hydrological Information Centre (HIC) of Flanders Hydraulics Research.

Further more, some intensive measurement campaigns are organised. Measurements of hydraulic characteristics (as discharge and water level) and of groundwater seepage and leakage are carried out. Also biomass and water quality information is collected. This multidisciplinary project asks for coherent

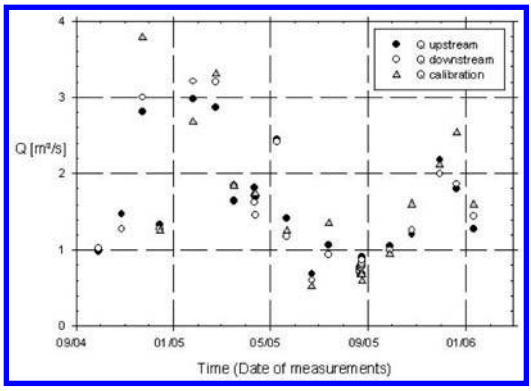

Figure 2. Measured discharge values Q in both upstream and downstream sections as a function of time.

collection of data. In 2005, the campaigns were organised in April and August.

2.3 *Data processing*

Up- and downstream discharge values in the channel are given in Figure 2. For each of the monthly measured values, the discharge upstream (black dots) and the discharge downstream (white dots) is indicated. The small difference between both values is due to groundwater inflow/outflow, to little tributary inflow between the sections and to inaccuracy of the measurements. Next to that, also the calculated discharge based on the calibration formula of the downstream weir, is added (triangles). In general, there is good agreement between this value and the others. The calibration value of November '04, July '05 and December '05 are higher, but it is not obvious what is the reason for that. Probably, a vegetation patch disturbs the free flow over the weir. Together with the discharges, the up- and downstream water stages are registered. The measured discharges and stages are used for the calculation of the roughness coefficient of the stretch.

The Hydrological Information Centre (HIC) of Flanders Hydraulics Research has registered the water levels and the discharge in the studied stretch during 2004. Using these values, the length of the stretch ($L = 1400$ m), a constant wetted cross section ($A = 13\ m^2$) and a constant wetted perimeter ($P = 16$ m), the Manning coefficient n can be calculated with the Manning equation (cf. Eq. (1)). Curves are presented in Figure 3.

First of all, it can be seen that the highest discharges occur during the winter period. During summer, the energy slope (i.e. the difference between the water level upstream and downstream) is bigger. The Manning coefficient is increasing from May until full summer, reaches the highest values in August and is decreasing from October to November. This trend accompanies the vegetation growth in spring and summer. Maximum values of the Manning coefficient in 2004 (according this approximative calculation method) are up to 0.3 which is lower than the values recorded for 2005 (Figure 4).

3 MANNING COEFFICIENT FOR BOTTOM ROUGHNESS

3.1 *Variation of the Manning coefficient*

In this section, the relation of the Manning coefficient to other variables is presented.

The three calculation methods (cf. section 1.3) for the Manning coefficient are applied in the stretch of the river Aa. Calculations are carried out separately for both the discharges measured up- and downstream.

For each of the monthly measurements, the roughness coefficient is plotted in Figure 4. The different calculation methods are indicated with a different symbol. Using the same calculation approach, the Manning coefficient based on the upstream discharge value and on the downstream discharge are comparable.

For the measurements of November, January and February, differences in the Manning coefficient are negligible. The spreading range is biggest for the measurements of September, May and June. During winter, the presence of vegetation remains rather constant, while during spring and summer, the Manning coefficient increases rapidly with the amount of vegetation.

Using an incorrect Manning coefficient while modelling flows in rivers can imply large deviations. As can be seen, during spring, Manning coefficients are up to 10 times higher then the values during winter.

From this, a seasonal trend is observed in the value of the Manning coefficient with low values appearing in January, February (winter), a slight increase in March and April and a fast rise in May and June. Then, the resistance remains high during summer. During winter, the amount of vegetation is decreasing, yielding lower flow resistance and a decreasing roughness coefficient. In summer, the effect is the other way round.

Comparing Figure 2 and Figure 4 for the same measuring period (September to July) shows that lower discharges correspond with higher Manning coefficients (cf. Figure 5). A larger amount of vegetation in the stretch, reduces the cross sections open to flow so that less water can pass in a given time period, which is the definition of discharge.

Figure 5 shows the relation between the discharge and the Manning coefficient. The discharge is calculated upstream and downstream in the stretch of the river Aa. The Manning coefficient is calculated with the numerical model Hec-Ras. As can be seen, higher Manning coefficients correspond with lower

Copyright © 2006 Taylor & Francis Group plc, London, UK

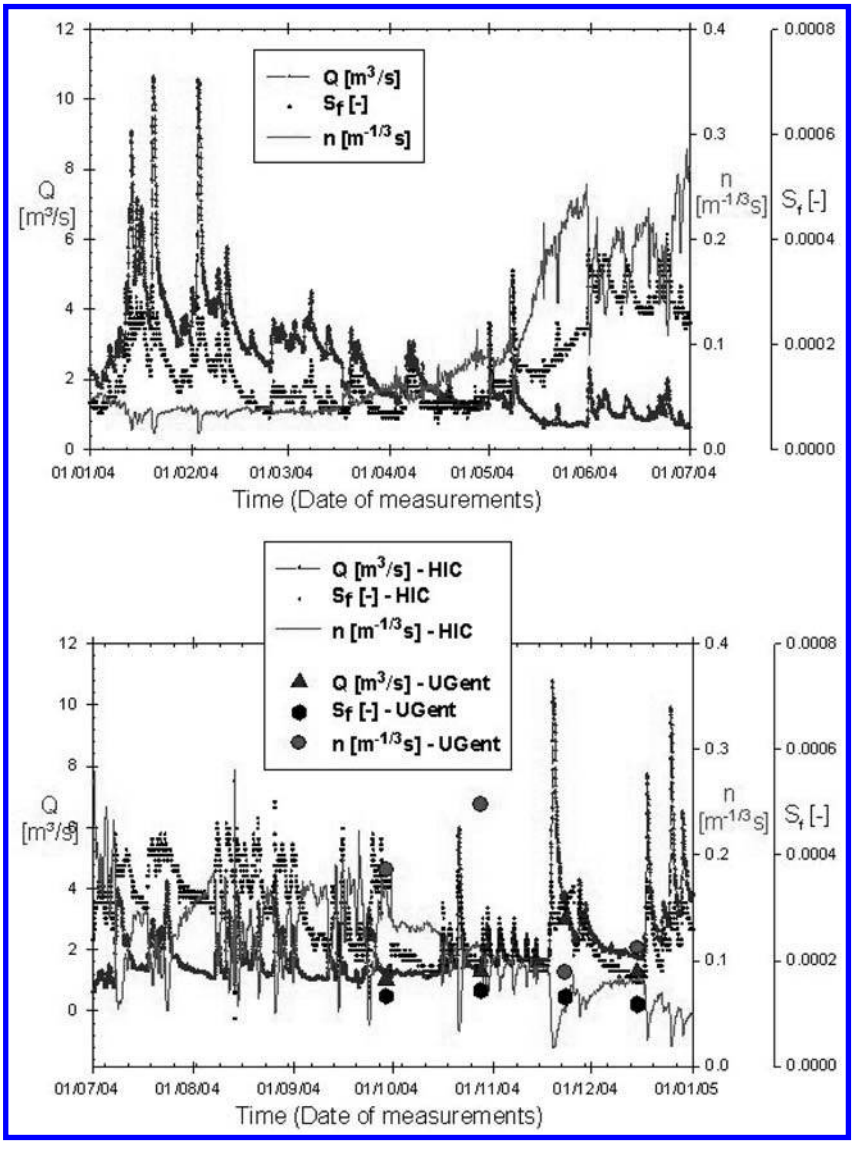

Figure 3. The discharge Q, the energy slope S_f and the Manning coefficient n, for the measurements of 2004 (HIC) (January–July) and (July–December).

discharges. Discharges are varying between 0.6 and 3.2 m^3/s. Manning values ranges between 0.05 and 0.5 $m^{-1/3}s$. The trend follows Eq. (1) and the same for upstream and downstream measured discharges.

Figure 6 shows the relation between the Manning coefficient and the upstream velocity. The trend is added and represents an exponentional path. Higher Manning coefficients correspond with lower velocities. Upstream velocities are varying between 0.04 and 0.022 m/s. This conclusion can also be connected to the aquatic weed growth; the more plants in the water, the more roughness in the river and the lower the velocities. In a cross section where the channel is obstructed by a wealthy plant growth, there is a higher resistance to water flow.

In Figure 7, the upstream and downstream water levels are plotted as a function of the Manning coefficient. Although there is no clear trend, it becomes evident that in general higher Manning coefficients (due to more aquatic plant growth) correspond to higher water levels. If a part of the cross section is obstructed by vegetation the water level will be higher.

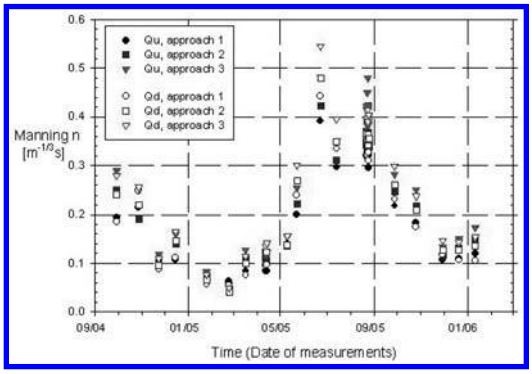

Figure 4. Manning coefficient n for the upstream (Qu) and downstream (Qd) value of Q: comparison of the values calculated using three approaches: Manning's equation given by Eq. 2 (1), fitting based on the Saint-Venant equations (HEC-RAS)(2), and fitting using an average section (3).

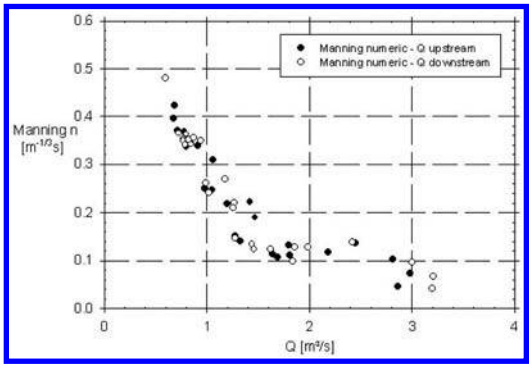

Figure 5. Relation between Manning coefficient n and upstream and downstream discharge Q.

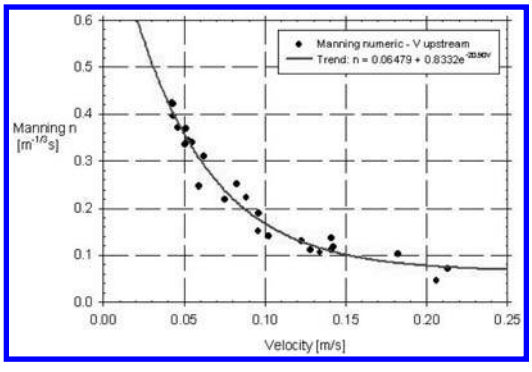

Figure 6. Relation between Manning coefficient n and upstream velocity.

In Figure 8, the Manning coefficient calculated with the numerical model Hec-Ras is plotted together with the measured wetted cross section A, upstream the stretch. The upstream wetted cross section of the Aa

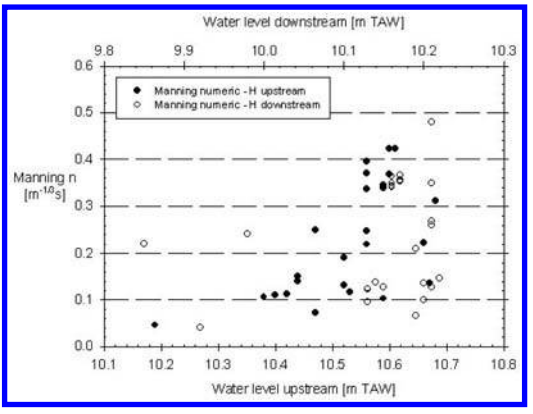

Figure 7. Relation between Manning coefficient n and water level.

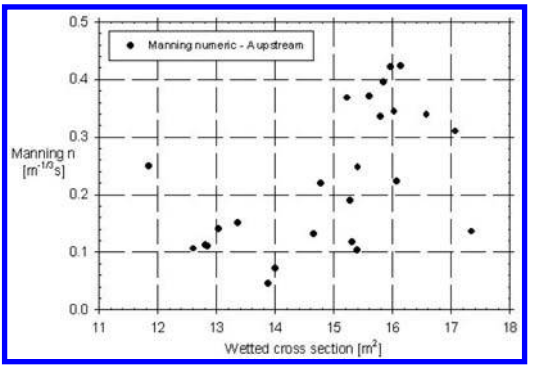

Figure 8. Relation between Manning coefficient n and upstream wetted cross section.

varies between about 12 and 17.5 m^2. The relation between wetted cross section and Manning coefficient is not clear, but in general lower wetted cross sections are corresponding to lower Manning coefficients. Because of a wealthy vegetation growth in the river, water levels will be higher and so, the wetted cross section is larger. More vegetation growth is also corresponding to a higher Manning coefficient.

Due to vegetation and the related influence of backwater, the energy slope along the stretch may vary substantially. Figure 9 shows a simulated situation in the stretch of the river Aa with a length of 1.4 km. Two cases are considered: a Manning coefficient of 0.046 $m^{-1/3}s$, which was calculated from the Manning formula (Eq. 1) and the measurements of February and a Manning coefficient of 0.423 $m^{-1/3}s$ (June).

First remark is that the Manning coefficient is 9 times higher in the month of June when there is a wealthy vegetation. Starting from the same downstream water level and using a discharge of 1 m^3/s, the upstream water level is calculated for both values of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

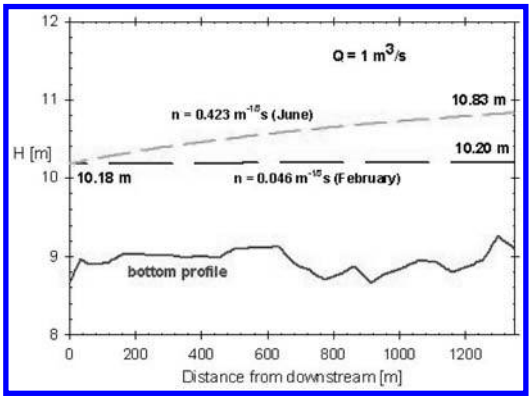

Figure 9. Influence of backwater of the Manning coefficient on the water level for a given discharge.

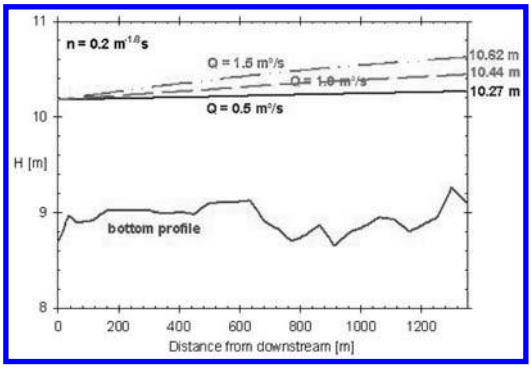

Figure 10. Backwater influence of the Manning coefficient on the discharge for a given amount of vegetation.

Manning coefficient. In June, an upstream water level of 10.83 m is calculated, while 10.20 m is obtained in February, which is a difference of more than 60 cm due to the presence of vegetation.

Because of the better water quality, the organic matter in the rivers has decreased and the clearness of the water has increased. Next to that, the agricultural activities in the neighbourhood of the river Aa bring fertilizers into the water. These factors are responsable for the explosive growth of the aquatic plants, resulting in a rise of the water level up to 60 cm.

Figure 10 shows the influence of the discharge on the energy slope S_f. For three different values of the discharge, the water surface profile is calculated. The Manning coefficient does not change. It seems that tripling the discharge results in an increase of the water level of 0.35 m. So, the impact of the vegetation on Sf is much bigger (Figure 9) and explains why a dangerous situation may occur with regard to inundation during summer floods.

Hydraulics Lab (HIC) and the values calculated with the numerical model Hec-Ras. The tabulated data are also shown in Figure 3. As can be seen, the measurements of October do not give a corresponding result. For the others, the discharges registered by HIC are higher. These discharges are registered downstream the stretch (downstream weir 4) while Ghent University measures between the two weirs. Differences can be due to that adaption. For the measurements of October, there were problems with the downstream measurements. Seeing the other values, a higher discharge would be more realistic. Furthermore, the Manning coefficients based on the HIC-values are calculated with an average wetted cross-section and an average wetted perimeter, which does not correspond with the natural situation. The same calculations have been carried out by using Hec-Ras (and based on the measurements of Ghent University) to have a more accurate result. The Hec-Ras results for the Manning coefficient agree more with the values calculated from the measurements of Ghent University (with the

Copyright © 2006 Taylor & Francis Group plc, London, UK

Manning equation) than with the registered values of HIC. All the calculations are based on the water levels measured (UG) or registered (HIC) at the same time.

Because of the higher discharges registered by HIC, the Manning coefficients, calculated with these values, are lower. The values of the discharge and the water level are important for the calculation of the Manning coefficient. Errors on the measurements can be the cause of large deviations in the calculations. So, measurements have to be carried out with the most care and precision. In November and December, the downstream discharge is also calculated with the formula of the calibrated weir. Therefore, the water height over the flap of the weir is measured. Results are values of 3.79 m^3/s (November) and 1.25 m^3/s (December), which are in the same range of the measured and registered values.

This comparison illustrates the importance of accurate information on hydraulic data with regard to the determination of the friction factor as a key-value in numerical modelling.

3.2 *Biomass influence*

A positive correlation between the biomass and the Manning coefficient was found by Brooker (1978) and mentioned in (Viaene and Vereecken 2001). The biomass in fact, is the amount of vegetation in the channel and is expressed in g/m^2 (horizontal surface). During peak growth of the vegetation (April–June), the biomass as well as the Manning coefficient are inversely proportional to the flow velocity in the water course (Viaene and Vereecken 2001), which is also clearly illustrated in Figure 6.

Presence of vegetation decreases the section and increases the roughness and by this also the water level for the same discharge value. Absence of an univocal correlation between discharge and water level at a gauge is attributed to seasonal changes in the amount of vegetation, quantitatively represented by the biomass.

The evolution of the Manning coefficient is related to the amount of vegetation (Figure 11). Starting from the measurements in January, the amount of macrophytes is determined. As can be seen, more biomass results in a higher Manning coefficient. An exponentional curve is fitted to the values in Figure 11.

For low values of the biomass (less then 100 g/m^2), the Manning coefficient is varying between 0.04 and 0.14 $m^{-1/3}/s$. This variation is due to different discharges. As can be seen on Figure 5, lower discharges correspond with higher Manning coefficients.

It becomes evident again that the Manning coefficient is strongly increasing in spring, due to explosive vegetation growth (Figure 12). During summer, the roughness reaches a peak value. After dying out of the plants, also the Manning coefficient is decreasing. This cycle is almost the same for each year. A sudden fall in the roughness during the vegetation period can be due to the wash away or flattening of a vegetation patch with large discharges. By this the discharge influences the roughness coefficient. The roughness decreases when the discharge increases. Hence, the variation of the Manning coefficient is influenced by discharge and vegetation.

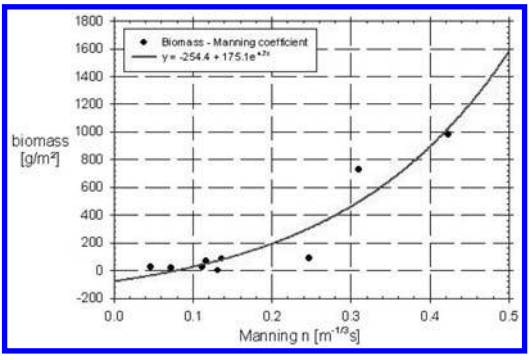

Figure 11. Relation between Manning coefficient n and biomass.

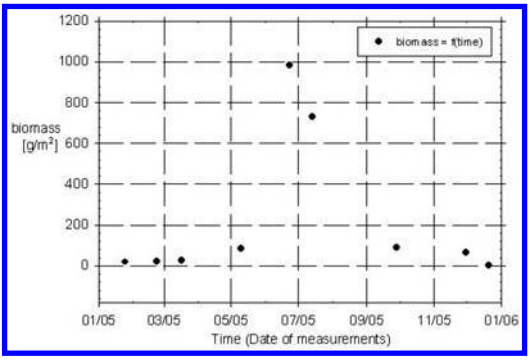

Figure 12. The measured biomass in the river Aa as a function of time.

3.3 *Manning coefficients in other rivers*

The relation between the measured biomass and the Manning coefficient n is investigated here. The calculated Manning coefficients and the dry biomass for the river Aa, the study area, are compared with values of the Desselse Nete and the Grote Kaliebeek.

The Desselse Nete is a river in the upstream part of the Nete basin. The river has still its meandering characteristics contrary to other rivers in the basin which have been straightened during the years.

The Kaliebeek is the largest tributary of the river Aa. This river is coming into the river Aa, near the border of Tielen and Poederlee (province of Antwerp, Belgium). The Grote Kaliebeek (originating in Oud-Turnhout) and the Kleine Kaliebeek (originating in Kasterlee)

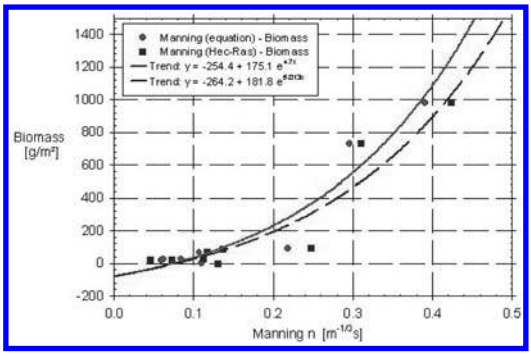

Figure 13. Relation between biomass and Manning coefficient for the river Aa.

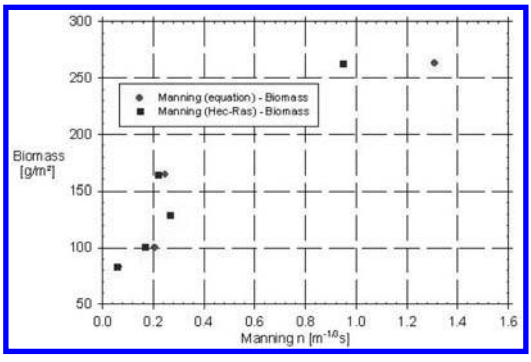

Figure 14. Relation between biomass and Manning coefficient for the Grote Kaliebeek.

are coming together near Tielen. From there, the river is known as the Kaliebeek.

For the river Aa and the Desselse Nete, an exponential trend is found. For the Grote Kaliebeek, the trend is less clear.

For rivers, the Manning coefficient is calculated using both the numerical model Hec-Ras and the Manning equation (Eq. (1)).

Figure 13 presents the exponential trend, found in the river Aa, study area, for both approaches of the calculation of the Manning coefficient.

As can be seen from Figure 14, for the Grote Kaliebeek, no exponentional trend is found. The data are collected in the period from May till the end of September. A stretch of 170 m is selected to measure the energy slope for the calculation of the Manning coefficient. For higher biomass, extremely high values of the Manning coefficients are registered. The biomass in the Grote Kaliebeek, is only a quarter of the biomass found in the river Aa, and nevertheless the Manning coefficients are higher (up to 1). An explanation could be found in the difference in wetted cross-section where the cross-section of the river

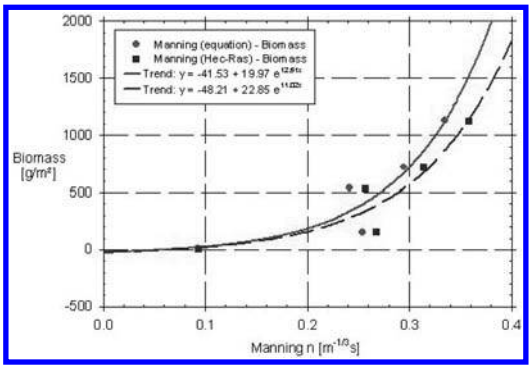

Figure 15. Relation between biomass and Manning coefficient for the Desselse Nete.

Aa is much bigger then the cross-section of the Grote Kaliebeek.

Figure 15 shows the results for the Desselse Nete. Biomasses higher then 1,000 g/m^2 are found. The data are representing regular measurements in the period from June till the end of September. A stretch of 200 m is selected to measure the energy slope for the calculation of the Manning coefficient. For the Desselse Nete, Manning coefficients as well as biomass can be found in the same range as in the river Aa.

4 CONCLUSIONS

An accurate and reliable numerical model must be based on the input of accurately determined parameters. Some of them are rather easy to determine, but others, like the Manning coefficient, vary as a function of time.

A correct prediction, based on numerical modelling, asks for correct calibration data. Good knowledge of the variation of the Manning coefficient n as a function of time, distance and water stage is needed. Therefore, it is necessary to carry out measurements on a regular basis and to collect hydraulic information all over the year. A numerical model based on a Manning coefficient measured once a year, may introduce large errors in the calculation results, since this roughness coefficient can change up to a factor ten from winter to summer conditions.

In this paper, the link between the amount of vegetation, the discharge, the velocities in the cross sections, the water level and the roughness coefficient has been put to evidence.

The relation between the biomass variation and the variation of the friction factor is obvious and should be further investigated.

Predicting vegetation growth in a river, in combination with information on discharges can lead to a

better estimation of the Manning coefficient and by this to more reliable results of numerical modelling.

ABSTRACT: In this paper, the effect of a rigid and flexible submerged vegetation, with a characteristic low density, on a transversal current was analyzed. Different configurations as vegetation type, flow depth and velocity were investigated in the laboratory flume. 3D velocity components and turbulence characteristics, such as turbulence intensity and Reynolds stresses, were conducted at different measurement points by the Acoustic Doppler Velocimeter (ADV) system. The velocity and turbulence profiles and distributions were plotted in horizontal and transversal sections, in order to quantify the effect of the two kinds of vegetation on the crossflow. The results showed a local behavior, due to the particular low vegetation density that do not allow to consider the flow field homogeneous at the stem scale. Besides, flow velocity deceleration and turbulence increase were stronger under the top of the rigid vegetated layer than in the case of flexible stems.

1 INTRODUCTION

The fact that a solid element, whatever it is in type and shape, creates a disturb to a crossflow is well established in the scientific word (e.g. Sumner et al. 1999, Kang 2003, Silvestrini & Lamballais 2004). The interest on a similar phenomenon, instead, is always high because of it is easy to find it ordinarily in nature, e.g. in river flows, and so in problems connected to natural channel management and restoration, which require engineering interventions.

The most common obstacle that crosses the current is the vegetation, which presence has been regarded both positively, e.g. for its fundamental ecological functions in the riverine environment and because it reduces the risk and effect of erosion, and negatively, e.g. for the effects of the hydraulic cross section reduction which hinders flow capacity and increases the river bed roughness. Nevertheless, current environmental river engineering prefers to conserve natural riverbank and floodplain vegetation.

Flow resistance of natural open channels, in particular the effect of flexible and rigid vegetation, is a well-established key of research in literature, from the past (e.g. Chow 1959, Barnes 1967) till nowadays (e.g. Ghisalberti & Nepf 2002, Järvelä 2004, Carollo et al. 2005). All the works concur that the main characteristics that define the hydraulic behavior of a single vegetation element are (i) its diameter, (ii) its height compared with the flow depth and then the possibility to be submerged under the flow surface or emergent, (iii) its shape and flexibility that distinguishes the case of flexible elements from that of rigid ones, and (iv) its plane distribution, that is its density. The contribution of different vegetation considered as roughness types to the total flow resistance depends strongly on the combination of the vegetative elements and presents considerable variability in time and space (Järvelä 2002a,b). For example, in nature during the growing season, leaves on willows contribute more to the total drag rather than the bottom grasses, while, in winter, when the willows are leafless, the last ones are likely to dominate the total flow resistance (Järvelä 2004).

The hydraulic behavior of rigid elements is similar to that of a fixed bed formed by elements of known geometry in large-roughness conditions (Petryk & Bosmajian 1975, Stone & Shen 2002). The flexible vegetation instead exhibits four different configurations, depending on the current speed: (i) erect, (ii) gently swaying, (iii) strong, coherent swaying (monami) and (iv) prone (Grizzle et al. 1996, Nepf & Vivoni 2000). For each configuration, different values of the inflection degree, i.e. the ratio between the bent vegetation height h_s and the vegetation height in the absence of current h_v, occur. For low values of flow velocity, the behaviors of the flexible elements is comparable with that of rigid vegetation.

Most efforts to study vegetal effects on a current have concentrated on analyzing submerged vegetation. In this case, according to El-Hakim & Salama

Copyright © 2006 Taylor & Francis Group plc, London, UK

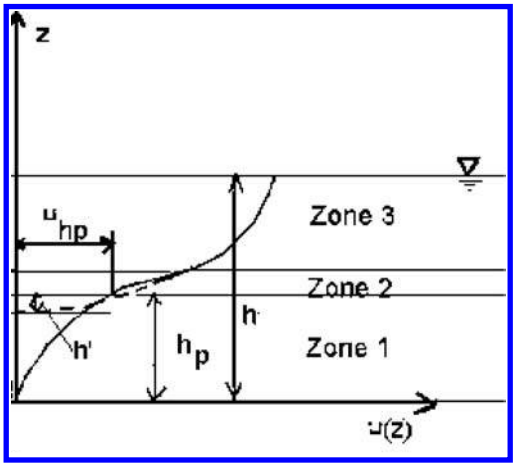

Figure 1. Classification of flow layers and the corresponding velocity profile in the case of totally submerged vegetation (adapted from El-Hakim & Salama 1992).

(1992), three different flow layers can be distinguished, as shown in Figure 1. Zone 1 refers to flow inside the canopy. The thickness of this layer is h_p, which denotes the deflected height of vegetation h_s in the case of flexible plants, while for stiff plants it coincides with the elements height h_v that is not influenced by the flow velocity. In Zone 3 the velocity distribution is assumed to be logarithmic, but the zero point of the velocity is assumed to be inside the vegetation (see broken line in Figure 1). The variable h' is called the shift of the zero point from h_p in the logarithmic velocity distribution, whereas u_{hp} is the velocity at the top of vegetation, where the profile present an inflection point and both the turbulent shear stress and the turbulence intensity assume the maxima values (Carollo et al. 2002). The confined region of shear containing the inflection point is called Zone 2, which can be considered a mixing and transition layer between the two zone described above. The distinction of these regions is more and more evident in the case of submerged flexible vegetation and, in general, with increasing vegetation density, defined as the number of vegetal elements per base area, due to the reduction of the momentum exchange between the two zones 1 and 3 (Kowen & Li 1980).

For large part, research on vegetated open channels has focused on flow resistance due to vegetation, in particular on the determination of the friction factor and the drag coefficient in the flow resistance law, by means of analytical flow models (e.g. Kutija & Hong 1996, Righetti & Armanini 2002, Stoesser et al. 2003) and laboratory flumes (Kowen & Unny 1973, Fathi-Maghadam & Kowen 1997, Wu et al. 1999, Kowen & Fathi-Maghadam 2000).

Traditionally, empirical approach to estimate flow resistance are often based on relating Manning's *n* to some parameters selected to describe the flow conditions, but nowadays the assessment of the resistance coefficient is still difficult to carry out. Moreover, most of works consider the vegetation as a wide turf and consequently the bed-friction coefficient is taken as the average of the local values, uniformly constant for all the channel. Less is known about the local effect of the vegetation when it is characterized by a very low concentration. Indeed, in this conditions, it is not possible to consider the flow field homogeneous and so assign constant values to parameters such as the resistance index, the bed-friction velocity and/or the drag force, for the whole canal.

The rood topic of the present work is the investigation of the hydrodynamic effects of both rigid and flexible vegetation on a crossflow, in terms of velocity and turbulence distribution. The research is limited to the case of relatively low current velocities and flow depths higher than the height of vegetation, which was identical for both the rigid and flexible type. Emphasis is put on assigning a minimal density to the artificial plants, as it is expected that in non-uniform, bed-friction conditions in the channel a local analysis is needful for better understanding the phenomenon. Therefore, to capture spatial variability within the array, multiple measurement points were set between each two consecutive elements on the three principal directions. The analysis of measurement data produces a good estimation of the different behavior of the current for the separate presence of the two kinds of vegetation reproduced in the laboratory flume.

2 EXPERIMENTAL METHODS

Experiments were carried out in a re-circulating glass-wall flume 8 m long, 0.3 m wide and 0.4 m deep, located at the Mediterranean Agronomic Institute (IAM) of Bari, Italy. Flow was released from a head tank (1.2 m × 1 m × 1.4 m) equipped with stilling grid and lateral weir, which ensured a smooth access of the water to the flume and maintained a constant head upstream. Two movable gates made in Plexiglas were constructed respectively at the upstream and downstream ends of the flume, to allow the passage of different discharges with different corresponding channel flow depths. At the downstream end of the flume, the flow was intercepted by a stilling reservoir (2 m × 1 m × 1 m) tooled up with four vertical grids to stabilize water and with a triangular weir (V-notch sharp crested weir) for measuring the flow discharge. The water head above the weir crest, on which depends the regression function of the discharge, was measured by an electrical hydrometer. Water disposal regained the pumping reservoir through the closed hydraulic circuit.

For rigid vegetated channel experiments, the plants were simulated by means of metallic cylinders with

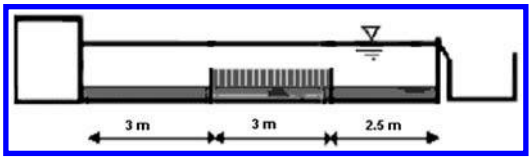

Figure 2. Schematic long-view of the laboratory flume (not to scale).

Figure 3. Photographs of the laboratory flume with rigid (left) and flexible (right) artificial vegetation.

rough lateral surface, while the flexible model array was constructed from commercial broom head. Both kinds of artificial vegetation were mounted in 3 m plywood board, perforated uniformly with holes of 3 mm, that is the diameter of the rigid elements, D, whereas, in the case of flexible vegetation, 8 single elements of the broom head with a diameter 0.4 mm each one were stacked. The three-meter long test area of each vegetation was located around the halfway of the flume (Fig. 2), but for all the channel length same boards were stuck on the bottom in order to obtain a uniform bed roughness. The stems were spaced along the longitudinal and transversal direction by a distance equal respectively to $\Delta x = 10$ cm and $\Delta y = 6$ cm, i.e. the stem density $\lambda_1 = \Delta S^{-2}$ was kept constantly equal to 400 stems/m^2 (Fig. 3). The height of the rigid elements, h_v, was equal to 10 cm and coincided with the flexible vegetation height in the absence of current.

The analyzed configurations differed in the artificial vegetation material, as described above, and in the two flow depths in the flume, $H = 21$ cm and $H = 30$ cm, which corresponded the mean current velocity $U_{C1} = 0.28$ cm/s and $U_{C2} = 0.19$ cm/s, respectively. For all the configurations, the vegetation was taken submerged, allowing us to observe the particular behavior of the crossflow at the top of the stems, depending on the relative submergences considered ($H/h_v = 2.1$ and $H/h_v = 3.0$). The bent height, h_s, of the flexible vegetation was estimated as the average of ten measurements by means of decimal rules fixed to the flume wall. Corresponding to the two given values of the water depth H, h_S was respectively 9.5 cm and 9.2 cm.

The mean velocity components (U, V, W) and the rms turbulence intensities (u′, v′, w′) along the stream-wise (x), lateral (y) and vertical (z) directions, respectively, together with the average Reynolds stresses ($-u'v'$, $-u'w'$, $-v'w'$) on the corresponding coordinate planes, were measured by means of the three-dimensional Acoustic Doppler Velocimetry (ADV) system. Exactly, the origin of the axial coordinate system for the measurements was located at the beginning of the vegetated channel area, in the central section of the channel, with the depth (z) defined as zero at the bottom and positive upwards, and the x-axis positive downstream. Mean and turbulent velocity statistics were estimated from 3000 records sampled at 25 Hz, with a measurement error for each record equal to ± 0.15 mm/s. The distribution of the stems was chosen so as to facilitate the measurements with the ADV probe.

3 RESULTS AND DISCUSSION

3.1 *Velocity field*

In order to study the variations of the velocity distribution at the local scale around both rigid and flexible individual element, several analysis of the velocity component data into the flume have been carried out, along longitudinal and horizontal sections.

Profiles of the time-averaged longitudinal velocity, U(z), are shown in Figure 4 for both kinds of stem (flexible in Fig. 4a and rigid in Fig. 4b), at different longitudinal distances from the plants. In particular, the vertical velocity profiles were measured at six different positions located at the centerline of the flume, in order to neglect the influence of the walls, around the stem fixed at the coordinate $x = 120$ cm. A deep analysis of Figure 4 shows the presence of two regions of flow motion, correspondingly inside and above the submerged vegetation. Exactly, for distance z from the bottom less than h_v or h_s, the current is subject to a strong slow motion due to the presence of the close element. Near the top of the vegetation, both the local velocity and its gradient increase progressively, producing at the vertical profile an evident inflection point and the typical S shape, as reported in literature (e.g. Kowen et al. 1969). Upon the vegetation, the velocity gradient decreases with z, with the concavity directed upward. These differences decrease as we move away upstream or downstream from the stem, and are particular evident for rigid elements. Differently, the six profiles plotted around the flexible plant do not present the same flat individual pattern, for each x-position, as the rigid case. Moreover, the velocity corresponding to the coordinate $x = 120$ cm, where is located the flexible stem plant, is not completely cancelled, as the flow escapes through the branches of the plastic plant. Thus, it is evident from Figure 4, (i) how local the impact of the flow on the vegetation is, in reference

Copyright © 2006 Taylor & Francis Group plc, London, UK

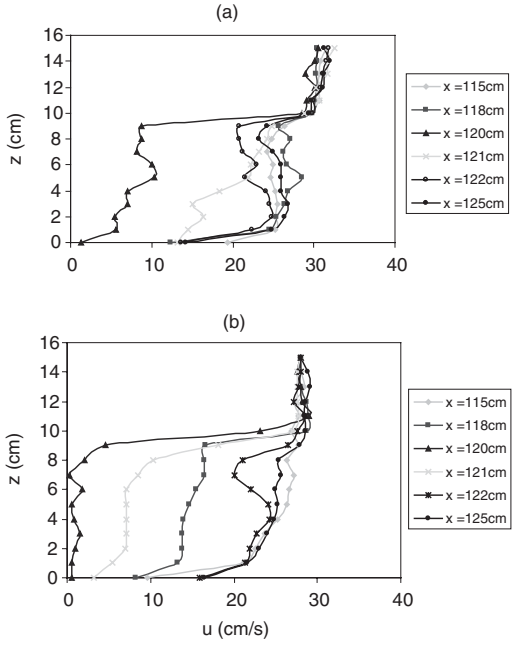

Figure 4. Vertical U-velocity profiles for water depth H = 21 cm in presence of (a) flexible and (b) rigid vegetation.

to the distance from a single stem, and (ii) how different the flow behavior is with the presence of rigid and flexible plants. Same results have been obtained for the configurations with flow depth equal to 30 cm.

To better highlight the local effect of the artificial vegetation on the crossflow, velocity data have been processed and plotted on horizontal planes at different levels. For the sake of brevity, hereafter there will be discussed results relating to a single plane distant from the channel bottom 5 cm and to the single configuration with flow depth of the cross section H = 30 cm, for both rigid and flexible plants. This is the case of Figure 5, which represents the distribution of the U-velocity component normalized by the mean velocity of the current, U_a, at z/H = 0.17, i.e. at the middle height of the stems, in the flume with flexible (Fig. 5a) and rigid (Fig. 5b) vegetation. Dashed contours, which represent values of $U/U_a \leq 0.5$, are localized around the vegetation stems. It should be meant that artificial vegetations delay the flow motion of about the 50% in a area confined to the location of each element. Nevertheless, the different kind of material sees to it that the shape of this area and so the preferred direction of the mutual interference between two consecutive arrays of stems is quite different for the two configurations. In fact, the isovel contours around the rigid plants are not circular but elliptical with major axis parallel to the longitudinal direction, which reveals the anisotropy of vegetation stem effects

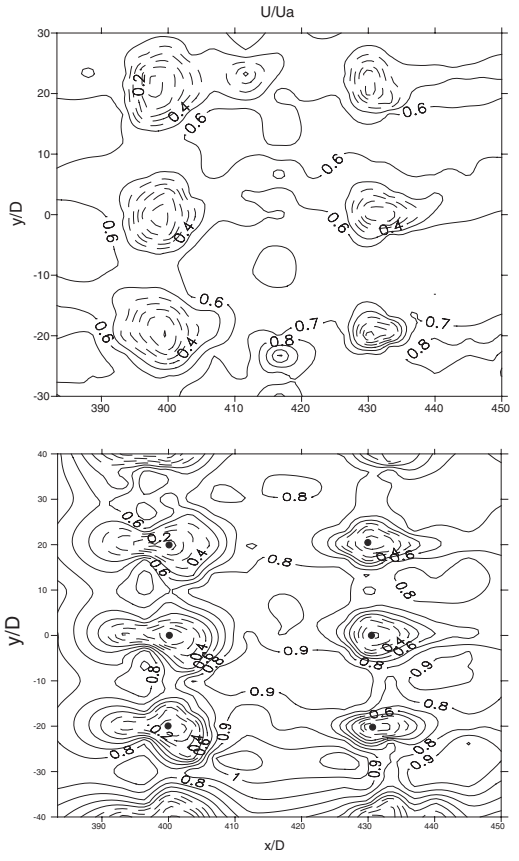

Figure 5. Distribution of the normalized velocity U/U_a in presence of (a) flexible and (b) rigid vegetation. Top view (z/H = 0.17). Black solid circles represent the rigid vegetation stems.

over the hydrodynamic flow distribution. Moreover, considering the continue contours representing values of $U/U_a \geq 0.5$, Figure 5 highlights that the flow pattern is strongly modified, i.e. the current is particularly delayed, by the presence of the flexible elements for all the depth analysed (Fig. 5a), while with rigid cylinders the normalized flow velocity at the middle longitudinal section of two arrays reach the value 1 or slightly large, which mean the negligence of the vegetation stem effects as long as going away from it (Fig. 5b). As a first justification of this different behavior, it must be taken into consideration that both the geometry of the vegetation elements and the turbulence characteristics of the flow affect the hydrodynamic resistance and the size of the vortical wakes generated downstream of the single element (Carollo et al. 2005). In the specific case of the flexible vegetation, because of at each measured location the element is constituted by a group of branches, which tend to open moving

Copyright © 2006 Taylor & Francis Group plc, London, UK

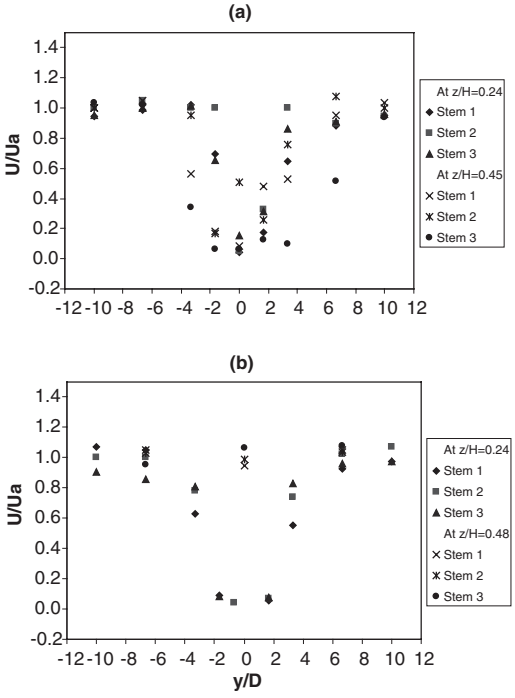

Figure 6. Similarity distribution of streamwise flow velocity U/U_a at $x = 120$ cm (water depth $H = 21$ cm) for three transversal aligned (a) flexible and (b) rigid stems, at two different levels.

upwards, it is understandable why the velocity is closed to zero value for a wide x and y range.

In order to study the different behavior of the flow velocity distribution around the vegetation stems, the values of U/U_a at $x/D = 400$, i.e. immediately beyond a row of plants, have been plotted against y/D, as shown in Figure 6, where the origin ($y/D = 0$) corresponds to the centre of each stem. Both flexible and rigid elements indicated by 1 are located in the axial symmetric longitudinal and transversal section, while stems 2 and 3 are positioned respectively on the right and the left side of stem 1 looking downstream. Data plotted in Figure 6 referred to the configuration with the water depth in the channel $H = 21$ cm. In each diagram, three of the six horizontal profiles of U/U_a correspond to the plane at the middle height of the vegetated zone ($z = 5$ cm), while the second level analysed is different for the flexible and rigid vegetations, as for the first one it coincide with the bent height h_s of the elements ($z = 9.2$ cm), which is less than the fixed height of the rigid stems ($z = 10$ cm). Nevertheless, the aim of the research in this stage has been the investigation of the particular hydraulic path of the flow inside the vegetated zone and just on its top, and the detection of the different behavior due to the particular kind of plants. A comparison of Figures 6a–6b demonstrates that the normalized U-velocity component profiles at $z = 5$ cm obtained around the flexible elements match those related to the rigid ones, with minimum velocity values close to zero in the y/D range between −2 and 2, i.e. just in proximity of each stem, while for larger absolute values of y/D the velocity tends to rich the average value of the current in the flume in absence of vegetation. Contrariwise, at the top of vegetations, the flow pattern is quite different. When the presence of the rigid elements seems to not disturb the current, which velocity values keep constant along the whole transversal section, the flexible vegetation branches make the horizontal velocity profiles more irregular but still similar to the Gaussian curve. Thus, it can be concluded that, halfway between two consecutive stems along the transversal direction, flow patterns in the vegetated area are similar to those of simple open-channel without vegetation, independently of the kind of vegetation. On the contrary, at the top of vegetations, only for the rigid stems, flow resistance disappears and velocity distribution fells to be uniformly similar to the current average value.

3.2 *Turbulence characteristics*

Aquatic plants convert mean kinetic energy into turbulent kinetic energy at the scale of the plant stems (rigid vegetation) and branches (flexible vegetation). This energy transfer, linked to wake generation, affects vegetative drag and turbulence intensity. Drawing on this physical link, turbulence intensity and Reynolds-stresses distributions have been obtained, with the intention of highlighting the influence of different kind of vegetation on the turbulence behavior of the current.

Representative profiles of the rate u'_{rms}/u, with u'_{rms} and u respectively the fluctuation root-mean square and the average of the instantaneous streamwise velocity at the same measurement points, are shown in Figure 7. The two plots refer to the same submerged condition for the flexible and rigid stems, but consider two different water depth of the flume. Profiles for both the considered cases stress a significant discontinuity of the normalized streamwise turbulence in a region near the top of the elements, characterizing the generation of a horizontal shear layer. However, a different behavior is recognizable for the two kinds of artificial vegetations. For the rigid rods, values of u'_{rms}/u peak just below the rod top, as data have been collected 1 cm beyond the element, maintaining same maximum magnitude independently of the hydraulic flume conditions. On the contrary, the maximum streamwise turbulence occurs above the element tops for the flexible canopy situation, particularly when the relative submergence H/h_s is small. Moreover, the influence of the submergence on the turbulent current path in presence of flexible vegetation appears visibly comparing

Copyright © 2006 Taylor & Francis Group plc, London, UK

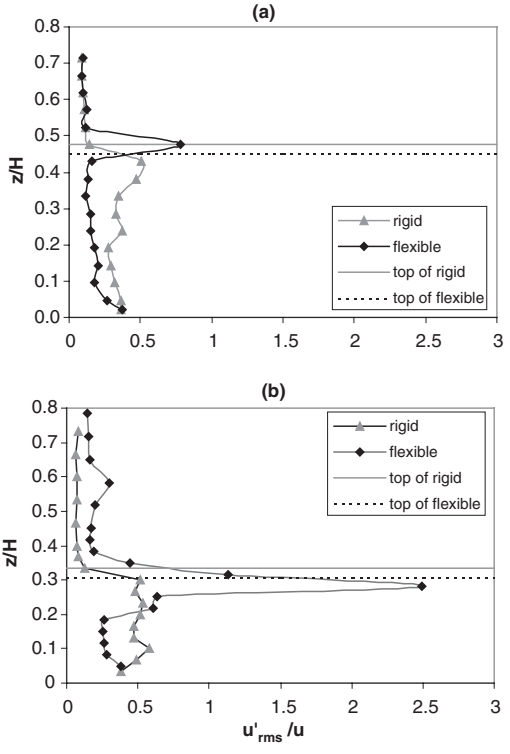

Figure 7. Representative profiles of the normalized, streamwise turbulence intensity u'_{rms}/u for rigid and flexible stems at x/D = 403.3 along the central longitudinal axis and with water depth (a) H = 21 cm and (b) H = 30 cm.

Figures 7a, b. A relatively higher magnitude of turbulence takes place within the flexible canopy when the water depth is H = 30 cm than the case of a lower level of flow depth. This last result is in agreement with findings for both single flexible rod and frond canopy by Wilson et al. (2003) that reveal a lowering of the peak with the decreasing of the flow depth. Same outcomes were pointed out in previous works about open channel flow of intermediate and small submergence of gravel beds (e.g. Bayazit 1976, Nezu & Nakagawa 1993). They found that the maximum turbulence intensity decreases considerably with decreasing submergence, justifying this phenomenon with the damping effect of large scale eddies, i.e. coherent structures like sweeps and ejections. For small and intermediate relative submergence, coherent structures cannot develop their whole size due to the limited flow depth or due to the too large roughness elements. These factors are assumed to lead to the damping of turbulent intensities (Stephan & Gutknecht 2002).

Thus, these observations indicate that also for flexi ble plant covered bed, the maximum value of turbulence intensity u'_{rms}/u is expected to increase with

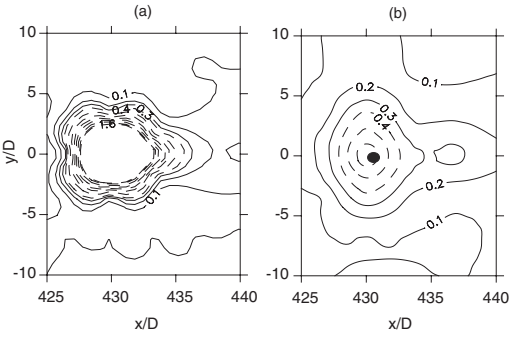

Figure 8. Distribution of the normalized, streamwise turbulence intensity u'_{rms}/u in presence of (a) flexible and (b) rigid vegetation. Top view (z/H = 0.17). Black solid circles represent the rigid vegetation stem.

increasing relative submergence H/h_s, as obtained in the present work.

To better understand the different behavior of the flow in the open channel due to the existence of two kind of plants, Figure 8 shows a representative horizontal map of the relative streamwise turbulence intensity at z/H = 0.17, i.e. at the middle height of the stems. Dashed contours represent values of $u'_{rms}/u \geq 0.40$ and are located in the proximity of both the rigid and flexible rods, where the turbulence intensities reach their maximum values. Nevertheless, high values of the turbulence intensity appear in a wider area surrounding the flexible stem than the rigid one, with the aptitude of turbulence spreading more intensely in the longitudinal direction.

In Figure 9, the vertical Reynolds stresses measured at the same two longitudinal positions (Figs 9a, b) in the channel with flexible and rigid vegetations have been plotted, with the aim of underlining the different spatial behavior of the turbulent current due to the distinct geometry of the rods. The shear stresses have been normalized by the friction velocity of the flume without vegetation but under the same flow condition (i.e. discharge and water depth). It is well know that, in open channel flow and for a value of z/H < 0.2, flow is sensitive to the bed shear stress effects (Nezu & Nakagawa, 1993). Therefore, the average bed shear stress, in this region and according to Prandtl's theory, can be estimated as follows

$$\overline{\tau_b} = \rho \frac{1}{z} \int - u' w' dz \qquad (1)$$

and thus

$$\overline{U^*} = \sqrt{\frac{\overline{\tau_b}}{\rho}} \qquad (2)$$

where ρ is the flow density. In general, for a channel with vegetation canopy, bed shear stress depends

Copyright © 2006 Taylor & Francis Group plc, London, UK

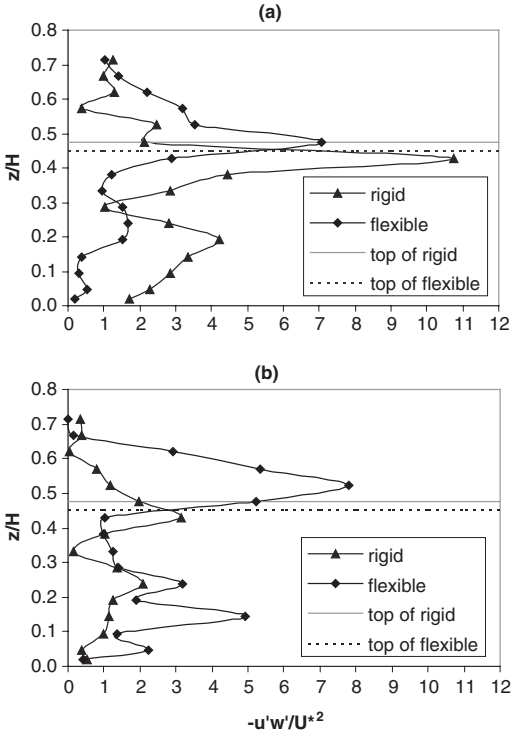

Figure 9. Representative profiles of the normalized, vertical Reynolds stress $-u'w'/U^{*2}$ for rigid and flexible stems along the central longitudinal axis at (a) x/D = 403.3 and (b) x/D = 483.3. Flow depth H = 21 cm.

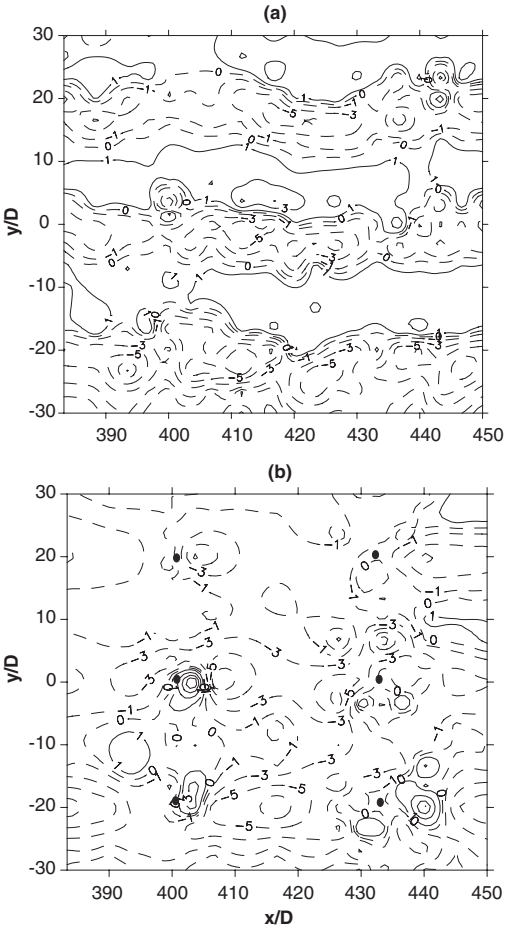

Figure 10. Distribution of the normalized, transversal Reynolds stress $-u'v'/U^{*2}$ in presence of (a) flexible and (b) rigid vegetation. Top view (z/H = 0.24). Black solid circles represent the rigid vegetation stems.

strongly by the presence of vegetation and then the friction velocity should be different from that one found in non vegetated channel. For our case study, the vegetation density was not very elevated to allow to uniform shear distribution. Thus, the friction velocity of the channel without vegetation has been considered more significant as parameter to utilise. Figure 9a shows that immediately beyond the artificial plants the magnitude of the dimensionless stress $-u'w'/U^{*2}$ presents a maximum in a layer close to the top of the elements, as observed in previous Figure 7, with higher value beyond the rigid element. Again, the eight plastic rods fixed in each measurement point shift the Reynolds stress peak to a higher level in the flow, above the canopy, than the single rigid element. This suggests that the plastic stems at their top inhibit the momentum exchange between the interior of the canopy and the overlying surface flow by confining the lower layer, and induce additional turbulence, which shifts the maximum turbulent stresses to a level above the top of the canopy and above the maximum value of the stress register ed for the rigid vegetation. To same results Wilson et al. (2003) came with their work about rod canopy and fronds canopy. What emerges from a comparison between Figures 9a and b is that the turbulent shear layer penetrates a relatively larger horizontal area of the flexible vegetation than the rigid one. So, although the shear generated turbulence 1 cm be-yond the flexible plants is reduced possibly due to the inhibition of the vertical momentum exchange by the greater surface area of the several plastic rods than the single rigid element, opposite outcome is reached at a middle distance between two consecutive stems (Fig. 9b). At this position, the influence of the rigid vegetation on the current seems to disappear, while the effect of the flexible stems is still attending.

As final analysis, Figure 10 shows the transversal Reynolds stress distribution normalized by the velocity friction of the channel, $-u'v'/U^{*2}$, in the

Copyright © 2006 Taylor & Francis Group plc, London, UK

horizontal plane at z/H = 0.24. Dashed contours represent the zero or negative values of stress, whereas the solid ones represent the positive values. In addition, it can be observed two different bitmapped areas, which show a distribution of a stress ranges between −1 and 1. The bitmapped area with more black concentration represents a stress values ranges between 0 and 1. In contrast, the bitmapped area with less black concentration illustrates the stress distribution between −1 and 0. Examining Figure 10a, white areas, of both positive and negative stresses, are located, approximately, along the longitudinal direction, with the only positive contours aligned to the flexible vegetation stems. In contrast, for the rigid rods showed in Figure 10b, a larger amount of white positive areas is located between two longitudinal arrays of stems, with connection in the transversal direction. Regularity of stress distribution between flexible stems depends upon emplacement of the last ones, which well transfer the effect of vegetation on flow patterns. Positive, vertical turbulent stresses correspond to development of positive velocity gradients, $\partial u/\partial z/ > 0$, whereas negative ones correspond to negative gradients, $\partial u/\partial z/ < 0$. As a result, alternate of positive and negative vertical stresses (velocity gradients), along longitudinal direction, as shown in Figure 10a, confirms the development of clock and anti-clock primary vortexes.

4 CONCLUSIONS

An experimental study has been conducted to explore the effect of two types of vegetation, i.e. rigid and flexible, on the flow velocity field and the turbulence structures. Metallic cylinders with rough lateral surface were used to simulate rigid plants, while commercial broom head acted as surrogate of the flexible vegetation. Additionally, artificial plants were submerged in all test runs, with same plant structures, stem lengths and plant densities. Particularly, the vegetation density has been selected with the aim of demonstrating that in non-uniform, bed-friction conditions in the channel, a local analysis is needful for better understanding the phenomenon. The paper also provides insight into the effect of different kinds of submerged plants on momentum transfer and addresses the issue of considering their effects on the current dependent on the relative submergence.

The measured velocity field shows lower magnitude in the vegetated layer than that in the surface-flow layer. This difference decreases as we move away upstream or downstream from the stem. As a first remark, this result can be justified by the particularly low vegetation density chosen for the experimental work. Moreover, it can be seen that near the top of the vegetation, both the local velocity and its gradient increase progressively, producing at the vertical profiles an evident inflection point. In particular, velocity profiles for the rigid plants show higher gradient than the case of flexible vegetation.

In addition to dictating the mean flow patterns, the presence of different vegetations also impacts turbulence structures. At the top of both vegetation kinds, a peak of turbulence intensity occurs, showing the largest value in the case of flexible plants. Finally, alternate of the positive and negative, transversal Reynolds stress distribution, between stems, implies the formation of clock and anti-clockwise vortices.

ABSTRACT: Vegetation is ubiquitous in rivers, strongly influencing both water conveyance and mass transport. The plant canopy influences both mean and turbulent flow structure, thereby affecting both advection and dispersion. In this paper, we focus on the longitudinal dispersion coefficient. Traditionally, it has been modeled by drawing analogy to rough boundary layers, even in the presence of dense vegetation. This approach is inappropriate in many cases, as the vegetation provides a significant dead zone, which may trap scalars and augment dispersion. This paper describes a new theoretical model for longitudinal dispersion in a vegetated channel. The flow is divided into two regions: (i) a shear layer above the canopy where flow is fast; and (ii) a relatively quiescent zone within the vegetation, where flow and mixing may be greatly diminished. Experimental results are shown to support the theoretical arguments posed in the derivation of the model.

1 INTRODUCTION

In fluvial systems, the primary impact of submerged vegetation is an increase in flow resistance and subsequent reduction in conveyance capacity (Kouwen et al. 1969; Stephan & Gutknecht 2002; Stone & Shen 2002, and references therein). However, recent work has shown in more detail how submerged vegetation dramatically alters the mean and turbulent structure of the flow (Ikeda & Kanazawa 1996; Ghisalberti & Nepf 2004; Poggi et al. 2004). In particular, the velocity profile is far from logarithmic over the full depth, so that traditional treatments of longitudinal dispersion in open channels cannot be directly applied to vegetated channels. While dispersion in flows with emergent vegetation has been studied (Nepf et al. 1997; White & Nepf 2003; Lightbody & Nepf 2006), the effects of submerged vegetation on dispersion have not to date been fully investigated.

The coefficient of longitudinal dispersion (K_x) describes the growth rate of the longitudinal variance (σ_x^2) of a tracer cloud in a shear flow, according to

$$K_x = \frac{1}{2}\frac{d\sigma_x^2}{dt}. \tag{1}$$

After sufficient time, σ_x^2 increases linearly with time, such that K_x is constant. Prior to this time, known as the Fickian limit, differential advection will dominate and the rate of increase in the variance will not necessarily be linear.

In a flow dominated by vertical shear, K_x is given by

$$K_x = -\frac{1}{H}\int_0^H u'' \int_0^z \frac{1}{D_z}\int_0^z u'' dz\, dz\, dz \tag{2}$$

(Fischer et al. 1979), where H is the flow depth, u'' is the deviation from the depth-averaged velocity, $\langle U \rangle$, and D_z is the vertical diffusivity. In an infinitely-wide straight channel with a logarithmic velocity profile, it can be shown analytically that $K_x = 5.93 u_{*H} H$ (Elder 1959). Here, u_{*H} denotes the friction velocity, determined from the relationship

$$u_{*H} = \sqrt{gSH} \tag{3}$$

where S is the surface slope. Elder's analytical prediction is comparable to dispersion coefficients observed in very wide ($w_c/H \sim O(10)$, where w_c is the channel width), straight, rough-bottomed laboratory channels (Fischer 1973). However, these conditions do

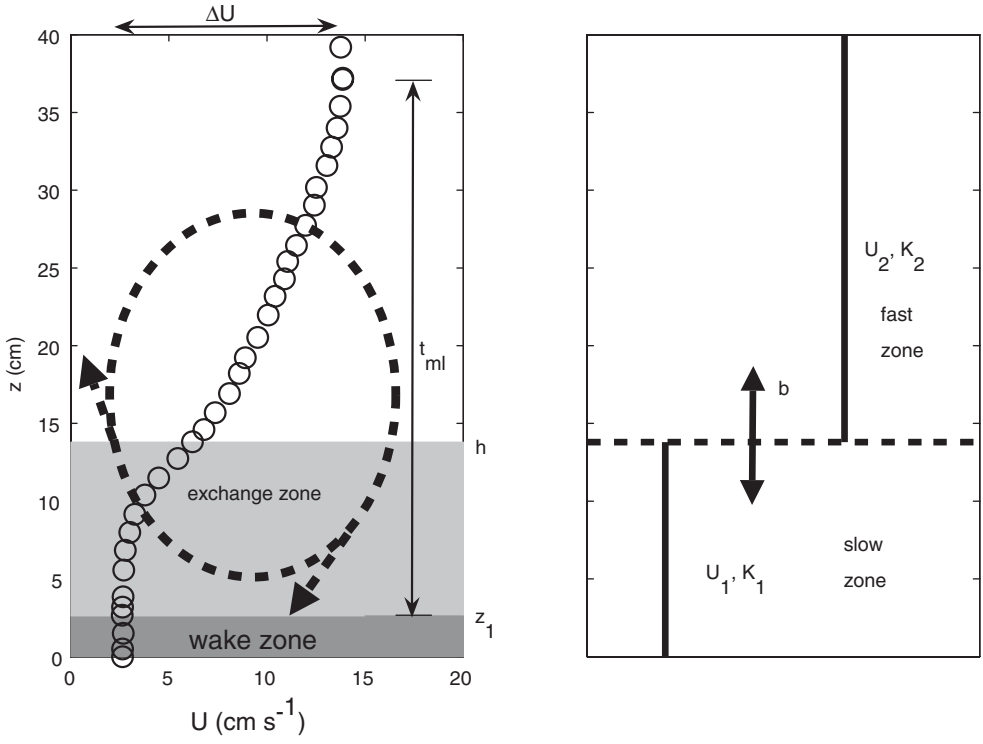

Figure 1. (a) The vertical profile of velocity (U), shown here for Run H (Table 1), resembles a mixing layer. The shear layer does not penetrate fully to the bed, separating the canopy into an upper ("exchange") zone ($z_1 < z < h$) with rapid vertical exchange and a lower ("wake") zone ($0 < z < z_1$) with greatly reduced turbulent velocity and length scales. The diffusivity in the exchange zone is typically an order of magnitude greater than the assumed value in the wake zone (D_w). (b) shows a schematic of the two zone model for the same run. The channel depth is divided into a fast overflow region of thickness ($H - h$) and and a layer of slow flow within the canopy ($0 < z < h$).

not hold in all fluvial systems. For example, lateral nonuniformities such as bends and dead zones can result in significant lateral shear and dramatically increased dispersion (Day 1975; Nordin & Troutman 1980; Davis et al. 2000). Likewise, the drag imparted by submerged vegetation generates velocity profiles and rates of vertical mixing that differ significantly from those in a logarithmic boundary layer (Ghisalberti & Nepf 2005), invalidating several assumptions behind Elder's analysis. Now that there is a greater mechanistic understanding of vegetated flows (to be described in §2), there is a new potential for the prediction of dispersion in vegetated channels. In this paper, we propose a simple model for shear dispersion in vegetated channels and validate it experimentally.

2 TWO-ZONE MODEL FOR VEGETATED CHANNELS

As first presented by Raupach et al. (1996), flows near the top of submerged vegetation most closely resemble mixing layers, rather than boundary layers (Fig. 1a). A mixing layer is a confined region of shear (of size t_{ml}) that separates two regions of approximately constant velocity. The total shear across the layer is denoted by ΔU. Much as in a free-shear-layer, the shear layer produced in vegetated flow is characterized by a street of coherent Kelvin-Helmholtz (K-H) vortices that dominate vertical transport between the canopy and overlying layer (Ikeda & Kanazawa 1996; Ghisalberti & Nepf 2005). These coherent structures do not always grow to encompass the entire flow depth (Nepf & Vivoni 2000). Consequently, as shown in Figure 1a, the canopy is often separated into an upper region of rapid vortex-driven transport (the "exchange zone") and a lower region with greatly reduced mixing (Nepf & Vivoni 2000). Denoting the canopy height as h and the bottom of the shear layer as z_1, the exchange zone spans $z_1 < z < h$. Vertical transport in the lower region (termed the "wake zone", $0 < z < z_1$) is dominated by stem-wake turbulence, with significantly smaller length and velocity scales than the shear-layer vortices. Consequently, the diffusivity in the wake zone

Copyright © 2006 Taylor & Francis Group plc, London, UK

(D_w) is typically an order of magnitude lower than that in the exchange zone (Ghisalberti & Nepf 2005). Nepf et al. (2006) showed that the penetration of shear ($h - z_1$) into a vegetation canopy is inversely proportional to the drag coefficient (C_D) and a canopy density parameter (a),

$$(h - z_1) \approx 0.2(C_D a)^{-1}. \tag{4}$$

Here, a describes the projected frontal area of the vegetation per unit volume and can be related to the familiar leaf area index (LAI) (Nepf & Vivoni 2000, and references therein).

The diminished velocity and turbulence in the canopy layer make it distinct from the overflowing water.We therefore propose a two-zone model for the vegetated channel, as shown in Figure 1b. Constant velocities (U_1 and U_2) are assumed for each zone. K_1 and K_2 are the independent dispersion constants in the slow and fast zones, respectively. Scalar transport across the boundary between the two layers is characterized by the layer exchange coefficient, b, which has dimensions T^{-1}.

This approach is similar to transient storage, or dead zone models, which were developed to explain observations of persistently skewed concentration distributions in natural channels (Day 1975; Nordin & Troutman 1980; van Masijk & Veling 2005). These observations have led to widespread consensus that an accurate analysis of longitudinal dispersion must explicitly consider the effects of "dead", or "slow" zones (Valentine & Wood 1977; Chikwendu & Ojiakor 1985). A plethora of multi-layer models have emerged (Thacker 1975; Smith 1981; Chikwendu & Ojiakor 1985; Chikwendu 1986a; Roberts & Strunin 2004, and references therein), attempting to characterize the effect of transverse variability in pipe and open channel hydraulics. The basis for most of these analyses involves the application of coupled advectiondispersion equations to each region of the flow.

Following Chikwendu's (1986b) approach, in our two-zone model the longitudinal dispersion coefficient at large times is given by

$$K_x = \frac{(\frac{h}{H})^2(\frac{H-h}{H})^2(U_2 - U_1)^2}{b} + (\frac{h}{H})K_1 + (\frac{H-h}{H})K_2. \tag{5}$$

This form highlights three different processes that contribute to dispersion in channels containing submerged vegetation. The first term of (5) represents dispersion that arises from inefficient exchange between the fast zone ($h < z < H$) and the slow zone ($0 < z < h$). In other words, scalars trapped in the slow zone are held up relative to the mass in the fast zone, increasing the spread in the longitudinal direction. For simplicity, we allow

$$(U_2 - U_1) = \beta_1 \Delta U, \tag{6}$$

where β_1 is an $O(1)$ scale constant. Also, we will show in §4 that $\Delta U \sim u_{*H}$. Next, the exchange coefficient, b, is determined by the magnitude of z_1/h. If $(z_1/h) \simeq 1$, vortex penetration is so limited that incanopy diffusion controls exchange between the layers, such that

$$b \simeq \frac{D_w}{h^2}. \tag{7}$$

However, if $(z_1/h) \ll 1$, canopy exchange is driven by the K-H vortices. Scaling arguments and experiments by Ghisalberti & Nepf (2005) show that vortexdriven exchange yields an exchange coefficient

$$b = \frac{\Delta U}{40h}. \tag{8}$$

Physical laboratory constraints, such as flume size, allowed a maximum experimental value of $z_1/h = 0.6$ to be obtained here. For most of the experiments, $z_1/h \ll 1$, such that this regime is the primary focus of the study.

The second term in (5) represents dispersion in the slow zone. K_1 is the dispersion coefficient that would be obtained for $0 < z < h$, if this region were detached from the flow above. Here, K_1 is assumed to be equivalent to the dispersion constant in an emergent canopy, which is a function of vegetation density, Reynolds number and bulk drag coefficient (White & Nepf 2003). The additive effect of vertical velocity shear could potentially be included by evaluation of (2) but this is likely to be insignificant. The contribution of K_1 to the overall dispersion is generally expected to be small, except in the limit as $H \to h$, and is therefore excluded from the model hereafter.

The third term in (5) contains K_2, which represents the longitudinal dispersion in the fast zone due to large-scale velocity shear in this region. Above the canopy, the velocity profile reverts to a logarithmic profile for $z > h$, with a virtual bottom boundary near $z = h$ (Kouwen et al. 1969; Nepf & Vivoni 2000; Carollo et al. 2002). Thus, Elder's simple analytical expression is expected to hold in the region $h < z < H$, yielding

$$K_2 = 5.9u_*(H - h) \tag{9}$$

where u_* is obtained from

$$u_* = \sqrt{gS(H - h)}. \tag{10}$$

Although the analysis of Nepf & Vivoni (2000) suggests that $z = z_1$ is a more appropriate choice for the lower limit to the logarithmic profile, simplicity and practical applicability of the model dictate the use of $z = h$.

Copyright © 2006 Taylor & Francis Group plc, London, UK

It should be mentioned that (5) is consistent with well-established dispersion theory for boundary layers, as it reduces to (9), with $u_* = u_{*H}$, in the limit of $H/h >> 1$. Similarly, in the limit of emergent vegetation ($H/h \rightarrow 1$), $K_x = K_1$.

Bearing the preceding arguments in mind, we can begin to simplify the slow zone model, given by (5). The exchange term is first simplified by substitution of (8), (6) and the scaled ratio $\beta_2 = \Delta U/u_{*H}$. As discussed previously, the slow zone dispersion term containing K_1 is dropped. Finally, K_2 is replaced by the right hand side of (9), yielding

$$K_x = 40\beta_1^2\beta_2\left(\frac{h}{H}\right)^2\left(\frac{H-h}{H}\right)^2 hu_{*H} + 5.9\frac{(H-h)^2}{H}u_* \quad (11)$$

For convenience, we combine the constants in the first term into a single parameter, β. Then, we divide through by $u_*(H-h)$ and rearrange, allowing us to obtain a nondimensional coefficient of longitudinal dispersion given by

$$\frac{K_x}{u_*(H-h)} = \beta\left(\frac{h}{H}\right)^3\left(\frac{H-h}{H}\right)^{1/2} + 5.9\left(\frac{H-h}{H}\right), \quad (12)$$

Alternatively, normalization by $u_{*H}H$ gives

$$\frac{K_x}{u_{*H}H} = \beta\left(\frac{h}{H}\right)^3\left(\frac{H-h}{H}\right)^2 + 5.9\left(\frac{H-h}{H}\right)^{5/2}, \quad (13)$$

which may be preferable for practical application.

3 METHODS

Experiments were conducted in a 24-m-long × 38-cmwide × 58-cm-deep, glass-walled recirculating flume (Fig. 2). The flow rate in the flume was controlled by a Weinman 3G-30P14 pump, with a capacity that ranged from 600 cm^3/s to 15,000 cm^3/s. A Signet flow gauge, with ± 200 cm^3/s accuracy, provided estimates of flow rate. A number of measures were taken to ensure smooth inlet conditions. A dense, 0.5-m-long array of emergent wooden dowels was used to break up turbulence. A mat of rubberized coconut fiber extended throughout the cross-section of the flume, to further dampen the turbulent inlet jet. Honeycomb flow-straighteners eliminated swirl, providing unidirectional flow in the downstream direction.

The model plant canopy consisted of maple cylinders (diameter, $d = 6$ mm), inserted in a random configuration into perforated Plexiglas boards, which covered the entire length of the flume. The dimensionless density (ad) represents the solid volume fraction within the canopy. It was varied between 0.015 and 0.048, within a range representative of dense aquatic meadows, as cited in Ghisalberti & Nepf (2004). Two canopy heights were employed, 7 cm and 14 cm.

Velocity measurements were taken by a two dimensional (2-D) laser Doppler velocimeter (LDV). Velocity profiles for runs A-I were measured by acoustic Doppler velocimeters, as reported in Ghisalberti & Nepf (2004). A 300 mW blue-green argon-ion laser was used in conjunction with a Dantec 58N40 flow velocity analyzer (FVA) unit. Vertical profiles, taken at mid-width in the flume, consisted of five-minute records at spacings of between 0.5 cm and 2 cm, depending on the precision required. All measurements were taken sufficiently far downstream of the start of the canopy such that the flow was fully developed (ie. $\partial/\partial x = 0$). The velocity statistics were temporally averaged and the standard Reynolds decomposition applied, yielding components of mean flow speed and turbulent fluctuation in the x- (longitudinal) and z- (vertical) directions,

$$u = U + u' \quad (14)$$

and

$$w = W + w'. \quad (15)$$

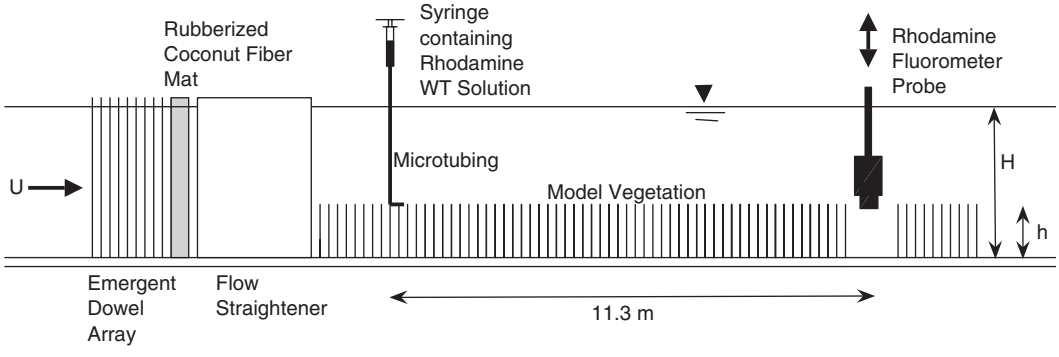

Figure 2. Experimental setup (not shown to scale).

Copyright © 2006 Taylor & Francis Group plc, London, UK

The LDV probe was aligned such that $W = 0$, since unidirectional mean flow was assumed. Reynolds' stress ($-\overline{u'w'}$) profiles were used to determine the distribution of momentum flux, which peaked near the top of the canopy in all cases and decayed towards the bed and free surface.

Twenty-seven different flow scenarios were investigated, with varying values of discharge, Q, and canopy density, ad. The water depth to canopy height ratio, H/h, was also varied between 1 and 4.25 to model vegetation conditions ranging from emergent to thoroughly submerged. The water depth Reynolds number ($Re_H = \langle U \rangle H/\nu$, where angle brackets denote depth-averaging) was between ~1,900 and 41,000 for the experiments. These values of Re_H are consistent with those observed in natural vegetated channels (Leonard & Luther 1995). The stemdiameter Reynolds number ($Re_d = U_1 d/\nu$) is more relevant to dispersion in the slow zone, and values within the experimental range $Re_d \sim 20$–580 correspond well to field conditions.

Tracer experiments were conducted by releasing a small pulse of fluorescent dye at the top of the canopy, 6 m downstream of the leading edge. This longitudinal position was observed to be well within the region of fully developed flow, determined by measured velocity profiles. The tracer consisted of a mixture of Rhodamine WT dye and isopropyl alcohol, with the latter added to render the solute neutrally buoyant in the flume. The dye was injected manually with a 60 ml syringe, through micro-tubing (1 mm inner diameter) that was glued to the top of a dowel at mid-width and oriented parallel to the mean flow. Care was taken to match the injection speed with the local water velocity, to limit near-field mixing effects. The duration of the injection was minimized, to mimic a pulse, and subsequent leakage of tracer into the flow was eliminated by withdrawal of the syringe.

The depth-averaged concentration of dye was measured as a function of time, at a location 11.3 m downstream of the injection point. This was done using a Rhodamine fluorometer, with a sampling rate of 8 Hz. In all cases, the travel time of the tracer cloud from its point of injection to the probe was much greater than the time taken to introduce the dye mixture. This confirmed that the initial condition closely resembled an instantaneous release. The fluorometer was mounted at mid-width in the flume on a pulley system that allowed smooth, precise maneuvering in the vertical plane. As the tracer cloud advected by, the fluorometer was repeatedly raised and dropped at timed intervals, so that the entire water depth was sampled. It was necessary to ensure that the velocity of the probe greatly exceeded the mean Lagrangian velocity of the solute, such that the resulting measurements approached depth-averaged concentration records. Experimental runs were terminated when it was evident that tracer mass in the leading edge of the cloud had fully recirculated around the flume. Each tracer experiment was repeated five times, to reduce random error.

The temporal variance, σ_t^2, of the measured concentration-time distributions was calculated using the method of moments (Aris 1956),

$$\sigma_t{}^2 = \frac{M_2}{M_0} - \left(\frac{M_1}{M_0}\right)^2. \tag{16}$$

M_i denotes the ith temporal moment of the distribution, obtained from

$$M_i = \int_{-\infty}^{\infty} t^i C(t) dt. \tag{17}$$

The velocity, U_c, of the tracer center of mass can be expressed as

$$U_c = X/\mu \tag{18}$$

where X is the distance between the point of injection and the fluorometer (11.3 m), μ, the mean arrival time of the solute cloud, is obtained from the relationship

$$\mu = M_1/M_0. \tag{19}$$

Combining results from five realizations of each experiment yielded ensemble-averaged values of U_c and σ_t. The "frozen cloud" approximation (Fischer et al. 1979, pp. 137) was then applied, meaning that the tracer mass was assumed not to disperse appreciably, as it passed the fluorometer. The spatial variance could then be inferred from the mean Lagrangian velocity of the tracer,

$$\sigma_x^2 = \sigma_t^2 U_c^2 \tag{20}$$

and longitudinal dispersion coefficients were estimated from $K_x = \sigma_x^2/2\mu$, an approximation of (1). Here, it was assumed that X was sufficiently large, in all cases, for the solute to have reached a Fickian dispersive regime. Fischer (1973) proposed that a "reasonable practical criterion" for this to be true, is that the dimensionless time scale for cross-sectional mixing

$$\tilde{t} = t\frac{\langle D_z \rangle}{H^2} \tag{21}$$

should be greater than 0.4. However, preliminary investigations using a numerical random walk model (Murphy, unpubl.) indicate that acceptance of this standard may result in up to 40% underprediction of K_x for tracer experiments in vegetated flows. In fact, errors of less than 10% in K_x may require a minimum of $\tilde{t} \simeq 1.2$, similar to Chatwin's (1972) stricter requirement of $\tilde{t} \geq 1.0$. There are potentially two reasons for this: (i) the depth average D_z in (21) underestimates

Copyright © 2006 Taylor & Francis Group plc, London, UK

the contribution from zones of significantly reduced diffusivity (this is a resolution issue, as discussed by Thacker (1975)), and (ii), concentration measurements at a single location dictate the approximation of (1) by $\sigma_x^2/2\mu$, which will remain an inaccurate predictor of K_x until some time after the onset of a Fickian regime. These subjects will be dealt with in greater detail, in a forthcoming publication.

4 RESULTS

Flow parameters for twenty-five of the twenty-seven experiments are listed in Table 1 (many of the parameters do not apply to conditions of emergent vegetation, so two runs with $H = h$ were omitted). The first eight rows in the table correspond to runs of the same letter in Ghisalberti & Nepf (2004).

The concentration-time distribution for run *A5* is shown in Figure 3. Note that individual realizations are consistent with the average, implying that five repetitions adequately describe each experiment. A nonzero skewness coefficient (also shown in Figure 3) reveals a slight deviation from Gaussian form that agrees with observations in natural channels (Nordin & Troutman 1980). The statistics of all temporal concentration distributions are presented in Table 2, along with the dispersion coefficients obtained from (1). In all cases, $Pe = U_c X/K_x >> 1$, where Pe is the longitudinal dispersion Péclet number. This confirms the prevalence of advection-dominated flow (Levenspiel & Smith 1957), validating the frozen cloud assumption, made in §3.

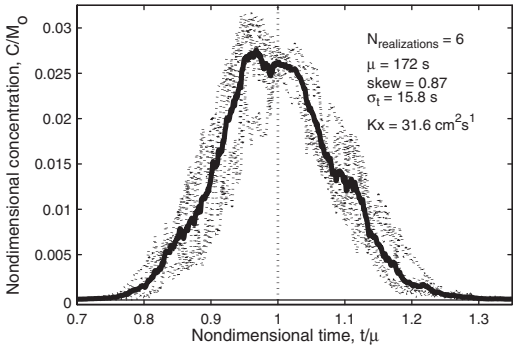

Figure 3. The collapse of the concentration-time curves for run A5. The ensemble average (solid line) is superimposed on the individual realizations (dotted curves). The time and concentration axes have been normalized by the mean arrival time (μ) and the total recovered mass of the solute (M_0), respectively. Normalization of the concentration data eliminates, so far as is possible, non-uniformities across realizations caused by slight differences in the masses of tracer injected (White & Nepf 2003).

Figure 4 shows that $u_* = \sqrt{gS(H-h)} \simeq \sqrt{-\overline{u'w'|h}}$ for the entire range of H/h. This is not surprising, given that the very definition of a shear velocity is $u_* \equiv \sqrt{\tau_o/p}$, where τ_0 is the shear stress at the bottom

* The uncertainty in K_x shown here is based on the root mean square of the measured variances. The values given do not contain any information about the closeness of the approximation, $K_x = 0.5\ \frac{\partial \sigma_x^2}{\partial t} \approx \frac{\sigma_x^2}{2\mu}$, discussed in §3. This is considered in an upcoming publication.

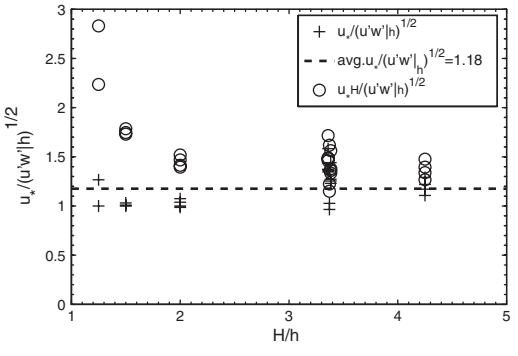

Figure 4. The relationship between the friction velocities, $u_* = \sqrt{gS(H-h)}$ and $u_{*H} = \sqrt{gSH}$, and the square root of the Reynolds stress evaluated at the top of the canopy. Shown for the range of experimentally observed H/h values.

of a logarithmic layer (Kundu & Cohen 2002, pp. 552). As such, this confirms the suitability of the choice of u_* as the characteristic velocity scale for dispersion in the fast zone, rather than u_{*H}, which is seen to vary considerably over a range of H/h conditions (Fig. 4). For thoroughly submerged vegetation ($H/h > 4-5$), the flow approaches a rough boundary layer, and $u*$ and u_{*H} are equally valid velocity scales for dispersion. However, as $H \to h$, the use of u_{*H} becomes increasingly inappropriate, since this parameter cannot accurately capture information about dispersion within the vegetated region, and overpredicts the shear stress at the bottom of the logarithmic layer.

The scaled ratio $\Delta U/u_{*H}$ is reasonably constant (see Figure 5), as anticipated in §2. The same data shows that $\Delta U \sim 6.3u_*$ is just as statistically accurate over the entire range of data. However, we see that in the transition from $H/h = 2$ to $H/h = 1$, the region in which the two zone model is most sensitive to the exchange term of (5), $\Delta U/u_*$ increases significantly. Thus u_{*H} is the more consistent scale for ΔU. This is because u_{*H} captures the total shear across the mixing layer, including the contribution from the region $z < h$, which is not necessarily negligible.

The velocity measurements in Table 1 show that $\beta_1 = (U_2 - U_1)/\Delta U$ is constant (0.68 ± 0.05). Furthermore, Figure 5 shows that $\beta_2 \simeq 4.5$, so given these values we would expect $\beta \simeq 83$. The least-squares best fit of (12) to the experimental data is shown in Figure 6 and yields (with 95% confidence) a value of $\beta = 93 \pm 11$, which agrees with our expectations, within uncertainty.

5 DISCUSSION

Figure 6 shows that the two layer model accurately captures the variation of the longitudinal dispersion coefficient with H/h. We see that as $H/h \to \infty$, velocity shear in the logarithmic fast zone dominates

dispersion. At this limit, the contribution from inefficient exchange between the layers is negligible, because the slow zone occupies only a small portion of the flow depth. At around $H/h = 2.7$, the two processes are of equal importance. As H/h decreases from this value, fast zone shear dispersion drops off gradually, while layer exchange becomes increasingly important, until a maximum is reached at $H/h \simeq 1.2$. This point also corresponds to a peak in the overall dispersion, as shown by the solid line in Figure 6. The exchange term then drops to zero from here, as $H/h \to 1$. At $H/h = 1$, neither process contributes to dispersion. There will be some contribution from stem-scale shear dispersion in emergent canopies but, as discussed in §2, the relatively low importance of this effect makes its inclusion here unwarranted, especially since $H/h = 1$ is relatively uncommon in rivers.

Increasing scatter in the data as $H/h \to 1$ in Figure 6 may be explained by an expected variability in the exchange coefficient, given by (8). This relationship was determined by Ghisalberti and Nepf (2005) for vegetated flows in which the free surface had negligible effect on the shear layer hydrodynamics. Nepf and Vivoni (2000) showed that this will not be the case when $H/h \leq 2$, as the turbulence length scales at the top of the canopy become confined by the water depth. Figure 5 shows that $(\Delta U/u_*) \simeq (\Delta U/\sqrt{-\overline{u'w'}})$ increases as $H/h \to 1$, meaning that turbulence transport is reduced relative to velocity shear in this limit. This is consistent with diminished eddy length scales for $H/h \leq 2$, as described in Nepf and Vivoni (2000). As discussed in the beginning of this section, this range of H/h corresponds to that in which the contribution of the exchange term in (5) is a maximum, so further investigation of this parameter is critical for improvement of the model.

The convenience of this model lies in the simplicity of the terms in (12) and (13). H, h, u_* and u_{*H} are all easily measured or calculated parameters. Neither the bulk drag coefficient, C_D, nor the canopy density, ad, are explicitly included in the formulation but are instead absorbed into the exchange term and friction velocity, u_*. This is advantageous for a number of reasons. Firstly, there is much about the mechanics of C_D that is still not fully understood (Nepf 1999) and so it is preferable to not need to estimate it. The advantage of including ad implicitly, is that (i), estimating the density of vegetation is often cumbersome and inaccurate, and (ii), u_* is a parameter that is familiar to hydraulic engineers, which increases the compatibility of the model with existing theory.

It should be noted that this model is based on observations and theory for dense canopies and may not extend fully to systems containing sparse vegetation, where plant spacing $\sim O(h)$ or greater.

6 CONCLUSIONS

A theoretical framework for evaluating the longitudinal dispersion coefficient in vegetated flows is proposed. A two-zone model is presented in terms of easily measured parameters, such as the water depth, the overflow friction velocity, u_*, and the height of the vegetation. The model shows good agreement with experimental observations. Three contributory processes are identified: large-scale shear dispersion above the canopy, inefficient exchange between the vegetated layer and the overflow, and stem-scale dispersion within the vegetation. The first two will generally dominate, with the latter only playing an important role in the limit of emergent vegetation. A transition from exchange-driven dispersion to logarithmicshear dispersion is observed at $H/h \simeq 3$.

Further improvement of the model's performance will require a careful examination of the time scales and processes governing exchange between the canopy and the overflow.

Turbulent characteristics of flows through emergent vegetation

P.M. Rowiński & A. Mazurczyk
Institute of Geophysics Polish Academy of Sciences, Warsaw, Poland

ABSTRACT: The results of experimental studies, aimed at the recognition of turbulence structure in channels with the simulated riparian woody vegetation, are discussed in the paper. The study embraces the experiments performed in a compound channel with high vegetation occurring on floodplains and in another channel with specially designed vegetated side pocket. The emphasis is put on the investigations of the influence of vegetation on turbulence characteristics. The analyses include vertical distributions of local mean velocities, turbulent intensities, bed shear stresses, autocorrelation functions and velocity spectra. Relevant temporal and spatial scales of turbulence are also evaluated. The logarithmic law does not apply to the vegetated areas and other methodology has to be checked to describe mean velocities. Also the turbulence characteristics are very strongly affected by the vegetation and particularly by wake vortices generated behind all vegetation rods. Recognition of their pattern is therefore crucial for understanding of momentum and mass transfer through vegetated areas.

1 INTRODUCTION

There is no doubt, that turbulence is a key factor determining the character and intensity of mass and momentum transport in rivers. A great deal of research has been recently devoted to the experimental studies of turbulence in vegetated channels (e.g. Baptist 2005; Ghisalberti and Nepf 2002; Tsujimoto &Kitamura 1992; Velasco et al. 2003). Khublaryan et al. (2004) as the main reason of that interest name the development of macrophytes which depends on the processes of turbulent mass exchange in a vegetated channel, on sediment transport and redeposition, oxygen regime of the environment and so on. All those processes are obviously influenced by turbulence structure. This list may be easily extended to the problems of the flow resistance, diffusion of matter, heat transfer, bed formation, development of various bed forms etc.

Nowadays, occurrence of vegetation on river floodplains is advisable due to its environmental functions, but brings additional complexity of hydraulic processes (Nepf 1999). We are, however, still lacking a comprehensive theory allowing to describe the turbulence structure in vegetated channels and the experimental studies in that direction are highly demanded.

Present study aims at the description of the selected properties of a turbulent flow field through emergent vegetation. To this end, flume experiments were used with model vegetation consisting of regular arrays of stiff vertical cylinders with variation in cylinder spacing employed. Different flow geometries were considered. More detailed description of the turbulence structure will be given elsewhere.

2 EXPERIMENTAL SETUP

2.1 *Laboratory channels' description*

Experiments were performed in two channels of different geometries. First part of investigations was carried out in the Hydraulic Laboratory of the Department of Hydraulic Structures, Faculty of Environmental Science at the Warsaw Agriculture University (further named WAU channel). In a straight open channel 16 m long and 2.10 m wide with symmetrical trapezoidal cross-section (Fig. 1) emergent aluminum pipes of 0.8 cm diameter were evenly placed in an uniform pattern ($m = 42$ trees/m^2) on two floodplains. They were representing stems of riparian trees. It was also assumed that the whole branch systems of trees were above water level and the effects like bending or waving of branches were not considered. The bed slope was 0.0005 and the water surface was kept almost parallel to the bed. Water level was constant – 28 cm in the main channel, 12 cm on the floodplains. Turbulence studies in that channel were already discussed in a previous publication but that study was based on 1D measurements with use of a special programmable electromagnetic velocity meter (Rowiński et al. 2002).

Second part of investigations was conducted in the Institute for Hydraulic Engineering at Braunschweig Technical University in Germany in a two-stage

Copyright © 2006 Taylor & Francis Group plc, London, UK

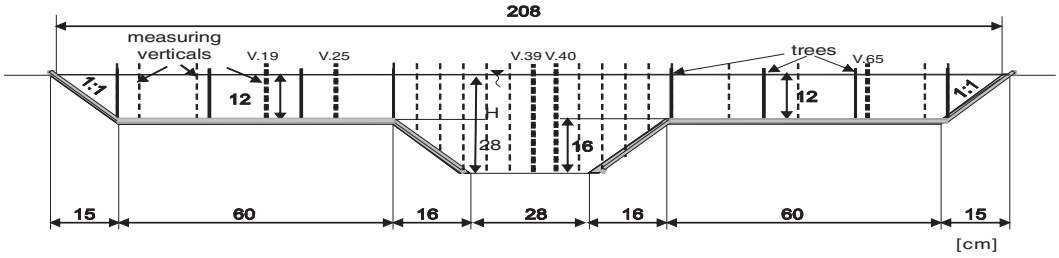

Figure 1. Cross-section of the laboratory channel in Warsaw (WAU).

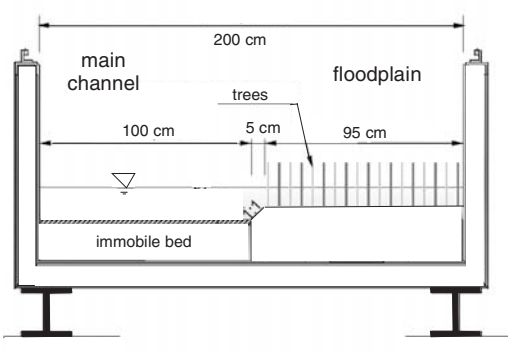

Figure 2. Cross-section of the laboratory channel in Braunschweig (BTU).

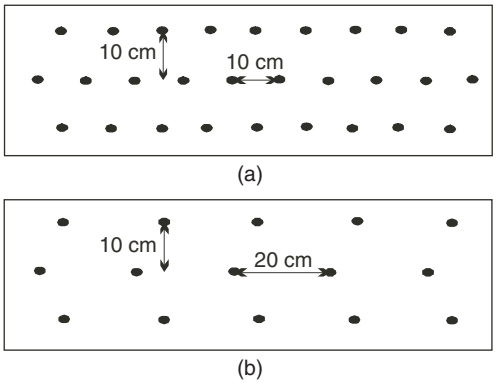

Figure 3. Two densities of sticks on floodplain in BTU (a) 95/m^2 and (b) 45/m^2.

laboratory channel with length of 30 m, width of 2 m, with 1 m wide one-side floodplain (Fig. 2) and the regulated bed-slope (0–1,5%) (Specht 2002). It will be further denoted as BTU channel. A 9-m-long side-pocket (angle 45°) was constructed on the floodplain. Plastic, rigid sticks with diameter of 1 cm were evenly placed in a floodplain-pocket (Fig. 3).

The experiment was carried out under steady-state conditions. The tests were run for the discharge 100 l/s and different arrangements of simulated trees (two sticks' densities and a case with no vegetation were considered) (Fig. 3). The slope was fixed at 0.0009.

2.2 *Measuring equipment*

Instantaneous velocities were measured with use of a three-component acoustic Doppler velocity meter (ADV) manufactured by Sontek Inc. ADV works on pulse-to-pulse coherent Doppler techniques in relatively high temporal resolution (Lohrmann et al. 1994). ADV proved to yield a good description of the turbulence characteristics when certain conditions related to the flow itself and the configuration of the instrument are satisfied (Garcia et al. 2005). The measurements were conducted with maximum frequency 25 Hz.

Buffin-Bélanger & Roy (2005) report, that for the most turbulent statistics sufficient record length for the measurements is 60–90 s. In cases of our experiments even longer time series (120–360 s) were recorded to provide reliability of data and constancy of higher order velocity moments.

2.3 *Measuring setup*

In case of WAU compound channel one cross-section in the middle of the flume was selected for measurements (Fig. 1). It consisted of 23 verticals – six on each floodplain and eleven in the main channel.

The velocities in BTU channel were measured at 12 cross-sections, but for the purpose of this study only the results from the middle cross-section – dividing the pocket into halves – will be presented.

3 RESULTS AND ANALYSIS

3.1 *Mean and friction velocities*

In a compound channel the velocity field is three dimensional (Knight et al 1994), but local longitudinal mean-time velocities give us the most insight into the flow structure. As shown on the contour map of isovels (Fig. 4) velocities in the main channel were definitely higher than on the floodplains and the

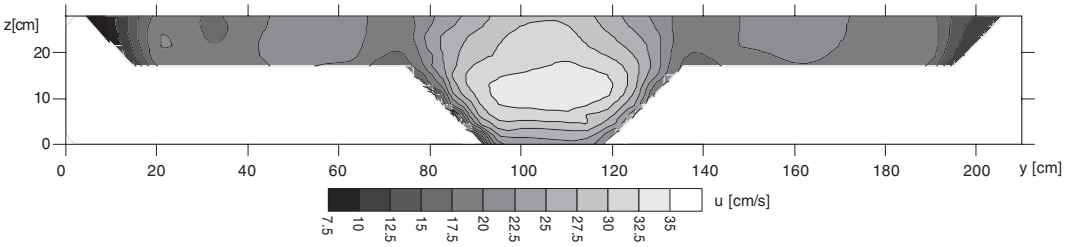

Figure 4. Contour lines for longitudinal mean-time velocities (WAU).

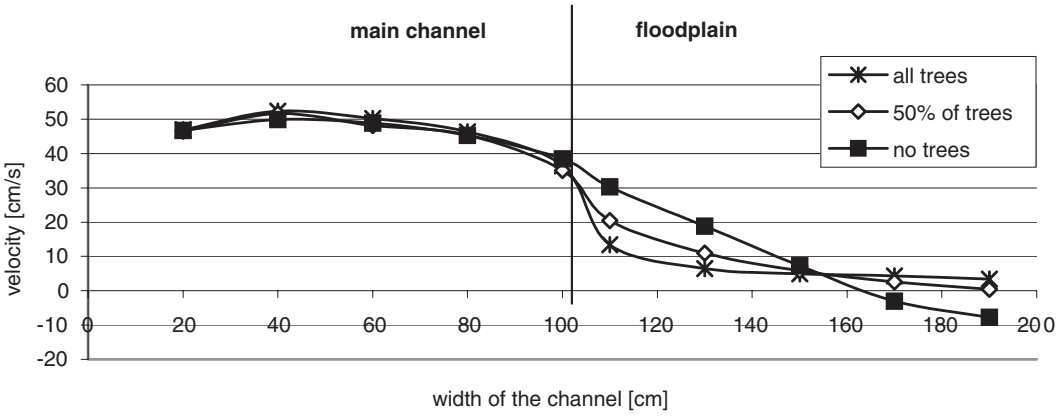

Figure 5. Transverse distributions of longitudinal mean-time velocities for two densities of trees and a case without vegetation (BTU).

flow could be easily divided into separate parts: two floodplain-flows with maximum velocity about 20 cm/s and the main-flow with velocities about two times higher. The main channel-floodplain interaction zone is rather small and velocities on the floodplains vary hardly crosswise.

The studies at BTU allowed for the investigations of the effect of vegetation density on the mean velocity field. Two densities of rods were considered, the occurrence of denser vegetation not only significantly lowered the mean-time velocities on the floodplain, but also constrained the mixing of water from the main channel and floodplain. Denser vegetation reduced visibly the size of the interaction zone (Fig. 5). Negative values of mean velocities in Fig. 5 are the results of the created secondary currents caused by the geometry of the side pockets (Mazurczyk 2004).

The investigations of the vertical distributions of longitudinal mean velocities are of particular importance. In vegetation-free areas one may expect that traditional approach pertaining to logarithmic or exponential distributions should apply. In vegetated areas flow is resisted not only by the boundary shear but also by drag exerted through the flow depth and therefore velocities are expected to be much more uniformly distributed over the flow depth. Fig. 6 presents examples of vertical distributions of mean velocities for both considered channels. In case of the main channel (WAU lab) the longitudinal velocities in the inner region ($z/H < 0.2$) to some degree fulfill the log-law equation (Nezu, Nakagawa 1993):

$$\frac{\overline{u}}{u_*} = \frac{1}{\kappa}\ln\left(\frac{zu_*}{\nu}\right) + A \qquad (1)$$

where $\overline{u}$ = mean-time longitudinal velocity, u_* = shear velocity, z = distance from the bed, κ = universal von Karman constant ($\kappa = 0.41$), ν = kinematic viscosity of water, A = integral constant. The main channel WAU is rather narrow and some interactions with the floodplains occur. Therefore the integral constant A varied in larger range (from 4.2 to 6) than suggested in literature.

In vegetated areas almost uniform vertical longitudinal velocity distributions are observed (Fig. 6). Various attempts to find simple mathematical formulae for vertical velocity distributions have recently been undertaken (Baptist 2005; Khublaryan et al. 2004; Rowiński and Kubrak 2002). The model proposed by Rowiński and Kubrak (2002) proved to provide good agreement with measured data. That model takes into consideration the forces acting on the volumetric element surrounding rods simulating

Copyright © 2006 Taylor & Francis Group plc, London, UK

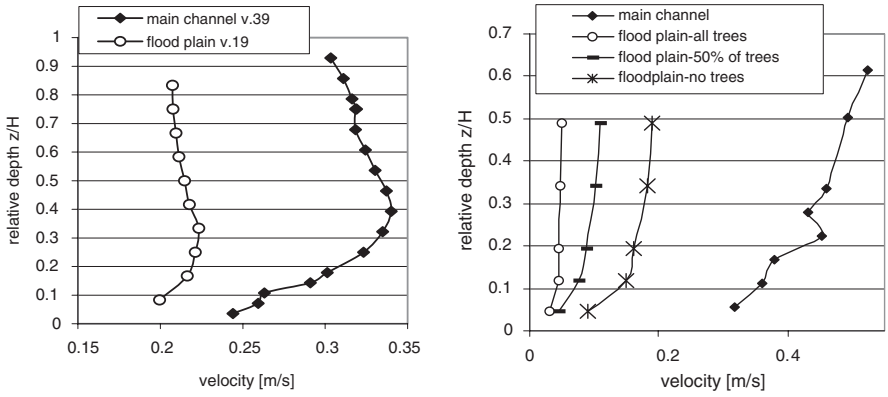

Figure 6. Examples of vertical profiles of longitudinal velocities in WAU (left) and BTU (right).

riparian trees. In the model a mixing length hypothesis was used but with the modification that the mixing length is a linear function of the distance from the bed up to a given level and further it is fairly constant due to the eddy generation by vegetation elements only. All the mentioned models account for flow resistance by means of a friction velocity or bed shear stress. Evaluation of bed shear stresses in vegetated channels is another still open research question.

3D measurements of turbulent velocities provide an opportunity to compare different methods of the evaluation of friction velocity. The detailed study of this kind has been recently given in (Rowiński et al 2005). In principle at the points in the centre of floodplains, friction velocities obtained by means of the near-bed Reynolds stress method and 1D iterative procedure, described in the mentioned paper of Rowiński and Kubrak (2002), provide similar results. The disadvantage of the near-bed Reynolds stress method is that it pertains to the detailed measurements of fluctuating velocities which in practice is rarely available. The method based on the bulk velocities, however, is relevant only at sufficiently large distance from the main channel and the sloping banks to neglect the effect of transverse momentum transport. Friction velocities on the vegetated floodplains varied in the range from 1 to 1.36 cm/s at WAU laboratory.

3.2 *Statistical properties of turbulence*

Second, third and fourth order statistics are frequently used to characterize turbulent velocity field. Particularly, the information on turbulent intensities is very important – these values have a direct impact on mass, momentum and energy transfer in the channel.

The relative turbulent intensities in three directions by definition are:

$$\sigma_x = \sqrt{\overline{u'^2}}\ /\bar{u} \quad \sigma_y = \sqrt{\overline{v'^2}}\ /\bar{u} \quad \sigma_z = \sqrt{\overline{w'^2}}\ /\bar{u} \qquad (2)$$

where u′, v′, w′ = fluctuating components and $\bar{u}$ = mean-time longitudinal velocity in the Reynolds decomposition of the instantaneous point velocity.

It has been observed that turbulence intensities in longitudinal direction are generally much larger than those in the vertical and transverse directions – turbulence is not isotropic in that areas. In the surface boundary layers (in the main channels in both WAU and BTU) their values are much smaller than in the vegetated areas. In principle, vegetation generates turbulence along whole verticals by creation of a wake behind a row of parallel rods. As can be seen in Fig. 7 larger density of vegetation creates larger turbulent intensities. The further increase, however, of the density of vegetation may cause damping of the magnitudes of root-mean squared velocities, similarly as in the atmospheric flows within plant canopies (e.g. Poggi et al. 2004). This condition was not checked in the present study. High relative turbulence intensities in flows through vegetation, often (especially in BTU) exceeding the value of 0.3, cause methodological problems. In such situations Taylor's frozen eddy hypothesis is violated and we may not assume that the properties of the eddies remain unchanged by the time they pass the sensor.

Taking the whole cross-section into consideration (case of WAU), one can observe that the calculated values are visibly higher above the slope between the main channel and the floodplain. Remarkable increase of intensities appear also near the sloping bank of the floodplains and in the main channel-floodplain interaction zones (Fig. 8).

Turbulent kinetic energy defined as:

$$k = 0.5\sqrt{u'^2 + v'^2 + w'^2} \qquad (3)$$

at selected verticals is shown in Fig. 9. The turbulent kinetic energy is produced by shear and wakes. In principle shear production converts mean kinetic energy to turbulence and at the same time wakes are

created as an effect of work against form drag. This is characteristic of turbulence in vegetated areas only and has very important consequences. Firstly it makes the vertical distributions of kinetic energy much more uniformly distributed, which is particularly evident in case of WAU. One may also suspect that this additional work against form drag may cause disturbances in the inertial subrange of the turbulence cascade which may bring about the deviation from the "−5/3" power law in the energy spectra – it will be shown further in the

paper. But this expectation is not confirmed in our study.

3.3 *Scales of turbulence*

Autocorrelation functions R(t) were used for the evaluation of macro time-scales of turbulence. Those functions exhibit very similar forms of decaying curves with an alteration of the domains of the positive and negative values (e.g. Fig. 10). The values of the time scale of turbulence T (the eddies' period), calculated as:

$$T = \int_0^\infty R(t)dt \qquad (4)$$

range over floodplains from 0.4 to 0.54 s and in the main channel from 0.2 to 0.46 s in WAU (Fig. 11). Taking into account a very rough approximation of spatial scales, by means of the Taylor hypothesis of "frozen turbulence" (which is not justified at few points at WAU channel with large turbulent intensities) one obtains the following. The distributions of the sizes of eddies do not reveal any stable regularity. But they have the tendency to decrease towards the channel bed within the main channel and to be rather uniformly distributed at verticals within floodplains (Fig. 12). The relative lengths of eddies are bigger on the floodplains and achieve values of 0.5 to 1 of the flow depths on the floodplains, whereas in the main channel the sizes of largest eddies do not exceed the value of 0.5 of the total water depth.

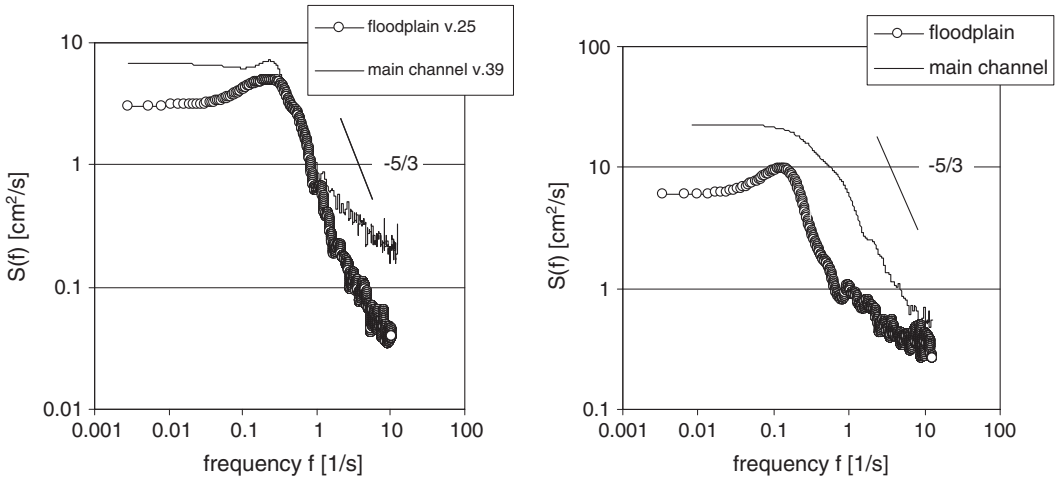

Figure 13. Frequency spectra for selected points in WAU at water depth z = 21 cm (left) and BTU at z = 9 cm (right).

3.4 *Frequency spectra*

Characteristic one-side frequency spectra at the selected measuring points are shown in Fig. 13. Those spectra are presented for both vegetation-free areas and for flows within emergent vegetation to reveal the basic differences.

There is easily distinguishable peak in the low frequency region corresponding to time periods analogous to the periods of motion of the macro turbulent eddies. The movement of large scale eddies is most likely the reason of the low-frequency flow velocity fluctuations.

For the eddies smaller than the energy containing eddies and much larger than dissipative eddies, turbulence is controlled solely by the dissipation rate and the size of the eddy. In this subrange the energy power spectrum should fulfill "−5/3" power law (Nezu & Nakagawa 1993). The inertial subranges can be easily indicated in both main channels of WAU and BTU and in most situations in vegetated areas.

4 CONCLUSIONS

Large scale turbulence structure has been investigated in two different channels with the simulated vegetation occurring on floodplains. The effect of vegetation is considerably high and it influences most of the turbulence characteristics in the channel. Particularly evident is the additional energy supply causing that turbulent intensities and turbulent kinetic energy become more uniformly distributed at verticals. It is also reflected in the frequency spectra at low frequencies. To complement the picture one should also provide a detailed study of Reynolds stresses together with their decomposition into four quadrants, providing the information on outward interactions, ejections, inward interactions and sweeps. Such information will be provided in a separate publication.

Longitudinal dispersion in a lowland river with submersed vegetation

T. Sukhodolova, A. Sukhodolov, H-P. Kozerski & J. Köhler
Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

ABSTRACT: Aquatic plants increase hydraulic resistance, modify transport and mixing processes. To assess quantitatively the impact of vegetation on these processes field tracer studies were performed on the Müggelspree river. Analysis of obtained data indicated that in early spring, when vegetation is absent and water discharges are relatively high, the volume of dead zones is small but their retention time is large. During the vegetation period the volume of dead zones increases with the increase of biomass but the retention time of dead zones decreases two orders of magnitude. In early spring the dead zones are represented predominantly by recirculation zones formed by flow separation on banks irregularities. In vegetative period the dead zones are formed by blocking effect of submersible and emergent vegetation occupying substantial part of the river cross-section though penetration time of these dead zones is comparable with the time scales of wakes evolving behind the plant canopies.

1 INTRODUCTION

Aquatic plants, or macrophytes, colonize lowland rivers and produce considerable biomass – a source of fine particulate organic material utilized by invertebrates (Cushing & Allan 2001). However their role in ecosystems is generally associated with the effect on river flow and habitats of many species of the aquatic life (Carpenter & Lodge 1986). A quantitative assessment of the effects of macrophytes represents therefore a challenging task for ecologists, river practitioners, and the community of hydrodynamic scientists (Denny 1988; Nepf 1999; Righetti & Armanini 2002).

Macrophytes form patchy patterns composed of stands variable in dimension and locality, having well defined margins leading to the development of significant gradients in flow velocities. Within the stands the flow is reduced due to the shading by stems and leaves of plants and hence the mixing processes are modified.

Mixing processes, in form of one-dimensional approach suitable for practical purposes in river studies, were for long time treated in frame of classical Fickian theory (Fischer 1966; Day 1975; Czernuszenko 1990; Sukhodolov et al. 1997). However, because of grooving evidence for inconsistency between field observations and the theory an alternate, model with dead zones, was proposed (Pedersen 1977; Valentine & Wood 1977; Runkel and Chapra 1993; Czernuszenko & Rowinski 1997). The advantage of using longitudinal dispersion model with dead zones is that the model is capable to describe complex asymmetric distributions of tracer concentrations in flows with stagnant or recerculating zones. Although the model vividly represents a convenient tool for studies in natural streams with vegetation, there has been relatively little reported in the literature about this aspect of the model application.

The purpose of this paper is to report the results of the field tracer studies exploring mixing processes and seasonal dynamics of these processes in a river reach with vegetation. Analysis of the data was completed using longitudinal dispersion model with dead zones there and the results are compared to the predictions of the Fickian theory.

2 THEORETICAL BACKGROUNDS

Longitudinal dispersion with dead zones combines two fundamental physical mixing processes, turbulent diffusion and advection, and constitutes of differential equations describing mass conservation for stream and dead zone segments (Czernuszenko & Rowinski 1997)

$$\frac{\partial C}{\partial t}+U\frac{\partial C}{\partial x}-D\frac{\partial^2 C}{\partial x^2}=\frac{\varepsilon}{T}\left(C_d-C\right) \quad (1)$$

$$\frac{\partial C_d}{\partial t}=\frac{\left(C-C_d\right)}{T} \quad (2)$$

where C and C_d are cross-sectionally averaged in-stream concentration and dead zone solute concentration, t is time, x is distance, U is mean flow velocity, ε is spatial average dead zone volume fraction $\varepsilon = A_d/A$, A_d is spatial average of dead zone cross-sectional area, A is cross-section area of the stream,

Copyright © 2006 Taylor & Francis Group plc, London, UK

T is dead zone time scale called also dead zone penetration time, and D is dispersion coefficient.

The system (1) and (2) transforms to the classical advection-dispersion equation when $\varepsilon \to 0$ and $T \to \infty$. To solve dead zone balance equations (1) and (2) one needs to specify boundary and initial conditions (Czernuszenko et al. 1997)

$$C_d(x,0) = C(x,0) = 0, \quad 0 < x < \infty \tag{3}$$

$$C(0,t) = C_0(t), \quad \lim_{x\to\infty} C(x,t) = 0 \tag{4}$$

Although hitherto analytical solutions of the boundary value problem (1)–(4) have been not found, the temporal moments of the concentration distributions were proposed recently (Czernuszenko & Rowinski 1997)

$$\mu_1 = \bar{t} = \frac{2D}{U^2} + \frac{x}{U}(1+\varepsilon) \tag{5}$$

$$\mu_2 = \sigma_t^2 = \frac{8D^2}{U^2} + \frac{x}{U}\frac{2D}{U^2}(1+\varepsilon) + 2\frac{x}{U}\varepsilon T \tag{6}$$

$$\mu_3 = Sk \times \sigma_t^3 = 2\frac{x^2 D}{U^4}(1+\varepsilon)^2\varepsilon + 64\frac{D^3}{U^6} + \tag{7}$$

$$\frac{x}{U}\left[12\frac{D^2}{U^4}(1+\varepsilon)^2 + 4\varepsilon T(\varepsilon+2) + 6\varepsilon T^2\right]$$

where μ_i, $i = 1, 2, 3$ are central moments of the temporal concentration distribution. The first moment characterizes the transport rate of the mass center of the concentration distribution and sometimes, specifically in freshwater biology, called stream retention time. The second moment characterizes the spreading rate of the solution cloud and the third one is representing the shape of the cloud and can be normalized with the second moment to obtain skewness coefficient.

Analysis of experimental and numerical studies of the boundary value problem (1)–(4) show that equations (5)–(7) adequately represent spatial evolution for temporal moments of concentration distribution (Czernuszenko et al. 1997). The temporal moments for the classical longitudinal dispersion model, exactly the same as presented by Nordin & Troutman (1980), can be obtained considering asymptotical behavior of the system (1) and (2). The moments (6)–(7) can be used to determine parameters of the dead zone model U, D, ε and T from results of tracer studies by means of nonlinear optimization procedure similar to the methods of moments in the classical dispersion model.

3 FIELD TRACER STUDIES

3.1 *Experimental river reach*

Tracer experiments were carried out during May–August 2005 on the downstream part of the river Spree

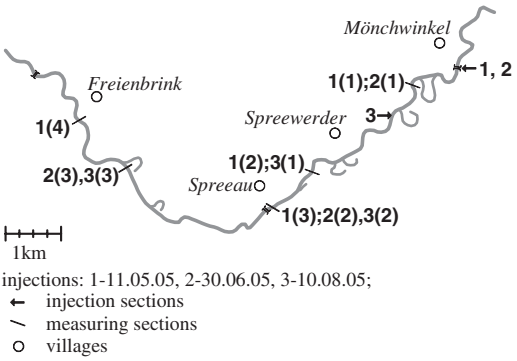

Figure 1. Experimental river reach on the Müggelspree river.

(Müggelspree) in Germany. The Spree river is a typical lowland river about four hundred kilometers in length, running from Lusatian mountains through several shallow lakes to Berlin, were it joins the Havel river. The Spree river is crossed by the Oder – Spree canal near Fürstenwalde where the river is completely intercepted by the canal. Therefore the source of the lower part of the river – Müggelspree – is located at the outlet of the canal near the village Grosse Tranke. The river reach between the bridge near the village of Mönchwinkel and the bridge at autobahn Berliner Ring was selected as the experimental river reach for this study (Figure 1).

The river channel on there is canalized slightly sinuous in plane with a trapezoidal shape of the cross-section. The banks are protected with a rip-rap of cobbles. The river within experimental river reach has only minor tributaries with discharge of few liters per second and the distributed groundwater inflow is small.

3.2 *Equipment and measurements*

Field measurement program included observations of downstream changes of the instantaneously injected tracer cloud and a set of hydrometric and morphologic measurements. The concentration of the tracer, flow rate and cross-sectional profiles of the riverbed elevations were measured in each experiment. Solution of uranin was used as the tracer in these studies. The solution was injected from a bridge as a surface line across the channel. Each injection consisted of 400 g of uranin AT dissolved in about 700 L of river water. The time of injection was within of 20 s and can be considered as instantaneous. Solution of uranin AT dye is ecologically harmless and allowed for scientific purposes in natural environments. However, because of sensitivity to the sun light, uranin solution exposed to the bright light decays relatively rapidly. To prevent considerable loses of the tracer the experiments were performed during the night time.

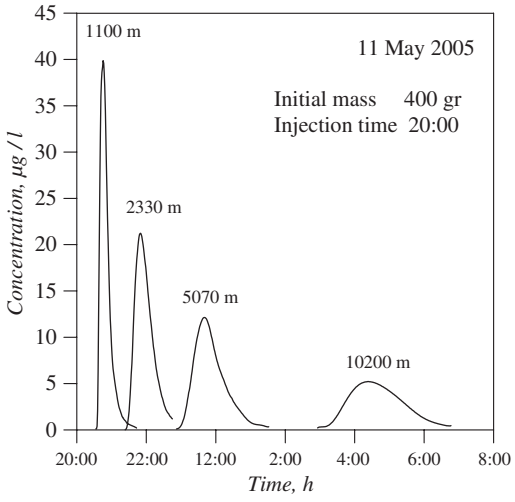

Figure 2. Examples of measured concentration curves.

Table 1. Hydraulic and morphometric characteristics.

No.	Date, month	Q, m^3/s	B (width), m	h (depth), m
1	11.05	9.0	25	1.06
2	30.06	2.8	23	0.87
3	10.08	7.5	27	1.54

The concentrations of the tracer cloud were determined using a back scat fluorometer (Haardt, Germany). Examples of concentration distribution are shown in Figure 2. A summary of hydraulic and morphological variables for the field tracer studies is presented in Table 1.

4 RESULTS AND ANALYSIS

4.1 *Evaluation of parameters*

Determination of model parameters was achieved by solving optimization problem in respect to the central moments (5) and (7)

$$\lim_{u,D,\varepsilon,T}\left\{F(u,D,\varepsilon,T)=\sum_{i=1}^{3}\sum_{k=1}^{N}\left[\mu_{i\,m}(x_k)-\mu_i(x_k)\right]^2\right\} \quad (8)$$

where F is the criterion function, k is the number of measured sections of the tracer cloud. This method to determine the parameters of the dead zone model may be less accurate than solving the optimizing problem by fitting measured concentration curves with the numerical solutions of boundary value problem (1)–(4). However, accurate numerical solution would require detailed information on the flow and river channel geometry for the entire river reach. In the absence of that information the performance of the moments method (8) is expected to be the same as for advanced techniques (Czernuszenko et al. 1997).

Table 2. Parameters of the dead zone model.

No.	U, m/s	D, m^2/s	ε	T, min
1	0.34	11.5	0.01	29.1
2	0.14	8.0	0.03	0.08
3	0.18	18.0	0.15	2.50

Parameters of the longitudinal dispersion model evaluated with optimization technique (8) are summarized in Table 2. Comparison of measured and predicted values for central moments of concentration distributions are shown in Figure 3. It can be seen from this figure that the analytical solutions (5)–(7) approximate spatial distributions of measured moments quite accurately. Specifically two first moments prescribed with deviations less then 5%. The scatter of the measured data about theoretical prediction (7) for the third central moment is about 20%. This scatter is explained by the sensitivity of numerical estimates of the third moment to the imperfections of measuring procedures. Thus, because of limited number of fluorometers some units were moved to downstream sections and the tails of concentration curves were cut on non-zero value. There were also errors associated with calibration procedures for the devices.

The results of tracer studies indicate substantial reduction of mean flow velocities of the flow during the vegetative period (Table 2). At the same time the data reveal a systematic increase in the values of dead zone volume and decrease of penetration times.

4.2 *Comparison with Fickian model*

To understand better the effect that dead zones cause on the mixing and transport processes it is useful to compare experimental data with predictions from classical model of longitudinal dispersion: $\varepsilon = 0$, $T = \infty$ in equation (1). Assuming instantaneous injection of the tracer, the downstream evolution of dimensionless maximal concentration is described as (Sukhodolov et al. 1997)

$$\frac{2A\sqrt{\pi\, DB/U}\, C_{\max}}{M} = \frac{1}{\sqrt{x/B}} \quad (9)$$

where $A = hB$ is cross-section area, and M is mass of injected tracer. Tracer studies in natural streams (Sukhodolov et al. 1997) indicate that equation (9) is satisfied quite accurately for the distances $x/B > 70$. Comparison of scaled measured maximal

Copyright © 2006 Taylor & Francis Group plc, London, UK

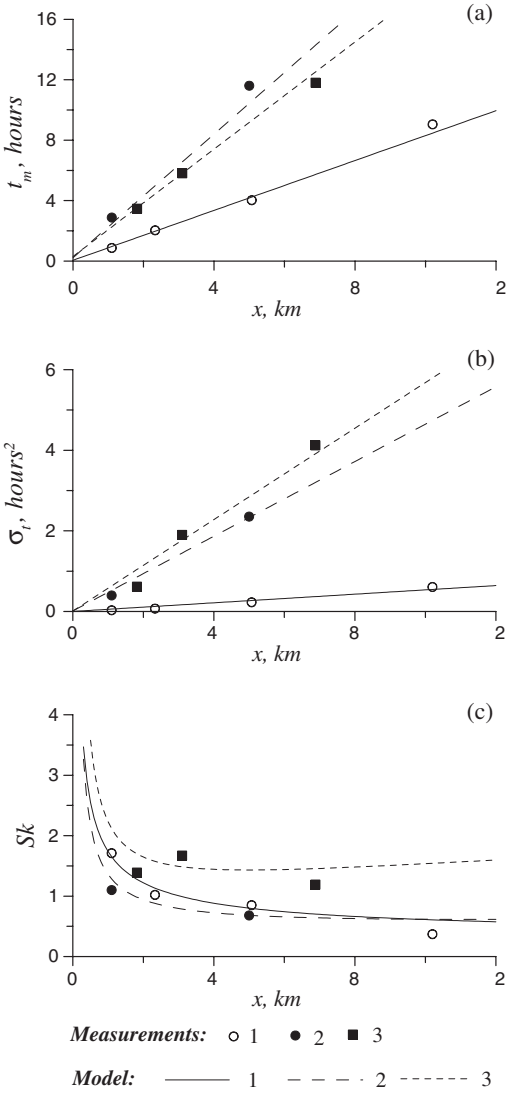

Figure 3. Downstream evolution of the central moments for concentration clouds; (a) retention time on the river reach, (b) variance of tracer cloud, and (c) skewness (numbers correspond to the experiment number in Table 1, 2).

concentrations of uranin with the predictions from relation (9) is demonstrated in Figure 4. It can be seen from this figure that measured data deviate systematically from (9) at distances $x/B > 70$ and the deviation magnitude increases with distance.

Dimensionless form for the variance of the tracer cloud is obtained from the definition of the dispersion coefficient

$$D = \frac{U^3\sigma_t^2}{2B}\frac{1}{x/B}, \quad \frac{U^3\sigma_t^2}{2DB} = x/B \qquad (10)$$

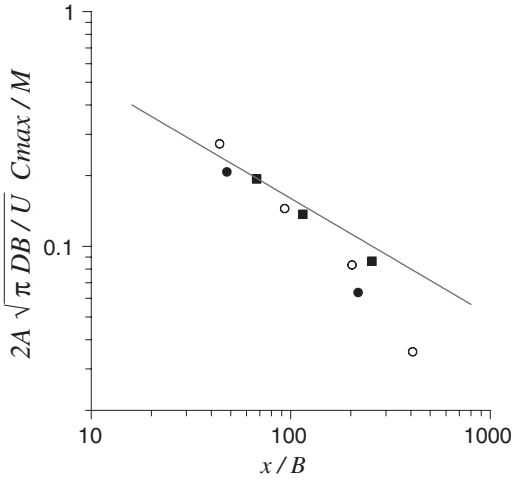

Figure 4. Decay of dimensionless maximal concentrations along the experimental river reach (the symbols are the same as in Figure 3).

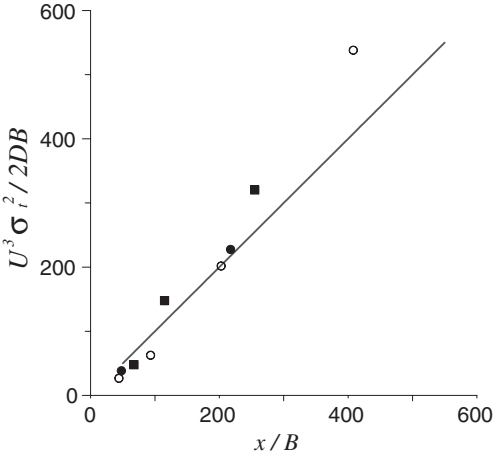

Figure 5. Decay of dimensionless maximal concentrations along the experimental river reach.

Measured downstream growths of the tracer cloud and its comparison with the linear relation (10) are shown in Figure 5. Systematic deviation from the classical dispersion process (10) is also evident at this plot. The size of the tracer cloud is evolving at higher rate than linear and, hence, equation (10) significantly underestimates variance of the distribution.

Relationship for skewness in Fickian model was obtained by Sukhodolov et al. (1997) in the form

$$Sk \sim \left(\frac{Uh}{D}\right)^{-1/2}\left(\frac{x}{B}\right)^{-1/2} \qquad (11)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

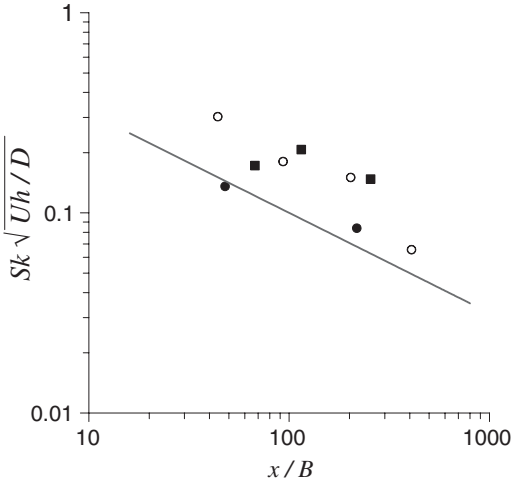

Figure 6. Variation of dimensionless skewness coefficients along the experimental river reach.

Measured data for skewness normilazed in accordance with (11) are plotted in Figure 6. The data reveal systematic deviations from (11) indicating that only in the channel free of vegetation the trend similar to Fickian model was observed. In vegetated channel the skewness was approaching constant state along the river reach.

4.3 *Dispersion coefficients*

In general form the longitudinal dispersion coefficient can be represented as

$$D = \frac{1}{2}\frac{\overline{dx'^2}}{dt} = \int_0^\infty \overline{U'(t)U'(t+\tau)} \qquad (12)$$

where x' is deviation of a liquid particle from its mean position, U' is deviation of the instantaneous longitudinal velocity of the particle from its average velocity, and τ is time shift. Neglecting the effect of turbulence in comparison with dispersion stipulated by non-homogeneous mean velocity field and performing simple transformations in (12), yields

$$D = \sigma_u^2 T_L \qquad (13)$$

where σ_u^2 and T_L are variance and time Lagrangian scale of mean velocity field. From physical considerations and based on dimensional analysis the Lagrangian scales can be related to Eulerian scales as (Sukhodolov et al. 1997)

$$\overline{\sigma_u^2} = \alpha^2 U^2 \qquad (14)$$

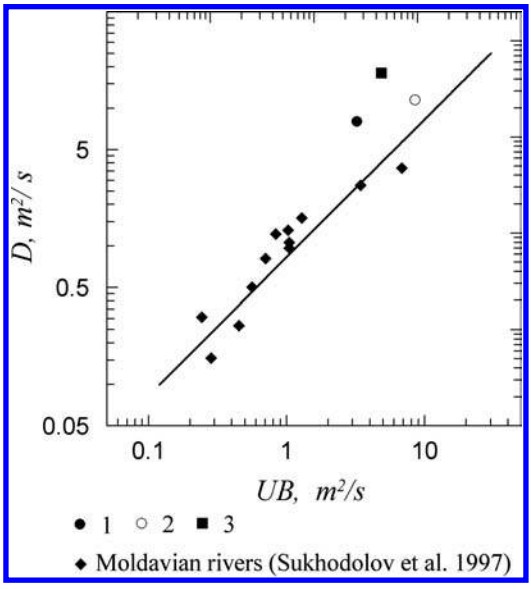

Figure 7. Relation between flow parameters and dispersion coefficient.

$$T_L = \beta\frac{B}{U} \qquad (15)$$

Substituting (14) and (15) into (13) one obtains

$$D = \alpha^2 \beta U B \qquad (16)$$

Coefficient α characterizes the degree of heterogeneity of mean velocity field in the river channel. Field tracer studies completed on small Moldavian rivers without vegetation provided the value 0.83 for the multiple parameter $\alpha^2\,\beta$.

Measured values of the dispersion coefficient and the values computed from flow parameters according to (16) are shown for comparison in Figure 7. The data of tracer studies completed in small rivers of Moldova are also indicated in this plot (Sukhodolov et al. 1997). Close correspondence between measured and predicted value of the dispersion coefficient can be reported for the flow without vegetation (point 1). In vegetated channel measured values of the dispersion coefficient were significantly higher than those predicted with equation (16).

4.4 *Dynamics of vegetative cover*

Depending on the weather and flow conditions on the watershed and in the river the in-stream vegetation begins to grow in the Müggelspree in April–May. The maximum in vegetation cover is observed in July–August and it gradually disappears in October–November. Observations of seasonal evolution of

Copyright © 2006 Taylor & Francis Group plc, London, UK

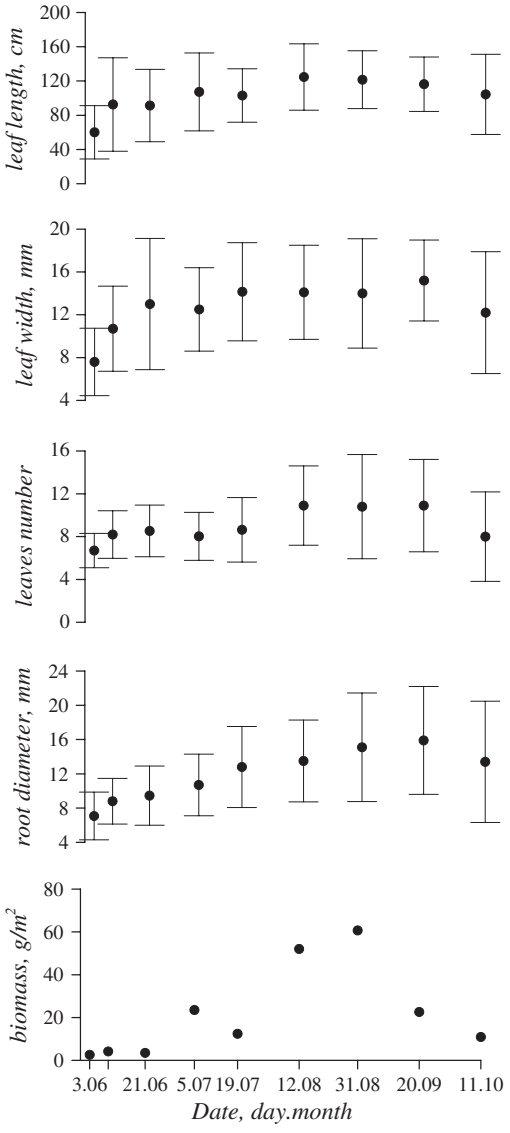

Figure 8. Dynamics of vegetation cover characteristics in the Müggelspree river near Freienbrink (observations during summer 2004).

Sagittaria Sagittifolia, a dominant submersible species in the Müggelspree river were performed near the village of Freienbrink (Figure 1). Patches of vegetation initially appear there as narrow ($2 \div 3$ m in width), elongated (length up to a 100 m) strips that widen and merge during the vegetative period. Noteworthy, the plants forming patches get their maximum characteristics quite fast – practically during the first three weeks and change non-significantly during the rest of vegetative period, Figure 8. At the same time the plants biomass grows quite monotonously and reaches its maximum at the end of summer. Some deviations are due to the spatial non-uniformity of the vegetative cover in the area of plants harvesting. Although the most characteristics of individual plants remain practically constant during the vegetation period, the diameter of plants near the root increases $1.5 \div 2$ times. This characteristic indicates rigidity of the plants and therefore controls bending angle.

5 DISCUSSION AND CONCLUSIONS

In this study the effect of submersible vegetation on longitudinal transport and mixing of dissolved substances in a lowland river is investigated. Tracer technique was employed in field measurements to quantify the spatial evolutions of the tracer cloud. Three sets of measurements were performed during the vegetative period. Obtained data were analyzed using longitudinal dispersion model with dead zones and allowed to examine temporal changes of the parameters. Performance of the dead zone model was compared to the classical Fickian model.

The results of the study indicate that downstream evolution of temporal moments of concentration curves is accurately predicted by the model of longitudinal dispersion with dead zones. Comparison of measured temporal moments with predictions of the classical Fickian theory of longitudinal dispersion indicated unacceptable large discrepancies.

Specific parameters of the dead zone model, dead zone volume and penetration time, exhibited a distinct behavior during the vegetative period. As might be expected, the relative volume of dead zone was increasing from 1% in May to 15% in August. Correspondently, the grows of biomass (dry weight per area of the river channel) indicated increase from 5 to 60 g/m^2. However, the penetration time – characteristic time scale of tracer residence in the dead zone decreased from 30 minutes to 2.5.

Phenomenologically the observation can be explained only by metamorphoses of dead zone. In early spring the dead zones are represented predominantly by recirculation zones formed because of flow separation on banks irregularities (Figure 9). Although these dead zones have considerable dimensions and retention times about 30 minutes, they are sparsely distributed on the river reach and respectively their relative volume is small. In vegetation period the dead zones are formed by blocking effect of submersible and emergent vegetative canopies occupying substantial part of the river cross-section though the penetration time of these dead zones is comparable with the time scales of wakes developing behind the plant canopies and ranges from 5 s to 3 minutes.

Theoretical analysis indicates that dispersion coefficient value is depending linearly on the mean velocity

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 9. A dead zone at the left bank of the Müggelspree river near Monchwinkel.

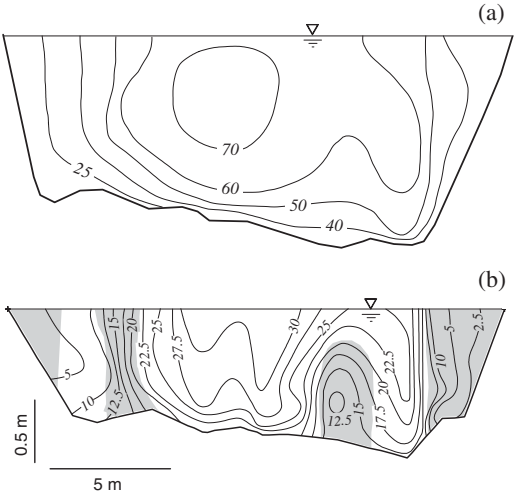

Figure 10. Downstream velocity isovels (cm/s) in the vegetation-free cross-section in May (a), and in the cross-section with vegetation (shaded areas) in July (b).

and the river width (16). Although mean velocity decreased two times in August as compared to non-vegetated conditions in May, dispersion coefficient values increased 1.6 times (Table 2, Figure 7). This observation can be explained by increasing non-uniformity of the mean velocity field because of vegetation. The results of our previous investigations of river turbulence on the reach (Sukhodolov et al. 1998; Sukhodolova et al. 2004; Sukhodolov & Sukhodolova 2005) provide qualitative estimates for the degree of non-homogeneity of the flow in vegetated channel. Figure 10 shows isovels of mean velocity field measured in the cross-section of the Müggelspree near the village of Freienbrink. Despite the large differences in discharge, plot (a) corresponds to 13.4 m^3/s while plot (b) to only 3.25 m^3/s, the maximal difference in the mean velocities are still nearly the same – about 20–25 cm/s. At the same time because of non-uniformity of the vegetative cover the differences in mean velocities observed in much larger areas across the flow making the dispersion mechanism more effective.

This case study provides valuable quantitative information about transport and mixing processes in natural environment subjected to intensive influence of the biological component of the fluvial ecosystem. We hope that results of the study will facilitate complex multidisciplinary investigations and understanding of flow-biota interactions.

ABSTRACT: We consider effects of bed and bank-side vegetation on hydraulic resistance of small streams, and develop simple quantitative relationships for predicting and quantifying these effects using the normalized plant characteristics. We conducted two field studies to explore effects of submerged aquatic and bank-side vegetation on stream hydraulics. In the first study, we examined the effects of aquatic plant biomass, stature and architecture on hydraulic conditions in five small streams representing a range of channel dimensions, flows and aquatic plant assemblages. In the second field study, we created experimental floods in a small stream to examine the effects of submerged bank-side vegetation on hydraulic conditions. The results of the studies and the relationships presented in the paper may be used to provide initial estimates of resistance coefficients for hydraulic modelling, predicting effects of aquatic weed management and bank-side planting on flood levels, and designing naturalisation and enhancement projects for small streams.

1 INTRODUCTION

Understanding of flow-vegetation interactions is important for both engineering (e.g., flood level estimates) and ecological (e.g., stream restoration) applications. In-stream (aquatic) and bank-side (terrestrial) vegetation are common in stream channels and have significant physical, biological, and biophysical functions. Interactions between flow and vegetation are complex and depend on environmental factors and plant characteristics such as mean flow velocity, turbulence, sediment transport, channel morphology, water temperature, plant morphology, age, size and spatial distribution of plant patches (e.g., Howard-Williams 1991). Flow conditions affect the roles of plants as suspended sediment filters, sinks for dissolved nutrients and contaminants, and habitat for other stream biota. On the other hand, plant structure and abundance affect flow depth, flood conveyance, sediment transport capacity, and other hydraulic and hydrologic parameters. Hereafter, we use the term aquatic plants to refer to vascular plants, bryophytes and macroalgae that occur on stream beds and require submergence. The term bank-side plants is used to refer to vascular terrestrial plants that occur on stream bank slopes, and which tolerate temporary submergence during high flow events.

The goals of the project reported in this paper were to examine vegetation effects on hydraulic resistance, and develop simple quantitative relationships for predicting and quantifying these effects using the plant characteristics with the greatest explanatory power. These relationships may be used to provide initial estimates of resistance coefficients for hydraulic modeling, which can be further calibrated by matching the observed and computed hydraulic parameters (e.g., Darby 1999). To progress with these goals, two field studies were completed to explore effects of submerged aquatic and bank-side vegetation on stream hydraulics. In the first study, we examined the effects of aquatic plant biomass, stature and architecture on hydraulic performance of five small streams representing a range of channel dimensions, flows and aquatic plant assemblages. In the second study, we created experimental floods in an urban small stream to identify the effects of submerged bank-side vegetation on hydraulic resistance. In this second study

Copyright © 2006 Taylor & Francis Group plc, London, UK

we focused on the effects of two bank-side vegetation parameters: planting density and general plant morphology. Most studies of flow-vegetation interactions have been conducted using artificial plants in laboratory conditions and the use of natural plants is generally limited to grasses (e.g., Yen 2002). In our studies, we maximized naturalness by conducting field experiments using naturally-occurring aquatic plants, and bank-side plants fabricated from natural plant materials.

Hydraulic resistance of stream channels is quantified using various resistance coefficients. In our study we used the most popular: Manning's n, Chezy's C, and Darcy-Weisbach's friction factor f, which are defined as

$$n = \frac{R^{2/3} S^{1/2}}{U},\quad C = \frac{U}{(RS)^{1/2}},\quad f = \frac{8u_*^2}{U^2} \text{ or } \sqrt{\frac{8}{f}} = \frac{U}{u_*} \quad (1)$$

where R = hydraulic radius; U = cross-sectional mean velocity; S = energy slope; $u_* = (gRS)^{1/2}$ = shear velocity; and g = gravity acceleration. Manning's n, Chezy's C, and Darcy-Weisbach's f are interrelated as $n = R^{2/3}S^{1/2}/U = R^{1/6}(f/8g)^{1/2} = R^{1/6}/C$. Although a wide range of theoretical and conceptual approaches are currently in use (e.g., Kouwen et al 1969; Petryk & Bosmajian 1975; Wu et al. 1999; Stephan & Gutknecht 2002; Yen 2002; Jarvela 2002, 2005; Wilson et al. 2003; Carrolo et al. 2005; Green 2005), there is a general agreement that resistance coefficients such as Manning's n, Chezy's C, and Darcy-Weisbach's f may be expressed as the following function of dimensionless arguments:

$$R_C = F(\mathrm{Re}, Fr, N, K, d, B, M, G, J, D, P) \quad (2)$$

where R_C = resistance coefficient (i.e., Manning's n, Chezy's C, or Darcy-Weisbach's f); F represents a function; Re, Fr, N, and K = flow parameters (Reynolds number, Froude number, non-uniformity/unsteadiness parameter, and relative submergence, respectively); d, B, and M = dimensionless parameters for bed material, bed form, and channel form (e.g., sinuosity), respectively; and G, J, D, and P = dimensionless parameters for vegetation (geometry, flexibility/stiffness, area/volume density, and patchiness, respectively). The form of the function F and its arguments are long-standing problems in hydraulic research, and they remain unclear today. In our study, we focused mainly on the effects of aquatic and bank-side vegetation on hydraulic performance of small streams (keeping other parameters similar), and development of quantitative relationships for predicting these effects. Below we present results for in-stream vegetation, then for bank-side vegetation, and conclude with a brief discussion of how our findings lend support to models of hydraulic resistance in vegetated channels.

2 EFFECTS OF AQUATIC VEGETATION

2.1 *Experimental sites and methodology*

For the first study, we selected approximately straight reaches at five small streams in Christchurch, New Zealand, covering a range of flow widths, depths, and plant species (Table 1). The aquatic plants at these stream reaches form elongated patches that cover 40–100% of the bed. At each site, five measurement campaigns were conducted over 6 months from summer to winter (January to June 2004). The same measurement cross-sections were used for each date/campaign with the following parameters measured.

1. Water levels at a reference cross-section every 20–30 min during the campaign, to monitor stationarity of hydraulic conditions.
2. 'Instant' water levels on both banks at five cross-sections for obtaining water surface slopes. The distance between cross-sections was 1–2 channel widths. Measurements were made using a Spectra-Physics Laserplane laser level and a custom-built hydrostatic measurement device. These data, together with cross-sectional areas and velocities, were used for calculating energy slopes following a standard procedure (e.g., Graf and Altinakar 1998).
3. Water discharge Q at a cross-section with minimum vegetation cover, which could be outside the experimental site.
4. Bed/bank elevation z_b, flow depth, height of the vegetation canopy h_c, plant species, and plant lengths l_p at 5 to 15 evenly spaced verticals (locations) in each of the five cross-sections.
5. Areal ρ_{Aw} and volumetric ρ_{Vw} biomass densities at each cross-section. To determine biomass densities, one vertical was selected at random along each cross-section, and all visible plant material was collected from a 0.085 m^2 area around the vertical. At the laboratory, the material was dried to constant weight (60°C for 3–4 days). Areal dry biomass density was defined as the ratio of dry weight to sampling area. Volumetric dry biomass density was defined as the ratio of dry weight to sampling volume, i.e., to the product of sampling area and canopy height. Corresponding wet densities were estimated from wet-dry weight conversion factors for each species. The above measurements were supplemented by measurements of plant volumes for estimating 'vegetation porosity', as the ratio of the fluid volume to the total sampling volume within the vegetation canopy.
6. Six-point vertical profiles of mean velocities and velocity standard deviations were made at two locations at each cross-section, using a Sontek Flow-Tracker acoustic Doppler velocimeter. For most velocity profiles, two points were measured

inside the vegetation canopy, one point at the vegetation-flow interface, and three points above the canopy. The duration of each measurement was 40 s. The measurement points within and above the canopy were evenly spaced. During very low flows, the number of measurement points in a profile was reduced.

Vegetation parameters obtained from the field data were patch-averaged and site-averaged. Both averages were then used to explore vegetation effects on flow resistance factors such as Manning's n, Chezy's C, and Darcy-Weisbach's friction factor f. Site averages included both vegetated and unvegetated areas of the stream bed.

2.2 *Dependence of resistance coefficients on aquatic vegetation parameters*

During the 6-month study, Manning's n, Chezy's C, and Darcy-Weisbach's f varied by an order of magnitude or more among sites and seasons (Fig. 1). Froude $Fr = U/(gH)^{1/2}$ and Reynolds $Re = (UH/\nu)$ numbers for each site indicate that flows were subcritical and fully turbulent, except for Snellings Drain ($\mathrm{Re} = 1000-5000$, Table 1), where flow may have been transitional from laminar to turbulent at lower water discharge. In the formulas above, H = site-averaged channel depth, and ν = fluid viscosity. Vegetation porosity during all measurement campaigns was higher than 0.98 and, therefore, effects of water displacement by plants on computation of hydraulic parameters could be neglected.

The key physical parameters of vegetation, assumed to influence hydraulic resistance and measured in our study, were relative roughness h_c/H, plant inclination factor l_p/h_c, areal vegetation cover W_c/W, and site-averaged relative roughness $[h_c(W_c/W)]/H = (W_c h_c/WH)$ [or relative submergence $H/[h_c(W_c/W)] = (WH/W_c h_c)$], where h_c and l_p = patch-averaged canopy height and plant length, respectively, obtained by averaging plant heights and lengths measured within all vegetation patches within an experimental site; W = site-averaged channel width, W_c = site-averaged cover of a cross-section by vegetation, and the site-averaged canopy height is defined as $h_c(W_c/W)$. Correlations between the resistance coefficients n, C, f and $U/u_* = \sqrt{8/f}$, and the preceding normalised vegetation parameters were generally high ($r^2 > 0.80$), except for plant inclination l_p/h_c ($r^2 = 0.15 - 0.33$). Among the vegetation parameters, the site-averaged relative roughness ($W_c h_c/WH$) had the highest predictive power (Figs 1a-1c), in agreement with results of field studies of vegetated rivers and canals in the Netherlands and Britain (Kouwen et al. 1969; Watson 1987; Green 2005).

Figures 1a to 1c show that the relationships $n = F(h_c W_c/HW)$, $C = F(h_c W_c/HW)$, and $f = F(h_c W_c/HW)$ can be best approximated by exponential functions $n = n_b \exp(\gamma_n h_c W_c/HW)$, $C = C_b \exp(\gamma_C h_c W_c/HW)$, and $f = f_b \exp(\gamma_f h_c W_c/HW)$, where subscript '$b$' indicates resistance coefficients in the absence of vegetation when $(h_c W_c/HW) \to 0$, and γ_n, γ_C, γ_f are coefficients ($r^2 = 0.89 - 0.91$). Exponential approximation suggests that a non-linear combination of bed surface and vegetation components in the overall hydraulic resistance is more likely than their linear superposition. The data from different sites and measurement campaigns collapse around the same lines in plots for Manning's n, Chezy's C, and Darcy-Weisbach's friction factor f (Fig. 1). This indicates that values of n_b, C_b, and f_b were approximately the same among sites, in agreement with visual observations that the bed surfaces were topographically similar. Figure 1d shows a plot for $\sqrt{8/f} = U/u_* = F(HW/h_c W_c)$ where the data is best approximated by a semi-logarithmic relationship. This is in agreement with the preceding exponential approximations for resistance coefficients, as, after re-arrangement, the

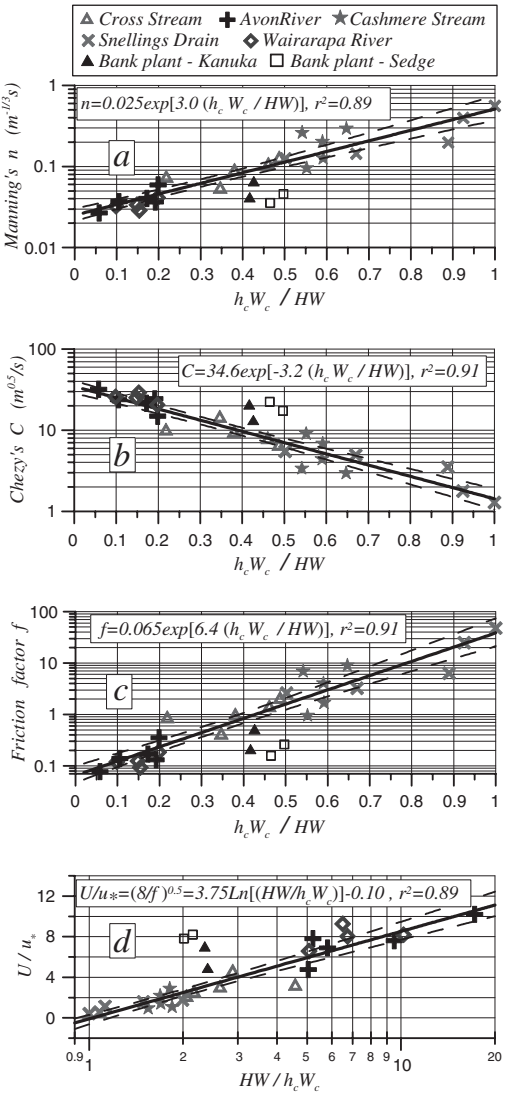

Figure 1. Relationships between resistance parameters n, C, f, and U/u_* and site-averaged relative submergence HW/h_cW_c for aquatic (in-stream) and bank-side vegetation. The regression approximations are shown by solid lines; 95% confidence intervals are shown with dashed lines.

semi-logarithmic equation for $U/u_* = F(HW/h_cW_c)$ produces curves for n, C, and f that appear exponential.

The plant inclination factor l_p/h_c had little explanatory power in the current study, although it has been considered useful for characterising hydraulic resistance in some vegetated streams (e.g., Kouwen & Unny 1973). This is partly because plant characteristics and flow conditions both changed between

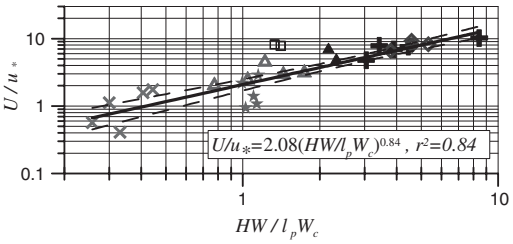

Figure 2. Relationships between resistance parameter U/u_* and site-averaged parameter HW/l_pW_c for aquatic (in-stream) and bank-side vegetation. Symbols are as in Figure 1. The regression approximation is shown by solid line; 95% confidence intervals are shown with dashed lines.

measurement dates at each site. As a result, the ratio l_p/h_c stays approximately constant during plant growth and, therefore, the parameter l_pW_c/HW provides nearly as good description of vegetation effects as h_cW_c/HW, with slightly reduced squared correlation coefficients in the exponential relationships for n, C, and f ($r^2 = 0.60 - 0.70$). Compared to the semi-logarithmic form of $U/u_* = C_1 \ln(HW/h_cW_c) + C_2$, the relationship $U/u_* = F(HW/l_pW_c)$ is slightly better approximated by a power function (Fig. 2).

Areal and volumetric biomass densities had little explanatory power compared to the relative vegetation parameters h_cW_c/HW and l_pW_c/HW described above. Between the two, areal density performed slightly better ($r^2 = 0.46 - 0.50$) than volumetric density ($r^2 = 0.25 - 0.26$).

3 EFFECTS OF BANK-SIDE VEGETATION

3.1 *Experimental sites and methodology*

For the second field study, we selected a straight reach of Milns Drain in Christchurch. The site had good access to municipal water supplies, which we used to generate experimental flood flows with substantial bank submergence. Site preparation for the flood experiments consisted of: (1) cutting the long grass on the drain bank-sides short; (2) filling the drain channel with gravel to raise the water level so bank submergence could be achieved at lower flow rates; (3) inserting baffles of plastic film into the gravel at 1 m intervals to reduce water flow in the gravel fill; (4) lining some depressions of the stream banks with fine gravel to smooth the bank surface; (5) building a temporary weir downstream of the working section to control flow levels and the water surface curve; and (6) assembling a piping system to supply water from an adjacent drain. The experimental reach was 60 m in length with a 50 m working section. The channel had a 60 cm wide rectangular cross-section with approximately 45° bank slopes above the drain channel

Copyright © 2006 Taylor & Francis Group plc, London, UK

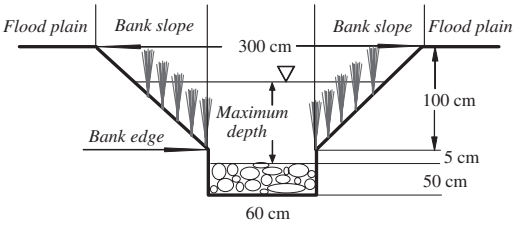

Figure 3. Cross-section of the experimental site of Milns Drain. Maximum flow depth shown in the sketch corresponds to the 'flood' level.

(Fig. 3). Water from three sources, a fire hydrant, a local water main, and an adjacent drain, was pumped into the drain 15 m upstream of the working section. Using water from three independent sources enabled us to precisely control discharge in the experimental reach.

The effects of bank-side vegetation on the hydraulic conditions and vice versa were assessed by comparing flow characteristics in the presence and absence of semi-artificial bank plants. We manufactured replicate bank plants using natural plant materials cable-tied to wire anchors. This approach allowed us to rapidly install and remove hundreds of plants between experimental runs, and to control planting density and spatial arrangement. Two native plant species were used that have contrasting architectures, *Kunzea ericoides* (kanuka) and *Carex* sp. (sedge). Kanuka and sedges are common stream bank plants in New Zealand, and both are frequently used in New Zealand stream enhancement and re-vegetation projects. Kanuka is a shrub with stiff divaricating branches and small (<1 cm length) leaves. Sedges are grass-like plants that form tussocks and have long (>10 cm length), unbranched, flexible leaves (Fig. 4).

We established six cross-sections and made hydraulic measurements in the absence of bank-side vegetation first. Then kanuka or sedge plants were installed on both bank slopes by inserting the wire anchors into the bank soil until flush with the soil surface. The hydraulic measurements were then repeated at the same cross-sections. Each plant species was used in two experimental runs, one at high plant density ($33.3\ m^{-2}$) and one at low density ($8.33\ m^{-2}$). The same spatial arrangement was used for both plant species and both densities (Fig. 5). Planting areas were strips 35–40 cm wide and 50 m long on each bank slope (Fig. 3).

The following experimental runs were conducted:

1. No bank-side vegetation, water surface at the bank edge.
2. No bank-side vegetation, water surface 30-cm above the bank edge.
3. Kanuka, high density, water surface 30-cm above the bank edge.

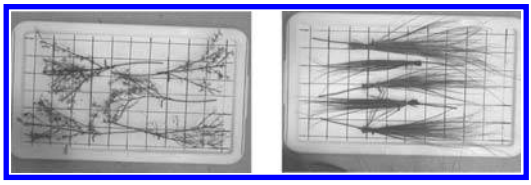

Figure 4. Semi-artificial plants used in the bank-side vegetation study. Left: Kanuka (*Kunzea ericoides*). Right: sedge (*Carex* sp.).

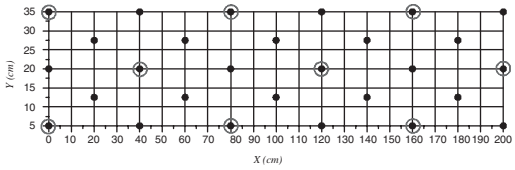

Figure 5. Spatial patterns of the semi-artificial plants. Dots: – high density, dots in circles: – low density. Y-axis shows distance above lower bank edge (see Fig. 3).

4. Kanuka, low density, water surface 30-cm above the bank edge.
5. Sedge, high density, water surface 30-cm above the bank edge.
6. Sedge, low density, water surface 30-cm above the bank edge.

Water level was kept constant during experimental runs 2 to 6 so that all changes in hydraulic resistance could be measured by changes in flow rate. The experimental protocol was similar to that described in section 2.1. The key parameters for each experimental run are listed in Table 2. The symbols used are the same as above, with one addition, the parameter N_A, which is the number of individual plants per unit area of stream bank.

3.2 *Dependence of resistance coefficients on bank-side vegetation parameters*

The most notable results of the bank-side vegetation study concern the effects of vegetation density N_A and species (i.e., plant architecture) on hydraulic resistance. Figure 1 compares effects of both species of bank-side vegetation with those of aquatic vegetation described in section 2. In the absence of bank-side vegetation, the resistance coefficients are comparable with those obtained for sites with low aquatic plant cover in the first study. The total roughness n of the channel with submerged banks and no bank-side vegetation is higher than that for the bankflow conditions (Table 2). The values in Figure 1 indicate that, at the same site-averaged submergence, the effects of bank-side vegetation are small compared to those of aquatic vegetation. For our field experiments, the increase in

roughness from an unvegetated state to a vegetated state is greater for aquatic vegetation on stream beds than for submerged terrestrial vegetation on stream bank sides (Fig. 1).

Figure 6 illustrates how plant density and differences between a rigid branching shrub (kanuka) and a flexible unbranched sedge influence hydraulic resistance. One may predict that bank slope roughness due to kanuka should be higher compared to that due to sedges, and both should be higher than bank slope roughness without plants (i.e., bare soil or grass only). Figure 6 agrees with this prediction and provides quantitative measures of bank slope planting effects on hydraulic resistance. The data suggest that Manning's n increases nearly linearly with plant density N_A. Kanuka and sedges represent two extremes in flexibility and architecture, so quasi-linear relationships between n and N_A may be postulated for a wide range of plant forms. Free terms in the relationships shown in Figure 6 represent the background roughness n_b without implanted plants on the bank sides. However, the relationships in Figure 6 are based on very limited field data and should be treated with caution.

4 DISCUSSION

Our results support two promising models, which represent two mainstream directions in studying hydraulic resistance in vegetated channels. The first model was suggested by Kouwen et al. (1969) who derived the relationship:

$$\sqrt{8/f} = \frac{U}{u_*} = C_1 \ln\left(\frac{A}{A_p}\right) + C_2 \quad (3)$$

where A = total cross-sectional area of the flow; A_p = part of the total cross-sectional area occupied by vegetation; C_1 and C_2 = coefficients depending on vegetation properties. Relationship 3 was originally derived using the logarithmic formula for velocity distribution above vegetation canopy uniformly covering the bed. Subsequent tests (e.g., Kouwen et al. 1969; Kouwen & Unny 1973) showed that for a range of hydraulic conditions this equation approximates experimental data reasonably well. The ratio A/A_p was originally considered for a straight section with a bed uniformly covered by vegetation. While typical for laboratory set-ups, such vegetation patterns are rarely seen in streams. For patchy vegetation cover, the ratio A/A_p can be interpreted as a site-averaged relative submergence, i.e., $A/A_p = (WHL/W_c h_c L) = (WH/W_c h_c)$ where L = reach length. Note that the reversed ratio A_p/A is known in the literature as the blockage factor (e.g., Kouwen et al. 1969; Green 2005). We believe that interpretation of A_p/A as the site-averaged relative roughness is more appropriate hydraulically. Figure 1 showing a plot for $\sqrt{8/f} = U/u_*$ demonstrates that our data closely match Kouwen et al.'s (1969) model equation 3. Theoretical justification of this equation, which is usually attributed to the logarithmic velocity distribution above vegetation canopies (Kouwen et al. 1969), may require revision. Indeed, although our direct velocity measurements showed deviation from the logarithmic profiles due to vegetation patchiness, the data can still be very well approximated by equation 3. We contend that an alternative derivation of relationship 3 that does not invoke the logarithmic formula is likely to be more plausible, because vertical velocity distributions in natural vegetated channels may not be logarithmic.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The second model was recently proposed by Carollo et al. (2005). Based on similarity considerations, Carollo et al. (2005) derived a relationship:

$$\sqrt{8/f} = \frac{U}{u_*} = A_o\left(\frac{H}{h_c}\right)^{\alpha_1}\left(\frac{u_* h_c}{\nu}\right)^{\alpha_2}\left(\frac{l_p}{h_c}\right)^{\alpha_3} \quad (4)$$

where A_o = coefficient depending on vegetation density; and α_i = empirical exponents. Equation 4 was derived for straight channels with beds uniformly covered by vegetation, as was equation 3. Carollo et al. (2005) showed that equation 4 provided a better fit to their flume data than equation 3. In section 2.2 we pointed out that the relationship $\sqrt{8/f} = U/u_* = F(HW/l_pW_c)$ is better approximated by a power function than by the semi-logarithmic formula $U/u_* = C_1 \ln(HW/l_pW_c) + C_2$ suggested by Kouwen et al. (1969). This result agrees well with Carollo et al.'s (2005) model. For low vegetation density Carollo et al. (2005) found that $U/u_* \propto (H/h_c)^{\alpha_1}(l_p/h_c)^{\alpha_3}$ with $\alpha_1 = 1.168$, $\alpha_3 = -0.861$, and $\alpha_2 = 0$. If we neglect the small difference between the exponents α_1 and $|\alpha_3|$, and assume $\alpha_1 \approx -\alpha_3 \approx 1$ then we may obtain $U/u_* \propto (H/l_p)^{\alpha}$ with $\alpha \approx 1$. Figure 2 shows that $U/u_* \propto (HW/l_pW_c)^{\alpha}$ with $\alpha = 0.84 \approx 1$. Thus, our data suggest that Carollo et al.'s (2005) model may be applicable to field conditions with patchy vegetation if, instead of H/l_p, a site-averaged parameter $H/[l_p(W_c/W)] = HW/l_pW_c$ is used.

Our aquatic plant data cover the entire range of possible values of site-averaged relative submergence (HW/h_cW_c) and (HW/l_pW_c) with different plant patch mosaics. However, no dependence on dominant plant species or patch mosaic patterns is apparent in Figures 1 and 2. The good fit for all sites to single curves, regardless of plant species composition, suggests that the general physical parameters for vegetation h_c/H, W_c/W, h_cW_c/HW, and l_pW_c/HW should be dominant roughness descriptors for hydraulic resistance. However, the bank-side vegetation data show that plant stature and architecture may be important factors, which should be studied at a wider range of parameters.

5 CONCLUSIONS

In this paper we examined the effects of aquatic (in-stream) and bank-side vegetation on hydraulic resistance over a range of stream dimensions and vegetation types, and suggested simple quantitative relationships for predicting and quantifying these effects using the site-averaged relative roughness (or submergence) and plant density. Effects of dominant aquatic plant species and their patch patterns were not significant. The data on aquatic plants from all sites collapsed around single curves, suggesting that the site-averaged physical parameters of vegetation may be the primary determinants of hydraulic resistance in vegetated streams, not species-specific parameters. Our results on aquatic plants support the applicability of both Kouwen et al.'s (1969) and Carollo et al.'s (2005) models, which can be extended for conditions of patchy vegetation, subject to selection of appropriate site-averaged vegetation measures. Compared to aquatic vegetation, the effects of bank-side vegetation at the same site-averaged relative roughness (or submergence) were smaller. For both aquatic and bank-side plants, plant shoot length was nearly as good a roughness descriptor as canopy height. This suggests that the plant length to canopy height ratio may be less important than previously assumed.

ACKNOWLEDGEMENTS

This study was partly funded by the Foundation for Research Science and Technology (New Zealand, contract CO1X0308), the Christchurch City Council (CCC), and the University of Aberdeen. The authors are grateful to CCC staff members O. Southen, and K. McCombs for help with site selection and technical and logistical support. A. Davey, M. Gee, S. Miller, C. Mohlmann, D. Sutherland and J. Sykes helped with field measurements, preparation of bank plants and laboratory analyses. R. Spigel, G. Smart, and an anonymous reviewer provided useful suggestions and comments on earlier drafts.

Interaction of vegetation, current and sedimentation

S. Schneider, F. Nestmann & B. Lehmann
Institute for Water and River Basin Management, Universität Karlsruhe, Germany

ABSTRACT: The incorporation of vegetation in stream restoration in urban areas is not just since the implementation of the European Water Framework Directive a desirable purpose for a healthy ecosystem. But vegetation causes conveyance loss, induces sediment problems and increases flooding. Because of these hydraulic and sediment uncertainties, hydraulic engineers have been reluctant to incorporate vegetation into designs of river restoration projects.

Therefore recommendations for the design and maintenance of riparian vegetation in nature-orientated water bodies, especially for urban areas are required. These recommendations are derived from the combination of a newly developed rating matrix with analysis of a hydraulic model. The hydraulic model identifies the interaction of dense vegetation and sedimentation, while the rating matrix calculates the flow velocity under considerations of vegetation succession.

1 INTRODUCTION

The European Water Framework Directive (WFD) has its main focus on enhancing water bodies. One of the aims is to achieve a diverse river ecosystem. Especially in urban areas the improvement of degraded waterways into nature-orientated rivers poses the challenge for hydraulic engineers and landscape and city planner.

The paper deals with the incorporation of vegetation in stream restoration and flood control projects. Hydraulic engineers have long been reluctant to incorporate different types of vegetation into designs since vegetation could cause conveyance loss, induce sediment problems, increase flooding, and disrupt normal channel-floodplain interactions. The tools generally used for evaluating open channel flow do not typically allow for consideration of the varied effects of vegetation.

Healthy riparian vegetation is of great value for an ecosystem; it stabilises stream banks, provides shade that prevents excessive water temperature fluctuations, performs a vital role in nutrient cycling and water quality, improves aesthetic and recreational benefits, and is immensely productive as wildlife habitat (Fischenich 2001).

The ability to predict or account for impacts associated with gradual developing vegetation on streams and flood control projects is hampered by the lack of recommendations for nature-orientated water bodies. Additionally, recommendations derived from hydraulic and numerical models regarding the maintenance of vegetation along river banks must play a more important role in guaranteeing flood water security even if the river restoration was done years ago.

The purpose of this paper is to investigate, how the growth of shrubs and trees influences flow velocities and sedimentation processes in cross sections.

2 METHOD

Vegetation increases flow resistance, changes backwater profiles and modifies sediment transport (Yen, 2002). In urban river restoration projects vegetation may be natural or planted to improve aesthetics, habitat or prevent erosion (Fischenich 2001). A prosperous river restoration which ensures flood security implies thought about the objective design of plants in cross sections.

Therefore hydraulic losses and flow resistance due to mixing plant arrangement were calculated with a rating matrix (see Figure 1) enhanced for practical use by Lehmann (2005). The interaction of vegetation and sedimentation rate is studied in a large-scale hydraulic model.

2.1 *Numerical rating matrix*

Resistance to flow is typically characterised by a roughness coefficient. Evaluating flow resistance caused by vegetation has generated a multitude of studies. Chow (1959) describes a roughness coefficient, where different aspects of flow resistance are

Copyright © 2006 Taylor & Francis Group plc, London, UK

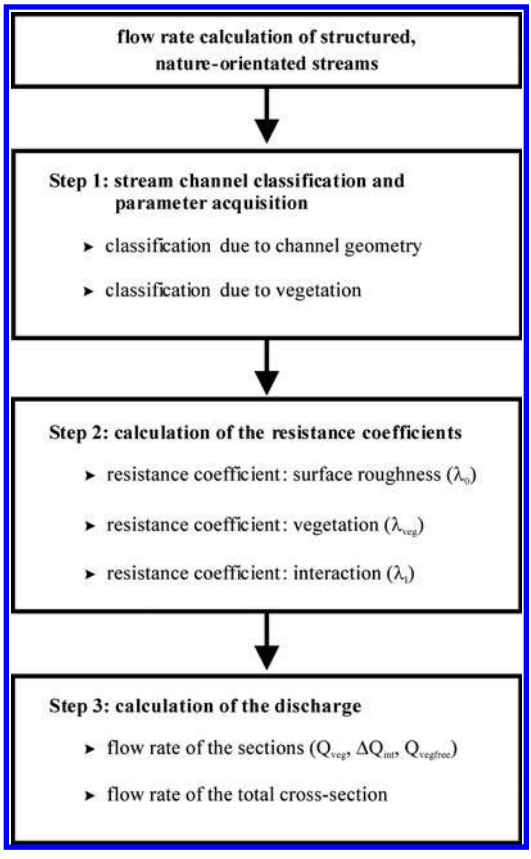

Figure 1. Principle of the rating matrix (Lehmann 2005).

combined. The effects of tall non-submerged vegetation on flow resistance were investigated by Li & Shen (1973). Petryk & Bosmajian (1975) estimated Manning values as a function of hydraulic radius and vegetation density for rigid vegetation in a group. Lindner (1982) presented an equation to compute the drag coefficient for a single plant arranged in a group. Pasche (1984) determined the computed drag coefficient of Lindner through an iterative process including experimental results with rigid cylinders.

The method used in the described rating matrix is based on the turbulence-theoretical equation of Pasche (1984) with modifications of Schumacher (1995), Oplatka (1998), Gerstkrasser (2000), Stephan (2002) and Schnauder (2004). Calculating flow rates for structured, nature orientated rivers is the aims of the presented rating matrix (see Figure 1).

Natural and near-natural rivers and streams are characterised by irregular cross-sections with a wide diversity in occurring roughness coefficients. At first geometric data have to be analysed to enter the hydraulic calculation. Therefore spatial surveying data

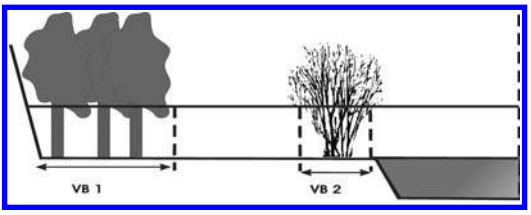

Figure 2. Simplified cross sections divided into vegetated (VB) and none vegetated section (Schneider 2005).

are abstracted (see Figure 2) into simplified geometric data to ensure the comparability of geometric and shaping parameters.

The sectional roughness coefficient and the resulting flow velocities are computed in step 2. Step 3 calculates the sectional flowing discharge to determine the flow rate of the total cross-section.

The challenge of the discharge calculation is the determination of the resistance coefficients. Therefore the cross section needs to be divided into areas where the resistance factor is either dominated by vegetation or by interaction and vegetation or by surface roughness.

The resistance coefficient caused by surface roughness (λ_O) is according to Keulegan (1938):

$$\lambda_0 = 8 * \left(2{,}5 * \ln\left(\frac{r_{hy}}{k_s} \right) + Br \right)^{-2} \quad (1)$$

with

$$Br = \begin{cases} 3{,}25 & for\ h/k_s \leq 4 \\ 0{,}1875 * (h/k_s) + 3{,}25 & for\ 4 < h/k_s < 20 \\ 6{,}25 & for\ h/k_s \geq 20 \end{cases} \quad (2)$$

Where λ_O = is resistance coefficient due to surface roughness; r_{hy} = hydraulic radius (m); k_s = equivalent sand roughness (m); Br coefficient (-); h = flow depth in observed section (m).

The resistance coefficient caused by vegetation is defined as:

$$\lambda_{ges,veg} = \lambda_0 + \lambda_{veg} \quad (3)$$

with

$$\lambda_{veg} = \frac{4 * c_D * h * d_{veg}}{a_x * a_y} * \cos(\alpha) \quad (4)$$

Due to missing c_D-value for vegetated area the c_D-value has to be calculated by iteration. Starting the iteration process the c_D-value (4) is firstly defined as 1.0 to calculate a flow velocity of the vegetated area (5).

$$v_{veg} = \frac{1}{\sqrt{\lambda_{ges,veg}}} * \sqrt{8 * g * r_{hy} * I} \quad (5)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

This v_{veg} needs to be verified by the following formula:

$$c_D = c_{W\infty} \cdot \left(1 + 1{,}9 \cdot \frac{d_{veg}}{a_y} \cdot c_{W\infty}\right) \cdot \left(\frac{v_{veg}}{v_m}\right)^2 + \Delta c_w \qquad (6)$$

with

$$\left(\frac{v_{veg}}{v_m}\right)^2 = 1{,}15 \cdot \left(\frac{a_{NL}}{a_x}\right)^{-0{,}48} + 0{,}5 \cdot \left(\frac{a_{NB}}{a_y}\right)^{1{,}1} \qquad (7)$$

and

$$c_{w\infty} = \begin{pmatrix} 3{,}07 \cdot \mathrm{Re}_{veg}^{-0{,}168} & für & \mathrm{Re}_{veg} < 800 \\ 1{,}0 & für & 800 \le \mathrm{Re}_{veg} < 8000 \\ 1{,}2 & für & 8000 \le \mathrm{Re}_{veg} < 10^5 \end{pmatrix} \qquad (8)$$

and

$$\Delta c_W = \frac{2}{Fr^2} \cdot \left(1 - y^*\right) \qquad (9)$$

with

$$\frac{y^* \cdot \left(y^{*2} - 1\right)}{2 \cdot \left(y^* - \frac{a_y}{a_y - d_{veg}}\right)} \overset{!}{=} Fr^2 \qquad (10)$$

a_{NL} and a_{NB} are calculated according to Pasche (1984). The iteration finishes at:

$$\left|1 - \frac{c_D}{c_D'}\right| \approx 0 \qquad (11)$$

Where $\lambda_{ges,veg}$ = total resistance coefficient of section with vegetation; λ_{veg} = resistance coefficient due to vegetation; I = slope; c_D = drag coefficient due to vegetation; h hydraulic flow depth in section (m); d_{veg} = average equivalent vegetation diameter (m); a_x = equivalent distance in flow direction (m); a_y = equivalent distance cross flow direction of vegetation elements (m); α = angle of inclination of section wall (only at triangular approximation); Re = Reynolds number; Δc_W = resistance coefficient due to the influence of a cylinder to surface waves; y^* = relative flow depth in front of and behind a rigid cylinder (m).

The calculation of the resistance coefficients in vegetated sections (VB, see Figure 2) presumes a close-by approximation of nature-vegetation.

Vegetation parameters are determined according to the recommendations of DVWK (1991). Firstly a control area (A_{pro}) within the vegetation area has to be defined. The control area typically has a size of 1–5 m^2. Inside this control area (A_{pro}) the equivalent vegetation parameter has to be determined. The vegetation parameter depends on the type of vegetation and the amount of branches and trees. To calculate the vegetation parameter one has to choose between the following equations:

– Control area dominated by shrubs

$$a_x = a_y = \sqrt{\frac{A_{pro}}{n_R}} \qquad (12)$$

– Control area dominated by trees

$$a_x * a_y = \frac{A_{pro}}{n_B} \qquad (13)$$

and

$$a_x = C * a_y = \sqrt{\frac{A_{pro}}{n_B \cdot C}} \qquad (14)$$

– Control area with trees and shrubs

$$a_x = a_y = \sqrt{\frac{A_{pro}}{n_E}} \qquad (15)$$

with

$$n_E = n_B + n_R \qquad (16)$$

$$n_R = \frac{n_{R,tree}}{A_{pro,tree}} * A_{pro} \qquad (17)$$

Where A_{pro} = control area (m^2); $A_{pro,tree}$ = control area trees only (m^2); n_R = number of all branches and rods within the control area; n_B = number of trees within the control area; n_E = number of all elements of vegetation within the control area; $n_{R,tree}$ = number of all elements of vegetation within the control area of trees only; C = factor, describing the dependence between a_x and a_y.

The resistance coefficient dominated by the interaction process also has to be calculated by iteration according to Schumacher (1995) and Pasche (1984).

Afterwards these three calculated resistance coefficients enter the computation of the total flow discharge for the regarded cross section (see Figure 1).

The verification of the model is based on observed nature data. Measured natural vegetation data regarding the amount of branches per m^2, the distances between the trees in and vertical to the flow direction and the average diameter of the branches (see Table 1) were recorded.

The recording of actual branch number and – diameter takes place at the height of 75% of the plant size respectively at the maximum water level. In average the control area was 1.5 m^2 for counting shrub branches and 12 m^2 for control areas, planted

Copyright © 2006 Taylor & Francis Group plc, London, UK

with trees, to calculate the required average distance parameters.

2.2 *Physical model*

In addition to the theoretical hydraulic disquisition the recommendations for nature-orientated design and maintenance of rivers and flood plains in urban areas are derived from carried out qualitative analysis of a hydraulic model.

The researched question is dominated by a gravity-depending flow involving free water surface. Therefore the main objective was to achieve an equality of the Froude number:

$$Fr_N = Fr_M \Leftrightarrow \frac{v_N}{\sqrt{g \cdot \ell_N}} = \frac{v_M}{\sqrt{g \cdot \ell_M}} \tag{18}$$

A scale model uses the method of direct (physical) simulations of hydraulic phenomena in the same medium as in nature. The scaling laws define conditions that must be satisfied to achieve the desired similarity between the model and nature. The ratio of a variable in nature to the corresponding variable in the model describes the scaling factor l_r. Creating dynamic similarity can be observed as long as the geometric similarity and the kinematic similarity is given. The geometric similarity is represented by:

$$\ell_r = \frac{\ell_N}{\ell_M} \tag{19}$$

The kinematic similarity represents the similarity of motions:

$$t_r = \frac{t_N}{t_M}; \quad v_r = \frac{\ell_N / t_N}{\ell_M / t_M} = \frac{\ell_r}{t_r}; \quad a_r = \frac{\ell_N / t_N^2}{\ell_M / t_M^2} = \frac{\ell_r}{t_r^2} \tag{20}$$

and the dynamic similarity represents the similarity of forces:

$$F_r = \frac{F_N}{F_M} \tag{21}$$

Where Fr_N = Froude number in nature, Fr_M = Froude number in model; g = gravity; ℓ_r = scaling factor; ℓ_N = length in nature; ℓ_M = length in model; t_r = time scaling factor; t_N = time span in nature; t_M = time span in model; v_r = velocity scaling factor; a_r = acceleration scaling factor; F_r = force scaling factor; F_N = force in nature; F_M = force in model.

The application of a very large and complex model (scale 1:6) with a moveable channel bed and a controllable detritus enabled a very demonstrative documentation of the current-detritus-interaction. This eventually affects the dynamics of the water body morphology by sedimentation and erosion processes.

The physical model experiments were carried out at the Theodor-Rehbock-Wasserbaulaboratorium in Karlsruhe utilising a large, partly glass-walled flume of 60 m length, 2.5 m width and 0.8 m depth. The design of the flume is characterised by a moveable bed with an additional feeding of fine particles for simulating sedimentation process.

A river stretch of 180 m in nature of the River Enz in Pforzheim, Germany, provided the basis for the design. The scaling factor was chosen to be 1:6. The represented river stretch of the River Enz is characterised by an armoured layer with an average diameter of 150 mm in nature LFU (2003), therefore according to the geometric scale factor the channel bottom had to be build up of gravel with an average grain diameter of 25 mm.

The challenge of this hydraulic model is the task of simulating fine sand sedimentation. Fine sand, downscaled according to the scaling factor, tends to coagulate. The result is an interruption of the dynamic simulation of the hydraulic model. Hence for the fine sand bed load simulation polystyrol-granulate was used with a density of $\rho_{PS} = 1300\ kg/m^3$. From this it follows that, under the terms of the dynamic similarity the size of the polystyrol-granulate is according to Kobus (1978):

$$\frac{d_{K_M}}{d_{K_N}} = \sqrt[3]{\frac{\rho_{K_N} - \rho_w}{\rho_{K_M} - \rho_w}} \tag{22}$$

The used polystyrol-granulate had a size of 2.5 mm. Where d_{KM} = diameter of sediment in model; d_{KN} = diameter of sediment in nature; ρ_{KN} = density of sediment in nature, ρ_{KM} = density of sediment in model, ρ_W = density of water.

With a constant addition of the polystyrol-granulate the discharge was set to 400 l/s. This represents a flood event with a 5 year return period. As long as the geometrical similarity is achieved the time scale in a Froude model is defined as:

$$t_r = \sqrt{l_r} \tag{23}$$

Difficulties arise out of the limited downscaling of fine sand. The interruption of the geometrical similarity of the fine sand material demanded a so-called "historical experiment". This is an imitation of the natural sedimentation behaviour and was in this case set to two hours according to Dorer (1984). The shorter identified time scale factor in the experiment than in the equation is due to the lesser density and the bigger size of the used granules.

Plenty of materials are used for simulating trees and shrubs in hydraulic models. Most of them are made out of different plastic or metal materials, however research compares these materials to natural behaviour are still missing. Therefore the use of flexible locust, broom-bristled and young willow branches were preferred for the simulation of bank vegetation.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Experiments were conducted with homogenous and mixed plant groupings. Altogether 11 different vegetation arrangements were studied, varying in plant density, spacing and size. Different vegetation arrangements (see Figure 3) along the stream bank were studied: collective shrubs stocks (see Fig. 4); tall forbs with young flexible shrubs; influence of branches cut near the bottom; dense woody vegetation; arrangements of shrubs in two lines varying in density and diagonal arranged shrubs (see Figure 3). An overview of the vegetation arrangement design is given in Figure 3.

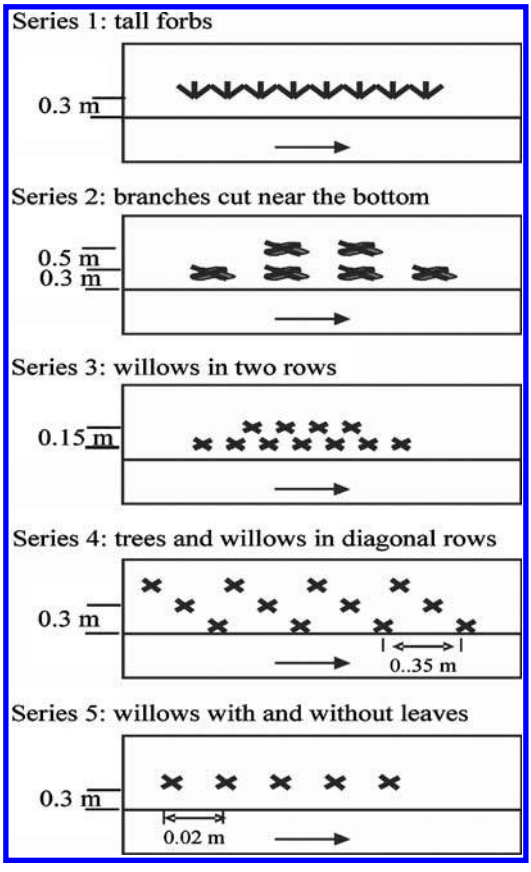

Figure 3. Overview of the vegetation arrangements in the hydraulic model.

Figure 4. Ideal vegetation for equivalent vegetation parameters calculation. (Bernhart).

3 EXPERIMENTAL RESULTS AND INTERPRETATION

3.1 *Numerical rating matrix*

One of the challenges is the abstraction of actual vegetation data into equivalent vegetation parameters. Vegetation simulation in hydraulic models is typically arranged in geometrical forms, with uniform distances between tree trunks (see Figure 4). In nature the density of plants per m^2 varies. Finding tall forbs near a collective of shrubs and trees is no curiosity (see Figure 5).

Branch numbers recorded in control areas vary according to the age of the shrubs. In average there could be found up to 50 rods per m^2 of one year old willows. The diameter of these branches is about 0.01 m. The resulting flow velocity, influenced by the willow roots, would be 0.27 m/s according to the rating matrix. The input-parameters of the presented results were set to $I = 0.002$, $r_{hy} = 3.0$ m, $h = 3.0$ m and $k_s = 2.0$. The diameter of the branches increases due to the growth of the plant. The average branches number per m^2 decreases. A three to five year old willow has less than half the number of branches per m^2 than a one year old willow, but three times the diameter of the branches.

Nevertheless the resulting flow velocity and therefore the discharge capacity in flood plains dominated by shrubs remains almost constant. Older willows grow in diameter; however the branch density is reduced. (see Table 1).

In sections dominated by trees the flow velocity can increase to more than double the amount as in sections dominated by willows. Trees with only a density of 1 tree/m^2 are typical for areas, where the maintenance has been very intensive in the first years after the

Figure 5. Typical plant arrangements in nature. (Schneider).

Table 1. Variations of vegetation arrangements and the corresponding flow velocity according to the rating matrix.

Vegetation			v_{veg} [m/s] for $k_s = 2$
Arrangement of shrubs			
50 branches/m^2	a_x	0,14	0,27
	a_y	0,14	
	d_{veg}	0,01	
30 branches/m^2	a_x	0,18	0,23
	a_y	0,18	
	d_{veg}	0,02	
20 branches/m^2	a_x	0,22	0,23
	a_y	0,22	
	d_{veg}	0,03	
10 branches/m^2	a_x	0,32	0,25
	a_y	0,32	
	d_{veg}	0,05	
Arrangement of trees			
1,5 trees/m^2	a_x	0,81	0,55
	a_y	0,81	
	d_{veg}	0,06	
1 tree/m^2	a_x	1,00	0,42
	a_y	1,00	
	d_{veg}	0,15	
8 trees/15 m^2	a_x	1,37	0,56
	a_y	1,37	
	d_{veg}	0,15	

planting. Hence this is typically for planted floodplain vegetation and reveals that river restoration projects with planted vegetation increase the reduction of flow velocity. Natural developed vegetation is characterised by less dense vegetation.

3.2 *Physical model*

The influence of the vegetation density on the sedimentation rate was observed.

Series 1: Tall forbs and high grass
A high sedimentation rate of fine sand can be observed between these types of riverine vegetation. High grass and tall forbs act like a sieve that filters the fine sand, increases the sedimentation rate and decreases the discharge capacities of the cross-section. Hence tall forbs and high grass should be carefully used.
Series 2: Branches cut near the bottom
This situation is typical for vegetation maintenance during higher water level especially in late fall or early spring time. Cutting of branches near the bottom causes high sedimentation rates in these areas.
Series 3: Willows in two rows
In this case the row placed at the flood plain side, showed a higher sedimentation rate than the row at the riverside. Additionally the hydraulic model revealed that the denser the flood plain row the higher the sedimentation rate.

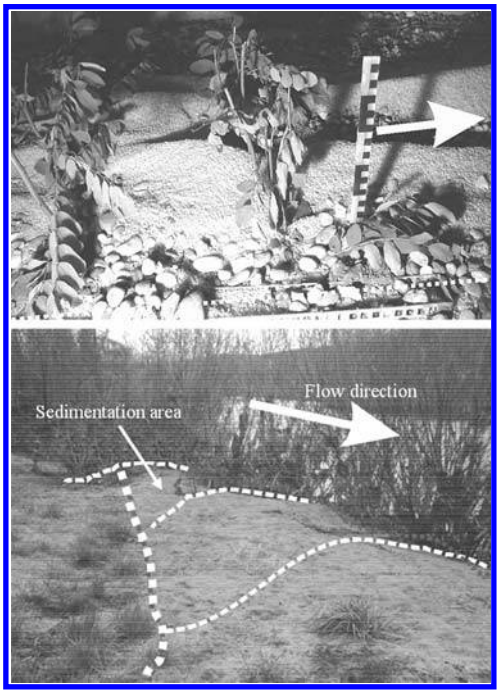

Figure 6. Sedimentation of sand caused by vegetation in the hydraulic model (top) and in nature (bottom). (Lehmann).

Series 4: Trees and willows in diagonal rows
This trail showed a very high sedimentation rate inside the vegetation arrangement (see Figure 4). The reduction of the sedimentation rate can be induced by removing willows in a line parallel to the flow direction. While removing willows in lines upright to the flow direction leads to an additional reduction of the small sedimentation rate.
Series 5: Old and young willows in one row with and without leaves
This type of riverine vegetation is a typical situation along streams in urban areas. The analysis showed that creating gaps in the row after several meters leads to an additional reduction of the sedimentation rate. Willows arranged in one row with gaps cause almost no sedimentation. The influence of leaves on the sedimentation rate is negligible; however it increases slightly when young flexible willows are very densely planted. Nevertheless these are the recommended vegetations arrangements in flood plain areas, where no sedimentation is allowable.

Summarising the hydraulic model research, it could be stated that collective shrubs stocks, dense woody vegetation and diagonally arranged shrubs cause sedimentation of fine sand within and behind vegetated sections (VB) where flow velocities are low. The dimensions of the sedimentation zone within

Copyright © 2006 Taylor & Francis Group plc, London, UK

reduced current velocities caused by vegetation could be calculated with the approach of Pasche (1984). Dense vegetation causes a reduction of flow velocity which increases the sedimentation rate. Due to this fact it is to recommend that in those dense vegetation arrangements the maintenance has to be enhanced.

4 CONCLUSION

To achieve a transfer from theory to practice it is necessary to define requirements of nature-orientated water body management in urban areas to help hydraulic engineers in their planning phase. The focus of finding practical recommendations for river management has to be laid on the interaction of current flow, morphology and vegetation along the stream banks.

The newly developed rating matrix for the estimation of the characteristics of discharge in nature-orientated streams is the result of a study of existing practical problems. The matrix enables the engineers to choose the appropriate rating method and ask for the appropriate parameters e.g. vegetation parameters. Additionally, the rating matrix helps to teach the hydraulic engineers the significance of their chosen parameters. Hence, a possibility is given to simulate the developing vegetation along the river banks by plain parameters. The rating matrix can calculate the influence of vegetation on the flow characteristics. The typical application area ranges from streams to smaller rivers with vegetated banks and flood plains.

Derived recommendations from the hydraulic model regarding the arrangement of the vegetation and the maintenance of that vegetation along the river banks should play a supplementary role especially during the planning of the restoration, the maintenance and for landscape planning aspects.

Large-scale motion induced by turbulent plunging jets in pools created by scouring of the riverbed

Pedro Manso, Anton Schleiss, Jean-Louis Boillat & Erik Bollaert
Ecole Polytechnique Fédérale de Lausanne (EPFL), Laboratory of Hydraulic Constructions (LCH)
Lausanne-Switzerland

ABSTRACT: Plunging jets are a common feature in fluvial systems occurring in waterfalls, weirs and dams. The erosive process generated by jet impact in the river bed is of interest for hydraulic engineers, as well as the diffusion, mixing and aeration processes. Experimental investigations were carried out to study the interaction between the diffusion of plunging jets and the geometry of the pool created by scouring of the riverbed. Circular jets with quasi-prototype velocities up to 30 m/s were produced to study jet diffusion in flat and laterally confined pools. The influence of laterally confining the diffusion of the jet was investigated by systematically testing several cylindrical confinements with diameters D_c of 5.6, 11 and 16.7 times the jet diameter D. Dynamic pressure measurements at 1 kHz were performed at the plunge pool bottom. Particular flow patterns such as surface oscillations inside the confined region, intermittent ejections, pool surface oscillations and ring vortices, were observed and documented for $D_c/D = 16.7$. The lateral confinement tested enhanced the development of the jet, changing the flow pattern in the pool and the impact pressures at the pool bottom. The origin of important recirculation currents that may lead to bank erosion was directly related with the water level above the river bed, being preferable to have deep confined pools than shallow confined or flat pools.

1 INTRODUCTION

The impact of a turbulent shear layer generated by the diffusion of plunging jets may scour the riverbed downstream of water releasing structures, weirs or waterfalls. Large recirculation currents may as well create undesirable erosion of the riverbanks. The turbulent mixing and air entrainment in the pool by plunging jets represent a major interest for water quality, since they contribute to the processes of degradation of organic matter and dilution of pollutants. These phenomena are directly related with the type of macro-turbulent flow in the pool, which often depends on its geometry. Riverbed and bank erosion have been observed in nature and real-size facilities, as well as investigated in reduced-scale laboratory facilities. Jet diffusion and impact loads in plunge pools have mainly been studied in pools with flat bottom (Cola 1966; May and Willoughby 1991; Ervine et al. 1997; Bollaert and Schleiss 2003). However, pool geometry may considerably differ in practice, as a function of the joint set patterns and the degree of fracturing of the rock mass (Figure 1). Extensive experimental work with idealized scour geometries using quasi-prototype velocity jets and aeration conditions have been performed by Manso (2006). The understanding of the physical processes governing the interaction between the pool flow patterns and jet diffusion may help engineers inferring the behaviour of a given plunge pool and providing adequate solutions for the mitigation of scour and bank erosion induced by recirculation currents. This paper presents results of experimental investigations with plunging jets in laterally confined plunge pools using near-prototype jet velocities and aeration conditions. Due to the difficulties of performing direct measurements of pool flow characteristics under such extreme conditions of air concentration and high Reynolds numbers, the approach consisted in measuring dynamic wall pressures. The analysis of the fluctuating characteristics of bottom pressures allows presenting evidence of the main flow features. This

analysis is correlated with direct observations of the flow motion.

2 EXPERIMENTAL WORK IN TYPIFIED SCOUR GEOMETRIES

The plunge pool is simulated by means of a round flat basin with variable pool depth – Figure 2. Modular steel cylinders were prepared to simulate lateral confinements of $D_c/D = 5.6$, 11 and 16.7 with a relative height of $t/D = 2.8$ (Figure 3). These lateral confined pools corresponds to intermediate stages of development of a plunge pool. The experimental work herein presented aims at documenting the flow field inside the pool by means of interpretation of wall pressure measurements. Systematic and extensive measurements of the flow field are yet unfeasible due to instrumentation limitations. The jet outlet is cylindrical with a nozzle diameter of 0.072 m and is 70 cm higher than the pool bottom. The facility produces jets with velocities up to 30 m/s, a maximum Reynolds number of 1.87×10^5 and a rather uniform velocity profile (Manso 2006). The 300 mm diameter upstream conduit supplies a maximum discharge of 120 l/s by means of a 63 m high head pump. Tests were performed for jet velocities ranging from 7.4 to 29.5 m/s.

The initial pool depth Y varies from 7.5 to 67 cm for aerated (plunging) jet conditions (about 1D to 9.3D) and 82 or 87 cm for non-aerated jet conditions (Y/D ratios of 11.4 and 12.1) for which the jet outlet is submerged. By increasing the pool depth, the travel length in the air is reduced. For a typical turbulence intensity of 4% the degree of jet break-up are $L/L_b = 0.02$ for Y/D = 9.3 and $L/L_b = 0.44$ for Y/D = 1.04. All tested jets are undeveloped at entry in the plunge pool. At entry in the pool, the jet entrains air in near-prototype conditions. Jet diffusion is axisymmetrical. Dynamic pressures at impact on the pool are representative of prototype conditions. From tests with pools with flat bottom (Manso 2006), impact conditions correspond to the impact of the jet core for $Y/D < 5.6$ (i.e. shallow pools) and to the impact of a fully developed jet for $Y/D > 9$ (i.e. deep pools). For the intermediate

range of pool depths, the impact conditions are highly dependent on the boundary conditions (i.e. transitional pools).

Pressure measurements were performed with micro piezoresistive transducers type KULITE XTM-190-17BAR-A (pressure range 0–17 bar absolute, 3 mm diameter diaphragm) flush-mounted on the pool bottom. Ergodic sampling was guaranteed with 3-min runs for an acquisition rate of 1 kHz. Selected data from measurement stations at $y/D = 0.35$ (point a) and $y/D = 2.08$ (point e) are presented hereafter.

3 FLOW BEHAVIOUR IN LATERALLY CONFINED POOLS

After impact on the pool bottom, the plunging jet divides into wall jets. In pools with flat bottom, large eddies are formed around the falling jet. The flow is highly aerated, disabling visualisation of the flow behaviour inside the pool. When the jet outlet is submerged, an external observer can see through the pool. In laterally confined pools, the wall jets are deflected upwards. After piercing through the water surface, they generate plunging jets of much less velocity (and momentum) than the main jets. These lateral plunging jets also entrain air into the pool. For deep pools and velocities between 7.5 and 20 m/s, good observation conditions are still found; for higher velocities, the air entrained by the laterally plunging jets reduces visibility starting from the surface.

For relative pool depths $Y/D \leq 5.6$ (i.e. shallow pools), the confinements generate geyser-like flow ejections. The lateral confinements deflect the bottom wall jet upward in the direction of the pool surface. For increasing pool depths, the upward flow is hindered by increased submergence and the ejections are reduced to a surface boil. This was observed for all the three lateral confinements tested.

The best visualisation conditions were obtained with the $D_c/D = 16.7$ wide confinement. For low velocities, there is little air in the outer pool region and the flow features inside the confinement are perceptible. For $Y/D = 4.2$, periodic surface waves (oscillations) are observed between the confinement and the falling jet with an estimated frequency of ≈1 Hz. The impact of these oscillating waves with the falling jets is clearly visible, leading to upward ejections (Figure 4, top). With regular frequency, these ejections reach heights of approximately four times the jet's diameter. For deeper pools, i.e. $Y/D > 4.2$, the surface oscillations are observed over the entire pool (Figure 4, bottom). The peaks and nodes of the pool surface oscillations rotate slowly clockwise in plan view. The amplitude of the oscillations is approximately twice the jet's diameter. The time series of the pressure signal obtained at $y/D = 2.08$ confirmed the presence of pressure head oscillations of ≈15 cm occurring with a frequency of 1–2 Hz.

For deep pools with $Y/D = 9.3$ and 11.4, the jet outlet is either intermittently submerged or permanently submerged, respectively. The formation of a ring vortex between the falling jet (in the centre) and the upward deflected jet (along the perimeter of the confinement) is clearly visible due to the presence of trapped air bubbles from initial pool filling (Figure 5). When jet velocity is reduced, pool currents fade out and the air bubbles go up by buoyancy. When the outlet is initially submerged, no air is entrained in the pool by the jet. Only a small quantity of air is entrained at

the surface through the boil. The ring vortex is saddle-like; its peaks and nodes rotate clockwise in plan view. It is a low pressure and low velocity flow region. For the range of jet velocities allowing visual observations (9.8–19.6 m/s), the vortex rotating frequency was estimated between 1 and 4 Hz. The vortex also expands and contracts in the radial direction. For $V > 19.6$ m/s, visual observation becomes difficult due to increased air entrainment through the surface boil. Depending on the ratio D_c/D, the upward currents may influence the development of the plunging jet and the dissipation of energy before impact on the bottom: the larger the confinement the lower the interference is. For large values of the tailwater depth (i.e. $h = Y - t$), the upward currents are pushed to the centre by the recirculation currents, increasing friction with the plunging jet and hindering the penetration of air bubbles in the pool. In this case, the deeper the confined region in comparison with the total depth Y, the lower the risk of formation of intense recirculation currents.

4 EVIDENCE OF FLOW FEATURES

4.1 *Turbulent pressures*

All the three lateral confinements change the pressure fluctuations at the pool bottom compared to the flat reference case. For transitional and deep pools, the energy content, i.e. σ^2, is reduced. Despite the reduction, more energy can be concentrated at frequencies corresponding to undesirable flow phenomena. As an example, macro-turbulent pool flows may produce air-water ejections that may affect ancillary structures located in the banks downstream of dams. Or, in case of fully fractured rock, the close matching with the resonating frequencies of rock fissures conjugated with a dynamic uplift may lead to loosening of blocks and their displacement in the pool.

Selected statistical properties of 3-min data sets simultaneous to the previous mentioned observations are presented in Table 1. A few conclusions can be drawn:

- the energy of pressure fluctuations is larger in shallow confined pools than in deep confined pools, as well as the maxima and minima of the pressure fluctuations.
- the skewness C_s is negative whenever core impact occurs and positive when developed jet impact conditions are obtained, in good agreement with previous findings in pools with flat bottom (Manso 2006). In other words, the analysis of extreme events shows that the probability distribution of pressure fluctuations is negatively skewed for shallow pools (i.e. the Gaussian variable $|z_{min}| < z_{max}|$) and positively skewed for deep pools.
- for a given pool depth Y/D the sign of the skewness and (excess) kurtosis K parameters are a function of jet velocity, meaning that jet diffusion and flow pattern are also a function of jet velocity and, of course, of pool geometry.

4.2 *Spectral distribution: influence of pool depth*

The breakdown of energy generated by different turbulent scales is described in terms of power spectra for points "a" and "e". Each spectrum is obtained from 3 runs of 65'536 points sampled at 1 kHz, divided in 64 blocks with 50% overlapping using Welch's periodogram method and a Hamming window. Spectra of turbulent fluctuations present three main features from low to high frequencies (Chassaing 2000): (1) the production zone, related to the mean characteristics of

Copyright © 2006 Taylor & Francis Group plc, London, UK

the energy source (the jet), (2) the energy redistribution zone from large eddies at low frequencies to progressively smaller vortexes (cascade of energy) and (3) the dissipation or viscous zone, where the energy of the small turbulent structures (high frequencies) is dissipated by viscosity. The transition from the redistribution to the dissipation zone is known as the inertial sub-range, where the slope of the spectra follow a $f^{-5/3}$ slope. In the reference case of pools with flat bottom, core impact conditions correspond to constant sloped spectra at approximately f^{-1} in a log-log scale, and developed impact conditions to a double sloped spectra that falls into dissipation for higher frequencies with slopes steeper than $f^{-5/3}$ (Bollaert and Schleiss 2003). The present facility generates core impact conditions for pools with $Y/D \leq 5.6$ and $17 < V < 30$ m/s (Manso 2006). Figure 6 presents spectra obtained in the wide pool with a jet velocity of 12.3 m/s and a wide range of pool depths. Spectra estimates are also divided by the variance σ^2 plotted against the Strouhal number defined as $St = f\lambda/V$, i.e. taking the scour depth t for length scale λ. The plots show traces of the visually observed phenomena at low frequencies, as well as the energy redistribution and decay for higher frequencies.

A detailed analysis of the computed spectra for an intermediate jet velocity of 14.7 m/s at points "a" and "e" shows that (Figure 7):

- At $y/D = 0.35$ ("a"), the oscillations inside the confinement occur for $Y/D = 4.2$ and 5.6. The peaks in spectral energy at 1–3 Hz are related to the ejections and pool surface oscillations. For $Y/D > 4$, the spectra are typical of developed jet impact conditions. The transition to the dissipation range occurs between 20 and 40 Hz. Disregarding the low-frequency disturbances, the spectra have a rather mild slope for $f < 25$ Hz. For $Y/D = 2.8$, the core impacts the bottom. In general, the oscillations disappear with increasing submergence, i.e. Y/D.
- At $y/D = 2.08$ ("e"), the oscillations inside the confinement are also visible for $Y/D = 4.2$. The spectra for $Y/D = 8.3$ shows rather "incipient" developed jet impact conditions. The spectra for $Y/D = 6.9$ and 9.3 are similar. Compared to results closer to the axis of the jet, these spectra have in general lower energy. Several spectra have less energy at lower frequencies than at high frequencies. The energy content at high frequencies is similar to that of spectra reflecting the impact of the turbulent shear layer of develop jets. The low energy at low frequencies shows that there are no major sources of turbulent energy at lower frequencies (apart from the oscillations for $Y/D = 4.2$) or, in other words, the kinetic energy of the flow is mainly in the mean field and in turbulent scales with high frequencies. In this case, the pressure transducer is under the influence of a bottom wall jet, developing close to solid boundary under the impact of turbulent shear layer.

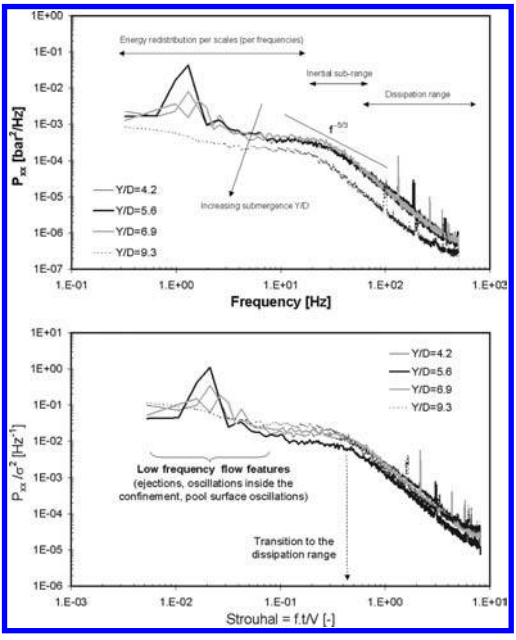

Figure 6. Spectral density functions for wide pools, $D_c/D = 16.7$, $t/D_c = 0.17$, $V = \mathbf{12.3\ m/s}$ and different pool depths Y/D. The bottom picture is dimensionless and the Strouhal number is defined in terms of the scour depth "t".

- The non-dimensional plots show that several spectra almost match, save those for $Y/D = 8.3$. This is a particular case, for which flow in the experimental set-up generated strong recirculation currents reduced considerably the "effective" pool level; this is considered an artifact of the facility but the results were nevertheless included for completion and comparison. Full matching of dimensionless spectra is herein interpreted as corresponding to similar flow conditions. For developed impact conditions, most spectra at $y/D = 0.35$ match, save the one for core impact (Y/D = 2.8) and the particular case of $Y/D = 8.3$ for which flow conditions are anyway different. At $y/D = 2.08$, spectra match in pairs: one for $Y/D \leq 4.2$, i.e. shallow pools, and another for $Y/D = 6.9$ and 9.3 for which there is already larger energy at lower frequencies due to enhanced development of the turbulent shear layer of the plunging jet.

4.3 *Spectral distribution: influence of the velocity*

Power spectra for $Y/D = 4.2$ (i.e. shallow pools) have been computed for all the velocities tested and are presented in Figure 8 for points "a" and "e" (Fig. 3). At $y/D = 0.35$ (point "a"), low frequency oscillations of about 1–4 Hz are identified for $V = 12.3$ to 17.2 m/s.

Copyright © 2006 Taylor & Francis Group plc, London, UK

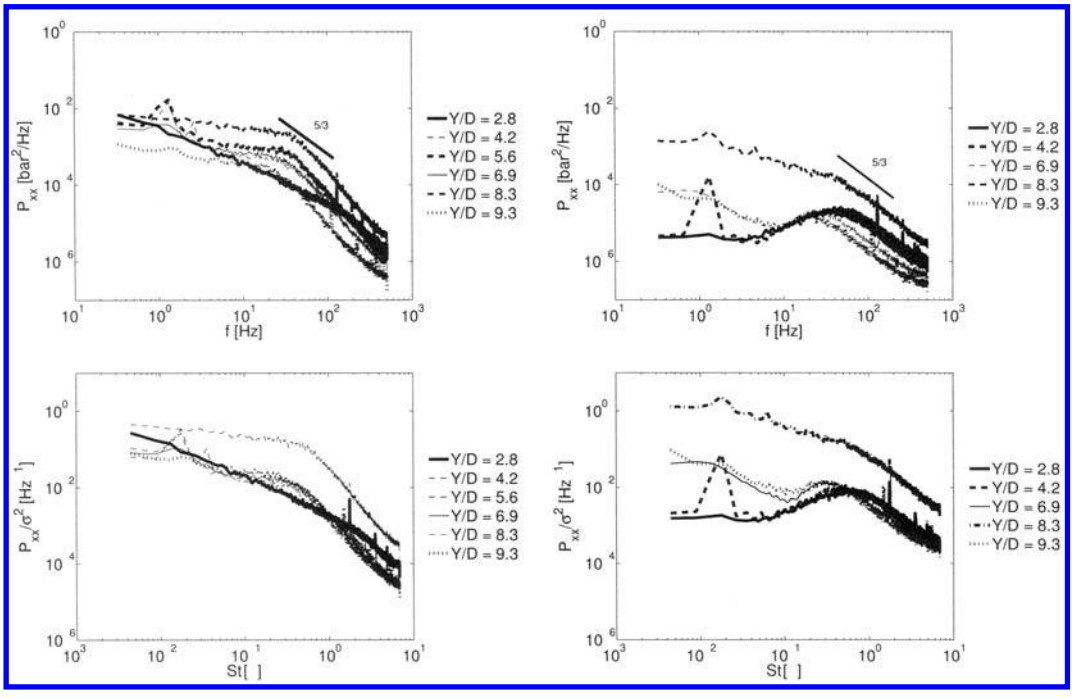

Figure 7. Spectral density functions for wide pools, $D_c/D = 16.7$, $t/D_c = 0.17$, $V = \mathbf{14.7\ m/s}$ and different pool depths Y/D: left) y/D = 0.35; right) y/D = 2.08. Strouhal number defined in terms of the scour depth "t".

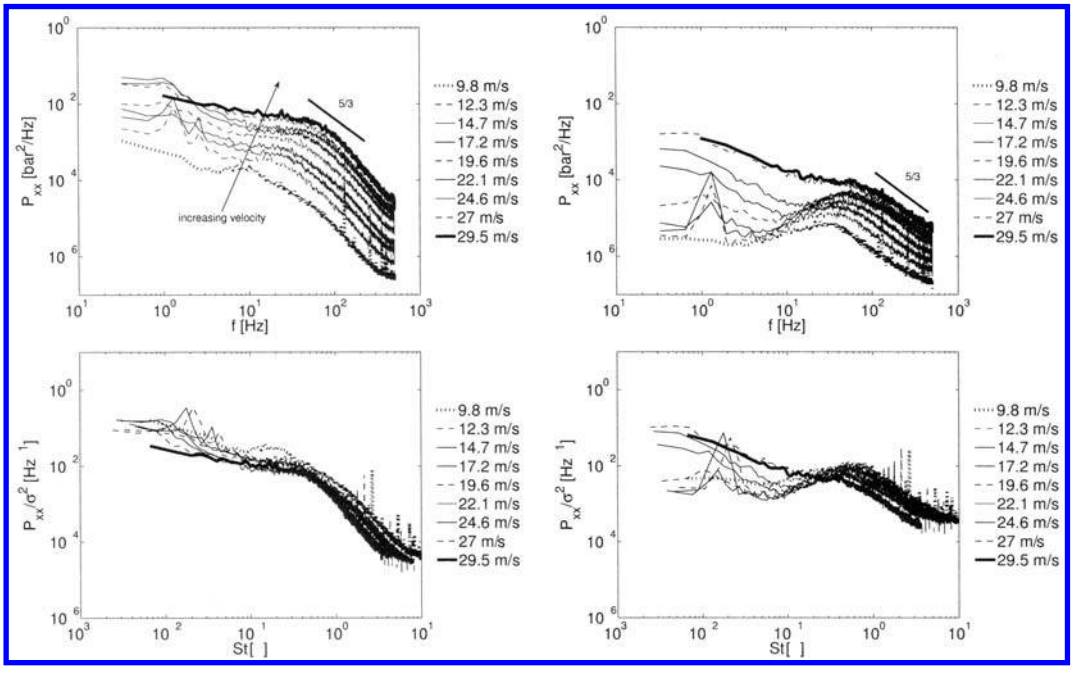

Figure 8. Spectral density functions for wide pools, $D_c/D = 16.7$, $t/D_c = 0.17$, **with** $Y/D = \mathbf{4.2}$ and different jet velocities: left) y/D = 0.35; right) y/D = 2.08. Envelope cases are highlighted.

Copyright © 2006 Taylor & Francis Group plc, London, UK

All spectra correspond to the impact of developed jets. At $y/D = 2.08$ (point "e"):

- low frequency oscillations are also observed at about 1 Hz for $V = 12.3$ to 17.2 m/s;
- all spectra for $V \leq 24.6$ m/s show much less energy up to 40–50 Hz than those for $V = 27$ and 29.5 m/s. Beyond these frequencies, all spectra have a similar decay;
- for $f > 50$ Hz, the spectra decay with a slope $\leq -5/3$ and thus is not clear if the dissipation range is attained.
- The reduction of spectral energy for $f < 40$–50 Hz is related to the formation of a bottom wall jet. The bottom wall jet does not have the same spectral energy of the impacting turbulent shear layer (TSL). For $V = 27$ and 29.5 m/s, the TSL impacts the bottom at $y/D = 2.08$. For $V = 12.3$ to 17.2 m/s, the surface oscillations are superposed to the wall jet.

In deep pools (e.g. $Y/D = 9.3$) no major change in the main flow features with jet velocity can be identified from the spectra.

The mentioned low-frequency flow patterns can also be clearly identified in dimensionless spectra for $Y/D = 4.2$ (Figure 8, bottom row) for Strouhal numbers of ≈ 0.01 defined in terms of t or 0.03 if the Strouhal number is defined in terms of the distance from the jet axis to the confinement R_c. According to Figures 6, 7, 8, the spectra enter the energy dissipation range for $St \geq 0.3$.

5 TYPICAL SCALES OF FLOW FEATURES

5.1 *Surface oscillations and ejections*

The frequency of pool oscillations *inside* the confinement f_δ can be defined as:

$$f_\delta = f(R_c, \frac{Y}{D}, V_i, ..) \quad (1)$$

In the present case, pool oscillation were only observed for $Y/D < 5.6$. The amplitude δ of oscillations over the *entire* pool is:

$$\delta = f(R_c, \frac{Y}{D}, V_i, \forall, d/s, ..) \quad (2)$$

where $\forall$ is the total volume of the pool and d/s stands for downstream conditions. In the present case, such oscillations are observed for $5.6 < Y/D < 9.3$.

5.2 *Developed flow impact conditions*

In most practical situations, core jet impact is limited to the very early stages of scour or spillway operation. Confining laterally the free diffusion of plunging jets modifies the flow pattern in the pool. This is reflected in the impact pressures at the pool bottom. Pressure fluctuations spectra show developed jet impact conditions for pool depths as shallow as $Y/D = 4.2$. For $Y < R_c$ core impact conditions are observed, but few tests were performed in these conditions. For $Y = 4 - 5.6$D, core impact conditions could occur for very large pools, i.e. $R_c > 8$D. For $Y > 5.6$ the core of the jet vanishes independently of the value of R_c.

For wide confined pools (TC), developed jet conditions are obtained starting from Y = 4.2D, which is $\approx R_{tc}/2$. In this case, developed impact conditions are obtained for:

$$Y \geq 0.5R_{tc} \quad \text{i.e Y} \geq 4.2\text{D} \quad (3)$$

In narrow pools (FC) developed impact conditions were obtained in all tests and thus:

$$Y \geq 2.8D = R_{fc} \quad \text{i.e Y} \geq 2.8\text{D} \quad (4)$$

However, for intermediate confined pools (SC) core impact is obtained for Y = 2.8D (i.e. $R_{sc}/2$). Therefore, to obtain developed jet impact conditions:

$$Y \geq 0.5R_{sc} \quad \text{i.e Y} \geq 2.8\text{D} \quad (5)$$

Two envelope expressions are derived:

$$Y \geq R_c \quad \text{for } 2.8\text{D} \leq R_c \leq 5.6\text{D} \quad (6)$$

and

$$Y \geq 0.75R_c \quad \text{for } R_c \geq 5.6\text{D} \quad (7)$$

It should be stressed that $Y = 0.75 \times 5.6\text{D} = 4.2\text{D}$ is less than the core development length in pools with flat bottom with the turbulent jets generated in the present experimental set-up.

5.3 *Induced currents and cells*

The most relevant current patterns identified in the cases of shallow and deep laterally confined pools are:

- the shear eddy, between the turbulent shear layer (TSL) and the confinement;
- the upward currents generated by the reflection of the bottom wall jets on the pool boundaries;
- the pool recirculation currents, that set in motion the volume of water *outside* the scour hole.

The shear eddy (or dissipation cell) was also described by (Puertas-Agudo 1994) based on visualisation of the flow structure during experiments. The shear cell is the most important of the three phenomena regarding impact pressures. For very narrow confinements, the shear cell does not develop and the deflected upward currents oppose directly to jet momentum. Depending on the direction of these upward currents and on their proximity to the diffusion region, they can

Copyright © 2006 Taylor & Francis Group plc, London, UK

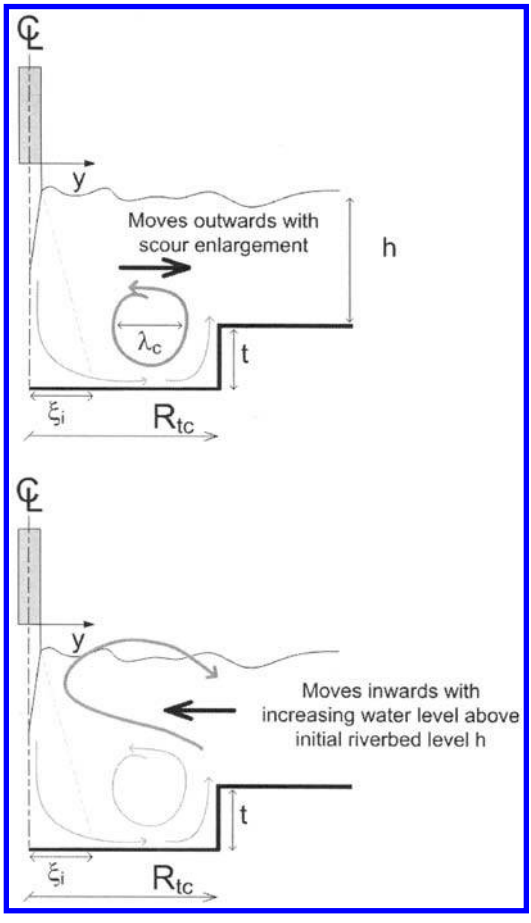

Figure 9. Shear eddy and recirculation currents behaviour. Dotted line corresponds to the theoretical shear layer in free jet diffusion of turbulent rough jets.

also hinder air bubble penetration in the pool. When the scour region is enlarged, this cell is created in between the jet and the upward currents – Figure 9. If scour keeps enlarging, the cell grow and is pushed outwards, remaining closer to the confinement than to the jet axis.

The pool circulation currents are highly relevant for back erosion but are generally overlooked in the definition of impact pressures and thus in the scour process. In fact, depending on the tailwater level h, these currents push the upward currents radially inwards and contribute to enhance dissipation and hinder air entrainment. For particular situations combining pool geometry, jet velocity and pool depth the generated circulation flow reduced the tailwater level locally at the plunging section. This was observed in the present facility for pools with flat bottom and $Y/D = 8.3$. The local reduction of pool depth generated impact pressures quite similar to those obtained for $Y/D = 6.9$. For the aforementioned reasons, circulation currents play an important role in the riverbed scour process, as well as in the bank erosion process.

5.4 *Definition of the length scale of the shear cell*

The observations of large-scale flow features (TC pool) allowed identifying the presence of a dissipation shear cell between the plunging jet and the upward currents. The location of this cell varies with the degree of confinement D_c/D, whereas its size is mainly function of a characteristic flow depth, either the scour depth t in confined geometries, or the pool depth Y in wide flat geometries. Its frequency varies with jet velocity, due to the influence of jet velocity on the definition of the interaction between the upward currents and the recirculation currents.

Despite the absence of direct velocity field measurements, some characteristics of such cells can be defined.

The width of the turbulent shear layer (TSL) at impact on a flat bottom is assumed $\xi \approx$ Y/3, according to several authors (Cola 1966; Beltaos and Rajaratnam 1974).

In the present set-up, the turbulent shear layer impacts the bottom between 1.4D (for $Y = 2.8$D) and 2.8D (for a maximum pool depth of 9.3D), assuming a diffusion spreading angle of 14° in pools with flat bottom. The ξ is maximum 3D. Hence, any narrow pool (FC) interferes directly with the TSL. The space between the axis and the confinement is shared between the "confined" shear layer and the upward currents.

The observation of the shear cell in wide pools (TC, in submerged jet conditions and for $t/D = 2.8$ only) allows estimating the cell's dimension $\lambda_c < R_{tc}/2$. In these conditions $Y = 11$D and $R_{tc} = 8.3$D. Therefore, $\lambda_c < 4.2D$ if assumed circular. From visual interpretation of the flow field, $\lambda_c <$ Y/2. The bundle of air bubbles that allowed visualisation did not exceeded 20 cm (i.e 2.8D).

For intermediate pools (SC, $R_c = 5.6D$) and for $t/D = 2.8$, the jet core impacts the bottom only for the minimum Y/D, i.e. $\xi = 0.33(2.8\text{D}) = 1.4$D. For all the other pool depths Y/D, developed jet impact conditions are registered. One can consider that:

- with a TSL width of 1.8D for $Y = 4.2$D and a shear cell of 2.8D, the upwards currents can still occupy 1.4D and have little influence over the plunging jet. This is good agreement with the results.
- with a TSL width of 2.8D for $Y = 9.3$D, λ_c is lower than 2.8D. In this case two possibilities can be considered: either λ_c is 2.8D or the TSL has to be smaller.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The previous analysis of the narrow, intermediate and wide confinements suggests that the y-length scale of the shear eddy, when existing, is of about 2.8D. This corresponds to $R_{sc}/2$ or $R_{tc}/4$. The x-length scale (vertical) is likely related with t, i.e. the depth of scour below initial riverbed. In fact, for $Y > t$ (i.e. $h \neq 0$) the recirculation currents in the region outside of the confined zone may influence λ_c. This can be visually observed in TC pools ($t/D = 2.8$) with $Y/D = 9.3/11.4$.

The length scale of the shear cell λ_c is thus defined as:

$$\text{if} \quad R_c = t \quad \text{and} \quad R_c > 2.8D \quad \text{and} \quad h \geq t \quad \Rightarrow \quad \lambda_c \approx t \qquad (8)$$

For pools that are *deeper than wider*, i.e. $R_c <$ t:

$$\text{if} \quad R_c > 2.8D \quad \text{and} \quad Y > 1.5t \quad \text{or} \quad Y \geq D_c \quad \Rightarrow \quad \lambda_c \approx R_c/2 \qquad (9)$$

assuming Cola's hypothesis for the impinging zone (i.e. 0.33Y). For pools that are *wider than deeper*, i.e. $R_c >$ t:

$$\text{if} \quad 4D < Y \leq 1.5R_c \quad \text{and} \quad R_c > 4.2D \quad \Rightarrow \quad \lambda_c \approx t \qquad (10)$$

For pools with flat bottom, λ_c is estimated based on Cola's statement that the centre of gravity of the cells is at 0.25Y. In these conditions:

$$\text{if} \quad Y > 5.6D \quad \Rightarrow \quad \lambda_c \approx 0.50Y \qquad (11)$$

However, in the present set-up, the outflow is controlled by side weirs. They define the pool level Y and influence the large recirculation currents in pools with flat bottom. (Puertas-Agudo 1994) observed $\lambda_c < 0.50Y$ due to the same "weir" effect.

5.5 *Evolution of the Strouhal number with scour depth*

The dimensions and frequency of the shear cell can be used to define a characteristic Strouhal number per pool geometry. The rotation frequency of the shear cell can be computed by:

$$\hat{f} = \frac{U_r}{\pi \lambda_c} \qquad (12)$$

where U_r is the rotation velocity, i.e. the velocity necessary to do one revolution of $\pi\lambda_c$ (perimeter) in a given period T. The Strouhal number corresponding to this turbulent flow pattern can be defined as:

$$St_2 = \frac{U_r}{\pi V} \qquad (13)$$

which is similar to the expression proposed by (Ervine et al. 1997). The rotation velocity is assumed as the velocity of the plunging jet at the entry of the impinging region (i.e. 0.25Y). This depth corresponds to the x-coordinate of the centre of the cell (Cola 1966; Puertas-Agudo 1994).

Based on these assumptions, the characteristic frequencies of shear cells are presented in Table 2. For the wide (TC) deep pool, the estimated frequencies range from 10 to 30 Hz, and are in agreement with the visual observations. The results are very sensitive to the U_r assumptions. Since there is no centreline velocity decay law available for each pool geometry, U_r values were obtained from the mean pressure values measured at stagnation (i.e. y/D = 0.35).

Rotating frequencies are estimated between 10–30 Hz in deep pools and 10–65 Hz in shallow pools. This is in good agreement with the indications from the spectral analysis. For several other geometries, the rotation frequencies obtained were lower than 20 Hz with St_2 not exceeding 0.16 (Manso 2006), with larger t/D ratios and combining different D_c/D geometries to compose stepped conical plunge pools.

Table 2. Characteristic cell frequencies, based on estimates of λ_c and U_r.

5.6 *The role of the shear eddy in energy dissipation*

Energy dissipation is done by jet diffusion through the pool and impact in the river bottom. In laterally confined pools the direct contact between the plunging jet and the upward currents enhances dissipation in the water column. If a shear eddy cell is formed, it will also contribute to the dissipation process. As the scour is enlarged, the eddy cell moves away from the jet, exposing the riverbed to higher mean pressures.

5.7 *The role of the shear eddy in abrasion*

Abrasion is a scouring process complementary to fracture propagation in rock and rock block displacement by dynamic uplift. When blocks are ejected, they join the pool flow. If the shear eddy has sufficient momentum to keep them in motion, blocks act as a rotating "mill stone" on the pool boundaries. Rock blocks get smaller in size, until they are light enough to be washed away by the flow. If the blocks are oversized compared with the eddy's momentum, they will rather hinder any rotational movement in the confined region.

6 CONCLUSIONS

The diffusion of plunging jets in laterally confined plunge pools has been studied experimentally and compared with diffusion in pools with flat bottom. Dynamic pressures were sampled at the pool bottom. Point statistics and a limited number of multi-point description of the spatial turbulent pressure field are dsicussed in this paper. The analysis of pressure distributions, spectral energy content and the visualisation of large-scale flow features show that:

- the geometry of the plunge pool is a key element in the definition of the mean and turbulent character of dynamic impact pressures on the pool boundaries;
- the flow patterns induced by the interaction of the turbulent shear layer with the pool geometry considerably alter jet diffusion and air bubble penetration in non-flat pools, compared to the most-documented case in literature of pools with flat bottom;
- confining laterally the evolution of plunge pool enhance dissipation in the water column, reduce impact pressures and ultimately reduce scour potential; and,
- wall pressure measurements can be used to infer characteristics of the turbulent flow field with high air content in the pool.

The presented analysis is part of a broad research in rock scour by high-velocity plunging jets. The thorough analysis of the key physical processes involved in jet diffusion in a highly aerated water pool, jet impact in solid boundaries and the scouring potential of the corresponding dynamic loads, is a basic requirement for the further development of comprehensive modelling tools of the scouring process.

Numerical investigation of the turbulent flow around a bridge abutment

A. Teruzzi & F. Ballio

OGS, Trieste, Italy

V. Armenio
Università degli studi di Trieste, Trieste, Italy

ABSTRACT: Bridge failures are frequently related to phenomena of local erosion at piers and abutments; literature on this topic does not provide fully satisfactory formulations to evaluate the scour depth. Since a detailed definition of the flow can improve the comprehension of the phenomenon, a numerical study on the turbulent flow around an obstacle archetypal of an abutment is presented. The turbulent flow characteristics are investigated by means of Large Eddy Simulation, obtaining results both on the averaged flow characteristics as on the instantaneous ones. The averaged flow around the obstacle is structured as a highly three-dimensional system of vortex structures; instantaneous structures are characterized by high vortex intermittency. The shear and normal stress distributions on the bottom-wall are analyzed in comparison with experimental observations relative to erosion phenomena. The numerical simulations are consistent with experimental observations on flow characteristics around an abutment in flat-bed condition and provide details on its three-dimensional features and instantaneous behavior.

1 INTRODUCTION

As documented in literature works (see for example Cardoso & Bettess 1999) local scour at piers or abutments is one of the most frequent cause of bridge failure. The erosion phenomenon is the result of the interaction between a complex three-dimensional turbulent flow and the river bed; since the definition of the flow features can improve the comprehension of the localized erosion phenomenon, in this work a study on the flow around an obstacle archetypal of an abutment is presented.

Several literature works on erosion problems propose various parametric formulas to evaluate maximum scour depth at bridge piers or abutments (see Melville & Coleman 2000 and literature therein cited), but the resulting values from the different formulations are very scattered, as showed in Cardoso & Bettes (1999), and therefore not really satisfactory in bridge design. In order to explain the dependency of the scour depth from the control parameters of the system, a comprehension of the erosion mechanism (the sediment-flow interaction) at the sediment scale could be useful. For such an approach it is relevant to define the flow field characteristics (in terms of velocities, vortexes, stresses, etc.) and the associated sediments motion features (as velocities, directions, mass-rate intensities, etc.).

In this work the turbulent flow characteristic aspects are investigated, and particularly a Large Eddy Simulation study of the turbulent flow around a trapezoidal obstacle on a flat-bed is presented. Examples of literature experimental results for similar configurations can be found in Ahmed & Rajaratnam (2000) and in Barbhuiya & Dey (2003) with flat-bed condition and with developed scour hole respectively. The literature results from experiments around abutments are averaged in time and do not describe the turbulent nature of the flow. A general description of the principal (averaged) vortex structures can be found in Melville & Coleman (2000), where the principal vortex is identified as the main responsible for the erosion process.

Numerical and experimental results of a turbulent flow field around an abutment in flat-bed configuration are presented in Chrisohoides et al. (2003) where a URANS model is used for numerical simulations. Their results are consistent with the description of an highly three-dimensional flow near the abutment, recognizing a complex system of multiple vortexes in front of the obstacle.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In this work the LES technique permits to define in details both the averaged flow characteristics as well as the instantaneous ones for the flow field around a trapezoidal obstacle; the attention is particularly focused on the area in front of the obstacle, correspondent to the region where the maximum scour depth is observed in erosion experiments. Results describing the three-dimensional flow structures are presented, as well as the shear and normal stress patterns on the walls. The latter variables are directly correlated to the scour process, and are therefore analyzed in comparison with observations of erosion experiments.

2 NUMERICAL MODEL

The turbulent flow results presented in this work are obtained by means of Large Eddy Simulations (LES). LES method is intermediate between RANS and DNS; it resolves the large, energy carrying scales and models the dissipative small ones, supposed isotropic.

The SGS stresses are evaluated by the generalized coordinates dynamic Lagrangian mixed model proposed in Armenio & Piomelli (2000), which in Cartesian frameworks can be written as:

$$\tau_{ij} = \overline{\bar{u}_i \bar{u}_j} - \overline{\bar{u}_i}\,\overline{\bar{u}_j} - 2C\bar{\Delta}^2 \left|\bar{S}\right| \bar{S}_{ij} \qquad (1)$$

where the overbar indicates the filtering operation, $\bar{u}$ are the velocity resolved components, $\bar{S}_{ij}$ is the resolved strain-rate tensor, $\bar{\Delta}$ is a term related to the filtering dimension and C is the model coefficient. The first two terms and the last one in (1) represent respectively the scale similar (Bardina et al. 1980) and the eddy viscosity part (Smagorinsky 1963). In the used dynamic Lagrangian model the coefficient C is evaluated during the simulation, using the energy content of the small resolved scales (Germano et al. 1991), and averaged over flow path lines (Menevau et al. 1996), since in the presented geometry there is not homogeneity directions over which averaging can be operated. Particulars on the model implementation, specifically on the formulation in curvilinear coordinates, can be found in Armenio & Piomelli (2000).

3 GEOMETRY AND PARAMETERS

The numerical simulations are carried out in a duct with rectangular cross-section and a near wall trapezoidal obstacle (representing an abutment). A sketch of the duct and obstacle geometry and of the coordinate system is presented in Figure 1. With reference to quantities indicated in Figure 1, the duct and obstacle dimension are: $B = 2.5\,h$, $L = 13.5\,h$, $b = 0.5\,h$, and $\alpha = 45°$.

The Large Eddy Simulations are carried out setting no-slip boundary condition on the duct and obstacle walls; the inlet condition is a series of cross-section velocity fields previously obtained from a developed and constant mass-rate turbulent flow in a straight rectangular duct, with same dimensions and flow-rate of the present case, but without the obstacle. The Reynolds number based on the duct height and bulk velocity at the inlet cross-section is equal to 7000. The number of grid points is $256 \times 64 \times 96$ respectively in the x-, y- and z-direction. The grid points are clustered in the y- and z-direction near the walls in order to assure that the viscous sub-layer is directly resolved; moreover the grid spacing along the x-direction is reduced in the obstacle region, since the complexity of the flow field in this area requires a higher definition.

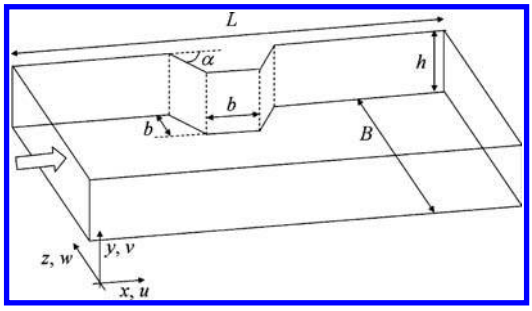

Figure 1. Sketch of duct geometry and coordinate system (not in scale).

The simulations are carried out with a constant time step corresponding to a Courant number close to 0.4. The mean quantities presented in section 4 are obtained by averaging on about 10 large eddy turn over time (LETOT) and over the two symmetric parts of the duct separated by the (x, z) half height plane, therefore all the averaged results are defined on the half duct.

4 RESULTS

4.1 *Flow field around the obstacle*

The numerical simulations allow the definition of the flow field around the trapezoidal obstacle in detail, and specifically to obtain information on its complex three-dimensional and turbulent characteristics.

The vortex structures are identified for the instantaneous and mean flow fields by the Q-criterion. In Figure 2 the results obtained for the averaged flow show a system of vortices in front of the obstacle and the vortex sheet detaching from the edge of the obstacle. Upstream the obstacle different structures can be identified: a corner vortex (indicated with I), with axis parallel to the y-direction, which is bended horizontally in proximity of the bottom wall and eventually joined to a horizontal vortex (II), thus creating a big structure rounding the obstacle (III), parallel to the (x, z)-wall; finally, a longitudinal vortex can

Copyright © 2006 Taylor & Francis Group plc, London, UK

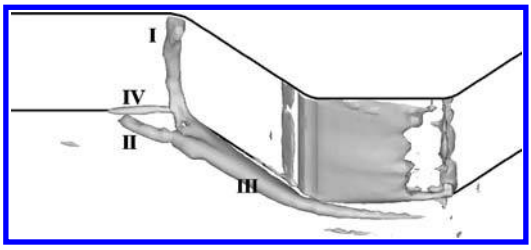

Figure 2. Vortex structures of the averaged flow (half duct).

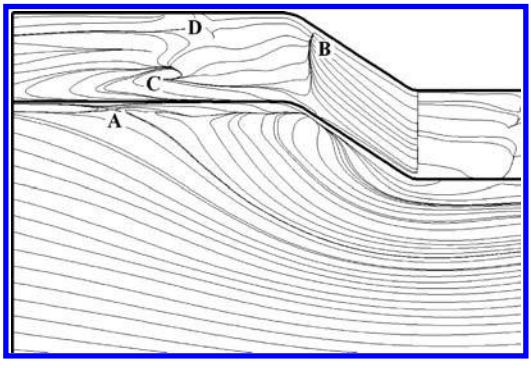

Figure 3. Stream-traces of the averaged flow on the (x, y)- and (x, z)-wall (half duct).

be observed in the corner between the (x, y)- and (x, z)-wall (IV). In Figure 2 the directions of the vorticity vectors associated to the described structures are qualitatively shown.

More details on the three-dimensional structures are provided by the shear stress traces on the walls. Figure 3 shows the stream-traces of the averaged flow on the (x, y)- and (x, z)-wall, revealing the flow topology resulting from the interaction between the incoming boundary layer and the adverse pressure gradient due to the obstacle. The averaged flow is probably affected by not fully developed statistics, since non-zero velocity component v on the symmetry plane are present. An enlarged schematic of shear lines topology is shown in Figure 4.

The trace of the circulation in front of the obstacle due to the (main) horizontal vortex II is clearly detectable on the (x, y)-wall (focus/node C). On the upstream wall of the obstacle an attachment line exits from node B directed vertically downwards; it eventually continues upstream on the bottom, connecting node B to the saddle A. Node B, as well as its counterpart on the lateral wall, i.e. the saddle D, are the direct consequence of the presence of vertical vortex I. Notice that saddle D should lay on the symmetry plane: we already discussed that the incomplete symmetry of the flow is due to incomplete convergence of the mean values.

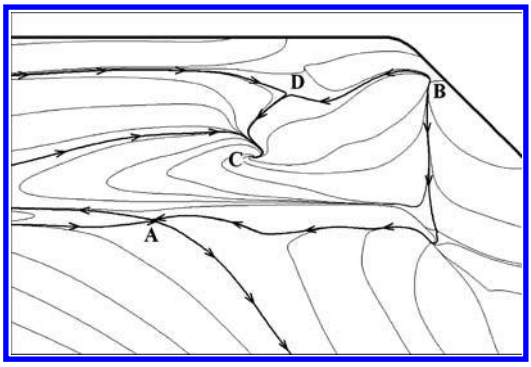

Figure 4. Sketch of topology (half duct).

The singular attachment line B-A (and its continuation A-C, partially not visible in the figures) delimitates the domain where the flow is pushed towards the lateral vertical wall by the vortices I and IV, while the outer streamlines directly follow the main path around the obstacle. Fluid particles within the "inner" domain enters either vortex I or vortex II, and are consequently transported in the outer region where the two vortices merge together and are stretched by the main flow.

The vortex sheet detaching from the abutment edge is basically two-dimensional, coherent with a 2D separation – reattachment pattern.

The averaged flow results are coherent with classics literature schemes about flow around abutments, but add details in the description of the backflow in front of the obstacle, particularly on the near (x, y)-wall region (not experimentally easy to investigate). Indeed the corner vortices I and IV, associated to the specific topology of this flow, are a distinguishing element with respect to the flow over symmetrical bodies (see for example results around bridge piers).

The analysis of the instantaneous values can provide significant additional information to be considered for the comprehension of the sediment-fluid interaction; indeed the river bed sediments interact with the intermittent turbulent flow, which characteristics are not necessarily revealed by the averaged features.

The instantaneous stream-traces on the walls near the obstacle give qualitative information on the instantaneous flow, particularly they reveal that some highlighted elements of the mean flow are permanent in the instantaneous one, while others are very intermittent. On the (x, y)-wall the instantaneous flow fields are very complex and, as expected, there is not symmetry with respect to the duct center plane, so the flow topology is not easily readable and referable to the main characteristics highlighted in the averaged flow. On the (x, z)-wall the saddle is not easily recognizable and very intermittent in time and position.

Figure 5a, b show an example of instantaneous stream-traces respectively on the (x, y)- and (x, z)-wall

Copyright © 2006 Taylor & Francis Group plc, London, UK

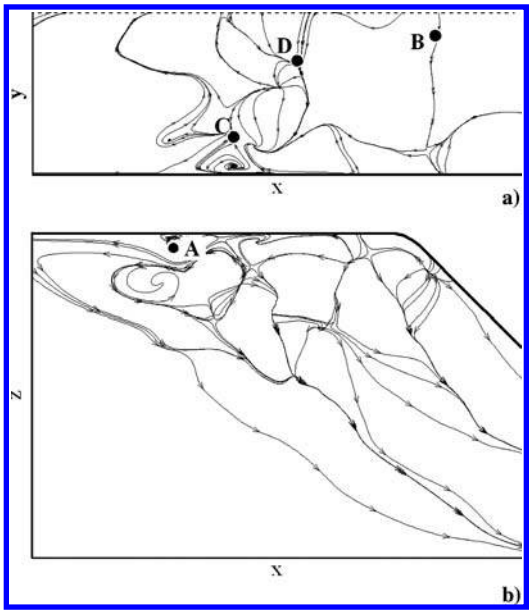

Figure 5. Instantaneous stream-traces: a) on the (x, y)-wall, b) on the (x, z)-wall (half duct).

(only the half part of the (x, y)-wall is reproduced). The position of the described singular points in the averaged flow are indicated, to highlight the differences between instantaneous and averaged topology.

In the instantaneous fields, the vortex system is quite different from the averaged one (see some examples of instantaneous vortexes in front of the obstacle in Fig. 6); several elongated vortexes in the flow direction can be recognized in all the analyzed time steps, while a very intermittent corner structure parallel to the y-axis is sometime present (see Fig. 6b). Typical detaching rolls are always recognizable at the obstacle edge, while the upstream vortex organization change significantly in time, see Figure 6a, b, c.

The evolution in time of the topological features and the differences between instantaneous and averaged flow emphasize the complexity in time and space of the flow obtained from simulations, which is representative of the one interacting with sediments around an abutment.

4.2 *Stresses*

Large Eddy Simulations of this study are representative of the flow around an abutment in a flat-bed river, that is at the beginning of the scour processs. In Oliveto & Hager (2002) the scour maximum depth evolution in time is analyzed; the authors observe that at abutments the scour starts at the edge of the obstacle, progressively moving towards the vertical wall as scour develops, so that the erosion process tends to

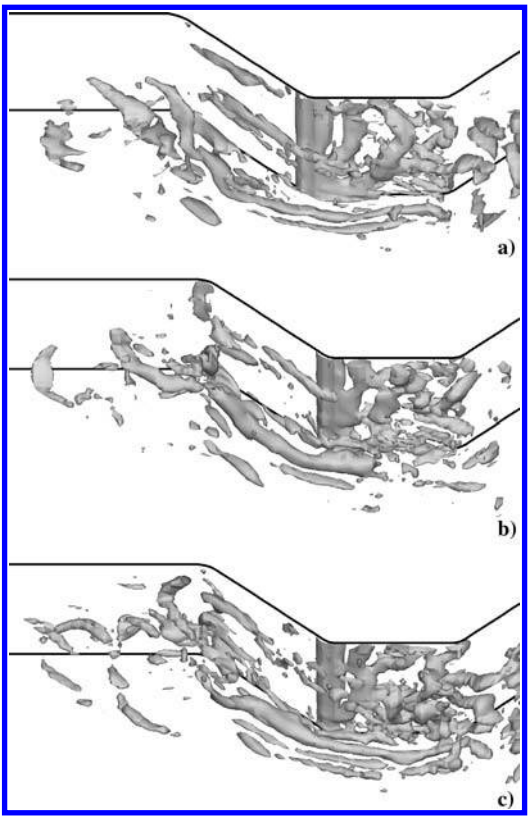

Figure 6. Examples of instantaneous vortex structures (half duct).

interest all the region upstream the abutment. Similar consideration were made in Teruzzi (2002). The experimental works of Molinas et al. (1998) and of Rajaratnam & Nwachukwu (1983) indicate that the maximum shear stress at the bed lies near the abutment edge. In the numerical simulations of Chrisohodes et al. (2003) the maximum shear velocity is localized in a similar position (they used an abutment geometry without edge).

The averaged results of stress distribution near the obstacle on the (x, z)-wall are presented in Figures 7, 8 and 9. Figure 7 shows the time-averaged shear stress module on the (x, z)-wall divided by $\bar{\tau}$, that is the mean shear stress in a straight duct with same dimension and Reynolds number of the present one; upstream and to the side of the obstacle there is a large region with shear stress higher than $3\bar{\tau}$, with a maximum of about $13\bar{\tau}$ at the obstacle.

Results of Figure 7 indicate that the region where the shear stresses exceed the mean value of the far field is concentrated in the edge region and in the wake, while no stress amplification is detectable in the proximity of the vertical wall. In a situation where the mean

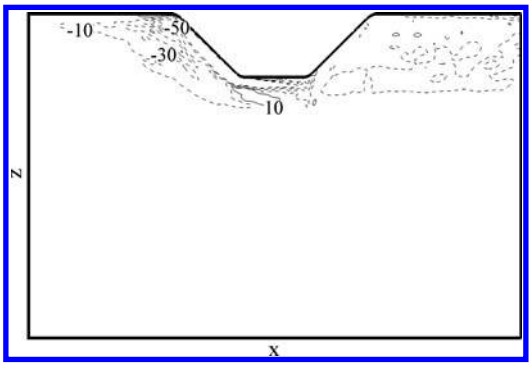

Figure 9. Averaged pressure gradient along the y-axis, normalized by $\bar{\tau}$ and h (dashed lines when negative).

value $\bar{\tau}$ is close to the incipient condition for grain motion, this result would indicate that the sediment motion could commence at the abutment edge (consistently with literature observation) but at the same time that no sediment transport and therefore no scour could be expected close to the vertical wall. The mean

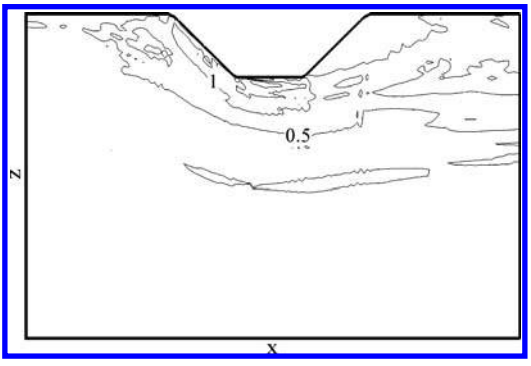

Figure 10. Shear stress module *rms*, normalized by $\bar{\tau}$.

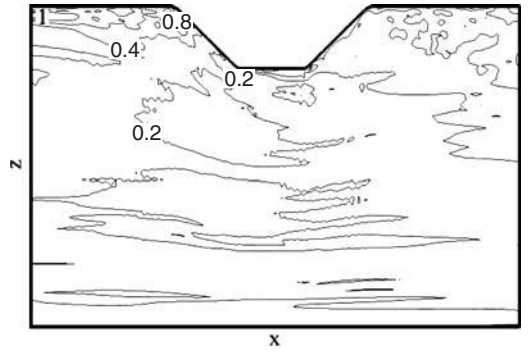

Figure 11. Variation coefficient of shear stress module.

shears are not able to explain the experimental experience of authors, which indicates that in the first instant of scour some sediment motion can be observed in the corner region.

The pressure distribution can play a role in the erosion process; in Figures 8 and 9 the normalized averaged pressure and its gradient along y-direction on the (x, z)-wall are respectively presented. The pressure minimum in Figure 8 lies at the obstacle edge, coherently with the maximum shear in this position. Maximum pressure values are positioned on the vertical wall, in front of the abutment, as a result of the blocking effect of the obstacle. It is possible that the pressure gradient can be an additional active factor for the scour process in the proximity of the edge, but this is hardly true in proximity of the vertical wall. In this area, however, the averaged vertical pressure gradient (Fig. 9) is particularly intense, so that, depending on the grain size, an uplift pressure effect can play a significant role on particle entrainment.

Due to the turbulent character of the flow, a relevant role in the erosion is played by the instantaneous quantities, specifically by the instantaneous shear stresses; indeed, in regions where the averaged shear stress module does not exceed the (average) critical value, grain

Copyright © 2006 Taylor & Francis Group plc, London, UK

movements can be explained by fluctuating components, which as indicated by statistics are higher than those of a flow over the standard plane-bed configuration for which incipient motion conditions are defined. From the detailed data of the Large Eddy Simulations it is possible to obtain τ', the *rms* of the shear stress module on the (x, z)-wall, which is showed in Fig. 10, normalized by $\bar{\tau}$. In Figure 11 the variation coefficient is plotted, where τ' values are normalized versus the local mean stress. Values of τ' have the same order of magnitude of $\bar{\tau}$, with maxima of about 1.5 $\bar{\tau}$ along the upstream face of the abutment; highest values of variation coefficient can be observed upstream the obstacle (in the corner and near the separation) revealing region where the instantaneous fluctuations of the shear stress module are of the same order of magnitude than the averaged ones. On the contrary near the obstacle edge the fluctuating terms are about 10% of the averaged shear stresses.

Results for the fluctuating components of shear stresses together with those for vertical pressure gradients may explain the erosion capacity of the flow field in the corner region, where mean shear stresses do not exceed those in the far field; on the contrary, for flat-bed conditions (beginning of the erosion process), mean shear values can be easily pointed as the prevailing scour agent in the edge region, coherently with previous literature observations.

5 CONCLUSIONS

In this work a Large Eddy Simulation study of the turbulent flow around an obstacle, archetypal of a bridge abutment, is presented, with aim to improve knowledge on the local scour phenomenon. Data from numerical simulations enables a detailed description of the turbulent flow field and stresses in the near obstacle region.

The flow field results are consistent with previous literature description of a complex highly three-dimensional system of vortex structures in front of the abutment. The instantaneous flow field analysis reveals high intermittency of the flow field characteristics and particularly of the flow structures organization in front of the obstacle. Maximum mean shear stress values are concentrated in a relatively small area at the abutment upstream edge, where the maximum scour capacity is typically located. Mean values alone are presumably not sufficient to explain the scour capacity in the corner region, close to the vertical wall: in this area fluctuating components as well as local pressure gradients may have an important role, so that standard sediment-fluid interaction models (incipient motion thresholds and transport equation) may be inadequate to describe the phenomenon.

The coherence of our results with observations from flume experiments gives value to the hypothesis that the studied flow field is representative of the phenomenon in spite of the wall boundary condition on the upper surface.

ABSTRACT: The effects of submergence and emergence on the mean flow and coherent flow structures around single groyne were experimentally discussed in the present study. In order to investigate the flow pattern around the single groyne, a scaled and schematized model was implemented and experiments were conducted by means of surface flow visualization technique and Particle Tracking Velocimetry (PTV). The results show the differences of the location and distribution of gyres generated downstream of the groyne, distribution of large scale turbulence around groyne tip and its downstream evolution.

1 INTRODUCTION

Groynes have been used for the stabilization of banks and for creating a navigation channel by confining the cross-sectional area, especially for large European rivers such as the River Rhine and the River Elbe. Therefore, studies on shallow flows and transport phenomena in groyne fields, have paid attention to the appropriate design for bank protection and obtainment of enough depth in the main channel as well as the proper environment for ecosystems. Also suitably designed groynes have been constructed all over Japan after the technical knowledge of the design was transferred from the Netherlands two centuries ago (however, a few groynes are date back to the 16th century in local region and they were empirically constructed).

Studies on flow patterns and transport process around groyne-like structures have recently and significantly developed as growth of experimental and computational techniques. Chen & Ikeda (1997), Kimura & Hosoda (1997), Uijttewaal et al. (2001), Weitbrecht & Jirka (2001) have studied the flow pattern of gyres and mixing layer with respect to the aspect ratio (length and distance between groynes). As for the exchange process between the main stream and the embayment, Altai & Chu (1997), Uijttewaal et al. (2001), Weitbrecht & Jirka (2001) have performed experimental studies by using dye concentration analysis. In addition to the above studies, scouring process were studied earlier by Garde et al. (1961), Gill (1972), Kuhnle et al. (2002) considering flow dynamics around the groyne tip. Furthermore, there are also some studies focusing on the suitable groyne design depending on purpose. Hentschel & Anlauf (2002) proposed an ecologically optimized design and Klaassen et al. (2002) proposed permeable pile groynes to reduce the turbulence level. Uijttewaal et al. (2002) also investigated the advantages and disadvantages of the various groyne designs to manipulate low turbulence level around the mixing layer. There are a few studies on field investigation by Sukhodolov et al. (2002) and Muto et al. (2004).

There are several studies on flow patterns around groynes as described in the above. However, a few studies focus on variations of water level, especially for submerged and emerged conditions. A typical Japanese river is characterized by large and sudden variations in discharge due to big amounts of rainfalls. As a result the groynes are often in submerged as well as emerged conditions. The present study, therefore focuses on the effects of submergence and emergence on the mean flow and coherent flow structures around a single groyne. Experiments were conducted with a scaled and schematized model of an existing Japanese groyne by means of surface flow visualization technique and Particle Tracking Velocimetry (PTV). This method is preferred because there are large velocity differences in the horizontal plane between the outside and inside of the dead zone behind the groyne. 2D-PTV codes were programmed in this study with inclusion of suitable ideas to make the calculation faster by using advantages of FFT and Direct Correlation

Photo 1. Typical groyne in Hiji River (NAGE at Watariba, located 18 km from rivermouth).

methods because many large images had to be processed. Furthermore, analytical techniques of proper orthogonal decomposition (POD) and space-time correlation are applied to reveal the coherent structures and their advection process, respectively. The experimental setup, analytical procedure and the differences of flow structure between the submerged and the emerged conditions around the groyne are explained and discussed in the following.

2 GROYNE IN HIJI-RIVER

One of the characteristics of Japanese-rivers is the large variation of discharge due to occasionally large rainfalls, so that the groynes are often in submerged and emerged conditions.

The study site is the Hiji River, located at Ozu City, in Ehime prefecture at north-west side of Shikoku Island, Japan (catchment area: 1,210 km^2, length: 103 km, annual rainfall: 1,800 mm). The Hiji River is famous for its many tributaries and narrow rivermouth resulting in frequent flooding. According to the investigation by the River Bureau of the Japan Ministry of Land, Infrastructure and Transport (http://www.mlit.go.jp/river/), 67 groyne-like structures (namely, flow-controlling structures) have been constructed from 16th century in the main Japanese rivers managed by the ministry. The groynes in Hiji River were constructed in 17th century (8 groynes still remain) and have a special name 'Nage' (Photo 1). They were used for creating a navigation channel and for protecting the bank. Due to the frequent flooding, the Nages are often in submerged and emerged conditions so that it is needed to investigate the detailed structure of flow pattern around the Nage for both conditions.

3 EXPERIMENTS AROUND SINGLE GROYNE

3.1 *Experimental setup and scaling model*

Experiments were conducted by means of surface flow visualization technique in laboratory of the Environmental Fluid Mechanics section of the Faculty

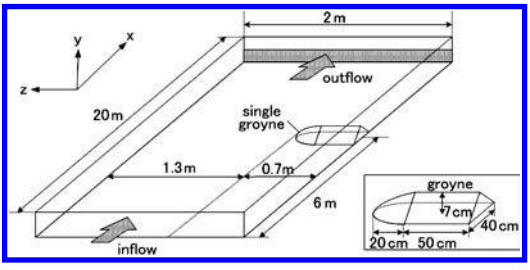

Figure 1. Experimental flume and groyne model.

Photo 2. Overview of area around groyne (Target area is indicated by square).

of Civil Engineering and Geosciences at Delft University of Technology, The Netherlands. Experimental flume is in 2 m wide and 20 m in length as shown in Figure 1.

One of typical groynes in Hiji River as indicated in Photo 1, was selected for this experiment and it is located at 18.8 km upstream from river mouth. Photo 2 shows an overview of area around the groyne. It is seen that there is a scouring area downstream of the groyne. It is considered that the scouring might be caused by submerged flow due to flooding. Furthermore, there is deposition at the downstream side of the scouring area. Because the water body around the deposition

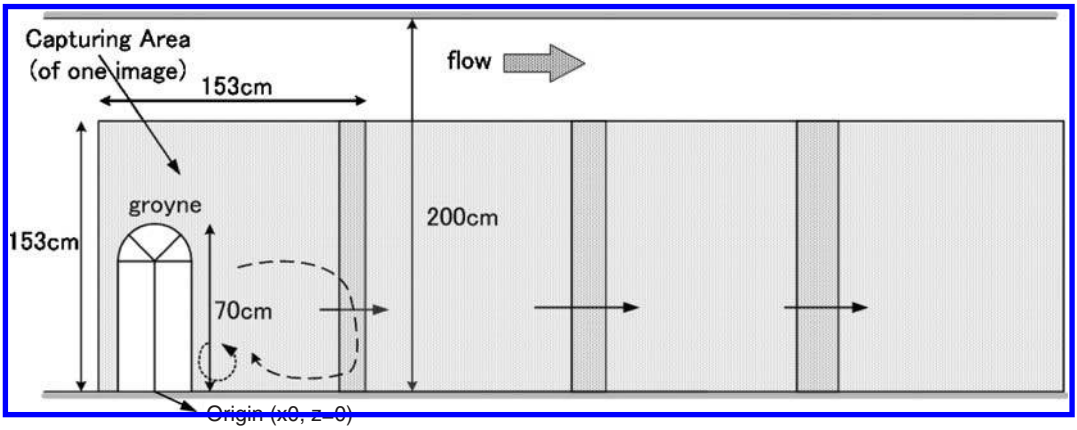

Figure 2. Capturing areas (4 sections shot with overlap).

is circulating and its velocity is low the sediments are transported and deposited from scouring area and mainstream. It is also considered that the sediment deposition in this area from mainstream can occur even in emerged condition as seen in Photo 2.

As for the scaling of the groyne model, it is estimated as ~0.342 considering the ratio of the length of groyne (41~48 m) to the river width (130 m). Therefore, scaling of the groyne model with this ratio was used with a length of 70 cm, width of 40 cm (at base) and a height of 7 cm as seen in Figure 1.

3.2 *Experimental conditions*

The groyne in the Hiji River will be submerged at 800 m^3/s discharge which corresponds to a water level of 2.8 m. Experimental conditions are determined by Froude similarity so that the Froude number becomes Fr ~ 0.2 using data of the Ozu water-level measuring point. Therefore, the discharges are determined as close as possible by considering the limitations of flow visualization technique providing an estimated value of about $Q = 20$ liters/sec for both the submerged and emerged conditions. Then the flow depths are also determined as $h = 8.5$ and 6.0 cm for submerged and emerged conditions, respectively.

3.3 *Image recording process*

Image recording was conducted by using a digital camera (Redlake ES1.0) and image acquisition software (Video Savant). The image size is 1018 times 1008 pixels for stream-wise and lateral directions, respectively. One recording section covers an area of 153 cm by 153 cm. Frequency of recording is 9.67 Hz, and capturing areas are shown in Figure 2. Because large scale vortices are generated near the tip of the groyne, long time series of recording were necessary. In order to obtain an impression of downstream development of the flow, 4 sections were recorded separately with some overlapping.

3.4 *Image processing and PTV analysis*

In the present study, the Particle Tracking Velocimetry (PTV) method is adopted and implemented in order to calculate velocities fast and accurately. The interrogation window size needs to be chosen carefully, because of the large velocity differences between outside and inside of dead zone behind the groyne. PTV results are used for calculating turbulence statistics and for visualizing flow pattern, respectively. Before applying the algorithm, some image pre-processing was done such as subtracting the background, removing noise, binarization and labeling of particle images.

There are a number of algorithms for the PTV analysis to determine the displacement of the particle image. One of them is an FFT algorithm which is fast in comparison with an alternative method of Direct Correlation. However, interrogation window size is limited to 16, 32, 64 and 128 pixels. On the other hand, Direct Correlation algorithm can use flexible interrogation window size or flexible search range but it takes a lot of time and the size of the interrogation area must be determined after the overall flow velocity is known. Therefore in this study, a 2D-PTV code was programmed with inclusion suitable ideas to make the calculation faster by using advantages of FFT and Direct Correlation methods as described below.

A flowchart of the code is explained in Figure 3. In this flowchart, the FFT algorithm is used for estimating the 1st temporal velocity. In this algorithm, the target particle is set at center position of interrogation window of the 1st image (step 1). In this step, it is better to set the size of the interrogation window to a large value to obtain a rough estimate of the overall velocity (64pix times 64pix are applied in this case). The cross-correlation function is calculated (at step 2) by using

the 1st interrogation window and the same-size and the same-position interrogation-window of 2nd image (i.e. 2nd inter-rogation window). After the calculation of the cross-correlation function, a displacement is seen between the peak and the center positions of cross-correlation area as seen in Figure 3. This displacement can be associated with the displacement of the target particle and its surroundings which correspond to the velocity (step 3). At this step, the problem remains regarding accuracy, because the velocity can vary over the large interrogation window. To cope with this disadvantage, in the subsequent step a direct correlation method is applied by using the now available overall velocity. The search range of the interrogation window in the direct correlation method is flexibly determined by dividing the overall velocity into an x and y component (step 4). The size of search range is adjusted to the overall velocity (step 5). This means a reduction of useless search area resulting in a procedure for a fast correlation calculation. The accurate velocity vector is calculated by direct correlation method under suitable search range (at step 6). Verification was done by comparing vectors with result from Lavision Flow Master by using a strong-vortex image by Stanislas et al. (2003). The images recorded in these experiments were processed by the above mentioned procedure with satisfactory results.

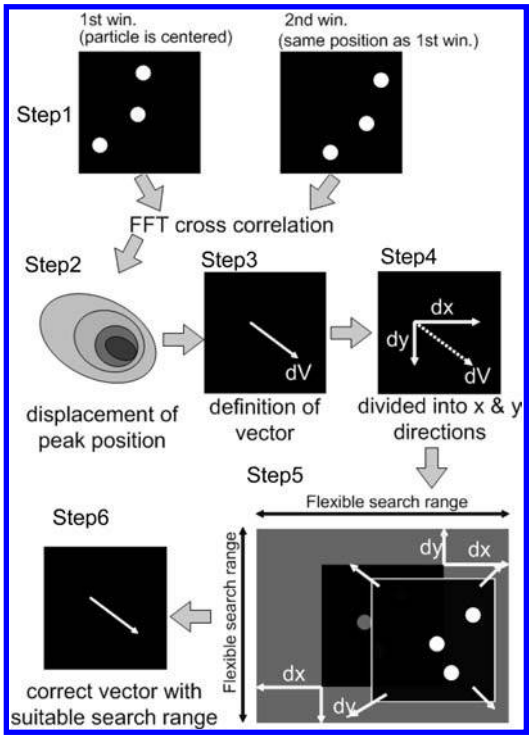

Figure 3. Flowchart of PTV code (by FFT & D.Corr Method with flexible search range).

3.5 *Statistical analysis for mean & coherent flows*

An important problem is how to estimate the turbulence statistics such as mean velocity, turbulence intensity, Reynolds stress etc., because PTV vectors are scattered according to the distribution of the particles. There are various options for the calculation of turbulence statistics. One is to use the information of all individual vectors the other is to use only the vectors interpolated on a regular grid. With the ensemble averaging method, some areas (or volumes) are determined in whole area. If vector exists in an area for one certain time, the vector is counted. Then, all vectors existing in the area are summarized and mean velocity is calculated. On the other hand, the 2nd method is to estimate the mean velocity by summarizing the interpolated vectors. In this study, the interpolated vectors in normal grid are applied to estimate the turbulence statistics because there might be deficit of vector point and series of interpolated vector profile are used in POD analysis as described in the following.

Here we try to obtain an impression of the fluctuating pattern and its coherent structures by applying POD (proper orthogonal decomposition). This method was proposed by Lumey (1967) and used to educe those turbulent structures that containing most of the energy (i.e. coherent flow structure). POD decomposes a signal onto a basis of non-specified functions chosen to represent the energy of the signal in the fewest number of modes. The calculus of variations reduces this maximization problem to the solution of a Fredholm integral equation of the first kind.

$$\int R_{uu}(x,x')\phi_u^{(n)}(x')dx' = \lambda_u^{(n)}\phi_u^{(n)}(x) \tag{1}$$

where, $\phi_u^{(n)}(x)$ is the Eigenfunctions and $\lambda_u^{(n)}$ is the Eigenvalue. Superscript n is the number of the Eigenfunction (i.e., number of mode). The above equation is explained by using stream-wise instantaneous velocity u as an example. In this equation, $R_{uu}(x,x')$ is the cross correlation of u velocities in the separated points (x,x').

$$R_{uu}(x,x') = \langle u(x)u(x')\rangle \tag{2}$$

where, $\langle\rangle$ denotes ensemble averaging. If the coordinate x is discrete, equation (1) reduces to an Eigenvalue problem as follows;

$$R_{uu}(x_i,x_j)\phi_u^{(n)}(x_j)\Delta x = \lambda_u^{(n)}\phi_u^{(n)}(x_i) \tag{3}$$

where Δx is the distance between points (x, x'). By solving the above equation, $\lambda_u^{(n)}$ and $\phi_u^{(n)}(x)$ are obtained. On the other hand, the instantaneous velocity $u(x,t)$ is presented as the summation of Eigenfunctions $\phi_u^{(n)}(x)$ with corresponding amplitudes $\alpha_u^{(n)}$.

$$u(x,t) = \sum_{n=1}^{\infty} a_u^{(n)}(t)\phi_u^{(n)}(x) \tag{4}$$

Because of the orthogonal expansion, the coefficient $a_u^{(n)}$ can be presented as follows;

$$a_u^{(n)}(t) = \int u(x,t)\phi_u^{(n)}(x)dx \tag{5}$$

As for Eigenfunction $\phi_u^{(n)}(x)$,

$$\int \phi_u^{(n)}(x)\phi_u^{(m)}(x)dx = \delta_{nm} \tag{6}$$

On the other hand, $R_{uu}(x,x')$ corresponds to the summation of Eigenfunctions.

$$R_{uu}(x,x') = \sum_{n=1}^{\infty} \lambda_u^{(n)} \phi_u^{(n)}(x)\phi_u^{(n)}(x') \tag{7}$$

Therefore, from the relation of equations (2),(5) and (6), the following equation is obtained.

$$\left\langle a_u^{(n)} a_u^{(m)} \right\rangle = \lambda_u^{(m)} \delta_{nm} \tag{8}$$

By means of the above relations, the ensemble averaged squared velocity of signal u is obtained as the summation of Eigenvalues:

$$\left\langle u^2(x,t) \right\rangle = \sum_{n=1}^{\infty} \lambda_u^{(n)} \left\{\phi_u^{(n)}(x)\right\}^2 \tag{9}$$

$$E_u = \int \left\langle u^2(x,t) \right\rangle dx = \sum_{n=1}^{\infty} \lambda_u^{(n)} \tag{10}$$

where E_u is the turbulent kinetic energy. Therefore, the maximum Eigenvalue corresponds to the maximum energy. Lumley (1981) mentioned that Eigenfunctions with the maximum, the 2nd or 3rd largest Eigenvalue are dominant in their contribution to the turbulent kinetic energy. It is implicitly assumed that large-energy flow structures can be associated with the large-amplitude Eigenfunctions.

In addition to the POD analysis, a space-time correlation analysis is applied in order to see how this technique can be used to estimate the advection of flow structures. For example, the space-time cross-correlation C_{uw} of stream- and span-wise velocities (u,w) is defined as follows;

$$C_{uw}(x,\Delta x;z,\Delta z,t,\tau) = \frac{\overline{u(x,z,t)w(x+\Delta x,z+\Delta z,t+\tau)}}{u'(x,z,t)w'(x+\Delta x,z+\Delta z,t+\tau)} \tag{11}$$

where, x and z are the fixed points, defined near the tip of the groyne in this study. Δx and Δz are distances between 2 separated points, t and τ are the time and the delay time, respectively.

4 RESULTS AND DISCUSSIONS

4.1 *Mean flow profiles*

Figures 4(a) and 4(b) show the mean vector fields for the emerged and submerged conditions, respectively. In addition, Figures 5(a) and 5(b) also show the streamlines corresponding to Figure 4. Obviously the mean flow patterns as observed at the free surface are completely different. The confinement of the cross-sectional area results for both cases in an increased velocity in the main stream, whereas in the submerged case the flow over the groyne attains a high velocity. The latter rapidly disappears as a result of flow separation in the vertical plane and associated vertical velocities. These three-dimensional effects make the interpretation of the flow pattern for the submerged case difficult. The emerged groyne induces a virtually

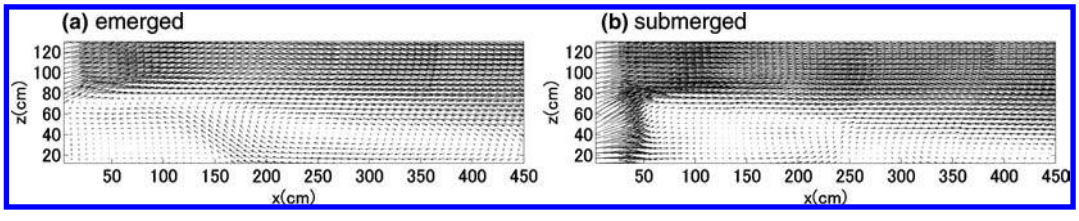

Figure 4. Mean vector profiles (U,W).

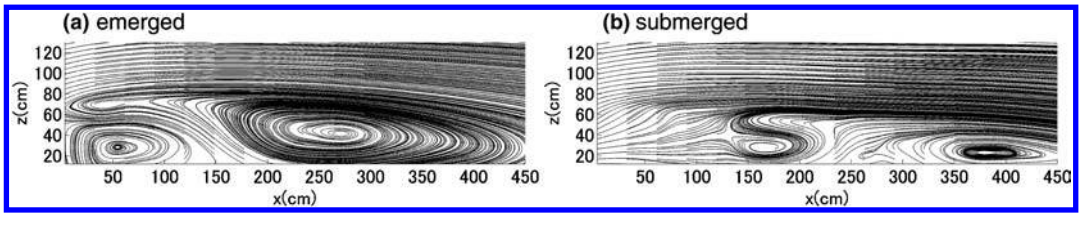

Figure 5. Streamlines.

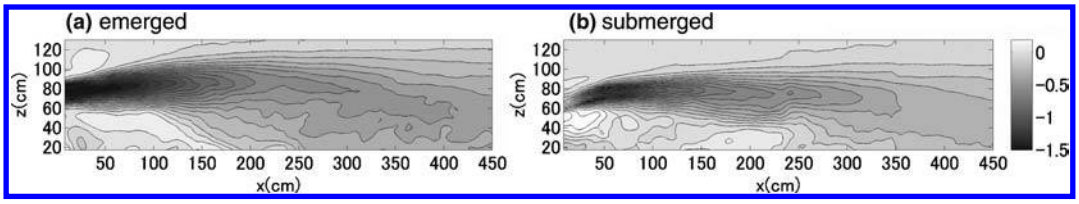

Figure 6. Mean vorticity.

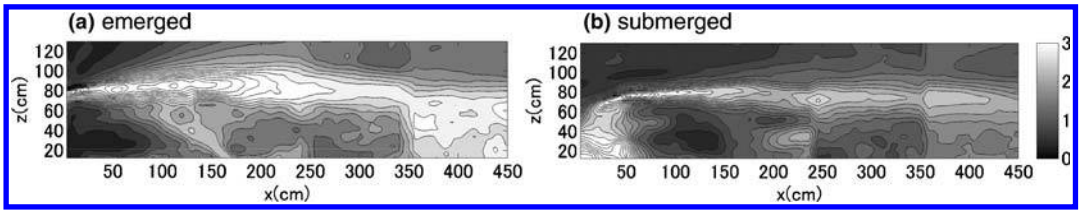

Figure 7. Stream-wise component of turbulence intensity u_{rms}(cm/sec).

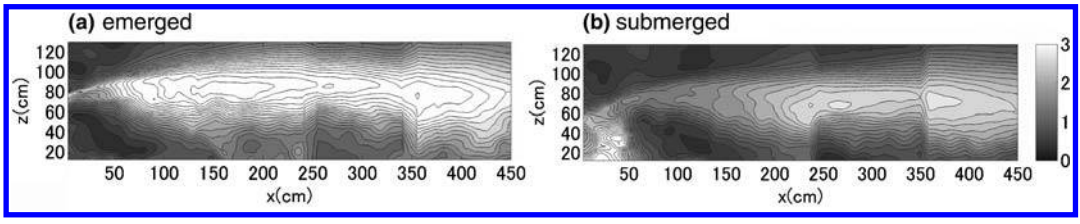

Figure 8. Span-wise component of turbulence intensity w_{rms}(cm/sec).

two-dimensional circulation pattern with the main primary gyre rotating in the clockwise direction. The much smaller secondary gyre receives its momentum from the primary gyre and rotates therefore anti-clockwise. At the location where the secondary gyre touches the main stream a narrow shear layer is found bridging a high velocity difference. Observation of the submerged case reveals 2 m downstream of the groyne the flow has become rather uniform over the vertical resulting in a small but also weak clockwise gyre. The complex streamlines seen in figure 5(b) in the range $x = 1.5$–2.0 m are due to three-dimensional time varying patterns.

It looks as through the overall disturbance of the main flow pattern due to the groyne is much smaller in the submerged case. In view of bank and bed protection the submerged groyne gives rise to small velocities near the bank except for the overflow location at the root of the groyne. Furthermore the three dimensional effects in the first two meters downstream are expected to have consequences for the stability of the bed. These effects could as well be responsible for the relatively low bed level just downstream of the groyne, as seen in photo 2.

Figures 6(a) and 6(b) show the contours of mean vorticity for the emerged and submerged conditions, respectively. In accordance with the vector field and streamlines, the large vorticity is concentrated in the shear layer downstream of the groyne tip following the contour of the interface with the stagnant zone. The emerged case exhibits a relatively wide area containing strong vorticity, reflecting the large portion of water that is substantially deflected by the groyne.

Regarding the turbulence properties, turbulence intensities in stream-wise and span-wise directions (u_{rms}, w_{rms}), and Reynolds stress profiles ($-\overline{uw}$) are shown in Figures 7, 8 and 9, respectively. As seen in these figures, the area most affected by turbulent fluctuations is the mixing layer where the horizontal shear is the source from which large-scale fluctuations emerge.

The area of streamwise fluctuations is narrow when compared with the spanwise fluctuations for both cases. Maximum values are found farther downstream in the submerged case, clearly at the location where the main gyre starts developing. As for $x < 2.5$ m, the horizontal motion is affected more by the small-scale three-dimensional turbulence. In the 0.5 m just downstream of the submerged groyne the turbulence intensities are enhanced as a result of the vertically separated flow.

The maximum momentum transfer (maximum Reynolds stress) is found in the mixing layer at 2 m downstream of the separation point at the location

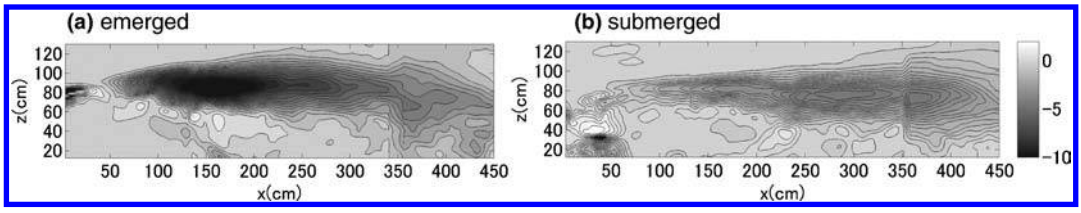

Figure 9. Reynolds stress $-\overline{uw}(\mathrm{cm}^2/\mathrm{sec}^2)$.

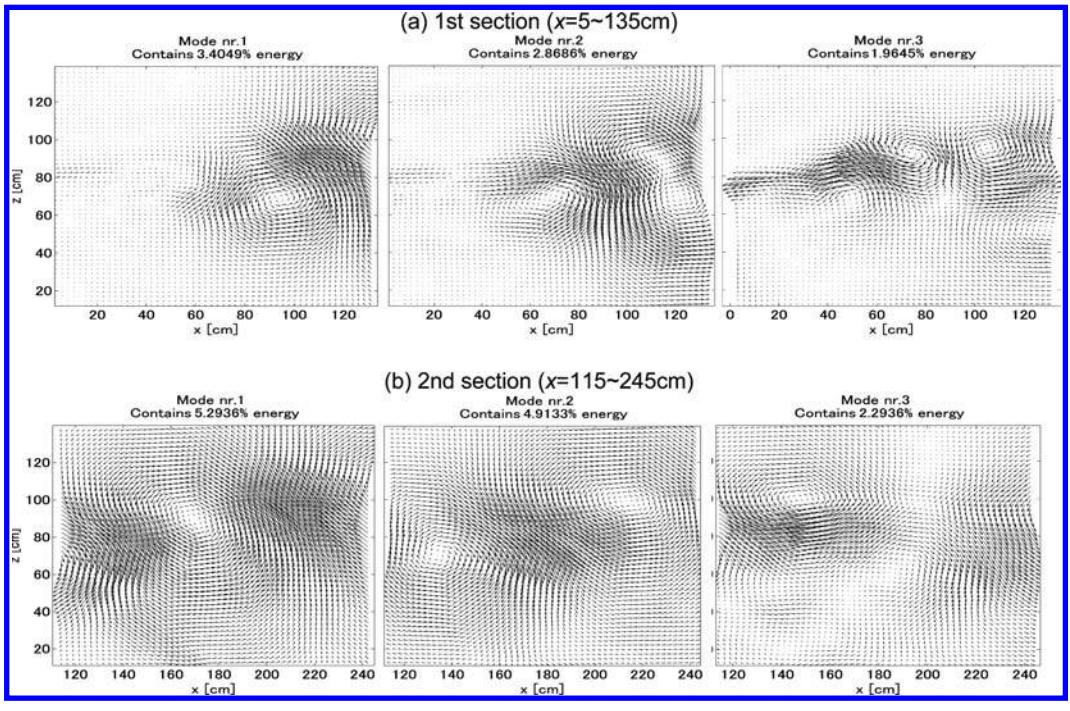

Figure 10. POD-decomposed flow-patterns under emerged condition.

where the primary gyre is in touch with the mixing layer. Apparently the high shear velocity and high vorticity as found close to the separation point do not result in an efficient transfer of momentum. The mixing length scale needed for that is found farther downstream. This holds for both the submerged and emerged cases.

4.2 *Coherent flow structures*

Figures 10(a) and 10(b) show the decomposed patterns under emerged conditions by using the POD method for the 1st capturing section ($x = 5 \sim 135$ cm) and the 2nd capturing section ($x = 115 \sim 245$ cm), respectively. Each figure is arranged with respect to the energy level of the mode number (up to 3). The decomposed pattern with the 1st mode can be interpreted as typical fluctuating pattern with the most energy content. As seen in the POD decomposed pattern of Figure 10, one typical pattern of circulating fluctuation is dominant with a relatively large scale along the high shear layer with highest energy (mode 1). This pattern indicates a kind of typical fluctuation in the region of high turbulence intensities as seen in Figures 7(a) and 8(a). These decomposed patterns reveal typical fluctuations that can not be seen in *rms* profiles. As for modes 2 and 3, the decomposed patterns are smaller than mode 1 and two or more typical fluctuation patterns are detected. In the 2nd section of Figure 10(b), the decomposed pattern with highest energy grows to larger scales up to a doubling of the pattern size when compared with all modes of Figure 10(a). It can be considered that the fluctuation pattern around this area expands in horizontal direction with the development of the shear layer.

Figures 11(a) and 11(b) also show the typical fluctuation pattern under submerged conditions which are

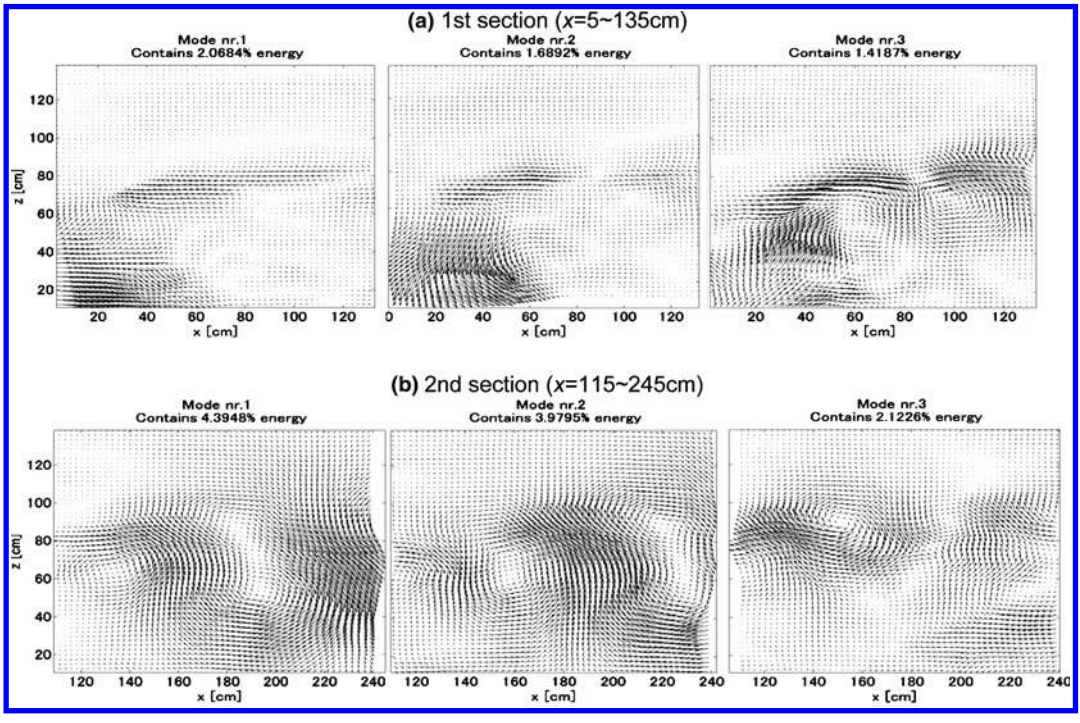

Figure 11. POD-decomposed flow-patterns under submerged condition.

decomposed by using the POD method similar as with Figure 10. As seen in Figure 11(a), two separate patterns near groyne are dominant and show the highest energy content (mode 1). In this region, high values of turbulence intensities are located near the tip of groyne and in the stagnant zone independently, as seen in Figures 7(b) and 8(b) and they are corresponding to the decomposed patterns. As for Figure 11(b) of the 2nd section, two of those typical fluctuating patterns are also seen in mode 2 and 3 but these are located slightly nearer to the right side of channel, which corresponds also to the region of high turbulence intensity. In addition, these patterns are located in the far field downstream of the groyne and shifted downstream due to the flow over the groyne showing the difference with emerged condition.

Consequently, a detailed fluctuating pattern can be revealed by means of POD analysis that is not possible to understand from mean profiles such as turbulence intensities (u_{rms}, w_{rms}).

An alternative way to analyze the large scale motion in the flow is displayed in Figures 12(a) and 12(b) where the contours are shown for the space-time correlation *Cuu* in the first capturing section ($x = 3 \sim 131$ cm), in accordance with Equation (11) for emerged and submerged conditions. The 2D autocorrelation function of the u-velocities is discussed in this section because it is expected that the conditions at the separation point will have a dominant effect on the downstream flow pattern. Therefore, the fixed point (indicated as dotted point in these figures) for the space-time correlation C*uu* is defined at neighborhood of groyne tip (i.e., $x_{fix} = 24.9$ cm, $y_{fix} = 67.9$ cm) for both conditions. The delay time τ is shown above each figure. It can be seen that the streamwise fluctuations at the fixed point are positively correlated to the main stream (white blob) and negatively with the stagnant zone (black).

The large correlation areas are advected downstream whereas, for the emerged case a lateral displacement is seen for especially the positively correlated area. It appear that the more uniform advection is found for the submergence on the groyne. These properties are corresponding to the near field pattern as seen in Figures 5.

Figures 13(a) and 13(b) show the contours of space-time correlation *Cuw* in the second capturing section ($x = 114 \sim 242$ cm) for the emerged and submerged conditions, respectively. The cross correlation between u-velocities at the fixed point and w-velocities at the distant point are discussed in this section because it is considered that the dominant stream-wise flow generated upstream from the groyne is entrained into span-wise direction through the shear layer. Therefore, the fixed point in this section is defined in the mixing layer (i.e., $x_{fix} = 136.0$ cm, $y_{fix} = 67.9$ cm).

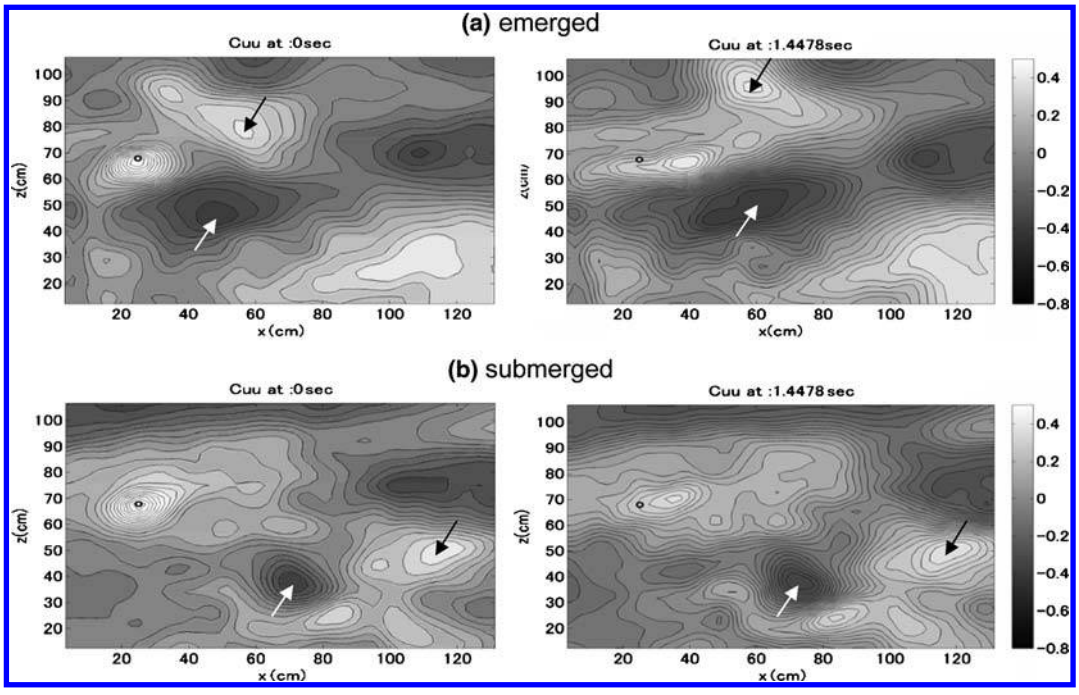

Figure 12. Space-time correlation *Cuu* in 1st capturing section ($x = 3 \sim 131$ cm).

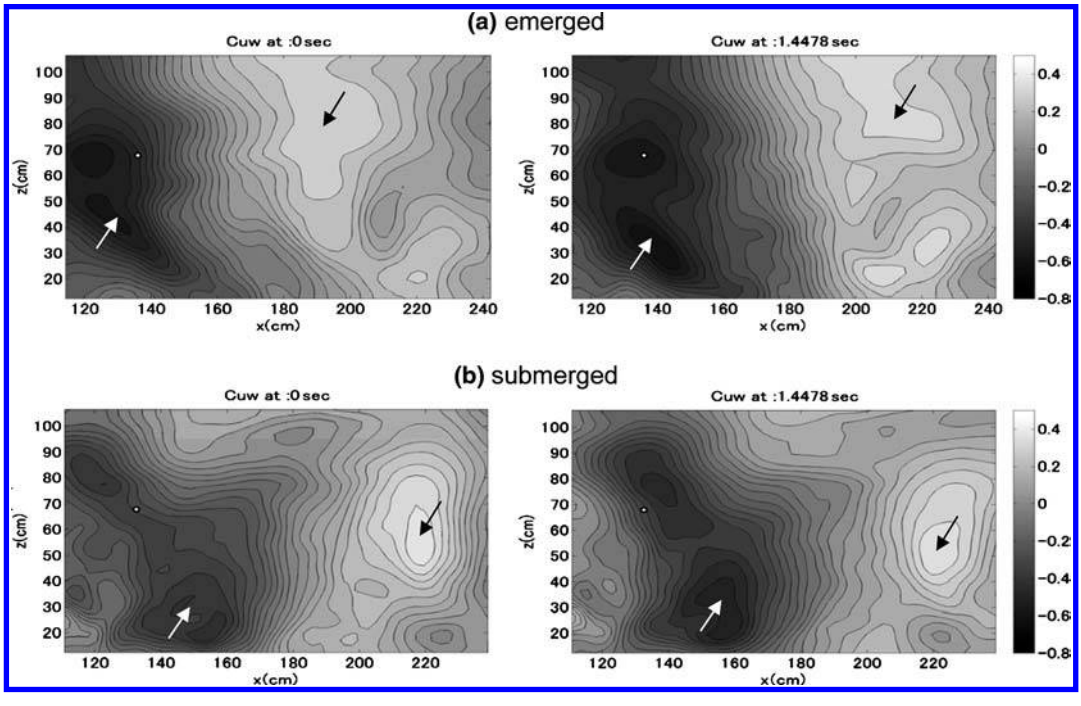

Figure 13. Space-time correlation *Cuw* in 2nd capturing section ($x = 114 \sim 242$ cm).

The negative correlation is found on the left side of the graphs whereas the positive correlation is found on the right hand side. It shows the typical distance over which the lateral velocity component changes sign thereby indicating the size of the coherent structure that contributes to the momentum transfer by the mixing layer.

5 CONCLUSIONS

In the present study, it is described that the groyne in Japan plays an important role for controlling the flow, navigation and protecting river bank. Due to big amounts of sudden rainfall, the groynes are often subjected to submerged and emerged flow conditions.

By taking account of such conditions, the effects of submergence and emergence on the mean flow and coherent flow structures around single groyne were experimentally investigated.

In order to analyze the flow pattern around the single groyne, a scaled and schematized model was implemented and experiments were conducted by means of surface flow visualization technique and Particle Tracking Velocimetry (PTV). For the PTV velocity determination an algorithm was implemented with a flexible search range making use of both FFT and Direct Correlation methods.

Furthermore, differences between submerged and emerged cases are discussed. The results show the difference in location where the main flow characteristics are seen in profiles of mean statistics, POD and space-time correlation for emerged and submerged flows. The most important differences are found in the area downstream of the groyne. The submerged case shows a clear separation zone in the vertical plane whereas the circulation associated with the emerged case lies predominantly in the horizontal plane. Further downstream the overall flow pattern looks quasi two dimensional with a clear circulation in the horizontal plane. The disturbance due to the submerged groyne appears much smaller than that due to the emerged groyne. Apart from the direct neighborhood of the groyne the submerged groyne is sufficiently shielding the bank from the high-velocity main stream.

The results of the POD and the spatial correlation analyses are clearly seen for the fluctuating pattern and large-scale motion, respectively. However, they are not effective answers so far. A further analysis is required. This includes also other techniques like conditional averaging and spectral analysis. The successful application of the PTV-technique has resulted in a dataset that is very useful for such analyses.

ACKNOWLEDGEMENT

The present study is a joint project with the Environmental Fluid Mechanics Section, Delft University of Technology, Netherlands, and was supported by Ehime University Fellowship 2005. The authors would like to give great appreciation to Profs H. Nakagawa and I. Nezu who recommended for study at Delft University. The staff members of the Institute for Hydromechanics at Karlsruhe University in Germany, are gratefully acknowledged for their hospitality.

Diverse riverbed figuration by using skew spur-dike groups

A. Tominaga

Graduate student, Nagoya Institute of Technology, Nagoya, Japan

ABSTRACT: Continuous spur dikes were often used to create diverse riverbed configuration with riffles and pools. In order to control sediment transport by using spur dikes, the effects of orientation were investigated. A spur-dike group was composed of three submerged spur dikes. Those spur-dike groups were set on both sidewalls alternately and the velocity distributions were measured. Then the flow structures were calculated by using a simple 3-D numerical model. The overriding flow on a spur dike was deflected to the direction normal to the spur-dike longitudinal line. In upstream-skew spur-dike groups, large scour holes were observed in front-edge regions of spur dikes and deposition regions were formed beside the sidewalls. In downstream-skew spur-dike groups, front regions of spur dikes and sidewall regions were largely scoured. In a range of the present experiments, the upstream-skew spur-dike group can produce the most dynamically varied bed formation. On the other hand, the downstream-skew spur-dike group tends to erode the sidewall region. These bed configurations were well related with the characteristic 3-D flow structures around submerged spur dikes.

1 INTRODUCTION

Spur dikes are often used for protecting levee from erosion during flood in middle and lower reaches of alluvial rivers. On the other hand, they provide diversity of flow to ecological surroundings by creating riverbed configurations with riffles and pools. In order to design adequate installation of spur dikes for this purpose, it is necessary to predict and control the flow structures and sediment transport around spur dikes. Several researchers have studied resistance characteristics such as the roughness and the deflection effects of submerged spur-dikes (e.g. Gill 1972, Klingeman et al. 1984, Fukuoka et al. 1998). In some cases, detailed flow structures around spur dikes around spur dikes were made clear on fixed bed (e.g. Rajaratnam and Nwachukwu 1983, Chen and Ikeda 1996). In cases of movable bed, research interests were concentrated on characteristics of local scour around spur dikes (e.g. Elawady et al. 2001 and Rahman and Muramoto 1997). Three-dimensional flow structures around submerged spur dikes have been clarified in regard to the relative height and the orientation angle (e.g. Elawady et al. 2000 and Tominaga et al. 2003). However, there are few examples evaluating the functions of spur dikes for providing diverse riverbed configuration.

Numerical simulations have become a powerful tool for predicting flow structures and sediment transport around spur dikes with complex design items (Kimura et al. 2002, Zhang et al. 2005). It is necessary to accumulate experimental data for developing numerical models that can predict three-dimensional flow structures and bed deformation.

We have studied flow structures over submerged spur dikes with different orientation by using PIV method (Tominaga and Tamoto 2003). We found that the orientation of submerged spur dike changes flow structures extremely and affect on sediment transport around them.

In this study, the flow structures and bed deformation were investigated in open channels with continuous spur-dike groups used to create diverse riverbed configurations. We concentrated on the effects of orientation on the riverbed configuration. A three-dimensional numerical model was adopted to predict such complex flow structures.

2 EXPERIMENTAL PROCEDURE

The experiments were conducted in a 13 m long and 0.6 m wide rectangular flume. As the method of creating diversity in straight open channels, a spur-dike group was composed of three submerged spur dikes and those spur-dike groups were set on both sidewalls alternately. The placements of spur dikes are shown in

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 1. The projection length, the interval length of each spur dike and the interval length of each group were uniformly set. The spur-dike model was made of 18 mm thick plywood. The distance between spur dikes was 22.5 cm and the angle of skew spur dikes was 45° to the streamwise direction. The projection length of the spur dike was arranged to 15 cm in all cases as shown in Figure 1. The height of the spur dike was 4 cm. The first spur dike was located at 5.8 m downstream from the entrance and the origin of stream wise axis was set at the upstream root of the first spur dike. The distance between alternate groups was 75 cm, and the fronts of spur-dike groups were located at $x = 0$ cm and 150 cm along the right bank and at $x = 75$ cm and 225 cm along the left bank. The experiments for a single group setting were preliminarily performed to clarify basic characteristics of bed deformation related to the orientation. The present placements of spur-dike groups were arranged based on the scour pattern in the case of single-group experiments.

The hydraulic conditions of experiments are shown in Table 1. In all cases, the discharge Q was 0.0125 m^3/s and the water depth h was adjusted to 8 cm at the section 4.5 m downstream from the channel entrance by controlling the downstream weir. As to the coordinates, x is the streamwise direction, y is the cross-stream direction and z is the vertical direction. Two components of the velocity (u and v) were measured by using an I-type electromagnetic velocimeter.

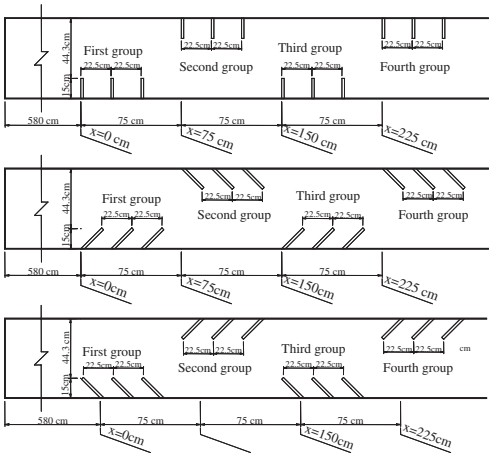

Figure 1. Placements of spur dike groups (Upper: Case A, normal spur dike, Middle: Case B, downstream-skew spur dike, Lower: Case C, upstream-skew spur dike).

Experiments were conducted in fixed and movable bed conditions. In cases of movable bed conditions, sand grains of 0.4 mm mean diameter were paved on the bed with 110 mm thickness from 4.5 m to 10.5 m in the streamwise direction. Sand feeding was not made because the moving bed conditions were static. After 1 hour from the flow start, bed configurations were measured by using a bed form visualizing equipment. At this moment, the bed deformation was not completely established, but it was recognized as almost stable state. The velocity was measured on this deformed bed, which was solidified by using cement.

3 NUMERICAL SIMULATION METHOD

The flow over a submerged spur dike becomes three-dimensional situation dominated by steep local currents. In practical sense, it is meaningful to consider a possibility for predicting fundamental flow structures by a low-order turbulence model. In this study, the streamwise component of the following Reynolds equation and continuity equation were solved numerically by using a zero-equation turbulence model.

$$\frac{\partial U_i}{\partial t} + \frac{\partial U_i U_j}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \frac{1}{\rho}\frac{\partial \tau_{ij}}{\partial x_j} \tag{1}$$

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{2}$$

where U_i is the mean velocities, p is the pressure and ρ is the water density. τ_{ij} is the Reynolds stress components and these are expressed by an eddy viscosity model.

$$\frac{\tau_{ij}}{\rho} = \nu_t\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) \tag{3}$$

where ν_t is the eddy viscosity. This eddy viscosity is given as follows, by assuming the log-law and linear distribution of the shear stress.

$$\begin{aligned} 0 \le \frac{z}{h} \le 0.8 \quad &: \quad \nu_t = \kappa u_* z\left(1 - \frac{z}{h}\right) \\ 0.8 \le \frac{z}{h} \quad &: \quad \nu_t = 0.16\kappa u_* h \end{aligned} \tag{4}$$

Table 1. Experimental conditions.

Discharge Q (lit/s)	Flow depth h(cm)	Channel width B(cm)	Energy gradient Ie	Mean velocity U_m(cm/s)	Froude number Fr	Reynolds number Re
12.5	8.0	59.3	0.00038	23.4	0.265	14400

where u_* is the friction velocity, h is the water depth and κ is the Karman constant ($\kappa = 0.41$).

The equations are discretized by a finite volume method with hybrid scheme and solved by the SIMPLE algorithm. The numbers of calculation grids are 206 in x-direction, 33 in y-direction and 21 in z-direction. The minimum grid lengths are $\Delta x = 5$ mm, $\Delta y = 10$ mm and $\Delta z = 4$ mm near the wall. A block masking method for a rectangular coordinate system is used to express spur dikes. As to the boundary conditions, the near-wall velocity is assumed to comply with the log-law that covers rough boundaries. The water depth h is modified according to the pressure p at a free surface control volume and the vertical coordinate z is rearranged dividing the water depth h proportionally. A water depth is fixed at the downstream end and a constant discharge is given at the upstream end. The water depth change was approximately 4 mm in the longitudinal direction.

4 FLOW STRUCTURES AROUND SPUR-DIKE GROUPS ON FIXED BED

The effects of spur-dike orientation were considered by measuring velocity distributions on fixed bed and comparing them with calculated ones. Figures 2 and 3 show velocity vectors on x-y plains of $z = 1.5$ cm and 6.5 cm in the normal case comparing the measured values with calculated ones. The calculated velocity vectors show good agreements with the measured ones on the plain of $z = 1.5$ cm even though the simple numerical model was used. Spur dikes generate the flow deflection and make the main flow meander slightly. The flow between spur dikes forms circulating motion. Separated zones behind spur-dike groups were remarkably narrowed compared with the single-group case. On the plain of $z = 6.5$ cm, the calculation also shows good reproducibility in accelerating and decelerating processes over spur dikes. A mild meandering is seen in these figures.

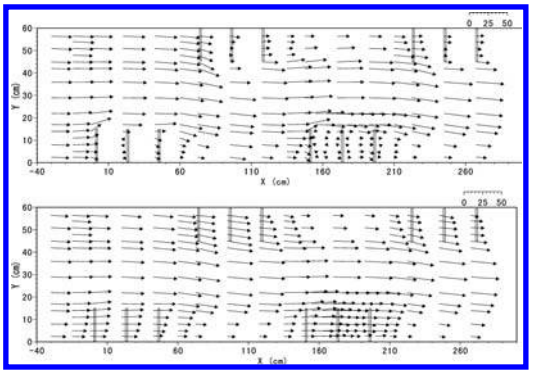

Figure 2. Measured velocity vectors in normal case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

Figures 4 and 5 show velocity vectors on x-y plains in the upstream-skew case. Though the skew spur dike was expressed by rectangular grids, the calculated values well reproduce the characteristics of experimental results. On the plain of $z = 1.5$ cm, a deceleration in

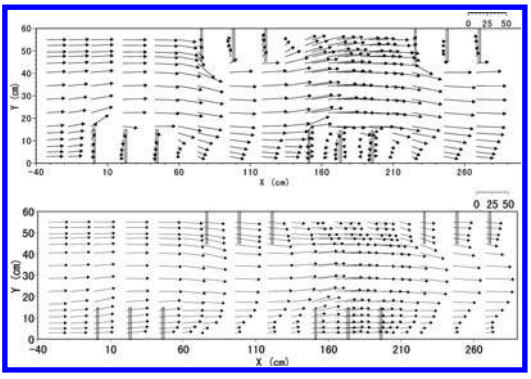

Figure 3. Calculated velocity vectors in normal case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

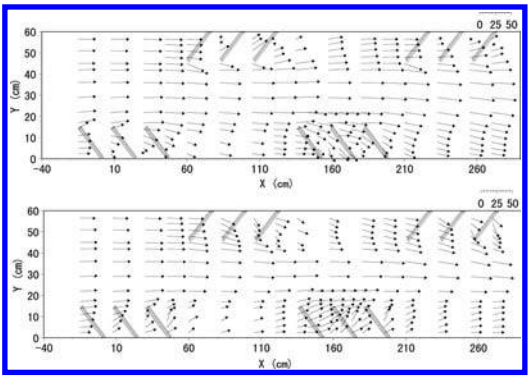

Figure 4. Measured velocity vectors in upstream-skew case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

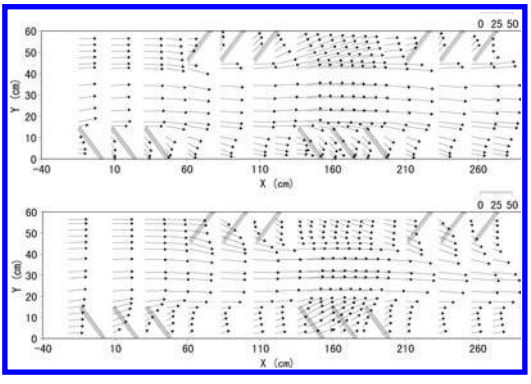

Figure 5. Calculated velocity vectors in upstream-skew case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

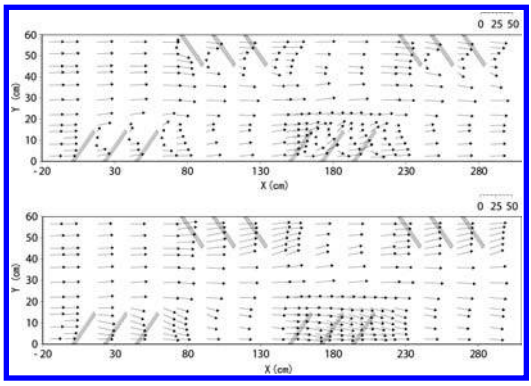

Figure 6. Measured velocity vectors in downstream-skew case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

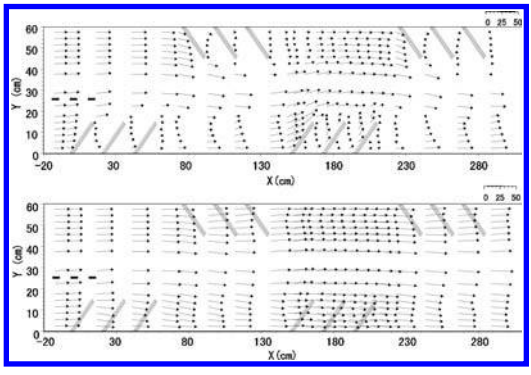

Figure 7. Calculated velocity vectors in downstream-skew case (Upper: $z = 1.5$ cm, Lower: $z = 6.5$ cm).

front of spur dikes was remarkable and the flow was angled toward the sidewall along the skew spur dike. As a result, the separated circulation does not appear and the flow toward the sidewall becomes significant in the interval zone behind the spur-dike group. On the contrary, the flow is deflected toward the center over the spur-dike group on the plain of $z = 6.5$ cm. This deflecting flow pattern is well reproduced by the present calculation. The primary velocity is decreased but the lateral velocity is not so varied through the process of going over the spur-dike group. Therefore, the angle of the velocity vector to the streamwise direction becomes larger on the last spur dike than on the head one. The flow toward the center maintains in the interval area between spur-dike groups. The flow in the sidewall region within the top line of spur-dike groups is decelerated uniformly and the velocity in the center region becomes relatively larger.

Figures 6 and 7 show velocity vectors on x-y plains in the downstream-skew case. The calculated values reasonably reproduce the characteristics of experimental results as well as the other cases. On the plain of

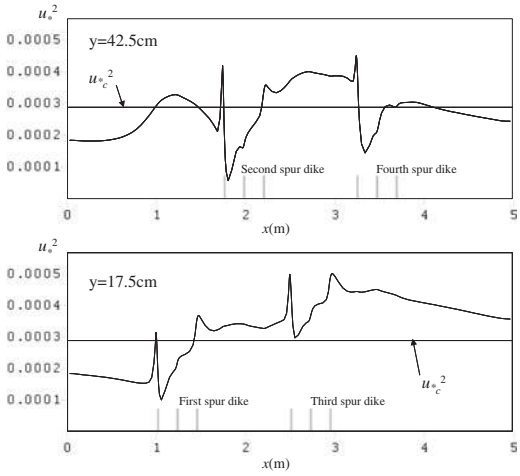

Figure 8. Streamwise distributions of calculated bed shear stress in normal case (Upper: $y = 42.5$ cm, Lower: $y = 17.5$ cm).

$z = 1.5$ cm, a deceleration at the top of a spur dike was remarkable but the flow near the spur-dike root is not so decelerated. The flow is angled toward the center in zones behind spur-dike groups. As a result, high-speed flows appear at both the sidewall and the center region. The calculated result shows a good agreement in the center region and the interval region of the sidewall, but the velocity inside the spur-dike group is underestimated. On the plain of $z = 6.5$ cm, the flow is angled toward the sidewall through the process of going over the spur-dike group. However, the velocity on the spur-dike group is rather accelerated in contrast to the upstream-skew case. The flow toward the sidewall remains in the interval region between spur-dike groups. As a whole, the main flow is distributed to the sidewalls and the velocity redistribution becomes uniform in the lateral direction. This outward deflected and uniformly distributed flow pattern is well reproduced by the present calculation.

Next, we consider the bed shear stress distributions on the fixed bed in order to predict the bed deformation by using the calculated results. Figures 8–10 show streamwise distributions of the bed shear stress divided by the density (square of the friction velocity) along the lines of 2.5 cm away from the top of a spur dike lines. The critical friction velocity, u_{*c}^2, corresponding to the sand used in the movable-bed experiment is indicated in this figure. The bed shear stress increases near the top of a spur dike. This may be a trigger of a scour around the top of a spur dike. Behind the head spur dike, it decreases rapidly especially in the normal and the downstream-skew cases. As to the effects of middle and last spur dikes, the bed shear stress increases at the top of a spur

Copyright © 2006 Taylor & Francis Group plc, London, UK

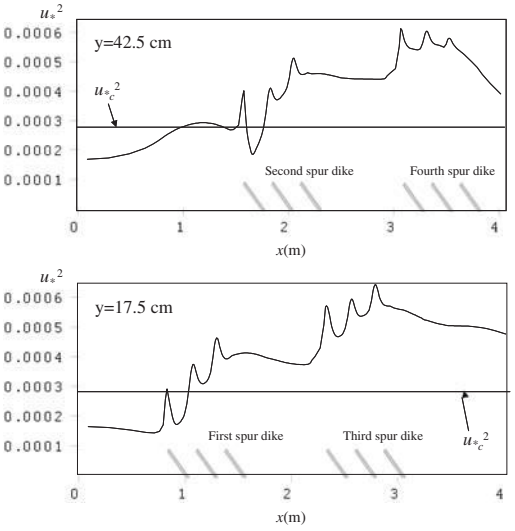

Figure 9. Streamwise distributions of calculated bed shear stress in upstream-skew case (Upper: $y = 42.5$ cm, Lower: $y = 17.5$ cm).

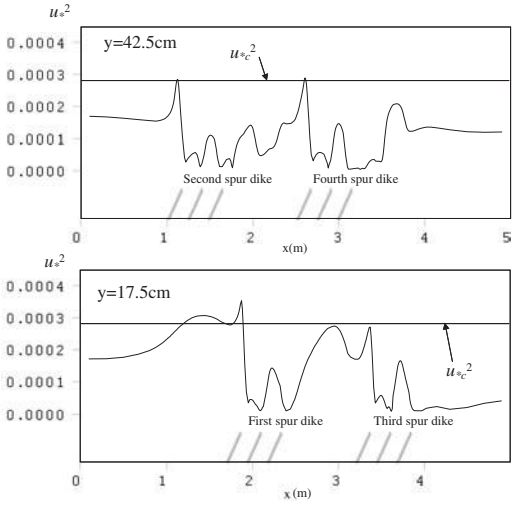

Figure 10. Streamwise distributions of calculated bed shear stress in downstream-skew case (Upper: $y = 42.5$ cm, Lower: $y = 17.5$ cm).

dike in the normal and upstream-skew cases. The second peak does not appear and the third peek comes near the first peek in the normal case. Three peeks appear increasingly from the first to the third in the upstream-skew case. Reversely, the bed shear stress decreases at the top of a spur dike and increases behind it in the downstream-skew case. The average shear stress remarkably decreases behind the head spur dike and increases behind the last spur dike in this case. The bed shear stress increases incrementally from the first group to the third in the normal and upstream-skew cases. The increasing rate is larger in the upstream-skew case since the main flow is accelerated due to the concentration of the main flow to the center region. While it decreases so much behind the head spur dike of the fourth group in the normal case, it does not so decrease in the upstream-skew case. Since the bed shear stress exceed the critical tractive force downstream from the first group, a local increase or decrease of the bed shear stress are related to the scour and the deposition in a movable bed. In the downstream-skew case, the maximum bed shear stress in front of the head spur dike does not change in the downstream direction and it does not exceed the critical tractive force. So, bed deformations are not expected along these lines in this case. However, they are not directly linked to the bed formation because the sand-feeding rate from the upstream side is different by location.

5 BED DEFORMATION BY SPUR-DIKE GROUPS

At first, we compare the effects of the spur-dike orientation on bed deformation for single group setting. Figure 11 shows the photographs of the bed configurations for three cases of orientation. The deference of the scour pattern is remarkable responding to the orientation. There is a deep scour at the top and deposition at the root of a spur dike in the upstream-skew case. On the contrary, there is a scour at the root and deposition at the top in the downstream-skew case. In the normal case, the bed form shows intermediate pattern.

Figure 12 shows the contours of the bed elevation for the single placement cases. As to the scour around the head spur dike of the normal case, a deep scour hole is produced centering on the top and is followed by a scour along the spur dike. Scours around the middle and last spur dikes become smaller at the top. In the interval region between spur dikes, front scours are not observed but small depositions appear in a central area. Scour holes propagate with undulation to the opposite bank at the angle of about 20°. The deposition line is observed behind this scour line in parallel.

In the upstream-skew case, a circular scour hole is generated centering on the top of the head spur dike. This scour is deepest and widest among three cases. The scour at the top area becomes smaller toward the middle and the last spur dike. Of particular significance is that a remarkable deposition occurs at a root region. This deposition height becomes larger toward downstream and exceeds the crest height at the last spur dike. The propagation angle of scour holes is about 17° that is smaller than the normal case. Deposition line starts from the root of the last spur dike parallel to the scour line.

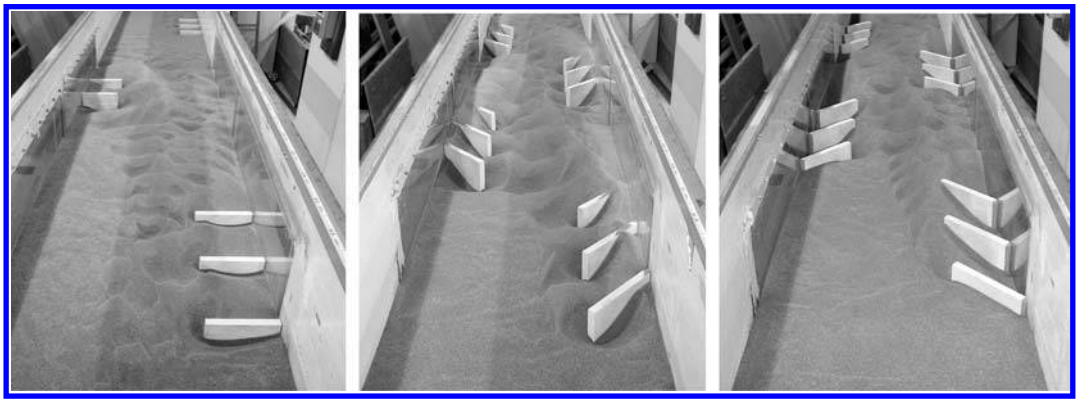

Figure 11. Photograph of bed configuration (Left: normal case, Middle: upstream-skew case, Right: downstream-skew case).

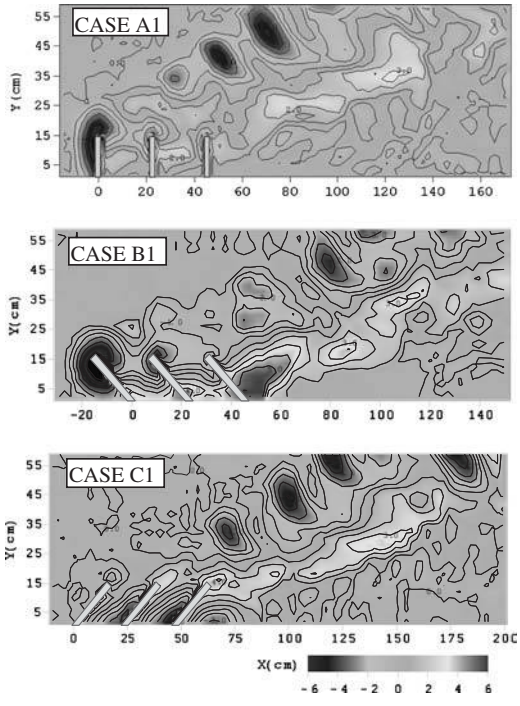

Figure 12. Contours of bed elevation of single placement (Upper: normal case, Middle: upstream-skew case, Lower: downstream-skew-case).

In the downstream-skew case, there is no scour in front of the head spur dike but a small scour hole is observed at the tip of the head spur dike. However, deep scour holes appear centering on the root of the middle and the last spur dike. It is likely to deposit at the top of the middle and the last spur dike and a small deposition line follows downstream skewing toward the opposite side. The scour propagation is also observed upstream of this deposition line.

The observed bed configurations in the spur dike region are well connected to the flow structures obtained by the PIV experiments (Tamoto et al. 2003). Figures 13 and 14 show their results of velocity vectors in the upstream- and downstream-skew spur dike. The most important feature is that flow direction passing over a spur dike becomes perpendicular to a spur-dike orientation. In the upstream-skew case, the center-oriented overflow comes down at the top of the second spur dike. This causes a strong downflow in the top region (right of Fig. 13). Then a strong inward flow is created near the bed (left of Fig. 13). Lastly, a backward upflow occurs in the root region (middle of Fig. 13). This flow sequence brings sands toward the sidewall and blowing up near the sidewall makes a large deposition behind the root of a spur dike.

In the downstream-skew case, the sidewall-oriented overflow comes down at the root of the second spur dike. This causes a strong downflow in the root region (middle of Fig. 14). Then a strong outward flow is created near the bed (left of Figure 14). Since the flow is strongly deflected by the first spur dike, the flow running through the top of the second spur dike becomes weak. In the top region, a small downflow is observed (right of Fig. 14). This flow structure makes a deep scour in front of a spur dike. It brings sands outward and may make small deposition at the top region.

By combining three spur dikes as a group structure, these effects of orientation are likely to be strengthened. The distance between the first group and the second group was determined to adjust the head of the second group to the center of scour hole at the opposite sidewall in the normal case. In the skew cases, this position is shifted downstream, but we did not change this distance for comparison.

Figure 15 shows the contours of bed elevation for the cases of four-groups setting. The characteristics of scour and deposition around the first group are almost similar to the single-placement case reflecting the effects of the orientation of spur dikes. However,

Copyright © 2006 Taylor & Francis Group plc, London, UK

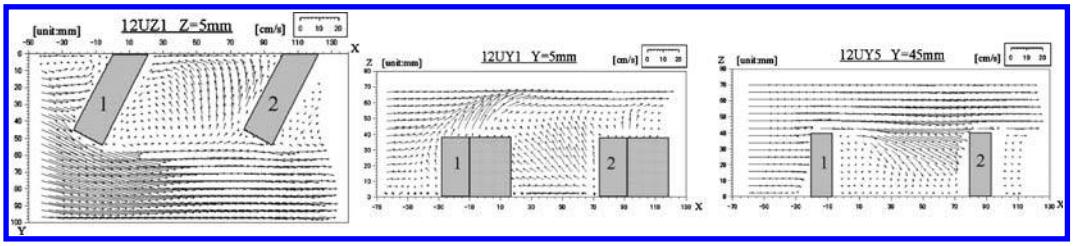

Figure 13. Velocity vectors in horizontal and vertical plains in upstream-skew case by Tamoto et al. 2003 (left: horizontal plain near the bed, middle: vertical plain near the sidewall, right: vertical plain near the top line of spur dikes).

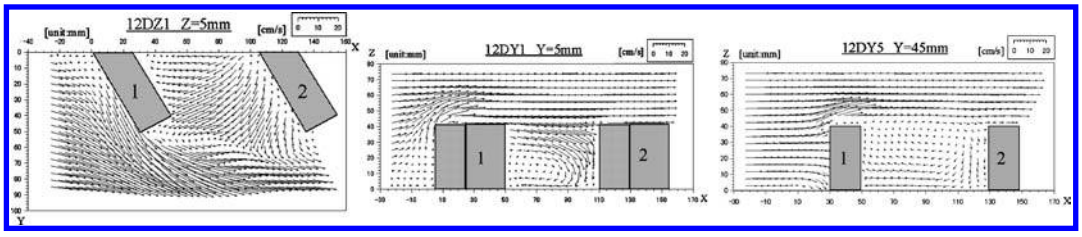

Figure 14. Velocity vectors in horizontal and vertical plains in downstream-skew case by Tamoto et al. 2003 (left: horizontal plain near the bed, middle: vertical plain near the sidewall, right: vertical plain near the top line of spur dikes).

the scour around the head spur dike is reduced and the following deposition area is narrowed in all cases. This reduction of bed deformation around the first group of alternate placement may be caused by the change of bed shear stress distribution from the single placement case.

In the normal case, the scour-hole propagation from the head of the first group reaches just at the head spur dike of the second group. This condition makes the maximum scour depth at this region. The similar scour holes are generated at the head spur dikes of the third and fourth group but the scour propagation does not appear along the line connecting head spur dikes. At the middle and the last spur dikes in a group structure, scour holes are small in all the groups. In the center region of this case, the scour and deposition are cancelled out and bed the deformation tends to be underdeveloped.

In the upstream-skew case, deep scour holes occur at the top of spur dikes from the second to the fourth group. Deep scour regions are generated along the top line from the head to the last spur dike. The scour propagation line observed in the single-group case shown in Figure 12 does not match the head scour of the second group. Therefore, the scour propagation line is pushed away from the opposite side to the center and it forms small scour area along the centerline of the channel. High deposition regions are widely produced spreading from the root of the last spur dike toward the center. In this way, the upstream-skew spur-dike groups can make dynamic riverbed deformation with riffle and pool.

In the downstream-skew case, deep scour holes appear in front of the middle and the last spur dikes in all the groups. The scour depth becomes larger from the middle to the last spur dike. The sidewall scour holes are generated behind the last spur dike and these scour depth increase as going downstream. Deposition areas appear from the top of the last spur dike to the downstream region in parallel to the streamwise direction. The scour propagation observed in the single-group case shown in Figure 8 does not appear in this alternate placement case. There is no significant bed deformation in the center region outside the spur-dike area.

Next, velocity distributions on the dynamically deformed bed were investigated in the upstream-skew case. Figure 16 shows the velocity vectors on the horizontal plains of $z = 1.5$, 4.0 and 6.5 cm. On the plain of $z = 1.5$ cm, the velocity could not be measured at some measuring points because of deposition. The flow inside the spur-dike region is steered toward the sidewall along the spur-dike wall in the same manner as the fixed-bed case. The main flow in the center region shows meandering feature that is a little more significant than the fixed bed case. On the plain of $z = 4$ cm, inflows toward the sidewall are observed in front of the middle and the last spur dikes. The flow overriding on a deposition area is observed in the interval regions of the spur-dike groups. This flow is bended toward the sidewall in these interval regions. On the plain of $z = 6.5$ cm, the flow deflected toward the center is observed over the spur-dike group in the same manner as the fixed-bed case. However, overriding flow

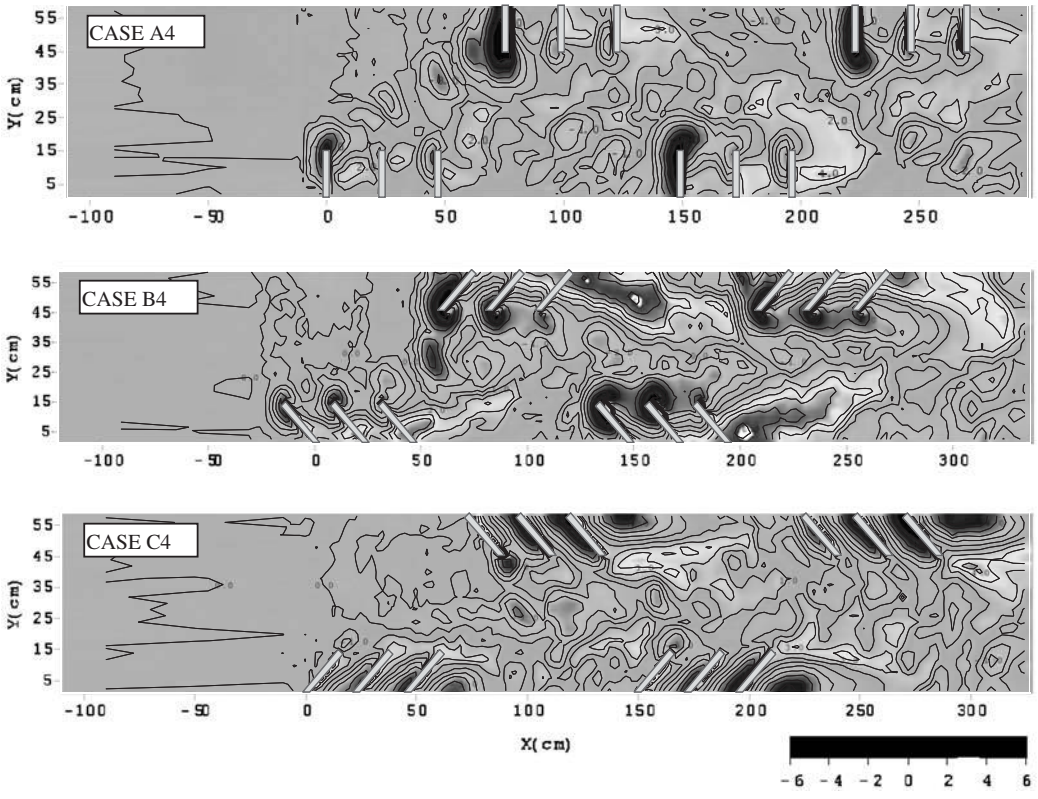

Figure 15. Contours of bed elevation of alternate placement (Upper: normal case, Middle: upstream-skew case, Lower: downstream-skew case).

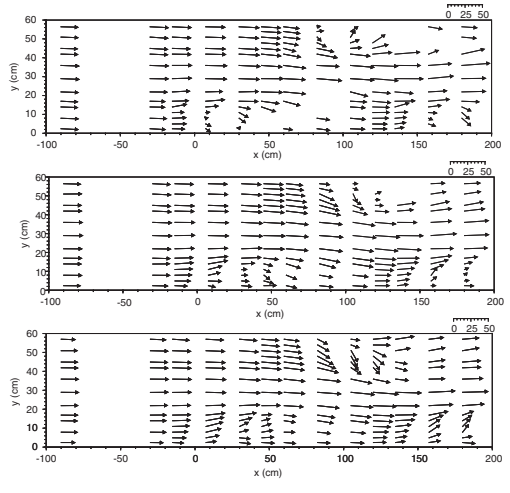

Figure 16. Velocity vectors after bed deformation in upstream-skew case (Upper: $z = 1.5$ cm, Middle: $z = 4$ cm, Lower: $z = 6.5$ cm).

toward the sidewall is observed on the deposition area behind the spur-dike group while the flow deflected toward the center is dominant in the fixed-bed case in this interval region.

6 CONCLUSIONS

It is found that the orientation of a submerged spur dike affects the flow and the bed deformation enormously. The overriding flow on submerged spur dikes generates characteristic flow structures and creates typical bed configurations. An upstream-skew spur dike angles the flow toward the sidewall near the bed and transport sands to the root of a spur dike. The overflow is deflected toward the center, decelerating the sidewall region and accelerating the center region. These sequent flow structures cause deep scours along the top line of the spur dikes and high deposition along the sidewall behind them. A downstream-skew spur dike accelerates the sidewall region and a downflow in front of the spur dike makes deep scour. In this case, the bed deformation in the center region becomes

Copyright © 2006 Taylor & Francis Group plc, London, UK

mild. The group-structure placement of skew spur dikes strengthens the characteristic effects of each spur dike and has a possibility to make diverse river configurations. In particular, the alternate arrangement of upstream-skew spur-dike groups is satisfactory to make riffles and pools in a straight river course. These fundamental flow structures can be reasonably predicted by using the present simple 3-D numerical model. It is expected to develop a numerical simulation model of bed deformation with 3-D flow prediction in the next step.

Turbulence analysis of vertical slot fish pass by in situ measurements and CFD modelling

B. Sokoray-Varga, S. Baranya & J. Józsa
Budapest University of Technology and Economics, Budapest, Hungary

ABSTRACT: Turbulence features in a operating vertical slot fish pass were explored first by means of analyzing in situ ADV data. The mean velocity field, its vorticity and important turbulence parameters were quantified. The swirling character of the flow was made visible, and the vertical velocity component proved to play an important role at places. As to turbulence features, the Eulerian space-scale provided valuable information on the dominant eddy size in the flow, expected to contribute to the detailed flow structure dependent analysis of the swimming performance of fish in various fish pass facilities. The order of magnitude of this eddy size was found quite close to the one of the fish migrating there. As a future design tool, a first implementation of the 3D k-ε SSIIM model was carried out and provided promising primary results. The CFD model could reasonably reproduce the important elements and overall complexity of the mean flow field, typical to vertical slot fish pass arrangements.

1 INTRODUCTION

In fluvial systems to make the stream-wise passage for fish possible at the presence of various man-made transversal obstructions such as damming is a more and more required element of the so-called good ecological status. In fact, transversal hydraulic structures controlling water level or discharge usually present insurmountable obstacles in themselves severely violating ecological continuity of the system where a number of fish species used to migrate according to specific rules. To minimize these negative effects a number of fish pass facilities have been conceived and successfully implemented well suited to the given local conditions.

One of the most popular solutions to the problem is the vertical slot fish pass. In such facilities the difference insurmountably large for fish between headwater and tailwater free surface levels is dissipated in a distributed way. In fact, it occurs in a series of pools interconnected by vertical slots, in portions small enough for the fish to cope with when migrating (see e.g. Wu et al. 1999). The design of such hydraulic facilities is usually performed by considering rather global hydrodynamic and ecological parameters, whereas suitability depends a lot on the flow features at a wide range of scales: pool- wide patter, large turbulence eddies and fine scale turbulence. Laboratory experimental studies have significantly contributed to answer such questions as presented by Wu et al. (1999) and Pea et al. (2003).

Moreover, important conclusions can be also drawn from measurements carried out on operating fish passes. However, in the ideal case an efficient design tool would be a CFD model validated for existing conditions and flexible enough to investigate different geometry and flow regime variants. The results of the first steps toward such an approach are presented in this paper, where in situ ADV (Acoustic Doppler Velocimetry) turbulence measurements and related 3D CFD modelling carried out in an operating vertical slot fish pass in Hungary are analysed.

2 FLOW PATTERN AND TURBULENCE ASPECTS IN VERTICAL SLOT PASSES

The upstream reach of the fish pass is a rectangular channel divided by baffles into a number of pools as usual for the vertical slot type of arrangement (Fig. 1). It continues then in a strongly irregular, meandering, landscape-friendly reach (Fig. 2).

When migrating up the stream, the fish swims basically in countercurrent. While passing through the series of pools the fish keeps on moving up the stream. As is known, in a pool of a vertical slot fish pass two rather distinct regions in flow pattern can be detected (Fig. 3). One of them is a direct flow region a jet-like, though often curved, high speed flow interconnecting the slots. The other is a large recirculation region, indirectly driven by the jet, and characterized by relatively small velocities (see e.g. Wu et al. 1999, Pena et al. 2003). After passing through the high velocity zone at the slot, the fish is assumed to leave the direct flow region and continue their way for a while in the recirculation region, in the zone just adjacent to the main

Figure 1. View of the vertical slot reach of the fish pass.

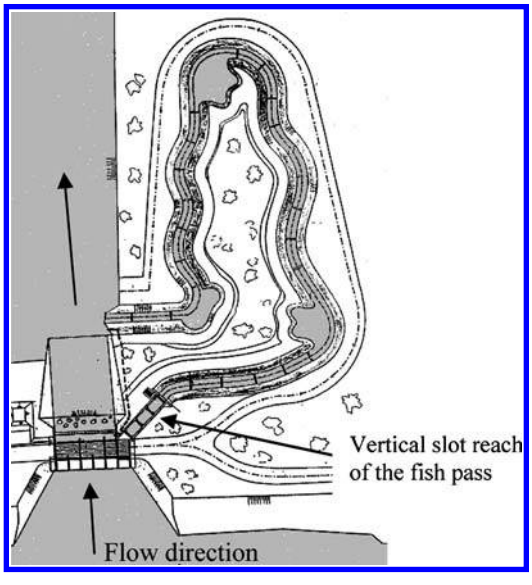

Figure 2. Plan view of the fish pass.

stream. In this way the two kinds of region in flow pattern enable them to find opportunities for a rest in the recirculation regions after swimming through the fast flowing zones, especially the one straight at the slot.

In a vertical slot fish pass the flow usually becomes highly turbulent even given calm conditions in the river

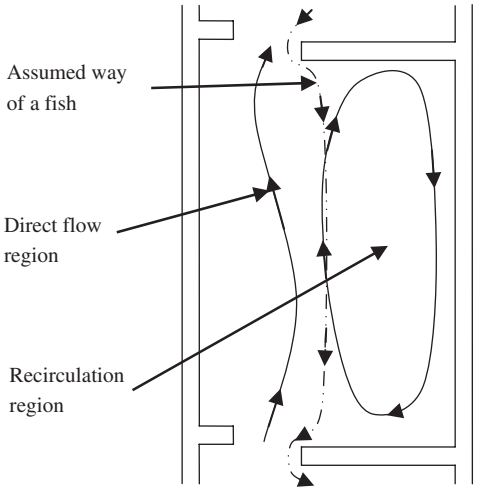

Figure 3. The two different regions in the flow pattern.

straight upstream. Hydro-biological investigations on the hydrodynamic impact on the swimming performance of fish have pointed out its scale-dependence (Nikora et al. 2003). In fact, turbulent eddies of scales smaller, comparable or much larger than fish size have certainly various impact on the motion of a fish (Fig. 4). In this paper we present a primary quantification of such parameters by evaluating the 3D ADV measurements carried out in an operating fish pass, supporting the evaluation also by CFD analysis. The aim is to contribute to the better understanding of fish pass hydrodynamics and to the embedded various flow features and structures with possibly different relevance on the swimming performance of fish (as sketched in Fig. 4). In fact, turbulent eddies much smaller than the size of the fish, are not expected to have significant impact on short term swimming. In turn, eddies with a scale comparable or somewhat larger than the size of a fish can present direct dynamic loading in terms of rolling, pitching and yawing. Eddies much larger than the fish will, of course, also have a considerable impact but mainly as a macroscale part of the advective flow pattern, with relatively slow space-time variation.

3 IN SITU FLOW MEASUREMENTS

In the upstream reach of the study fish pass the pools are generally characterized by high speed flow and complex turbulence conditions. In order to capture the essential of turbulence in such field conditions, the Vector ADV of Nortek was applied, providing 3D velocity vectors in a small (around 1 cm^3) sampling volume at 16 Hz as a default sampling rate in time, which can be set up to 64 Hz (for more details see Nortek AS 2001).

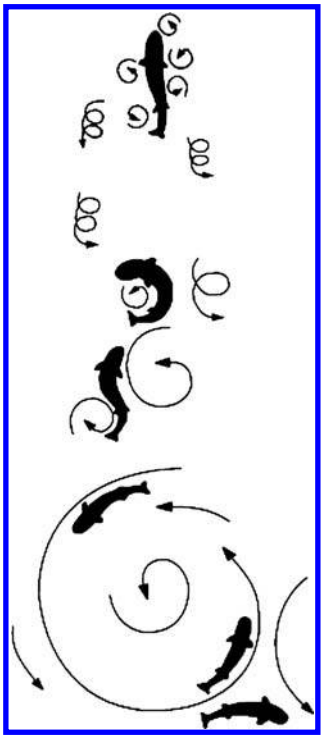

Figure 4. The fish in flow with various characteristic turbulent eddy sizes (after Odeh et al. 2002).

The field measurements took place in the downstream part of the 3rd pool of the vertical slot fish pass in the two cross-sections (A and B) as presented in Figure 5, at points shown in Figure 6. In both cross-sections the measurements included 5 verticals with 6 points in each, forming a regular raster. During the measurement period the flow conditions were practically steady, with a discharge estimated to 0.6 m^3/s and mean depth to 0.90 m (in the measurement region). Velocities were measured at each selected location for 2 min at a sampling rate of 16 Hz, considered sufficient to capture all the important scales. The local coordinate system was a pool longitudinal axis aligned one as seen in Figure 5, with z pointing upward.

As one single ADV was available, only, the velocity time series obtained in situ subsequently were assumed as samples of stationary flow conditions. They served then to estimate both the large scale mean pattern and the turbulent space-time structure of the flow.

4 FLOW MEASUREMENT ANALYSIS

As usual the measured instantaneous spatial velocity vector

$$\mathbf{v}(t) = u(t)\cdot\mathbf{i} + v(t)\cdot\mathbf{j} + w(t)\cdot\mathbf{k} \qquad (1)$$

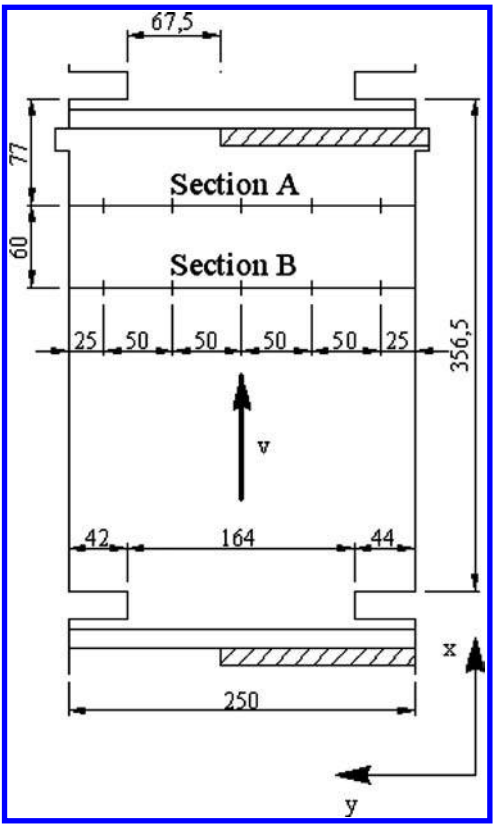

Figure 5. Plan view of the pool and the measurement sections (dimensions indicated in cm).

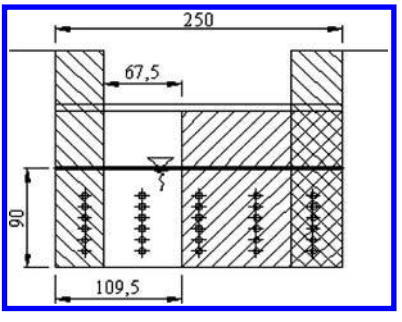

Figure 6. The measuring points in the selected cross-sections (dimensions indicated in cm).

was handled according to the Reynolds decomposition

$$\begin{aligned} u(t) &= U + u'(t), \\ v(t) &= V + v'(t), \\ w(t) &= W + w'(t), \end{aligned} \qquad (2)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

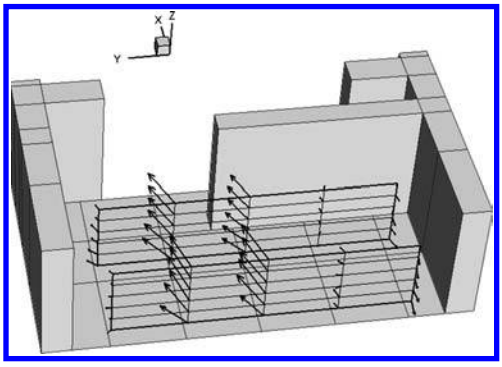

Figure 7. Layout of the measurement points with mean velocity vectors.

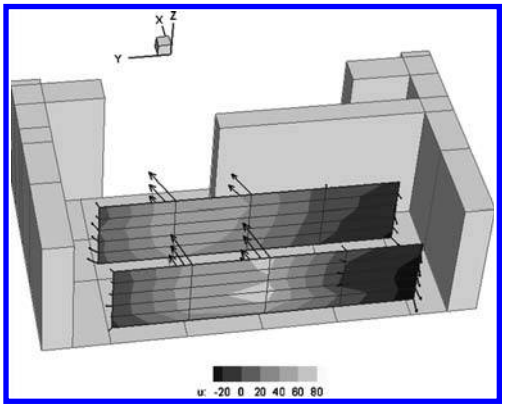

Figure 8. Measured mean velocity vectors and the distribution of the x-component of the mean velocity in cm/s.

where $u(t)$, $v(t)$, $w(t)$ are instantaneous velocity components in x, y, and z direction, respectively, U, V and W are their Reynolds-averaged mean values and $u'(t)$, $v'(t)$ and $w'(t)$ the instantaneous fluctuation around the mean.

The results of the time series analysis are displayed in the measurement cross-sections mostly as appropriately interpolated fields using Tecplot. In the figures one looks downstream. Note that the colour scales are different from figure to figure.

Figure 7 shows the mean velocity vectors which show the mean spatial structure of the flow even in themselves, making it possible to distinguish the jet region and the much slower recirculation zone adjacent to that. Symptoms of swirling can also be seen.

In Figure 8 the cross-sectional distribution of the x-wise velocity component is displayed putting a light onto the direct through-flow, the slow recirculation flow region and the highly sheared zones. The highest velocities in the direct through-flow region exceed

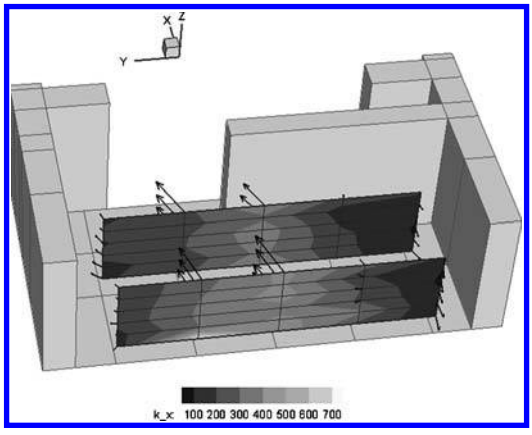

Figure 9. Distribution of the x-component of the turbulent kinetic energy in cm^2/s^2.

0.80 m/s. It can also be seen that curved contracting way the main stream approaches the outlet slot. In the recirculation region the velocities go up to 0.30 m/s at most.

The variance of the fluctuation components u', v' and w' provided the estimation of the turbulent kinetic energy. The cross-sectional distribution of its component in the x-direction

$$k_x = \frac{1}{2}(\overline{u'^2}) = \frac{S_u^2}{2}, \tag{3}$$

which shows in Figure 9 that the largest values develop in the shear layer between the jet and the recirculation region, well known as turbulence production zone.

The autocorrelation function $\rho(\tau)$ of the fluctuation terms having calculated, one could estimate the

$$T_{EI} = \int_0^\infty \rho(\tau)\mathrm{d}\tau \tag{4}$$

Eulerian integral time scale T_{EI} (usually sufficient to integrate as far as the first zero point), and also the

$$L_{EI} = U \cdot T_{EI} \tag{5}$$

integral length scale by assuming the Taylor hypothesis. This is considered as an order of magnitude estimation of the energy containing dominant eddy size (see e.g. Bedford 1993). The cross-sectional averaged value of these length scales calculated for the measurement points in all the three directions are summarized in Table 1.

As was mentioned before, the eddy size is expected to be a good indicator of its impact rate on the swimming fish. The obtained average values are somewhat different in the different directions but have got the

Table 1. Averaged Eulerian integral length scales in cm.

	x-direction	y-direction	z-direction
Section A	20	12	11
Section B	28	20	13

Table 2. Alternative Eulerian integral length scales in cm.

	x-direction	y-direction	z-direction
Section A	15	9	7
Section B	21	11	7

same order of magnitude. In fact, these values fall just in the range of the fish size observed to use regularly the fish pass. Moreover, one should also note that the bottom of the pool is roughened by large rip-rap with an approximate size close to what was found as characteristic eddy size.

As is known, much better eddy size estimate could be obtained from Lagrangian autocorrelation functions but such measurements are difficult to perform in situ. The Taylor hypothesis looses its validity especially in regions with mean velocity close to zero. As an alternative, the standard deviation of the fluctuation was also used as characteristic velocity scale providing

$$L'_{EI} = T_{EI} \cdot \sqrt{\overline{u'^2}} \,. \tag{6}$$

The calculated cross-sectional averaged values of L'_{EI} are summarized in Table 2.

The nearly stationary conditions made it possible to evaluate some further large scale features of the flow. Though the measurement were carried out in two cross-sections, only, the x-component of the

$$\boldsymbol{\omega} = \frac{1}{2}\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right)\cdot \mathbf{i} + \frac{1}{2}\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right)\cdot \mathbf{j} + \\ + \frac{1}{2}\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right)\cdot \mathbf{k} = \frac{1}{2}\nabla \times \mathbf{v} = \frac{1}{2} rot\mathbf{v} \tag{7}$$

total vorticity vector could be, nevertheless, estimated as

$$(rot\mathbf{v})_x = \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right)\cdot \mathbf{i} \tag{8}$$

by appropriate finite difference approximation. The calculated vorticity fields can be seen in Figure 10. As was already expected from the velocity vector field, one can distinguish two large swirling structures, one on the left hand side presenting clockwise, and another one on the right hand side presenting anti-clockwise rotation.

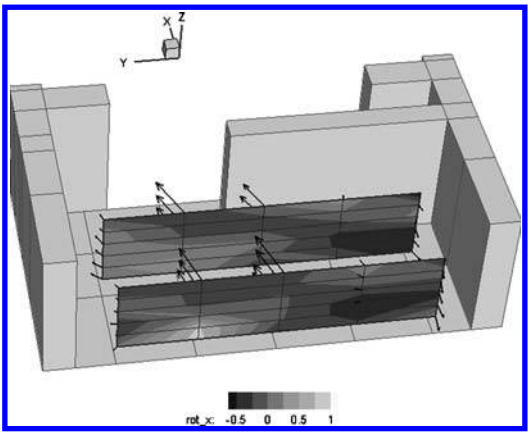

Figure 10. Cross-sectional distribution of the x-component of the vorticity vector in 1/s.

5 CFD MODELLING

In order to make steps toward an efficient future design tool, a 3D turbulence CFD model was implemented to the investigated part of the study fish pass. The primary goal was to reproduce realistic 3D flow patterns verified by the measured ones and get a more refined insight to the complexity of the flow.

5.1 *Applied CFD code*

The numerical model used in this study is the CFD code called SSIIM (Olsen 2002). It solves the Reynolds-averaged Navier-Stokes equations with the two-equation k-ε turbulence closure (see e.g. Rodi 1984) in three dimensions for non-hydrostatic conditions.

The Reynolds-averaged Navier-Stokes equations are written in a compact form as follows:

$$\frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial x_j} = \frac{1}{\rho}\frac{\partial}{\partial x_j}\left(-P\delta_{ij} - \rho \overline{u'_i u'_j}\right), \tag{9}$$

where U = time-averaged velocity, u' = velocity fluctuation, P = pressure, x_j = Cartesian space co-ordinates, δ_{ij} = Kronecker delta, ρ = fluid density.

The eddy viscosity concept with k-ε turbulence closure is used to model the Reynolds stress terms as follows:

$$-\rho \overline{u'_i u'_j} = \rho \nu_T \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) - \frac{2}{3}\rho k \delta_{ij} \tag{10}$$

where ν_T = eddy viscosity coefficient, k = turbulent kinetic energy.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In the model, in which ε represents the rate of turbulent energy dissipation, a transport equation is solved both for k and ε as a result of which the eddy viscosity coefficient can be evaluated as

$$\nu_T = c_\mu \frac{k^2}{\varepsilon} \tag{11}$$

where $c_\mu = 0.09$.

The governing equations are solved in a finite volume context by using the SIMPLE method (Patankar 1980) on a three-dimensional, non-orthogonal curvilinear structured grid.

5.2 *Applied mesh and boundary conditions*

In the CFD model three pools of the investigated fish pass were included resulting in 13 m total length and 2.50 m width. A mesh with 260×50 cells provided 0.05×0.05 m horizontal resolution, whereas in the vertical 7 layers were used with decreasing spacing toward the bottom where strong gradients were expected to occur in the flow variables.

Velocity measurements carried out by means of the ADV provided the discharge close to 0.60 m^3/s. This value was applied then as upstream boundary condition. As downstream water level 0.90 m was prescribed.

Equations 9 and 10 are valid inside the fluid flow in the free turbulence zone, whereas next to the boundaries the flow characteristics are calculated from the following boundary layer formula (Schlichting 1979):

$$\frac{U}{u_*} = \frac{1}{\kappa} \ln\left(\frac{30y}{k_s}\right), \tag{12}$$

where U = velocity parallel to boundary, u_* = friction velocity, κ = von Karman constant, y = distance of the investigated point from the wall, k_s = roughness height. Since the investigated fish pass was constructed from concrete with relatively smooth surface, a Strickler parameter equal to 40 $m^{1/3}/s$ and roughness height corresponding to that was adopted all along the pool boundary surface. As the bottom is covered by large stones, to take into account this fact a simple first approach was to define regularly placed solid cubes 0.2 m size in the mesh, represented by the two lowest model layers as a sort of macro-roughness (see Fig. 11).

5.3 *Model results*

Steady-state velocity patterns were calculated and compared to field measurement results. Using a reference system identical to the one applied in the previous chapter, in Figure 11 the distribution of the

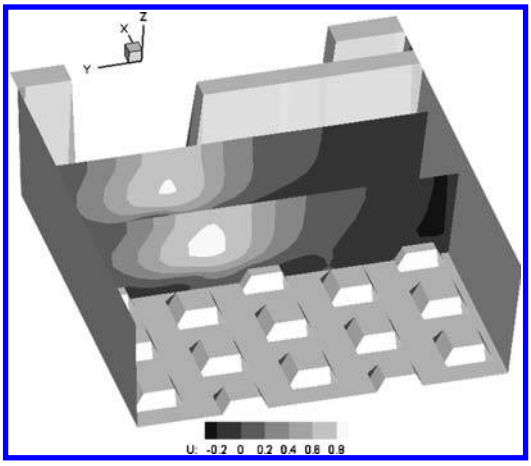

Figure 11. Distribution of the x-component of the Reynolds-averaged velocity in the measurement cross-sections in m/s.

Reynolds-averaged x-wise velocities is plotted in the two measurement cross-sections. Fairly good agreement can be observed with measured data (see Fig. 8), which means that the roughness conditions could be reasonably approximated in the CFD model (note that close to the side walls and to the free surface field velocity data could not be gathered).

A path-line representation of the flow using the surface layer velocity field provides a good insight into the modelled pattern as is seen in Figure 12. Both the direct through-flow and the large recirculation region (even on the left hand side of the jet) accompanied with some further, smaller corner eddies develop in a way close to what was measured in situ.

In Figure 13 four representative path-lines show the strong three-dimensionality of the flow. Indicating the elevation in grey-scale, one can see how a neutrally buoyant particle moves both horizontally and vertically, resulting locally in up- or downwelling in the large recirculation region. For instance the particle entering the domain on the right-hand side close to free surface carries out three loops before leaving the domain close to bottom. On the left-hand side the opposite occurs, namely the particle arriving into the pool close to bottom first rises then is entrained into the main through-flow. The other two particles released well in the jet will go through remaining all along in it with little change in elevation.

The velocity vector field in the layer just below the crest level of the bottom cubes is given in Figure 14 and provides some further explanation to the motion of particles discussed above. In the direct through-flow region relatively high velocities develop, whereas close to the vertical walls of the pool vectors point in general opposite to the main steam.

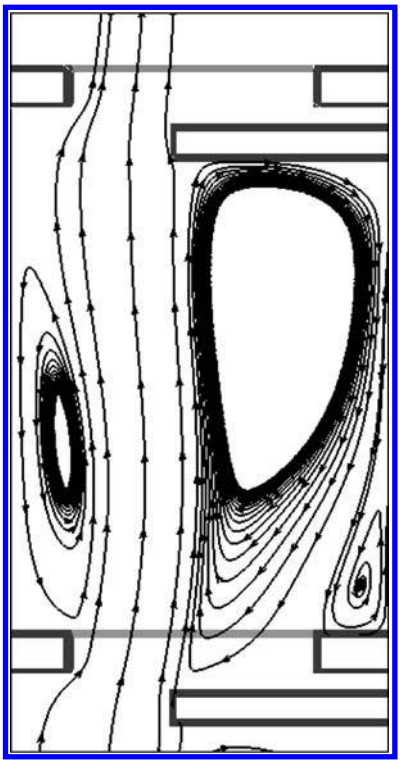

Figure 12. Path-lines in the near-surface layer.

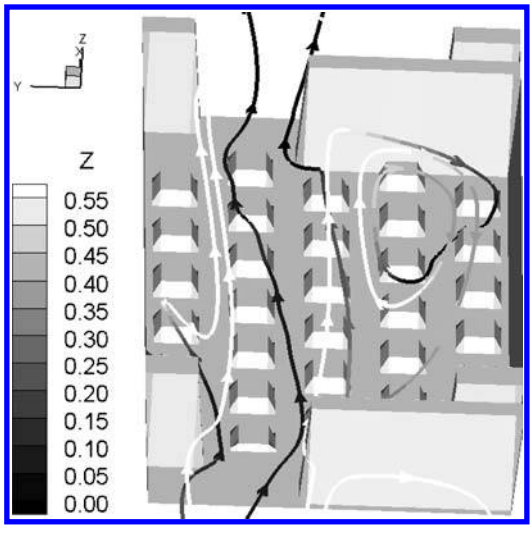

Figure 13. Visualization of characteristic path-lines and their elevation.

Velocity vectors taken close to the measurement cross-sections are displayed in Figure 15 both in the near-surface layer (black) and in a lower layer, nevertheless, well above the crest level of the bottom

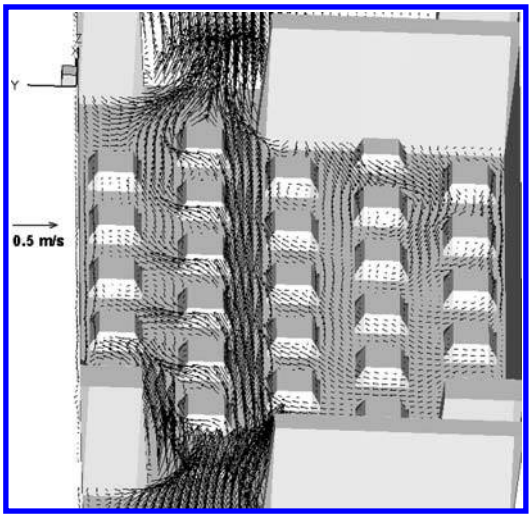

Figure 14. Velocity vector field close to the bottom.

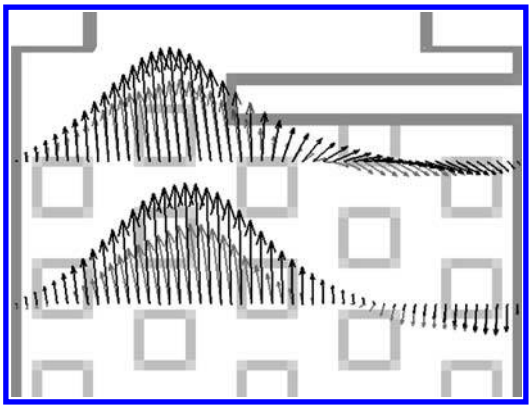

Figure 15. Velocity vectors close to free surface (black) and above the crest level of the bottom cubes (grey) in the two measurement cross-sections.

cubes. One can clearly see the character of the spanwise distribution of the velocity similar to the one observed in the nature. Moreover, based on the flow directions one can also see the swirling character of the main stream again in a sense identical to the observed one. The recirculation region can also be identified with its strong three-dimensionality close to the downstream wall, all that underlining the necessity of the 3D modelling approach.

As to the free surface variation, steep slope zones obviously appear in the vicinity of the narrow slots (Fig. 16). There the change of the water level is some centimetres within a short distance, seemingly also reasonably captured by the applied CFD model.

6 DISCUSSION AND CONCLUSIONS

Turbulence features in an operating vertical slot fish pass were explored by means of analyzing ADV data. In quasi-stationary flow conditions the mean velocity field, its vorticity as well as a number of important turbulence parameters could be quantified. The vorticity field made the swirling character of the flow even more visible. The vertical component of the velocity, often neglected in laboratory scale model studies, proved to play an important role at places.

As to turbulence features, what was shown in a novel way is the importance of the estimation not only of the kinetic energy, but also further parameters such as the Eulerian integral time- and space-scale. The latter can provide valuable information on the dominant eddy size in the flow thus contributing to the detailed flow structure dependent analysis of the swimming performance of fish in various fish pass facilities. Interestingly, the order of magnitude of this eddy size was found quite close to the one of the fish migrating there. Of course, further research is needed to investigate the above mentioned impact in details, and also the role of the large scale bottom roughening in there development.

Future design or improvement of the operation of existing fish passes could, nevertheless, best carried out by mean of 3D CFD turbulence models once suitably validated in existing conditions, including preferably a number of geometry set-up and flow regime. A first implementation of the 3D k-ε SSIIM provided promising primary results to reach this goal. The CFD model could reasonably reproduce the important elements and overall complexity of the mean flow field, typical to vertical slot fish pass arrangements.

A next step in CFD modeling will be the more realistic representation of the large scale bottom roughening including also a parameter sensitivity study on it, moreover, the numerical estimation of the local dominant eddy size by using the calculated turbulent kinetic energy and dissipation rate fields. Reasonable fitting of the latter with the ones observe in nature would really enhance the robustness of the CFD model in fish pass design.

ACKNOWLEDGEMENTS

The research was partially supported by OTKA Grant T030792 on “Measurement and parameterization of spatial characteristics of free surface flows”. The authors wish to thank N. R. B. Olsen and N. Ruether for all their valuable support in implementing SSIIM in the project.

Stability analysis of turbulent water jets onto both rigid and mobile beds

C. Adduce, M. la Rocca & P. Mele
Dipartimento di Scienze dell'Ingegneria Civile, Università degli Studi RomaTre, Roma, Italy

ABSTRACT: A laboratory-theoretical investigation on the stability of jets developing downstream of a drop structure is presented. Two series of laboratory experiments were performed with both a mobile and a flat rigid bed downstream of the drop. The discharge and the downstream water depth were varied and two kinds of jet flow were observed developing downstream of the drop: a surface wave jet and an oscillating jet. The oscillating jet is an unstable flow configuration. Both velocity and free surface flow measurements were performed. Starting from laboratory measurements, a mathematical model, which investigates the stability of the surface wave jet both over a flat and a scoured bed, was developed. The modified De Saint-Venant equations, i.e. with correction terms accounting for the curvature of the streamlines, were obtained from the theoretical velocity and pressure profiles. The stability of the surface wave jet is affected by the presence of the scoured bed, which weakens its stability properties.

1 INTRODUCTION

When the main stream interact with hydraulic structures as drops, gates, spillways, a jet flow may develop. Several investigations, performed with a flat rigid bed or a mobile bed, (Adduce and Mele, 2004; Chatterjee, et al., 1994; Dey and Westrich, 2003; Farhoudi and Smith, 1985; Gijs and Hoffmans, 1998; Hassan and Narajanan, 1985; Kurniawan, et al., 2001; Wu and Rajaratnam, 1998; Fritz and Hager, 1998; Ohtsu and Yasuda, 1991b) observed this kind of flow. If the jet flow develops over a mobile bed, it may endanger the structures' stability, because it may produce a deep scour hole.

Different kinds of jet flow, related both to different hydraulic conditions and hydraulic structures' geometry, were observed (see Ohtsu and Yasuda, 1991a, Ohtsu and Yasuda, 1991b; Hager, 1992; Wu and Rajaratnam, 1998; Fritz and Hager, 1998).

Three flow conditions were observed for submerged overflow structures, with the downstream water depth higher than the structure's height: (a) plunging flow, also referred to impinging flow, with a submerged main flow and a surface roller; (b) surface wave (breaking or not breaking) flow, with the main flow along the free surface and a bottom recirculation zone; (c) surface jet flow, similar to the surface wave flow, but with a nearly horizontal free surface (see Wu and Rajaratnam, 1998; Fritz and Hager, 1998; Bukreev, 2001). A transition condition between the "surface state" (surface wave flow) and the "bottom state" (plunging flow) was observed by Bukreev (2001).

The aim of the present paper is to investigate, by both laboratory experiments and a mathematical model, the influence of the bed geometry on the surface wave jet stability. Jet flow was produced by the interaction of the main flow with a drop structure, followed by a rigid apron. Two series of laboratory experiments were performed in order to develop surface wave jets (U1, U2, U3) and oscillating jets (T1, T2,T3), downstream of the drop, followed by a mobile bed. The jet-sediments interaction produced a scoured bed. The same experiments were repeated with a fixed horizontal bed (tests U1FB, U2FB, U3FB, T1FB, T2FB,T3FB).

A mathematical model, following the work by Montes and Chanson (1998) was developed, starting from the analytical determination of the velocity and pressure fields in presence of a surface wave flow. Such velocity and pressure fields, unlike Montes and Chanson (1998), were obtained accounting for a scoured bed. A comparison between the theoretical and the measured velocity profiles was performed, in order to have an idea of the validity of the theoretical model. A modified version of the De Saint-Venant equations, i.e. with correction terms accounting for the curvature of the streamlines, was developed and used to perform a stability analysis of the surface wave jet, both with a flat and a scoured bed. The result of this analysis is that a scoured bed weakens the stability properties of the surface wave flow.

The paper is set out as it follows: the experimental apparatus is described in section 2; the laboratory experiments are presented in section 3; the

Copyright © 2006 Taylor & Francis Group plc, London, UK

mathematical model is described in section 4; a comparison with laboratory measurements is shown in section 5. The conclusions of the work are presented in section 6.

2 EXPERIMENTAL APPARATUS

Laboratory experiments were performed at the Hydraulics Laboratory of RomaTre University, in a 17 m long, 1 m high and 0.8 m wide flume of rectangular cross section. Scouring tests were carried out in a 0.3 m high, 0.8 m wide and $L = 3$ m long sediment recess section, made by raising artificially the flume bed. An uniformly graded sand characterized by $d_{50} = 0.7$ mm and a density $\rho_s = 2650\ kg/m^3$, was used to fill the sediment recess section in order to have a mobile bed. All the scouring tests were conducted in clear water scour conditions. A trapezoidal drop of height $D_p = 0.15$ m followed by a rigid apron of length $L_p = 0.5$ m was positioned upstream of the test section, as it is shown in Figure 1. A control gate, positioned at the end of the flume, was used to change the downstream water depth. The water level in the flume was measured using a resistive point gage of accuracy ± 0.10 mm. The water discharge at the inlet was controlled by an inlet valve and measured by an electromagnetic flowmeter. For a detailed description of the experimental apparatus see Adduce (2004).

At the end of the experiment, velocity measurements were performed by an Ultrasonic Doppler Velocity Profiler (UDVP). The Ultrasonic Doppler Velocity Profiler, first developed for medical studies on blood flow Willemetz (1990), is today used to perform measurements both in transparent (Ito et al., 2001; Hurther, 2001; Rolland, 1994) and optically opaque fluids and high temperature fluids (Eckert & Gerberth, 2002), giving spatiotemporal velocity information. The UDVP consists of a piezoelectric probe, which works both as emitter and receiver of a signal consisting of ultrasonic bursts traveling across the fluid and backscattered by the targets, i.e. small air bubbles or particles, moving with the flow. For a detailed description of the UDVP technique, see Willemetz (1990, 2001). The UDVP probe measures profiles of the velocity component parallel to the probe axis. In order to measure the profiles of the horizontal and the vertical velocity components three probes with the same emitting frequency were used, following the technique showed in Longo et al. (2001) and Adduce (2004). Two probes were tilted with respect to the vertical direction of an angle of 20°, while a third probe was positioned parallel to the vertical direction. Velocity measurements were performed along the flume centerline.

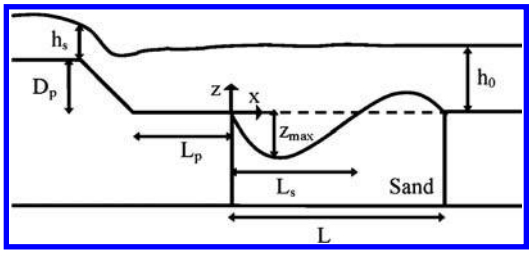

Figure 1. Definition sketch of the test section in the x-z plane.

3 LABORATORY EXPERIMENTS

Two series of laboratory experiments were performed with both a mobile (scouring experiments) and a flat rigid bed downstream of the drop. The discharge and the downstream water depth were varied and two kinds of jet flow were observed developing downstream of the drop: a surface wave jet and an oscillating jet. The oscillating jet is an unstable flow configuration. For a detailed description of the different kind of jet flow see Bukreev (2001) and Adduce (2004).

Before starting each scouring experiment, the level of the mobile sand bed, positioned in the sediment trap, was set to the same height of the fixed bed. In order to avoid the undesirable scour of the sediment bed, the control gate was completely closed and the flume slowly filled with the water pumped from the laboratory water reservoir by an auxiliary pumping device. The water discharge was then slowly increased, starting from zero, and set to the desired experimental value, paying attention to avoid any movement of the sand bed. The experiment started when the downstream water depth was set to the desired experimental value by opening the control gate. The water discharge was kept constant for the entire duration of the experiment.

Two series of scouring experiments were run, as it shown in Table 1: series U (surface wave jet) and series T (oscillating jet). We stopped the experiments when the measured maximum scour depth, plotted versus logarithm of time was sensibly constant (Adduce et al.,

Table 1. Experimental parameters for the experiments with a scoured bed: Q, discharge; h_s, water depth over the drop; h_0, downstream water depth over the rigid bottom; z_{max}, maximum scour depth.

Run	Q (l/s)	h_s (cm)	h_0 (cm)	z_{max} (cm)

U1FB	31.01	4.80	19.88	–
U2FB	33.10	5.00	20.36	–
U3FB	37.40	5.20	20.78	–

2004, Adduce, 2004). For the present experiments the maximum scour depth did not increase with the logarithm of time after about 6 hours, as a consequence the duration of scouring experiments was set to 10 hours. For a detailed description of the scouring process due to different kinds of jets see Adduce (2004).

The considered values of the experimental parameters: water discharge (Q), water depth over the drop (h_s), water depth downstream of the sediment trap (h_0) and maximum scour depth measured along the flume centerline (z_{max}), are shown in Table 1.

The series U and T were repeated with the same hydraulics parameters, but with a flat rigid bed, in order to investigate the influence of the bed geometry on the jet stability. The experimental parameters used for the experiments performed with a flat rigid bed are shown in Table 2.

Figure 2a-c shows the comparison between the scoured bed, measured at the end of the run and the theoretical scoured bed used in the mathematical model and which will be defined in the following of the paper.

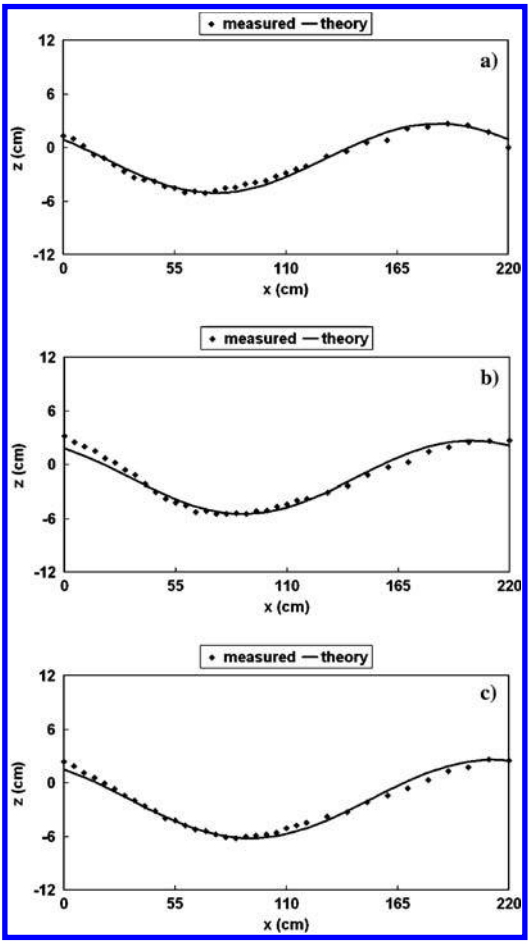

Figure 2. Comparison between measured and theoretical scour profiles: a) Run U1; b) Run U2; c) Run U3.

4 STABILITY ANALYSIS OF A SURFACE WAVE JET

The stability analysis is performed starting from the motion equations considered in the streamline centered s-n system of reference (Rouse, 1938). The quantities required for the description of the phenomenon are defined in Figure 3a. Moreover we assume that the considered motion condition occurs in the plane s-n. Let $\boldsymbol{V}$ be the velocity vector, defined as $\boldsymbol{V} = V(s,n)\boldsymbol{e}_s$, being V the modulus, $\boldsymbol{e}_s$ the unit vector tangent to the instantaneous streamline, s the coordinate on it and n the coordinate along the direction normal to the instantaneous streamline.

The equations of motion are:

$$V\frac{\partial V}{\partial s} = -\frac{1}{\rho}\frac{\partial p}{\partial s} - g\frac{\partial z}{\partial s} - \frac{1}{\rho}\frac{\partial \tau}{\partial s} \tag{1}$$

$$\frac{V^2}{R} = -g\frac{\partial}{\partial n}\left(z + \frac{p}{\rho g}\right) \tag{2}$$

where R is the radius of curvature of the instantaneous streamline. The term $(1/\rho)\partial\tau/\partial s$ accounts for head losses.

As a consequence, equation (1) gives the modified Bernoulli equation

$$z + \frac{p}{\rho g} + \frac{V^2}{2g} + \frac{\tau}{\rho g} = const \tag{3}$$

Inserting equation (3) in (2), the following equation for the determination of V is obtained

$$\frac{V^2}{R} = V\frac{\partial V}{\partial n} + \frac{1}{\rho}\frac{\partial \tau}{\partial n} \tag{4}$$

which is the same obtained by Montes and Chanson (1998), but the term $(1/\rho)\partial\tau/\partial n$, which accounts for the variation of the tangential stress along the n coordinate.

Copyright © 2006 Taylor & Francis Group plc, London, UK

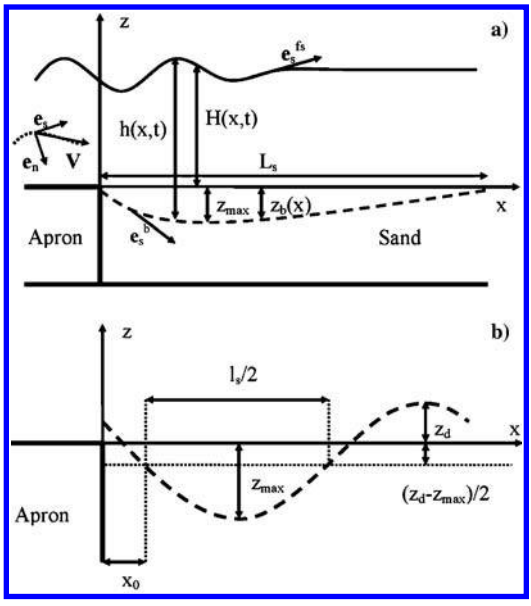

Figure 3. Definition sketch for the mathematical model.

Now, adopting the geometrical hypothesis of Montes and Chanson (1998), introducing the dimensionless variable η, defined as:

$$\eta = \frac{z - z_b(x)}{h(x,t)} \tag{5}$$

and expressing the geometrical quantities as known functions of the respective bottom and free surface quantities, equation (4) becomes:

$$\left[a_1\eta^k + a_2(1-\eta)^k\right]V^2 + V\frac{dV}{d\eta} + \frac{1}{\rho}\frac{d\tau}{d\eta} = 0 \tag{6}$$

being k a positive constant of order unity (Montes and Chanson, 1998). The coefficients appearing in equation (6) account for the curvature of the streamlines and are defined as:

$$a_1 = -\frac{hH''}{\left[1+(H')^2\right]}, a_2 = -\frac{hz_b''}{1+(z_b')^2} \tag{7}$$

Where

$$H(x,t) = z_b(x) + h(x,t) \tag{8}$$

and

$$H' = \frac{\partial H}{\partial x},\ z_b' = \frac{dz_b}{dx},\ H'' = \frac{\partial^2 H}{\partial x^2},\ z_b'' = \frac{d^2 z_b}{dx^2} \tag{9}$$

In order to obtain velocity profiles from equation (6) it is necessary to describe the behavior of the stress along the coordinate η. In this work it is assumed that inside of the region where the flow is expanding (upstream of the abscissa of maximum scour depth x_{sd}) the term which accounts for the curvature of the streamlines is not negligible with respect to the other two, while inside of the region where the flow is accelerating (downstream of the abscissa of maximum scour depth), the term which accounts for the curvature of the streamlines in equation (6) is less important than the other two terms. As a consequence equation (6) assumes the following different expressions, respectively upstream and downstream of the abscissa of maximum scour depth:

$$\begin{cases} \left[a_1\eta^k + a_2(1-\eta)^k\right]V^2 + V\dfrac{dV}{d\eta} + \dfrac{1}{\rho}k\left[\tau_{fs}\eta^{k-1} + \tau_b(1-\eta)^{k-1}\right] = 0 \quad (x \le x_{sd}) \\ V\dfrac{dV}{d\eta} + \dfrac{d}{d\eta}\left\{\left(kh\eta\sum_i\left[-\dfrac{(-1)^i}{i!}\left(\dfrac{hu_*}{\nu A}\eta\right)^i\right]\right)^2\dfrac{1}{h}\dfrac{dV}{d\eta} + \nu\right\}\dfrac{1}{h}\dfrac{dV}{d\eta} = 0 \quad (x > x_{sd}) \end{cases} \tag{10}$$

For $x \le x_{sd}$ the following law is adopted for the stress

$$\tau\ \tau = \tau_{fs}\eta^k + \tau_b(1-\eta)^k \tag{11}$$

being τ_{fs}, τ_b the tangential stresses respectively on the free surface and on the bottom. The former can be neglected, while the latter can be expressed as:

$$\tau_b = \rho u_*^2 = \rho g\frac{U^2 n_m^2}{h^{1/3}} \tag{12}$$

being U the depth averaged velocity and n_m the Manning's coefficient.

For $x \ge x_{sd}$ the tangential stress is described by means of an eddy viscosity model, due to the fact that the motion tends to become more regular, based on the mixing length hypothesis (Rodi, 2000; Nezu and Nakagawa, 1993):

$$\tau = \frac{\rho}{h}\left[l_m^2\frac{dV}{d\eta} + \nu\right]\frac{dV}{d\eta} \tag{13}$$

It is assumed that $dV/d\eta$ is always positive for $x \ge x_{sd}$ and that l_m the mixing length is given by the following polynomial approximation of the Van Driest expression (Rodi, 2000; Nezu and Nakagawa, 1993):

$$l_m = kh\eta\sum_i\left[-\frac{(-1)^i}{i!}\left(\frac{hu_*}{\nu A}\eta\right)^i\right] \tag{14}$$

where $k = 0.43$ is the Von Karman constant, ν the kinematic viscosity of the water, A a damping factor, which

Copyright © 2006 Taylor & Francis Group plc, London, UK

for open channel flows is equal to 26 (Nezu and Rodi, 1986), and

$$u_* = n_m \sqrt{\frac{g}{h^{\frac{1}{3}}}} U \tag{15}$$

the friction velocity.

The general solution of equations (10) can be expressed as a power series

$$V(x,\eta) = U(x) f(\eta) = U(x) \sum_i \alpha_i \eta^i \tag{16}$$

whose coefficients α_i $(i = 2, 3, \ldots)$ are defined by means of recurrence relations, as functions of the coefficients α_0, α_1, obtained substituting the solution (16) in the differential equations (10) and equating terms with the same power of η. Two boundary conditions are necessary in order to define the coefficients α_0, α_1 as functions of the flow characteristics. Such boundary conditions are the following:

$$\begin{cases} U = \int_0^1 V d\eta \Rightarrow \int_0^1 f d\eta = \sum_{i=0}^{N} \frac{\alpha_i}{(i+1)} = 1 \\ \left.\frac{dV}{d\eta}\right|_{\eta=\frac{d_{50}}{h}} = h \frac{u_*}{\kappa d_{50}} \end{cases} \tag{17}$$

The derivation of the first boundary condition is straightforward. The second boundary condition is derived imposing that the velocity profile has the same inclination of the logarithmic profile in correspondence of the bottom: i.e. for $\eta = h/d_{50}$. Once the analytical expression (16) of V is completely determined, the expressions of the horizontal and vertical velocity components as well as the pressure can be obtained. In particular this latter is given by:

$$p = \rho g h (1-\eta) + \rho h \int_\eta^1 \left(a_2 (1-\xi)^k + a_1 \xi^k \right) V^2 d\xi \tag{18}$$

where the hydrostatic and dynamic pressure contributions are distinguishable.

In Figure 4a-d a comparison between the measured and predicted velocity profiles of the horizontal velocity component at four different locations, $x = 5$ cm (Figure 4a), $x = 65$ cm (Figure 4b), $x = 105$ cm (Figure 4c) and $x = 165$ cm (Figure 4d), respectively, for test U1 is shown. The agreement between measured and predicted velocity profiles is good, showing the validity of the assumed hypothesis.

Velocity components and pressure (18) depend on $z_b(x)$, $h(x,t)$, $U(x,t)$, $H(x,t) = z_b(x) + h(x,t)$, as well as on the Manning's coefficient. In this work $z_b(x)$ is obtained by interpolating experimental data, while

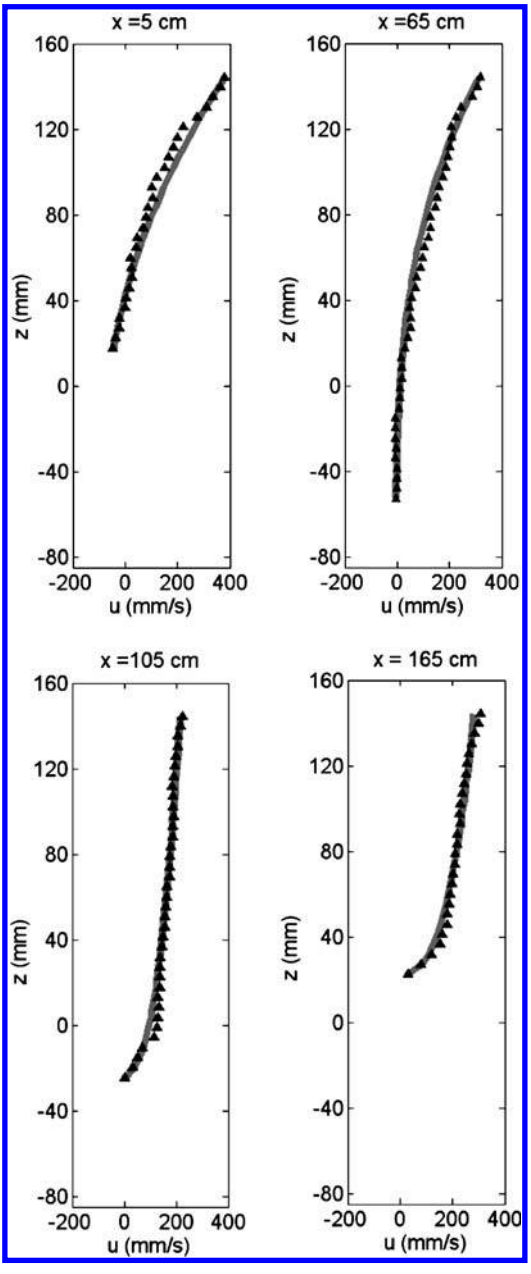

Figure 4. Comparison between measured and predicted profiles of the u velocity component at four different locations for test U1.

the Manning's coefficient is calculated as (Marchi and Rubatta, 1980):

$$n_m = \frac{(2d_{50})^{\frac{1}{6}}}{24\sqrt{g}} \tag{19}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

At last evolution equations for $h(x,t)$, $U(x,t)$ can be obtained depth –averaging the mass and momentum balance equation. The result is:

$$\begin{cases} \dfrac{\partial h}{\partial t} + \dfrac{\partial Uh}{\partial x} = 0 \\ \dfrac{\partial U}{\partial t} + g\dfrac{\partial}{\partial x}\displaystyle\int_0^1 \left(\frac{V^2}{2g} + h\eta + z_b + \frac{p}{\rho g} \right) d\eta = -g n_m^2 \frac{U|U|}{\Re^{4/3}} \end{cases} \quad (20)$$

where n_m, and $\Re$ are, respectively, the Manning's coefficient and the hydraulic radius, defined in the usual way for open channel flow with a mobile bed (Garde and Ranga Raju, 1977, Marchi and Rubatta, 1980). Equations (20) are the classic De Saint Venant equations for free surface flows, in which curvature effects connected to the free surface and bottom profiles have been accounted for. At last, the unknown functions $h(x,t)$ and $U(x,t)$ are defined as the sum of a base flow and an unsteady perturbation with a known dependency on time:

$$\begin{cases} h(x,t) = h_0(x) + h_1(x)e^{\gamma t} \\ U(x,t) = U_0(x) + U_1(x)e^{\gamma t} \end{cases} \quad (21)$$

It is supposed that the perturbations are small quantities with respect to those of the base flow. Then, after having substituted expressions (21) in equations (20), quadratic and higher order perturbation terms nonlinear terms are discarded. Imposing that the expressions (21) satisfy equations (20), a linear, homogeneous differential system is obtained for the evolution of the perturbation flow, given the base solution $h_0(x)$, $U_0(x)$. The parameter γ, which can be considered as an eigenvalue of such linear and homogeneous differential problem, gives information on the stability of the base solution: if the real part of γ is positive, perturbations imposed on the base solution will tend to destroy the base solution and then this latter is considered unstable. On the contrary, if the real part of γ is negative, perturbations imposed on the base solution will tend to decrease with time and the base solution is considered stable. Of course, such conclusions are considered valid in the framework of a linear stability analysis: i.e. they are valid in the early stage of the perturbations.

5 COMPARISON WITH LABORATORY MEASUREMENTS

Base flow is assumed to be known and given by the following interpolating expressions for $H_0(x)$, $z_b(x)$, obtained by laboratory measurements of free surface and bottom profiles:

$$H_0(x) = h_d + \eta \sin\left(\frac{2\pi x}{l_0} \right) \quad (22)$$

$$z_b(x) = \frac{z_d - |z_{\max}|}{2} - \left(\frac{z_d + |z_{\max}|}{2} \right) \sin\left(\frac{2\pi(x - x_0)}{l_s} \right) \quad (23)$$

l_0 and η are respectively the measured wavelength and amplitude of the free surface undulations, defined respectively as the distance between the first two crests of the free surface and half the distance between first crest and first throat over the eroded bed. With reference to Figure 3b, z_{max} is the maximum scour depth, z_d is the dune height, x_0 is the abscissa where the scour depth is equal to

$$z_b(x_0) = \frac{z_d - |z_{\max}|}{2} \quad (24)$$

and l_s is the scour hole wavelength defined in Figure 3b. With such a definition of the bottom wavelength, the expression (23) best fits the scour profile, as it is possible to see in Figure 2a-c. As a consequence the mean velocity profile $U_0(x)$ is given by:

$$U_0(x) = \frac{Q}{b h_0(x)} = \frac{Q}{b[H_0(x) - z_b(x)]} \quad (25)$$

Q being the discharge, considered constant with respect to time.

The experimental configurations considered, both for a flat and a scoured bed, are shown in Table 3, where Fr_d is the downstream Froude number, defined as:

$$Fr_d = \frac{Q}{b h_0 \sqrt{g h_0}} \quad (26)$$

Table 3. Experimental configurations: Fr_d, downstream Froude number; l_0, measured wavelength of the free surface undulations; η_0, measured amplitude of the free surface undulations; l_s, scour wavelength.

Run	Fr_d	l_0 (m)	η_0 (m)	l_s (m)	Stability
T1	0.15	0.12	0.0045	2.2	Unstable
T2	0.17	0.15	0.0030	2.0	Unstable
T3	0.18	0.18	0.0020	2.8	Unstable
U1	0.14	0.35	0.0030	2.2	Stable
U2	0.15	0.25	0.0040	2.3	Stable
U3	0.16	0.35	0.0035	2.9	Stable
T1FB	0.15	0.20	0.0029	–	Stable
T2FB	0.17	0.25	0.0034	–	Stable
T3FB	0.18	0.20	0.0031	–	Stable
U1FB	0.14	0.25	0.0054	–	Stable
U2FB	0.15	0.25	0.0144	–	Stable
U3FB	0.16	0.25	0.0139	–	Stable

Copyright © 2006 Taylor & Francis Group plc, London, UK

The stability of the experimental configurations can be performed by adopting the following expression for the perturbation flow:

$$\begin{cases} h_1(x) = a\,Cos\left(\frac{2\pi}{l_0}x\right) + b\,Sin\left(\frac{2\pi}{l_0}x\right) \\ U_1(x) = c\,Cos\left(\frac{2\pi}{l_0}x\right) + d\,Sin\left(\frac{2\pi}{l_0}x\right) \end{cases} \quad (27)$$

by substituting them in the correspondent linear, homogeneous differential system and by averaging this latter with respect to x. At last, imposing a suitable solvability condition, an algebraic, fourth order equation is obtained for γ. The real part of this latter gives indications on the stability of the base flow.

Figure 5a-f and Figure 6a-f, in which the horizontal axis represents the wavelengths of the surface wave jet, the vertical axis the downstream Froude number, show the results of the stability analysis. Both in Figure 5a-f and Figure 6a-f lines separate the unstable from the stable region: the stability region is on the right of the lines. The six stable and unstable experimental configurations are represented in the diagrams by diamonds.

Horizontal lines limit the area over which it is physically possible to have a hydraulic jump for the experimental conditions considered. So the stability diagram is divided into three regions: the stable region on the right, the unstable region on the left and the no hydraulic jump region in the lower part.

The presence of a scoured bed weakens the surface wave jet stability properties. As a matter of fact, in Figure 6a-f, relative to the comparison of the stability diagrams with flat bottom (Figure 6a-c) and with scoured bed (Figure 6d-f), the stability characteristics of the oscillating jet are modified passing from the flat bed to the scoured bed both because the stability areas increase and because the characteristics of the free surface undulations (amplitude and wavelength) change, i.e. the experimental point changes its position. So the transitional jet becomes stable if the bed is flat.

The comparison of the free surface undulations amplitudes of tests U1-U3 and U1FB-U3FB, shown in Table 3, highlight how the presence of a scoured bed increases the dissipation. The increased dissipation is due to the expansion of the flow in presence of a scoured bed.

In conclusion, the stability analysis of the modified De Saint-Venant equations (20) gave good results, because, starting from the experimental values of discharge, downstream water depth, free surface undulations amplitude, length and maximum scour depth, it was able to highlight stability and instability areas to which experimental points belong.

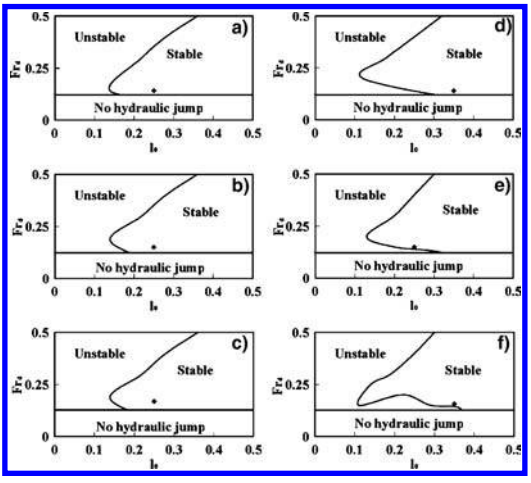

Figure 5. Stability diagrams for tests: U1FB (a), U2FB (b), U3FB (c), U1 (d), U2 (e), U3 (f).

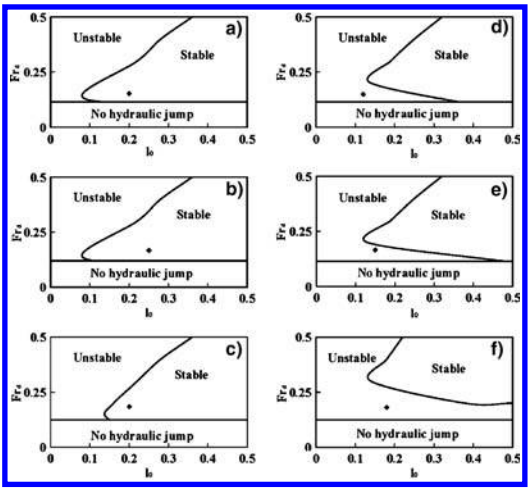

Figure 6. Stability diagrams for tests: T1FB (a), T2FB (b), T3FB (c), T1 (d), T2 (e), T3 (f).

6 CONCLUSIONS

The dependence of turbulent jets stability on bed geometry is investigated by both a laboratory and a theoretical study. Jet flow was produced by the interaction of the main flow and a drop, followed by a rigid apron. Two series of laboratory experiments were performed with both a mobile and a flat rigid bed downstream of the drop. The discharge and the downstream water depth were varied and two kinds of jet flow were observed: a surface wave jet and an oscillating jet. The oscillating jet is an unstable flow configuration. Both velocity and free surface flow measurements

Copyright © 2006 Taylor & Francis Group plc, London, UK

were performed. Starting from those laboratory measurements, a mathematical model, which investigates the stability of the surface wave jet both over a flat and a scoured bed, was developed. A mathematical model, derived starting from the momentum equation, in the s, n coordinate system, permitted to obtain analytical expressions for the horizontal and vertical velocity component and for the pressure. The stability analysis of the surface wave jet both on a flat and a scoured bed, performed by a modified version of De Saint-Venant equations allows the classification of the experimental configuration under consideration. The mathematical model was able to reproduce velocity profiles in different location along the scour, revealing the validity of the assumptions made. The comparison between the analysis of the surface wave flow on flat and scoured bed highlighted the influence of the scoured bed on the stability of the surface wave flow. The scoured bed weakens the stability properties of the surface wave flow, so that stable configurations with a flat bed are unstable with a scoured bed. Moreover, the presence of the scour increases the dissipation: as a matter of fact larger surface wave amplitudes are found with a flat bed than a scoured bed. This fact is easily explained by the expansion of the flow occurring with the scoured bed.

Investigation of the velocity and pressure fluctuations distributions inside the turbulent horseshoe vortex system around a circular bridge pier

G. Kirkil, G. Constantinescu & R. Ettema
Civil & Environmental Engineering Department, IIHR-Hydroscience & Engineering The University of Iowa, M. Stanley Hydraulics Laboratory, Iowa City, IA

ABSTRACT: Large eddy simulation with a dynamic sub-grid scale model is used to study the spatio-temporal structure of the horseshoe vortex (HV) system around a bridge pier of circular section in a shallow channel with a flat bed. It is found that the structure of the turbulent HV system varies considerably in space and time, though, typically, a relatively stable, necklace like vortical structure (primary vortex) is present around the upstream face of the cylinder and oscillates randomly. The simulation captures the presence of bimodal aperiodic chaotic oscillations inside the HV system region, as well as the sharp increase in the resolved velocity fluctuations and pressure fluctuations observed in previous experimental investigations of high Reynolds number junction flows. It is observed that in the bimodal region the histogram of the velocity fluctuations displays a double-peak shape for all the velocity components except the one along the core of the primary HV.

1 INTRODUCTION

Natural river channels are subject to continuous change in geometry due to the interaction between the flow and the erodible boundaries. In particular, the study of scour associated phenomena at bridge piers and abutments (Melville, 1997) is a problem of paramount importance for bridge designers due to the fact that scouring of the river bed takes place near these structures. As a consequence, the resulting weakening of the bridge foundation during flood events is the main cause of bridge failure. Despite a great deal of studies (see for instance Melville, 1997) which focused mainly in predicting the dimensions of the scour hole and maximum scour depth, a clear understanding of the mechanisms that govern the interaction of the approach flow with the bridge abutment and the river bed is still lacking. We think that a better understanding of the flow structure in the scour region and, more generally, of the flow physics of junction flows, will be useful toward developing new methods to predict the scour around bridge piers.

A wide range of turbulent scales are present around the bridge pier and control the transport process. Regardless of the exact form of the pier, one the main mechanisms (Dargahi, 1989, Simpson, 2001) that drives the formation and future evolution of the scour hole is the formation of a necklace like vortical structure, commonly known as the horseshoe vortex (HV) system. Thus, to understand the scour mechanism, one has first to be able to qualitatively describe the structure of the coherent vortices part of the HV system in the different flow regimes and to quantitatively characterize its effect on the flow and the river bed, near the pier base. In this paper we are interested in studying the HV system at the start of the scouring process (flat bed conditions) in the case of a pier with a circular section. A similar investigation of the flow under equilibrium scour conditions was described in Kirkil et al. (2005).

The separation of the upstream boundary layer and the formation of a separation (stagnation) line on the bottom surface around the pier are a consequence of the adverse pressure gradients induced by the presence of the pier. These streamwise adverse pressure gradients are also the main cause of the formation of necklace vortices around the upstream part of the pier base. These horseshoe vortices are a consequence of the reorganization of the boundary-layer vorticity downstream of the separation line. The primary HV has the same sense of rotation as the vorticity in the upstream boundary layer. The HV will stretch around the pier and fold around the upstream part of it, very close to the bottom, partly because of the spanwise pressure gradients. Consequently, the sides of the vortex lines will become oriented in the streamwise direction, with the vorticity being of opposite sign in the two sides (legs). The main necklace vortices entrain higher velocity fluid from the outer layer along the upstream face of the pier toward the bed in what is generally called the downflow. As a result of the interactions between the downflow, the bed and the HV

Copyright © 2006 Taylor & Francis Group plc, London, UK

system, the drag around the upstream side of the pier is increased. In the case of an incoming turbulent flow, the location, size and intensity of the HV eddies are observed to be highly varying in time, to produce high turbulence and pressure fluctuations (Simpson, 2001, Dargahi, 1989) and to induce high bed shear stresses.

Recent experimental investigations (Devenport & Simpson, 1990, Rife et al., 1992, Chen et al., 2000, Wei et al., 2001) using Particle Image Velocimetry (PIV) and Laser Doppler Velocimetry (LDV) techniques have increased considerably our understanding of the intricate structure of the horseshoe vortex system, especially in the symmetry plane. Dargahi (1989) used hydrogen-bubble techniques and hot film anemometry to investigate the turbulent HV system in front of a circular bridge pier. He observed that vortices were shed from the separation region, similar to the case of a laminar HV system. The turbulent HV system was found to contain, at most times, several primary vortices rotating in the same direction and a number of bed-attached vortices rotating in opposite direction. Measurements of the mean flow-fields around a surface mounted cylinder in an open channel with a flat bed ($Re_D \sim 10^5$) were reported by Graf & Yulistiyanto (1998). The mean components of the velocity and turbulent stresses were measured using an Accoustic Doppler Current Profiler (ADCP), both upstream and downstream the cylinder. The mean extent of the HV region was estimated, but no attempts were done to visualize the coherent structures inside the HV system or downstream the cylinder. Chen et al. (2000) investigated the flow past cylinders of different shapes at $Re_D = 32{,}000$ and observed that, in average, the turbulent HV system is characterized by the formation of a large primary vortex that oscillates chaotically around a mean position.

One of the most interesting phenomena associated with the turbulent HV system is the presence of bimodal aperiodic chaotic oscillations which are one of the main causes of the observed sharp increase of the velocity fluctuations, turbulence production, Reynolds stresses and pressure fluctuations inside the HV region (Devenport & Simpson, 1990, for a Rood wing, and Olcmen & Simpson, 1994, for the case of an elliptic nose NACA tail wing). This phenomenon which consists of the flow in the HV region switching between two modes at times intervals whose probability density function is likely Markovian was observed first by Devenport & Simpson (1990) in the study of the flow past a surface mounted wing shaped cylindrical body at very high Reynolds numbers ($Re_D \sim 10^6$, where D corresponds to the maximum thickness of the wing). In the bimodal region, the histogram of velocity fluctuations was observed to display a double-peak shape. The switching was observed to take place at a relatively low frequency compared to the oscillation (passage frequency) of the vortices inside the HV system. In a related study of the flow past the Rood wing, Rife et al. (1992) measured the mean frequency (f) of the velocity fluctuations associated with the bimodal oscillations at around St $(= fD/U) = 0.05$, where the maximum width of the wing was used as the length scale (D) and U is the mean velocity. This suggests that the low-frequency oscillations are not produced by the coherent structures in the HV region, but rather due to fluctuations in the momentum in the outer part of the boundary layer that are recirculated as they impinge on the wing nose. It is however believed that the bimodal aperiodic large-scale horseshoe vortex phenomenon is a common feature of junction flows in the turbulent regime, provided that the surface mounted body is blunt enough.

Despite the new information obtained from recent experimental studies, a detailed quantitative description of the HV system around the base of a circular pier is still not available. Eddy-resolving numerical simulations like Large Eddy Simulation (LES) which obtain the whole three-dimensional (3D) fields as part of the time-accurate solution have the advantage of allowing an in-depth investigation of the HV system at an arbitrary number of polar planes or in other relevant sections, at no additional cost. They also allow direct estimation of the spatio-temporal distribution of the bed-shear stress and pressure fluctuations in its immediate vicinity. As pointed out by Simpson (2001) in his review of junction flows, LES appear to be the best suited numerical technique to capture the details of the HV dynamics, due to the large range of energetic scales and associated frequencies that are present in the HV region. It is very doubtful that unsteady RANS methods, even with second order closures, will be able to accurately capture the flow physics in the bimodal flow region.

2 NUMERICAL METHOD AND SIMULATION SETUP

A recently developed massively parallel LES flow solver (Mahesh et al., 2004) is used in the present work. The algorithm, that was developed for unstructured grids, is non-dissipative (central-differences schemes are used to discretize all operators in the governing equations, including the convective terms and no filtering of the resolved velocity field is used), yet robust at high Reynolds numbers on highly skewed meshes. Discrete energy conservation was found essential to ensure this behavior. The dynamic Smagorinsky model is used to account for unresolved turbulence effects.

Figure 1 shows a sketch of the computational domain with the convention used to identify the vertical sections cutting at a certain polar angle ϕ relative to the free stream velocity. The y axis is perpendicular to the channel bed. The physical domain extends

Instantaneous and mean structure of the horseshoe vortex system; a) and b) visualizations of the instantaneous structure using Q-isosurfaces at two different time instants; c) instantaneous in-plane vorticity contours in y/D = 0.04 plane; d) visualization of the primary mean horseshoe vortex and corner vortex using Q-isosurfaces.

5D upstream of the cylinder and 10D downstream, where the length scale D is the cylinder diameter. The depth of the channel, H, is constant and equal to 1.12D. The lateral extent of the domain is 16D. The cylinder Reynolds number is $Re_D = UD/\nu = 16{,}000$, where U is the mean channel velocity and ν is the molecular viscosity. To enhance the generality of the results presented in the paper at a particular value of the Reynolds number, all the variables are nondimensionalized with the cylinder diameter, D, and the mean channel velocity, U. The inflow conditions, which contain realistic turbulence fluctuations, are obtained from a separate LES simulation in a periodic channel of identical section, at the same channel Reynolds number. The LES velocity fields are then fed in a time-accurate way through the inflow section. The grid density is varied throughout the domain such that a very dense mesh is generated in the HV region, in the detached shear layers and inside the turbulent wake. The unstructured mesh contains over 4 million cells distributed using a paving technique that allows maintaining a high quality of the mesh while varying substantially the mean size of the elements among the different regions. Near the solid surfaces, the first layer of cells is situated at about one wall unit, $\Delta y^+ (= \Delta y.u_\tau/\nu) = 1$, (the non-dimensional friction velocity u_τ/U is conservatively assumed to be equal to 0.04) from the solid surfaces. Typical computational cell dimensions in the HV region away from the walls and inside the detached shear layers are 4-20 wall units. A detail view of the free surface mesh around the cylinder is shown in Figure 1a. The time step was 0.002 D/U. The simulation was run on 24 processors of a Xeon PC Cluster with Myrinet.

3 RESULTS

The degree of intermittency of the HV eddies was found to be high and the overall structure of the HV system was observed to change significantly in time. However, at most times the presence of a large primary vortex (PV) that oscillates and changes his coherence randomly was observed. The simulation also captured the presence of several secondary coherent unsteady vortices, part of the HV system. For instance, the Q criterion is used in Figures 2a and 2b to educe the main coherent structures in the region around the base of the pier in two instantaneous solutions. The common feature of the results in Figures 2a and 2b is the presence of a relatively large necklace vortex (PV) along with a small corner vortex (CV) right at the junction between the cylinder and the bed. Though the PV is present in both frames, its position relative to the cylinder and extent in the polar direction is found to vary significantly. In Figure 2a, the PV covers the region defined by polar angles in the interval $-90° < \phi < 90°$, while in Figure 2b the PV is present only in the region $-90° < \phi < 45°$ and is located closer to the cylinder. More details about the instantaneous vortical content of the HV region is given by snapshots of the in-plane instantaneous vorticity $(\sqrt{\omega_x^2 + \omega_z^2})$ contours, plotted in a plane parallel to the bed situated at y/D = 0.04 (Figure 2c). At that particular instant of time, the PV is present in the region defined by $-90° < \phi < 70°$. Additionally, a secondary necklace structure is visible at negative polar angles upstream the PV. In fact, animations show that the HV region is populated by necklace like eddies whose extent in

Copyright © 2006 Taylor & Francis Group plc, London, UK

the polar direction is highly variable in time. Random formation and shedding of small necklace "new" vortices from the separation region is observed. Some of these vortices will merge with the primary vortex that is being stretched, and form a "new" primary vortex, others will loose their coherence rapidly. Some of them can move over the PV before merging with it or, in some cases, two secondary vortices may oscillate around each other and, eventually, merge together. The overall scenario observed for the evolution of the HV system in our simulation is very close to that observed by Kim et al. (1991) who studied the turbulent HV system in front of a wing shaped body (Rood wing) for $16{,}500 < \mathrm{Re_D} < 62{,}000$.

However, when the instantaneous flowfields are averaged, only the PV and CV structures are present. This is evident in Figure 2d where the vortical structure of the mean flow is visualized using Q isosurfaces. Q is defined as the second invariant of the velocity gradient tensor and regions of positive Q are considered as vortical regions (Jeong & Hussain, 1995). One should observe that the legs of the PV eddy educed using the Q criterion are not exactly parallel with the mean flow direction. An indication of the decay of the intensity of PV at high polar angles and then in the leg region is given by the fact that the PV has the largest cross section in the $\phi = 0°$ plane. The cross section is decaying with the increase in the absolute value of the polar angle.

To visualize the position of the mean HV system relative to the cylinder, one can also look at the distributions of the turbulent kinetic energy (tke) and pressure fluctuations in various polar planes along with the flow patterns shown by 2D streamlines. This was done in Figures 3a ($\phi = 0°$) and 3b ($\phi = 45°$) using the pressure fluctuations. The region characterized by high pressure fluctuations correlates well with the main vortex in the 2D streamline plot (compare Figures 3b and 3c). The 2D streamlines in Figure 3c also show the presence of a bottom attached vortex just upstream of the PV and of the corner cortex CV. This vortex was also observed to form in experimental visualizations of the flow in turbulent HV system around the circular pier (Dargahi, 1989).

Clearly the turbulence inside the HV region dominates the surrounding turbulence. The ratio between the largest pressure fluctuations inside this region and that of the surrounding flow is close to ten, in agreement with the experimental measurements of Devenport & Simpson (1990) obtained at a much higher Reynolds number. It is unlikely that the high tke and pressure fluctuations levels in the HV region are produced only by turbulence mixing. Related to the variation of the intensity of the PV as it wraps around the cylinder, a detailed analysis of the flow in different polar sections (similar to the two frames in Figure 3) confirmed that the intensity of the pressure

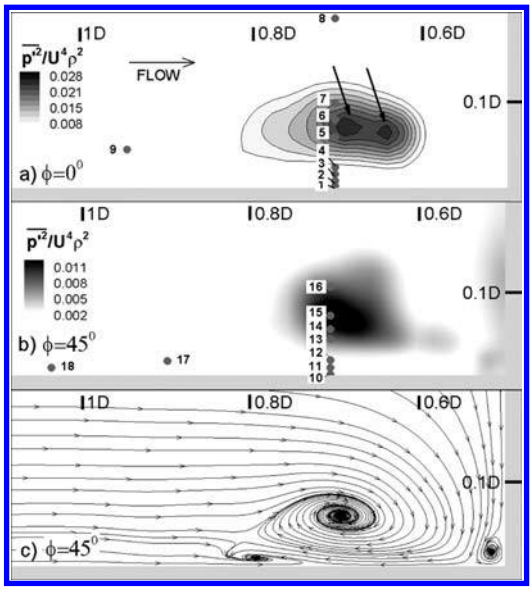

Figure 3. Visualization of the primary vortex in the mean flow; a) mean pressure fluctuations, $\phi = 0°$plane; b) mean pressure fluctuations, $\phi = 45°$plane; c) mean 2D streamlines, $\phi = 45°$ plane.

fluctuations and tke decays with the absolute value of the polar angle (see also distributions of vertical velocity fluctuations in Figure 13). Moreover, until $\phi = 70°$, the PV vortex gets closer to the cylinder (see also vertical velocity fluctuations distributions in Figure 3). The average position of PV is between $r/D = 0.6$ and $r/D = 0.8$, where the radius is measured from the center of the cylinder. Also, it is worth mentioning the fact that in Figure 3a the distribution of the r.m.s. pressure fluctuations has two areas of relatively high values in the HV region. We are going to see that this double peak distribution is induced by the oscillations of the PV between the two modes identified by Devenport & Simpson (1990). Interestingly, the pressure fluctuations levels inside the CV are higher in the $\phi = 45°$ plane compared to the $\phi = 0°$ plane though the double peak distribution is not present.

Another way to visualize the instantaneous structure of the flow in the HV region and to investigate the reason why the double peak structure is present in the pressure fluctuations distributions (Figure 3a), vertical velocity fluctuations (Figure 13) and turbulent kinetic energy distributions (not shown) at low polar angles is to examine the distributions of the out-of-plane instantaneous vorticity and 2D streamlines in different polar planes around the cylinder and at different time instants. This was done in Figure 4, where the structure of the HV system in the $\phi = 0°$ plane at different time instances was visualized. It was observed that at some time instances the PV was situated closer

to the cylinder and its coherence was relatively high. A unique, relatively circular, patch of vorticity appeared to be associated with the PV. Two time instances when the HV system had these characteristics which, according to Devenport & Simpson (1990), correspond to the zero-flow mode are shown in Figures 4a and 4b. At the opposite range, in terms of the observed states of the HV region, the overall size of the PV appears to be sensibly larger, its shape is elliptical, its coherence is lower as the positive vorticity distribution within the HV region is much more diffused (less compact) and the center of this region is situated at a larger distance from the cylinder. These states are associated with what is called the backflow mode (Figures 4c and 4d). Observe also the sheet of negative vorticity beneath the PV which is much longer in the frames corresponding to the backflow mode. This sheet of negative vorticity is in fact due to the presence of a near-wall jet of variable intensity in that region. The jet is clearly visualized in the in-plane velocity vector plots in Figure 5b when its intensity is at its highest (backflow mode). In the same figure, separation from the bed is taking place at about 0.35D–0.4D from the face of the cylinder. In contrast to that, in Figure 5a corresponding to the case when the HV system is in the zero-flow mode, the intensity of the jet flow is much smaller, separation takes place at only 0.2D from the cylinder and the normal velocities above the separation region are larger. Additionally, a weak recirculation region is observed upstream of the jet separation region, consistent with the experiments of Devenport & Simpson (1990).

The formation of the backflow mode is thought to be due to entrainment of patches of high-velocity low-vorticity fluid from the free-stream flow that get entrained in the HV regions via the downflow. The unsteady reversed jet-like flow beneath the HV region increases its momentum and also forces the PV to move away from the cylinder. As this large but not very coherent necklace vortex system gets stretched around the cylinder, its cross section gets smaller, the intensity of the jet like flow beneath it decreases, the PV becomes more compact and moves closer to the cylinder face. During this time, in which the HV is in the zero-flow mode, the flow becomes more stable until a new patch of free-stream flow is injected in the HV region or the interactions between the main necklace vortex with the secondary vortices are strong enough to destabilize the flow and produce again a larger, less compact vortex. Devenport & Simpson (1990) also associated the zero-flow mode with the injection of a patch of rotational low-momentum fluid from the outer region of the boundary layer inside the HV region.

More evidence and explanation of the existence of the two modes and their effect on the flow in the HV region is given by analysis of the probability density function (pdf) plots of the velocity components.

This information is shown in Figures 6 to 8 for the streamwise, vertical and spanwise components on a vertical line intersecting the mean PV vortex (position of the points 1 to 8 is shown in Figure 3a) in the $\phi = 0°$ plane. The pdf's of the streamwise and vertical velocities are shown in Figures 9 and 10 (position of the points 10 to 16 is shown in Figure 3b) in the $\phi = 45°$ plane. Additionally, the pdf's of the streamwise and vertical velocities at two points situated outside the HV region (points 17 and 18 in Figure 3b) are shown in Figure 11. In the $\phi = 0°$ plane, the bimodal behavior of the pdf's for the streamwise u-velocity starts from $y/D = 0.008$ (Point 2) and continues up to $y/D = 0.08$ (Point 6) inside the mean primary vortex. Close to the bed ($y/D = 0.002$) and above the PV region ($y/D > 0.1$) the bimodal behavior is absent. The bimodal distribution is also observed for the vertical velocity component, but the bimodal region in the same section is shifted upwards ($0.02 < y/D < 0.15$). In agreement with the findings of Davenport & Simpson (1990), no bimodal region is detected in the pdf's of the spanwise (along the core of the PV) velocity component in the $\phi = 0°$ plane (Figure 8). In the $\phi = 45°$ plane, a bimodal region is observed for all three Cartesian velocity components (this is normal, as none of them is oriented along the core of the vortex), but the size of the bimodal region appears to shrink ($0.01 < y/D < 0.06$ for u and $0.02 < y < 0.06$ for v). As expected, outside

the HV region, the pdf's of the velocity components have a single peak (Gaussian) shape (Figure 11).

The time intervals corresponding to successive mode switching was computed at several points in the bimodal region. It was observed that the most common time between events corresponds to a non-dimensional time interval of about 2.96D/U which is comparable to the most probable residence time (~4.14D/U) calculated by Davenport & Simpson (1990) in their study of flow around a cylindrical wing body at Reynolds numbers larger than one million.

A range of energetic frequencies around St(= fD/U) = 0.1 – 0.18 was present in the resolved velocity and pressure spectra (not shown). This band of low frequencies does not appear to be related to the oscillation of the primary vortex or to the shedding of secondary vortices from the separation region toward the PV which take place in a higher frequency band ($0.3 < St < 0.6$) but rather with the bimodal oscillations. The lower frequency range is consistent with results obtained by Rife et al. (1992) who measured the mean frequency of the velocity fluctuations associated with the bimodal oscillations at around St = 0.05 (the maximum width of the wing was used as the length scale). Power spectra determined from the present simulation show the presence of an inertial resolved range until St ~ 40. The predicted spectral information appear to be consistent with that from the experimental study of the flow past a circular pier at $Re_D = 39{,}000$ of Dargahi (1989). The Strouhal number range corresponding to the energetic frequencies in the velocity spectra was measured between 0.058 and 1.15. The lower part of the range is likely to be associated with the bimodal oscillations. The spectra measured by Wei et!al. (2001) at $Re_D \sim 10{,}000$, when the initially laminar boundary layer is becoming turbulent in the HV region, contained a range of energetic frequencies in the interval St = 0.15 to 0.95. In their experiments the cylinder section was square. Taking into account the different conditions between the aforementioned experiments and our simulation, our results look reasonable.

More information about the effect of the scillation of the PV vortex between the backflow mode and the zero-flow mode is given by the distributions of the velocity fluctuations in a horizontal direction corresponding to the local polar angle ("polar" direction) in that section (Figure 12) and by the vertical velocity

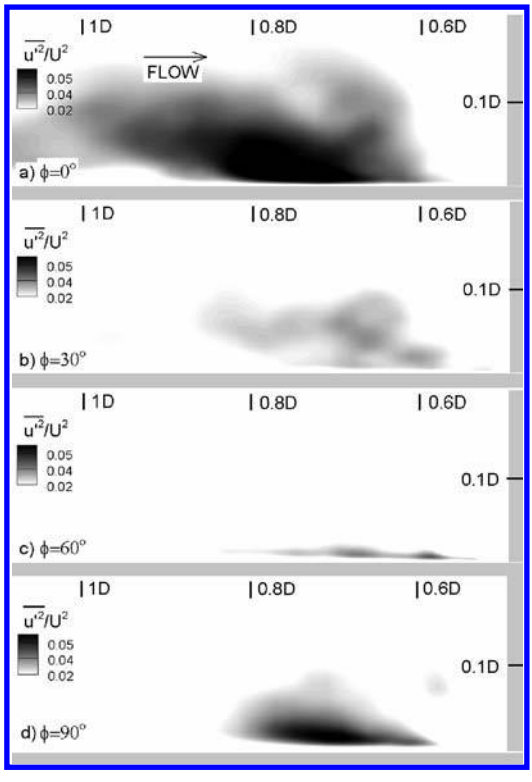

Figure 12. Distribution of velocity fluctuations in a horizontal direction oriented after the local polar angle ("polar" direction); a) $\phi = 0°$ (streamwise fluctuations) b) $\phi = 30°$; c) $\phi = 60°$; d) $\phi = 90°$ plane.

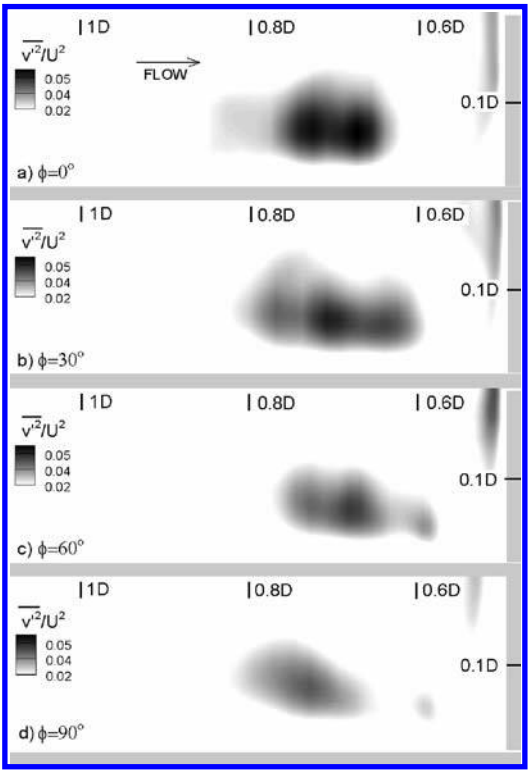

Figure 13. Distribution of vertical velocity fluctuations; a) $\phi = 0°$; b) $\phi = 30°$; c) $\phi = 60°$; d) $\phi = 90°$ plane.

fluctuations (Figure 13) in the $\phi = 0°$, 30°, 60°, 90° planes.

The regions of high vertical velocity fluctuations in Figure 13 correlate very well with the mean position of the PV vortex. The double peak structure is still present even in the $\phi = 60°$ frame of Figure 13. The change in the overall shape of the core of the PV with the polar angle from strongly elliptical in the symmetry plane to relatively circular in the legs is due precisely to the decay of the intensity of the mode switching phenomenon with the polar angle. The resolved velocity fluctuations in the "polar" direction are peaking much closer to the floor in the region in which the intensity of the intermittent reversed wall-attached jet is highly variable in time (e.g., see Figure 12a in which the "polar" direction is streamwise oriented), as the flow switches between the two modes. So, the high velocity fluctuations in regions characterized by a low magnitude of the polar angle are directly associated with the mode switching and to a lesser degree due to locally high values of the small scale turbulence in that region. The decay of the velocity fluctuations in the "polar" direction with the polar angle (for $|\phi| < 60°$) is much sharper compared to that observed for the vertical fluctuations.

Observe also the relatively high vertical velocity fluctuations very close to the cylinder face due to modulations in the intensity of the downflow by the eddies transported in the outer flow. These eddies are being stretched as they are projected toward the bed and can strongly interact with the PV. The velocity fluctuations inside the CV are relatively low.

The distribution of the total tke production in the symmetry plane (Figure 14a) clearly shows that in the HV region and, in particular, in the sub-region associated with the chaotic mode switching, the turbulence energy production is high. The elongated patch of high positive production ($-0.88 < x/D < -0.68$, x measured from the center of the cylinder) contains two peaks, again corresponding approximately to the positions of the PV in the two extreme modes. A very elongated region, in which the production is negative, is observed close to the bottom wall, between the upstream face of the cylinder ($x/D \sim -0.53$) and $x/D \sim -0.65$. It is interesting to notice that these features of the distribution of the total production term in the symmetry plane are very similar to those of the measured tke production in front of a wing shaped body at much higher Reynolds numbers by Devenport & Simpson (1990). Figures 14a, 14b and 14c show the distributions of the main terms contributing to the total production $-2\overline{u'^2}\partial U/\partial x(D/U^3)$, $-2\overline{v'^2}\partial V/\partial y(D/U^3)$ and $-2\overline{u'v'}\partial U/\partial y(D/U^3)$, respectively. Consistent with the high intensity of the streamwise velocity fluctuations recorded in the region corresponding to the intermittent wall attached jet (see Figure 12a) and with the deceleration of the backflow in the positive

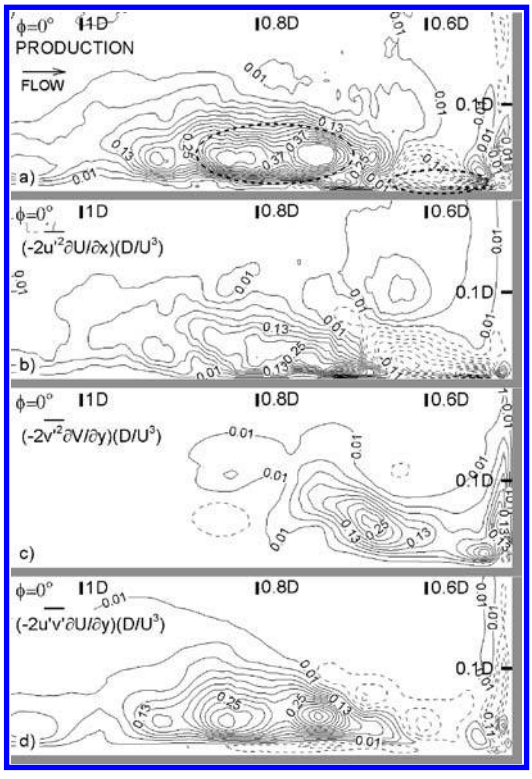

Figure 14. Contours of the turbulent production terms in the turbulent kinetic energy equation, $\phi = 0°$ plane; a) total production; b) $-2\overline{u'^2}\partial U/\partial x(D/U^3)$; c) $-2\overline{v'^2}\partial V/\partial y(D/U^3)$; d) $-2\overline{u'v'}\partial U/\partial y(D/U^3)$.

x direction, as the jet loses streamwise momentum, a region of high positive $-2\overline{u'^2}\partial U/\partial x(D/U^3)$ values is observed beneath the mean PV. In between the extremity of this region and the upstream face of the cylinder, another region of relatively high negative values of this term is present. In this region the backflow accelerates before moving beneath the center of the PV. The production term associated with the vertical Reynolds stress shows high positive levels in a region closer to the cylinder that corresponds to the PV being in the zero flow mode. Interestingly, the maximum values are comparable to the ones recorded for the other main two terms. Finally, the primary Reynolds shear stress production term $-2\overline{u'v'}\partial U/\partial y(D/U^3)$ shows a two positive peak distribution, similar to the total production term. The first peak is situated just upstream of the patch of fluid characterized by high values of $-2\overline{v'^2}\partial V/\partial y(D/U^3)$. The large values of the primary shear stress in the region of high $-2\overline{u'v'}\partial U/\partial y(D/U^3)$ values are due mostly to the bimodal large-scale flow oscillations. The large mean streamwise velocity gradient in the normal direction is mostly due to the

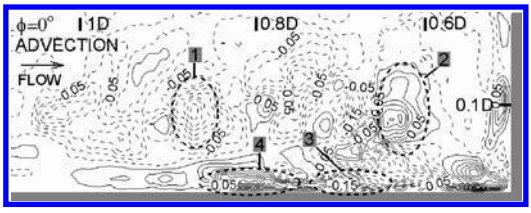

Figure 15. Contours of the total advection term in the turbulent kinetic energy equation, $\phi = 0°$ plane.

position of the patch close to the center of the PV. The contributions from the other production terms were found to be small in the symmetry plane.

The contours of the total advection term in the tke equation (Figure 15) show a more complex distribution. Two areas of positive tke advection and two areas of negative tke advection are observed in the symmetry plane around the mean position of the PV. The relative positions of these regions relative to the PV are very similar to the ones observed by Devenport & Simpson (1990) in the symmetry plane upstream of a wing shaped body. The regions of high absolute value of advection do not coincide with the approximate position of the PV as it switches between the two modes because the advection does not depend on the values of the Reynolds stresses that, as we have seen, are strongly amplified in the PV region. The region 1 of high negative advection in Figure 15 covers part of the upstream side of the mean PV and extends upstream into the separating boundary layer. The negative values of the advection in this region are due primarily to the strong variation of the normal Reynolds stresses in the streamwise direction, as they are transported toward the pier. In region 2, situated immediately downstream the mean PV, the advection values are positive but the absolute values are not as high as those present in region 4. In this region the incoming flow, deflected by the presence of the PV, is starting moving downwards into the downflow. In region 2 the vertical velocity fluctuations are observed to vary significantly in both the streamwise and vertical directions (Figure 13a). The elongated patch of high negative values situated close to the bed, slightly to the right of the PV center, is denoted as region 3 in Figure 15. This region corresponds to the upstream part of the near wall jet flow beneath the PV and is characterized by a sharp increase in the streamwise velocity fluctuations in the upstream direction (see Figure 12a). As the mean jet velocity is oriented in the streamwise direction away from the cylinder, the most important contribution comes from the term $-U\partial\overline{u'^2}/\partial x(\mathrm{D/U^3})$. Region 4, in which high positive values of the advection term are observed, is situated near the bed but slightly upstream of the PV and of region 3. The positive values in this region correspond to a gain of turbulence energy. This area corresponds to the deceleration and separation regions of the near bed jet flow in which the streamwise velocity fluctuations are decaying in the streamwise direction as we go away from the cylinder. Additionally, due to the detachment of the jet from the bed, the peak in the streamwise fluctuations is moving away from the bed, in the direction of the jet flow, and a non-zero mean vertical velocity component is present. Thus, the contribution from $-V\partial\overline{u'^2}/\partial y(\mathrm{D/U^3})$ can be significant. Finally, a region of high positive advection produced by the interaction of the downflow with the bed surface is present near the junction between the cylinder and the bed ($-0.65 < \mathrm{x/D} < -0.5$). This region was outside the measurement window in the experiments of Devenport & Simpson (1990).

4 CONCLUSIONS

The present numerical investigation shows that the structure of the turbulent HV system that develops in front of the upstream face of a circular pier varies considerably with the polar angle around the cylinder. The bimodal velocity probability phenomenon observed to occur in front of surface mounted bluff bodies at much higher Reynolds numbers (Simpson, 2001) was found to be present in the flow around a circular bridge pier at a moderate Reynolds number ($\mathrm{Re_D} = 16{,}000$). In agreement with Devenport & Simpson (1990), the bimodal structure was found to be present only in the velocity components perpendicular to the core of the PV. This bimodal structure of the HV region is induced by the oscillations of the PV between two modes. In the first one, called the zero-flow mode, the PV is more compact and situated closer to the upstream face of the pier. In the second one, called the backflow mode, patches of high-momentum low-vorticity fluid from the outer flow are entrained in the downflow and from there into the HV region. As a result, the coherence of the PV is lower, its size is sensibly larger and its center is situated farther from the pier. The injection of high momentum outer flow is also the cause for the formation of a relatively high streamwise momentum near wall jet that is present beneath the PV and eventually detaches upstream of it. During the zero-flow mode the near wall jet is still present, but its momentum is much lower.

The HV system was found to strongly modify the turbulence structure upstream the pier nose mainly because of the amplification in the levels of the turbulent velocity and pressure fluctuations in the HV region. Most of this amplification in the region corresponding to the mean PV was shown to be related to the bimodal aperiodic chaotic mode switching phenomenon that is especially strong at polar angles smaller than 45° and eventually disappears in the legs

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the horseshoe vortices. The low frequency oscillations of the PV between the zero-flow mode and the backflow mode and the variations in the intensity of the intermittent wall-attached jet beneath it, induce high bed shear stress values. Additionally, relatively large pressure fluctuations are present in the immediate vicinity of the bed, beneath the HV system. These flow features can significantly accelerate the sediment entrainment in the case of a movable bed and explain the efficiency of the HV system in removing sediment during the scouring process. The region of bimodal flow was also shown to be one of large turbulence production. Additionally, it was found that the production terms associated with the normal Reynolds stresses were comparable to the one due to the primary shear stress similar to the findings of Devenport & Simpson (1990) for a highly turbulent flow in front of a wing shaped body. The tke advection was shown to be concentrated in several regions around the mean position of the PV, consistent with the measurements of Devenport & Simpson (1990).

An analysis of the interactions between the horseshoe vortices (in particular, their legs) with the detached shear layers and between the vortex tubes that populate these detached shear layers and the bed, which may explain scour/deposition phenomena near the downstream face of the cylinder and past it, will make the object of a future paper.

The scour-hole problem due to sluice gates: Quadrant analysis of the turbulence characteristics in the presence of Görtler vortices

I. Albayrak & U. Lemmin
Laboratory of Environmental Hydraulics (LHE), Ecole Polytechnique Fédérale de Lausanne, Switzerland

ABSTRACT: Turbulence characteristics and their effect on the erosion capacity of a wall jet issuing from a sluice gate are experimentally investigated. From a loose bed experiment the Görtler number was calculated and an instability analysis was to carried out. In the present case, the Görtler number and the curvature parameter are well above their critical values, and longitudinal vortices occur along the concave scour hole. These Görtler vortices make the wall jet unstable and strongly contribute to suspend the bed sediment particles by increasing the wall shear stress. With surface particles fixed, a scour- hole bed of equivalent roughness was created and intensive instantaneous velocity measurements using a 3D Acoustic Doppler Velocity Profiler (ADVP) at several positions along the channel axis were carried out. A quadrant analysis in the streamwise and transversal planes shows that all along the scour hole, ejection and sweep events dominate turbulence in the inner layer of the wall jet and contribute to Reynolds shear stress more than outward and inward interactions. Above $0.6y/y_{1/2}$, outward and inward interactions slightly dominate.

1 INTRODUCTION

Extensive research on the dynamics of wall jets issuing from a sluice gate has been carried out in relation to local scour, heat, mass and momentum transfer and engineering applications. Wall jets can cause significant local scour downstream of hydraulic structures, and local scour on a large scale can lead to failure of structure foundations.

The turbulence characteristics of wall jets are closely related to their erosion capacity and sediment transport. A plane turbulent wall jet and a wall jet along a concave surface have different turbulence structures. Therefore, their effect on local scour and sediment transport are different. The occurrence of counter-rotating longitudinal Görtler vortices changes the turbulence structure of the wall jet along a concave surface (Kobayashi et al, 1983) and increase the sediment transport rate above the critical Görtler number (Hopfinger et al., 2004).

The existence of Görtler vortices was first shown experimentally by Gregory and Walker (1956) on the basis of flow visualizations and by Tani (1962) on the basis of direct in-flow measurements. The critical conditions of Görtler instability were given by Tani (1962) and Kobayashi & Fujisawa (1980, 1983) on a stability diagram of turbulent wall jets relating the curvature parameter and velocity ratio. A detailed study of Görtler instability is found in Floryan (1991) who experimentally and theoretically investigated its mechanism, and linear and nonlinear stages of this instability.

An experimental and numerical study investigating the local scour downstream of a sill followed by a rigid apron was carried out by Adduce et al. (2004). They proposed a 1D mathematical model simulating the local scour downstream of a sill and showed a good agreement between the measured scour profiles and the predictions with the model.

Görtler vortices and their contribution to the sediment erosion along a concave surface were studied experimentally by Hopfinger et al. (2004). They found that streamwise Görtler vortices play an important role in sediment transport by creating turbulence.

The primary purpose of this study is to investigate experimentally turbulence characteristics and their effect on the erosion capacity of a wall jet issuing from a sluice gate. The non-linear behavior of the counter-rotating streamwise Görtler vortices which make the wall jet unstable along the scour hole and lift up bed sediment particles was studied in relation to instability analysis based on Görtler numbers and flow events that are responsible for the initiation and transport of sediment motion. An experimental investigation of the conditionally sampled covariance events $u'w'$ in the streamwise direction and $v'w'$ in the across stream plane is reported in this paper. This was accomplished by performing intensive instantaneous velocity

measurements using the 3D Acoustic Doppler Velocity Profiler (ADVP) developed by Lhermitte and Lemmin (1994) and Rolland and Lemmin (1997) at several points in a fixed scour hole. The velocity measurements were complemented with video data taken with a non intrusive digital video camera with 25 frames per second to record the bed profile and to visualize and count the counter-rotating streamwise vortices. In the first part of this paper, the experimental set-up, procedure and instrumentation are described. In the second part, the instability analysis in terms of Görtler number and a quadrant analysis of the instantaneous velocity data obtained with the ADVP in relation to the local erosion potential of the counter-rotating streamwise vortices are presented.

2 EXPERIMENTAL SETUP, INSTRUMENTATION AND PROCEDURE

Experiments were conducted in a re-circulating horizontal flume with a rectangular cross-section and glass side walls as shown schematically in Figure 1a. The flume is 17 m long, 0.5 m wide and 0.8 m deep. Figure 1b shows the fixed concave scour hole, the configuration of the wall jet and the definition of the parameters used here. In order to obtain a 3.8 m long, 0.35 m deep test section at a distance of 5 m from the inlet of the flume, the upstream and the downstream ends of the flume were raised by inserting rigid panels. The test section was filled with uniformly graded sand of average grain diameter $d_{50} = 2$ mm. Firstly, a loose bed experiment was conducted in order to calculate the Görtler number and to carry out an instability analysis of the counter-rotating streamwise vortices. After the loose bed experiment, the surface particles in the 0.2 m radius scour hole were fixed to create a scour hole bed of equivalent roughness. The sluice gate from which the wall jet issues was located 4.9 m from the inlet, and the gate opening was $b_0 = 5$ cm for all experiments reported here. The downstream water depth was kept constant during the experiments $h_2 = 22.4$ cm. In order to maintain the initial jet velocity, $U_0 = \sqrt{2g\Delta h}$, the upstream water depth, h_1, was controlled. The slope of the channel was zero. The Acoustic Doppler Velocity Profiler (ADVP) was used to measure the three

velocity components simultaneously across the water depth at 12 different streamwise sections along the centerline of the flume.

The high space and time resolution of the ADVP measurements allowed us to correctly evaluate the turbulence information and establish a correlation between velocity components without any specific requirements for the flow condition. In the present study, the ADVP system was multistatic. The system consists of a central beam emitter and four wide-angle receivers placed around the center providing one redundancy to eliminate the signal noise and to control the quality of the velocity data (Hurther and Lemmin, 2000). The spatial and temporal resolution of the ADVP system presented here are equal to $\cong$3 mm and 0.032 s, respectively. The duration of the velocity measurement at each position in the scour hole is over 600 s.

The instantaneous water surface and bed profile were recorded by using a digital camera with 25 frames per second. The recorded video data were treated by computer using such software as i-movie and graphic solutions by Adobe.

The flow conditions (Table 1) for the tests conducted here are identical with those defined in an earlier study (Hopfinger et al., 2004). First, the mobile bed was covered with a thin plate which had no influence on the flow conditions and on the onset of scouring. The upstream and downstream water levels were then adjusted to obtain $\Delta h = 2.6$ cm. As soon as the plate was withdrawn from the channel at t = 0s, the scouring progressed rapidly. The scouring progress was filmed with the camera starting at t = 0s. The scour hole reached a quasi-steady-state depth $h_s = h_m$ in time $t = t_s$. Figure 1b shows the characteristic dimensions of the scour hole shape. The sediment streaks in the scour hole and their variation across the channel were observed with a second video camera looking downstream. In the first run, for time t = 100s, the deepening rate was large (short-time regime) and the Görtler vortices were clearly visible from the recorded video data. The instability analysis was made with the method reported in Hopfinger et al. (2004). The calculated Görtler number (Table 1) was found to be above the critical value. To study the turbulence characteristics of the wall jet along the concave scour hole and the counter-rotating streamwise Görtler vortices, a second run was conducted. In the second run, the experiment was stopped at t = 100s and the scour hole was fixed using a chemical glue. All velocity measurements and analyses presented here were carried out in the fixed concave scour hole (run 3).

3 MEAN FLOW CHARACTERISTICS

The mean 2D velocity vectors measured with the 3D ADVP at 12 measurement sections of the scour-hole (large curvature) are presented in Figure 2. Jet entrainment and return flow occur early on, and the wall jet

passing over the apron attaches to the scour hole bed at around x/b = 3.81. The wall jet remains attached to the fixed sediment surface until point x/b = 10 where the flow separates. A second return flow zone between x/b = 11.5 and x/b = 24 occurs near the wall as clearly seen in Figure 2.

4 INSTABILITY ANALYSIS

Counter-rotating streamwise Görtler vortices may develop in a concave boundary layer owing to centrifugal instability. Based on observed erosion by these vortices, the corresponding control parameter for this instability, the Görtler number, was calculated according to the method suggested by Hopfinger et al. (2004). We observed that the sediment streaks lifted up by the streamwise vortices appeared and disappeared randomly and their values varied with time as reported by Hopfinger et al. (2004). From the high quality images recorded with the video camera (Fig. 3) in the loose bed experiment (run 1), the radius of curvature, R, and the wave length λ of the sediment streaks, were determined for the time around 100 s. The number of streaks, n, was counted in each video frame (Fig. 3) and the wavelength, λ, and the wave number, α, were calculated as:

$$\lambda = B/n, \qquad \alpha = 2\pi\lambda \tag{1}$$

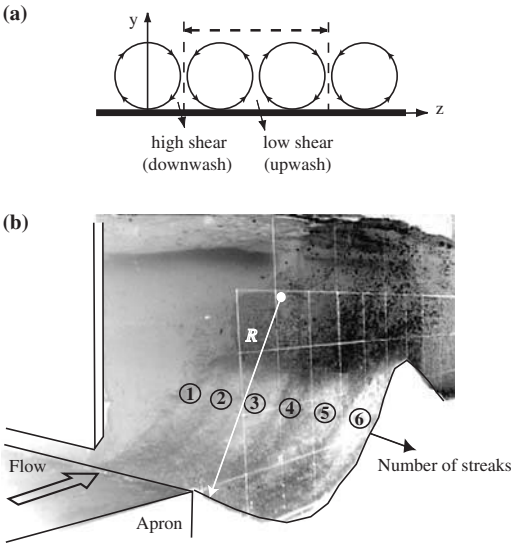

Figure 3. (a) The pattern of streamwise streaks, (b) Longitudinal sediment streaks formed by Görtler vortices for run 1.

The number of streaks, n, given in Table 1 is a mean value of several pictures. For the laminar boundary layer, the Görtler number is:

$$G = \mathrm{Re}_\theta \left(\frac{\theta}{R}\right)^{1/2} \tag{2}$$

where θ is a viscous length scale which is equal to $(\nu x/U)^{1/2}$ or to the momentum thickness. R is the radius of curvature and $\mathrm{Re}_\theta = U\theta\nu$. In the present study, the flow is turbulent and of the wall-jet type. Thus we calculated the Görtler number for turbulent boundary layers on a concave wall as given by Hopfinger et al. (2004).

$$G_T = \frac{U_m}{\nu_T}\sqrt{\frac{\theta}{R}} \approx 31\sqrt{\frac{\theta}{R}} \tag{3}$$

where U_m is the maximum local velocity and ν_T is the eddy viscosity. The calculated Görtler number for the present study is 2.86, well above the critical value. Figure 4 shows the experimental value presented here on the Görtler number-wave number diagram of Tani (1962). In both the loose and fixed bed experiments for R = 0.205 m, the Görtler vortices are not steady. They tend to move about in a seemingly random manner, i.e. they come together, separate, appear and disappear. As mentioned by Hopfinger et al. (2004), the stronger vortices, which can carry a sediment load, survive long enough to carry the particles up the bed slope.

Another instability criterion based on the linear stability theory is found in Kobayashi et al. (1983). The stability diagram of turbulent wall jets relating the curvature parameter and the velocity ratio $\beta = U_\infty/U_m$, where β is a ratio of the free stream velocity U_∞ outside of the wall jet to the maximum velocity U_m was given. The present wall jet corresponds to $\beta = 0$ assuming $U_\infty = 0$. The curvature parameter $y_m/R = 0.22$, is well above the critical

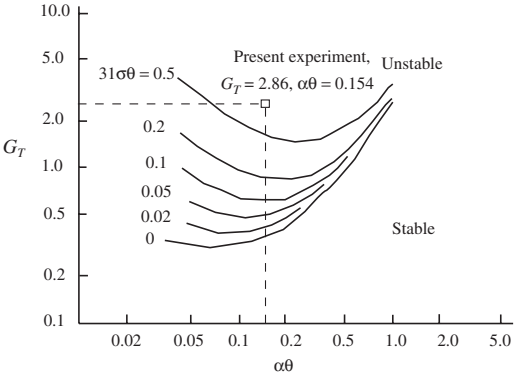

Figure 4. Dimensionless wave number, $\alpha\theta$, versus the Görtler number (Tani, 1962). The present experiment is indicated with the square symbol.

Copyright © 2006 Taylor & Francis Group plc, London, UK

curvature parameter 0.05. Since the theoretical analysis includes some approximations, we expect that longitudinal vortices will occur in the present case. The fact that a strong increase of turbulence in the present experiment occurred shows the existence of longitudinal vortices caused by centrifugal instability.

Both theoretical and experimental instability analysis show that in the present case, the Görtler number and the curvature parameter are well above their critical values and longitudinal vortices occur along the concave scour hole.

5 CONTRIBUTION OF THE GÖRTLER VORTICES TO SEDIMENT TRANSPORT

The action of the wall jet issuing from the sluice gate creates a scour hole. Total shear stress is a key element for sediment erosion and transport. The critical value of shear stress for the initiation of sediment motion is given by the following relationship:

$$\theta = \frac{U_f^2}{g(s-1)d} \tag{4}$$

in which U_f = friction velocity, g = acceleration by gravity and s = the particle specific gravity. The quantity θ is a Shields parameter based on the particle size d. The Shields parameter can be written in terms of bed shear stress by:

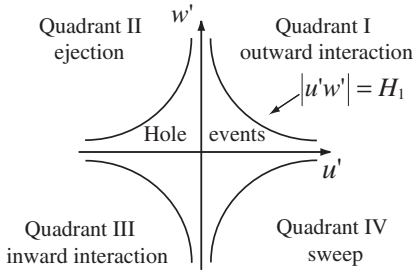
$$\tau_{crit} = \tau_b / g(s-1)d \tag{5}$$

where τ_b is the bed shear stress. The critical value of the Shields parameter for the initiation of motion over an almost flat bed is $\tau_{crit} = 0.035$ (Graf 1971). The total effective shear stress consists of the shear stress due to the boundary-layer turbulence τ_t and Görtler vortices τ_G and is expressed by

$$\tau_b = \tau_t + \tau_G \tag{6}$$

$$\tau_t = \rho(c_f/2)U_m^2 \text{ and } \tau_G = \rho(c_{fG}/2)U_m^2 \tag{7}$$

where c_f and c_{fG} are the friction coefficients for the boundary-layer turbulence and the Görtler vortices, respectively. For the present experiment, $c_f = 0.014$, $c_{fG} = 0.014$ and $\tau_b \approx 0.007(1+4)\,\rho U_m^2$ were obtained with the expression under the same experimental conditions and Görtler number at location x/b = 7 ($x \approx 1.7(x_m - l)$) presented in Hopfinger et al. (2004). The measured value of the shear stress in the wall region of the turbulent wall jet at x/b = 7 is ρ 0.0066 N/m^2 and is almost the same as the value calculated with the expression, $\tau_b \approx 0.007(1+4)\,\rho U_m^2$. These results agree well with the experiments by Kobayashi & Fujisawa (1983) and Hopfinger et al. (2004). The measured effective shear stress, τ_b, which is active and responsible in sediment transport, is well above the critical value and shows a remarkable mobilizing force in the scour process. Görtler instability increases the shear stress at the locations corresponding to downwash induced by the counter-rotating streamwise vortices and decrease at locations corresponding to upwash (Floryan, 1991). From the present observations, in the downwash region, the vortices easily moved sediment at the wall by increasing the wall shear stress and eventually lifted up sediment to the main body of the flow in the upwash regions by forming ridges on the bottom. The process repeated itself as time progressed. Thus, Görtler vortices play an important role in local erosion and sediment transport.



6 THE QUADRANT ANALYSIS OF THE INSTANTANEOUS VELOCITY

Two different sets of coherent structures are found in turbulent boundary layers. The inner layer is governed by the eddy structure, whereas in the outer flow, large-scale structures control the entrainment into the boundary layer. Most of the production of Reynolds stress and turbulent energy occurs in the inner layer and is related to wall eddies involved in a sequence of events called the 'bursting process'. The bursting phenomenon in turbulent flows was discovered by Kline et al. (1967). The bursting process may be composed of cycles of sweeps ($u' < 0, w' > 0$) and ejections ($u' > 0, w' > 0$), and inward ($u' < 0$, $w' < 0$) and outward ($u' > 0$, $w' > 0$) interactions (Fig 5; modified from Nezu and Nakagawa, 1993). Blackwelder & Kaplan (1976) showed that two counter-rotating streamwise vortices form and act to pump low-speed fluid away from the wall, forming the low speed streaks and consequently an inflexional velocity profile. This causes an instability similar to that found in the boundary layers. Oscillations within this instability terminate in a rapid ejection of fluid away from the wall. This motion has a rapid timescale and is called 'burst'. The growth and breakdown of streamwise vortices via the Görtler instability mechanism are similar to those found in transitional and turbulent flow fields (Bippes, 1972).

The flow events in the bursting process are responsible for the onset of sediment motion. The sweeps cause the initiation of bedload motion on the stream bed, whereas the ejections are primarily responsible for the particles' suspended motion. Nelson et al. (1995) showed that the outward interactions also contribute to bedload transport.

(b) Transversal section (w_2)

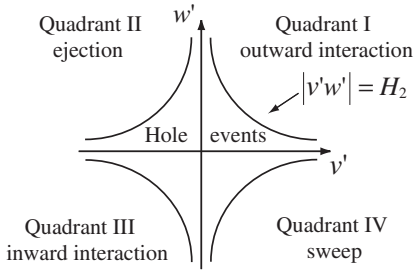

Figure 5. Schematic division of events in the (a) longitudinal and (b) transversal planes.

7 THEORETICAL ASPECTS OF THE CONDITIONAL STATISTICS OF RELATIVE COVARIANCES

In this section, the contribution of bursting events to Reynolds stress will be presented. u', w', v' are the zero mean fluctuating longitudinal, vertical and transversal velocity components, respectively. The normalized velocity fluctuations are:

$$\hat{u} = u'/\sqrt{\overline{u'^2}}\ , \hat{w} = w'/\sqrt{\overline{w'^2}} \text{ and } \hat{v} = v'/\sqrt{\overline{v'^2}} \qquad (8)$$

In Figure 5, the covariance terms for the different planes of the relative shear stress are $w_1 = u'w'/\overline{u'w'}$ and $w_2 = v'w'/\overline{v'w'}$. The joint probability functions of $\hat{u}$, $\hat{w}$ and $\hat{v}, \hat{w}$ are denoted by $p(\hat{u}, \hat{w})$ and $p(\hat{v}, \hat{w})$, respectively (8). The detailed mathematical expressions are found in Nakagawa and Nezu (1977). The following equations are given:

$$\begin{aligned} p_{k,2}(w_k) &= p_G(w_k) + \varphi_k^{-}(w_k) \\ p_{k,4}(w_k) &= p_G(w_k) - \varphi_k^{-}(w_k) \end{aligned} \quad (w_k > 0) \quad k = 1,2$$

$$\begin{aligned} p_{k,1}(w_k) &= p_G(w_k) + \varphi_k^{+}(w_k) \\ p_{k,3}(w_k) &= p_G(w_k) - \varphi_k^{+}(w_k) \end{aligned} \quad (w_k < 0) \qquad (9)$$

where the index a in $p_{k,a}$ denotes the quadrant in the kth plane, with the longitudinal plane (1) and transversal plane (2).

From (9), the time fraction $T_{k,a}(H_k)$ and the contribution to the Reynolds stress $RS_{k,a}(H_k)$ corresponding to each event are presented as a function of the threshold levels H_k by the following expressions:

$$T_{k,a}(H_k) = \begin{cases} \int_{H_k}^{\infty} p_{k,a}(w_k)dw_k & k=1,2 \quad a=2,4 \quad H_k \geq 0 \\ \int_{-\infty_k}^{H_k} p_{k,a}(w_k)dw_k & k=1,2 \quad a=1,3 \quad H_k \leq 0 \end{cases}$$

$$RS_{k,a}(H_k) = \begin{cases} \int_{H_k}^{\infty} w_k p_{k,a}(w_k)dw_k & k=1,2 \quad a=2,4 \quad H_k \geq 0 \\ \int_{-\infty_k}^{H_k} w_k p_{k,a}(w_k)dw_k & k=1,2 \quad a=1,3 \quad H_k \leq 0 \end{cases} \qquad (10)$$

As shown in Figure 5, the contributions to the Reynolds stress can be associated with five events. Event 5 is called the 'hole event' term when $|w| < H.T_{k,5}$ and $RS_{k,5}$ are given by

$$T_{k,5} = 1 - \sum_{a=1}^{4} T_{k,a}(H_k) \qquad k = 1,2$$

$$T_{k,5} = 1 - \sum_{a=1}^{4} T_{k,a}(H_k) \qquad k = 1,2 \qquad (11)$$

8 RESULTS AND DISCUSSION

Figure 6 presents the experimental quadrant fractional contributions of the relative covariance term w_1 calculated from (9) at section x/b = 7 in the fixed scour hole. As seen from Figure 6, in the inner layer of the wall jet ($y/y_{1/2} \leq 0.5$), ejections and sweeps contribute more than outward and inward interactions and that ejection events show significantly larger values than other events. Coherent structures, ejections and sweeps, are the main turbulent energy producers. The contributions of inward and outward interactions are less in the inner layer, but are more important than other events in the outer layer. This result is consistent with a near-wall turbulence model suggested by Kastrinakis et al. (1977) in which ejections from low-speed streaks occur between pairs of intense counter rotating streamwise vortices.

The time fraction of the hole events $T_{1,5}$ is shown in Figure 6. It is clearly seen that the variation of $T_{1,5}$ in the inner layer is weak. For $H_1 = 10$, the time fraction of the hole events is more than 90%. The contribution to event generation is less than 10%. In this case, the

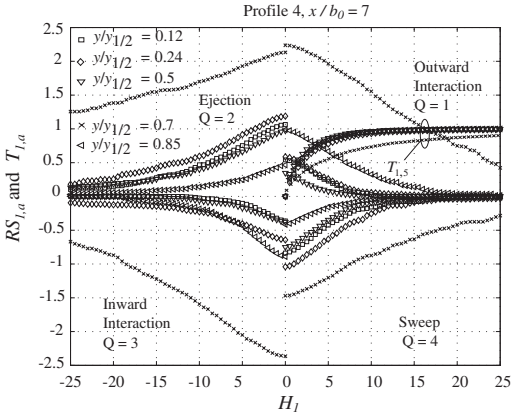

Figure 6. Fractional contributions to Reynolds stress versus threshold level H_1 and time fraction occupied by the hole events $T_{1,5}$ for profile 4 in the longitudinal plane.

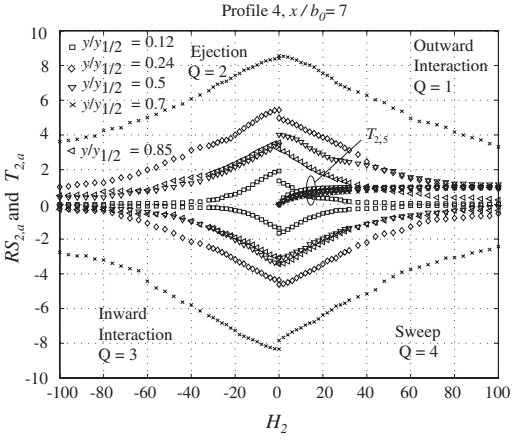

Figure 7. Fractional contributions to Reynolds stress versus threshold level H_2 and time fraction occupied by the hole events $T_{2,5}$ for profile 4 in the transversal plane.

sweep event decreases rapidly with H_1 and only the ejection event contributes to the Reynolds stress. The time occupied by this event is very short. The ejection event manifests itself in the form of a very sharp pulse as indicated by Nakagawa & Nezu (1977). This indicates that the nonlinear growth of Görtler vortices continues, that they approach each other, form a pair, and lift up some sediment (In next section, the nonlinear development of Görtler vortices will be shown). In the outer layer ($y/y_{1/2} > 0.5$), the negative contribution to Reynolds stress appears and the outward interaction shows slightly larger values than the inward interaction.

For the covariance events w_2 in the transversal plane of the turbulent wall jet, the same quantities as in Figure 6 are presented in Figure 7. We can observe for $T_{2,5} \approx 0.90$ that near the wall, $y/y_{1/2} = 0.12$, the contribution of ejection events is slightly greater than that of sweep events. However, it can be seen that in general the contribution of all events in a bursting cycle is nearly equal and symmetrical, independent of the threshold level H_2 and depth. Hurter et al. (2000) observed a similar distribution of all events in the transversal plane in the boundary layer of open-channel flow.

In order to compare quantitatively the time fraction, $T_{1,a}$ occupied by all quadrants in the longitudinal plane, Figure 8 illustrates their profiles over the depth for the threshold level $H_1 = 0$. In profile 4, it is clearly seen that the time occupied by ejection and sweep events within a bursting cycle in the inner layer is higher than that of the outward and inward interactions, whereas in the outer layer, the outward and inward interactions occupy more time. In the wall region of all profiles in the scour hole, the sweep events occupy more time than other events and the magnitude of the fraction of

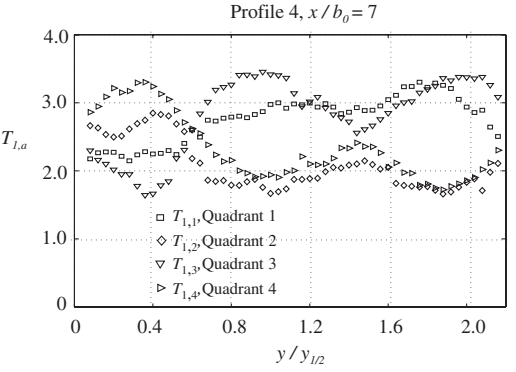

Figure 8. Distributions of the time fraction occupied by each event with $H_1 = 0$.

time $T_{1,a}$ satisfies the relation sweep > ejection > outward interaction ≅ inward interaction. These results agree well with those obtained by Nagakawa and Nezu (1977).

9 OBSERVATION OF STRUCTURAL FLOW FEATURES IN A WALL JET ALONG A SCOUR HOLE

Figure 9a shows a close up of the 2D velocity vectors of profile 4 for the time between t = 40s and 42s. Flow patterns such as ejections, sweeps, upwellings and downwellings in the water column are presented with the Reynolds shear stress distribution corresponding to the same time interval. The ejection events can be seen in Figure 9a in the wall region at t = 40.10, 40.60,

Copyright © 2006 Taylor & Francis Group plc, London, UK

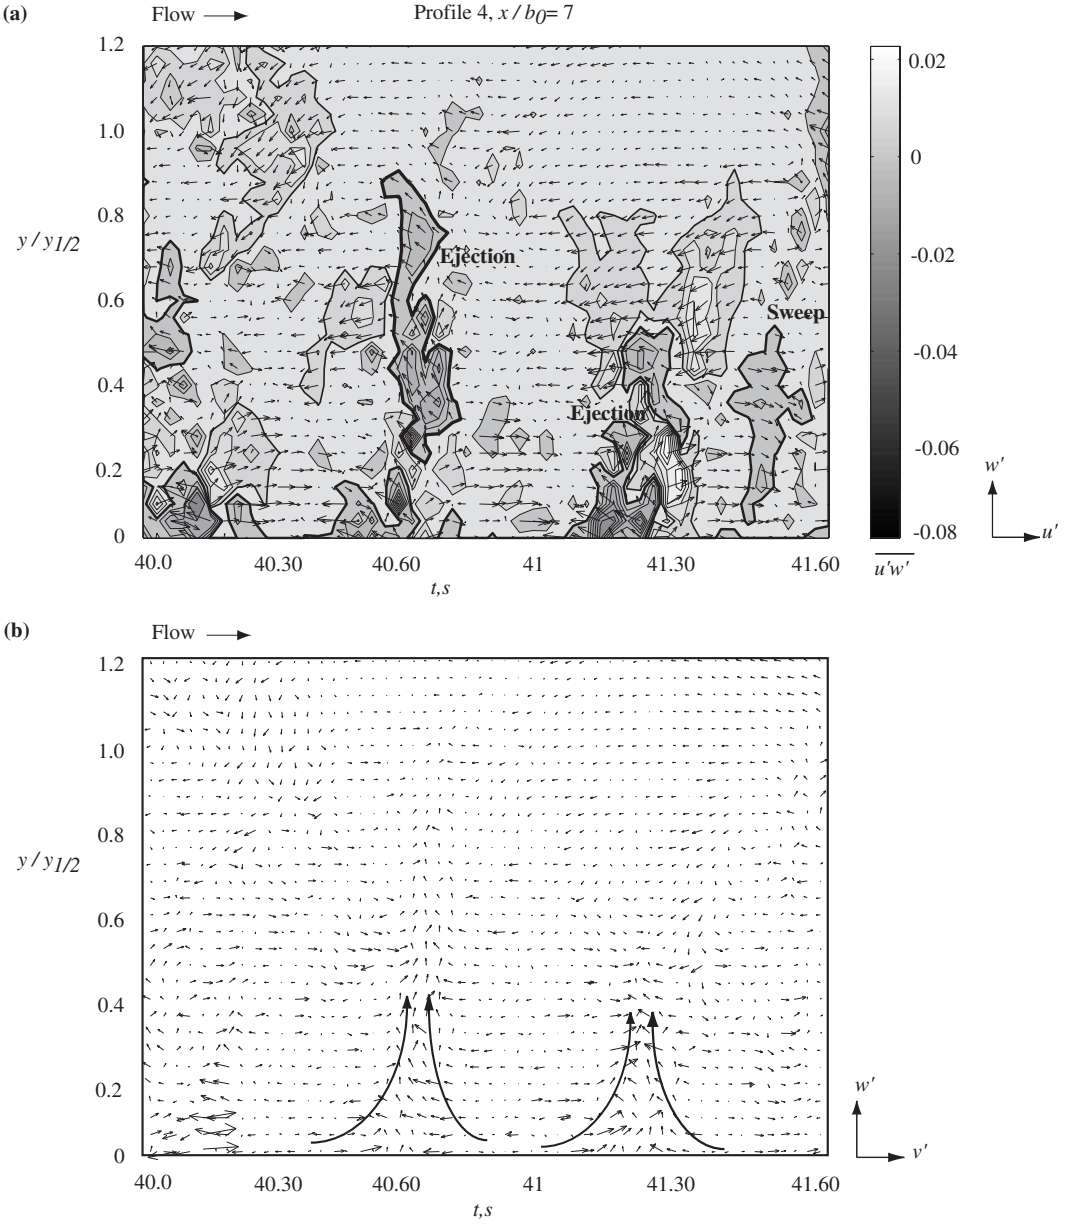

Figure 9. 2D velocity vectors of profile 4 for the time between t = 40s and 42s in longitudinal plane (a) and transversal plane (b).

41.30. For t = 40.60, the coherent shear stress structure (ejection) extends up to $y/y_{1/2} = 0.9$. A sweep event at t = 41.50s at $y/y_{1/2} = 0.3$, can be seen in Figure 9a. From the Reynolds shear stress map, it is seen that the contribution of the high-shear layer such as an ejection event to the Reynolds shear stress is significant. In the outer layer, the inward and outward events are found dominant at several locations (in Fig. 9a, at t = 40.30s at $y/y_{1/2} = 1$, at t = 41.60s at $y/y_{1/2} = 0.5$).

As can be seen in Figure 9b, there is a clear indication of streamwise vortices at t = 40.60 and 41.30. The matching between u′-w′ and v′-w′ flow field patterns is quite remarkable. Between two counter-rotating Görtler vortices, an outward event in the transversal

Copyright © 2006 Taylor & Francis Group plc, London, UK

plane occurs at t = 40.60s corresponding to the ejection event in the longitudinal plane. At the center of the Görtler vortices ($y/y_{1/2} = 0.40$), the transversal velocity is zero and the vertical velocity is at a maximum near the bed. This spanwise pattern of the Görtler vortices agrees well with those observed by Petitjeans et al. (1997).

10 CONCLUSION

This study experimentally investigated turbulence characteristics and their effect on the erosion capacity of a wall jet issuing from a sluice gate. It was demonstrated that due to the curvature of the scour-hole bed, Görtler vortices occur on the upslope side of the hole. In the present case, the Görtler number and the curvature parameter are well above their critical values, and between six and seven longitudinal vortices occur along the concave scour hole. These Görtler vortices make the wall jet unstable. They also strongly contribute to the suspension of the bed sediment particles by significantly increasing the wall shear stress.

With surface particles fixed, a scour- hole bed of equivalent roughness was created and intensive instantaneous velocity measurements using a 3D Acoustic Doppler Velocity Profiler (ADVP) at several positions along the channel axis were carried out. The mean velocity profiles indicate that the jet remains attached to the wall all along the scour hole. Recirculation occurs in the layers above the wall jet. A quadrant analysis in the streamwise and transversal planes shows that all along the scour hole, ejection and sweep events dominate turbulence in the inner layer of the wall jet and contribute to Reynolds shear stress more than outward and inward interactions. Above 0.6 $y/y_{1/2}$, outward and inward interactions slightly dominate. Ejections in the longitudinal direction correlate with upwash zones between the Görtler vortices.

Temporal flow evolution of sediment embedded circular bridge piers

Jens Unger & Willi H. Hager
VAW, ETH Zurich, Zurich, Switzerland

ABSTRACT: Bridge hydraulics has become an important issue in river engineering given the importance of bridges as a basic infrastructure. Many of the current research works investigate empirically the temporal advance of scour depth. In contrast, this paper presents some major results on the flow characteristics around a circular cylindrical bridge pier mounted in a mobile sediment bed resulting from an experimental study conducted at Versuchsanstalt für Wasserbau, Hydrologie und Glaziologie VAW during the past four years. The internal flow features were investigated by a newly developed *Particle Image Velocimetry* setup. This installation allows for a quasi 3-dimensional visualization of the velocity field around a bridge pier by means of horizontal and vertical planes. The main characteristics of the down-flow, the horseshoe vortex system and the tailwater vorticity field were detected from the non-intrusive and instantaneously measured velocity fields; additionally the bed-shear stresses were calculated in the scour region. This work, therefore, provides novel insight into the complex and fascinating two-phase flow around circular bridge.

1 INTRODUCTION

A common reason for bridge failure is the collapse of its foundation. The acting hydraulic load causes local erosion around the sediment embedded bridge pier or abutment. This so-called scour is able to endanger the stability of the complete bridge construction. Therefore, a number of bridge scour research projects are presently conducted all over the world. Most of these focus the prediction of the maximum scour depth and scour extension, generally as a function of time for steady hydraulic conditions, e.g. Breusers & Raudkivi (1991), Hoffmans & Verheij (1997), Melville & Coleman (2000) or Oliveto & Hager (2005). In contrast, the governing internal flow features of the scour process have received comparatively little attention. A limiting factor so far was the available experimental technique. The standard instrumentation was mainly intrusive, thus appreciably disturbing the flow and consequently the scour process.

Melville & Raudkivi (1977) conducted an early research work on the flow characteristics in scour holes. They investigated the flow field around a circular bridge pier using four vertical plans at 0°, 30°, 60° and 90° relative to the approach flow direction, by using a DISA hot-film anemometer in addition to the hydrogen-bubble technique. All experiments were confined to clear water scour conditions and a fixed sediment bed for two conditions: (1) The initially flat bed and (2) the 'equilibrium' scour hole. The main results concern the flow patterns, the turbulence intensity distribution and the boundary shear stress distribution in the scour region. Based on this work numerous studies were realised to refine the specific flow structures. Thus, Qadar (1981) investigated the interaction between the horseshoe vortex and the scour hole. In addition, Dargahi (1989) detected the simultaneous presence of various vortices above a fixed smooth bed at the leading pier front. The down-flow characteristics in front of the pier were observed by Ahmed & Rajaratnam (1998) and Sarker (1998) by means of a Preston tube and *Acoustic Doppler Velocimetry* (ADV), respectively. A more detailed study was presented by Graf & Yulistiyanto (1998) and expanded by Graf & Istiarto (2002). Therein, an ADV Profiler was used to measure instantaneous velocity components in a defined profile of the flow field around a circular bridge pier for fixed and mobile bed configurations, respectively. These works refer to the flow pattern up- and downstream of the bridge pier, the longitudinal distribution of bed-shear stresses in the axis of symmetry and the turbulent kinetic energy. Barbhuiya & Dey (2004) obtained similar results in a semicircular pier arrangement placed at the channel sidewall.

All these studies use intrusive and non-instantaneous velocity-measuring methods. As stated, this technique disturbs the turbulent flow field considerably and does not allow recording the highly unsteady flow patterns in the horseshoe vortex system due to the point-wise

Copyright © 2006 Taylor & Francis Group plc, London, UK

velocity readings. The present research work aims at a detailed temporal description of the flow patterns around bridge piers using *Particle Image Velocimetry* (PIV), a non-intrusive and instantaneous measuring technique. The knowledge of these coherent plane flow structures allows determining the bed-shear stresses rather than a point-wise description of the flow.

2 EXPERIMENTAL SETUP

2.1 *Physical model*

The hydraulic model tests were conducted in the VAW scour channel, with a maximum discharge of $Q = 130$ l/s and a maximum water depth of 0.40 m. The rectangular channel had a width of $B = 1$ m, and a length of 13 m with a working section of some 5 m. A detailed description of this scour channel is provided by Hager et al. (2002). Two sediments were used: (1) an almost uniform sediment with a median sediment size of $d_{50} = 1.14$ mm and a sediment non-uniformity of $\sigma = (d_{84}/d_{16})^{1/2} = 1.18$, and (2) a sediment mixture with $d_{50} = 5.00$ mm and $\sigma = 2.29$. The semicircular pier models had diameters of $D = 0.457$ and 0.260 m. The plexiglass pier was always attached to the glassed channel sidewall, to visualize both the flow characteristics around the bridge pier and inside the scour hole. Preliminary tests demonstrated that this configuration has only a minor effect on the flow field with regard to the boundary layer development along the glass wall (Unger 2006, Unger & Hager 2006). The present research considered only clear water scour conditions with no notable sediment transport in the approach flow region. Consequently the threshold Froude number $\mathrm{F}_t = V_o/V_t$ varied between $0.60 \leq \mathrm{F}_t \leq 1.05$, with V_t as threshold velocity and V_o as approach flow velocity. The discharge varied in a range of $0.025 \leq Q \leq 0.110$ m^3/s resulting in a densimetric Froude number $\mathrm{F}_d = V_o/(\mathrm{g}' d_{50})^{1/2}$ between 1.83 and 3.22, with $\mathrm{g}' = [(\rho_s - \rho)/\rho]\mathrm{g}$ as the reduced gravitational acceleration, ρ as the fluid density and ρ_s as the sediment density. Table 1 summarizes the experimental conditions of the present research.

To initiate an experiment, the sediment bed was set horizontally by using a grading mechanism. After the half cylinder was positioned at the glass wall, the pump was started and the discharge slightly increased to the test value, thereby carefully inhibiting sediment entrainment around the pier. Next, the water level was slowly lowered, using the flap gate in the tailwater. Once the first particle moved, the time was set to $t = 0$ and the water depth was further reduced to the test value. Normally the water and the sediment surface topographies and the velocity vector field were measured at times $t = 60$, 180, 360, 600, 1200, 2400, 3600, 7200, 14440, 28800 and 86400 s, therefore from 1 minute to 1 day after sediment entrainment.

2.2 *Instrumentation*

Two different measurement techniques were employed, namely (1) a combined surface measuring unit consist of a Laser Distance Sensor (LDS) plus an Ultra Sonic Sensor (USS) and (2) a large-scale Particle Image Velocimetry (PIV) setup to measure instantaneously the unsteady and highly turbulent plane flow field. The combined LDS/USS unit was mounted on a movable high precision carriage allowing for displacements in all three space directions. The accuracy of the simultaneous sediment- and water surface readings was ± 0.5 mm.

Figure 1 shows a sketch of the planar PIV-setup. It provides instantaneous velocity vector fields both in horizontal sections around the pier and in vertical sections parallel to the mean flow direction. For the plan view observations, the nearly horizontal water surface was covered with a thin plexiglass-plate to inhibit optical problems with surface waves. Given that the approach Froude number varied typically between 0.2 and 0.5, hydrodynamic effects can be neglected (Unger & Hager 2005). A flashed Xenon-stroboscope ① was used to illuminate the light sheet layer. This plane was spanned by a fiber-optic line-converter ⑤, which was linked to the stroboscope with a fiber bundle ④. The Programmable Timing Unit (PTU) ③ was the key element for timing the PIV system. The PTU received the external Transistor – Transistor – Logical (TTL) start trigger from the CCD camera ②

and controlled its exposure in synchronisation with the stroboscope flash. The first flash was sent out just before the interline transfer of the CCD sensor started and the second flash was released thereafter. Each pair of this double frame single exposure images allowed for a velocity vector calculation by cross-correlation. With a frame rate of 60 Hz of the progressive scan monochrome CCD camera the time resolution of the PIV system was 30 Hz. The used seeding particles had a diameter of 0.5 mm and were mixed with water in a container ⑥ prior to injection ⑧ by a pump ⑦ (Unger 2006).

3 EXPERIMENTAL RESULTS

3.1 *Flow in vertical plane*

Figure 2 shows the temporal evolution of the vertical flow field in the channel axis, parallel to the mean flow direction, as streamline plots, for times $t = 60$, 180, 600 and 2400 s (run D6). At time $t = 60$ s no scour has yet occurred in the pier symmetry plane, because the sediment entrainment starts at an angle of about $\phi = 75°$ from pier symmetry axis. The streamlines in the approach flow region $x/h_o < -2.50$ are nearly parallel such that the flow is not affected by the presence of the pier and the vertical velocity profiles have a standard logarithmic distribution. It was demonstrated that the effect of the pier on the upstream flow field extends to approximately a distance of $x = -(h_o D^2)^{1/3}$ measured from the leading pier front (Unger 2006). For run D6, a distance $x/h_o = -2.60$ results, therefore. Closer to the pier, in the region $-2.50 < x/h_o < -1.50$, the flow is decelerated but conserves a logarithmic velocity profile. Toward the pier, the flow is strongly deflected in the vertical direction, resulting in an up-flow toward the water surface and a down-flow toward the sediment surface due to the presence of a stagnation point. The up-flow develops into a relatively small surface recirculation, whereas the down-flow is deflected in the transverse channel direction. Close to the sediment bed in the region $-1.50 < x/h_o < -0.50$, a so-called initial vortex develops, additionally (Fig. 2a).

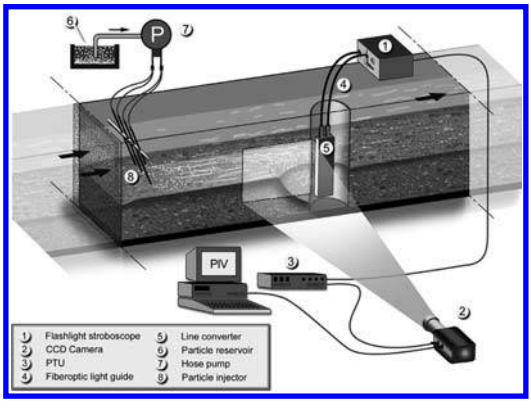

Figure 1. Scheme of the PIV-setup.

At time $t = 180$ s the scour has migrated from the pier side to the symmetry plane, without an appreciable change of the flow in the approach flow region as compared to $t = 60$ s. From the scour hole boundary a vertical flow deflection toward the instantaneous sediment surface is observed. Furthermore, the down- and up-flows, the surface recirculation and the stagnation point have established. In contrast to $t = 60$ s, the initial vortex has disappeared by now. Thus, the down-flow is deflected in the transverse channel direction along the scour surface. The scour hole then continuously deepens and the horseshoe vortex system is developed. At time $t = 600$ s it consists in the initial stage of a single vortex located directly above the rim in the scour hole. At $t = 2400$ s this vorticity field is divided into a primary horseshoe vortex plus one or even more secondary vortices. Both, the primary- and the secondary horseshoe vortices rotate clockwise. Note that the approach flow, the down- and up-flows, the stagnation point as well as the surface recirculation essentially conserve their structure, independent from the scour hole development.

Due to the large hydraulic load of run D6, the evolution of the different flow patterns is relatively fast. For

hydraulic conditions with smaller values of F_d and F_t this progress requires much more time (Unger 2006).

3.2 *Flow in horizontal plane*

Figure 3 refers to the analogous flow fields as shown in Figure 2 at identical times t in three horizontal planes, namely (1) at $Z_S = z_S/(D^2 h_o)^{1/3} = +0.20$ corresponding to approximately an elevation $z_s = h_o/2$ above the original sediment surface, (2) at the original sediment surface $Z_S = 0$ and (3) inside the scour hole at $Z_S = -0.20$. The plots for $Z_S = -0.20$ additionally show the instantaneous scour boundary as a dashed

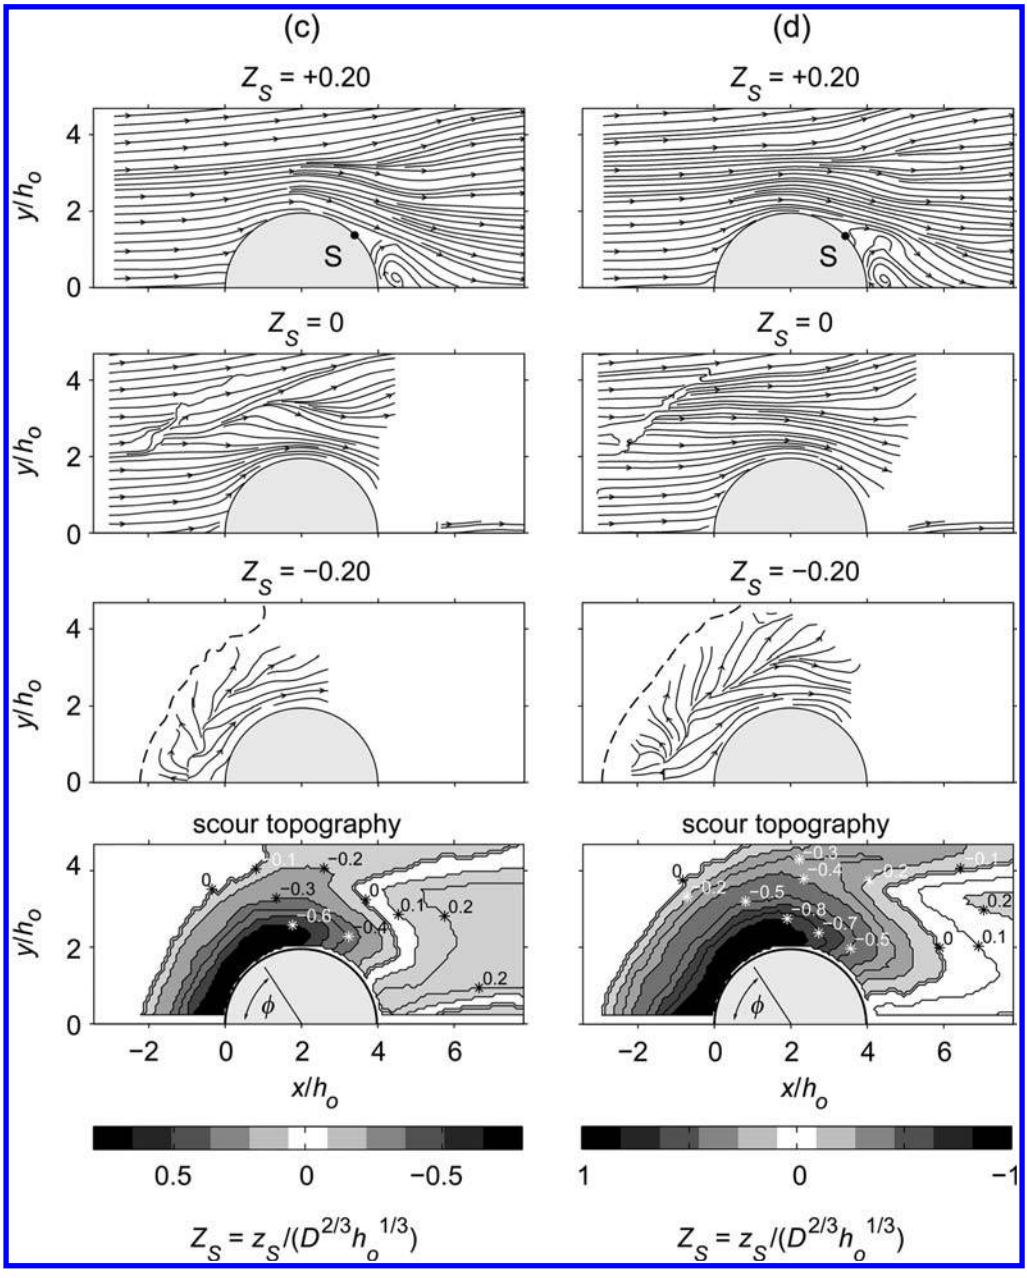

Figure 3. Continued. $t =$ (c) 600 s and (d) 2400 s; (- - -) scour extension.

line. Finally, the dimensionless scour topography with the same scaling is plotted for each time.

At depth $Z_S = +0.20$ the flow field is similar for all times. Upstream from the pier, the flow is relatively uniform, as reflected by the parallel and constantly spaced streamlines. Closer to the pier, from $x/h_o \cong -2.00$, the flow is deflected in the transverse channel direction y and accelerated, with the maximum velocity at an angle of $\phi = 75°$, resulting there in sediment entrainment. Simultaneously, the pressure along the pier decreases to its minimum at $\phi = 75°$. Beyond this region at an angle of $90° \leq \phi \leq 120°$ the flow separates from the pier due to the well-known pressure increase (Schlichting & Gersten 1997). The

Copyright © 2006 Taylor & Francis Group plc, London, UK

position of the separation point S is subject to turbulent fluctuations and eventually migrates in the region $90° \leq \phi \leq 120°$ as specified above. Downstream of the separation point is the turbulent wake zone consisting of highly unsteady vortices. These vortices are transported downstream by the mean flow and dissipated by turbulence production. The flow beyond the downstream plot end is redistributed and relatively uniform.

The flow of the plane $Z_S = 0$ is more complex than at $Z_S = +0.2$. Whereas upstream of the pier in the region $y/h_o < -2$ only minor differences are visible, the instantaneous scour circumference generates a separation line. Up to $\phi = 150°$ and for $Z_S \leq 0$ the flow does not separate from the pier and the flow is attached to it as with the Coanda effect. This phenomenon is discussed below.

Consider now the flow field in the horizontal plane $Z_S = -0.20$ (Fig. 3). At times $t = 60$ and 180 s a source flow develops at the pier front, due to the down-flow. The source flow is deflected in the transverse channel direction along the pier perimeter. This is in agreement with the vertical flow fields shown in Figure 2, containing no recirculation in the scour hole. During the next two time steps $t = 600$ and 2400 s an attached node line is developed in the scour, with the origin at $y/h_o = 0$ and $x/h_o \cong -1.00$ and -1.20, respectively. This singularity extends from the pier periphery along the scour hole in a constant distance of $\sim 1.00 \cdot D/4$ and $\sim 1.20 \cdot D/4$, respectively. As observed in the vertical planes, this structure is an indication for the existence of a vortex system (Fig. 2). The horseshoe vortex in Figure 2 is of spatial structure, surrounding the pier like a thick cord, therefore.

Figure 3 shows in addition the temporal evolution of the scour topography. The scour zone starts at an angle of $\phi \cong 75\circ$ for $t = 60$ s. The sediment deposition zone in this early stage is close to the pier immediately downstream from the scour zone. With increasing time, the scour zone migrates toward the pier front and expands laterally. At $t = 600$ s, the maximum scour depth has reached the pier front, and the sediment deposition zone has successively migrated downstream beyond the pier end. In the further scour process, the maximum scour depth and the scour expansion increase logarithmically with time (Melville & Coleman 2000, Oliveto & Hager 2002).

4 DISCUSSION OF RESULTS

4.1 *Principle flow features*

From the previously presented results pertaining to run D6, and the detailed analysis of the experimental program (Table 1), four principle flow phases around a cylindrical bridge pier may be identified. Figure 4 shows these phases schematically in the vertical plane of the pier symmetry axis.

As mentioned, sediment entrainment and scour activity starts always at roughly $\phi = 75°$, due to the locally high velocities in this region. During *phase* 1, the pier front has not yet undergone any scour. Upstream of the pier the mean flow is relatively uniform with a logarithmic velocity distribution. Toward the pier front, the flow is first decelerated and upon reaching it deflected (Fig. 4a). The stagnation point at the pier front divides the approach flow into two parts, (1) the *up-flow* toward the water surface and (2) the *down-flow* toward the instantaneous sediment surface. Unger (2006) demonstrated, that the geometric position of the stagnation point remains constant with time and may be described with a linear function of the reference length $z_R = (D^2 h_o)^{1/3}$ and the median sediment size d_{50}. Near the water surface the up-flow generates constantly a small *surface recirculation*. Its diameter, geometric position and vortex strength are also time-independent and depend on the densimetric Froude number F_d and the ratio z_R/d_{50}, respectively.

Close to the sediment surface a relatively small non-scour inducing *initial vortex* results from the down-flow in *phase* 1. During *phase* 2 this initial vortex disappears, and the down-flow close to the simultaneous sediment surface is completely deflected in the transverse channel direction. The relative time T_0 relating to the start of phase 2 depends mainly on threshold Froude number F_t describing the entrainment of sediment in the approach flow channel. Further, the flow around the pier is decelerated and thereby increasing the scour surface from $\phi = 75°$ mainly in the upstream direction.

The characteristic *horseshoe vortex system* develops eventually in *phase* 3. It consists first of a scour inducing *primary vortex*, to where the maximum scour depth migrates in the pier symmetry axis. Due to the continuous scour depth progress the discharge section increases resulting in a smaller flow velocity along the pier side, associated with a reduction of the scour advance in the lateral scour hole region.

In *phase* 4 the effect of the primary horseshoe vortex increases. The vortex diameter expands and one or more *secondary vortices* are generated. Both the primary and the secondary vortices rotate clockwise and induce additional small opposite-rotating vortices. The main horseshoe vortex generates the typical rim in the scour hole upstream from the pier. The high bed-shear stresses generated by this vortex result in a continuous deepening of the scour hole. When the slope of the scour hole attains its critical value avalanches slide toward the pier and the sediment is transported downstream. This process is repeated periodically and causes the main scour advance during phase 4.

A detailed description of the horseshoe vortex and the down-flow is given by Unger (2006). Therein,

Copyright © 2006 Taylor & Francis Group plc, London, UK

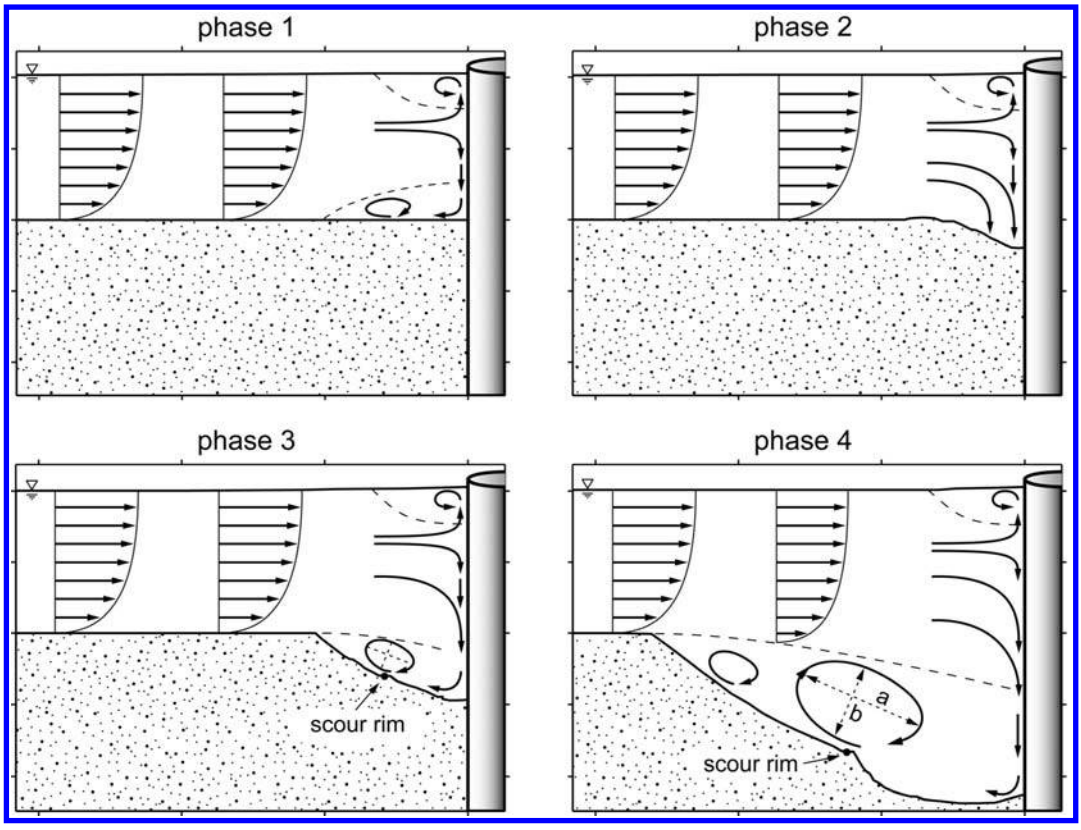

Figure 4. Principle vertical flow features around a circular bridge pier in the pier symmetry axis. *Phase* 1: initial vortex, *Phase* 2: flow deflection in transverse channel direction, *Phase* 3: scour evolution inducing horseshoe vortex system and *Phase* 4: fully developed horseshoe vortex system with one primary and several secondary vortices.

general velocity profiles are derived as a coupled square and exponential function. It is demonstrated that the maximum vertical down-flow velocity component reaches up to $0.75 \cdot V_o$ depending mainly on the ratio z_R/d_{50}. By means of normalization with the instantaneous scour depth the velocity profile function of the down-flow remains constant with time, in contrast to the velocity distribution through the centre of the primary horseshoe vortex. Here the maximum velocity governing the induced shear stress increases logarithmically with time and its geometric position moves toward the instantaneous sediment surface.

Figure 5 shows a sketch of the principal flow features in the horizontal plane. The arrows represent typical streamlines along the instantaneous sediment surface, and the flow separation zones in the wake of the pier are limited with dashed lines. In *phase* 1, the scour just started at roughly $\phi = 75°$, the sediment deposition zone being close to the pier. Upstream from the pier the flow is first decelerated and then deflected in the transverse channel direction, associated with a flow acceleration. Simultaneously the pressure along the pier periphery decreases up to the minimum value at $75° \leq \phi \leq 115°$ resulting further downstream in the flow separation zone due to the pressure increase. With a pier Reynolds numbers $R_D = (V_o D)/\nu$ between $5 \cdot 10^4$ and $3.5 \cdot 10^6$ (with ν as kinematic viscosity) for the present experiments, the geometric position of the pressure minimum and the separation point are subject to turbulent fluctuations. The reason is the permanent switch of laminar and turbulent separation linked with the possible turbulent re-attachment or a fully turbulent wake flow (Schlichting & Gersten 1997, Achenbach 1968). Downstream from the separation point S extends the turbulent wake zone. Because of the increased scour surface, the separation point in *phase* 2 migrates downstream along the pier perimeter. Note, that the plotted arrows represent streamlines along the instantaneous sediment topography of the scour hole, such that no migration of the separation point above the original sediment elevation was observed. The wake zone reduces due to migration of

Copyright © 2006 Taylor & Francis Group plc, London, UK

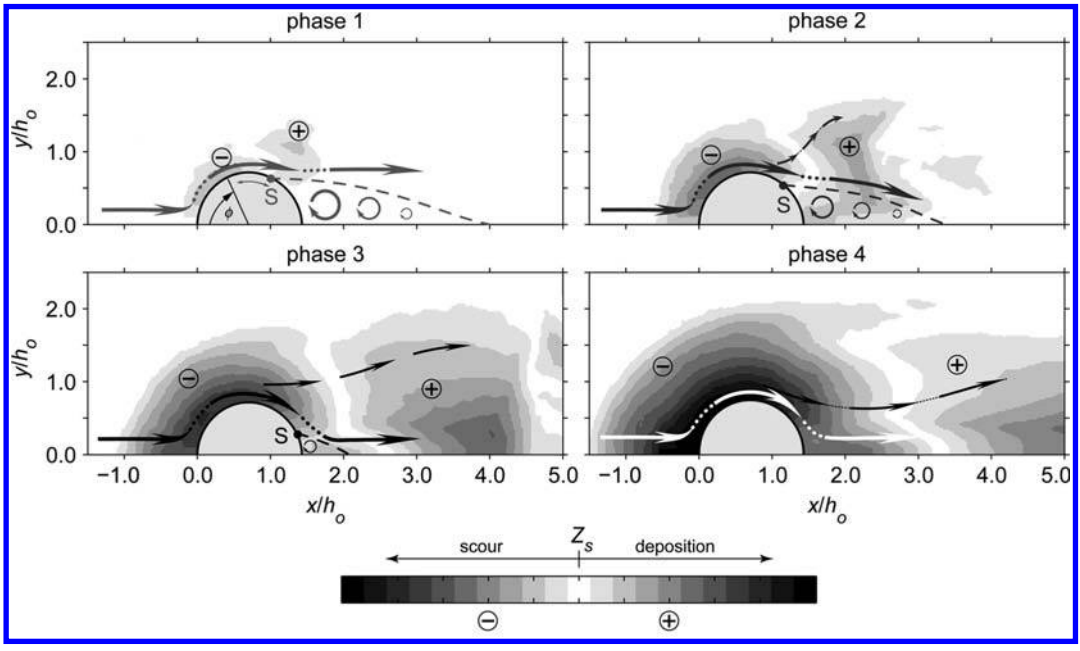

Figure 5. Principle horizontal flow features around a circular bridge pier close to the instantaneous sediment surface (see Figure 4).

the separation point. Additionally the flow separates near the pier side, due to the sediment deposition zone downstream of the pier.

In *phase* 3 the flow below $Z_S = 0$ follows practically along the entire pier perimeter and is similar to a Coanda flow, because: (1) Due to the continuous scour hole enlargement the pressure along the pier surface close to the instantaneous sediment surface increases. Consequently, the pressure gradient decreases and the flow separates at a larger angle ϕ, and (2) the special scour topography in this region effects the flow like a curved training wall. Additionally, due to the sediment deposition, the flow separation is much smaller because of the continuous downstream migration of this zone.

Finally, in *phase* 4, the flow below $Z_S = 0$ is completely attached to the pier perimeter. Because of the large and deep scour hole the flow velocity around the pier decreases and the scour advance decelerates, therefore. The main scour activity is concentrated to the pier front zone resulting from the fully developed main horseshoe vortex.

4.2 *Bed-shear stresses*

The estimation of a bed-shear stress from experimental data is a difficult task. Given that the direct experimental measurement techniques are limited both for laminar and turbulent flows, the available velocity distributions were used to approximate the effective bed-shear stresses. A detailed analysis confirmed the modified mixing layer concept (Unger 2006). Based on the velocity components v_x and v_z close to the instantaneous sediment surface, the velocity $v_{par} = (v_x^2 + v_y^2)^{1/2} \cdot \cos\alpha$ parallel to the bed was calculated with α as the instantaneous angle of the scour hole above the velocity vector considered. The bed-shear stress τ was subsequently computed as,

$$\tau = \rho\kappa^2 z_{par}^2 \left(\frac{\mathrm{d}v_{par}}{\mathrm{d}z}\right)^2 \tag{1}$$

with $\kappa = 0.40$ as the von Kármán constant and z_{par} as the normal distance of the instantaneous sediment surface to the origin of v_{par}. The critical (subscript c) bed-shear stress τ_c for entrainment is,

$$\tau_c = \rho V_*^2 \tag{2}$$

Here, V_* is the critical shear velocity determined according to Hager & Oliveto (2002) as

$$V_* = 1.08 D_*^{1/12} \left(\frac{R_{ho}}{d_{50}}\right)^{1/6} \left(\mathrm{g}' d_{50}\right)^{1/2} \tag{3}$$

Herein, $D_* = (g'\nu^2)^{1/3}/d_{50}$ is the dimensionless sediment size and $R_{ho} = Bh_o/(2h_o + B)$ the hydraulic radius of the approach flow. A similar method to estimate the bed-shear stresses inside the scour hole was

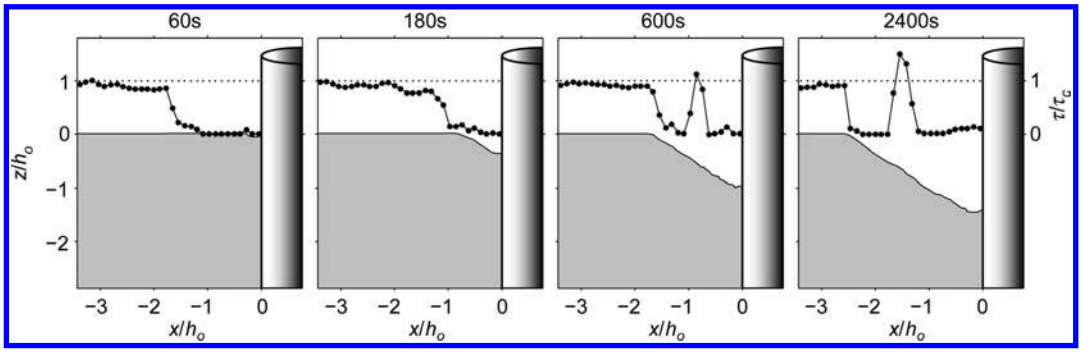

Figure 6. Relative bed-shear stresses τ/τ_c in the pier symmetry axis for run D6.

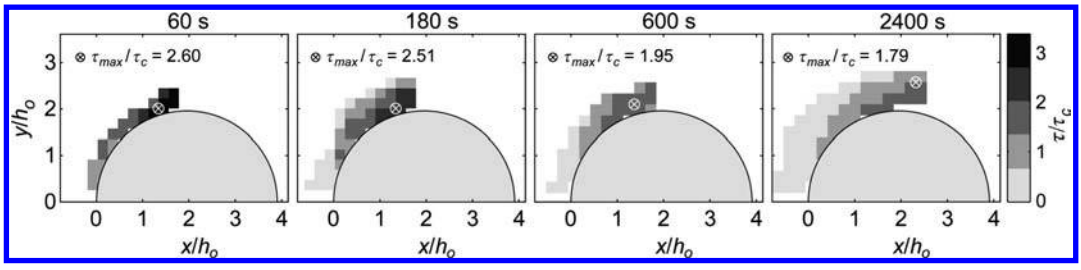

Figure 7. Relative bed-shear stresses τ/τ_c in the horizontal plane closest to the instantaneous scour surface for run D6.

also used by Barbhuiya & Dey (2004), Dargahi (1989), Graf & Istiarto (2002) and Graf & Yulistiyanto (1998).

The computed bed-shear stresses for the vertical flow field are shown in Figure 6 for the times considered in Figs. 2 and 3. In the approach flow region upstream from the instantaneous scour hole the relative bed-shear stress τ/τ_c is roughly constant and close to the critical value of $\tau/\tau_c = 1$. This is in agreement with the flow threshold Froude number $F_t = 0.98$. At time $t = 60$ s, corresponding to *phase* 1, the relative bed-shear stress reduces rapidly from $x/h_o \cong -1.5$ to the leading pier front, due to flow deceleration. Therefore, the initial vortex in phase 1 induces only minor shear stresses. At time $t = 180$ s corresponding to *phase* 2 this sudden bed-shear stress reduction migrates downstream to the starting point of the scour hole. In p*hase* 3 at $t = 600$ s, the horseshoe vortex develops, resulting in a relative bed-shear stress peak $\tau/\tau_c > 1$ directly below the horseshoe vortex centre. Finally in *phase* 4 at time $t = 2400$ s this peak increases and migrates upstream. Thus, the scour progress in the pier front zone is mainly governed by the primary horseshoe vortex. Directly at the starting point of the scour hole the relative bed-shear stress reduces in all four phases rapidly to $\tau/\tau_c = 0$ from the approach flow value τ_o.

The sediment close to the scour perimeter *slides* into the scour hole instead of being entrained from where it is transported downstream by the horseshoe vortex. Figure 6 demonstrates that bed-shear stresses are $\tau/\tau_c > 1$ in the vertical streamwise plane only after the formation of the primary horseshoe vortex and below the centre of it.

Figure 7 shows the corresponding horizontal bed-shear stress distribution close to the instantaneous scour surface and its maximum value τ_{max}/τ_c. The bed-shear stress was computed in the same manner as previously. Note that the calculated bed-shear stresses result from velocity vectors at the currently lowest elevation (here at $Z_S = -0.20$). Due to the particular scour topography, the velocity field and the resulting bed-shear stress distribution cover only the region close to the pier perimeter, and no general horizontal bed-shear stress distribution is available so far.

At scour beginning during *phase* 1, the maximum relative bed-shear stresses of $\tau/\tau_c \cong 3$ are located at $\phi \cong 75°$ to 90°, as previously described. In the whole region $0° \leq \phi \leq 90°$ the bed-shear stresses reach values $\tau/\tau_c > 1$, so that the scour at the pier side develops fast associated with the migration of the maximum depth toward the pier front. During *phase* 2 the bed-shear stress distribution is similar to phase 1. In the further progress, the bed-shear stresses decrease continuously in the observed scour region. Simultaneously the maximum bed-shear stresses migrate downstream along the pier perimeter. For $t = 600$ s, thus in *phase* 3, the computed bed-shear stress data near the pier front attain values $\tau/\tau_c < 1$, whereas bed-shear stresses $\tau/\tau_c > 1$ result besides the pier for $\phi > 45°$. In *phase* 4

Copyright © 2006 Taylor & Francis Group plc, London, UK

this decrease continues so that the scour deepening migrates downstream of the pier to $\phi > 90°$. The scour progress upstream from the pier is mainly related to the primary horseshoe vortex. Because of the localized observational region, the resulting shear stresses from this vortex are not included in Figure 7. Unger (2006) gives a generalized approach to compute directly the induced bed-shear stresses.

5 CONCLUSIONS

A large scale Particle Image Velocimetry (PIV) setup as a non-intrusive and simultaneously velocity measuring technique was successfully applied to bridge pier scour to obtain further insight into the temporal evolution of the flow features and the scour process. This contrasts most of the previous studies on the fascinating flow features around a circular bridge pier, arranged in a mobile sediment bed using point-wise and intrusive instrumentation. The present experimental observations contribute to pier scour experimentally and to the validation of numerical simulations concerning scour hydraulics. Using the instantaneous velocity fields the main flow patterns may be described from a spatial point of view.

The presence of a cylindrical pier results in flow deflection with the following main features: (1) stagnation point, (2) up-flow with a (3) surface recirculation and (4) down-flow close to the leading pier front, besides (5) the initial vortex upstream of the pier that eventually develops into (6) the horseshoe vortex system. In the horizontal planes (7) separation from the pier sides, (8) a wake zone downstream of the pier and (9) several singularities inside the scour were observed. The temporal evolution of these characteristics was described with 4 main phases in terms of the governing hydraulic and geometric parameters. Finally, an approach to predict the bed-shear stresses was attempted, based on the velocity field close to the instantaneous sediment surface. This paper gives a compact overview on some fundamental findings of a scour research project, therefore.

A numerical model for local scour at piers according to the unit stream power approach

M.E. Cunninghame & N.P. Armitage
Department of Civil Engineering, University of Cape Town, Rondebosch, South Africa

ABSTRACT: Local scour threatens the integrity of river bridges and fluvial structures. A numerical model for local scour hole evolution at a circular pier using incremental manual channel bed deformation was investigated. The three-dimensional flow field was computed in Fluent 6.2 by solution of the steady Reynolds-Averaged Navier Stokes equations using the k-ε model for turbulent closure. The bed geometry was then manually adjusted in proportion to the applied unit stream power to simulate scour and deposition. This procedure of flow field computation and bed deformation was repeated to simulate scour hole evolution. A slope correction factor was applied to the critical stream power required for incipience in the scour hole. The numerical model shows promise for simulation of local scour hole evolution although automated bed deformation procedures and alternative slope correction formulae must be developed.

1 INTRODUCTION

Local scour threatens the integrity of river bridges and fluvial structures. In a recent study of scour damage in South Africa, Armitage *et al.* (2005) found that local scour is evident at approximately 60% of scour-damaged bridges in the country.

Accurate and consistent methods are needed to predict local scour. Empirical formulae are inconsistent in their predictions of maximum scour depth (Johnson 1995) and each has a limited range of application. Physical models are time consuming and therefore expensive. Numerical models have undergone rapid development in the past decades. Olsen & Melaaen (1993) developed a non-transient, three-dimensional (3D), finite volume code which computed changes in channel bed elevation from the sediment concentration in bed-adjacent cells to simulate scour and deposition processes. Olsen & Kjellesvig (1998) developed this model further to incorporate time dependence and an adaptive grid to model temporal scour hole evolution. More recently, Nagata *et al.* (2002) investigated automated procedures for local scour hole evolution using stochastic models to describe sediment transport processes. Although reasonable agreement with physical model data was obtained, it was noted that the model required further development.

The objective of this study was to investigate a numerical model for simulating temporal scour hole evolution. Development of a clear-water local scour hole in uniform, quartzitic sand at a circular pier, studied by means of a physical model by Ahmed (1995), was simulated numerically. The commercial CFD code FLUENT V6.2 was used to compute the flow field and the unit stream power model was applied to predict patterns of scour and deposition. The channel bed deformation was computed as a function of the scour potential at the channel bed and the incremental bed adjustments were implemented manually.

2 THEORETICAL BACKGROUND

2.1 *Numerical model for flow computation*

The flow field was computed by solution of the steady Reynolds-Averaged Navier-Stokes (RANS) equations using the k-ε model for turbulent closure. The general form of the RANS equations is as follows (White 1991):

$$\rho\frac{D\mathbf{u}}{Dt}=\rho\mathbf{g}-\nabla p+\frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)+\delta_{ij}\lambda div\mathbf{u}\right] \qquad (1)$$

where ρ is the fluid density; $\mathbf{u}$ is the velocity vector; t is time; $\mathbf{g}$ represents gravitational acceleration; p is the pressure; μ is the fluid viscosity; u_i is the velocity component in the x_i direction; and λ is Lamé's constant.

The k-ε turbulence model was selected as it offers a reasonable compromise between accuracy and computational cost and has been widely used and validated

Copyright © 2006 Taylor & Francis Group plc, London, UK

(Versteeg & Malalasekera 1995). The k-ε model has been successfully applied to modelling open channel flow and local scour by numerous investigators (e.g. Ali & Karim 2002, Nagata *et al.* 2002, Olsen & Melaaen 1993, Richardson & Panchang 1998, Salehi Neyshabouri *et al.* 2003). The transport equations for the turbulent kinetic energy k and dissipation rate ε are (Rodi 1984):

$$\frac{\partial}{\partial t}(\rho k)+\frac{\partial}{\partial x_i}(\rho k u_i)=\frac{\partial}{\partial x_j}\left[\left(\mu+\frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right]+G_k+G_b-\rho\varepsilon-Y_M+S_k \quad (2)$$

$$\frac{\partial}{\partial t}(\rho\varepsilon)+\frac{\partial}{\partial x_i}(\rho\varepsilon u_i)=\frac{\partial}{\partial x_j}\left[\left(\mu+\frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right]+C_{1\varepsilon}\frac{\varepsilon}{k}(G_k+C_{3\varepsilon}G_b)-C_{2\varepsilon}\rho\frac{\varepsilon^2}{k}+S_\varepsilon \quad (3)$$

where σ_k and σ_ε are the respective turbulent Prandtl numbers for k and ε; and G_k and G_b represent the generation of turbulent kinetic energy due to mean velocity gradients and buoyancy respectively. The turbulent viscosity μ_t is computed by combining k and ε as follows:

$$\mu_t=\rho C_\mu\frac{k^2}{\varepsilon} \quad (4)$$

The constant terms in Equations 2, 3 and 4 have the standard values (Rodi 1984): $C_{1\varepsilon}=1.44$, $C_{2\varepsilon}=1.92$, $C_\mu=0.09$, $\sigma_k=1.0$ and $\sigma_\varepsilon=1.3$.

2.2 *Unit stream power theory*

According to stream power theory, energy is expended by the flow in doing work on sediment particles to initiate and maintain sediment motion. The conservation of energy for a fluid element may be stated as follows (Versteeg & Malalasekera 1995):

$$\rho\frac{Di}{Dt}=-pdiv\mathbf{u}+div(k_T\,gradT)+\Phi+S_i \quad (5)$$

where i is the internal energy; k_T is a conduction coefficient; T is the fluid temperature; and S_i accounts for external energy sources. The dissipation function, Φ, accounts for work done by viscous stresses, τ_{ij}, in the energy equation (Eq. 5) and is an expression of the applied unit stream power, P_t (W/m^3), in three dimensions (Armitage 2002). P_t is defined as:

$$P_t\equiv\Phi=\tau_{ij}\frac{\partial u_i}{\partial x_j} \quad (6)$$

For an incompressible, Newtonian fluid, P_t may be expressed in terms of velocity components u, v and w in the respective x, y and z directions as follows:

$$P_t=\mu\left[2\left(\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial y}\right)^2+\left(\frac{\partial w}{\partial z}\right)^2\right)+\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)^2+\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)^2+\left(\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}\right)^2\right] \quad (7)$$

This 3D unit stream power model is suitable for describing sediment transport in a numerical model as local velocity components are computed throughout the domain in the solution process. For local scour, this complete 3D description is also more accurate than that of 1D and 2D models linking sediment transport to mean velocities (Rooseboom 1975, Yang & Song 1979), which are often a poor reflection of flow conditions near the channel bed.

2.3 *Critical unit stream power for incipient motion*

Armitage (2002) analysed a large set of experimental incipient motion data consisting of 529 data points from eight researchers to establish the boundary between scour and deposition. Armitage proposed that the critical unit stream power required for incipient motion, P_{tc}, is some fraction, η, of that required for particle suspension, P_r. Incipient motion begins with rolling and sliding of sediment particles. These modes of motion are sustained by less energy or stream power than that required for particle suspension. The critical unit stream power is thus (Armitage 2002):

$$P_{tc}=\eta P_r \quad (8)$$

where η is a function of the nature of the boundary layer, that is, whether the boundary layer is laminar, transitional or turbulent. For rough turbulent boundaries $\eta=1/67$. If ρ_s is the sediment particle density and v_{ss} is the particle settling velocity, P_r is given by:

$$P_r=(\rho_s-\rho)gv_{ss} \quad (9)$$

For incipient motion on sloping channel beds, a slope correction factor, ψ, for the longitudinal and transverse bed slopes, β and γ respectively, must be incorporated. If ϕ is the sediment angle of repose and the bed slope angles are taken as positive measured downwards from the horizontal plane, ψ is given by (Chiew & Parker 1994):

$$\psi=\sqrt{\cos\beta\left(1-\frac{\tan\beta}{\tan\phi}\right)\cos\gamma\left(1-\frac{\tan^2\gamma}{\tan^2\phi}\right)}^{1/2} \quad (10)$$

For rough turbulent boundaries, the critical unit stream power required for incipience on a sloping channel bed, $P_{tc,\beta\gamma}$, is related to that required on a horizontal bed, $P_{tc,0}$, as follows:

$$P_{tc,\beta\gamma}=\psi^3P_{tc,0} \quad (11)$$

3 MODEL DESCRIPTION

The numerical model was based on a physical laboratory model studied by Ahmed (1995) for clear-water local scour of uniform, cohesionless quartzitic sand at a 64 mm diameter circular pier. The sand had a median diameter of 0.88 mm and an angle of repose of 35°.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The bed was subject to a steady flow of 50 l/s with an approach depth of 182 mm and Froude Number of 0.17. An equilibrium clear-water local scour hole with a maximum depth of 54 mm near the upstream face of the pier was established after 220 hours in the physical model.

The finite volume commercial CFD code, Fluent V6.2, was used to solve the flow field in three dimensions using the k-ε model with default constants for turbulent closure. The stratified flow of air and water through the computational domain was modelled using the Volume of Fluid (VOF) method (Hirt & Nichols 1981) to track the free surface. Logarithmic velocity distributions for uniform open channel flow as well as values of k and ε were specified as boundary conditions at the upstream and downstream domain boundaries. The height of wall adjacent cells was chosen such that $y^+ \approx 30$. The wall unit, y^+, is defined as follows:

$$y^+ = \frac{u_* y}{\nu} \tag{12}$$

where y is the distance from the boundary to the wall-adjacent cell centre and ν is the kinematic fluid viscosity. The shear velocity, u_*, in Equation 12 is defined in terms of the bed shear stress τ_0 as:

$$u_* = \sqrt{\frac{\tau_0}{\rho}} \tag{13}$$

A steady solution was computed to give the initial distribution of the applied unit stream power on the channel bed prior to the commencement of scour. It was found that the maximum applied power, $P_t = 17\ \mathrm{W/m^3}$, did not exceed the critical value for incipience of $29\ \mathrm{W/m^3}$, suggesting that no scour would take place (Fig. 1). It is suspected that the error lies in the fact that the power dissipation function (Eq. 7) is very sensitive to the depth at which it is computed near the channel bed as velocity gradients are very high in this region.

A critical stream power of $P_{tc,0} = 5\ \mathrm{W/m^3}$ was simply assumed to facilitate development of the model. This simply implies that scour commences at a lower intensity of particle motion.

The scour potential, Ω ($\mathrm{W/m^3}$), was calculated as the difference between the applied stream power P_t computed by the solver and the assumed critical stream power, corrected for bed slope where applicable, as follows:

$$P_{tc,\beta\gamma} = \psi^3 P_{tc,0} \tag{14}$$

$$\Omega = P_t - \psi^3 P_{tc,0} \tag{15}$$

The critical scour potentials at which scour and deposition would commence, Ω_{scour} and Ω_{depo} respectively, were then chosen. Therefore,

$$\text{if } \Omega > \Omega_{scour}\text{, scour occurs} \tag{16}$$

$$\text{if } \Omega < \Omega_{depo}\text{, deposition occurs} \tag{17}$$

The vertical adjustment, Δy, applied to each node at which scour or deposition would occur was calculated as a function of the difference between the computed and critical scour potentials. Relaxation factors C_{scour} and C_{depo} for scour and deposition respectively, were introduced to convert the difference in scour potential into a vertical node movement. These factors were calibrated to limit the adjustment of the vertical coordinate of any node to a maximum of 5 mm at any one adjustment. The bed adjustment algorithm can therefore be summarised as follows:

$$\text{if } \Omega > \Omega_{scour}\text{, then } \Delta y = -C_{scour}(\Omega - \Omega_{scour}) \tag{18}$$

$$\text{if } \Omega < \Omega_{depo}\text{, then } \Delta y = +C_{depo}(\Omega - \Omega_{depo}) \tag{19}$$

The linear adjustments described by Equations 18 and 19 were applied in the first four adjustments.

It was found that with further adjustment, the channel bed became undulating with sharp peaks and troughs. For the fifth and sixth bed adjustments, functions of the form:

$$\Delta y \propto \sqrt{\Omega - \Omega_{scour}} \tag{20}$$

were employed in an attempt to generate a "smoother" channel bed within and around the scour hole. The following functions were thus applied in these final two adjustments:

$$\text{if } \Omega > \Omega_{scour}\text{, then } \Delta y = -C_{scour}\sqrt{\Omega - \Omega_{scour}} \tag{21}$$

$$\text{if } \Omega < \Omega_{depo}\text{, then } \Delta y = +C_{depo}\sqrt{\Omega - \Omega_{depo}} \tag{22}$$

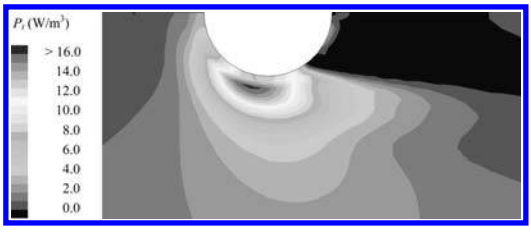

Figure 1. Initial distribution of applied stream power on the flat channel bed prior to scour.

4 RESULTS

The local scour hole generated by six manual bed adjustments is shown in Figures 2 a–f. Shaded plots of P_t are superimposed on the scour hole bathymetry. The colour scale is the same as that in Figure 1. Local scour commenced at the pier sides at approximately 70 to 80 degrees to the symmetry planealong the channel centreline.

Copyright © 2006 Taylor & Francis Group plc, London, UK

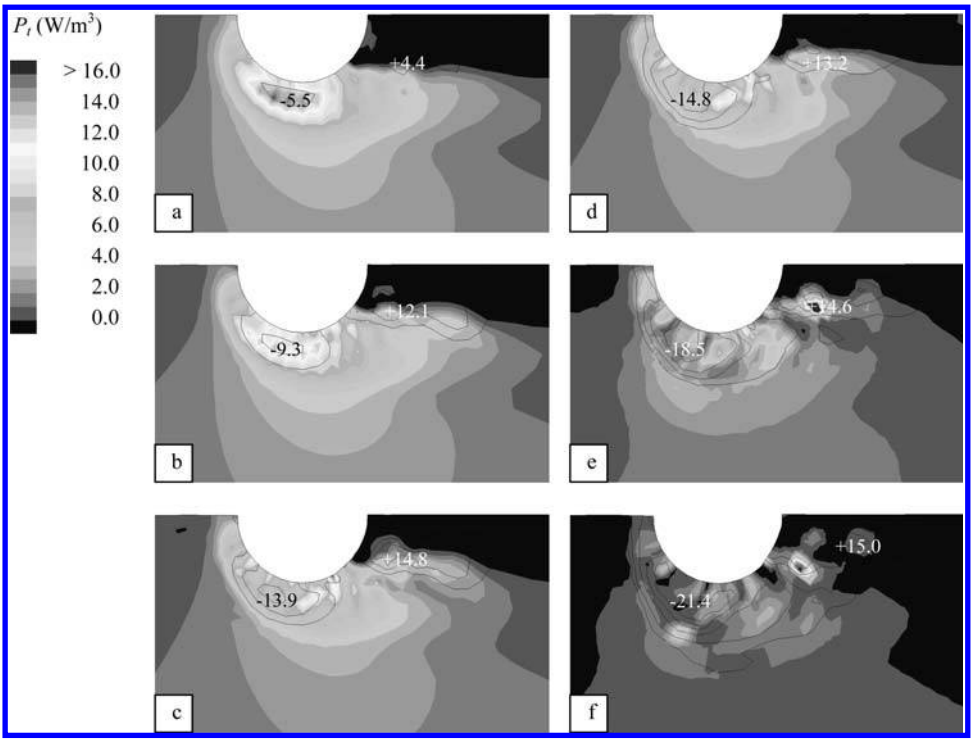

Figure 2. Distribution of applied stream power at the channel bed during manual bed adjustment. (Contour lines indicate bed elevation in mm; contour interval = 4 mm).

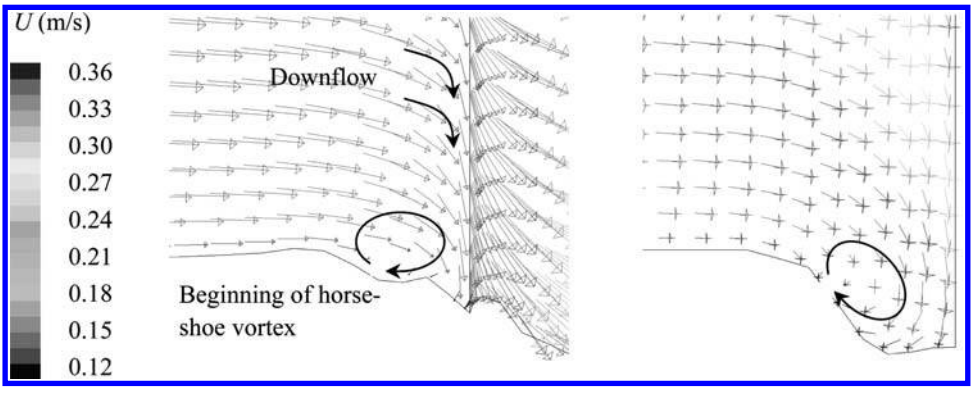

Figure 3. Initial development of the horseshoe vortex at the upstream face and at the side of the pier at 60 degrees to the channel centreline, after bed adjustment 4.

During the adjustment process, the scour hole migrated upstream to extend around the upstream face of the pier although the maximum scour depth remained at the side of the structure.

The initial development of small lateral scour holes and migration of the scour hole around the upstream face of the pier correspond to the temporal patterns of local scour hole development observed in physical models (Breusers & Raudkivi 1991, Dargahi 1990, Graf 1998).

The maximum downflow velocity at the upstream face of the pier, v_{max}, increased steadily during the bed deformation process with the evolution of the scour hole. Prior to scour, $v_{max} = 0.34U$, where U is the mean approach velocity, was computed by the model. After the 6th adjustment, $v_{max} = 0.42U$ was

Copyright © 2006 Taylor & Francis Group plc, London, UK

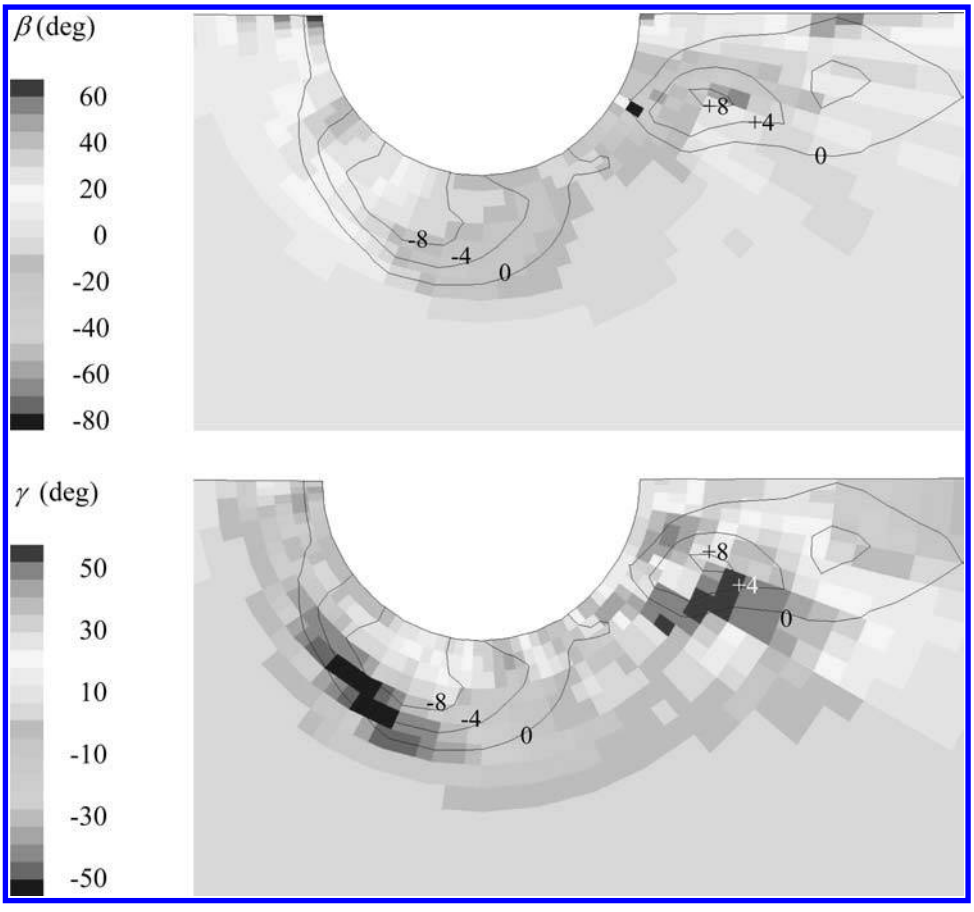

Figure 4. Distribution of streamwise (β) and transverse (γ) slope angles on the channel bed after adjustment 4 ($\phi = 35°$, depth contours shown in mm).

computed. These values correspond well with the theoretical value $v_{max} = 0.4U$ given by Raudkivi (1998) for a flat channel bed, that is, prior to the commencement of scouring. The initial development of the horseshoe vortex around the base of the pier is evident and shown in Figure 3 for the 4th adjustment as an example. The mesh near the channel bed is, however, not fine enough to resolve this clearly.

Accurate modelling of downflow at the upstream face of the pier and the horseshoe vortex in the scour hole around the pier base is essential for local scour simulation as the horseshoe vortex is a most influential mechanism in the local scouring process (Graf & Isitiarto 2002, Hoffmans & Verheij 1997).

The manual bed adjustments used to generate the scour hole of Ahmed (1995) were stopped after the sixth adjustment as the process is extremely tedious when undertaken manually and the slope correction formula (Eq. 10) became undefined at an increasing number of nodes with subsequent adjustments.

Figure 4 shows that the angle between the bed and velocity vectors near the channel bed exceeded the sediment angle of repose of 35° in many regions. At the first adjustment, ψ was undefined at 3 nodes but by the 6th adjustment, ψ could not be computed and was therefore estimated at 40 nodes on the channel bed. The chosen slope correction formulation does not allow computation when $|\beta| > \phi$. Dey *et al.* (1995) studied the flow fields in clear-water local scour holes and noted that the slope of the scour hole sides attain a "dynamic angle of repose" which exceeds ϕ by 10 to 20%.

5 CONCLUSIONS

A numerical model, employing incremental bed adjustment based on the unit stream power theory, was investigated for simulation of the temporal development of a local scour hole at a circular pier.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The model shows promise for application to local scour problems.

The method of incremental bed adjustment until the unit stream power model indicates that an equilibrium hole has developed is a useful technique for generating local scour holes. This method is an alternative to time-accurate simulation of clear-water scour hole development, which would require a substantial amount of computing power as time scales for local scour are long. It is, however, necessary for the investigated procedure to be automated, allowing smaller vertical bed deformations to be used at each adjustment.

The initiation of scouring and early patterns of scour hole development predicted by the numerical model correspond well with the characteristics of local scour holes observed in physical models. A lateral scour hole initiated at the side of the pier and then migrated upstream. The numerical model produced good predictions of the flow patterns around the pier and within the scour hole. The downflow at the upstream face of the pier and formation of the horseshoe vortex around the pier base were evident. Correct representation of these features in the numerical model is most important as the development of downflow at the upstream pier face and the horseshoe vortex at the base are highly influential in the scouring process.

It is felt that a numerical model for local scour, such as that investigated, can be implemented in a general, commercial CFD code such as Fluent. Underestimation of the applied stream power on the channel bed requires attention in future use of the stream power model. In addition, alternative slope correction formulae or algorithms, which facilitate computation even when the bed slope exceeds the sediment angle of repose, must be developed for implementation in an automated bed adjustment model. The dynamic angle of repose should be accounted for. It may also be necessary to write in additional code to control the mesh quality as the bed deforms.

Conservative scheme for flow numerical modeling of submerged bridges

M. Catella & G. Bechi
Department of Civil Engineering, Florence University, Florence, Italy

ABSTRACT: A one-dimensional numerical model to study river hydrodynamics of submerged bridges in open-channel flow is presented. The St. Venant equations, written in a conservative form, are solved by employing a finite volume method. The resulting scheme has been extensively tested under unsteady flow conditions by reproducing various open channel and bridge geometries both ideal and real, with non-uniform grids and without any interpolation of topographic survey data and including subcritical, supercritical and transcritical flows with and without shocks. The proposed model provides a great versatility, stability and robustness moreover capturing transcritical sections and conserving mass.

1 INTRODUCTION

The prediction of flood wave propagation in a natural channel is an important feature in hydraulic engineering analysis and in the design for river man-agement and civil protection. Moreover one of the major challenging problem on this subject is the analysis of the river hydrodynamic behavior at bridge sites.

Several studies have been performed in recent years both on local flow and scouring processes around piers or abutments (Umbrell et al., 1998; Biglari & Sturm, 1998; Ahmed & Rajaratnam, 1998; Ahmed & Rajaratnam, 2000).

Nowadays the topic of bridge backwater has become more of a concern (Naudascher & Medlarz, 1983; Hunt et al., 1999; Martín-Vide & Prió, 2005). In the past, flooding caused by bridge constrictions was considered a serious hazard, due to the lack of accurate computational methods of the backwater amount (Kaatz & James, 1997).

Usually, numerical schemes employ local boundary conditions to relate the characteristics of flow upstream and downstream the bridge faces, where the hypothesis of small two dimensional effects disappoint. As mentioned by Natale et al. (2004), some numerical models, such as ISIS (Rosu & Ahmed, 1999) and TEVERE (Natale et al., 1999), are able to reproduce only subcritical flow regime. Others, such as MIKE 11 (DHI, 2000), simulate both subcritical and supercritical flows. Nevertheless transcritical flow conditions are treated by reducing the inertial term influence as the Froude number grows, neglecting them if the Froude number becomes greater than one.

Under low flow condition, the water depth on both sides of the bridge is sufficiently lower than the gate opening height and thus free-surface flow condition is established. Pressure flow condition occurs whenever the water surface elevation exceeds the bottom elevation of the bridge deck's structural members. When the approaching flow begins to overtop the bridge deck, the deck behaves like a broad-crested weir. Under this condition, the flow changes from exclusively submerged pressurized flow under the bridge to a combination of weir and submerged pressurized flow (Umbrell et al., 1998).

The objective of the present analysis is to focus on the bridge hydrodynamic modeling under submerged conditions.

Free-surface flow under a bridge with piers and abutments is modeled by means of the water continuity and momentum equations, by considering a loss of wetted cross sectional area and an increase in wetted perimeter.

Furthermore, this study does not address the special problem of weir flow over the bridge deck.

2 GOVERNING EQUATIONS

Consider a system of orthogonal Cartesian axis (x, y, z) with unit vectors ($\bar{i}, \bar{j}, \bar{k}$). The vertical z-axis is positive in the upwards direction and the horizontal x-axis, corresponding to the projection of the thalweg line on the plan $z = 0$, is positive downstream. Considering weak values of bottom slope, channel cross sections are assumed to be orthogonal to the x-axis. As usual in the one-dimensional scheme the flow is straighten in the plan.

The control volume V at the *jth* cell is defined by the channel reach included between two vertical cross sections j and $j + 1$ orthogonal to the x-axis. The control surface S is then compounded respectively by the

Copyright © 2006 Taylor & Francis Group plc, London, UK

upstream cross section S_j, the downstream cross section S_{j+1}, the wetted surface S_l, delimited by S_j and S_{j+1}, and the water free surface S_{pl}.

The momentum equation applied to the control volume V and projected on the horizontal x-axis, reads:

$$\rho \frac{\partial}{\partial t} \int_{x_j}^{x_{j+1}} Q dx + S_{tj+1} - S_{tj} + \int_{S_l} (p\bar{n} - \bar{\tau}) \cdot \bar{i} dS_l = 0 \qquad (1)$$

where $\rho =$ water density; $Q =$ liquid discharge; $p =$ pressure; $\bar{n} =$ unit vector outward normal to S; $\bar{\tau} =$ shear stress (viscous + turbulent); and $\bar{S}_{tj}$ is the momentum function defined as follows:

$$\bar{S}_{tj} = \int_{S_j} (p + \rho v^2) \bar{i} dS \qquad (2)$$

Particular attention is posed to the treatment of the source terms of the Equation (1) related from one hand to the hydrostatic pressure acting on the wetted surface S_l and on the other hand to the shear stress. Following Catella & Solari (2005), Equation (1) reads:

$$\begin{aligned} &\frac{\partial}{\partial t} \int_{x_j}^{x_{j+1}} Q dx + \left[\beta \frac{Q|Q|}{A} + gI_1 \right]_{x_j}^{x_{j+1}} + \\ &- g\left[A_{j+1}(h_m - z_{gj+1}) - A_j(h_m - z_{gj}) \right] + \\ &+ \frac{\Delta x_j}{2} \left[B_{j+1} \left(\frac{Q|Q|}{(CA)^2} \right)_{j+1} + B_j \left(\frac{Q|Q|}{(CA)^2} \right)_j \right] = 0 \end{aligned} \qquad (3)$$

where $\beta =$ Boussinesq velocity distribution coefficient; $A =$ wetted cross sectional area; $g =$ gravitational acceleration; $I_1 =$ first moment of the wetted cross section with respect to the free surface; $h_m =$ average elevation of the water surface within the jth cell; $z_g =$ center mass elevation of the wetted cross section; $\Delta x_j =$ distance between the vertical cross sections j and $j+1$; $B =$ wetted perimeter; and $C =$ dimensionless Chézy coefficient.

The integral form of the continuity equation under the assumption of no lateral inflow or outflow is:

$$\frac{\partial}{\partial t} \int_{x_j}^{x_{j+1}} A dx + [Q]_{x_j}^{x_{j+1}} = 0 \qquad (4)$$

Introducing the usual discretization:

$$\frac{\partial}{\partial t} \int_{x_j}^{x_{j+1}} G dx \cong \frac{G_m^{n+1} - G_m^n}{\Delta t^n} \Delta x_j \qquad (5)$$

(where G is an arbitrary variable, G_m its average value within the $j_t h$ cell and n the time step index) we obtain a $2(N-1)$ equations system function of $2(N-1)$ variables A_m and Q_m average values of the wetted cross sectional area A and the liquid discharge Q in each $N-1$ cells defined by a N grid points approximation of the entire reach length. The N grid points are generally provided by topographic surveys at not equidistant discrete locations x_j.

The assignment of the $2N$ variables A and Q to the N grid points from the $2(N-1)$ average values within each cell follows a criterion based on the Froude number of the average flow of the upstream and downstream cells between the interface to assign.

3 NUMERICAL SCHEME

The solution of the present equations system is conducted by following a decoupled procedure.

Firstly, by assuming a fixed-bed, the solution of water continuity and momentum equations is conducted by applying an explicit two steps predictor-corrector conservative scheme based on a finite volume method (Catella & Solari, 2005).

The proposed technique, composed by a sequence of two sub-steps in which the spatial derivatives are taken in the same directions, reads:

$$\mathbf{U}_j^p = \mathbf{U}_j^n - \frac{\Delta t^n}{\Delta x_j} [\mathbf{F}_{j+1}^n - \mathbf{F}_j^n] + \Delta t^n \mathbf{S}(\mathbf{U}^n, x) \qquad (6)$$

$$\mathbf{U}_j^c = \mathbf{U}_j^n - \frac{\Delta t^n}{\Delta x_j} [\mathbf{F}_{j+1}^p - \mathbf{F}_j^p] + \Delta t^n \mathbf{S}(\mathbf{U}^p, x) \qquad (7)$$

where the superscripts p and c indicate the predictor and the corrector steps, while $\mathbf{U}$, $\mathbf{F}$ and $\mathbf{S}$ are the vectors of conserved variables, fluxes and source terms, respectively.

The solution at the new time level $n+1$ is then evaluated as an average between the two sub-steps:

$$\mathbf{U}_j^{n+1} = 0.5 \cdot \left(\mathbf{U}_j^p + \mathbf{U}_j^c \right) \qquad (8)$$

In the present model Q is always assigned by allocating Q_m to the downstream intercell starting from the inflow boundary condition. To assign A, a criterion based on the Froude number of the average flow of the upstream and downstream cells across the interface to assign is applied in addition to an appropriate boundary condition at the upstream or downstream edge of the channel. In particular, if the average flows in the jth and $j+1th$ cells are both subcritical, A at the $j+1th$ intercell takes the value of A_{mj+1}, in the opposite case, both supercritical, the value of A_{mj}. In the case of transcritical flows, if the average flows in the jth and $j+1th$ cells are subcritical and supercritical respectively, A at the $j+1th$ intercell takes the critical value, in the opposite case, supercritical and subcritical respectively, a criterion based on the momentum

Copyright © 2006 Taylor & Francis Group plc, London, UK

function of the flows in the upstream and downstream cells across the interface to assign is applied.

For the stability of the present explicit scheme, the Courant-Friederich-Lewy number N_{CFL} must satisfy the following condition:

$$N_{CFL} = \Delta t \cdot \frac{\max_i \left[\left| \frac{Q}{A} \right|_i \right] + \max_i \left[\sqrt{\frac{g \cdot A}{\alpha \cdot b}}_i \right]}{\min_i [\Delta x_i]} < 1 \quad 1 \le i \le N \tag{9}$$

where $\alpha =$ Coriolis velocity distribution coefficient.

4 BRIDGE HYDRAULIC ANALYSIS

Consider a horizontal girder bridge with a determined gate opening height a and without any cross section constriction or enlargement. Under these assumptions the pressure flow under the bridge can be approximated to the pressure flow under a vertical sluice gate.

In mild slope channels, upstream the bridge the water surface elevation increases due to the presence of the obstruction generating a backwater profile. Downstream, depending on the opening height of the gate, different regimes may be present. If the opening height is higher than the critical depth a submerged outflow occurs. While, if the opening height is lower than the critical depth a hydraulic jump may occur. In this latter case, the hydraulic jump may be submerged (Fig. 1) or not (Fig. 2) if the conjugate depth corresponding to the gate opening multiplied by the contraction coefficient is lower or higher than the downstream water depth, respectively.

In steep slope channels, a transition from supercritical to subcritical regime takes place upstream the obstacle, being the water depth just upstream the bridge always greater than the critical depth. Assuming no downstream control on water surface elevation, the water depth tends to the normal depth downstream the bridge. If the gate opening height is higher or lower than the normal depth, the water profile extends between the critical and the normal depth or below the normal depth, respectively (Figs. 3–4).

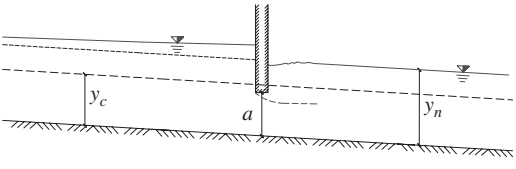

Figure 1. Sketch of water surface profile affected by a bridge in a mild slope channel: submerged jump case.

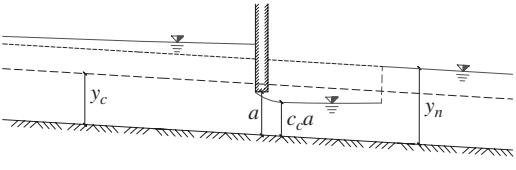

Figure 2. Sketch of water surface profile affected by a bridge in a mild slope channel: non-submerged jump case.

The water surface profile through a pressurized bridge is estimated by following a two step computational procedure.

Firstly, before analyzing the bridge, the solution of water continuity and momentum equations is conducted by applying the explicit two steps predictor-corrector conservative scheme based on a finite volume method (see Chapter 2). Secondly, the bridge analysis is initiated.

In the present model, the hydraulic analysis of pressurized bridge requires the definition of a minimum of three cross sections. The entrance and the exit cross sections are located immediately upstream and downstream the bridge faces, respectively. While, the third cross section is located downstream the bridge reasonably close to the exit section to ensure the applicability of the momentum theorem.

First, the type of water surface profile in the exit cross section should be calculated.

If a supercritical flow regime is found in the third cross section a free outflow occurs.

Vice versa a submerged or non-submerged jump (i.e. submerged or free outflow) may occur downstream of the gate if the flow depth of the *vena contracta* is higher or lower than the conjugate depth of the downstream undisturbed subcritical flow, respectively.

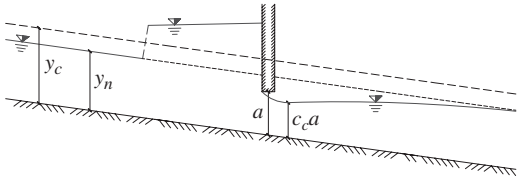

Figure 3. Sketch of water surface profile affected by a bridge in a steep slope channel: the gate opening height is lower than the normal depth.

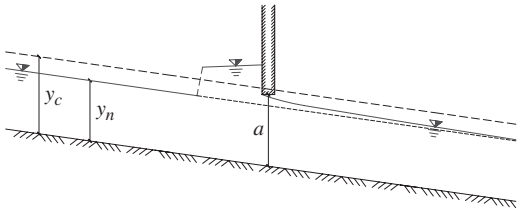

Figure 4. Sketch of water surface profile affected by a bridge in a steep slope channel: the gate opening height is higher than the normal depth.

Copyright © 2006 Taylor & Francis Group plc, London, UK

At the occurrence of a submerged outflow, the wetted cross sectional area A at the exit cross section takes the average value of A_m within the downstream cell delimited between the exit and the third cross section. Otherwise, if a free outflow occurs, A takes the value of the contracted area $c_c\hat{A}$, where c_c is the contraction coefficient and $\hat{A}$ is the area of the gate opening. Note that the flow depth of the *vena contracta* is located at the exit bridge cross section.

Next, the flow depth at the entrance cross section should be estimated. Due to the short length of the reach, information can be assumed to propagate instantaneously inside the bridge. Thus the water levels upstream and downstream the bridge can be evaluated by applying steady flow relationships. Besides, the upstream flow depth can be calculated by assuming a constant liquid discharge throughout the bridge faces and by applying the Bernoulli equations between the entrance and the exit cross sections:

$$y_0 + \alpha\frac{Q^2}{2gA_0^2} = c_c a + \hat{\alpha}\frac{Q^2}{2g(c_c\hat{A})^2} + \Delta E \tag{10}$$

where the subscript 0 indicate the entrance cross section and ΔE is the specific energy loss.

In free outflow case the specific energy loss is assumed to be negligible ($\Delta E = 0$), while in the case of submerged outflow the specific energy loss is defined by:

$$\Delta E = \xi\frac{\left(\hat{\alpha}\dfrac{Q}{c_c\hat{A}} - \alpha_0\dfrac{Q}{A_0}\right)^2}{2g} \tag{11}$$

where $0 < \xi \leq 1$ is the local head-loss coefficient between the entrance and the exit cross sections.

Note that the assumption of energy conservation in the vicinity of the obstacle only holds if the induced flow curvatures are small.

5 HYSTERESIS BOUNDARY REGION

In the present model, pressure flow conditions are achieved whenever water surface elevation of the undisturbed flow exceeds the bottom elevation of the bridge deck ($y_0 = a$). Therefore, the height of the gate opening corresponds to the upper limit of water depth defining the detachment threshold between free-surface and pressurized flows. Following Defina & Susin (2003) the water depth upper limit can be written in terms of dimensionless parameters as follows:

$$\frac{a}{y_c} = F_0^{-2/3} \tag{12}$$

where y_c = critical depth; $F_0 = U_0/\sqrt{gy_m\alpha^{-1}}$ is the Froude number of the undisturbed flow immediately upstream the bridge and y_m is the average flow depth of the equivalent rectangular cross section characterized by the same wetted cross sectional area and water surface width.

Hence, when the undisturbed flow depth becomes slightly higher than the gate opening height a pressurized flow is obtained and a backwater effect is established. Starting from this flow state, if the water depth starts to go down under the gate opening height two different scenarios can be drawn. In subcritical flow regime a decrease in water depth under the gate height reestablishes an undisturbed free-surface flow. While in supercritical flow regime the hysteresis effect of the hydraulic jump significantly affects the hydraulic phenomenon.

The hysteresis occurrence in a supercritical flow regime approaching an obstacle has been widely investigated both experimentally and theoretically (Muškatirović & Batinić, 1977; Baines, 1984; Austria, 1987; Lawrence, 1987; Baines & Whitehead, 2003; Defina & Susin, 2003). In open channel flow, when a transition between supercritical and subcritical flow occurs, an hysteretic behavior is observed in a particular range of values of the governing variables (Austria, 1987). Hysteresis or multiple equilibria correspond to situations where two different flow states may exist for the same external steady conditions (Baines, 1984), and the actual regime depends on the previous history of the flow (Muškatirović & Batinić, 1977; Defina & Susin, 2003).

In particular, the hysteretic behavior of the flow under a vertical sluice gate or a girder bridge concerns the possibility that, for a given height of the gate opening, a supercritical approaching flow may either continue undisturbed or undergo a supercritical to subcritical transition upstream the gate (Defina & Susin, 2003).

The lower limit of water depth defining the detachment threshold between pressurized and free-surface flows in supercritical regime can be evaluated by applying the Bernoulli equation between the undisturbed flow upstream the bridge and the *vena contracta*. Again, following (Defina & Susin, 2003) the water depth lower limit can be written in terms of dimensionless parameters as follows:

$$\left(\frac{a}{y_c}c_c\right) + \frac{1}{2}\left(\frac{a}{y_c}c_c\right)^{-2} = \frac{1}{2}\left(-1+\sqrt{1+8F_0^2}\right)F_0^{-2/3} + \frac{2F_0^{4/3}}{\left(-1+\sqrt{1+8F_0^2}\right)^2} \tag{13}$$

Therefore if the water depth increase over the upper limit or decrease under the lower limit a pressure or a free-surface flow is established respectively. In subcritical regime upper and lower limit of water depth

Copyright © 2006 Taylor & Francis Group plc, London, UK

are both defined by Eq. (12), while in supercritical regime upper and lower limit are obtained by mean of Eqs. (12) and (13) respectively defining the boundaries of the hysteresis region.

The present numerical scheme is able to predict for the same range of parameters both an undisturbed supercritical flow and a flow with a stationary hydraulic jump upstream the bridge and to compute the proper flow state by including the past history of the flow.

6 APPLICATIONS

To analyze the performance and the reliability of the present numerical algorithm devoted to describe the flow regimes throughout the bridge, several schematic test cases are conducted under unsteady flow conditions including subcritical, supercritical and transcritical flows with and without shocks.

In all the following numerical tests a 1000 m long and 25 m wide rectangular channel is employed. In particular, an intermediate reach of the Vezza Creek (North Tuscany) is taken as a prototype to find out an average channel width, a roughness coefficient and the flood hydrograph. Thus, the inflow liquid discharge corresponds to a 50 years return period flood hydrograph (see Fig. 5). The hydrograph lasts 9 hours and the discharge values range between 34.5 m^3/s and 366.5 m^3/s.

In the computations the channel is outlined by 100 cells ($\Delta x = 10$ m), N_{CFL} is set equal to 0.9 and the value of the Manning coefficient is set equal to 0.029 $s/m^{1/3}$. Note that the solutions are not affected by the N_{CFL} values, therefore the chosen time step size is very close to the maximum allowed by numerical stability.

Moreover in the following tests, to make plain the problem, the contraction coefficient c_c is always set equal to 1, thus the contracted area is equal to the area of the gate opening.

Note that no changes must be introduced in the numerical scheme to model bridge in natural irregular geometries.

In mild slope channels the bottom slope is 0.001, while in steep slope channel the bed slope is 0.01.

In subcritical flow, the discharge at the upstream side and the normal flow depth at the downstream side are imposed as boundary conditions. In supercritical flow, the liquid discharge and the normal depth are specified as upstream boundaries.

All the girder bridges are characterized by horizontal low chord and no constrictions. In single bridge cases the structure is delimited by two cross sections located at $x = 490$ m and $x = 500$ m, respectively. In two bridges in series cases, the structures are characterized by different gate opening heights and each one is still delimited by two cross sections.

6.1 *Mild slope channel tests*

Firstly the single bridge test case is conducted. The gate opening height is set equal to 2 m. The evolution of the water level profiles at different time instants are reported in Figure 6. Figure 6 shows that the theoretical behavior is correctly reproduced. Upstream a continuous backwater profile is formed. When simulation time is about 2 hours, pressure-flow condition is established. As the water surface continues to rise, the pressurized flow under the bridge increases as the degree of submergence increases. Downstream, submerged outflows always occur, since the conjugate depth of the downstream undisturbed subcritical flow is lower than the flow depth of the *vena contracta* $c_c a$ at all times. In Figure 7, discharge values versus water depths are plotted at the entrance and the exit cross sections, respectively, pointing out the backwater effect triggered by the bridge.

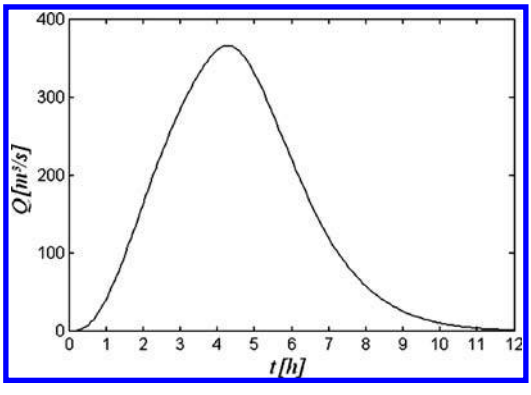

Figure 5. Liquid discharge hydrograph for return period of 50 years.

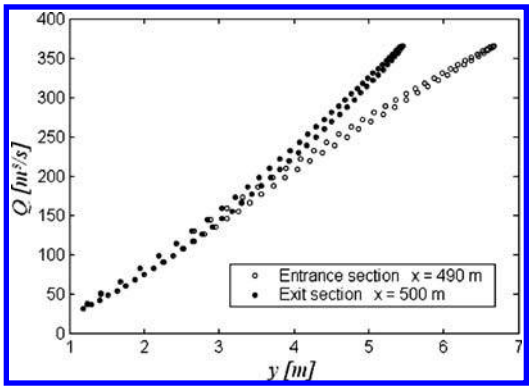

Figure 7. Single bridge test case in a mild slope channel: discharge versus water depth values. Results are plotted at two different river stations (entrance and exit cross sections).

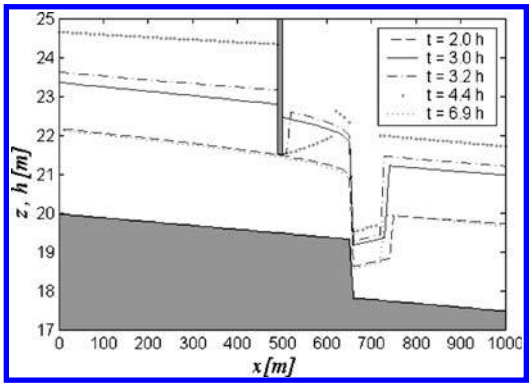

Figure 8. Single bridge and dam test case in a mild slope channel: temporal sequence of water surface level. Bed level and bridge structure are sketched in solid grey.

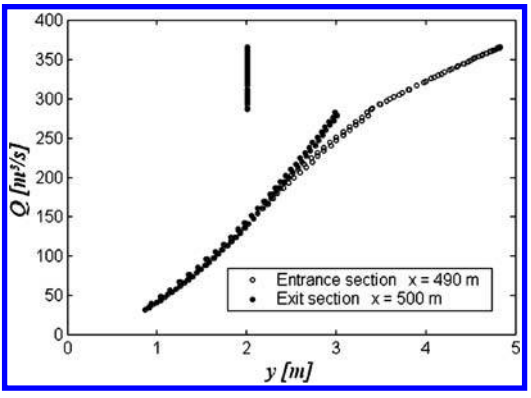

Figure 9. Single bridge and drop test case in a mild slope channel: discharge versus water depth values. Results are plotted at two different river stations (entrance and exit cross sections).

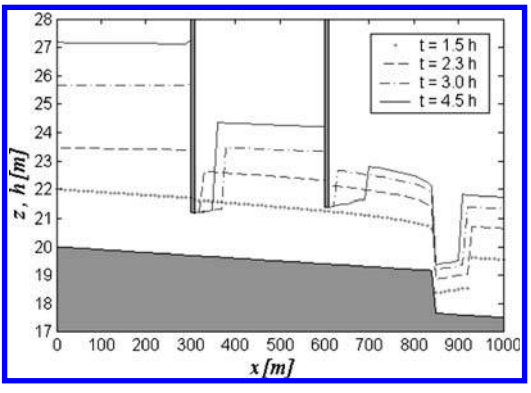

Figure 10. Two bridges in series test case in a mild slope channel: temporal sequence of water surface level. Bed level and bridge structures are sketched in solid grey.

Secondly a single bridge test case with a downstream control on water depth is analyzed. Bridge and channel geometries are the same of the previous test, to which a 1.5 m high drop located 150 m downstream the exit cross section is added. The flow is therefore influenced by the water level above the drop. The water surface profile develops between the normal and the critical depths dropping in the downstream direction. Hence, at time equal about 3.2 hours, the outflow, which is submerged, changes into free and a hydraulic jump occurs (see Fig. 8). In spite of the previous test case, the free outflow is allowed due to the lower values assumed by the flow momentum quantities in the channel reach between the two inline structures. As water surface continues to rise, the supercritical reach length downstream the bridge increases as the degree of submergence increases. In Figure 9, discharges versus water depths are reported just upstream and downstream the bridge. The submerged to free outflow transition induces a suddenly abrupt reduction of the water level. In fact until the outflow is free, the water depth at the exit cross section is set equal to the gate height.

Next two bridges in series are modelled in order to investigate their mutual interaction. The entrance cross sections are located at $x = 300$ m and $x = 600$ m, respectively. The first gate opening height is set equal to 1.5 m, while the second one is set equal to 2 m. A 1.5 m high drop located $x = 840$ m is added. The temporal sequence of the water level profile during the flood hydrograph is reported in Figure 10. Figure 10 shows that, due to the drop control on water depth, a free outflow begins downstream the first bridge at time equal to about 2.3 hours, while the second structure is still characterized by a submerged outflow. The smaller is the gate opening height, the earlier is the beginning of the outflow transition. The resulting hydraulic jump,

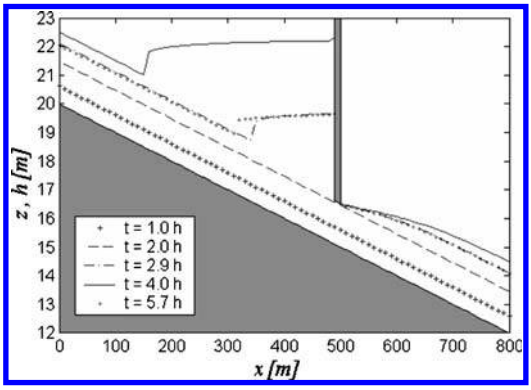

Figure 11. Single bridge test case in a steep slope channel: temporal sequence of water surface level. Bed level and bridge structures are sketched in solid grey.

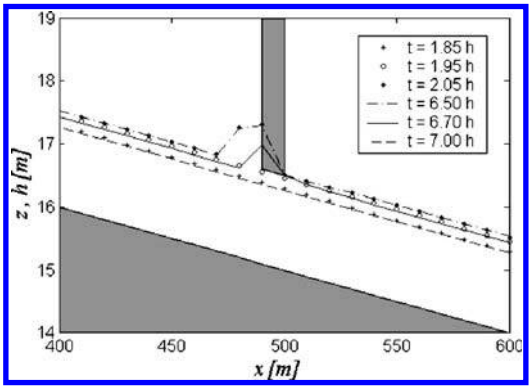

Figure 12. Hysteretic behavior of the flow: under the same range of parameters both an undisturbed supercritical flow and a flow with a stationary hydraulic jump upstream the bridge are computed.

located between the two structures, starts to migrate downstream. The supercritical reach length, immediately downstream the first bridge, rather than increases as the submergence degree increases, is bordered downstream by the rising backwater effect. Besides, at the edge of the rising part of the flood hydrograph, the hydraulic jump moves upstream toward the exit section of the first bridge.

6.2 *Steep slope channel tests*

Firstly a single bridge test case is conducted again. The gate opening height is set equal to 1.5 m. In Figure 11, the sequence of water level profiles at different time instants are plotted, showing that also in this flow regime the theoretical behaviour is correctly reproduced. During the rising part of the hydrograph, once the water surface elevation exceeds the gate opening height, the flow passes abruptly from a supercritical flow regime to a subcritical one. Therefore the water depth upper limit defining the detachment threshold between free-surface and pressurized flows is equal to 1.5 m ($Q = 165.0\,m^3/s$). As the water surface continues to rise, the hydraulic jump propagates in the upstream direction. During the falling part of the hydrograph the jump location moves back towards the bridge. Note that in these latter flow conditions, the subcritical reach length is characterized by a greater extension as emerged by the comparison between the two water profiles plotted in Figure 11 at times equal to 2.9 h and 5.7 h, respectively. Moreover the pressurized flow still endures despite the water surface level becomes lower than the gate opening height due to the hysteretic behavior of the flow. As Figures 12–13 point out, the numerical model is able to reproduce the hysteresis phenomenon, which is developed under a particular range of values of the governing variables due to the occurrence of a transition between

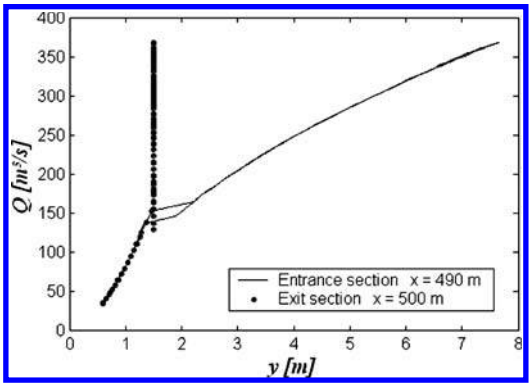

Figure 13. Single bridge test case in a steep slope channel: discharge versus water depth values. Results are plotted at two different river stations (entrance and exit cross sections).

supercritical and subcritical flows. In the present test case, lower limit of water depth defining the detachment threshold between pressurized and free-surface flows is about 1.42 m ($Q \cong 145.2\,m^3/s$). Downstream free outflow occurs at all times.

Finally two bridges in series are modelled in order to investigate their mutual interaction in supercritical flow regime. The entrance cross sections are located at $x = 400$ m and $x = 700$ m, respectively. The first gate opening height is set equal to 2.0 m, while the second one is equal to 1.5 m. The water level profile sequence during the flood hydrograph is reported in Figure 14. Figure 14 shows that the backwater effect induced by the downstream bridge rises and moves upstream as the discharge increases. Thus a submerged outflow downstream the first bridge for high discharge values is established.

7 APPLICATION TO AN EXPERIMENTAL TEST CASE

The numerical scheme is here applied to simulate the propagation of a shock wave impacting two consecutive sluice gates.

To verify the bridge hydraulic modeling, the numerical scheme is applied to reproduce the experimental activity carried out by Natale et al. (2004) in the Hydraulic Laboratory of Pavia University.

The channel is 9.3 m long, 0.48 m wide with rectangular cross section and horizontal bed. A removable dam is located at $x = 3.36$ m.

Two vertical sluice gates were positioned at $x = 8.40$ m and $x = 9.30$ m. The gate opening heights were 0.04 m and 0.02 m for the upstream and the downstream gate, respectively.

In the computations the rectangular channel is described by 186 cells ($\Delta x = 0.05$ m), N_{CFL} is set equal to 0.1 and the Manning coefficient is set equal to 0.008 s/m$^{1/3}$. No difference in the solution appears by using different N_{CFL} values.

Initially, the water depth upstream the dam was equal to 0.20 m, while the bed was dry downstream.

At $t = 0$ s, the dam was suddenly removed and dam-break waves propagated upstream and downstream along the channel.

In Figures 15–16 the water level hydrographs at two different cross sections located at $x = 7.95$ m and $x = 8.30$ m are plotted, respectively.

The proposed numerical model shows a very good agreement between computed and measured water depths at the cross section closest to the upstream sluice gate (Fig. 16).

A good agreement is also achieved in the comparison between numerical and laboratory results obtained in Station 1. Even if Figure 15 shows a slightly overestimation of the computed values between 6.0 s and 7.0 s resulting from the hydraulic jump modeling. In fact, the present numerical scheme spreads the hydraulic jump extension over two cross sections only, where the conjugate water depths of the jump occur. Therefore, while the jump is moving upstream, in Station 1 either the supercritical flow depth or the subcritical flow depth due to backwater is possible.

8 CONCLUSIONS

A one-dimensional numerical model to study submerged bridge hydrodynamics is presented.

The St. Venant-Exner equations are solved by employing a finite volume method.

The governing equation system is solved in the following unknowns: wetted cross sectional area and liquid discharge of the average flow in each cell. The assignment of these unknowns along the river intercells is based on a Froude number criterion of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

upstream and downstream average cell flow across the node point.

The main characteristic of the present method is the employment, as conservative variables of the governing equations, of average quantities within each cell independently from the adopted spatial grid.

The present model is extended to simulate the river hydrodynamics of submerged bridges by employing local boundary conditions to relate the characteristics of flow upstream and downstream the bridge faces.

The numerical scheme is able to model the bridge backwater, free and submerged outflows and the hysteretic behavior of the flow in the transition between supercritical and subcritical regime upstream the bridge deck's structural member. In particular, the backwater amount at the entrance cross section is computed by an energy balance between the upstream and downstream faces of the bridge.

The scheme is successfully applied to various unsteady benchmark problems including subcritical, supercritical and transcritical flows modeling single or multiple bridges and involving downstream control on water surface elevation. The good agreement between model results and experimental data reveals the suitability of the adopted methodology.

Since the extraordinarily conceptual and algorithm simplicity, the proposed model provides a great versatility, stability and robustness.

ACKNOWLEDGMENT

The authors wish to acknowledge Prof. Enio Paris for his help and his valuable comments and suggestions.

Turbulent flow field modeling as an aid to the analysis of scour and for a protection scheme

ABSTRACT: Bridge scour is one of the main causes of bridge failure and to determine the scour hole depth due to a given flood and adopt countermeasures, it is important to know the scouring mechanisms. Scouring is marked by a complex three-dimensional flow around the piers, which can be modeled using the Navier-Stokes equations and a turbulence model, such as the k-ε model. A model of this type was applied to analyze the scouring around and downstream of the piers of Shimanto River Bridge (Japan). Considering the true shape of the piers (two cylinders joined by a collar) and the shape of the scour hole around the piers several situations were simulated. The results show that for a certain flow condition the collar works as a shield against the downward flow found at the upstream face. Based on the flow field within the scour hole, a riprap protection could be recommended.

1 INTRODUCTION

When a unidirectional flow approaches an obstacle protruding in a river channel, such as bridge piers, it turns into a three-dimensional one, generating turbulences and vorticities, which contributes to an increase in flow velocity, leading to an increment in the shear stress over the river bed. The shearing dislodges the riverbed material from around the piers easing the entrainment of it by the flow and creating a scour hole. This process is known as bridge scour. The continuous process of scouring may lead to a bridge failure and this fact exerts a strong influence on the bridge design (Melville & Coleman, 2000).

Among the factors influencing the scour the following are the most important: flood frequency, flow velocity, flow depth, pier shape and size, sediment grading, pier alignment relative to the flow, degree of contraction, type of sediment transport (clear water or live-bed scour), and contraction length (Breuseres & Raudkivi, 1991). Some of them can be accessed quantitatively, however, others are difficult to quantify. The most needed information in bridge design is the scour depth caused either by a storm event or for a given design flood. Based on the measurable variables, experiments have been conducted and techniques for measuring scour depth have been developed (Aragão et al., 2005), resulting in a variety of equations for predicting scour depth, usually applied in bridge design (Jain, 1981).

For several years, flume experiments were the only way available for verifying some theories and guidance in bridge design (Johnson, 1995; Jain, 1981; Breusers & Raudkivi, 1991). Then with these, bridges were designed, considering large safety margins to compensate for uncertainties intrinsic in the process of predicting such scour depths. As a drawback, high costs and conservative designs were usually found. Furthermore, those equations give good results only when applied to flume data where the experimental conditions are controlled.

Scour processes involve a three-dimensional approach, not possible to be quantified easily, neither 'in loco' nor through laboratory experiments. In order to describe the flow field in its three-dimensional aspect there exist the continuity equation, the averaged Navier-Stokes equations, and some turbulence closures. However, to achieve the flow field description it is necessary to solve those equations or their simplifications in the time and space domain, which was not easy until few years ago. With the advent of fast digital computers and the development of theories about algorithms for solving complex equations, the simulation of flow field could finally be achieved with success. Here a model involving those equations has been used for analyzing the mechanisms of bridge

Copyright © 2006 Taylor & Francis Group plc, London, UK

scouring, having as a case study, the problem found at the Shimanto River Bridge in Japan. There will be described in the following sections the method used for doing the simulations and the data needed for providing a bases for comparison between the results from the model and those found at the field.

2 SCOURING AROUND BRIDGE PIER

The flow field around a pier is complex and this is further aggravated by the development of the scour hole. Scour at bridge pier is influenced by turbulence and vorticity.

Considering a cylindrical pier as an example, as the flow approaches the cylinder it decelerates, coming to rest at upstream face of the pier. The associated stagnation pressures are high near the surface, where the deceleration is large, and decrease downwards. In response to this downwards pressure gradient, the strength of the downwards flow in front of the cylinder reaches a maximum value just below the bed level when a scour hole is present. This downward flow impinging on the bed is pointed as the main scouring agent (Breusers & Raudkivi, 1991; Melvile & Colleman, 2000). In conjunction with the downward flow action, a horseshoe vortex appears and transports the dislodged material downstream. The separated flow at the upstream face reunites downstream, creating wakes that suck up sediments from the bed and also transport the entrained material (Figure 1).

Over the last century scouring around bridge piers received much attention due to the cost involved in bridge reconstruction and a complete protection against scouring may not be feasible. The results, of the knowledge thus obtained, are translated into formulae that estimate the depth of scour due to a given flood. However, the application of different formulae to a given problem results in different values of scour depths (Johnson, 1995). Hence, these results obtained should be used with certain care.

To be realistic, a scour simulation model should represent the three-dimensional flow field and the sediment transport process adequately. Some attempts have been made but the geometries of the models utilized are very simple. Moreover, theoretical modeling of this process still needs further researches before the mechanism is truly understood. In the present work, the simulation of the flow field as an aid to the analysis of the scouring process is attempted.

3 MODELING OF FLOW FIELD AND TURBULENCE MODEL

3.1 *Simulation of flow field*

Scour appears as a resultant of the interaction between turbulent flow and the movable stream bottom.

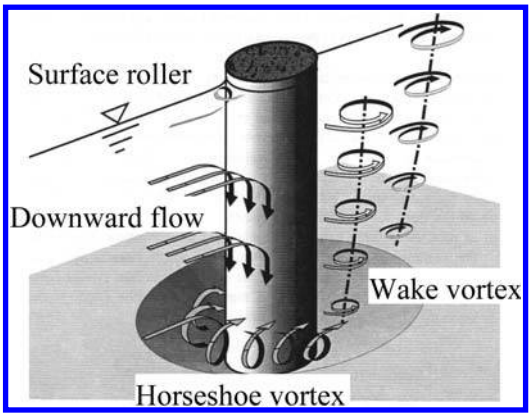

Figure 1. Scouring around a cylindrical pier and its characteristics (*after Melville and Coleman, 2000*).

Therefore, to understand the scour mechanism is primordial to realize first the flow pattern surrounding bridge piers. Flow field simulation consists in obtaining to fluid flow problems with the aid of the computers.

The equations governing the fluid flow problem are the continuity equation (Equation 1), the average Navier-Stokes (Equation 2), and the energy equations. These equations form a system of coupled non-linear partial differential equations. However, in taking an average Navier-Stokes equation for a turbulent flow, some information about fluid motion is lost and hence, an additional term known as Reynolds stress form appears (Rodi, 1980).

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \rho u_i}{\partial t} + \frac{\partial \rho u_i u_j}{\partial x_i} = \frac{-\rho \partial \overline{u_i u_j}}{\partial x_i} - \frac{\partial p}{\partial x_i}, \quad i = 1,2,3;\ j = 1,2,3 \tag{2}$$

$$\overline{-u_i u_j} = \mu_T \left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right) - \frac{2}{3} \delta_{ij} k \tag{3}$$

where ρ is the local fluid density, t is time, x_i is the position vector in the ith coordinate direction, u_i is the ith fluid velocity component, p is the pressure, τ_{ij} is the Reynolds stress, δ_{ij} is the Kronecker delta function ($\delta_{ij} = 1$ if $i = j$; δ_{ij} if $i \neq j$), k is the specific turbulent kinetic energy described in the next section.

3.2 *Turbulence model*

To recover the lost information, a turbulence model for the Reynolds stress term must be introduced. It is represented in terms of mean flow quantities and some

Copyright © 2006 Taylor & Francis Group plc, London, UK

turbulence parameters. To this end, a variety of turbulence models have been proposed (Hwang & Jaw, 1998). Among them, the two-equation standard k-ε model (Launder & Spalding, 1974) has gained credibility due to its simplicity and the approach used for describing the terms k-ε which employs the Boussinesq eddy viscosity concept (Equation 3) as described in Equation 4, 5, 6, 7:

$$\frac{\partial \rho k}{\partial t}+\frac{\partial \rho u_i k}{\partial x_i}=\mu_t G-\varepsilon+\frac{\partial}{\partial x_i}\left[\left(\mu+\frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_i}\right] \quad (4)$$

$$\frac{\partial \rho \varepsilon}{\partial t}+\frac{\partial \rho u_i \varepsilon}{\partial x_i}=\frac{\varepsilon}{k}(C_{\varepsilon 1}\mu_t G-C_{\varepsilon 2}\rho\varepsilon)+\frac{\partial}{\partial x_i}\left[\left(\mu+\frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_i}\right] \quad (5)$$

$$G=-\overline{u_i u_j}\frac{\partial u_i}{\partial x_j} \quad (6)$$

$$\mu_t=\frac{C_\mu \rho \kappa^2}{\varepsilon} \quad (7)$$

where k and ε are the specific turbulent kinetic energy and turbulent kinetic energy dissipation rate, respectively, μ_t is the eddy viscosity coefficient, C_μ is a dimensionless model constant, assumed as equal to 0.09. The values of the empirical constants have been established as $C_{\varepsilon 1}=1.44$, $C_{\varepsilon 2}=1.92$, $\sigma_k=1.0$, and $\sigma_\varepsilon=1.3$ (Hwang & Jaw, 1998). The shear stress was calculated based on the values of μ_t for each node.

Utilizing this turbulence model, the flow field around bridge at the Shimanto River Bridge in Japan, was simulated.

3.3 *Numerical resolution*

Equations 1 to 6 constitute the basic set of partial differential equations used for simulating the three-dimensional flow field. These equations should be discretized and solved individually. However, the dependent variables obey the same generalized conservation principle and, therefore, can be reduced to a single convective-diffuse conservation equation.

To solve the equations mentioned above over the computational domain, the finite-volume discretization concept is used. This implies a division of integral computational domain into a series of small, elementary control volumes (cells) over which the integration is carried out. Curvilinear coordinates (either orthogonal or body-fitted) can be used to define the cells.

Patankar (1980) states the procedure necessary for discretizing the governing equations of the model. It consists in integrating the governing equations over the control volume shown in Figure 2. The volume integrals are converted to surface integral for the control volume using Green's theorem; the individual

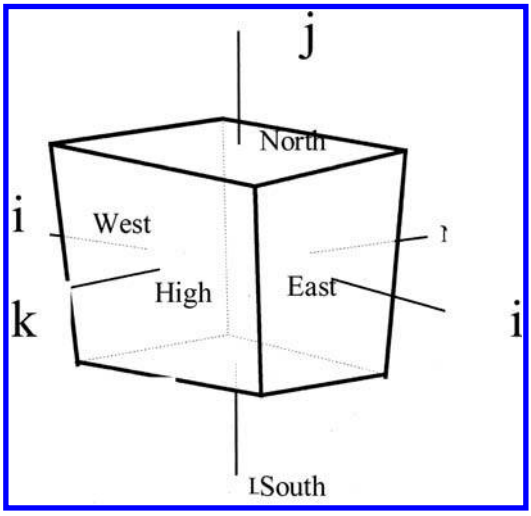

Figure 2. Cell face nomenclature for the model.

fluxes at the face of each cell are then estimated using appropriate interpolation procedures.

The equations described previously are numerically resolved in a general purpose CFD (computational fluid dynamic) package named STORM/CFD 2000 (Simunet Corporation, 2000) which can simulate, over the time and space domain, the fluid flow in various situations. This package also has powerful flow field visualization for a post-processing work.

Before starting the simulations several initial boundary conditions should be provided. Among these conditions, initial flow velocities, geometric arrangement of the elements, and the type of turbulence model to be applied are necessary.

4 CHARACTERISTICS OF THE STUDY SITE

The Shimanto river bridge is located in the south-eastern part of Kochi prefecture (in Shikoku Island, Japan). The bridge site is 9.5 km upstream of the river estuary. The bridge is 508 m in length, and is founded on 13 compound piers (P1 to P13), formed by joining two cylindrical piers, through a concrete collar (Figures 3, 4). Eight of these piers are located inside the main river channel. The span between each pier is about 53.6 m. The riverbed material is of the sand-gravel type whose $D_{50}=20$ mm and $D_{84}=50$ mm (Aragão et al., 2003).

To avoid the scour processes around the piers and between them, some scour control measures were installed, which consisted of a square slab footing (23 m × 23 m), built around the piers, and a concrete block, simulating a pavement, installed between the piers. These countermeasures were flat when constructed, but after successive floods, the slab footing

Copyright © 2006 Taylor & Francis Group plc, London, UK

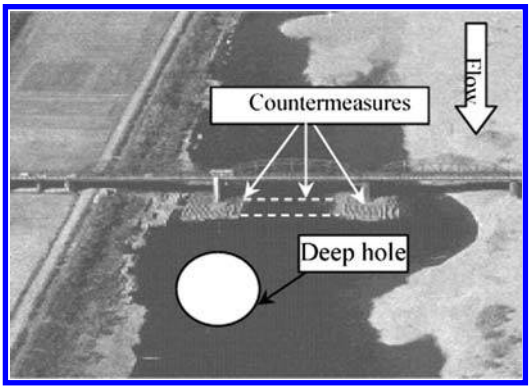

Figure 3. Shimanto River Bridge.

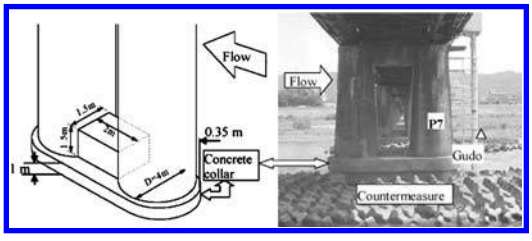

Figure 4. Pier of Shimanto River Bridge (schematic representation and real shape).

deformed and the concrete block subsided, assuming a fan shape. To register the water level, two measuring sections were installed: one upstream of the bridge (Gudo II) and another at the pier 7 (Gudo). Several floods have been registered at the bridge section as a result of heavy rainfall caused either by typhoons or by wet fronts (Aragão et al., 2003).

Over a long period of observation, data on channel cross-section at 23 different river sections as well as on the bed elevation have been collected. Based on those data, a profound scour hole of 10 m deep and located at 30 m, downstream of the bridge (Figure 2) was detected. The causes of this hole are not well known and need to be investigated as otherwise it may enlarge and compromise the bridge structure. In 2001, an underwater video robot was used to verify the riverbed condition around the hole, its deepness and real shape. Those data showed a continuous process of aggradation and degradation along the river, permitting the perception of the contour lines of the area surrounding the bridge (Figure 5), and the calculation of flow velocity ($n = 0.03$) (Table 1).

5 FLOW FIELD MODELING

Based on the bridge characteristics and on the data about the floods observed at the bridge site (Table 1),

* T.P.W stands for water level (m); U is flow velocity calculated through Manning equation (m/s); h is flow depth (m); Fr is Froude number in which flow depth is the characteristic length.

three-dimensional flow field modeling was attempted. In order to achieve this objective, the model needs specifications regarding the initial boundary conditions such as the initial flow velocity, the geometry of the pier structure and the type of turbulence model, among others. Some of these data can be collected in situ. However, others are closely related to the flow field being simulated. In turn, this will depend on the shape of the scour hole around the piers for a given flood and the velocity that would cause such a scour hole. Such information is also needed over the entire target area where the flow is being simulated.

Considering the real field conditions of the bridge section (Section 4), obtaining these data in real time would be a very costly and time consuming work. Thus, based on the principle of similarity, if model tests could be carried out in a laboratory flume,that would reproduce the observed field conditions, it would be

Copyright © 2006 Taylor & Francis Group plc, London, UK

possible to estimate closely the required input data for the flow field modeling.

With this objective in mind, experiments were conducted in a flume and for this purpose, the riverbed for the model was considered to be fixed and flat. The water flow was modeled by means of a rigid-lid boundary, and the surface was approximated as a slip wall. The main objective in simulating this configuration was to find the probable causes of the scour processes and the role of each factor in preventing or contributing to the scour around the bridge.

Admitting the conditions stated above, flow field modeling was carried out considering the following situations: 1) with a single compound model pier, 2) with two compound model piers, 3) with one scaled compound pier, 4) with two scaled compound piers, and 5) simulation of the flow field with the presence of the deep scourhole downstream of the bridge.

5.1 *Flume experiments*

In order to understand well the mechanisms behind the scouring around the bridge (Figure 5), and to provide the values of the hydraulic variables that would be used as boundary conditions for flow field modeling, flume experiments were considered as a viable option. The initial geometry of the existing countermeasures, and the Froude numbers associated with each flood flow (Table 1) were taken into account. The laboratory installations consisted of the following: a re-circulating flume (20 m × 0.5 m × 0.5 m); model piers with and without bed protection, scaled to 1/100 and 1/200 of the real size; an experimental section formed by a thick sand bed (1.71 m long, 0.5 m wide, and 0.20 m deep) located at 12 m from the inlet of the flume (Figure 6). Uniform sediment mixtures with different median sizes, $D_{50} = 1.42$ mm, and $D_{50} = 0.45$ mm were used and the discharges varied from 5 to 20 l/s (Table 2).

The experiments with one compound pier were conducted under clear-water conditions and with two compound piers, the experiments were conducted under live-bed conditions. Thus, in the latter case, an additional sediment source became necessary. This was achieved by setting the model piers in the middle of the sand bed installed in the flume, so that the sediment from upstream could serve as the incoming sediment load. Later on, the squared area shown by dashed line in Figure 5 was geometrically scaled to 1/200 and the cross-section of the riverbed within this interval was molded by using Styrofoam. This mold was then impressed on the test section (Figure 7), and the river bed was made up with a sand of $D_{50} = 0.45$ mm size. The measurement of flow velocities at different depths within and outside the hole were carried out with a Pitot tube. Following a methodology proposed by Suzuki et al. (1997), a critical diameter Dc for a given u_*,

that would resist erosion due to the shear stress caused by the movement of water inside the deep hole was calculated according to Equation 8:

$$D_c = \frac{u_*^2}{sg\tau_c} \tag{8}$$

in which, u_* is the shear velocity; g is the gravitational acceleration, τ_c is a dimensionless critical shear stress (≅0.05), $s = ((\rho_s/\rho)\text{-}1)$, ρ_s is the density of the gravel, ρ is the water density. Sediments with the size equal to Dc was then placed over the target area in three different layers (as indicated in Figure 7) and discharges varying from 8 l/s to 15 l/s were applied.

5.2 *Flow modeling*

5.2.1 *Single compound pier*

To simulate the flow field around just one compound pier, experimental data for the pier of 4.8 cm, flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

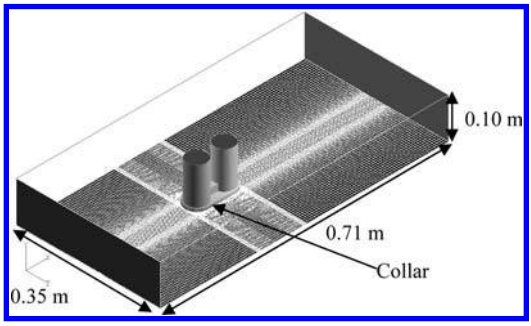

Figure 8. Geometry used for the flow simulation around a compound pier model.

depth of 10 cm for a discharge Q, of 15.8 l/s with a mean flow velocity of 0.31 m/s was chosen. Based on these, the shear velocity was calculated as 0.02 m/s. The attack angle of the flow was set to zero. The flow was assumed to be steady and turbulent for applying the standard k-ε model for turbulence simulation. The bottom was considered non-slippery whose roughness height was 1.4 mm (the D_{50} value of the uniform sand used during the experiments). The mesh associated with this geometry had 148 nodes stream-wise, 72 nodes cross-stream-wise, and 13 nodes depth-wise.

Based on these considerations, the flow field was simulated for two different cases: 1) the flume bed set at the level of the upper face of the collar (Figure 8) and, 2) the flume bed set at the level of the lower face of the collar. The purpose of these two simulations was the following: 1) to verify the flow field conditions at the beginning of the experiment, and 2) to verify the flow field around the collar when the scour hole is already formed.

5.2.2 *Two compound piers*

The flow field was simulated for the case of two compound piers, the scour hole geometry for the model had the dimensions of 1.74 m long, 0.50 m wide, and 0.047 m deep. For this geometry, the associated grid consisted of 164 stream-wise nodes, 171 nodes across the stream and 20 nodes depthwise. Each pier was 0.022 m in diameter. The non-slip bed had a roughness of 1.42 mm, the D_{50} of the first sand mixture (Section 5). To simulate the flow field with this configuration, data from one of the experiments in which flow velocity was 0.3 m/s with an associated discharge of 12.5 l/s, and the shear velocity of 0.021 m/s was utilized. The geometry of the model piers is shown in Figure 9.

5.2.3 *One scaled compound pier*

For the simulation of flow field with the scaled real size of the compound pier, the collar surrounding the piers was omitted (Figure 4), since, the collar is, generally, only exposed after the occurrence of multiples

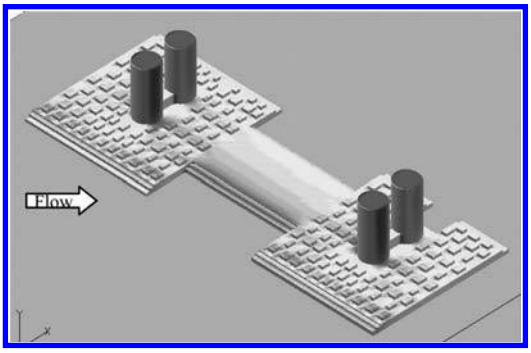

Figure 9. Geometry used for the flow field simulation of the two compound pier models with countermeasures.

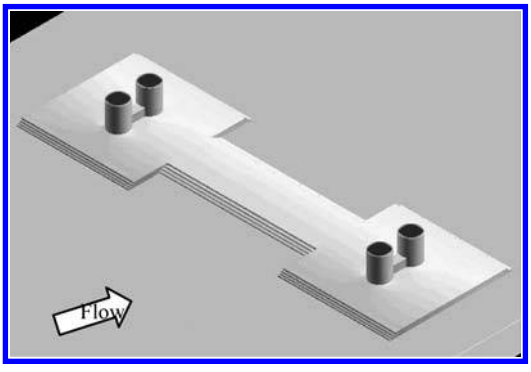

Figure 10. Geometrical pattern used for flow field simulation around two compound piers.

floods or during a very large event. The conditions used for simulation corresponded to: a pier diameter of 4 m, flow depth of 6 m, bed roughness equal to 5 cm (the D_{50} of the riverbed), total length of 200 m, mean flow velocity of 3.8 m/s, and an attack angle of the flow set to zero. These hydraulic conditions led to a shear velocity equal to 0.21 m/s and a flow discharge corresponding to 9,800 m^3/s, at the site observed on 29th August, 1971. The mesh associated with this geometry had 148 nodes along the stream, 72 nodes across, and 13 nodes depth wise.

5.2.4 *Two scaled compound piers*

For this case, the model geometry had the following dimensions: 328 m along the stream, 107.64 m wide, and 6 m in depth. The associated mesh had 323 nodes stream-wise, 220 nodes cross-stream-wise, and 25 nodes depth-wise. The flow conditions comprised of: initial velocity of 3.4 m/s, steady flow, pier diameter equal to 4 m, and a non-slippery bed, whose roughness was equal to 5 cm(D_{50} of the riverbed). These conditions were observed during the flood registered on 31st May, 2003. Figure 10 shows the geometrical pattern used for simulation of the flow field.

Copyright © 2006 Taylor & Francis Group plc, London, UK

5.2.5 *Simulation of the flow field inside the deep scour hole*

In order to verify the predictability of the 3D flow simulation model, the true geometry of the shape of the scour hole (Section 4; Figures 5 and 7) and its related flow conditions were modeled with $Q = 12.5$ l/s and $U = 0.38$ m/s, and Dc = 2.5 mm. The grid had 350 nodes stream-wise, 150 nodes cross-stream-wise, and 25 nodes depth-wise. The other conditions were similar to those stated in the previous section.

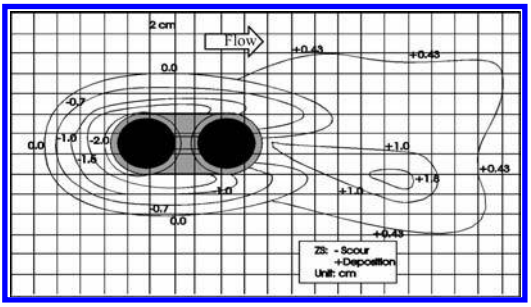

Figure 11. Zs/D vs. Ns for uniform sand and an attack angle = 0.

6 RESULTS AND DISCUSSION

6.1 *Scouring around one compound pier*

In the flume experiments, the resultant bed elevations for $Q = 12.5$ l/s with a mean velocity of 0.30 m/s is shown in Figure 11. It is seen that the scouring occurs not only at the upstream face of the pier, but also propagates downstream (Sections 2 and 3). The bed material removed due to the action of both downward flow and the horseshoe vortex is deposited a little further from the downstream face. At the downstream face the negative pressure caused by the wake vortex also removes the bed material which is entrained and is deposited further downstream from the pier. The scour depth, Zs, was normalized by the pier diameter, D, (Zs/D). In Figure 11, the aggradations are denoted by a plus sign and degradations are marked by a minus sign. Such bed variations are a direct consequence of the increase and decrease in flow velocity caused when the approaching flow meets the compound pier.

During for flow modeling, the first attempt was to simulate the flow field at the beginning of the scour process, when the collar is covered by the bed material. For this situation and considering a ratio of y/h = 0.2, the resultant flow field is presented in Figure 12. Here it is observed a considerable increase in flow velocity at the upstream face, caused by vortices and higher values of this variable at the laterals of the pier, which certainly will cause high scouring. Figure 12 shows areas of negative velocity where the combined effect of the horseshoe and wake vortex works (Figure 13) as an additional scouring agent. Then, from X/D = 7, where the scouring agents loose power and the velocity decreases, deposition occurs.

When the collar surrounding the two cylinders is exposed (Figure 14), the overall velocities around the pier are smaller than those found when the collar is covered (Figure 12) since it works as a shield against the downward flow, reducing its scouring effect. Yet, when the collar is completely uncovered (Figure 14), allowing the flowing water to reach its lower face, the scouring appears stronger than before and a very large amount of material is removed from around the pier, creating a deep hole.

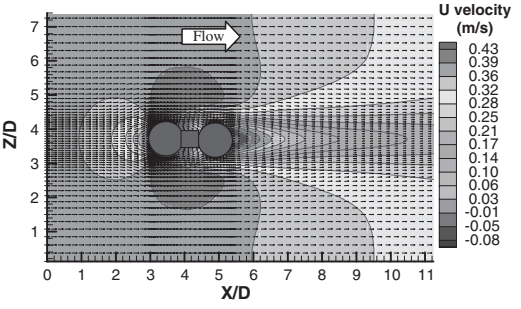

Figure 12. Velocity vectors around the compound pier model and at the scouring initiation.

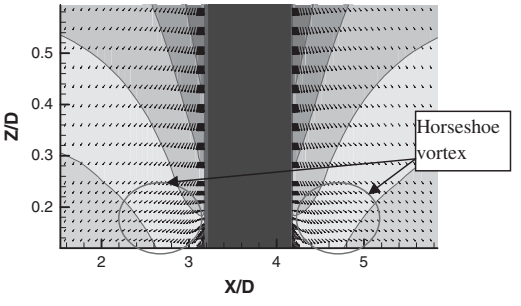

Figure 13. Velocity vectors on the Y-Z plane and at the upstream face of the compound pier model.

Similar results were also observed by Ettema (1980), Dargahi (1990), and Chiew (1992). If this situation takes place at a bridge site, the pier destruction is a matter of time.

The same comment can be extended to the scouring processes around the real sized compound pier. However, for that situation the velocities around the piers are expressively higher, leading to notable bed removal. Measurement campaigns done at the bridge site (Aragão, 2004) showed that for a flood event of Q = 3,500 m^3/s the degradation was around 0.9 m, which is a matter of concern because floods of that

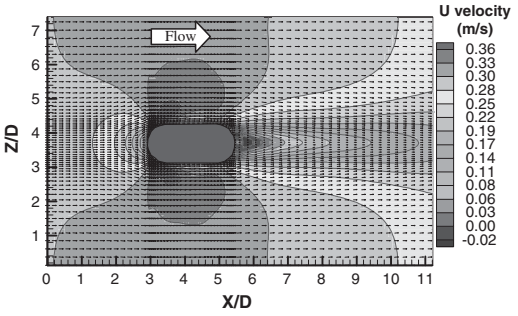

Figure 14. Flow field around the compound pier model after the scouring initiation.

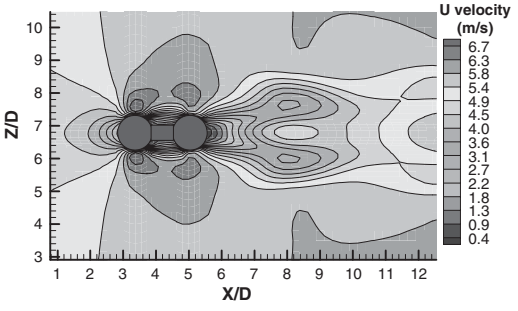

Figure 15. Contour of U velocity around the compound pier.

magnitude or higher are often observed. The simulation showed that for the situation proposed at Section 5.2.3, the velocity at the laterals of the piers reaches almost 6.7 m/s. The wake vortex described by Dargahi (1990), Breusers & Raudikivi (1991), and Graf & Istiarto (1998) are indicated by the negative velocities at the downstream face of the pier (Figure 15). In addition, at X/D = 7 and further downstream, the flow tends to reach the same velocity found upstream of the pier at X/D = 1. This can be translated into a huge amount of turbulent kinetic energy that is generated and is dissipated, mainly at the laterals of the pier in the interval $3.8 < X/D < 4.8$. In other words, a high gradient of energy is dissipated from upstream to downstream, contributing to decrease of energy of transport and scour of the flow.

6.2 *Scouring around two compound piers*

For the boundary condition stated in Section 5.1 the results from the experiments were conducted and the bed variation around the piers represented in Figure 16. In this figure it is observed that past the pavement in between the piers a scouring develops and extends to X/D = 22 from which, the removed material is deposited. It is important to say that the same

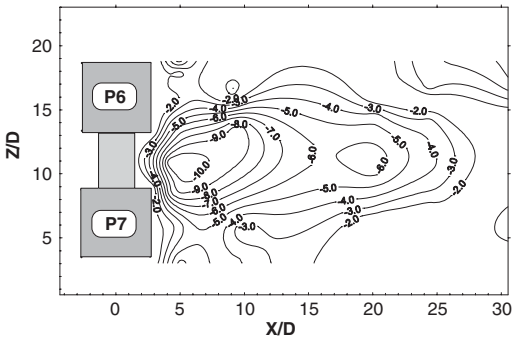

Figure 16. Bed elevation (mm) past the piers (Q = 15 l/s, H = 4 cm, h = 6.8 cm, U = 0.44 m/s).

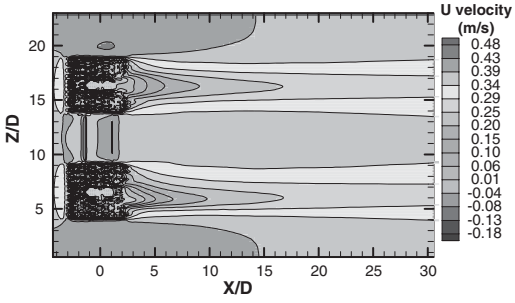

Figure 17. Contour of U velocity around the compound pier model.

behavior was observed when other discharges were applied. In addition, the results show that the deepest point change its location according to the discharges as does the depth of the scour hole, which gets closer to the downstream face of the piers as the discharge increases.

As stated in Section 5.2.3, the hydraulic conditions found during the experiments were applied as the initial values for the flow simulations, resulting in the contour map of U velocity around the piers for y/h = 0.2 as displayed in Figure 16. In this figure it is possible to notice that on the countermeasure, that surrounds the piers, the velocity gets close to zero, but, immediately past such structures, this variable reaches a value of 0.3 m/s. This variation can also be considered an agent for dislodging and entraining the bed material.

As expected, the constriction caused by the piers increased the velocity in the area between them up to 75% more than the initial one. Scour certainly would occur there, but the pavement in between the piers prevented the bed from being removed. Figure 17 also shows a region of high flow velocities starting upstream of the riprap to its downstream edge constituting an effective scour area.

Copyright © 2006 Taylor & Francis Group plc, London, UK

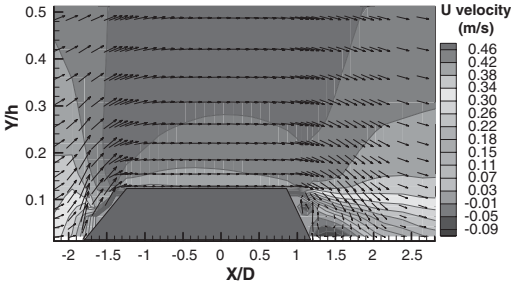

Figure 18. Velocity vectors over the link between the two compound pier models.

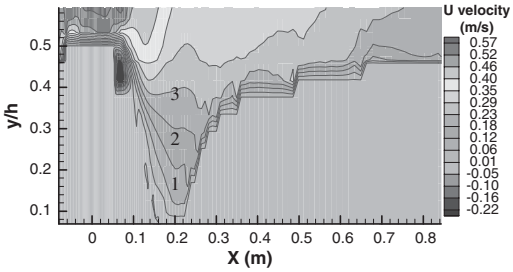

Figure 19. Contour of U velocity along the longitudinal line.

With a high degree of accumulated kinetic energy, due to the constriction, the flow passing over such pavement acts first as a jewt that removes the material and then as an important agent in sediment entrainment as shown in Figure 18. This figure also shows that this jet hits the bottom more than once, constituting an effective scour agent. These aspects of the flow field can only be observed through careful and timeless measurements or though simulation of the flow field.

Considering the similarities between the prototype and the model, the results found for the model piers can be extended to the real sized compound piers (Section 5.2.3). The simulation of this arrangement confirmed these results obtained for the model piers.

For both model piers and the real sized compound piers, the riprap around the piers and between them was decisive in preventing the bridge failure due to the scouring at its foundation. Also, the accumulation of energy and its dissipation streamwise, can explain the degradations and aggradations around the bridge (Figures 16 to 18).

6.3 *Scouring past the piers and simulation of the flow field inside the deep scour hole*

The velocity measurement at three sites, 1, 2, 3, with Pitot tube (Figure 7) resulted in the following values: 1) 0.14 m/s, 2) 0.34 m/s, and 3) 0.38 m/s. The experiments were conducted with three different critical diameters (1 mm, 2 mm, and 3 mm), Section 5.1, allowed to conclude that such a countermeasure not only prevented the target area from being scoured, but also induced the deposition of the bed material from upstream inside the hole. For some runs the aggradation inside the hole was about 2 cm. In addition, for the first Dc (3 mm), the rim of the hole and the areas upstream and downstream of it were preserved. For Dc = 1 mm and 2 mm, the area inside the role was also preserved, however, outside the hole and over the rim, the riprap was removed, proving these sizes could protect the hole, but scouring could be expected somewhere downstream.

The intention of finding a suitable riprap size during the experiment was to transfer such knowledge to the bridge site. Considering the scale factor involved (1/200) and the target area (Figure 5) a Dc = 3 mm means rocks or concrete blocks of 60 cm leading to a very high cost. Then, to allow for cost reduction, feasibility, and safety, Dc = 2.5 mm was also tested and the riprap remained undamaged in this case also.

As for the simulation of flow inside the scour hole downstream from the bridge, the arrangement proposed in Section 5.2.5 provided means to model the flow field around the piers and inside the scour hole (Figure 19). This figure shows the variation of the flow velocity with the flow depth, which in turn agrees with the values measured during the related experiments described above.

Considering the geometrical similarity the model, the bed material of $D_{50} = 2.5$ mm (the critical diameter of the present experiments) and finally that the values simulated at points 1, 2, and 3 are close to those measured, this simulation permits to conclude that the use of flow field modeling for analyzing scour around bridge piers and the related consequences, constitute a valuable tool. In other words, the present model could not only predict the measured values but also, reproduce the variations in flow velocities at different sites locations and outside the scour hole.

7 CONCLUSIONS

In order to analyze the mechanism involved in scouring around bridge piers a 3D turbulent flow modeling has been utilized. The data used as a base for comparison are from the Shimanto River Bridge where advanced scour processes have been identified not only around the bridge foundations, but also downstream from them. Based on the finding from flow modeling and flume experiments and considering similarities it is possible to conclude the following: the bed variation around a compound pier could be explained through the analysis of the flow field; the collar around the pier at times works as a shield against the downward flow. However, if the scouring goes beyond the lower face

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the collar then the scouring is more intense than before. The presence of riprap around two compound piers was decisive in preventing the area from being scoured, but contributed somehow to the excavation of a deep scour hole downstream of the bridge; the mechanism of such a process could only be understood with the flow field modeling. To prevent further scouring inside the deep hole the use of a riprap formed by three layers of a critical diameter was tested and could be recommended.

Predictions of turbulent flows around a bridge pier using various numerical models

I. Kimura
Dept. of Civil and Environmental Engineering, Matsue National College of Technology, Matsue, Japan

T. Hosoda & S. Onada
Dept. of Civil Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: Turbulent flow structures around bridge piers are examined numerically using various computational models focusing on vortex shedding and water surface elevations. Four different types of numerical models, namely, two kinds of 2D plane model, a quasi-3D model (a 3D model with hydrostatic assumption) and a full-3D model, are considered. As a turbulence model, a simple 0-equation model with linear and non-linear constitutive equations are used for the 2D plane model and a 2nd order non-linear k-ε model with effects of strain and rotation parameters are applied for the quasi-3D and full-3D models. First, laboratory test is carried out to obtain data for verification. Then, the computations are performed under the same conditions as the laboratory test. The numerical results showed that the 2D and full 3D models could capture well the height of water elevation at the upstream region of the pier though the quasi-3D model under-predicted it. The 2D model overestimated the depth of the hollow behind the pier. The quasi-3D model considerably over-estimated the length of the re-circulation zone.

1 INTRODUCTION

The upstream region of bridge piers in rivers is often become a weak-point of flood control because the water surface is elevated due to the flow resistance caused by the piers. It is therefore important to develop a numerical model, which can predict the flow patterns around piers with practical accuracy from the viewpoint of disaster prevention. In this paper, the turbulent flow structures and water surface variations around bridge piers with square cross-sections are numerically investigated using various numerical models. Four different models, namely, two kinds of 2D (two-dimensional) plane models, quasi-3D model (3D model with hydrostatic assumption) and full-3D model, are applied and the results are compared. As a turbulence model, a simple 0-equation model with linear and non-linear constitutive equations are used for the 2D plane models and a non-linear k-ε model with effects of strain and rotation parameters proposed by Kimura & Hosoda (2003) are applied for the quasi-3D and full-3D models. A laboratory test was carried out prior to the numerical tests in order to obtain data for verifications using a rectangular open flume under the conditions of $\mathrm{Re} = 8400$ and $\mathrm{Fr} = 0.54$. A rectangular cylinder is used as a model of a bridge pier. The computations using a finite volume method were performed in the same conditions as those in the laboratory test and the results were compared focusing on the Karman vortex shedding, a horseshoe-vortex formation and water level distributions around the cylinder.

2 NUMERICAL MODELS

2.1 *Full-3D model (F3D model)*

2.1.1 *Basic equations*

The Reynolds averaged 3D flow equations with contravariant components of velocity vectors on a generalized curvilinear movable coordinate system are used as governing equations. The equations are described as follows.

[Continuity equation]

$$\frac{1}{\sqrt{g}}\frac{\partial V^{\alpha}\sqrt{g}}{\partial \xi^{\alpha}} = 0 \tag{1}$$

[Momentum equation]

$$\frac{\partial V^{i}}{\partial t} + \nabla_j\left[V^{i}(V^{j} - W^{j})\right] + V^{i}\nabla_j W^{j} + V^{j}\nabla_j W^{i} = F^{i} - \frac{1}{\rho}g^{ij}\nabla_j p + \nabla_j\left[-\overline{v^{i}v^{j}}\right] + 2\nu\nabla_j e^{ij} \tag{2}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

[k equations]

$$\frac{\partial k}{\partial t}+\nabla_j\left[k(V^j-W^j)\right]+k\nabla_j W^j = -g_{il}\overline{v^i v^j}\nabla_j V^i-\varepsilon+\nabla_j\left\{\left(\frac{D_t}{\sigma_k}+\nu\right)g^{ij}\nabla_i k\right\} \quad (3)$$

[ε equations]

$$\frac{\partial \varepsilon}{\partial t}+\nabla_j\left[\varepsilon(V^j-W^j)\right]+\varepsilon\nabla_j W^j = -C_{\varepsilon 1}\frac{\varepsilon}{k}g_{il}\overline{v^i v^j}\nabla_j V^i - C_{\varepsilon 2}\frac{\varepsilon^2}{k}+\nabla_j\left\{\left(\frac{D_t}{\sigma_k}+\nu\right)g^{ij}\nabla_i\varepsilon\right\} \quad (4)$$

where ξ^I = generalized curvilinear coordinate, t = time, V^i = contravariant component of the velocity vector of flows, W^i = contravariant component of the velocity vector of grid motion, p = pressure, ν = molecular dynamic viscosity, ρ = density of water, k = turbulent energy, ε = turbulent energy dissipation rate, g_{ij} and g^{ij} = covariant and contravariant component of metric tensor, $g=\det(g_{ij})$ and F^i = contravariant component of gravity acceleration. ∇^i indicates a covariant differential, for instance,

$$\nabla_i A^k = \frac{\partial A^k}{\partial \xi^i}+A^j\Gamma_{ij}^{\ k} \quad (5)$$

where Γ^k_{ij} = Christoffel symbol described as

$$\Gamma_{ij}^{\ k}=\left\{\begin{matrix}k\\ij\end{matrix}\right\}=\frac{1}{2}g^{km}\left(\frac{\partial g_{jm}}{\partial \xi^i}+\frac{\partial g_{im}}{\partial \xi^j}-\frac{\partial g_{ij}}{\partial \xi^m}\right)=\frac{\partial \xi^k}{\partial x^p}\frac{\partial^2 x^p}{\partial \xi^i \partial \xi^j} \quad (6)$$

To calculate a complex turbulent flow with separation and vortex shedding, a 2nd-order non-linear k-ε model by Kimura & Hosoda (2003) is adopted as a turbulence model. This model has been applied to various flow fields, such as, a flow around a spur dikes (Kimura et al 2004), a flow around a surface-mounted cubic obstacle (Kimura & Hosoda 2000) and a compound open channel flow (Kimura et al 2001). The constitutive equations of the model are described as follows.

$$-\overline{v^{*i}v^{*j}} = D_t S^{ij}-\frac{2}{3}k\delta^i_s g^{sj}-\frac{k}{\varepsilon}D_t\left[\alpha_1 Q_1+\alpha_2 Q_2+\alpha_3 Q_3\right] \quad (7)$$

$$D_t = C_\mu\frac{k^2}{\varepsilon} \quad (8)$$

$$Q_1 = S^{i\alpha}g_{\alpha l}\Omega^{lj}+S^{j\beta}g_{\beta l}\Omega^{li} \quad (9)$$

$$Q_2 = S^{i\alpha}g_{\alpha l}S^{lj}-\frac{1}{3}S^{k\alpha}g_{\alpha m}S^{m\beta}g_{\beta k}\delta^i_l g^{lj} \quad (10)$$

$$Q_3 = \Omega^{i\alpha}g_{\alpha l}\Omega^{lj}-\frac{1}{3}\Omega^{k\alpha}g_{\alpha m}\Omega^{m\beta}g_{\beta k}\delta^i_l g^{lj} \quad (11)$$

$$S^{ij} = g^{j\alpha}\nabla_\alpha V^i + g^{i\alpha}\nabla_\alpha V^j \quad (12)$$

$$\Omega^{ij} = g^{j\alpha}\nabla_\alpha V^i - g^{i\alpha}\nabla_\alpha V^j \quad (13)$$

The model coefficients are essentially not constants but functions of the strain parameter S and the rotation parameter Ω. In this study, all the coefficients are given as functions with one variable M for simplicity as follows (Kimura & Hosoda 2003).

$$\alpha_1=-0.1325 f_M,\quad \alpha_2=0.0675 f_M,\quad \alpha_3=-0.0675 f_M \quad (14)$$

$$f_M=\left[1+0.02M^2\right]^{-1},\quad M=\max[S,\Omega] \quad (15)$$

$$C_\mu=\min\left[0.09, 0.3/(1+0.09M^2)\right] \quad (16)$$

$$S=\frac{k}{\varepsilon}\sqrt{\frac{1}{2}S^{i\alpha}g_{\alpha j}S^{j\beta}g_{\beta i}},\quad \Omega=\frac{k}{\varepsilon}\sqrt{\frac{1}{2}\Omega^{i\alpha}g_{\alpha j}\Omega^{j\beta}g_{\beta i}} \quad (17)$$

Equations (14) and (15) were adjusted through the consideration of the distribution of turbulent intensities in a simple shear flow (Kimura & Hosoda 2000). Equation (16) was tuned to satisfy the realizability constraints in a simple shear flow and possible singular points in both 2D and 3D flows (Hosoda et al 2001).

The standard linear k-ε model is also applied for the comparison of turbulence models. The constitutive equation of the standard model is

$$-\overline{v^{*i}v^{*j}} = D_t S^{ij}-\frac{2}{3}k\delta^i_s g^{sj},\quad D_t = C_\mu\frac{k^2}{\varepsilon} \quad (18)$$

where C_μ is 0.09 (=const.).

2.1.2 *Outline of numerical method*

The differential equations governing the mean-velocities and the turbulence field are solved with the finite volume method on full-staggered grid system. The arrangement of hydraulic variables on a full-staggered grid is shown in Figure 1. The metric tensor and Cristoffel symbol are defined only at grid points to save computer memory and the values at other positions are interpolated at each computational step.

QUICK scheme is applied to the convective inertia terms and the central differencing is used for the diffusion terms in the momentum equations. The hybrid central upwind scheme is applied to the k and ε equations for the computational stability. Adams-Bashforth scheme with second-order accuracy in time is used for time integration in each equation. The basic equations are discretized as fully explicit forms and are solved successively along the time axis step by step. The pressure field is solved using iterative procedure at each time step using SOLA algorithm by Hirt et al. (1975).

Copyright © 2006 Taylor & Francis Group plc, London, UK

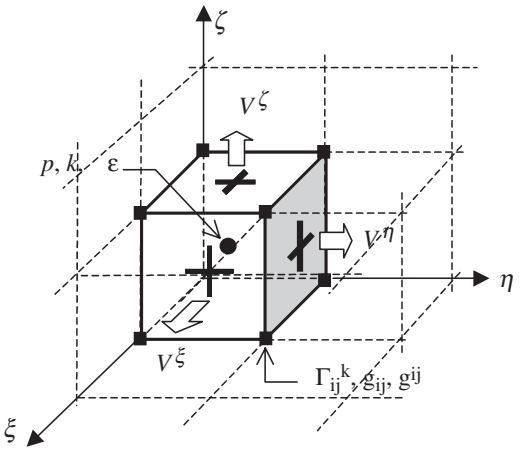

Figure 1. Arrangement of hydraulic variables and metric tensors on full staggered grid (F3D, Q3D models).

2.1.3 *Boundary conditions*

Since the present turbulence model is a high Reynolds number type, the wall function approach is applied as the wall boundary conditions for k and ε. The wall friction is evaluated by the log-law. At the downstream end of the computational domain, the longitudinal gradients of all variables are assumed to be zero. At the boundary inlet, the level of k is chosen to be $(0.02U_0)^2$ (U_0 = averaged velocity). The value of ε at the inlet is determined from the value of k at the inlet and Equation (8) by specifying the ratio $D_t/\nu = 10$ (Bosche & Rodi 1998).

The free surface elevation is solved by the simple relation in Equation (19) since the contravariant components of the velocity vector are used in the basic equations (Takizawa et al. 1992).

$$\Delta h = \sqrt{g_{33}} V^3 \Delta t \tag{19}$$

where Δt = time increment and Δh = surface elevation during Δt. To consider the rapid attenuation of turbulent intensities in the depth-wise direction near the free surface, the eddy viscosity is multiplied by the following dumping function (Hosoda 1990)

$$f_s = 1 - \exp\left(-B\frac{(h-y)\varepsilon_s}{k_s^{3/2}}\right), \quad (B = 10) \tag{20}$$

where sub-s indicates the value at the surface layer. The turbulence dissipation rate at the surface layer is evaluated by the following formula proposed by Sugiyama et al. (1995) to calculate the secondary currents of 2nd kind.

$$\varepsilon_s = \frac{C_{\mu 0}^{3/4} k_s^{3/2}}{0.4\Delta y_s}, \quad (C_{\mu 0} = 0.09) \tag{21}$$

2.1.4 *Initial conditions*

At the beginning of the calculation, U (=velocity in the longitudinal direction (x-direction)) = U_0 (=averaged bulk velocity), V (=velocity in the transverse direction (y-direction) = 0, $k = k_{in}$ and $\varepsilon = \varepsilon_{in}$ (k_{in} and ε_{in} are the values of k and ε at the inlet boundary) are specified over the whole computational domain. In order to avoid the influence of the initial conditions, the numerical results after 50 seconds from the initial conditions are used for the following examinations.

2.2 *Quasi-3D model (Q3D model)*

The momentum equation in the vertical direction can be simplified as the following form when the hydrostatic assumption is assumed.

$$g^{3j}\nabla_j p = \rho F^3 \tag{22}$$

Since the iteration procedure to obtain a pressure field (SOLA) becomes unnecessary under this assumption, the CPU time in the quasi-3D model becomes considerably smaller than that in the full-3D model. The turbulence model in the quasi-3D model is same as that in the Full-3D model.

2.3 *Plane 2D linear model (2D-L models)*

2.3.1 *Basic equations*

Basic equations are depth averaged ones composed of a continuity equation and momentum equations as

$$\frac{\partial h}{\partial t} + \frac{\partial M}{\partial x} + \frac{\partial N}{\partial y} = 0 \tag{23}$$

$$\frac{\partial M}{\partial t} + \frac{\partial uM}{\partial x} + \frac{\partial vM}{\partial y} + gh\frac{\partial h}{\partial x} = gh\sin\theta + \frac{\partial(-\overline{u'^2}h)}{\partial x} + \frac{\partial(-\overline{u'v'}h)}{\partial y} + \nu\left[\frac{\partial}{\partial x}\left(h\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(h\frac{\partial u}{\partial y}\right)\right] \tag{24}$$

$$\frac{\partial N}{\partial t} + \frac{\partial uN}{\partial x} + \frac{\partial vN}{\partial y} + gh\frac{\partial h}{\partial y} = \frac{\partial(-\overline{u'v'}h)}{\partial x} + \frac{\partial(-\overline{v'^2}h)}{\partial y} + \nu\left[\frac{\partial}{\partial x}\left(h\frac{\partial v}{\partial x}\right) + \frac{\partial}{\partial y}\left(h\frac{\partial v}{\partial y}\right)\right] \tag{25}$$

where h = depth; (u, v); depth-averaged velocity; (M, N) = discharge flux (M = hu, N = hv); (τ_{bx}, τ_{by}) = bottom shear-stress; ν = dynamic viscosity; θ = bottom slope of main channel; = depth-averaged Reynolds stress tensors (u_1' = u', u_2' = v') and β = momentum coefficient (1.0 for turbulent flow, 1.2 for laminar flow).

Components of the bottom shear-stress vector are evaluated by

$$\tau_{bx} = f\rho u\sqrt{u^2+v^2}/2; \quad \tau_{by} = f\rho v\sqrt{u^2+v^2}/2 \tag{26}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where f = friction factor related to local Reynolds number $Re' \equiv uh/\nu$, evaluated as follows:

$$f = 6/R_e' \quad (R_e' \le 430) \ , \tag{27a}$$

$$\sqrt{2/f} = A_S - \left[1 - \ln\left(R_e' - \sqrt{f/2}\right)\right]/\kappa \quad (R_e' > 430) \tag{27b}$$

where $\kappa = 0.4$, $A_S = 5.5$.

2.3.2 *Turbulence model*

The following linear constitutive equation has been used in usual 0-equation models.

$$-\overline{u_i' u_j'} = \nu_h \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \frac{2}{3} k \delta_{ij} \tag{28}$$

where k = depth-averaged turbulent kinetic energy. Neze & Nakagawa (1993) proposed an empirical formula for vertical distribution of k as

$$k/u_*^2 = 4.78 \exp(-2z/h) \tag{29}$$

where z = direction perpendicular to the bottom bed. The depth-averaged turbulent kinetic energy becomes the following formula when equation (29) is integrated from the bottom to the surface.

$$k = \gamma_k u_*^2 , \quad \gamma_k = 2.07 \tag{30}$$

The eddy viscosity coefficient ν_t is given as

$$\nu_t = \alpha h u_* \tag{31}$$

where α is a constant (=0.2).

2.3.3 *Numerical scheme*

The numerical methods in the plane 2D models are similar to those in the F3D and Q3D models, namely, a finite volume method on full-staggered grid with the QUICK scheme for convective terms and the Adams Bashforth method for time integration. The arrangement of hydraulic variables in 2D model is shown in Figure 2.

The friction of walls is evaluated by log-law. The eddy viscosity is multiplied by the following two functions in order to reproduce the velocity profile near walls.

$$f_{d1} = \left[1 - \exp\left(-\frac{1}{C_{vm}} \frac{u_{*w} l_w}{\nu} \right) \right]^2 \tag{32}$$

$$f_{d2} = \begin{cases} 1 & , \quad l_w \ge h \\ \dfrac{l_w}{h}\left(1 - \dfrac{l_w}{h}\right) & , \quad l_w < h \end{cases} \tag{33}$$

where, l_w: distance to wall, u_{*w}: friction velocity at wall and C_{vm}: constant (=50.0).

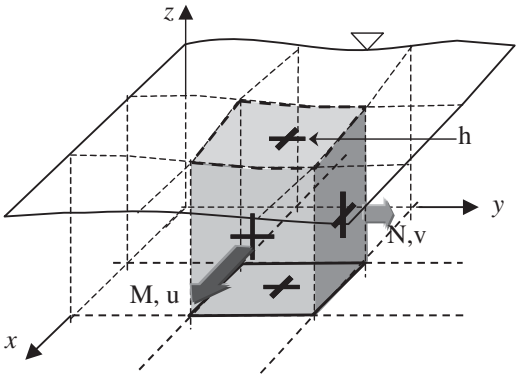

Figure 2. Arrangement of hydraulic variables in plane 2D models (2D-L, 2D-NL models).

2.3.4 *Plane 2D non-linear model (2D-NL model)*

A 2nd order non-linear formula with 0-equation model is adopted in the constitutive equation of the Reynolds stresses in the 2D-NL model as

$$-\overline{u_i u_j} = \nu_t S_{ij} - \frac{2}{3} k \delta_{ij} - \lambda_p \frac{h}{u_*} D_t \sum_{\beta=1}^{3} C_\beta \left(S_{\beta ij} - \frac{1}{3} S_{\beta\alpha\alpha} \delta_{ij} \right) \tag{34}$$

$$S_{1ij} = \frac{\partial U_i}{\partial x_\gamma}\frac{\partial U_j}{\partial x_\gamma}, \quad S_{2ij} = \frac{1}{2}\left(\frac{\partial U_\gamma}{\partial x_i}\frac{\partial U_j}{\partial x_\gamma} + \frac{\partial U_\gamma}{\partial x_j}\frac{\partial U_i}{\partial x_\gamma} \right), \quad S_{3ij} = \frac{\partial U_\gamma}{\partial x_i}\frac{\partial U_\gamma}{\partial x_j} \tag{35}$$

where ν_t is an eddy viscosity coefficient and C_1-C_3 are model coefficients. The model constants, C_1-C_3 are tuned as the following functions of the strain and rotation parameters considering the distributions of turbulence intensities in a simple shear flow.

$$C_1 = 0.4 f_M(M), \quad C_2 = 0, \quad C_3 = -0.13 f_M(M) \ ,$$
$$f_M(M) = (1 + 0.02 M^2)^{-1} \ , \quad M = \max[S, \Omega] \tag{36}$$

$$S = \lambda_p \frac{h}{u_*} \sqrt{\frac{1}{2}\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i} \right)^2} \ , \quad \Omega = \lambda_p \frac{h}{u_*} \sqrt{\frac{1}{2}\left(\frac{\partial U_i}{\partial x_j} - \frac{\partial U_j}{\partial x_i} \right)^2} \tag{37}$$

$$\lambda_p = \frac{\alpha}{\gamma_k C_\mu} = 1.07 \tag{38}$$

Though the expression of the eddy viscosity is given in equation (31) like 2D-L model. α in equation (31) is tuned as not a constant but a function of the strain and rotation parameters in this model as

$$\alpha(M) = \min\left[0.2, \ 0.3\gamma_k \lambda_p / (1 + 0.09 M^2)\right] \tag{39}$$

The function above was tuned considering the realizability in the similar way as that in F3D model.

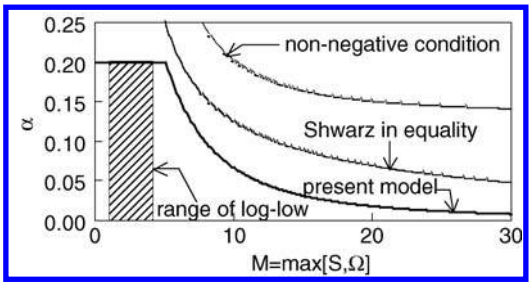

Figure 3. α(M) in the non-linear 0-equation model (2D-NL) and realizability conditions.

Figure 3 shows the function of α(M) together with the realizability conditions.

The other part of the model is same as that in the plane 2D linear (2D-L) model.

3 LABORATORY TEST

A laboratory test was performed to obtain data for assessment of model performance. The experimental flume is a 10 m long, 20 cm wide and 30 cm deep tilting flume. A rectangular wood cylinder of 4 cm × 4 cm in the cross-section and 20 cm in the length is mounted at the center of the bed. The plan and vertical views of the flow field are shown in Figure 4 and the hydraulic conditions are listed in Table 1. The water level and the velocity field around the cylinder are measured using a digital point-gauge and a propeller-type anemometer (diameter of the propeller is 3mm), respectively. The Karman vortex shedding was visualized using aluminum powder.

4 COMPUTATIONAL RESULTS

4.1 *Computational conditions and CPU times*

The computations were performed under the conditions of the preset laboratory test. The numerical grid for all models in a horizontal x-y plane is shown in Figure 5. The computations were performed using PC with CPU: Dual Xeon 2.4 GHz, RAM: 512 MB and Open MP parallel computing. The CPU times for real time of 10(sec) are 1.7(min) in 2D-L model, 2.0(min) in 2D-NL model, 284(min) in Q3D model and 365(min) in F3D model.

4.2 *Time mean flow patterns*

Figure 6 shows the time-mean velocity vectors in a horizontal x-y plane. This figure shows that the lengths of the recirculation zone behind the cylinder in 2D models are not affected by turbulence models.

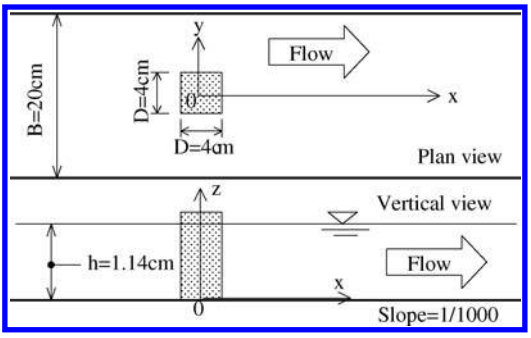

Figure 4. Schematic diagram of the flow domain.

Table 1. Hydraulic parameters in the laboratory test.

h(cm)	U_0(cm/s)	D(cm)	B/D	h/D	Re	Fr
1.14	18.18	4.0	5	0.285	8400	0.54

h: depth, U_0: mean velocity, D; side-length of cylinder B: channel width, Re: Reynolds number (=U_0D/ν), Fr: Froude number.

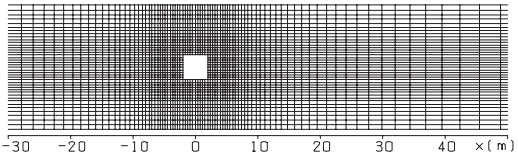

Figure 5. Numerical grid around the cylinder (x-y plane).

Note that the length closely depends on spatial dimensions. The length by the Q3D model yields longest recirculation zone.

Figure 7 shows the time-averaged velocity vectors in a vertical x-z plane along the x-axis at the upstream region of the cylinder by Q3D and F3D models. A vortex in the clockwise direction can be seen in both the results. The vortex means a formation of a horseshoe vortex around the cylinder. A diameter and a velocity of the vortex by F3D model are a little larger than that by Q3D model.

4.3 *Characteristics of vortex shedding*

Figure 8 shows snap shots of plan velocity vectors in the numerical results. This figure shows that all models can generate the Karman vortex shedding and the starting points of the vortex in 2D models locates much nearer to the pier than those in 3D models due to the shorter recirculation zone.

Figure 9 shows the temporal variations of velocities in x-direction (u) in the laboratory test and computational result of 2D-L, 2D-NL and F3D models.

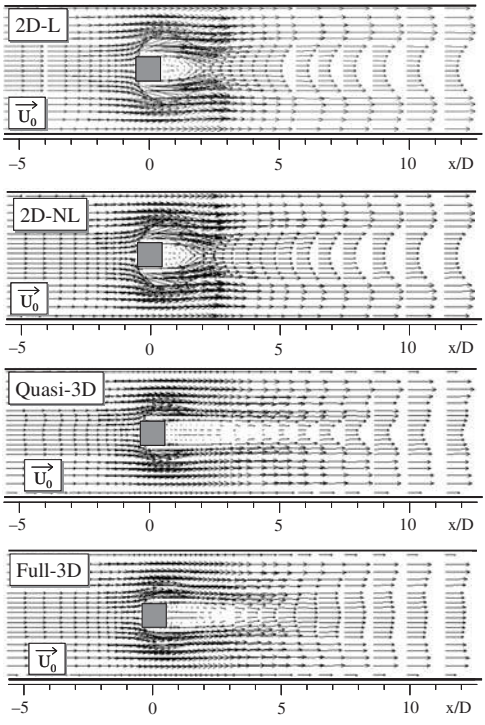

Figure 6. Time mean flow patterns in an x-y plane.

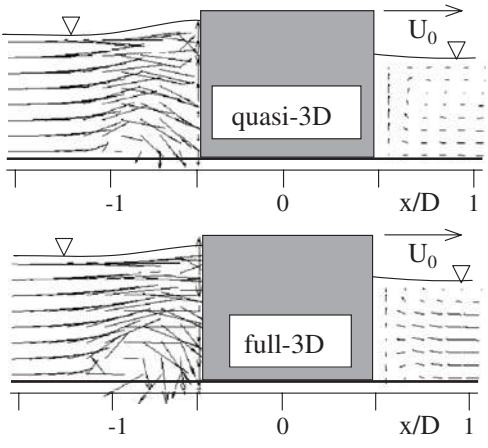

Figure 7. Time-mean flow patterns in a x-z plane (y/D = 0).

The locations of the measurement points are shown in the figure. The Strouhal number of the Karman vortex shedding in the laboratory test is estimated as $St = (fD/U_0) = 0.24$ from this figure. The Strouhal numbers in both 2D and 3D numerical results are in good agreement with the experimental value. The experimental result shows that the period of the oscillation at the centerline (y/D = 0) is larger than that at

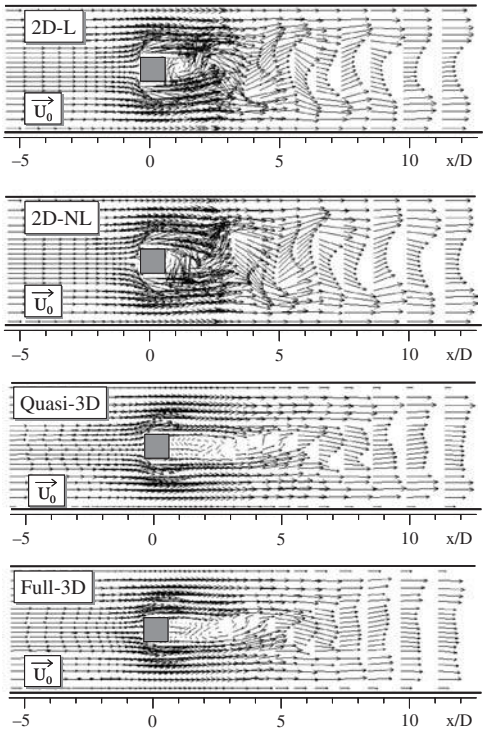

Figure 8. Snap shots of flow patterns in an x-y plane.

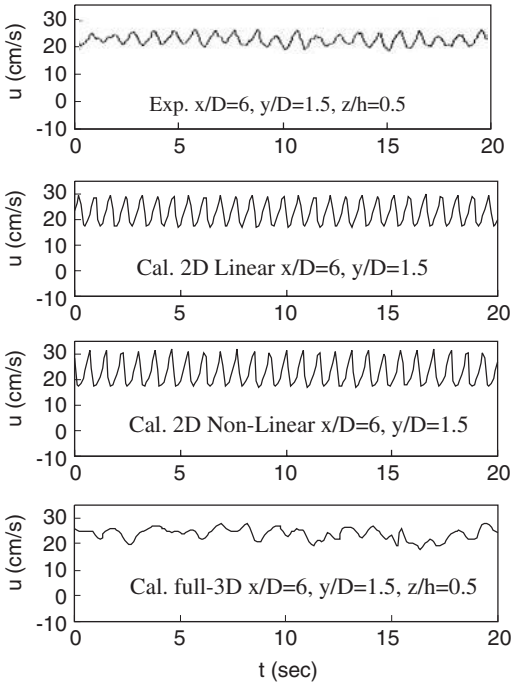

Figure 9 (b). Temporal variation of U (x/D = 6, y/D = 1.5).

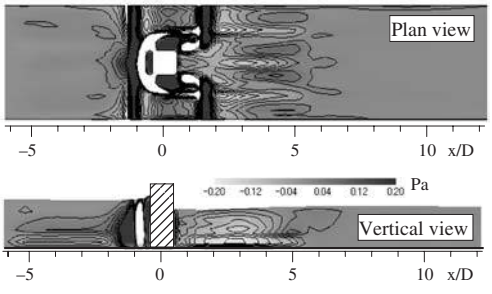

Figure 10. Time-averaged dynamic pressure distribution by the full 3D (F3D) model.

y/D = 1.5. The numerical results with 2D-L, 2D-NL and F3D models can capture this feature though the amplitude at y/D = 1.5 by 2D-L and 2D-NL models are larger than the experimental result. F3D model can capture reasonably both amplitude and period of the oscillation.

4.4 *Dynamic pressure by F3D model*

Figure 10 shows the time mean distribution of the dynamic pressure (=total pressure – hydrostatic pressure) by F3D model. The upper figure shows the profile in the horizontal plane at half the depth and

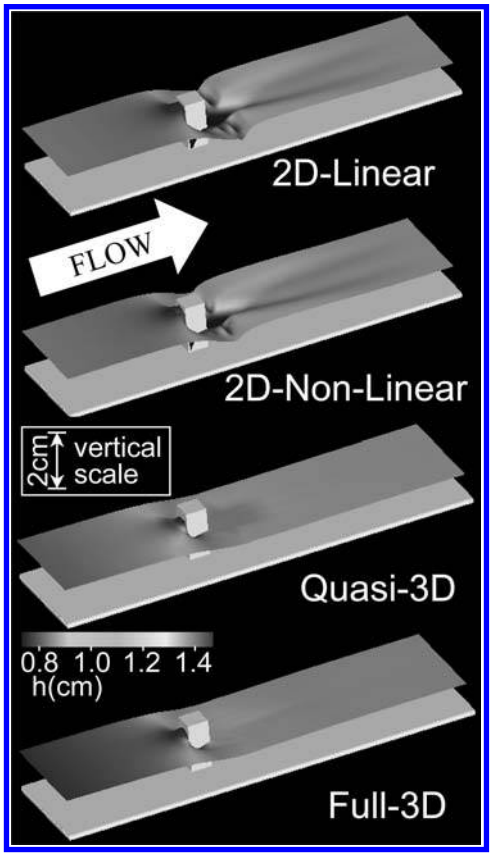

Figure 11. Time-mean surface profiles by different models.

the lower one shows the profile in the vertical section along the x-axis. The vertical scale in the latter one is enlarged 5 times compared with the horizontal scale. The horizontal distribution shows that the dynamic pressure becomes negative along the horseshoe vortex because the flow in the vortex is affected by the centrifugal force. A negative pressure is generated again along separation zones at both the sides of the downstream region of the cylinder. A positive dynamic pressure can be seen between the horseshoe vortex and the cylinder. In the vertical section, a negative dynamic pressure can be seen in large area at upstream region of the cylinder, where the stream pattern forms a saddle point due to the impingement of the flow on the cylinder. The computed pressure field seems to be reasonable considering the 3D flow pattern though the direct comparison with an experiment is not feasible due to the lack of experimental pressure data.

4.5 *Water elevation around the cylinder*

Figure 11 shows the comparison of time-averaged water level distributions by 4 models. This figure

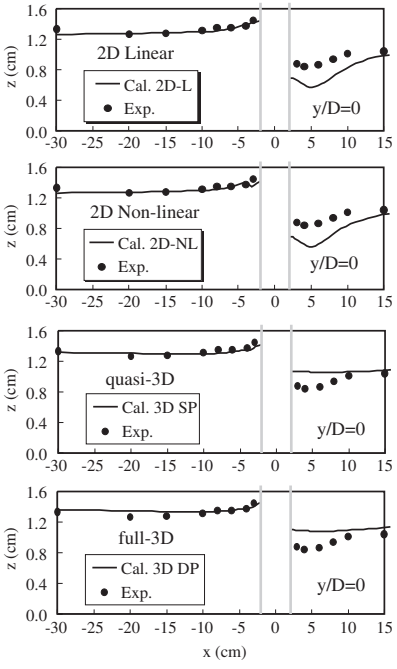

Figure 12 (a). Surface profile in the longitudinal direction at $y/D = 0$.

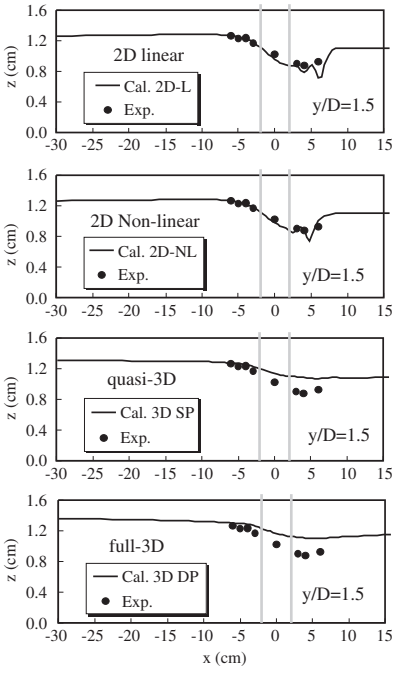

Figure 12 (b). Surface profile in the longitudinal direction at $y/D = 1.5$.

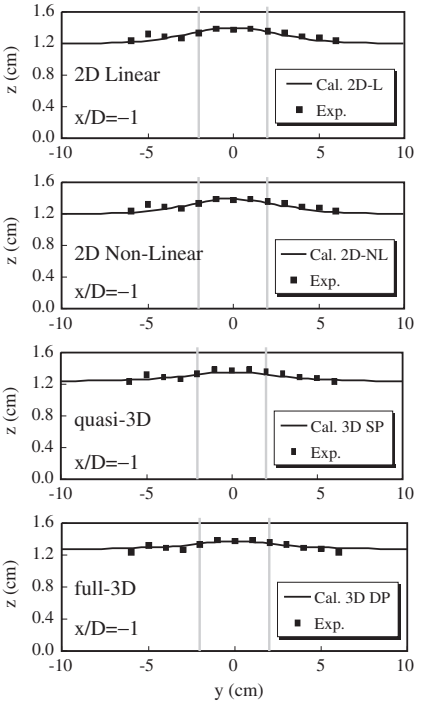

Figure 13 (a). Surface profile in the cross-section at $x/D = -1$.

shows that the hollow of the water surface behind the cylinder becomes deepest by the 2D-NL model and shallowest by the Q3D model.

Figures 12 (a) and (b) shows the computed time-averaged surface profiles in longitudinal directions at $y/D = 0$ and $y/D = 1.5$, respectively together with the experimental results. It is pointed out that all the models can capture well the surface profile at upstream region of the cylinder, on the other hand, the 2D-L and 2D-NL models over-predict the decrease of the depth behind the cylinder and Q3D and F3D models under-predict it. The prediction of the backwater effect is important from the viewpoint of flood control. The maximum depths at upstream region are 1.45 cm in the experiment, 1.45 cm in 2D-L and 2D-NL, 1.42 cm in Q3D and 1.45 cm in F3D models. Therefore, Q3D model slightly under-predicts the depth of the backwater. In the section of $y/D = 1.5$, the results by 2D-L and 2D-NL models are in good agreement with the experimental result though other 2 models predict the profile too flat.

Figure 13 shows the depth profiles along the cross-sections at $x/D = \pm 1.0$. The profiles in all models are in good agreement with the experimental result at $x/D = -1.0$ thought the Q3D model slightly under-predict the water elevation. In the section of $x/D = 1.0$, the effect of turbulence model in 2D model can be seen

Copyright © 2006 Taylor & Francis Group plc, London, UK

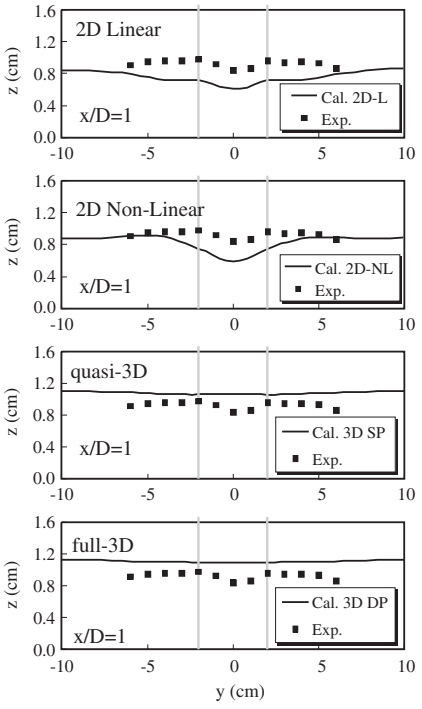

Figure 13 (b). Surface profile in the cross-section at x/D = 1.

clearly, i.e., the 2D-NL model yields better prediction of the cross-sectional water level than 2D-L model.

5 CONCLUSIONS

We investigated the turbulent open channel flow around a rectangular cylinder focusing on the Karman vortex shedding and the water level distributions using 4 different models. The main findings of the results are listed as follows.

1. The length of the recirculation zone behind the pier is generated smaller in plane 2D models than those in 3D models.
2. The fluid oscillation due to the vortex shedding attenuate more rapidly in the full-3D model than that in plane 2D models.
3. The depth variation around the cylinder is overestimated by the plane 2D models and underestimated by quasi-3D model.
4. The non-linear 2D model improved the prediction of water depth distributions compared with the linear 2D model.

ACKNOWLEDGEMENT

The authors are grateful to Yoko Watanabe and Yukari Sumi for assistance on the laboratory tests.

Validation of a new model to account for bed slope effect for prediction of equilibrium condition in loose bed channels with significant suspended sediment transport

Jie Zeng, George Constantinescu & Larry Weber
Civil & Environmental Engineering Department, IIHR-Hydroscience and Engineering, The University of Iowa, M. Stanley Hydraulics Laboratory, Iowa City, IA

ABSTRACT: A fully three-dimensional non-hydrostatic model (Zeng et al., 2005a, 2005b, 2006) using RANS models without wall functions and with capabilities to account for bed roughness effects in open channels and river reaches is used to predict the equilibrium flow, suspended and bed load sediment transport, and bathymetry in the S-shaped channel with vertical lateral walls (case CH13) studied experimentally by Onishi (1972). The bed load transport is modeled using a non-equilibrium model. A new procedure is proposed to account in a consistent way for bed slope gravitational force effects not only for the bed load transport component, as was done in the original formulation of the model, but also for the suspended sediment load. The calculations are started with a flat bed. The bed levels, streamwise velocity and suspended sediment concentration profiles are compared with experimental data at several sections. It is found that though the predictions of the streamwise velocity and concentration profiles given by the original and new versions are very similar, the new version of the model yields better agreement with the experimental data for the bed level profiles.

1 INTRODUCTION

In meandering rivers and bended channels the sediment transport and secondary currents in the transverse direction cannot be neglected, as they are responsible for the highly irregular bed profiles observed around regions of high channel curvature. The main characteristic of the bed deformation in these bends is the formation of a point bar near the inner bank and of a pool at the outer part of the bend. The flow, sediment transport and associated bathymetry evolution are determined to a large degree by the helical motion of the water due to the action of the centrifugal forces present in regions of high channel curvature. As a consequence of the action of these forces, a pressure gradient is induced between the inner and outer banks. This pressure gradient is balanced near the free surface by a secondary current which, near the bed, is oriented from the outer toward the near inner bank. The secondary flow modifies the transversal distribution of the streamwise velocity profile, induces a vertical velocity component in the section, and redistributes the magnitude and direction of the bed shear stresses and sediment transport along the bend (Blanckaert and De Vriend, 2004). In particular, the magnitude of the bed shear stress is amplified compared to the values observed in the straight part of the channel. As a consequence, under mobile bed conditions, sediment particles move, near the bed, toward the inner bank where, eventually, they deposit and raise the bed level by forming a point bar. Concomitantly, the mean flow velocity and bed shear stress increase in the region close to the outer bend, erosion is initiated and a pool is created. As the scour develops in the outer region, the transversal slope increases until the force induced by the secondary current against the transversal slope is balanced by the (downwards) component of the gravitational force acting on the particle in the same direction. At this point equilibrium is reached and the bathymetry would not change anymore in time. These conditions are observed to be approximately reached in most curved bends, but there are flows for which such an equilibrium state cannot be reached. Non-local effects due to the redistribution of the flow and sediment motion as one advance downstream in the bend can contribute to the local increase of the transverse bed slope.

One-dimensional (1D) models are clearly not appropriate to predict morphological changes in curved bends due to the presence of highly non-uniform bed profiles in the transverse direction. 2D depth averaged models suffer from similar deficiencies, though to a lesser degree compared to 1D models, especially for prediction of flow and sediment

Copyright © 2006 Taylor & Francis Group plc, London, UK

transport processes in alluvial channels in which regions of strong channel curvature are present. Though empirical corrections are available to incorporate the effects of strong secondary currents and non-equilibrium effects (Duc et al., 2004, Choi et al., 2005, Vasquez et al., 2005), these 2D or quasi 3D models need lots of calibration and introduce additional assumptions on the flow (e.g., related to the inertial adaptation of the secondary flow, radius of the curvature of the streamlines, the presence of linear of quadratic distribution shapes for the velocity components, etc.) which are not always true in a complex application.

To accurately capture the aforementioned effects, full 3D numerical and turbulence models that can account for history effects and can accurately capture the intensity of the secondary currents have to be used. Still, because of the empiricism related especially to the bed load transport modeling, model validation and a certain degree of calibration (though much more reduced than the one required by 2D or quasi 3D models) is necessary even if fully 3D hydrostatic or non-hydrostatic models are employed. In this regard, comparison of computed results with experimental data corresponding to well-controlled laboratory experiments is essential before application of the model to predict flow, sediment and morphological changes in real river reaches. Due to the advances in computational power, the use of fully 3D non-hydrostatic models using advanced RANS closures that include sediment transport capabilities is becoming more common. Recent examples include the work of Wu et al. 2000, Fang and Rodi (2003), Olsen (2003) and Ruther and Olsen (2005).

In the following, the previously developed finite-differences 3D non-hydrostatic model of Zeng et al. (2005a, 2005b, 2006) is applied to calculate the flow, sediment transport and bathymetry at equilibrium conditions in the S-shaped channel studied experimentally by Onishi (1972). The model uses deformable grids in the vertical direction, does not use wall functions, and the RANS closures (the Spalart-Allmaras model is used in this paper) are implemented in versions that can account for roughness effects. This test case is the first application of the model to a meandering channel flow in which the suspended sediment load is comparable to the total load. Thus, the need to consider more carefully some processes that can be neglected when the model is applied to cases when the bed load transport is dominant. The most important one is to account for bed-slope gravitational effects on sloped surfaces for the suspended sediment. The need to do that is clear if we consider the extreme case when the bed load transport can be neglected, and the bathymetry changes are due to the entrainment/deposition of suspended sediment. A new procedure to account for these effects is proposed and tested for the case corresponding to experiment CH13 conducted by Onishi (1972). The main idea is to rewrite the non-equilibrium bed-load transport equation proposed by van Rijn (1987) as an equation for the total sediment load.

2 HYDRODYNAMIC AND SEDIMENT TRANSPORT MODELS

In the present model, the 3D incompressible RANS and turbulence/sediment transport equations are first transformed in generalized curvilinear coordinates. However, the primitive variables (Cartesian velocity components, V_i) for which the momentum equations are solved are left unchanged (partial transformation approach). The continuity and momentum equations are:

$$J\frac{\partial}{\partial \xi^j}\left(\frac{V^j}{J}\right)=0 \tag{1}$$

$$\frac{\partial Q}{\partial t}+A_j\frac{\partial Q}{\partial \xi^j}-J\frac{\partial E_{vj}}{\partial \xi^j}+H=0 \tag{2}$$

where x_i are the Cartesian coordinates and ξ^i are the curvilinear coordinates. In equation (2), $Q=(V_1,V_2,V_3)^T$ is the Cartesian velocity vector; J is the Jacobian $\mathrm{J}=\partial(\xi^1,\xi^2,\xi^3,)/\partial(x_1,x_2,x_3)$, $V^i=V_j\xi^j_{xi}$ are the contravariant velocity components, $\mathrm{A_j}=\mathrm{diag}(V^1,V^2,V^3)$ and $E_{vj}=E^1_{vj},E^2_{vj},E^3_{vj}$ are the vectors containing the viscous and turbulence fluxes and, finally, H is the pressure gradient vector

$$H=\left(\xi^k_{x1}\frac{\partial\Phi}{\partial\xi^k},\xi^k_{x2}\frac{\partial\Phi}{\partial\xi^k},\xi^k_{x3}\frac{\partial\Phi}{\partial\xi^k}\right)^T \tag{3}$$

The governing equations, including the ones solved part of the turbulence and suspended sediment transport models, are non-dimensionalized using a length scale $\mathrm{H_0}$ (water depth at the inlet) and a velocity scale U (bulk velocity in the inlet section) such that formally the Reynolds number ($Re=\mathrm{UH_0}/\nu$) replaces the molecular viscosity ν, and the Froude number ($Fr=U/(\mathrm{gH_0})^{0.5}$) is used to scale the free surface deformations. The modified pressure Φ is defined as $\Phi=p+2/3k$ and the effective piezometric pressure P is defined as $P=p/\rho+z/Fr^2-2/3k$, where p is the pressure, z is the free surface elevation and k is turbulence kinetic energy. The Froude number enters the solution through the free-surface boundary condition assuming that the deformable free surface model is turned on (for more details on this see Zeng et al., 2005a). The velocity components are set equal to zero on all solid surfaces. At the outflow all variables are extrapolated from the interior. The pressure is extrapolated from the interior of the domain on all boundaries except at the free surface.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The eddy viscosity is calculated using the Spalart-Allmaras (SA) model in the simulations discussed in the present paper. In the SA model only one transport equation is solved for the modified viscosity $\tilde{\nu}$ based on which the eddy viscosity is evaluated. At the lateral walls, that are considered smooth in the present simulations, $\tilde{\nu}$ is set equal to zero. To account for bed roughness effects, the distance to the rough walls is redefined (see also Spalart, 2000, Zeng et al., 2005b) as: $d = d_{\min} + 0.03k_s$ where $d_{\min}$ is the distance to the nearest rough wall. At the bed, that is treated as a rough surface, the value of $\tilde{\nu}$ is estimated (Spalart, 2000) by solving $\partial\tilde{\nu}/\partial n = \tilde{\nu}/d$ where n is the wall normal direction. This makes $\tilde{\nu}$ and the eddy viscosity to be formally non-zero at the rough bed. The equivalent bed roughness is estimated using a formula proposed by van Rijn (1984) in the case in which small bed forms are present:

$$k_s = 3d_{90} + 1.1\Delta(1 - e^{-25\psi}) \tag{4}$$

where the first term accounts for the sand grain roughness contribution and the second term represents the bed form contribution. In equation (4), $\psi = \Delta/\lambda$ where Δ and λ are the height and length of the sand waves, respectively. Following van Rijn (1984) and Wu et al. (2000) the length λ is assumed to be $\lambda = 7.3H$ and the parameter ψ is estimated from:

$$\psi = \Delta/\lambda = 0.015(d_{50}/H)^{0.3}\left(1 - e^{-0.5T}\right)(25 - T) \tag{5}$$

in which H is the local water depth, d_{50} and d_{90} are the median and 90% diameters of the bed material, and T is the non-dimensional excess shear stress given by van Rijn (1987).

A fractional step method is used to solve the RANS equations. All terms in the pressure Poisson equation are discretized using second-order accurate central differences. The momentum and turbulence transport equations are discretized using second order accurate upwind differences for the convective terms. All other operators are calculated using second-order central discretizations. All terms are treated implicitly, including the source terms in the transport equations for turbulence quantities ($\tilde{\nu}$). To accelerate the convergence of the resulting system of equations toward steady state (equilibrium), local time-stepping techniques are used. An approximate factorization technique is used to simplify the inversion of the discrete form (left hand side) of the momentum, pressure-Poisson and turbulence transport equations. The equations are solved implicitly using the alternate-direction-implicit (ADI) method. The implementation of the deformable free surface module in which the proper kinematic and dynamic boundary conditions are applied at the top boundary is described in Zeng et al. (2005a).

An advection-diffusion scalar transport equation with an additional settling-velocity source term is solved to determine the local sediment concentration C and the suspended sediment fluxes at the top of the bed load layer for simulations in which the suspended sediment load cannot be neglected. The equation is not solved up to the wall, as are the momentum equations, but rather up to the interface with the bed load layer (δ(x,y)) which typically corresponds to a k = constant surface in the computational grid. In curvilinear coordinated, the equation is:

$$\frac{\partial C}{\partial t} + V^j \frac{\partial C}{\partial \xi^j} - \omega_s \delta_{3i} \frac{\partial C}{\partial \xi^j}\frac{\partial \xi^j}{\partial x_i} - J\frac{\partial}{\partial \xi^j}\left(\frac{g^{ij}}{J}\left(\frac{\nu + \nu_t}{\sigma_c}\right)\frac{\partial C}{\partial \xi^i}\right) = 0 \tag{6}$$

where ω_s is the setting velocity of the sediment, δ_{3j} is the Kronecker delta symbol with $j = 3$ indicating the vertical direction and σ_c is the Schmidt number. Its role is to relate the sediment (turbulent) diffusivity to its (eddy) viscosity. At the free surface, the total vertical flux of suspended sediment is set to zero:

$$\frac{\nu + \nu_t}{\sigma_c}\frac{\partial C}{\partial \xi^j}\frac{\partial \xi^j}{\partial x_3} + \omega_s C = 0 \tag{7}$$

At the interface between the suspended sediment and the bed load layers (z = δ(x,y) such that there is no ovelap between the two layers) situated not far but not necessarily at the reference level z = a, following van Rijn (1987) and Wu et al. (2000), the entrainment rate is assumed to be equal to the one under equilibrium conditions. The total vertical sediment flux at the interface is equal to the net sediment transport (deposition minus entrainment) across the interface.

$$\frac{\nu_t}{\sigma_c}\frac{\partial C}{\partial \xi^j}\frac{\partial \xi^j}{\partial x_3} + \omega_s C = D_b - E_b \tag{8}$$

$$D_b - E_b = \omega_s C - \omega_s C_{b**} \tag{9}$$

where C_{b**} is the equilibrium concentration at z = δ, $D_b = \omega_s C_b$ is the deposition rate and $E_b = \omega_s C_{b**}$ is the entrainment rate at the top of the bed layer. The value of C_{b**} can be calculated assuming Rouse formula to be valid between the reference level where $C = C_{b*}$ (z = a) and the interface between the bed and the suspended load layers (z = δ(x,y)). There is no unique way to choose the reference level a. In some cases it is taken equal to the bed roughness, in other cases it is taken as a percentage of the total depth (see also Lin & Falconer, 1996). At the inlet section a concentration profile needs to be prescribed, while at the sidewalls and outlet a zero gradient boundary condition is imposed.

The empirical formulas proposed by van Rijn (1987) are used in the present study to estimate the

Copyright © 2006 Taylor & Francis Group plc, London, UK

equilibrium concentration at the reference level (C_{b^*}) needed to calculate $C_{b^{**}}$ in (9), the equilibrium bed load transport rate (Q_{b^*}) and the non-equilibrium adaptation length (L_s). The last two variables are needed to close the non-equilibrium bed transport model. In this model, the mass balance equation for the sediment within the bed load layer (van Rijn, 1987), in which the storage term is neglected, is:

$$(1-p')\frac{\partial z_b}{\partial t} - D_b + E_b = -\nabla Q_b = -J_b\left(\frac{\partial}{\partial \xi}\left(\frac{Q_{b\xi}}{J_b}\right)+\frac{\partial}{\partial \eta}\left(\frac{Q_{b\eta}}{J_b}\right)\right) = 0 \quad (10)$$

In the above equation p' is the porosity, J_b is the Jacobian of the geometric transformation in the bed load layer, $(J_b = \partial(\xi,\eta)/\partial(x,y))$, z_b is the bed level above a datum, $Q_{b\xi}$ and $Q_{b\eta}$ are the components of the bed-load transport in the two directions. Then, one assumes that the relation between the bed change due to deposition from the bed load layer is:

$$(1-p')\frac{\partial z_{b_bed_load}}{\partial t} = \frac{1}{L_s}(Q_b - Q_{b^*}) \quad (11)$$

such that the total change in the bed elevation is:

$$(1-p')\frac{\partial z_b}{\partial t} = D_b - E_b + \frac{Q_b - Q_{b^*}}{L_s} \quad (12)$$

The equation for the bed load rate Q_b is derived from equation (10) in which we made the substitution corresponding to the model assumed in equation (12):

$$\frac{(Q_b - Q_{b^*})}{L_s} + \nabla Q_b = 0 \quad (13)$$

One should make the important observation that equation (13) which is solved to determine the bed load Q_b is the same for both the case when the suspended sediment transport module is active and for the case when the suspended sediment transport can be neglected. However, in the first case the total bed elevation change will be partly due to the net entrainment/deposition of suspended sediment at the top of the bed load layer (see equation 10).

To close the model, one has to express $Q_{b\xi}$ and $Q_{b\eta}$ function of Q_b. When the bed becomes sloped, the gravitational force on the particles will resist the shear force to further carry the particles to the upper part of the slope. The sediment transport direction will deviate from the local direction of the bed shear stress. In this study, the relationship of Delft Hydraulics (see Sekine and Parker, 1992) is used:

$$Q_{b\xi}/Q_{b\eta} = \left(\sin\theta_b - \beta\frac{\partial z_b}{\partial l_\xi}\right)\Big/\left(\cos\theta_b - \beta\frac{\partial z_b}{\partial l_\eta}\right) \quad (14)$$

where $\theta_b = \tan^{-1}(\tau_{b\eta}/\tau_{b\xi})$ is the angle between the bed shear stress vector and the streamwise direction, $\beta = \beta^*\,(\tau_c^*/\tau_L^*)^m$, τ_L^* is the nondimensional longitudinal Shield stress $\tau_L^* = \tau_* \cos\theta_b/\rho\, Rgd_{50}$, $R = \rho_s/\rho - 1$ ρ_s is the sediment density, ρ is the water density, the critical shear stress $\tau_c^* = \rho u_{*cr}^2$ is given by Shields diagram, m is a coefficient (m = 1), $\beta^* = \alpha_G/\tau_c^*$, $\partial z_b/\partial l_\xi$, $\partial z_b/\partial l_\eta$ are the streamwise and transverse bed slopes, and α_G is a coefficient typically in the range 0.45–0.7. In the present simulations we used $\alpha_G = 0.6$. The bed load transport rate at the inlet is the only variable needed to be specified. Once z_b is calculated, the grid points between the bed level and the free surface are redistributed vertically based on the new positions of the water surface and bed level elevations.

Before presenting the method to account for bed slope effects for the suspended sediment load component, we will review the main equations that are solved for the three types of possible applications.

In the first type of applications in which the suspended sediment transport can be neglected, D_b and E_b are set to zero in (12). The equations to be solved are (12) and (13) with $Q_{b\xi}/Q_{b\eta}$ given by (14).

In the second type of applications in which the bed load transport can be neglected, first the concentration field C is determined from equation (6) with boundary conditions given by (7) and (8). Then, the deposition and entrainment rates are evaluated using their definition, and the net entrainment/deposition rate is calculated from (9). This value is then introduced in (12) with $Q_b = Q_{b^*} = 0$ to calculate z_b.

In the third type of applications in which both the bed and suspended loads cannot be neglected, the concentration C, deposition and entrainment rates are obtained in the same way as for the second type of applications, Q_b is obtained from (13) and (14) and, finally, z_b is obtained from (12).

In simulations in which the suspended sediment load becomes comparable or larger than the bed load, it is important to account for bed slope effects for the total load Q_T. To do that in our model, we define the total load (considered as a vectorial relationship in the horizontal directions) as simply:

$$Q_T = Q_b + Q_S \quad (15)$$

where Q_S is the suspended sediment load flux in the local water column from the top of the bed layer to the free surface. By taking the divergence of (15) we obtain using the mass conservation equation in the water column corresponding to the suspended sediment domain (between $z = \delta(x,y)$ and free surface) and neglecting the storage term:

$$\nabla Q_T = \nabla Q_b + \nabla Q_S = \nabla Q_b - D_b + E_b \quad (16)$$

Then, we rewrite equation (13) for the total load using equations (15) and (16):

$$\frac{1}{L_s}(Q_T - Q_S - Q_{b^*}) + \nabla Q_T + D_b - E_b = 0 \quad (17)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

As the new variable in (17) is Q_T, we rewrite (12):

$$(1-p')\frac{\partial z_b}{\partial t} = -\nabla Q_T \tag{18}$$

where use was made of equations (10) and (16). At this point the new model is closed, provided that we are able to estimate Q_S from the concentration field and a formula to split Q_T after the two horizontal directions (ξ, η) is available.

To evaluate Q_S, one simply has to apply the definition to calculate the two components of the flux in the horizontal directions (x,y):

$$Q_{Sx} = \int_s^h \left(uC - \frac{\nu + \nu_t}{\sigma_c}\frac{\partial C}{\partial x} \right) dz' \tag{19}$$

$$Q_{Sy} = \int_s^h \left(vC - \frac{\nu + \nu_t}{\sigma_c}\frac{\partial C}{\partial y} \right) dz' \tag{20}$$

The magnitude of the suspended sediment flux is:

$$Q_S = \sqrt{\left({Q_{Sx}}^2 + {Q_{Sy}}^2 \right)} \tag{21}$$

To introduce bed slope effects directly for Q_T, the same splitting formula (14) is used, but with Q_b replaced by Q_T:

$$Q_{T\xi} / Q_{T\eta} = \left(\sin\theta_b - \beta\frac{\partial z_b}{\partial l_\xi} \right) \Big/ \left(\cos\theta_b - \beta\frac{\partial z_b}{\partial l_\eta} \right) \tag{22}$$

Thus, the divergence operator ∇Q_T can be calculated in curvilinear coordinates (ξ, η). The concentration, and the deposition/entrainment rates are obtained in the same way as in the second type of applications.

3 VALIDATION

The meandering flume experiments for sediment transport conducted by Onishi (1972) are used to estimate the predictive abilities of the original model (Method 1) and of the new version (Method 2) that accounts for bed slope effects for both the suspended and the bed loads, for a test case in which the suspended sediment load is comparable to the bed load.

The curved flume configuration shown in Figure 1 consists of two identical 90^0 bends disposed in opposite directions. The first bend is preceded by a short straight section (4.27 m long) ahead of which sand and water are supplied by a retour circuit. Two straight sections of same length are used to connect the two bends and to extend the exit from the second bend. The channel sidewalls are vertical, the total channel width is 2.34 m and the radius of the bends is 8.54 m. In the test case CH13 that is simulated in the present

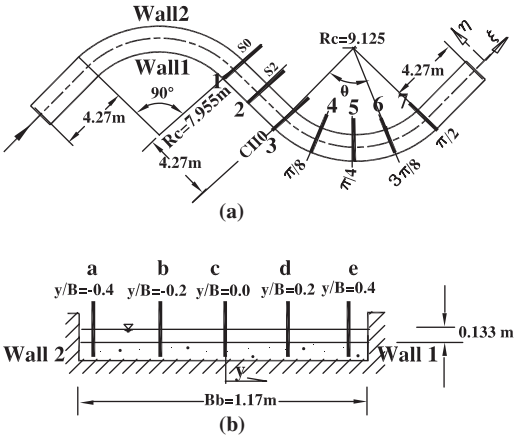

Figure 1. Experimental setup showing location of cross-sections and stations where vertical velocity and concentration profiles were measured. (a) flume layout; (b) cross-section at the start of the experiment.

study, the actual width of the channel was 1.17 m. The inflow water depth was $H_0 = 0.133$ m and the mean inflow velocity was $U = 0.536$ m/s. The corresponding Froude and Reynolds numbers were 0.469 and 71,454, respectively. The experiments were conducted using sand with median diameters of $d_{50} = 0.255$ mm and $d_{90} = 0.355$ mm. The average slope of the water surface was 0.0018. In the experiment, the bed was leveled with an uniform layer of sand. The experiment was carried out continuously for more than 3 days, until equilibrium steady state bathymetry was reached. The bathymetry, mean streamwise velocities and concentration profiles were then measured at selected sections (see Figure 1a) downstream the first 90° bend.

The numerical simulations started with a flat sand bed similar to the experiment and continued until equilibrium flow and bathymetry conditions were reached. The length of the outlet straight reach was increased by 4.5 m to minimize the influence of the outlet boundary conditions on the solution in the downstream part of the channel. To be consistent with the physical experiments in which sediment and water were supplied by a retour circuit system, the calculated distribution of the suspended sediment concentration and the bed load transport rate at the outlet were used to specify the bed load transport rate and mean (laterally averaged) concentration profile at the inlet boundary.

The numerical simulations were carried out using the SA model on a mesh with 320,000 ($90 \times 101 \times 35$) grid points. The first point off the channel sidewalls and bottom was situated at $\Delta n/H_0 \sim 0.00035$, corresponding to a non-dimensional distance of one in wall units ($\Delta n^+ = 1.0$). The value of the bottom roughness calculated using equation (4) was found to be situated well into the fully rough regime ($k_s \sim 0.005$ m

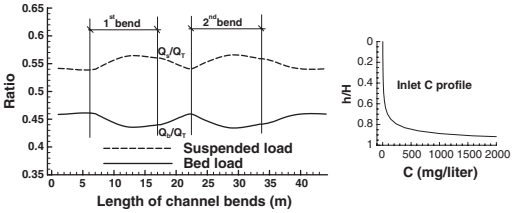

Figure 2. Ratios of suspended sediment and bed loads to total load along longitudinal direction and suspended sediment concentration profile in the inlet section at equilibrium.

corresponding to $k_s^+ \sim 280$ in the initial straight part of the channel). The streamwise velocity distribution at the inlet was taken from a precalculated fully-developed SA solution obtained in a straight channel of identical section to the inflow section. The channel Reynolds number was the same in the preliminary and curved channel simulations. The value of the Schmidt number was equal to 0.7. The reference level corresponding to the depth of the bed load layer was taken equal to $6.0d_{90}$, corresponding to about 1.5% of the water depth at the inflow section. A total of 12 grid points were used in the vertical direction to resolve this region.

Figure 2 shows the variation of the ratio of the cross-section averaged suspended sediment load to the total load in the longitudinal direction. As the results of the two simulations were very close, only Method 2 results are shown. The average value of this ratio for the simulated flow conditions was found to be close to 0.56, confirming the fact that the suspended sediment component plays an essential role in the overall sediment transport process. The largest values of this ratio ($\sim$0.575) are observed to occur toward the middle of the two 90^0 bends. The minimum values ($\sim$0.54) occur at the end of the straight section between the two bends and the near the end of the channel. In the same figure, the width averaged suspended sediment concentration distribution over the depth at equilibrium conditions is shown.

Figure 3 shows the predicted bed levels in seven cross-sections (see Figure 1a) at equilibrium state along with experimental results from two sets of measurements. Overall, most of the predicted bathymetry profiles agree well with the experimental measurements for both simulations. In particular, excellent agreement is observed at section 1 situated just at the entrance into the straight reach between the two bends. At sections 2 and 3 situated in the same straight transition channel, some overprediction of the scour (up to 0.03 m) are observed near $Y = 0.25$ m (Y is the positive/negative distance measured from the center of the channel in a section) and around $Y = 0.5$ m (close to wall 2), respectively. Just after the entrance into the second 90^0 bend (section 4), the water depth

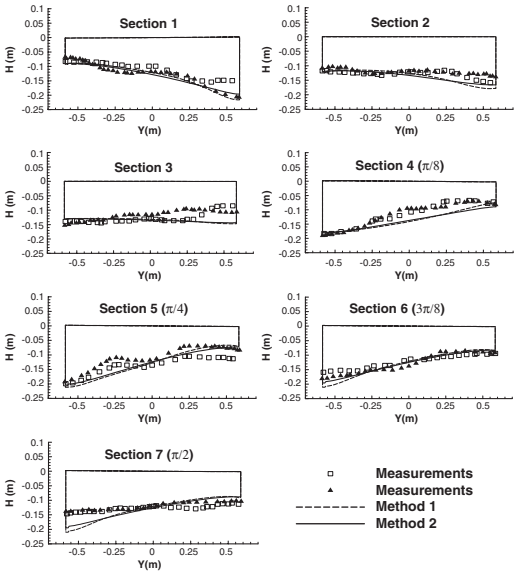

Figure 3. Comparison between predicted and measured bed levels at equilibrium conditions.

is accurately predicted near both sidewalls. However, some overprediction of the scour (up to 0.025 m) is observed to occur in the range $-0.1\,\text{m} < Y < 0.4\,\text{m}$ toward the center of the cross-section. Both simulations predict a decay of the water depth between wall 2 (inner wall for the second bend) and wall 1 at a practically constant slope, while in the experimental data the slope appears to be much smaller toward wall 2. In section 5, situated at the middle of the second bend, the agreement can be considered satisfactory taking into account the scatter between the two sets of experimental data. However, a careful analysis of the experimental profiles shows the presence of a break in the slope of the water depth decay from the inner to the outer wall between $-0.25\,\text{m} < Y < 0\,\text{m}$, where the slope becomes slightly negative. This results in the simulations overpredicting the scour around $Y = 0.25$ m by about 0.02 m. The predictions by the two methods at sections 6 and 7 show some differences especially near the outer wall (wall 1). In particular, at section 6 situated half distance between the middle and the end of the second bend, the agreement is excellent for Method 2. Method 1 overpredicts the scour near the outer wall by about 0.02 m. Same trends are observed at the exit from the second bend (section 7). However, at this location both simulations overpredict the scour in the region situated close to the outer wall by as much as 0.04 m. This is because the simulations predict a longer recovery distance for the bed to become again relatively flat after the exit from the second bend.

Figure 4 shows the streamwise velocity distribution is several representative sections along the S-shaped

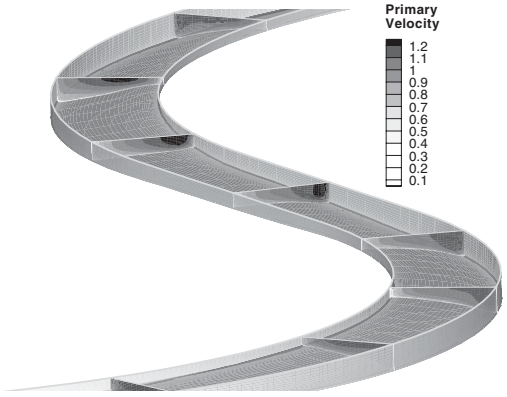

Figure 4. Predicted velocity magnitude contours at representative sections within the channel. Computational mesh is also shown in the same figure.

channel. The main observation is the fact that the bathymetry and the streamwise velocity distribution in equivalent sections in the two bends is not exactly anti-symmetric as one would expect in a meandering channel containing a large number of opposite bends. One can observe that in the middle of the straight channel between the two bends, the region of high streamwise velocity is situated closer to wall 1. This region of high velocity magnitude appears to be smaller and situated closer to the outer wall (wall 1) inside the second bend compared to the position and shape of the corresponding region inside the first bend. Though at the exit from the first bend the flow is far from being symmetric with respect to the center of the channel, at the exit from the second bend the return to symmetry for both the bathymetry and the streamwise velocity distribution in the section is much more noticeable.

Figure 5 shows the streamwise velocity profiles at four stations (Figure 1b) situated in the same seven sections in which the bathymetry profiles were compared. To facilitate comparison, the depth shown on the vertical axis is nondimensionalized by the local water depth. The results from the two methods are very close, so in the following discussion we will refer to them as the simulation results. Only one set of measurements was available for the streamwise velocity. The experimental results indicate a very clear tendency of the flow to divert toward the outer bank of the two channel bends. For instance, the streamwise velocity value away from the bottom is close to 0.6 m/s at station S1b (first number denotes the section number, second letter denotes the relative position inside the section as shown in Figure 1b) near the outer wall of the first bend and close to 0.4 m/s near the inner wall. Same trend is observed in sections 2 and 3 situated inside the straight channel reach connecting the two bends (compare stations S2b with S2e and S3b with S3e). The trend starts being inverted at section 4. At section 7 situated at the exit from the second bend (the corresponding section for the first bend will be S1), the difference between the velocity near the outer and inner walls is comparable to the one observed to occur toward the end of the first bend. The outer wall values are very similar (around 0.65 m/s, compare S1b with S7e) but the values at station b are close to 0.50 m/s compared to 0.4 m/s observed at station S1e. This is however misleading as the station corresponding to S7b is S1d (anti-symmetric with respect to the center of the channel, see Figure 1b). The streamwise velocity values away from the bed are close to 0.5 m/s at station S1d. Still, as already pointed out when discussing Figure 4, the velocity profiles at corresponding sections are not exactly anti-symmetric. The overall agreement between the experiment and simulations is good. The simulations successfully capture the shift of the region characterized by high streamwise velocities from wall 2 to wall 1 over the second bend. At the first three sections situated inside the transition channel, the only noticeable disagreement occurs at stations S3b and S3c. At station S3b the predicted velocities are larger than the measured ones from the bed up to mid channel depth, while at station S3c the opposite is observed. At the entrance into the second bend (section 4) the velocities are underpredicted at station S4e near wall 1 by about 0.07 m/s. Inside the second bend, the simulations tend to overpredict the measurements at stations S5b, S6b and S7b at $Y/B = -0.2$ midway between the inner wall (wall 2) and the center of the section. However, the predictions at the center of the channel in the same sections are quite accurate with the exception of station S5c where the velocities are overestimated near the bed. The predictions at the same sections in the outer bend region are quite accurate.

Figure 6 shows the contours of the predicted bottom shear stress ($\tau/\rho U^2$) inside the channel bend at equilibrium. As expected, a patch of relatively high shear stress values is present at the entrance into the first bend closer to the inner wall. As one moves downstream, the area of high bed shear stress switches toward the deeper outer wall region inside the first bend. Inside the straight transition channel between the two bends the bed shear stress remains high on the wall 2 side showing that the flow is far from being axisymmetric with respect to the center of the channel at the entrance into the second bend. Thus, one should not expect the flow inside the first and second bends to be exactly anti-symmetric. The region of high shear stress switches from wall 2 to wall 1 over the second half of the second bend, as wall 1 becomes the outer wall. The bed shear stress peaks at a distance of about 4 m from the end of the second bend. The bed shear stress values in the region close to wall 1 decay slowly as the flow tries to recover toward a symmetric

variation of the bathymetry and velocity distribution with respect to the axis of the channel in the straight reach at the end of the meandering channel.

Figure 7 shows the suspended sediment concentration profiles at five stations (Figure 1b) inside each of the seven sections (Figure 1a) at which experimental measurements were taken. The predictions of the two methods were found to be very close to each other. The

simulation results at most stations are in good agreement with the experiment. This is true especially for stations a and e situated the closest to the two banks. The simulations tend to underestimate the concentration of the suspended sediment in the upper layer, near the free surface, and in the middle layer, especially in the central parts of the sections situated in the second bend (stations b, c and d). For example, the concentration is underestimated away from the bed region at station d between sections 2 and 6 and at station c (mid-distance between the two lateral walls) between sections 2 and 4. However, this trend is not uniform as at some of the stations in the same regions the agreement is quite good (e.g., stations S6c, S7d). Conversely, the suspended sediment concentration in the region situated just above the bed load layer tends to be overestimated by the simulations. One should also mention that the sediment concentration

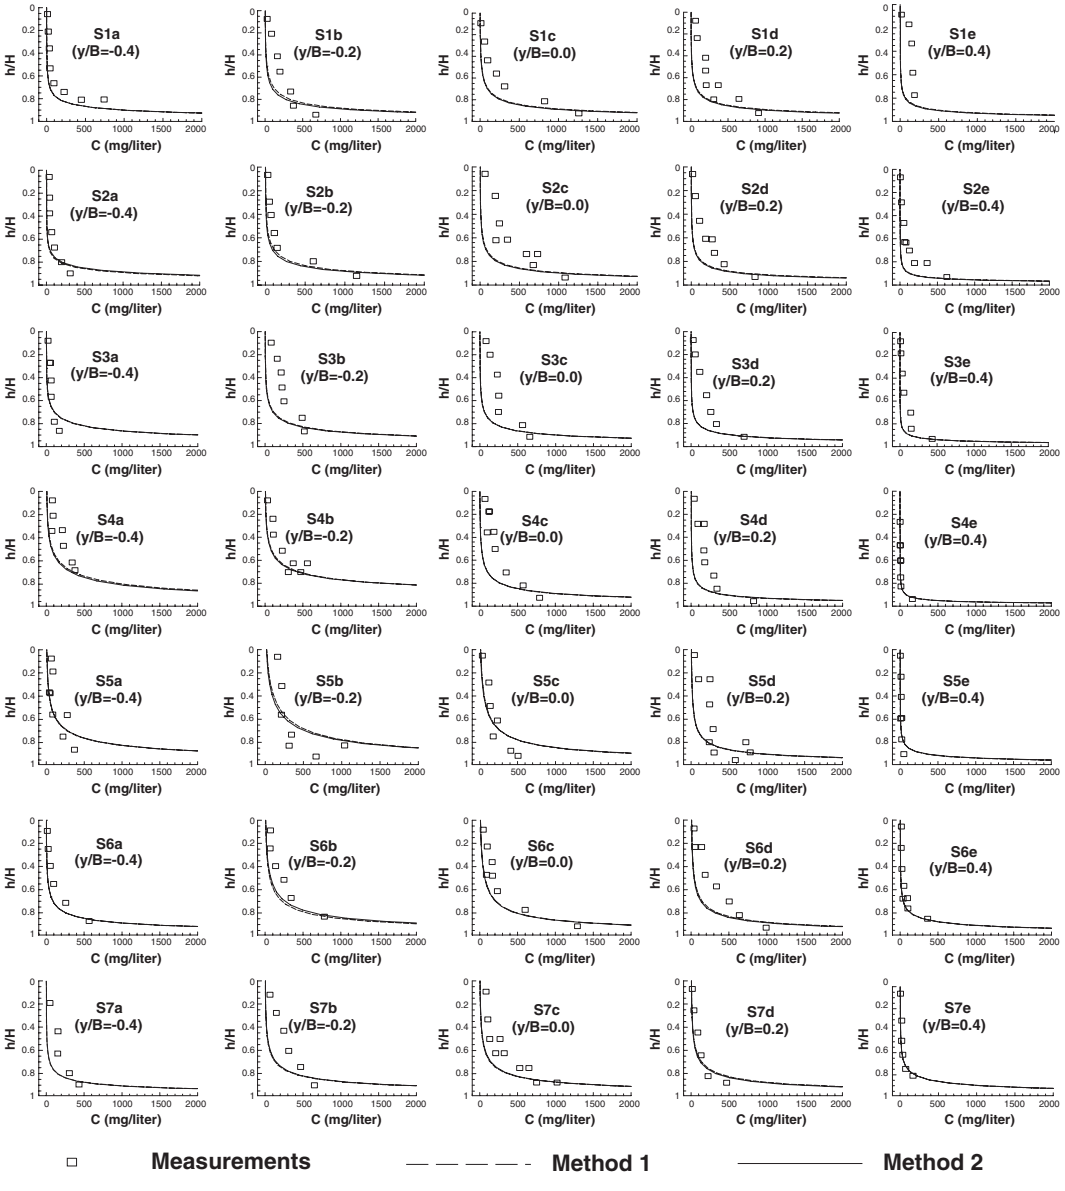

Figure 7. Comparison between predicted and measured suspended sediment concentration profiles at equilibrium conditions.

Copyright © 2006 Taylor & Francis Group plc, London, UK

measurements appear to have lots of scatter and sometimes show unphysical large values of the concentration near the free surface (e.g., see station S5b), so the error bar on the concentration measurements is probably quite high. Unfortunately, Onishi (1972) does not provide an estimation of the measurement errors. Quite probably, the bathymetry prediction errors reflect quite strongly into some of the observed errors in the prediction of the suspended sediment concentration throughout the channel. However, the important thing about the suspended sediment concentration field is that its prediction is accurate enough such that the net influx of sediment at the top of the bed layer is captured with sufficient accuracy such that the predictions of the bathymetry contours at equilibrium conditions are quite accurate.

4 CONCLUSIONS

A fully 3D non-hydrostatic model developed by Zeng et al. (2005a, 2005b, 2006) to predict the flow, free surface deformation, bed load and suspended sediment transport and bed morphology in open channels at equilibrium conditions was tested for the case of the flow in an S-shaped channel studied experimentally by Onishi (1972) in which the suspended sediment load was comparable to the bed load. Additionally, a new formulation of the model capable to account for bed slope gravitational force effects for both the suspended and the bed load components was proposed and tested for the same flow. Comparison of the simulation results with the experiments showed that though both formulations were able to predict reasonably well the bathymetry, streamwise velocity and suspended sediment concentration profiles, the new formulation was able to predict slightly more accurately the bathymetry in the deep regions of the scoured channel, where the original version of the model was found to predict too large bed-slope values. It is expected that the new formulation will be able to give even better predictions compared to the original one in cases in which very large water depth variations (or, equivalently large slopes, especially in the transverse direction) are observed at equilibrium conditions over small distances. Investigation of such a case is under way.

ACKNOWLEDGEMENTS

A PIV/PTV experiment on sediment transport in a horizontal open channel flow

W.A. Breugem & W.S.J. Uijttewaal
Environmental Fluid Mechanics Section, Delft University of Technology, The Netherlands

ABSTRACT: In this paper, sediment transport in a turbulent open channel flow is studied using a combined PIV-PTV technique. We introduced 350 μm polystyrene particles at three different streamwise locations near the free surface in a $Re = 10,000$ flow. It is shown that a distance of the order $h<u>/v_{rms}$ is needed for the sediment profile to become completely developed. At smaller distances, gradient diffusion modeling cannot be applied. In this situation, the downward transport of sediment is governed by sweeps with a vertical scale of the order of the water depth, whereas ejections are the main contributor to the upward flux of sediment in the fully developed situation. Because of this, the particle streamwise velocity is higher than the fluid velocity when the particles are still adapting, but lower than the fluid velocity in the fully developed situation. Some examples of instantaneous flow structures transporting the particles are shown.

1 INTRODUCTION

The transport of suspended sediment particles is important in geophysical problems as sand is transported in rivers and estuaries. It can as well be important for application in process engineering. Systematic experimental investigations on these processes date back at least half a century (Vanoni, 1946), but the limited understanding of turbulence and experimental difficulties have limited the amount of progress.

In recent years, a great deal of progress has been made in the experimental methods used to study particle laden flows. The use of equipment such as phase-Doppler-anemometry (PDA) and combinations of Particle Tracking Velocimetry (PTV) and Particle Image Velocimetry (PIV) has enabled researchers to determine the velocity of both sediment and fluid separately. These investigations (Kaftori *et al.*, 1995b; Best *et al.*, 1997; Muste & Patel, 1997; Kiger & Pan, 2002; Righetti & Romano, 2004; Nezu & Azuma, 2004; Muste *et al.*, 2005) show that the mean particle velocity is lower than the fluid velocity, which can be attributed to the preferential concentration of particles in regions of low fluid velocity. The only exception is the near-wall region, where particles are faster than the fluid, because they keep their higher velocity due to their inertia while descending in sweeps.

Less agreement exists on the fluctuating particle velocity. Both smaller wall-normal particle velocities were reported (Muste & Patel, 1997; Kiger & Pan, 2002) and larger ones (Kaftori *et al.*, 1995b; Best *et al.*, 1997; Righetti & Romano, 2004) when compared to the fluid wall-normal velocity fluctuations. The streamwise fluctuating particle velocity generally did not differ much from the fluctuating fluid velocity.

Measurements of the sediment concentration profiles, which determine the total sediment transport in combination with the mean sediment velocity, have not lead to identical conclusions. The lack of agreement concerned the Prandtl-Schmidt number β, a measure for the diffusion of sediment compared to streamwise momentum, which is used in analytical formulations for the sediment concentration profile such as the Rouse equation. It has been found to be both higher (Nezu & Azuma, 2004) and lower (Cellino & Graf, 1999) than one, whereas Muste *et al.* (2005) report both smaller and larger values for nylon and sand particles respectively. Nikora & Goring (2002) even found β to vary over the water depth.

From the above, it can be concluded that the knowledge on sediment laden flows is still limited and the experimental data that exist yield contradictory results. Furthermore, all these investigations were done in fully-developed situations, whereas in many practical applications, these conditions are rarely found.

The present paper aims at providing more insight into the mechanics of particle transport. Hereto, an experimental investigation of a particle laden flow in a open channel was performed. Both instantaneous fluid and particle velocities were measured with a combined PIV-PTV technique. Polystyrene particles with a diameter $d_p \approx 350\ \mu m$ were used as pseudosediment

Copyright © 2006 Taylor & Francis Group plc, London, UK

particles. Flow velocities and sediment were chosen such that a direct comparison to a Direct Numerical Simulation (DNS) with particle tracking (used by for example Uijttewaal & Oliemans (1996) for particles in a gas) is feasible. These simulations are currently being performed at the Kramers Laboratory of Delft University of Technology.

The sediment was fed to the flow near the free water surface at different distances from the measurement section, thus providing data on the development of a plume of sediment. This also gives some further insight in the the dispersion process, as the interesting situation arises that the flux due to gravity and turbulent diffusion work in the same direction, thus allowing us to find the turbulence structures that are important for dispersing the sediment.

2 EXPERIMENTAL SETUP

The experiments were performed in an open channel, with a length of 23.5 m a width of 0.495 m and a height of 0.50 m (Fig. 1). The walls and bottom were made of glass in order to have a hydraulically smooth boundary. The water was pumped from a buffer into the flume. At the downstream side, the water level was controlled with an adjustable weir, followed by three pipes allowing the water to return to the buffer. In order to perform the fluid velocity measurements, the water was seeded with 10 μm hollow glass spheres ($\rho = 1100\, kg/m^3$).

As pseudo-sediment, 347 μm ($\sigma = 45\, \mu m$) polystyrene particles were used, which had a density ρ_p of 1035 kg/m^3. We measured a terminal velocity v_T of 2.2 mm/s, which compares well with the theoretical estimate of 2.1 mm/s ($Re_p = v_T d_p/\nu_f = 0.71$). The particles were fed to the channel with a particle feeder that consisted of two vessels. In the first vessel ($V = 80\, l$), a mixer was used to mix the particles with the water, using baffles and a specially adapted bottom shape to obtain a homogeneous mixture. This sediment mixture was pumped into a second smaller vessel, from which it was led into the channel. The concentration of the mixture after it had left the mixing vessel was measured with an infrared turbidity meter (Oslim) with a sample frequency of 10 Hz, in order to check the stationarity of the concentration influx. In order to obtain a constant mixture discharge, the water level in the second vessel was held constant by letting the surplus flow in a third vessel from which the mixture was pumped back to the mixing vessel. The sediment mixture entered the channel through a nozzle with an inner diameter of 1 cm at the channel's centerline and its center located at 0.7 cm below the free surface. The inflow velocity was manually adjusted to the channel velocity. Preliminary tests, in which the mixture flowing from the nozzle was collected for a concentration measurement showed that no demixing occurred in the second vessel and that concentration of the mixture coming from the nozzle was constant and correlated well with the turbidity measurement. Downstream of the weir, the particles were collected in a filter.

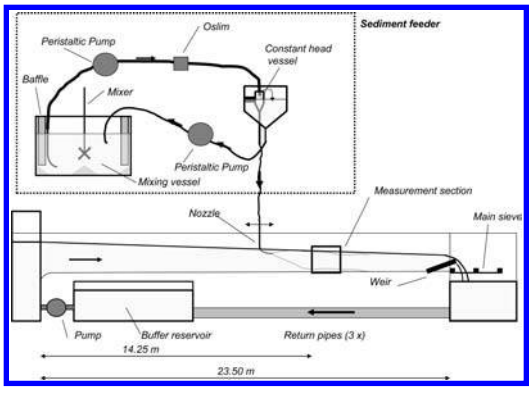

Figure 1. Experimental setup.

The measurement section was located at a distance of 14.25 m from the channel entrance. At this location, a combination of both PIV and PTV was used to measure the velocities of the polystyrene particles and the fluid. A 50 mW double pulsed laser was used to illuminate all particles in the measurement area. A light sheet was made with a cylindrical lens and two spherical lenses and its width was set to 1.0 mm with an adjustable slit. A 1 cm wide glass plate was put on the free surface in a streamlined device to let the laser light penetrate the free surface. Images were recorded with a Kodak Megaplus ES 1.0 $1008 \times 1018\, pix^2$, 15 Hz CCD camera with a 55 mm lens ($f\# = 2.8$). The time between the two image frames was set to 6.0 ms, resulting in particle displacements of about 25 pixel between two frames with the objective to increase the displacements of the relative motion above the experimental accuracy, which is of the order of 0.1 pixel for the algorithms used here. Note that the time between the frames is still significantly smaller than the Kolmogorov timescale (estimated at 50 ms), which means that the error made by approximating the particle movement as a straight line will be small. At the measurement section, a 1 cm wide strip of absorbing fluorescent paint was used in combination with an optical filter in front of the camera, to diminish laser light reflections from the bottom.

Three sets of experimental data were collected. All of these sets were measured at $Re = 10{,}000$ ($Re_* = 508$), which was obtained by setting the centerline velocity to 0.20 m/s and the water depth to 0.050 m. This velocity was chosen to ensure a sufficient amount of sediment in the water column ($u_*/v_T \approx 5$). The only variable that was changed between these sets was the position of the nozzle, which was placed at 80 cm, 175 cm and 375 cm from the measurement section,

Copyright © 2006 Taylor & Francis Group plc, London, UK

i.e. at $x_{in}/h = 16$, $x_{in}/h = 35$ and $x_{in}/h = 75$. During the measurements, it appeared that the discharge from the nozzle in the $x_{in}/h = 16$ case was somewhat lower than in the other cases. The volumetric sediment concentration in the mixing vessel was $1.2\,10^{-2}$. For each set, a sequence of 300 double images was recorded at 15 *Hz* and another sequence of 15×300 double images was recorded at 2 *Hz*. In this second series, the time interval between two velocity measurements (0.5 *s*) was significantly larger than the Eulerian integral timescale, estimated as $h/<u> \approx 0.25\,s$, which means that all velocity measurements in this set are approximately independent. Because of the large number of samples, the measurement period for a set was about one and half hour. Before and after the measurement, the water levels were measured at five different locations in order to check whether the flow was stationary. This showed a variance of less than 0.4% for the water levels at each location and a variance of 2.2% for the u_* determined from the water level slopes. The variance of the Oslim output was about 2% with a trend in the data of less than 3%/*h*, indicating that the sediment concentration that was introduced in the flume was approximately constant in time. For comparison, also four sets of 300 double images were recorded at a frame rate of 2 *Hz* for the flow in the channel, without the nozzle and any sediment input, which we will call the clear water flow (CWF).

The data were processed with a modified version of the method of Kiger & Pan (2000) to discriminate between sediment and tracer particles. This algorithm consists of the following steps.

1. The recorded image is filtered with a median filter with a filter size of 7 pixels. This eliminates the tracer as well as small scale noise from the image. From now on, the resulting image will be called the sediment image.
2. The sediment image is subtracted from the original image. This leads to an image of the tracers. However, some leftovers of the brightest sediment particles are clearly visible in this image.
3. A median filter with a filter width of 7 pixels is applied to the subtracted image in order to determine the location of the sediment particle leftovers and then subtracted from the result of the preceding step. The result is called the tracer image.
4. A PIV algorithm (LaVision, 2002) is applied to the tracer image with first a 64×64 window (50% overlap) and then two 32×32 window (75% overlap) iterations. The results are post-processed with a median filter to eliminate vectors that differ significantly from their neighbours. This leads to 126×126 vectors with distance of 0.37 *mm* (3.76 wall units) between each other. The number of good vectors was on average 98.7%, 93.2%, 95.4% and 95.8% for the respective cases: the clear water flow, $x_{in}/h = 75$, $x_{in}/h = 35$ and $x_{in}/h = 16$. Peak locking was found to be negligible as the histogram of the subpixel displacements did not show any peaks.
5. A PTV algorithm developed by Eindhoven University of Technology (van der Plas *et al.*, 2003) was applied to the sediment image. This algorithm uses the centroid of the particles to determine the particle velocities, where the mean velocity profile of the fluid from the PIV measurements was used as an initial guess for the particle velocities, with a maximal allowed deviation of 8 pixels. Particles on the edge of the measurement area are eliminated, because they generally result from the inability of the median filter to eliminate tracers at the edge of the image. A histogram of the subpixel displacements of the particles showed negligible bias to integer displacements (peaklocking).
6. Errors due to lens distortion were eliminated with a third-order polynomial fit to a picture of a calibration grid.

3 RESULTS

3.1 *Mean quantities*

The mean velocity profile in wall coordinates is shown in figure 2. The friction velocity $u_* = \sqrt{\tau/\rho}$ was determined by fitting the $<u'v'>$ profile in the clear water flow and it was found to be 1.02 *cm/s*. For comparison, the generally accepted law of the wall $u^+ = 1/\kappa\ ln(y^+) + A$ is plotted with $\kappa = 0.41$ and $A = 5.29$, as found by Nezu & Rodi (1986). Our data generally compares well with the law of the wall, but is slightly higher (with a maximum shift of $\pm 0.4\,u_+$). The boundary layer, which develops due to the small glass

on the water surface can clearly be seen. Its thickness agrees well with the Blasius estimate (as cited in Pope, 2000) $\delta/x \approx 4.9(U_0 x/\nu_f)^{-1/2}$, which gives a thickness of about 2.9–3.8 *mm* (0.06–0.08 *h*).

After the particles were injected, they formed a plume of sediment. Quite soon, the first particles started reaching the channel bottom, where they formed streaky structures similar to those observed previously by Rashidi *et al.* (1990); Kaftori *et al.* (1995a); Niño & García (1996); Kiger & Pan (2002).

The mean sediment concentrations are shown in figure 3. All statistics for the particle phase were interpolated on a grid, that was refined near the water surface, where the concentration gradient is largest (at least for the $x_{in}/h = 16$ case) and near the bottom, where the velocity and turbulence gradients were largest. In order to do so, the upper edge of the ith grid cell y_i was defined by:

$$y_i = \frac{h}{2}\left(\frac{tanh(1.7Z_i)}{tanh(1.7)} + 1\right); \qquad (1)$$

where h is the water depth and $Z_i = -1 + 2i/n$, n is the number of cells. The concentration was determined by counting the number of particles in each grid cell and dividing by the area of the grid cell. The concentrations were normalized with the concentration at $y/h = 0.072$, which is the lowest grid cell where dc/dy was negative as the increasing near-wall sediment concentration is presumably due to the removal of particles attached to the image edge in the data processing. Scaling the $x_{in}/h = 16$ case with a reference concentration near the wall was done for easy comparison with the other cases, but there are no physical reasons for doing so. For comparison, we plot the Rouse distribution:

$$\frac{c(y)}{c(y_0)} = \left(\frac{h-y}{y}\frac{y_0}{h-y_0}\right)^{\frac{w_T}{\beta\kappa u_*}} \qquad (2)$$

with $\beta = 0.7$, and $c(y_0)$ is the concentration at the reference height y_0.

At $x/h = 16$, the sediment is predominantly at the height where it was injected, but already at $x/h = 35$ a concentration profile has developed that is quite similar to the Rouse profile. This is unexpected, as the distance is much shorter than an adaptation length of say $L/h \approx <u>/v_T = 100$ (i.e. the distance a particle travels in the time it needs to settle to the bottom. The influence of the introduction of sediment is still clearly visible in all measured cases at $y/h > 0.8$ (the nozzle was at $0.8 < y/h < 1$).

That the conditions are indeed almost fully developed can be seen from the mean vertical velocity profile (Fig. 4). Note that because the fully developed situation ($x_{in}/h = 75$) is the reference to which we compare, we have placed this situation on the left in each figure. In the $x_{in}/h = 16$ case, the particles have a mean downward velocity of up to $0.5\,u_*$, whereas the vertical fluid velocities are zero up to experimental uncertainty, which for the discrete window shifting PIV algorithms is of the order of 0.1 pixel per frame ($0.08\,u_*$). In the $x_{in}/h = 35$ or 75 cases, the mean vertical particle velocity has reduced to zero too.

The velocity deficit profiles are shown in figure 5, where the centerline velocity Umax is the maximum velocity. We calculated the particle velocity statistics by averaging the velocities of all particles in a grid cell. In this way, concentration weighted statistics are obtained similarly to those used in two-fluid modeling (e.g. Drew, 1983; Simonin *et al.*, 1993; Enwald *et al.*, 1996).

At $x_{in}/h = 16$, the mean particle velocity is up to $0.25\,u_*$ faster than the mean fluid velocity, but in the course of development it decreases to a value that is $0.3\,u_*$ slower than the mean fluid velocity at $x_{in}/h = 75$, which compares well with previous investigations. This phenomenon can be explained by looking a bit deeper in two-fluid modeling theory. The momentum

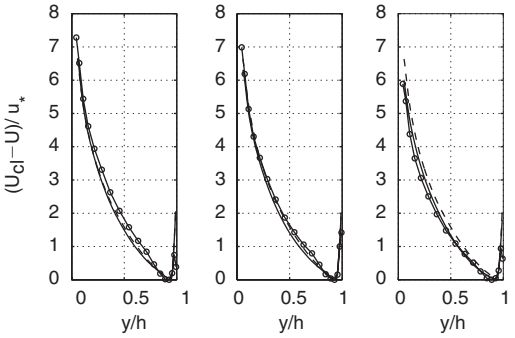

Figure 5. Velocity deficit profiles. Left: $x_{in}/h = 75$; Middle: $x_{in}/h = 35$; Right $x_{in}/h = 16$; Symbols as in figure 4.

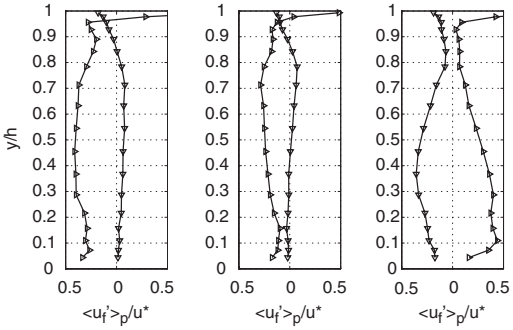

Figure 6. Drift velocity. Left: $x_{in}/h = 75$; Middle: $x_{in}/h = 35$; Right $x_{in}/h = 16$; – ▷ –: streamwise direction – ▽ –: wall normal direction.

equation in the i-direction for the particle phase is (with only Stokes drag working on the particles):

$$\frac{DC < u_{p,i} >_p}{Dt} = \underbrace{-\frac{\partial C < u'_{p,i} u'_{p,j} >_p}{\partial x_j}}_{\text{Particle Reynolds stress contribution}} + \underbrace{\frac{\rho_p - \rho_f}{\rho_p} g_i}_{\text{Buoyancy}} + \underbrace{\frac{C}{\tau_p} < u_{rel,i} >_p}_{\text{Stokes drag}} \quad (3)$$

where D/Dt is the time derivative in a frame moving with the mean particle velocity, τ_p is the particle time scale, C the ensemble averaged concentration, $u_{p,i}$ is the particle velocity, ρ_p and ρ_f the particle and fluid densities, and $<>_p$ and $<>_f$ denote ensemble averaging over the particle and fluid phase respectively. Simonin *et al.* (1993) found that the average of the relative velocity in the i-direction $<u_{rel,i}>_p$ in the drag term of equation 3 can be expressed as:

$$\begin{aligned} < u_{rel,i} >_p &= < u_{p,i} >_p - < u_f >_p \\ &= < u_p >_p - < u_f >_f - < u'_f >_p \end{aligned} \quad (4)$$

Note that $<u_{p,i}>_p$ (the particle velocity averaged over all particles) is equal to the flux of particles divided by the mean concentration. It is clear that the fluctuating fluid velocity seen by the particle $<u'_f>_p$ in principle does not need to be equal to zero. In a homogeneous, stationary situation, equation 3 for the vertical direction reduces to :

$$< u_{p,y} >_p = < u_{f,y} >_f + < u'_{f,y} >_p + \underbrace{\tau_p \frac{\rho_p - \rho_f}{\rho_p} g_y}_{=v_T} \quad (5)$$

Equation 5 physically means that the mean particle velocity (i.e. the flux per unit of concentration) is equal to the settling velocity added to mean vertical fluid velocity and the extra $<u'_f>_p$ term. Simonin *et al.* (1993) called $<u'_f>_p$ the drift velocity and used a gradient diffusion hypothesis for the closure of this term. In fact, the drift term is comparable to the $<c'v'>$ term in traditional advection-diffusion models.

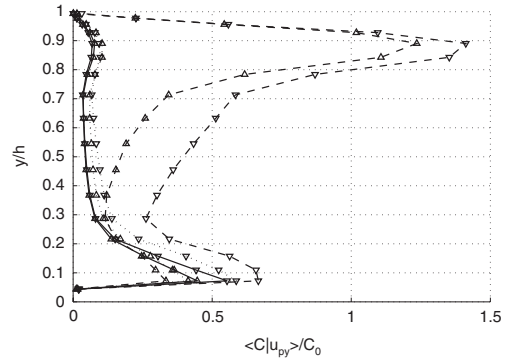

Figure 7. Conditionally averaged concentration profile. Conditioned on upward moving particles: (– △ –); Conditioned on downward moving particles: (– ▽ –). Dashed line: ($x_{in}/h = 16$); Dotted line: ($x_{in}/h = 35$); Solid line: ($x_{in} = 75$).

We determined the drift velocities from our measurements using bicubic interpolation to determine the fluid velocity on the particle location (Fig. 6). This figure clearly shows that at $x_{in}/h = 16$, the vertical fluid velocity seen by the particles is downward, which means that the particles are found more often in sweeps than in ejections, thus in fluid structures where the fluid velocity is higher than the mean streamwise velocity, which is also obvious from figure 6. This result in a larger number of particles moving down than up (Fig. 7). Rather interestingly, the absolute values of the drift velocity in both streamwise and wall normal directions increase in downward direction at

Copyright © 2006 Taylor & Francis Group plc, London, UK

least down to $y/h = 0.3$ for the $x_{in}/h = 16$ case. The explanation for this is that at this short distance, only particles which were in the strongest downward turbulence structures can reach the near wall locations, and therefore only those that have the largest vertical drift velocities. The streamwise velocities in these structures are those from high up in the flow, so they will deviate more from the mean flow here than nearer to the free surface. At $y/h = 0.3$, the concentration gradient changes sign, whereas the vertical drift velocity does not, although it decreases in magnitude. Simonin *et al.* (1993) uses a gradient diffusion hypothesis for modeling the drift velocity:

$$< u'_{f,y} >_p = \frac{-D_{yy}}{C} \frac{\partial C}{\partial y} \tag{6}$$

where D_{yy} is the diffusion coefficient. Using this equation would lead to negative diffusion coefficients for $y/h < 0.3$. Apparently, the sediment flux is still determined by sediment advected from near the free surface in turbulence structures with a vertical scale of the order of the water depth, and the effect of the locally negative concentration gradient (at $y/h < 0.3$) is to slow down the drift velocity, rather than to determine its direction.

An estimation of the Lagrangian integral timescale $T_L \approx L_E/u_{rms}$ (Hinze, 1975) (L_E is the Eulerian integral length scale, which scales with the water depth in the outer layer) gives $T_L \approx 5\,s$ and hence a distance of $<u>_b\, T_L = 1\,m = 20\,x_{in}/h$ would be needed for the long term diffusion in Taylor's (1921) diffusion theory to become completely applicable. For short distances, Taylor (1921) requires that the dispersion $<y'^2>$ scales with $<v'^2> t^2$, which means that the spreading is determined by an advective process. This coincides quite well with our measurements, as in the $x_{in}/h = 35$ case, a stationary situation has developed, where the mean vertical particle velocity is approximately zero. In the $x_{in}/h = 16$ case on the other hand, the situation such a stationary situation has not developed yet.

At $x_{in}/h = 75$, the vertical drift velocity has a value just above zero, but lower than the fall velocity, although according to equation 5, we would expect those to be equal. It is not clear whether our signal to noise ratio is not good enough to resolve velocities of the order of magnitude of the settling velocity or that equilibrium is still not reached and a larger vertical drift velocity still has to develop. For $y/h > 0.85$, the vertical drift velocity is still negative, suggesting that the clearly visible effect of the sediment injection are still present. The streamwise drift velocity in these cases are negative, indicating that the sediment has already started to be preferentially concentrated in ejections rather than in sweeps, which explains the mean streamwise velocity being lower for the particles than for the fluid. Note that the number of upward and downward moving particles in this case is equal except near the bottom (Fig. 7), which is in agreement with Kiger & Pan (2002).

3.2 *Turbulence characteristics*

The fluctuating fluid and particle velocities are shown in figure 8 and 9. Apart from the area affected by the sediment injection ($y/h > 0.8$), the streamwise fluctuating particle velocities do not differ much from the fluctuating fluid velocities, which was also found in previous investigations. In the $x_{in}/h = 35$ and 75 cases, the wall normal fluctuating velocities are slightly larger (5%) than the fluctuating fluid velocities for $0.3 < y/h < 0.8$, but they are substantially larger in the near wall region. In these fluctuations, the influence of the sediment introduction is also clearly visible. Note that particle velocity fluctuations that are larger than fluid velocity fluctuations are in agreement with the

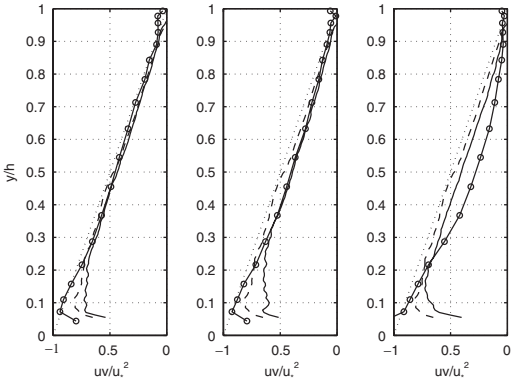

Figure 10. Reynolds stress profile. Mean flow profiles. Left: $x_{in}/h = 75$; Middle: $x_{in}/h = 35$; Right $x_{in}/h = 16$; Symbols as in figure 4.

experiments from Kaftori *et al.* (1995b), who used similar particles as we used, with those from Best *et al.* (1997) and those from Muste *et al.* (2005), but in contradiction with the theory (Hinze, 1975).

The fluid and particle Re-stresses are shown in figure 10. At $x_{in}/h = 16$, the particle Re-stresses are well below the fluid Re-stresses for $y/h > 0.2$ and they clearly do not follow a straight line. During the development to a stationary profile, the particle Restress profile increases and straightens until it becomes equal to the fluid Re-stress profile. The lower Re-stresses at $x_{in}/h = 16$ can possibly be explained by the fact that the particles in this stage are mainly found in sweeps, which although they occur during a larger fraction of time than ejections in the outer layer, their contribution to the Re-stresses is smaller (Nezu & Nakagawa, 1993). Apparently, this is not compensated by the fact that the particles are located in those sweeps that have the largest vertical velocities, especially near the bottom.

3.3 *Instantaneous flow structures*

In order to verify the conclusions that were drawn based on the statistical information obtained in the preceding paragraphs, we now inspect some instantaneous images of both particle and fluid velocity (Fig. 11 and 12) from the 15 *Hz* datasets. In these figures, we subtracted a constant velocity of 0.18 *m/s* (0.9 U_{max}) as was recommended by Adrian *et al.* (2000). This has the advantage compared to using a Reynolds decomposition, that the velocity gradients are not altered. Figure 11 shows an example of particles that are being entrained by a strong ejection, in the $x_{in}/h = 35$ case. Two hairpin vortex heads are visible, one downstream of the ejection rotating in the direction of the shear, and one upstream rotating opposite to the shear. Vortex heads rotating against the direction

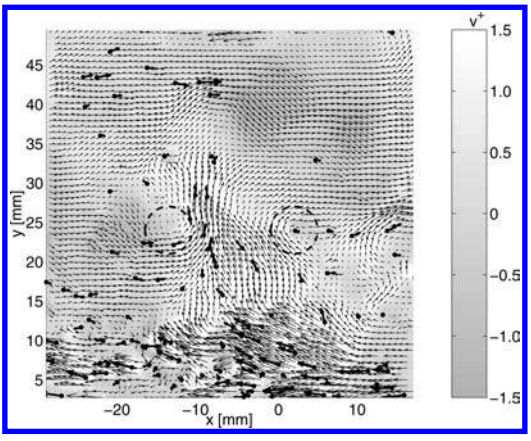

Figure 11. Example of an instantaneously measured flow structure in the $x_{in}/h = 35$ case. Fluid vectors are shown in dark gray, particles in black. Vertical velocities are indicated with gray background colors. Vortex heads are marked with a dashed circle.

of the shear are not rare events, although less common than those rotating in the direction of the shear (Portela, 1997). According to Adrian *et al.* (2001), these vortices originate from the merging of two hairpin vortices. The combined induction of both vortices explains why this is a rather extreme ejection, with a larger wall-normal than streamwise extend.

Although these violent ejections are rather sporadic, it does not automatically mean that they are not important, because a very intermittent character of the sediment fluxes has been noted by Hurther & Lemmin (2003) and Nikora & Goring (2002), who noted flatness factors of $c'v'$ of about 30 and more than 10 respectively (in contrast with 3 for a Gaussian distribution). Note that entrainment by somewhat weaker ejections is encountered frequently in these images.

By examining this ejection event in time (it was visible in four consecutive time frames), it was clearly visible how the structure advected through the measurement frame. The structure did not appear to change significantly during this 0.26 *s* ($O(0.1T_L)$), nor did it seem to move much upward. The particles on the other hand, could clearly be seen to move upward through the structure. This means that during the entrainment process, apparently a flux of sediment is caused by almost static flow structures. This is a clear contrast with the findings of Mutlu Sumer & Deigaard (1981) and Niño & García (1996), who suggest that the velocity structure is moving itself and taking the particles with them, until the flow structure looses coherence. Their explanation is presumably due the use of flow visualization to study the fluid structures as the dye advects in the same way as the sediment particles. Landahl (1993) estimated the viscous timescale T_v for convected disturbances

Copyright © 2006 Taylor & Francis Group plc, London, UK

to decay to be $T_v = (L^2/(v_f(d<u_f>/dy)^2)^{(1/3)}$, which gives timescales in the outer layer of 50–500 s, which is one to two orders of magnitude larger than our estimation of the Lagrangian timescale with $T_{L,i} \approx L_{E,i}/u_i'$ (Philip, 1967; Hinze, 1975). The latter time scale is a measure of how long it takes a particle to cross a structure of size $L_{E,i}$ with a characteristic velocity u_i', which is indeed what we saw happening in the entrainment process. If the structure itself would have moved vertically as well with a velocity of the order of magnitude of the fluid ejection had (and thus as the particles would have except for gravity), this would lead to significantly longer Langrangian time scales. Christensen & Adrian (2002) measured the acceleration of hairpin vortices in a turbulent channel flow and found that although the vortices move upward slowly, this movement is an order of magnitude smaller than the instantaneous vertical velocities.

The preceding compares with the frequent observation (e.g. Squires& Eaton, 1991) in homogeneous turbulence that the integral Eulerian time scale in a frame moving with the mean velocity is larger than the Lagrangian timescale (although not an order of magnitude). The integral time scale in this moving frame is then determined by a combination of the structures drifting away vertically and viscous decay. Yet, statistical data on the three different time scales in channel flow is very rare and it is especially not known how all three time scales vary over the depth. It might be possible that young hairpin vortices near the wall ascend faster, because of their stronger self induction. The DNS that is currently being performed might provide valuable insight into this.

In the $x_{in}/h = 16$ case, mainly sweeps are responsible for transporting the particles downwards. An example is shown in figure 12. The sweep apparently exists because of induction from the hairpin vortex in the lower left part. This explains why sweeps are weaker than ejections, as the latter structures are not only induced by the head of the hairpin vortex, but also by its neck and legs. The sweep can be seen to transport many particles downward, whereas the areas without vertical velocities low in the water column are almost void of particles. Following this structure (as well as others) confirmed that the flow structures moved only very slowly vertically, while the particles were moved through the structure, similar as was found for the ejections. In this case, similar strong ejections as in figure 12 did not result in large entrainment, just because at $x_{in}/h = 16$ less sediment particles were present in the low velocity layer from where the fluid was ejected, and thus decreasing the probability that a large ejection would transport much sediment upward, although some ejections with some particles were found near the bottom, thus explaining the increase of the vertical drift velocity toward zero for $y/h < 0.3$.

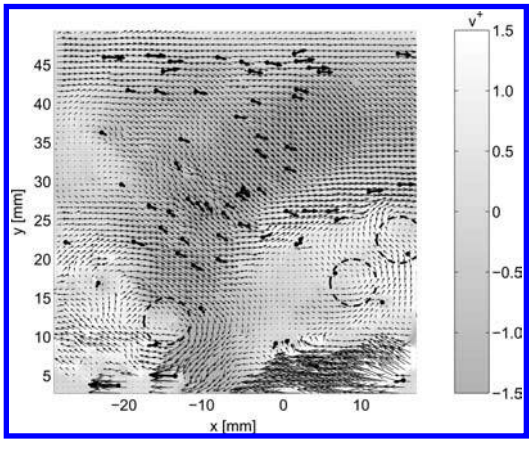

Figure 12. Example of an instantaneously measured flow structure in the $x_{in}/h = 16$ case. Symbols as in figure 11.

4 SUMMARY AND CONCLUSIONS

In this paper, an experiment was performed to measure both the fluid and sediment velocities with a combinated PIV-PTV technique in a turbulent open channel flow, using 350 μm polystyrene particles. The particles where introduced at three different locations upstream from the measurement area and near the free surface. It was found that already at $x_{in}/h = 35$, the sediment concentration developed into a shape similar to the Rouse profile, although the sediment's initial conditions remain visible for a significantly longer distance. After the profile has developed completely, the mean particle velocity is slower than the mean fluid velocity because the particles are found mainly in ejections. At $x_{in}/h = 16$, the sediment concentration has the highest values high in the water column. Here, the particles are found more often in downward going fluid structures (sweeps), which have a streamwise velocity higher than the mean fluid velocity causing the mean particle velocity to be faster than the fluid velocity. The dispersion process at this short distances is mainly affected by advection of sediment from above, rather than by turbulent diffusion and the use of a gradient diffusion hypothesis would lead to a negative eddy diffusion coefficient for $y/h < 0.3$. Note that this still not explains why particles concentrate in a particular turbulence structure.

For all cases, the streamwise fluid and particle turbulence profiles were found to be approximately equal, whereas the particle wall normal turbulence intensities were significantly larger than the fluid ones near the wall ($y/h < 0.3$), but just slightly larger for the outer region of the flow ($0.3 < y/h < 0.8$). In the $x_{in}/h = 16$ case, the particle Reynolds stresses are lower than fluid

Copyright © 2006 Taylor & Francis Group plc, London, UK

Re-stresses in the center of the flow, presumably due to the fact that the particles are located in sweeps, rather than ejections, the latter of which contribute more to the total Reynolds stresses.

Examples of instantaneous flow structures supported the estimation of the Lagrangian integral time scale with $T_l \sim L_E/v_{rms}$ (Hinze, 1975), which is vital for the determination of diffusion coefficients in Taylor's (1921) diffusion theory. Yet, a sound statistical basis is currently lacking as Lagrangian data, both from experiments and simulations, remains scarce. The DNS simulations in combination with particle tracking that are currently being performed at the Kramers Laboratory of Delft University of Technology can provided more insight in this matter.

The implications from this investigation are twofold. First of all, it shows that gradient diffusion modeling of sediment fluxes is especially awkward to predict sediment transport with a scale $L_p < O(h < u > /v_{rms})$. This scale was determined by estimating the distance traveled by the fluid in one Lagrangian time scale, estimated with $T_l \sim h/v_{rms}$. In these cases, it seems necessary to use more advanced models like transport equations for the drift velocity (Simonin *et al.*, 1993), which in the scalar case reduce to the Reynolds flux equations. Secondly, because the large scale turbulence structures, which proved to limit the utility of gradient diffusion models for short Lagrangian timescales, are also present in the fully developed cases, it seems necessary to include large scale transport in order to improve the current modeling of sediment concentrations in fully developed conditions. An example of a modeling approach that incorporates large scale transport processes is given by Nielsen & Teakle (2004).

ACKNOWLEDGEMENT

The financial support from STW, WL|Delft Hydraulics and KIWA Water Research is highly appreciated. We thank Synbra Technology in Etten-Leur for providing us the polystyrene particles.

Towards a Direct Numerical Simulation (DNS) of particle motion close to river beds

A.E. González & F.A. Bombardelli
Department of Civil & Environmental Engineering, University of California, Davis, CA, USA

Y. Niño
Department of Civil Engineering, University of Chile, Santiago, Chile

ABSTRACT: The Basset force that takes part in the momentum equations for a solid particle moving close to a wall can make the numerical solution of these equations computationally time consuming. Reductions of the computational cost of the Basset term are therefore strongly needed. In this paper, we present and discuss a methodology to deal with the difficulties associated with the Basset force. We use an approximation of the Basset term based on a semi-derivative (fractional mathematics), and we redefine the integration time of the term. These results constitute the first step of a larger project aimed at integrating fluid and particle motion close to a river bed using an Eulerian-Lagrangian approach.

1 INTRODUCTION

The prediction of particle motion close to a rigid or movable wall is an extremely complex task. Depending on the particle size and on flow conditions, particles may either move along the bed by rolling and saltating, or may "fly" in suspension relatively far from the boundary. Recent numerical simulations of sediment transport close to walls have satisfactorily estimated the global amount of material put into motion, and they have provided information on the characteristics of the particle trajectories (Sekine & Kikkawa (1992), Hu & Hui (1996), Niño & García (1998), Schmeeckle & Nelson (2003)). In these studies, the flow field has been specified via either the law of the wall (Niño & García (1998)) or measurements (Schmeeckle & Nelson (2003)).

Very recently, some authors have incorporated aspects of the two-phase flow theory in describing particle-laden flows for industrial applications. Generally speaking, particle-laden flows have been considered as a two-phase system in which the fluid and solid phases obey basic conservation laws coupled through interactions forces.

One of the forces in those two-phase models is the well known Basset force, which highly affects the motion of small particles (Sommerfeld (1992), Sommerfeld (2003), Portela & Oliemans. (2003), Ten Cate et al. (2004)). This force, which represents the "memory" of the particle, requires the calculation of the relative acceleration along the particle trajectory. Depending on the length of the simulation time, the computation of the Basset force could be extremely time consuming. In the event that numerous interacting particles are simulated, the inclusion of the Basset force may render the whole computation inviable. Therefore, any attempt to reduce the computational cost associated with this term will benefit the entire modeling effort.

Based on these ideas, in this paper we focus on methods to reduce the computation time of the Basset force. In section 2, we present the Lagrangian model to track the particles in a turbulent flow, and in section 3, we describe a new method to compute the Basset force (introduced by Tatom in 1988; to the best of our knowledge, not put to work until now), which is based on semi-derivatives. In section 4, we describe a new strategy to evaluate the integration time for the Basset integral. Finally, we discuss the results in section 5.

Our results are relevant for the development of numerical models which integrate fluid and particle motion close to river beds, using Eulerian- Lagrangian approaches.

2 EQUATIONS FOR SEDIMENT PARTICLE SALTATION IN A TURBULENT BOUNDARY LAYER

One of the most recent and complete forms of the governing equations for the motion of a small spherical particle in an unbounded fluid (within the Stokes drag

Copyright © 2006 Taylor & Francis Group plc, London, UK

range) was presented by Mei et al. (1991), based on the equations proposed earlier by Maxey & Riley (1983). The ith component of these equations can be written as:

$$\rho_s\left(\frac{dU_{pi}}{dt}\right)=g_i(\rho_s-\rho)-\frac{18}{d_p^2}\left(U_{pi}-U_{fi}-\frac{1}{24}d_p^2\nabla^2U_{fi}\right)+$$
$$+\frac{9}{d_p}\left(\frac{\rho\mu}{\pi}\right)^{1/2}\int_0^t\frac{d}{d\tau}\left(U_{fi}-U_{pi}+\frac{1}{24}d_p^2\nabla^2U_{fi}\right)\frac{d\tau}{\sqrt{t-\tau}}+$$
$$+\rho C_m\frac{d}{dt}\left(U_{fi}-U_{pi}+\frac{1}{24}d_p^2\nabla^2U_{fi}\right)+\rho\frac{DU_{fi}}{Dt} \qquad (1)$$

where ρ and ρ_s denote fluid and particle density respectively, U_p and U_f indicate the instantaneous particle and fluid velocity, respectively, μ denotes the dynamic viscosity, C_m refers to the added mass coefficient, d_p indicates the particle diameter, g is the acceleration of gravity, t denotes time and τ is a dummy variable for integration. The terms on the right hand side of (1) correspond to the following forces per unit volume: buoyancy, Stokes drag, Basset history force, and forces due to added mass and fluid acceleration, respectively. The operator D(·)/Dt indicates the material derivative using the fluid velocity in the advective term, as opposed to the particle velocity employed in d(·)/dt.

Niño & García (1994) modified the previous expression to consider large particles in a turbulent flow; this turbulent flow was characterized by the log-law expression for the time-averaged velocity. They averaged the velocities over turbulence, neglected second order terms and added lift and Magnus effects on the particle acceleration (González (2006)). They also modified the expression for the drag force to be able to simulate cases of larger Reynolds numbers. Expressions (2) and (3) below provide the dimensionless equations developed by Niño & García to calculate the streamwise and vertical particle velocities (u_p and v_p, respectively), considering the particle diameter as a length scale and the shear velocity u^* as a velocity scale.

$$\frac{du_p}{dt}=\alpha\frac{\sin\theta}{\tau_*}-\frac{3}{4}\alpha C_D\left(u_p-u_f\right)\left|u_r\right|+\alpha C_m v_p\frac{du_f}{dy}$$
$$+\frac{9\alpha}{\sqrt{\pi R_p}\tau_*^{1/4}}\int_0^t\frac{d}{d\tau}\left(u_f-u_p\right)\frac{d\tau}{\sqrt{t-\tau}} \qquad (2)$$

$$\frac{dv_p}{dt}=-\alpha\frac{\cos\theta}{\tau_*}-\frac{3}{4}\alpha C_D v_p\left|u_r\right|+\frac{3}{4}\alpha C_L\left(\left|u_r\right|_T^2-\left|u_r\right|_B^2\right)-$$
$$-\frac{9\alpha}{\sqrt{\pi R_p}\tau_*^{1/4}}\int_0^t\frac{d}{d\tau}v_p\frac{d\tau}{\sqrt{t-\tau}}+\frac{3}{4}\alpha\left|u_r\right|\left(S-\frac{1}{2}\frac{du_f}{dy}\right) \qquad (3)$$

In these equations C_D and C_L denote the drag and lift coefficients, respectively, u_r, u_{rT} and u_{rB} are the relative velocity at the center, top and bottom of the particle, respectively, α is defined as $(1+R+C_m)^{-1}$, R is defined as $(\rho_s/\rho-1)$, τ^* is given by u^{*2}/gRd_p, R_p is given by $(R\,g\,d_p^3)^{0.5}/\nu$ and S is defined as $\Omega\,d_p/u^*$, where Ω is the particle angular velocity. Mathematically, this is an initial-value problem for which initial conditions are needed. After computing the velocities, the positions of the particles are determined by simple integration.

These equations govern the "flight" time between rebounds of the particle against the wall. In fact, gravity acts against turbulence fluctuations and pull the particles downwards. To simulate the rebound against the wall, we employed a stochastic model, following Niño & García (1994). The model assumes a bed formed by uniformly-packed spheres and it computes the particle velocity after the collision by considering coefficients of restitution and friction in addition to the particle velocity immediately before the collision. The angle of contact of the incoming particle and the particle at the bed is treated as a random variable (González (2006)).

Niño & García (1994, 1998) compared the results provided by their saltation model with their own experimental observations, obtaining a good agreement.

3 BASSET FORCE COMPUTATION

The particle trajectory equations presented can be easily integrated using the standard fourth-order Runge-Kutta method. However, the Basset term presents extra difficulties because the denominator in the integrand vanishes when the upper integration limit is enforced. Therefore it is necessary to devise a method to circumvent this problem.

Niño & García (1994) employed a method first suggested by Brush et al. (1964) that consists in dividing this integral in two terms (see Equation 4 below).

$$\int_0^T\frac{\frac{du_{ri}}{dt}}{\sqrt{T-t}}dt=\int_0^{T-\delta t}\frac{\frac{du_{ri}}{dt}}{\sqrt{T-t}}dt+2\sqrt{\delta t}\left(u_j\frac{du_{fi}}{dx_j}-\frac{du_{pi}}{dt}\right) \qquad (4)$$

Tatom (1988) in turn proposed to approximate this term using the Riemman-Liouville integral definition of a semi-derivative. The Basset term is calculated as follows:

$$\int_0^T\frac{\frac{du_r}{dt}}{\sqrt{T-t}}dt=\Gamma\left(\frac{1}{2}\right)\frac{d^{-0.5}\left(\frac{du_r}{dt}\right)}{dt^{-0.5}} \qquad (5)$$

where $\Gamma(\cdot)$ represents the gamma function (Abramowitz & Stegun, 1970). For a general function f(x), the

Copyright © 2006 Taylor & Francis Group plc, London, UK

semi-derivative is calculated using an infinite series, as proposed by Oldham & Spanier (1974):

$$\frac{d^q f}{dx^q} = \lim_{N\to\infty}\left\{\left(\frac{x}{N}\right)^{-q}\frac{1}{\Gamma(-q)}\sum_{k=0}^{N-1}\frac{\Gamma(k-q)}{\Gamma(k+1)}f\left(x-\frac{k\,x}{N}\right)\right\} \quad (6)$$

where q is an arbitrary value. In this case the value of q is equal to -0.5. We have adopted this last methodology in our work with the objective of reducing the computational cost of the Basset term. To the best of our knowledge, this way of computing the Basset term has not been incorporated into particle models so far.

To check the accuracy of this method, a test case was adopted. We picked the following arbitrary function $f(x) = x^3/3$, and we calculated the Basset integral both numerically and analytically. The analytical solution for this expression is given by:

$$\int_0^T \frac{\frac{df(t)}{dt}}{\sqrt{T-t}}dt = \int_0^T \frac{\frac{dt^3}{3dt}}{\sqrt{T-t}}dt = \frac{16}{15}T^{2.5} \quad (7)$$

For an arbitrary value of T equal to 100, the Basset integral presents a value equal to 106,034. This value was considered as a reference value, for error calculations, as follows.

The numerical approximation of the Basset integral depends on the number of terms (N) used in the sum in (6). The value of N was varied between 5 and 50,000 in order to analyze the accuracy of this approximation. The results of the numerical integration of the test function f(t) using the expression (5) are presented in Figure 1. We defined the relative error as the relative difference between the numerical integration and the value obtained from the analytical expression. As expected, the error associated with the numerical approximation decreases as the number of terms (N) increases. A value of N equal to 1,000 appears to be reasonably large for obtaining accurate results. However, the application of this parameter in the particle tracking code must be carefully studied. For a long simulation time, the value of the parameter N could be unmanageable and other strategies should be considered.

The results obtained using the approximation of the Basset term as a semi-derivative were compared with results obtained using the approximation proposed by Brush et al. (1964). Figure 2 shows the relative difference in the calculation of the Basset integral using both methods. The results were obtained for a single particle jump considering $R_p = 53$ and $\tau^* = 0.056$. The results show that the percentage of error between both approximations is less than the 3%. A large portion of this small difference is attributed to the fact that we are comparing the semi-derivative approximation with the first term in Brush et al.'s method (Eq. 4).

Figures 3 and 4 show results in terms of jump length and height. The relative error between both

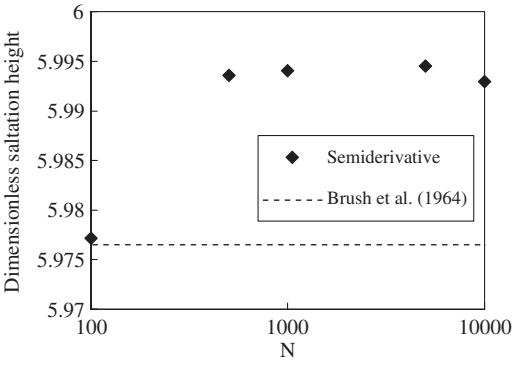

Figure 4. Dimensionless jump height as computed using the semi-derivative method and Brush et al.'s (1964) method. $R_p = 53$. $\tau_* = 0.056$.

approximations is less than 0.5%, which indicates a very good agreement between both methods. In addition to providing a close estimate to the Basset force, this methodology reduces the computational time by 20% as compared with the Brush et al.'s method. (In these computations, the forces of buoyancy, virtual mass, drag and Basset were considered.)

4 MEMORY TIME PERIOD IN THE BASSET FORCE

The integral associated with the Basset force must be performed, by definition, between the beginning of times and the current time of the computation. The integration of the particle relative acceleration along the simulation time requires a large storage capacity that could eventually make the simulation inviable. Since it can be assumed that the collision of the particle with the wall may likely eliminate correlation between velocities in jumps separated by long distances, it seems reasonable to consider that only the most recent events influence the current particle velocity (see Mei (1990)). It is thus reasonable to assume that the effect produced by far away events with respect to the current particle velocity could be disregarded.

Considering the previous argument, a new Basset integral definition is proposed. The approximation of this term is given by the following expression:

$$\int_0^T \frac{\frac{du_{ri}}{dt}}{\sqrt{T-t}}\,dt \approx \int_{T-T_{back}}^{T} \frac{\frac{du_{ri}}{dt}}{\sqrt{T-t}}\,dt \qquad (8)$$

where T_{back} represents the time interval where the history of the particle affects the current particle velocity. There is no formal definition for T_{back}; however this "memory time period" should be related to certain particle time scales and/or flow characteristic times.

The behavior of particles is controlled by the particle time scale τ_p – particle relaxation time- which, from the steady state balance between inertia and the linear Stokes drag, is defined as:

$$\tau_p = \frac{\rho_s d^2}{18\nu} \qquad (9)$$

Large particle characteristic times are associated with large particle sizes and denote large particle inertia (large particles require a large amount of time to modify its trajectory under any flow change). On the other hand, small particle time scales (associated with small particles) indicate that the particle rapidly changes its trajectory under a change of flow conditions.

In order to define a flow characteristic time, it is necessary to study the flow structures that may affect the particle trajectory close to a boundary. The term coherent structure is used to represent a spatial flow pattern that remains identifiable for some period of time, such us ejection and sweep motions. Experiments with sediment particles by Niño & García (1996) indicated that these structures maintain their identity for as long as 60 to 80 wall time units, and extend vertically a distance of about 100 wall units. Using dimensional analysis, a flow characteristic time is defined herein using these concepts:

$$\tau_f = 80\frac{u_*^2}{\nu} \qquad (10)$$

To define the value of T_{back}, two methods are proposed, as explained below.

Model 1

The memory time T_{back} is obtained by choosing the biggest value between the particle relaxation time and the flow characteristic time, and then multiplying it by a factor C.

Model 2

An alternative definition for T_{back} can be obtained by considering the memory time in terms of a number of previous jumps. If N_{back} is the number of jumps considered in the computation of the Basset term, the value of T_{back} is defined from the beginning of the N_{back}^{th} jump.

In order to compare the results obtained from both approximations to T_{back}, the code was run using the semi-derivative approximation for the Basset force for a simulation time equal to 1,000 non dimensional units. In this case only drag, virtual mass, Basset and buoyancy terms were considered. Values for $R_p = 100$ and $\tau_* = 0.056$ were used. Initial conditions for both models were identical. Both approximations are compared in terms of average particle jump height and

Copyright © 2006 Taylor & Francis Group plc, London, UK

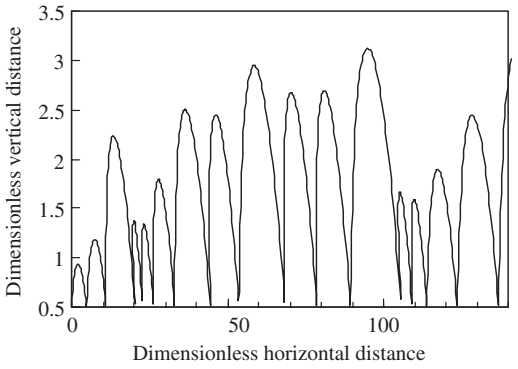

Figure 5. Simulated succession of saltations. $R_p = 100$. $\tau_* = 0.056$.

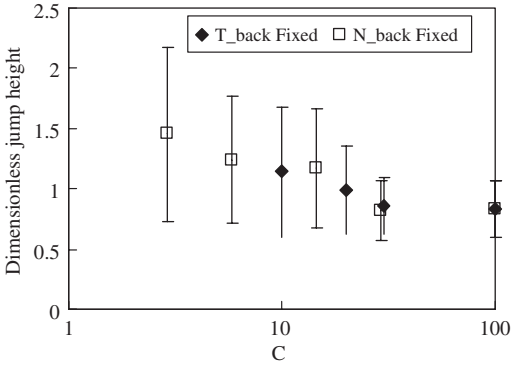

Figure 6. Comparison of the average jump height computed using the semi-derivative approximation for the Basset force. Multiple jumps (stochastic collisions). $R_p = 100$. $\tau_* = 0.056$.

length. These 1,000 time units are equivalent for these flow conditions to approximately 50 particle jumps. In order to compare both results, the results obtained from the second model are presented in terms of an equivalent value of the factor C. The stochastic collision model causes the height and length of each jump to be different, such that statistically- meaningful parameters can be obtained, as it is observed in Figure 5.

Figures 6 and 7 present the results obtained in terms of average jump length and height respectively. The intervals denote the range of jump heights or lengths. The number of times that the particle/flow time is considered in the Basset integral is given by C. We notice that fixing a number of particle or fluid time scales (whichever is larger) gives similar results than using a number of previous steps, clearly indicating that there is a loss of correlation between current and previous jumps. The value of C equal to 100 represents the computation of the Basset term from the beginning of the particle movement (T-T_{back} equal to 0).

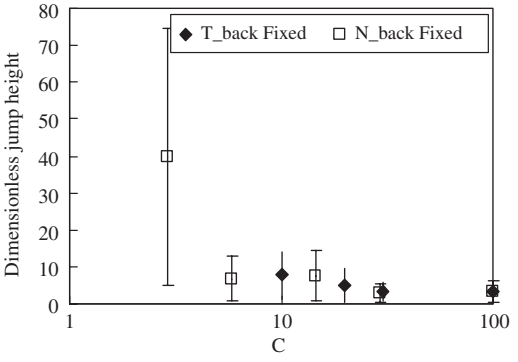

Figure 7. Comparison of the average jump length computed using the semi-derivative approximation for the Basset force. Multiple jumps (stochastic collisions). $R_p = 100$. $\tau_* = 0.056$.

5 FURTHER RESULTS

In order to have a better definition of the necessary number of previous jumps to be considered in the Basset term, a series of additional simulations were performed, covering a wider range of values of R_p and τ^*.

Vojir & Michaelides (1994), Niño & García (1996), Mordant & Pinton (2000), Armenio & Fiorotto (2001) have shown the importance of the Basset force in the definition of the trajectory of small particles. Considering the particle characteristics used by these authors in their analysis, we considered very small particle sizes and flow velocity between 0.07 and 0.5 m/s in our simulations. Electro- chemical forces, that are present in the case of very small particles, have been left outside of the analysis for this paper.

We decided to run the program for a long simulation time (1,000 dimensionless time units) in order to have a significantly large number of jumps to study, independent of the initial conditions of the particle. A *reference* simulation was defined (i.e., calculating the Basset integral from the beginning of the particle motion) which was represented with a value of N_{back} equivalent to 500. The reference simulation provides the value of the Basset integral classically defined, as the integration of the whole particle history. Simulations using values of N_{back} equal to 100, 50, 25, 10 and 5 were compared with the reference simulation to analyze the influence of this parameter in the precision of the Basset integral.

For each parameter of study (particle velocity and jump length and height), we specified an interval consisting of one deviation standard with respect to the average value of the reference simulation (drawn as dashed horizontal lines in each figure). This interval helps to determine the degree of departure of the Basset integral computed with a limited number

Copyright © 2006 Taylor & Francis Group plc, London, UK

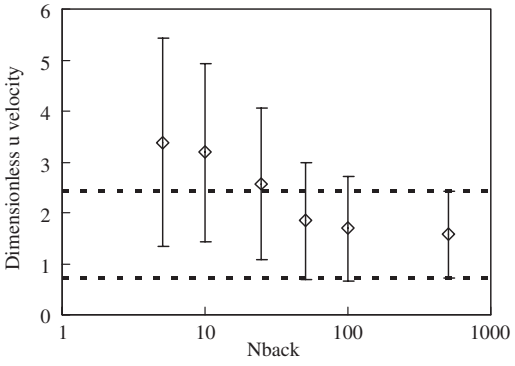

Figure 8. Average dimensionless horizontal velocity u vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.056$.

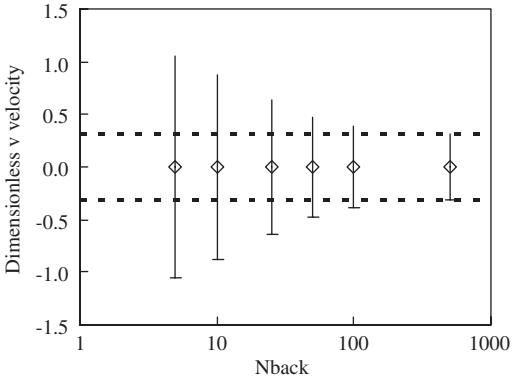

Figure 9. Average dimensionless vertical velocity v vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.056$.

of previous jumps, as compared with the reference simulation.

To analyze how the value of N_{back} affects value of the Basset integral, the following criterion was established: if the average value of the parameter to study lie inside of the interval defined by the reference simulation (dashed lines) then the value of N_{back} affects the value of the Basset integral little. Therefore, we are interested in defining the minimum value of N_{back} that affects little the value of Basset integral in order to reduce the computation time of the simulation under different particle and flow conditions. Three different simulations were performed, as it is described below.

5.1 *First run*

The first run was performed using a value of R_p equal to 100 and a value of τ_* equal to 0.056. The results are presented in Figures 8 to 11. In each figure, the dotted lines represent the reference range.

Figure 8 shows that for a value of N_{back} equal to 25 the average horizontal velocity is outside of the

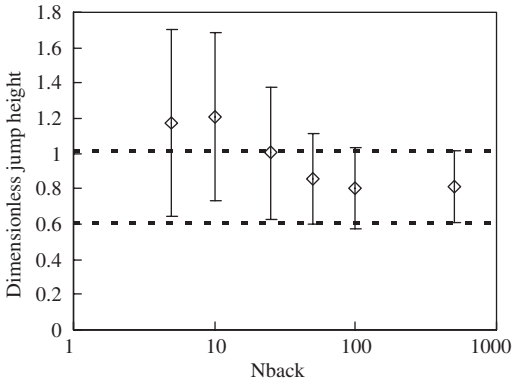

Figure 10. Average jump height vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.056$.

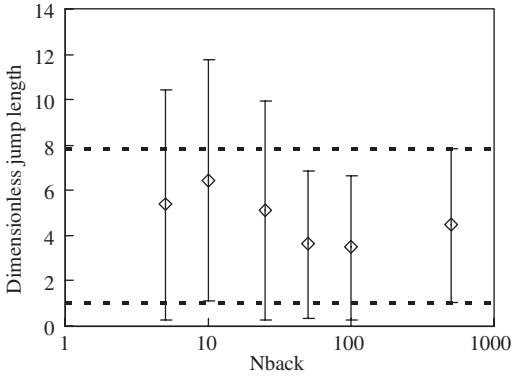

Figure 11. Average jump length vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.056$.

reference interval. However, all the remaining figures show that for N_{back} equal to 25 the average parameter value is inside this interval. Therefore a values of N_{back} equal to 50 or 75 particle jumps seems appropriate under these conditions.

Another important result is obtained from this simulation: the computational time is reduced in approximately 70% of the original simulation time using a reduced integration time.

5.2 *Second run*

The second run was performed using a value of Rp equal to 100 and a value of τ_* equal to 0.28. Even though the simulation time is large, the total number of jumps obtained for the reference simulation is only 22. The results are presented in Figure 12.

Results depicted in Figure 12 show that for a value of N_{back} equal to 5 the average jump length lays outside the reference interval. It seems that a more appropriate

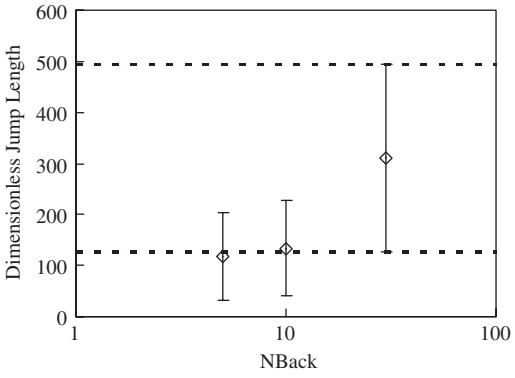

Figure 12. Average jump length vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.28$.

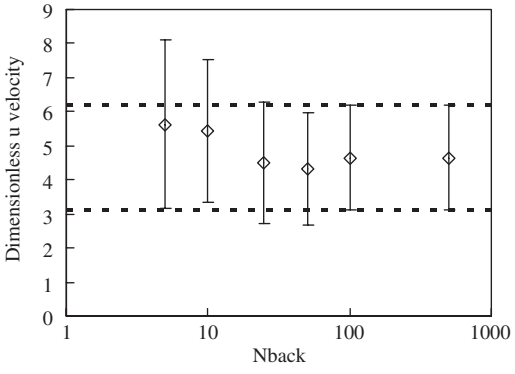

Figure 13. Average dimensionless horizontal velocity u vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.11$.

value for N_{back} is 10; however the number of jumps simulated does not allow for a conclusive result.

5.3 *Third run*

The third and last run was performed using a value of R_p equal to 100 and a value of τ_* equal to 0.11. The results are presented in Figures 13 to 16.

In Figures 13 to 16, for all the parameters studied, the reference range is large enough to contain all the values of N_{back} evaluated. However, selecting a number of jumps between 10 and 25, it is possible to argue that a satisfactory compromise between computing time reduction and representation of the integral (the physics of the problem) has been achieved.

5.4 *Time reduction*

The simulation time directly depends on the value of N_{back} selected for each simulation: the smaller the value of N_{back}, the smaller the simulation time is.

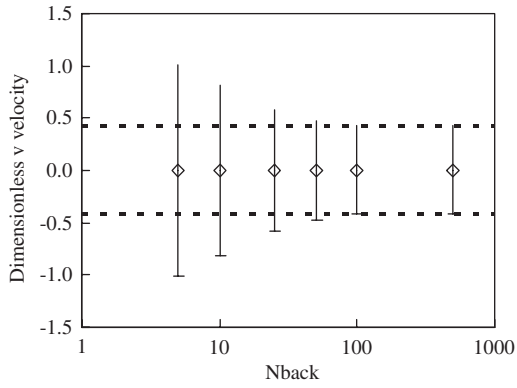

Figure 14. Average dimensionless vertical velocity v vs. number of jumps in the past (N_{back}). $R_p = 100$. $\tau_* = 0.11$.

6 CONCLUSIONS

Computations of particle trajectories in fluids are in general relatively affordable using Lagrangian approaches. However, these calculations could be very time consuming due to the Basset integral, which considers the contribution of the particle history. This term has a relatively large importance for small particles. In this paper we have discussed an alternative to minimize its computational time. The use of a semi-derivative approximation to calculate the Basset integral was found to reduce the computational time by 30%. In addition, this method is simple to implement and it does not require any assumption on the velocity flow field.

In order to reduce further the computational time, we have proposed to reduce the integration time considered in the Basset integral. It has been assumed that only events occurring to the particle in the proximities of the current time are relevant. The concept of T_{back}, the memory time period, has been introduced, i.e., the interval of time where the history of the particle affects the current particle movement.

Two different approaches were devised: to calculate T_{back} considering a fluid-particle characteristic time or considering a determined number of previous jumps in the particle trajectory.

In order to study the minimum number of jumps that affects little the value of the Basset integral, three different simulations were performed. The simulations were performed considering a small particle size (under flow conditions equivalent to 0.07–0.5 m/s).

We concluded that the minimum number of past jumps to be considered in the Basset term varies between 25 and 50, depending on flow conditions. Very importantly, the approximation of the Basset force using the T_{back} concept reduces the computational time of the code, between 70 to 90 percent of the original simulation time.

The results obtained in this paper provide important information for the development of numerical models for particle motion close to the river beds, which is the long term goal of our project.

Modelling sorting over the lee face of individual bed forms

Astrid Blom
University of Twente, Water Engineering & Management, The Netherlands

Maarten G. Kleinhans
University of Utrecht, Fac. Geosciences, Dept. Physical Geography, The Netherlands

ABSTRACT: River dunes, alternate bars, and subaqueous deltas are often characterised by a lee face at about the angle of repose. Transport of mixed-size sediment over the crest of such a bed form results in grain size-selective deposition of particles over the lee face. The complex interaction between two different deposition mechanisms, i.e. grain fall from suspension and grain flows at nearly the angle of repose, results in coarse particles preferentially depositing at the lower elevations of the lee face, and fine particles at the upper ones. In this study we develop a simple empirical model describing the sorting of particles over the lee face of a bed form. This lee face sorting model is calibrated and verified on data from flume experiments with deltas and dunes. Field data of lee face sorting over dunes in an ebb-tide dominated mouth bar of the river Teign, UK, are used to validate the model. The lee face sorting model describes the grain size-selective deposition over a lee face well, although the model does not reproduce the deposition of fines from suspended load which slightly modifies the sorting by producing a fine deposit at the base of the bed forms.

1 INTRODUCTION

Migrating river dunes composed of mixed sediment are characterised by various types of sediment fluxes (Kleinhans 2002, Blom et al. 2003): (1) deposition of particles over the lee face; (2) the formation of coarse bed layers underneath migrating dunes; (3) the winnowing of fines from the trough surface and subsurface; and (4) vertical sediment fluxes due to the variability in bed form trough elevations. This paper focusses on the first mechanism, viz. the deposition process on the lee side of individual bed forms and the sediment sorting therein. Erosion of sediment from the stoss side and deposition of the eroded sediment on the lee side make a dune migrate downstream. In dunes and bars, sediment is commonly sorted over the lee face in an upward fining manner (e.g. Bagnold 1941, Allen 1965, Kleinhans 2004). This macroscopic sorting results from various microscopic sorting processes.

First, sediment settles from the bed load and suspended sediment in the flow expansion downstream of the brinkpoint (Fig. 1). Most of the sediment deposits just downstream of the brinkpoint but a smaller amount, notably the finer grades, settle further downstream (Jopling 1965, Jopling 1967). This sediment may be preserved as a toe or bottomset. In this settling process, the deposit is fining in the downstream direction and consequently along the lee slope of the dunes. The grain fall process continues to build up a wedge on the lee side of the dune until the static angle of repose is reached.

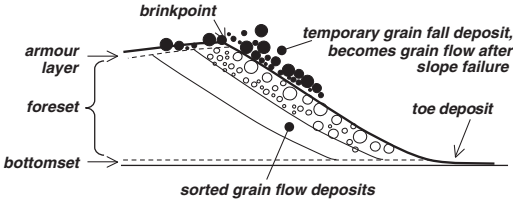

Figure 1. Sorting and definitions in dune deposits. The stoss side of the dune is eroded. The eroded sediment is deposited just downstream of the brinkpoint until the slope fails and the grains flow down the slope and becomes sorted. The toe deposit from settled suspended sediment is sometimes preserved as a bottomset.

Second, when the static angle of repose is exceeded, the slope fails and the remobilised sediment avalanches down the slope as a grain flow (Allen 1965, Hunter and Kocurek 1986). During the grain flows on the lee side, the sediment is sorted such that the larger grains deposit further down the lee slope and smaller grains deposit near the top of the dunes. In subaqueous dunes, mostly the grain flow deposits are preserved

Copyright © 2006 Taylor & Francis Group plc, London, UK

(Kleinhans 2004), so the sorting in grain flows determines the sorting in dunes. This process is only indirectly affected by the flow conditions; it is mostly a process of slope failure of a noncohesive sediment.

When the grain flow commences, kinematic sieving takes place. The mixture dilates because the grains vibrate in the motion. The smaller grains percolate downwards through the increased pores of the dilated mixture. In this process the larger grains are pushed upwards. So, the sorting is coarsening-upwards in the incipient grain flow (Kleinhans 2005). Next, the large grains roll further down the slope than the small grains, because large grains on a bed of small grains roll much more easily than small grains on a bed of large grains (Makse 1997). Hence, the fine sediment of the incipient grain flow deposits near the top of the dune, whereas the coarse sediment deposits further down the slope (Kleinhans 2005).

Experiments with sediment mixtures deposited as laboratory deltas[1] demonstrate that the sorting process can be very efficient: almost no coarse sediment is deposited near the top and almost no fine sediment is deposited near the bottom, except the sediment mixed in from the grain fall. This was found for both well- and poorly sorted mixtures (Kleinhans 2005). Sometimes grain flows do not travel down the whole lee slope at once, but subsequent grain flows re-entrain this sediment and continue the sorting process. Also, protruding large grains from the previous grain flow are dragged down the slope by the next grain flow, which further increases the vertical sorting efficiency (Kleinhans 2005).

A model describing the grain size-selective deposition over the lee face of individual dunes is particularly useful as part of a new type of sediment continuity model for rivers dominated by dunes and sediment mixtures (Blom and Parker 2004, Blom et al. 2006). In a morphodynamic river model, such a sediment continuity model describes the interaction among grain size-selective sediment transport, sorting processes and changes in mean bed level. Hirano (1971) was the first to develop a sediment continuity model for sediment mixtures. Parker et al. (2000) made a step forward by developing a sediment continuity model based on a probability density function of active bed surface elevations rather than discrete and homogeneous bed layers. Blom and Parker (2004) and Blom et al. (2006) have extended the Parker et al.

Blom and Parker (2004) propose a simple empirical model describing the grain size-selective deposition over the lee face of individual dunes. The formulation by itself was not properly calibrated and validated, as Blom et al. (2006) calibrate the complete sediment continuity model, including the sub-model of lee face sorting, upon data from a small number of flume experiments. Although the lee face sorting model acted reasonably well for these flume experiments, the model appeared to behave problematically for situations in which the sediment mixture becomes uniform. Kleinhans (2005) proposes a simple empirical model describing the variation of the arithmetic mean grain size down the lee face of individual bed forms. Yet this model does not satisfy the laws of mass conservation of the various grain size fractions in the mixture. This paper presents an improvement to the Blom et al. (2006) lee face sorting model, which is based on a relatively large set of data on sorting over lee faces of individual bed forms.

2 PARAMETER DEFINITIONS

This section lists the main parameters and definitions used in the present paper. We use the same notation as used by Blom and Parker (2004). The quantity $F_{leeloci}$ denotes the volume fraction content of size fraction i in the sediment deposited at elevation z at the bed form lee face. As we assume the density of the grains not to depend on grain size, grain size distributions based on volume fractions are equal to the measured grain size distributions by weight. The lee sorting function w_i determines to what extent a specific size fraction that is transported over the bedform crest is deposited at a certain elevation of the lee face and is defined as

$$\omega_i = F_{leeloci}/F_{leei} \tag{1}$$

where F_{leei} denotes the volume fraction content of size fraction i in the lee deposit.

A first constraint to the lee sorting function is that integration of the composition of the deposited sediment over the lee face, $F_{leeloci}$, must result in the composition of the lee face deposit, F_{leei}:

$$F_{leei} = \frac{1}{\Delta}\int_{\eta_b}^{\eta_t} F_{leeloci}\, dz \tag{2}$$

where Δ, η_b, and η_t denote bed form height, bed form trough elevation, and bed form crest elevation, respectively. Two other constraints are

$$\sum_i^N F_{leeloci} = 1 \qquad 0 \le F_{leeloci} \le 1 \tag{3}$$

where N denotes the number of grain size fractions. Equation (3) expresses that, at each bed elevation, the total volume fraction content of all size fractions must equal unity and the volume fraction content of each size fraction must be larger than or equal to zero and smaller than or equal to unity.

[1] A delta is here defined as a slope at about the angle of repose over which sediment is deposited when the water depth suddenly and largely increases, due to, for instance, a river flowing into a deep lake or ocean. (2000) sediment continuity model to conditions dominated by dunes.

Based on earlier analyses of measured sorting profiles (Kleinhans 2004, Kleinhans 2005, and Blom et al. 2003) and following the approach by Blom and Parker (2004), we assume that a size fraction is deposited over this uniformly sloped lee face with its volume fraction content *decreasing or increasing linearly with elevation*, and propose the following form for the lee sorting function, ω_i:

$$\omega_i = (1 + \delta_i z^*) \tag{4}$$

where z^* is a dimensionless vertical co-ordinate relative to the average elevation of the lee face:

$$z^* = (z - \eta_a)/\Delta \tag{5}$$

where η_a denotes mean bed level. By definition, for triangular dunes $z^* = -1/2$ at the lower limit of the lee face and $z^* = 1/2$ at the upper limit of the lee face. The lee sorting parameter δ_i depends on grain size, and Equations (1) and (4) show that it is defined as:

$$\delta_i = \frac{d\omega_i}{dz^*} = \frac{1}{F_{leei}} \frac{dF_{leeloci}}{dz^*} \tag{6}$$

It can be found that (1) together with (4) indeed meets the constraint in (2).

Another important parameter is the arithmetic mean grain size of the lee deposit, ϕ_{mlee}:

$$\phi_{mlee} = \sum_i^N \phi_i F_{leei} \tag{7}$$

where ϕ_i denotes the grain size of size fraction i on ϕ-scale[2]:

$$\phi_i = -^2\log\left(\frac{d_i}{d_{ref}}\right) \tag{8}$$

[2] Equation (8) equals the conventional manner in which the arithmetic mean grain size is calculated. Yet this is the mathematically correct notation, as logarithms cannot be taken of nondimensionless parameters. As a result, the arithmetic grain size (ϕ) is correctly dimensionless.

where d_i denotes grain size, and in which the reference grain size d_{ref} equals 1 mm. The arithmetic standard deviation of the lee deposit, σ_a, and the dimensionless bed shear stress, τ^*, are defined by, respectively

$$\sigma_a^2 = \sum_i^N (\phi_i - \phi_{mlee})^2 F_{leei} \tag{9}$$

$$\tau^* = \tau / [(\rho_s - \rho) g d_{mlee}] \tag{10}$$

where the geometric mean grain size of the lee deposit, d_{mlee}, is given by

$$d_{mlee} = d_{ref}\, 2^{-\phi_{mlee}} \tag{11}$$

and where the bed shear stress, τ, is determined from

$$\tau = \rho\, g\, a\, s \tag{12}$$

where a denotes water depth and s energy slope. Note that in case of the laboratory deltas (Kleinhans 2005, Termes 1986), the shear stress is based on the water depth and energy slope just upstream from the delta face.

3 FLUME AND FIELD DATA

Table 1 lists the data sets applied in the calibration, verification, and validation of the lee face sorting model. The 'Klein05a', 'Klein05b', and 'Termes86' data sets consider sorting over the lee faces of laboratory deltas, while the other data sets consider sorting over the lee faces of dunes. In the data sets natural sediment mixtures are used, except for the 'Klein05b' and 'Blom03a' data sets. All experiments were dominated by bed load transport. The amount of suspended load transport was negligible (data set 'Blom03a', see Blom et al., 2003) to very limited (other data sets).

For all lee faces in the data sets listed in Table 1, Figure 2 shows the following parameters: (1) the geometric mean grain size of the lee deposit, d_{mlee}; (2) the

Copyright © 2006 Taylor & Francis Group plc, London, UK

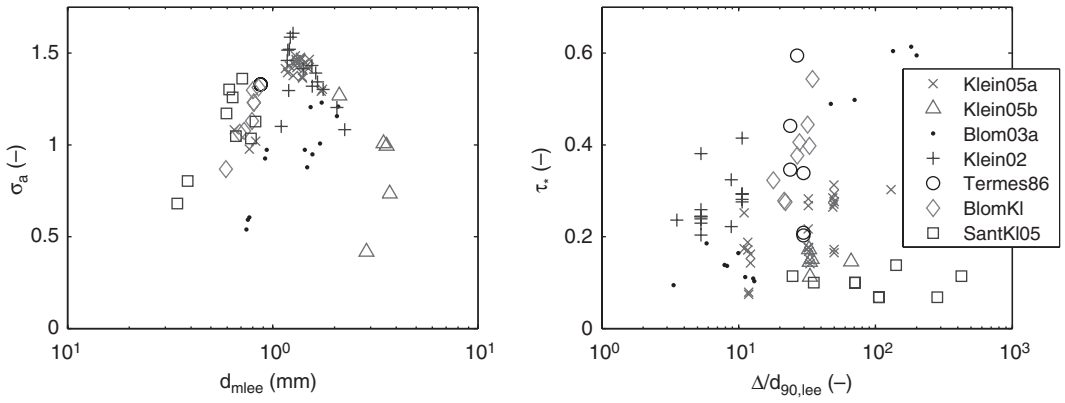

Figure 2. (a) Relation between the geometric mean grain size of the lee deposit, d_{mlee}, and the arithmetic standard deviation of the lee deposit, σ_a. (b) Relation between the ratio of bed form height, Δ, to the d_{90lee} of the lee deposit and the dimensionless shear stress, τ^*. The data sets are listed in Table 1. Each data point denotes one lee face.

arithmetic standard deviation of the lee deposit, σ_a; (3) the ratio of bed form height, Δ, to the d_{90} of the lee deposit[3]; and (4) the dimensionless shear stress, τ^*. For a detailed description of the data sets, we refer to the publications listed in Table 1.

4 MODEL FOR LEE FACE SORTING

In this section we propose a new empirical model for lee face sorting.We now define the relative grain size, ϕ_{rel}, which indicates the difference in the arithmetic grain size of size fraction i and the arithmetic mean grain size of the lee deposit:

$$\phi_{rel} = \phi_i - \phi_{mlee} \tag{13}$$

Figure 3 shows the relation between the relative grain size, ϕ_{rel}, and the lee face sorting parameter, δ_i, for the experimental data used in the calibration phase. The figure confirms that if the grain size on ϕ-scale of size fraction i, ϕ_i, is smaller than the arithmetic mean grain size of the lee deposit ($\phi_i < \phi_{mlee}$), the lee face sorting parameter, δ_i, is negative. In other words, if size fraction i is coarser than the geometric mean grain size of the lee deposit, the size fraction shows a preference to be deposited at the lower elevations of the lee face. The figure also shows that a size fraction finer than the geometric mean grain size of the lee deposit ($\phi_i > \phi_{mlee}$) shows a preference for the upper elevations of the lee face.

Note that for values of the relative grain size larger than unity the scatter is relatively large. This seems to be partly due to the larger probability of these size fractions being deposited from grain fall forming a fine

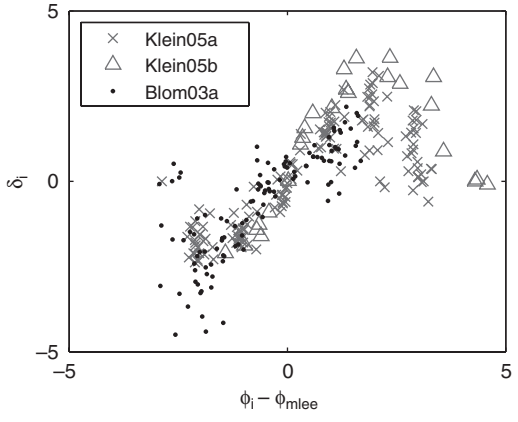

Figure 3. Relation between the relative grain size, ϕ_{rel}, and the lee sorting parameter, δ_i, for the experimental data used in the calibration phase.

toe set, which significantly influences the sorting trend of the size fractions over the lee face. Figure 3 shows that, if the grain size of a size fraction becomes equal to the geometric mean grain size of the lee deposit ($\phi_i = \phi_{mlee}$), the lee face sorting parameter, δ_i, equals about zero, which means that the sorting of this size fraction over the lee face is negligible. In other words, the size fraction will be deposited over the lee face uniformly.

To find out whether the parameter δ_i/ϕ_{rel} is influenced by other factors, Figure 4 shows its relation with (a) the dimensionless shear stress, τ^*, and (b) the arithmetic standard deviation of the lee deposit, σ_a. Although there is experimental evidence that the sorting trend becomes smaller with increasing shear stress due to capture of suspended sediment (Allen 1965, Kleinhans 2005), this does not cause a significant

[3] The d_x denotes the grain size for which x% of the sediment mixture is finer.

Copyright © 2006 Taylor & Francis Group plc, London, UK

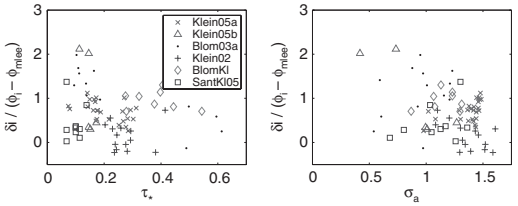

Figure 4. Lack of relation between the ratio of the lee sorting parameter, σ_i, to the relative grain size, ϕ_{rel}, and (a) the dimensionless shear stress, τ^*, and (b) the arithmetic standard deviation of the lee deposit, σ_a, for all data sets listed in Table 1 except 'Termes86'. Here each data point denotes one lee face.

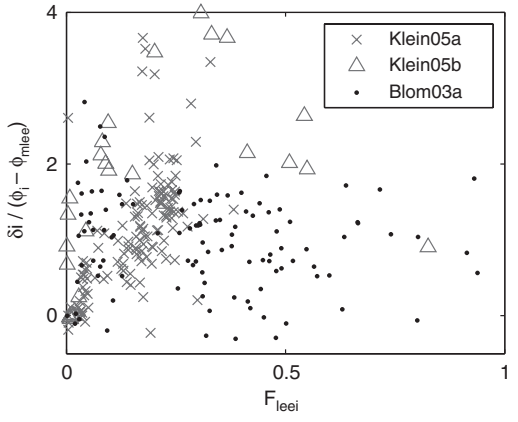

Figure 5. Relation between the ratio of the lee sorting parameter, δ_i, to the relative grain size, ϕ_{rel}, and the volume fraction content of the size fraction in the lee deposit, F_{leei}, for the experimental data used in the calibration phase.

deviation of the general sorting trend (Figure 4a). We therefore neglect the dependency of the lee sorting parameter on shear stress. Figure 4b shows that the arithmetic standard deviation of the lee deposit, σ_a, does not have a clear effect on lee face sorting.

Figure 5 shows the relation between the ratio between the lee sorting parameter δ_i and ϕ_{rel} and the volume fraction content of the size fraction in the lee deposit, F_{leei}. It appears that, besides its effect on the arithmetic mean grain size of the lee deposit (see Eq. (7)), F_{leei} affects lee face sorting also in another way: the ratio of δ_i to ϕ_{rel} appears to approach zero when F_{leei} approaches zero (Fig. 5). This can be understood as follows. If F_{leei} of size fraction i approaches zero, the preference of this size fraction for either upper or lower elevations of the lee face must decrease to zero. In other words, the size fraction will be distributed over elevations uniformly. Otherwise the volume fraction content of this size fraction in the deposit at elevation z^*, $F_{leeloci}$, may become smaller than zero, which is

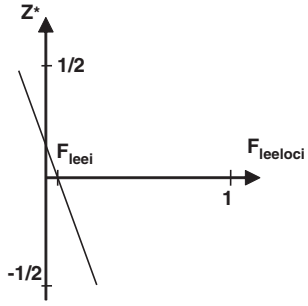

Figure 6. Physically unrealistic variation of the volume fraction content of size fraction i in the lee face deposit at elevation z^**, $F_{leeloci}$, for a relatively coarse size fraction for which the volume fraction content of the size fraction in the lee deposit, F_{leei}, approaches zero. This illustrates the fact that the lee sorting parameter, δ_i, should approach zero when F_{leei} approaches zero.

physically unrealistic. The latter situation is presented in Figure 6.

Summarizing, we have the following requirements for the new lee face sorting model:

- The relation between the lee sorting parameter, δ_i, and the relative grain size, ϕ_{rel}, seems to be more or less linear.
- If the grain size of size fraction i equals the arithmetic mean grain size ($\phi_i = \phi_{mlee}$), then δ_i should approach zero.
- For the range of data considered here, no obvious relation is observed between the lee sorting parameter, δ_i, and bed form height, Δ, between δ_i and the dimensionless shear stress, τ_*, and between δ_i and the standard deviation of the mixture, σ_a.
- If the mixture becomes uniform ($F_{leei} = 1$ and $\phi_i = \phi_{mlee}$.), then δ_i should approach zero.
- If the volume fraction of size fraction i in the lee deposit approaches zero ($F_{leei} = 0$), then δ_i should approach zero.

We now propose the following model for the lee sorting parameter, δ_i, which fulfills the above requirements:

$$\delta_i = a\, F_{leei}^{b}\, (\phi_i - \phi_{mlee'}) \tag{14}$$

In order to have (14) fulfill the constraint given by (3a), an 'adapted' arithmetic mean grain size of the lee deposit, $\phi_{mlee}0$, now needs to be defined:

$$\phi_{mlee'} = \frac{\sum_i^N \phi_i F_{leei}^{(1+b)}}{\sum_i^N F_{leei}^{(1+b)}} \tag{15}$$

As in the next few sections we will compare predictions by the new lee face sorting model to predictions

Copyright © 2006 Taylor & Francis Group plc, London, UK

by the model by Blom et al. (2006), we show their definition of the lee face sorting parameter:

$$\delta_i = \gamma \frac{\phi_i - \phi_{mlee}}{\sigma_a} (\tau_b^*)^{-\kappa} \quad (16)$$

where $\gamma = 0.3$ and $\kappa = 0.5$. The constant γ weights the relative importance of the grain-size term on the right-hand side of (16), while the value of $\cdot$ sets the relative importance of the dimensionless bed shear stress term.

5 MODEL CALIBRATION

For the model predictions, the volume fraction content of size fractions transported over the bed form crest, F_{leei}, is used as input and is determined from the measured sorting profile over the lee face, $F_{leeloci}$, according to (2). For the experimental data used in the calibration phase, we have derived a best fit of Equation (14) for $a = 2.1$ and $b = 0.43$. Now Figure 7 shows the relation between the measured values for the lee sorting parameter δ_i according to (6) and predicted values for δ_i, for the experimental data used in the calibration phase. In the left-hand plot δ_i is predicted according to the lee face sorting model by Blom et al. (2006) (Eq. (16)), and in the right-hand plot according to the new model (Eqs. (14) and (15)). Note that optimal predictions would result in the relation represented by the line.

The mean prediction error e of both models is calculated from:

$$e = 1/M \sum_{1}^{M} \sqrt{((\delta_{i,meas} - \delta_{i,calc})^2)} \quad (17)$$

where M denotes the number of data points. For the Blom et al. (2006) model the mean prediction error e equals 0.91, while for the new model the mean prediction error equals 0.73, which means a significant improvement of the present model with respect to the one by Blom et al. (2006). Note that the predicted sorting of the natural mixtures (data set 'Klein05a') agrees somewhat better with the measured data than the artificial mixtures (data sets 'Klein05b' and 'Blom03a').

Figures 8, 9, and 10 shows the predicted sorting profiles (lines) together with the measured ones (symbols), for a selection of lee sides from the data sets 'Klein05a', 'Klein05b', and 'Blom03a', respectively. The model shows fine results for the natural mixtures in Figure 8, while for the artificial mixtures in Figure 9 the predicted sorting is somewhat smaller than the measured one. The model shows reasonable results for the artificial tri-modal mixtures in Figure 10.

6 MODEL VERIFICATION

Figure 11 shows the relation between the the measured values for the lee sorting parameter δ_i according to (6) and predicted values for δ_i, for the experimental data used in the verification phase (data sets 'Klein02' and 'BlomKl'). Data set 'Termes86' is not included in Figure 11, as measured volume fraction contents of size fractions over the lee faces are not available. Therefore measured values for δ_i cannot be determined.We can see that for data set 'BlomKl' the predicted sorting improves with respect to the model by Blom et al. (2006), while for data set 'Klein02' the predicted sorting is too strong and worse with respect to the model by Blom et al. (2006). The latter is perhaps due to the fact that the height of the dune faces was relatively small with respect to the d_{90} (also see Fig. 2b). In other words, the lee face height was only a few of

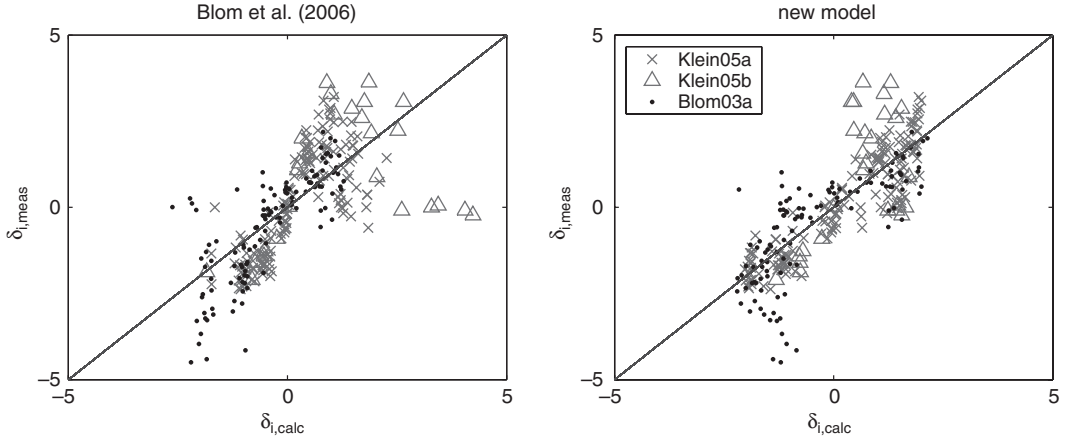

Figure 7. Relation between the predicted and measured values for the lee sorting parameter, δ_i, for the experimental data used in the calibration phase.

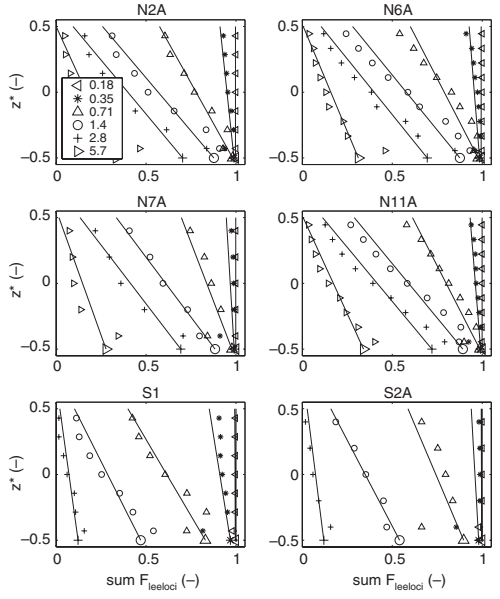

Figure 8. Volume fraction contents of grain size fractions deposited down lee faces of laboratory deltas composed of natural mixtures; selection from data set 'Klein05a' (Kleinhans, 2005). Measured volume fraction contents are indicated by the symbols and computed ones by the lines. The large marker at the lower limit of a line indicates the specific geometric grain size, which is shown in the legend (in mm). The volume fraction content of a specific size fraction is indicated by the difference between two lines or two types of symbols. For instance, the volume fraction content of the 2.8 mm fraction is indicated by the difference between the crosses and the triangles pointing right.

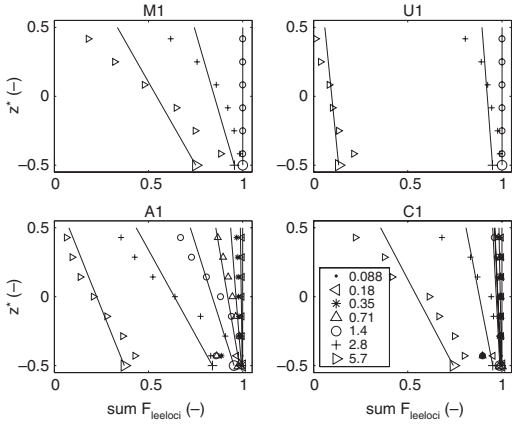

Figure 9. Volume fraction contents of grain size fractions deposited down lee faces of laboratory deltas composed of artificial mixtures; selection from data set 'Klein05b' (Kleinhans, 2005). For explanation of the figure, see the caption of Figure 8.

the d_{90} grains high, which decreased the effectivity of the sorting process.

For the flume experiments conducted by Termes (1986) on sorting down laboratory delta faces, only data on the variation of the d_{10}, d_{50}, and d_{90} over the lee face was available. For the model prediction, the composition of the lee deposit, F_{leei}, was assumed equal to sediment fed at the upstream end of the flume. Figure 12 shows the predicted and measured values for d_{10}, d_{50}, and d_{90} over the lee face. Although the delta height varied between the experiments, the measured data is plotted in a single figure, as dune height does not significantly affect the predicted sorting profile. The predicted sorting profile does not vary between the experiments. For data set 'BlomKl', Figure 13 shows that the measured sorting of size fractions is not always linear. Yet the predicted sorting profiles shows reasonable agreement with the data. For data

set 'Klein02', the predicted sorting is much stronger than the measured one (Fig. 14).

7 MODEL VALIDATION

Data from an ebb-tide dominated mouth bar of the river Teign at Teignmouth, UK (Van Santen and Kleinhans 2005) is used to validate the model (Fig. 15). Although the measured deposition of grain sizes does not always show a linear trend with lee face elevation, the results are quite satisfactory.

8 DISCUSSION

The proposed lee face sorting model (Eqs. (1), (4), and (14)) describes sorting due to grain flows. It

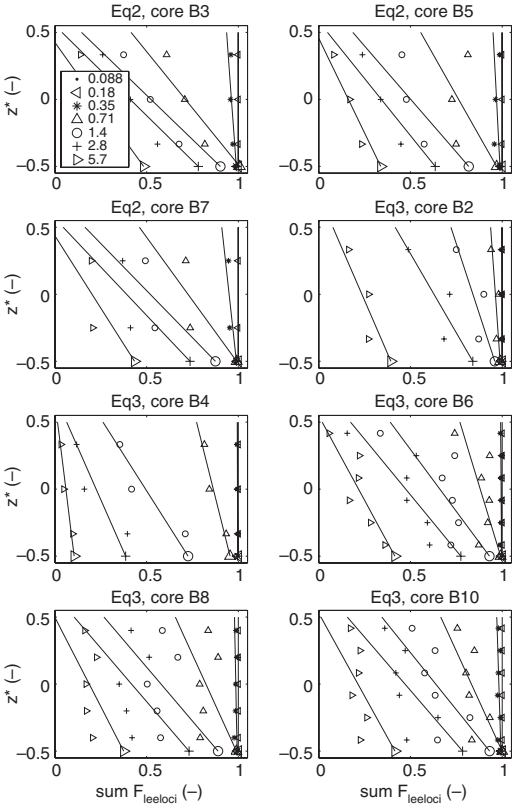

Figure 14. Volume fraction contents of grain size fractions deposited down lee faces of laboratory dunes; selection from data set 'Klein02' (Kleinhans, 2002). For explanation of the figure, see the caption of Figure 8.

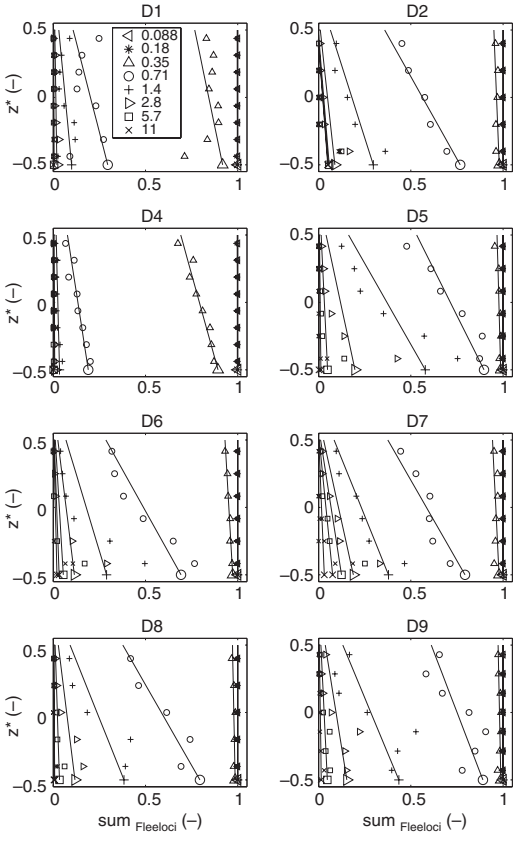

Figure 15. Volume fraction contents of grain size fractions deposited down the ebb-tide dominated mouth bar of the river Teign; selection from data set 'SantKl05' (Van Santen and Kleinhans, 2005). For explanation of the figure, see the caption of Figure 8.

essentially predicts that the sediment is sorted linearly and as efficiently as possible. Of the coarsest sediment, almost nothing is deposited near the top and and a maximum amount near the bottom of the dune, while its deposition rate over the lee face decreases almost linearly with elevation. For the finest finest sediment passing the bed form crest the opposite is valid, as observed most clearly in the deltas of the 'Klein05a' runs (Figs. 8. This efficient sorting breaks down when the grain flow process breaks down. On one end of the spectrum, the grain flow ceases to occur on lee faces with a height smaller than a few times the largest grains, where a lee slope at the angle of repose is difficult to observe anyway. Consequently, in very low dunes and bed-load sheets the sorting is less than perfectly efficient, as observed in the 'Klein02' runs (Fig. 14). The less efficient sorting can also be expected in bed load sheets. On the other end of the spectrum, the lee slope becomes so long that the grain flows do not make it to the bottom of the slope. Instead, they halt at some point and are later rejuvenated by a next grain flow. This situation is expected for very high bars or large and complex deltas, but not for the range of heights of river dunes commonly considered in modelling river morphodynamics.

The present work is limited to conditions with dominant bed load transport. The proposed lee face sorting model describes sorting by grain flows at the angle of repose, which are initiated by the sediment delivered to the brinkpoint of the dune. For the deltas, the water depth over the delta was very small compared to the basin depth. The suspended sediment was therefore strongly decelerated by the flow expansion over the lee side and deposited near the top where it was mixed and sorted into the grain flow. The flow is much deeper, however, over dunes, so that the deceleration is much less important and the grains are suspended over a range of heights. The coarsest sediment will settle fast and deposit near the top, but the finer grades will settle only slowly and mix into the toe and trough

Copyright © 2006 Taylor & Francis Group plc, London, UK

zones (Jopling 1965). In other words, the addition of sediment by grain fall depends on the concentration profile of the suspended sediment, and on the flow expansion over the dune troughs. This process cannot straightforwardly be described by the present lee face sorting model, because it requires a dependence on shear stress for the suspension process, and a dependence on dune height, which depends on water depth (and to some extent on shear stress).

9 CONCLUSIONS

In this study a simple and empirical model for lee face sorting was developed. In the model and in most observations, the deposition of fines over the lee face decreases linearly with elevation (and vice versa for coarse material). The proposed model is suitable for lee faces of dunes and deltas for which the deposition process is dominated by grain flows. If the finer part of the transported sediment is suspended, it may settle on the lower lee face or at the toe. This modifies the sorting profiles to a non-linear shape and may create a fine bottom set in deltas and bars. This process cannot straightforwardly be implemented in the present lee face sorting model, which limits the applicability to conditions in which the lee face deposition is dominated by grain flows (also see Section 1). In the experiments, we found no significant differences in the measured sorting profiles between dunes and deltas except for the finest fractions, indicating that the grain flow sorting process is the same.

For the conditions considered in this analysis, the standard deviation of the mixture and the dimensionless shear stress appear not to affect the sorting profile. For higher values of the shear stress, however, we expect the sorting trend to become smaller with increasing shear stress. The dune height appears not to affect the sorting mechanism. Yet for small values of the ratio of dune height to the d_{90}, (Δ/d_{90lee}) in combination with a relatively high shear stress, which is valid for data set 'Klein02' (see Fig. 2b), the observed sorting trends appear to be significantly smaller than the ones predicted by the new lee face sorting model.

For very small parameters of the volume fraction content of a size fraction in the lee deposit (F_{leei}), the size fraction does not show a preference for certain elevations of the lee face and is distributed over the lee face uniformly. This effect has been incorporated in the present version of the model.

Entrapment of fines in coarse sediment beds

B.G. Krishnappan & P. Engel
National Water Research Institute, Environment Canada, Burlington, Ontario, Canada

ABSTRACT: In this paper, a fine sediment entrapment study using a rotating, circular flume is described. An existing flocculation and settling model was modified for the analysis of the experimental data. An entrapment coefficient, relating the rate of entrapment to the settling rate of sediment at the sediment-water interface, was introduced in this study for the first time. It was applied as one of the boundary conditions to the model and determined through model calibration using the experimental data. The entrapment coefficient obtained in this study was found to depend on the bed material type when the bed sediment was immobile. But, when the bed sediment was mobile, the coefficient depended on both bed material type and bed shear stress. A systematic study is planned to determine the plane bed entrapment coefficient for different bed material types and bulk hydraulic characteristics.

1 INTRODUCTION

Entrapment of fine sediment in coarse river bed substrate impacts on both the roughness characteristics of the river bed and the quality of river habitat. Fine sediment fills the interstitial space and changes the grain size distribution of the material forming the bed layer. It also alters the porosity and permeability of the stream bed, which in turn can have an effect on the ecology in the hyporheic zone. Ecological studies carried out in spawning streams in England and Wales have implicated deposited fines for the decline of salmonid fisheries (Olsson & Persson (1988); Acornley & Sear (1999)). Egg-to-hatching success of salmonids is strongly influenced by the rate of supply of the dissolved oxygen and the rate of removal of carbon dioxide and metabolic wastes, which are governed by the permeability of the spawning beds (Hausel & Coble (1976); Iwomoto et al. (1978); Turnpenny & Williama (1980)). Intra gravel movement and eventual emergence of newly hatched fry or alevins are controlled by the porosity of the spawning beds. Excessive accumulation of fine sediment can block the interstitial pathways, smother the surface of the gravel and cause concretion of the spawning substrate (Philips et al. (1975); Crisp (1993)).

Entrapment of fines in coarse gravel beds has been studied extensively in the laboratory and to a limited extent in the field (Elliott and Brooks (1997a); (1997b); Packman et al. (2000a); (2000b); Fernald et al. (2001); Marion and Bellinello (2002); Packman and Mackay (2003); Zaramella and Packman (2003); Marion et al. (2004)). Laboratory studies have been carried out primarily in straight channels with bed-forms. These studies have led to the formulation of a bed-form induced advective pumping model to calculate the colloid exchange between the water column and the hypoheic zone (Packman et al. (2000); (2004)). In this model, the dynamic head variation along the stream bed, due to the presence of bed-forms, was considered as the driving force for the subsurface flow in the hyporheic zone. Assuming a sinusoidal variation for the dynamic head and using Darcy's law, Elliott and Brooks (1997) derived a theoretical expression for the advective subsurface flow field. The induced advective pore water flow carries the fine sediment through and out of the bed. The net exchange of fine sediment from the stream into the hyporheic zone takes place because of the settling velocity of the sediment particles and the sediment immobilization in the bed due to the filtration effect (Packman et al. (2000)).

The infiltration effect described in the above model depends on the steepness of bed-forms. As the steepness of the bed-forms decreases, the advective flow velocity decreases and becomes zero when the bed is plane. Therefore, the pumping model described above will fail to treat the entrapment of fines under plane bed conditions. Experimental studies of entrapment of fine sediment under plane bed conditions are limited. Therefore, to fill this knowledge gap, a new research program has been initiated at the National Water Research Institute in Burlington, Ontario, Canada. Fine sediment entrapment experiments are being carried out using a rotating circular flume. The experimental data are analyzed using a modified flocculation and settling model that was formulated for predicting the fine sediment transport characteristics in rotating circular flume assemblies

(Krishnappan & Marsalek (2002)). The details of the experimental program and the model are outlined in this paper.

2 EXPERIMENTAL PROGRAMME

2.1 *Rotating circular flume*

The entrapment experiments are being carried out in a rotating, circular flume. The flume is 5.0 m in mean diameter, 0.30 m wide and 0.30 m deep. It rests on a rotating platform, which is 7.0 m in diameter. A counter rotating top cover (ring) fits inside the flume with close tolerance, (∼1.5 mm gap on either side) and it makes contact with the water surface in the flume. The maximum rotational speeds of the flume and the ring are 3 rpm respectively. Figure 1 shows a schematic view of the flume and the complete details of the flume can be found in Krishnappan (1993).

The flows generated in the flume are nearly two dimensional and the bed shear stress distribution across the width of the flume is fairly uniform as can be seen in Figure 2. In this figure, the bed shear stresses are plotted as a function of transverse distance across the width of the flume with rotational speed, N_f as a parameter. The ring speed, N_R had to be slightly larger than the flume speed in order to minimize the secondary circulations. For the tests shown in this figure, the ratio N_R to N_f was maintained at 1.167. The flume bed surface was smooth and the depth of water in the flume was 0.12 m. The points are measured values and the lines represent predictions from a three dimensional, hydrodynamic model called PHOENICS (Rosten & Spalding (1984)). It can be seen from this figure that the model predictions agree very well with the measured data. The model is used as an operating tool to predict the relationship between the bed shear stress and the rotational speeds of the flume assembly under both smooth and rough bed conditions (Krishnappan & Engel (2004)).

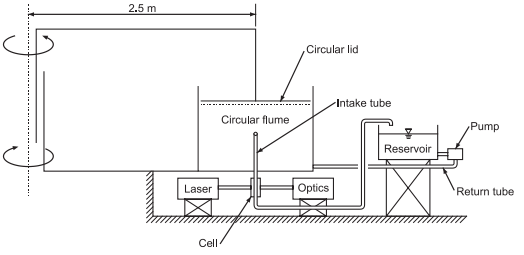

Figure 3. Schematic representation of the arrangement of the Malvern Particle Size Analyzer mounted on the flume.

The flume is equipped with a Malvern Particle Size Analyzer for measuring the size distribution of sediment flocs in suspension. The instrument is placed directly underneath the flume as shown schematically in Figure 3. A short tube connects the sampling point to the sample cell. The sample is drawn through the sample cell continuously by gravity. The sample, after passing through the sample cell, flows into a reservoir from where it is pumped back into the flume. The instrument operates on the principle of diffraction of a laser beam. As the beam crosses the sample in the sampling cell, the light is diffracted by the particles in the sample. The diffraction pattern is then measured using a light sensitive sensor consisting of a series of photodiodes mounted in semi circular arcs. A microprocessor in the instrument converts the diffraction pattern into a particle size distribution using the Fraunhofer diffraction theory (Weiner (1984)).

2.2 *Experimental procedure*

For an entrapment experiment, the flume bed was covered with coarse gravel of a certain size to a certain thickness. The flume was then filled with tap water to a depth of 0.12 m above the top surface of the gravel layer. The flume was operated at a speed high

enough to keep the injected sediment in suspension for about 20 minutes. During this time, a thick slurry of kaolin was injected into the flume. Care was taken to maintain the water level in the flume by pumping the excess water out. The rate of pumping was equal to the rate of slurry injection, and therefore, the top cover maintained contact with the water surface at all times. After the injection of kaolin, the flume and the ring speeds were lowered to a level commensurate with the desired bed shear stress, and maintained at that level for the duration of the experiment. An experiment lasted about five hours. During this time, the kaolin concentration in the water column and the size distribution of the kaolin particles were monitored at regular intervals of time. The concentration of kaolin was determined by collecting samples, which were then dried and weighed. The size distributions were obtained with the Malvern Particle Size Analyzer. Altogether, six experiments were conducted for three different bed conditions and two different bed shear stresses. These test conditions are summarized in Table 1.

2.3 *Experimental results*

The concentration variation as a function of time for all the six tests is shown in Figure 4. From this figure, one can see that the entrapment of kaolin occurs in both 8 mm gravel and 1 mm sand beds. When comparing the concentration variation of the impervious runs with those for porous beds, one can see that entrapment occurs in plane, porous beds. As expected, it is more pronounced in the 8 mm gravel than in the 1 mm sand. Furthermore, the data in Figure 4 show that the bed shear stress also plays a role in the entrapment of fine sediment in porous beds.

3 THEORETICAL CONSIDERATIONS

The results of the entrapment experiments were analyzed using a mathematical model that was developed for analyzing the fine sediment transport processes in a rotating circular flume (Krishnappan & Marsalek (2002)). According to this model, the motion of the

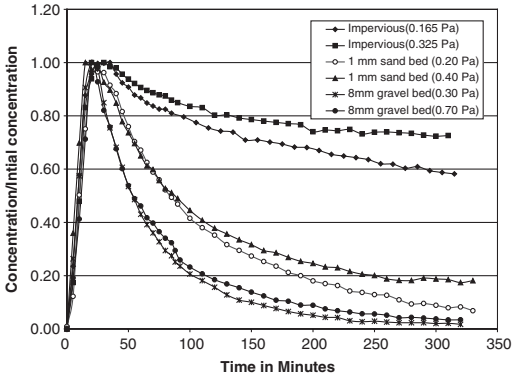

Figure 4. Concentration vs time curves for all the six tests summarized in Table 1.

settling sediment is considered as a two stage process: a transport or a settling stage and a flocculation stage. The model is adopted to examine the entrainment process by incorporating a new boundary condition for the settling stage of the model. Some of the salient features of the model, including the new boundary condition, are discussed here for the sake of completeness.

3.1 *Settling stage*

The governing equation for the settling stage was obtained from mass balance considerations, and assuming that the flow in the rotating flume is uniform in the longitudinal and tangential directions, the one dimensional mass balance equation as shown below was adopted.

$$\frac{\partial C_k}{\partial t} + w_k \frac{\partial C_k}{\partial z} = \frac{\partial}{\partial z}(\Gamma \frac{\partial C_k}{\partial z}) + S \qquad (1)$$

where, C_k is the concentration of kaolin in size fraction k, w_k is the settling velocity of that fraction and Γ is the dispersion coefficient in the vertical direction. The symbol t stands for time axis and the symbol z stands for the coordinate axis in the vertical direction. S is the source/sink term.

The boundary conditions used for the settling stage are as follows:

at the free surface:

$$- w_k C_k - \Gamma \frac{\partial C_k}{\partial z} = 0 \qquad (2)$$

at the bed:

$$- w_k C_k - \Gamma \frac{\partial C_k}{\partial z} = q_e + q_d + q_{entrap} \qquad (3)$$

The free surface boundary condition expresses the balance between the settling flux and the dispersive

Copyright © 2006 Taylor & Francis Group plc, London, UK

flux. In other words, there is no external input of sediment at this boundary. At the bed surface, it is assumed that the settling and dispersive fluxes are balanced by the net amount of sediment exchanged at the sediment-water interface. The sediment exchange at the sediment-water interface can occur in three ways. 1) Sediment can be eroded from the bed because of the shear stress induced by the flow and can be entrained into the water column (q_e). 2) Sediment can settle to the bed and stays at the bed as the deposited sediment (q_d). 3) Sediment can settle to the bed and a portion of the settled sediment gets into the pores of the bed sediment and become unavailable for further erosion and entrainment (q_{entrap}).

The first two components of the sediment exchange at the sediment water interface have been studied extensively in the literature. A number of formulations exist to quantify these components. For example, the erosion rate of fine sediment has been studied by Partheniades (1962); Mehta & Partheniades (1982); Parchure (1984) and Lick (1982) just to name a few. Deposition characteristics of fine sediment have been studied by Krone (1962); Mehta & Partheniades (1975); Lick (1982) among others. In this study, the approach proposed by Krone (1962) has been adopted. According to this approach, net deposition flux was calculated as:

$$q_d = Pw_s C_b \tag{4}$$

where P is a probability parameter which gives a measure of the probability that a floc, settling to the bed, stays at the bed. Krone (1962) proposed a relationship for P as:

$$P = (1 - \frac{\tau}{\tau_{crd}}) \tag{5}$$

where τ is the bed shear stress and τ_{crd} is the critical shear stress for deposition, which is defined as the bed shear stress above which none of the initially suspended sediment would deposit.

The third, entrapment component, is introduced for the first time in this study. It is assumed that this component is directly proportional to the settling flux near the bed and is expressed as:

$$q_{entrap} = \alpha w_s C_b \tag{6}$$

where α is the proportionality constant and is termed as the entrapment coefficient. The entrapment coefficient is expected to be a function of porosity of the gravel substrate, thickness of the gravel bed layer and the permeability of the substrate. It was determined in this study by fitting the model predictions to the measured concentrations in the water column. In other words, it was treated as a calibration parameter and was determined as part of the calibration process.

3.2 *Flocculation stage*

The flocculation stage was modeled on the basis of the coagulation equation (Fuchs (1964)) shown below:

$$\frac{\partial N(i,j)}{\partial t} = -\beta N(i,t)\sum_{j=1}^{\infty} K(i,j)N(j,t) + \frac{1}{2}\beta\sum_{j=1}^{\infty} K(i-j,j)N(i-j,j)N(j,t) \tag{7}$$

where $N(i,t)$ and $N(j,t)$ are number concentrations of particle size classes i and j respectively. $K(i,j)$ is the collision frequency function, which is a measure of the probability that a particle of size i collides with a particle of size j in unit time and β is the cohesion factor, which defines the probability that a pair of collided particles will coalesce and form a new floc. β accounts for the effects of cohesion properties such as the electrochemical properties of the sediment-water mixture, effects of polymers secreted by micro-organisms etc.. In this study, β is treated as an empirical parameter and was determined through the calibration of the model using experimental data.

The first term on the right side of equation (7) gives the reduction of particles in size class i because of flocculation of these particles in size class i with all other size classes. The second term gives the generation of new particles in the size class i because of flocculation of particles in smaller size classes. In this process the mass of particles is assumed to be conserved. Equation (7) was simplified by considering the particle sizes in discrete size classes as shown in Figure 5. In this figure, the continuous particle size space is considered in discrete size ranges. Each range is considered as a bin containing particles of certain size range. For example, r_1 is the geometric mean radius of particles in bin No.1. The particle ranges were selected in such a way that the mean volume of particles in bin i is twice that of the preceding bin. The volume ranges of the various size ranges are shown in Figure 5.

Under this scheme, when particles of bin i flocculate with particles in bin j ($j < i$), the newly formed

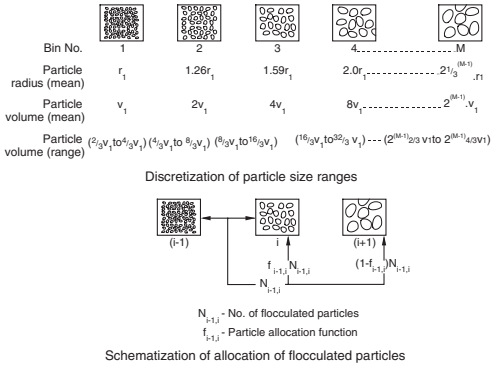

Figure 5. Schematic representation of flocculation stage.

Copyright © 2006 Taylor & Francis Group plc, London, UK

particles will fit into bins i and $i+1$. The proportion of particles going to these bins can be calculated by considering the mass balance of particles before and after flocculation. With this simplification, the coagulation equation can be expressed in discrete form as follows:

$$\frac{\Delta N_i}{\Delta t} = -\sum_{j \le i} \beta K(r_i, r_j) N_i N_j + \sum_{j<i} f_{i,j} \beta K(r_i, r_j) N_i N_j + \sum_{j<i-1} (1 - f_{i,j}) \beta K(r_i, r_j) N_{i-1} N_j \quad (8)$$

where $f_{i,j}$ is the allocation function given by:

$$f_{i,j} = (\rho_{s,i} V_i + \rho_{s,j} V_j - \rho_{s,i+1} V_{i+1}) / (\rho_{s,i} V_i - \rho_{s,i+1} V_{i+1}) \quad (9)$$

where, ρ_s denotes the density of the flocs and V is the volume of the flocs. The density of the flocs is dependent on their size of the flocs, and an empirical relationship proposed by Lau & Krishnappan (1997) was adopted in this study. The form of the relationship is as follows:

$$\rho_s - \rho = \rho_p \exp(-bD^c) \quad (10)$$

where ρ_s, ρ and ρ_p are densities of flocs, water and parent material forming the floc (the last one measured in water, i.e. submerged density) respectively. D is the diameter of the floc and b and c are empirical coefficients to be determined through model calibration. The settling velocity of flocs, needed for the settling stage of the particle motion, was calculated using the above density relation and Stoke's Law. The resulting expression is as follows:

$$w_k = (1.65/18) \exp(-bD_k^c) g D_k^2 / \upsilon \quad (11)$$

where g stands for acceleration due to gravity and υ stands for the kinematic viscosity of water.

The collision frequency function $K(i,j)$ takes different functional forms depending on the collision mechanisms that bring the particles to close proximity. The mechanisms considered in this study include 1) Brownian motion (K_b), 2) Turbulent fluid shear (K_{sh}), 3) Inertia of particles in turbulent flow (K_I) and 4) Differential settling of flocs (K_{ds}). An effective collision frequency function, K_{ef} was calculated in terms of the individual collision functions as follows:

$$K_{ef} = K_b + \sqrt{(K_{sh}^2 + K_I^2 + K_{ds}^2)} \quad (12)$$

The collision frequency functions for the individual collision mechanisms can be found in Valioulis & List (1984).

The break-up of flocs due to turbulent fluctuations of the flow was modelled using a scheme proposed by Tambo & Watanabe (1979). According to this scheme, a "collision-agglomeration" function was introduced as a multiplier to the collision frequency function, K_{ef}. This produced an effective collision frequency that resulted in an optimum floc size distribution for a given level of turbulence. The function proposed by Tambo and Watanabe is as follows:

$$\alpha_R = \alpha_0 (1 - \frac{R}{S+1})^n \quad (13)$$

where R is the number of primary particles contained in a floc and S is the number of particles contained in the biggest floc for the given level of turbulence. The parameters α_0 and n assume values of 1/3 and 6 respectively.

3.3 *Calibration of the model*

3.3.1 *Input parameters*

To model the flocs in different size classes, the initial size distribution of the flocs has to be known as well as the turbulent diffusion coefficient and the collision frequency functions.

The initial size distribution was obtained from the size distribution data measured using the Malvern Particle size analyzer. Typical data obtained for the kaolin used in the present experiments is shown in Figure 6.

The turbulent diffusion coefficient, Γ was assumed to be equal to the momentum diffusivity, which was determined by simulating flow characteristics in the rotating flume using the PHOENICS model (Rosten & Spalding (1984)). The PHOENICS model is a three dimensional hydrodynamic model and it employs the $\kappa - \varepsilon$ turbulence model to close the system of governing equations. From the predictions of flow characteristics, a cross sectional average value of Γ was computed and used in this study.

The collision frequency functions for the different collision mechanisms considered in the flocculation process were calculated using the flow characteristics

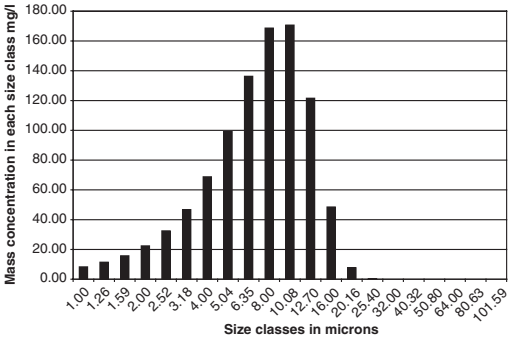

Figure 6. A typical size distribution of kaolin measured at the beginning of an experiment in the present study.

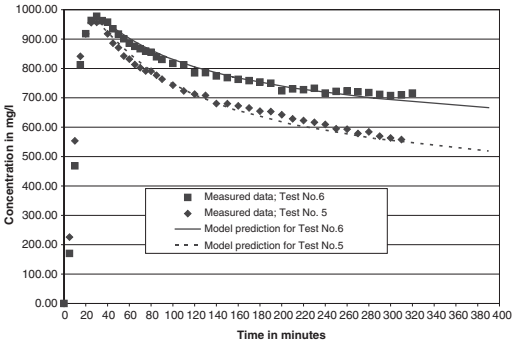

Figure 7. Comparison of model values and the measured data for impervious bed tests.

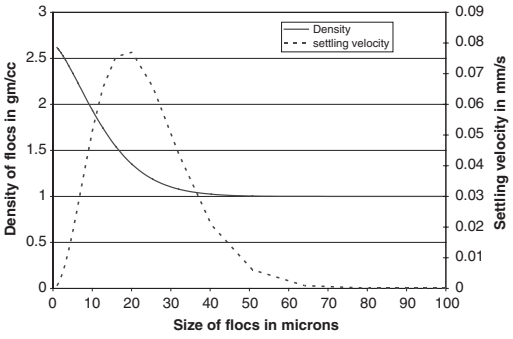

Figure 8. Density and settling velocity of kaolin as predicted by the model.

predicted using the PHOENICS model. The main flow parameter required for this purpose is the turbulent energy dissipation rate ε, which is one of the flow parameters computed in the PHOENICS model.

3.3.2 *Calibration procedure*

The impervious bed tests (i.e. Tests 5 and 6) were used to calibrate the settling and flocculation stage of the model and obtain the settling velocity parameters b and c and the flocculation parameters β. For this case, there is no entrapment in the bed. As a result, the entrapment coefficient $\alpha = 0$. The calibration was carried out using a trial and error procedure. To start the procedure, the values of b and c given by Lau and Krishnappan (1997) were used, and a range of β values were tried in the model, and the size distribution of the sediment flocs were determined. These distributions were then compared with the measured size distributions (not shown in this paper). The β value that gave the closest agreement was chosen. Using this chosen β value, a range of b and c values were tried in the model and the variation of concentration as a function of time was determined. This variation was then compared with the measured data and the set of values that gave the closest match was chosen. The process was repeated until the size distribution predictions and the concentration-time variation predictions agreed well with the measured data. Such a convergence was achieved within a small number of iterations (within five). The values that gave the best fit of the model results to the measured data are: $\beta = 0.2$, $b = 0.02$ and $c = 1.45$. These values are valid only for the kaolin particles tested in this study. The comparison between the computed and the measured values for the two impervious tests are shown in Figure 7.

From Figure 7, one can see that the computed values and the data agree very well for the two impervious bed tests indicating that the model describes the sedimentation process very well. For these tests, the flocculation process is significant. It was not possible to obtain such a fit by using the settling stage alone (i.e. by equating β to be zero).

4 RESULTS AND DISCUSSION

4.1 *Variation of density and settling velocity*

When the calibrated values of b and c are substituted into the density and settling velocity relations (i.e. in Equations 10 and 11), the variation of density and settling velocity as a function of floc size can be determined as shown in Figure 8.

Figure 8 shows that the density of the flocs decreases as a function of floc size, and for flocs greater than about 45 microns, the density of the floc becomes almost equal to that of water. The settling velocity exhibits a complex behaviour. It increases as a function of floc size for lower values of floc size, reaches a maximum value for the floc size of about 20 microns and then decreases with further increase in floc size. There is experimental evidence in the literature to support the above noted dependence of settling velocity of flocs on floc size (see. Petticrew (2005) and Atkinson et al. (2005)).

4.2 *Entrapment coefficient*

The entrapment coefficients were determined by applying the calibrated model to the entrapment experiments (i.e. for tests 1 to 4). In other words, values of β, b and c, obtained from the calibration of the model with impervious conditions were used for these computations. In these applications, the entrapment boundary condition (i.e. Eqn. 6) was adopted and the value of α was adjusted until the measured concentrations agreed with the values obtained with the model. Comparisons of the measured concentrations and the best fit values for Test No. 1 and Test No. 3 are shown in Figures 9 and 10 respectively. These figures indicate that the model agrees with the measured data reasonably well, showing once again that the model

describes the sedimentation and entrapment processes very well. The agreement for Test No. 2 and 4 was similar to those for Test No. 1 and 3, and hence are not shown here. The entrapment coefficients obtained with the model fit are listed in Table 2. The values for Test No. 1 and 2 are the same (i.e. 0.94), whereas the values for Test 3 and 4 are 0.19 and 0.48 respectively. Higher values for the larger size bed material are expected because of the higher porosity. For the smaller size bed material, the entrapment coefficient is considerably smaller (0.19) because of the lower porosity. However, for Test No. 4, which has the same bed material as Test No. 3, the entrapment value is higher (0.48). This is due to the fact that for Test No. 4, the bed shear stress was larger and, at this bed shear stress, movement of the bed material occurred and bed-forms developed. The increased entrapment rate is due to this bed-form formation.

Presence of bed-forms causes enhanced entrapment because of the advective pumping mechanism that was

Table 2. Entrapment coefficient for all tests.

Test no.	Bed shear stress in Pa	Bed material size (D_{50}) in mm	Entrapment coefficient α
1	0.3	8	0.94
2	0.7	8	0.94
3	0.2	1	0.19
4	0.4	1	0.48
5	0.17	0	0.00
6	0.33	0	0.00

described earlier. The entrapment process under the presence of bed-forms can be considered to consist of two components: one due to the bed-forms and the other due to plane bed. As the plane bed transform into undulating bed, the component due to plane bed could be overshadowed by the component due to bed-forms (advective pumping). More research is needed to unify the two different entrapment processes. Furthermore, additional experiments are needed to fully investigate the dependence of entrapment coefficient on the bed characteristics such as porosity, bed depth and permeability for the case of stationary, plane beds.

Plans are already underway to carry out a comprehensive study. Theory of dimensional analysis will be used to derive the dimensionless parameters determining the entrapment coefficient.

5 SUMMARY AND CONCLUSIONS

Entrapment of fine sediment into coarse gravel substrate was studied using a rotating circular flume. The flume bed was covered with coarse sediment. Two different sizes of sediment were used (median sizes: 8.0 mm and 1.0 mm). A pre-mixed slurry of kaolin was injected into the flume, and the concentration of kaolin in suspension was monitored as a function of time to evaluate the entrapment of kaolin into the coarse sediment substrate. A calibrated flocculation and settling model was used to compute the concentration variation in the flume as a function of time. An entrapment boundary condition was introduced in the model to simulate the fine sediment entrapment in the coarse gravel substrate. The model results compared with the measured data well for both pervious and impervious bed conditions. A systematic study is planned to determine the entrapment coefficient for various bed material types and bulk hydraulic parameters.

ACKNOWLEDGEMENTS

The authors wish to thank Mr. Robert Stephens of the Aquatic Ecosystem Impacts Research Division of Environment Canada for carrying out the entrapment experiments in the rotating circular flume.

Can a two-layer morphological model compete with common sediment transport formulae?

C. Savary & Y. Zech
Dept. of Civil and Environmental Engineering., Université catholique de Louvain, Louvain-la-Neuve, Belgium

ABSTRACT: In opposition to the common approach based on the Saint-Venant – Exner equations, a two-layer model does not introduce the solid discharge as a closure relation. The solid discharge is one of the main unknowns of the differential system and depends on the expression of the various shear-stresses at each layer interface. Once the corresponding friction coefficients calibrated for one situation, the two-layer model is able to generate the water depth and the solid discharge for any situation. In several versions of the two-layer model, each relying on different assumptions, the sediment transport was calculated for a wide range of Froude numbers. A basic model assuming identical velocity in both the water and the transport layer revealed to be unsatisfactory. Allowing the velocity in the two layers to be distinct leads to good agreement with common sediment transport formulae. Assuming distinct concentrations in the transport layer and in the bed results in still better agreement.

1 INTRODUCTION

In fluvial hydraulics, different sets of equations are used to model the interaction between water and sediment. The most usual are the Saint-Venant – Exner equations (see for example Vreugdenhil & de Vries, 1967; Rahuel, 1988; Correia, 1990; Correia et al., 1991), where a transport layer is not explicitly considered. In this case, two closure equations have to be added to the partial differential equation system, one dealing with the friction slope (e.g. by the Manning relation) and the other providing the solid discharge by any common formula (e.g. by the Meyer-Peter–Müller (1948) relation).

In contrast, the two-layer approach (Capart, 2000) takes explicitly the transport layer in consideration. The model accounts for the solid discharge as a main variable, while the friction is represented by the various shear-stresses at each layer interface. The solid discharge is influenced by the friction coefficients associated to those shear stresses. In uniform flow conditions, the solid discharge calculated by the two-layer model or by the common formulae should be the same, allowing to calibrate the friction coefficients.

Once calibrated for one situation (e.g.: a given bottom slope), using either experimental or theoretical data, the two-layer model is able to generate the water depth and the solid discharge for any situation (e.g.: other bottom slopes), without use of any transport formula. In that sense the method offers an alternative to common transport formulae.

The comparison between common transport formulae and several versions of the two-layer model, each relying on different assumptions, is tested. First, analysis and comparisons are made in the case of a model allowing different mean velocity in the water and the transport layer, but the same sediment concentration in the transport layer as in the fixed bed (Capart & Young, 2002). Then a model (Spinewine, 2005) assuming distinct concentrations in the transport layer and in the bed is tested. A simplified model (Capart, 2000) assuming identical velocity in both layers is tested. For each of those models, the sediment transport (solid discharge, transport layer depth and velocity) is calculated for a wide range of Froude numbers and grain diameters.

2 TWO-LAYER MODEL

To calculate morphodynamic evolution, a two-layer model developed by Capart (2000) and improved by Capart & Young (2002) is proposed. This two-layer numerical scheme is documented in more details in Chen et al. (in press), where it is applied to flows involving water and mud layers. In this paper, a one-dimensional point of view is taken into account. Assuming the shallow-water hydrostatic pressure distribution, the flow is divided in two layers constituted of incompressible fluid. The main variables are the thickness of the water layer h_w and of the transport layer h_s, the velocity in each layer u_w and u_s,

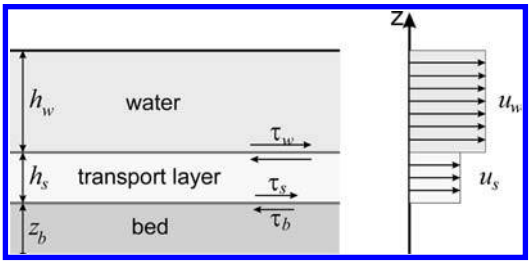

Figure 1. Two-layer model.

respectively, and the level of the interface between the transport layer and the bed z_b (Fig. 1).

The transport layer and the fixed bed are constituted of a water-sediment mixture with a sediment concentration C, assumed as constant in time and in space. The volumetric density of this transport layer is $\rho'_s = (1-C)\rho_w + C\,\rho_s$, where ρ_w and ρ_s are the water and the grain density, respectively. In fact, sediment mobilisation often requires a decrease of concentration (Spinewine, 2005) but, for the sake of simplicity, this is not taken into account in the model here presented. The velocity in the transport layer is allowed to be distinct from the velocity in the water layer, but they are assumed to be uniform in both layers. As only the bed load is modeled, there is no mass and momentum exchange between the transport layer and the water. The only possible mass exchange occurs between the bed and the transport layer. The five-equation system proposed by Capart & Young (2002) results from mass (Equations 1–2) and momentum (Equations 4–5) conservation in each layer and from the definition of the erosion rate e_b (Equation 3).

$$\frac{\partial h_w}{\partial t}+\frac{\partial h_w u_w}{\partial x}=0 \tag{1}$$

$$\frac{\partial h_s}{\partial t}+\frac{\partial h_s u_s}{\partial x}=e_b \tag{2}$$

$$\frac{\partial z_b}{\partial t}=-e_b \tag{3}$$

$$\frac{\partial h_w u_w}{\partial t}+\frac{\partial\left(h_w u_w^2+\frac{1}{2}gh_w^2\right)}{\partial x}+gh_w\frac{\partial(z_b+h_s)}{\partial x}=-\frac{\tau_w}{\rho_w} \tag{4}$$

$$\frac{\partial h_s u_s}{\partial t}+\frac{\partial\left(h_s u_s^2+\frac{1}{2}gh_s^2\right)}{\partial x}+gh_s\frac{\partial\left(z_b+\frac{\rho_w}{\rho_s}h_s\right)}{\partial x}=\frac{\tau_w}{\rho'_s}-\frac{\tau_b}{\rho'_s} \tag{5}$$

where the erosion rate e_b depends on the shear stresses τ_s and τ_b.

$$e_b=\frac{\tau_s-\tau_b}{\rho'_s u_s} \tag{6}$$

The shear stress between the water and the transport layer τ_w and the shear stress applied on the fixed bed τ_s are assumed to follow a Chézy-like friction law:

$$\tau_w=\rho_w C_{f,w}|u_w-u_s|(u_w-u_s) \tag{7}$$

$$\tau_s=\rho'_s C_{f,s}|u_s|u_s \tag{8}$$

where $C_{f,w}$ and $C_{f,s}$ are water and sediment friction coefficients. The resistance shear stress to the flow, exerted by the fixed bed, is expressed by a Mohr–Coulomb relation.

$$\tau_b=\tau_{crit}+tg\varphi(\rho'_s-\rho_w)gh_s \tag{9}$$

where τ_{crit} is the threshold value of τ_s allowing erosion and φ is the repose angle of the soil.

3 UNIFORM FLOW TWO-VELOCITY MODEL

In uniform steady flow conditions, (1) and (2) disappear and (4) and (5) simplify since the partial derivatives $\partial/\partial t = 0$ and $\partial/\partial x = 0$, except $\partial z_b/\partial x = -S_0$:

$$-gh_w\frac{\partial z_b}{\partial x}=gh_w S_0=\frac{\tau_w}{\rho_w} \tag{10}$$

$$-gh_s\frac{\partial z_b}{\partial x}=gh_s S_0=\frac{\tau_b}{\rho'_s}-\frac{\tau_w}{\rho'_s} \tag{11}$$

The sediment transport is in equilibrium, which means that neither erosion nor deposition occurs, thus

$$\tau_b=\tau_s \tag{12}$$

The unit liquid and solid discharges can be defined

$$q_w=u_w h_w \tag{13}$$

$$q_s=u_s h_s \tag{14}$$

Equations (10–14) and (7–9) form a set of 8 uniform-flow equations linking 13 parameters: S_0, q_w, q_s, h_w, h_s, u_w, u_s, τ_w, τ_s, τ_b, τ_{crit}, C_{fw} and C_{fs}. In uniform-flow condition, if five of them are known, the others may be deduced.

It is thus possible to calibrate the two friction coefficients, C_{fw} and C_{fs}, either from measurement or from estimation of only five parameters.

For example, for a given discharge q_w in a channel of slope S_0 with mobile bed whose characteristic diameter is d, the water depth h_w may be deduced from any uniform-flow relation.

If now the solid discharge q_s and the critical shear stress τ_{crit} are computed from any empirical formula, we obtain a set of five parameters (the water depth h_w,

Copyright © 2006 Taylor & Francis Group plc, London, UK

the discharges q_w and q_s, the slope S_0 and the critical shear stress τ_{crit}) required to calibrate C_{fw} and C_{fs}. If experimental data are available, they can be used to deduce the flow parameters h_w and q_s , existent uniform flow and solid discharge relations are no more required.

Once those coefficients are calibrated, one may investigate the behaviour of the two-layer model in other flow conditions by considering various combinations of q_w and S_0. For each combination, it is possible to compute q_s, h_w, h_s,u_w,u_s, τ_{crit}, τ_w, τ_s and τ_b.

To analyse the two-layer model behaviour, an example was computed with the following data: a unit water discharge $q_w = 10\,\mathrm{m^3/s/m}$ in a channel, whose bed is constituted of uniform grains of diameter d varying from 1 to 10 mm; the density $s = \rho_s/\rho_w = 2.65$, and the repose angle of the soil $\varphi = 30°$.

For each diameter, the calibration of C_{fw} and C_{fs} was done for a bottom slope S_0 corresponding to the value of the Froude number $\mathbf{Fr}_w = 2$. The Manning roughness coefficient n may be evaluated from the Strickler formula

$$K = \frac{1}{n} = \frac{26}{d^{1/6}} \tag{15}$$

and the water depth h_w may be deduced from the Manning uniform-flow relation:

$$q_w = \frac{1}{n} h_w^{5/3} S_0^{1/2} \tag{16}$$

The corresponding transport q_s and critical shear stress τ_{crit} are evaluated from Meyer-Peter–Müller formula.

$$q_s = 8\sqrt{g(s-1)d^3}\left(\left(\frac{n_b'}{n_b}\right)^{3/2}\frac{\gamma_w R_b S_0}{(\gamma_s-\gamma_w)d} - 0.047\right)^{3/2} \tag{17}$$

$$\tau_{crit,MPM} = 0.047(\gamma_s-\gamma_w)d_{50} \tag{18}$$

where n_b is the Manning roughness coefficient corresponding to the bed, n_b' is the Manning roughness coefficient taking bed forms into account (if no bed forms occurs, the ratio $n_b'/n_b = 1$), R_b is the hydraulic radius related to the bed, γ_w and γ_s are respectively the water and the bed volumetric weight.

Then, for each diameter, a range of bottom slopes is explored. Using the set of equations (10–14) and (7–9), it is possible to compute the various parameters as a function of the Froude number.

$$\mathbf{Fr}_w = \frac{u_w}{\sqrt{g h_w}} \tag{19}$$

From Figures 2 and 3, it clearly appears that as well the sediment-layer depth h_s as its velocity u_s increase

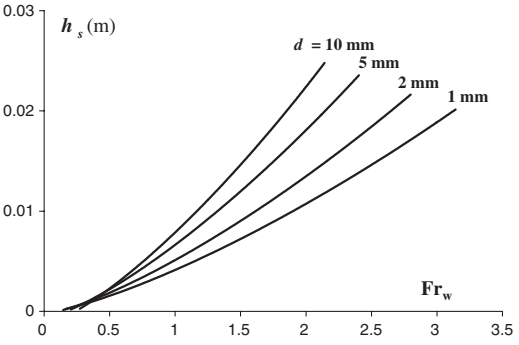

Figure 2. Evolution of the sediment-layer depth h_s (computed with the two-layer model) with Froude number $\mathbf{Fr}_w$ ($d = 1$ to 10 mm) ($q_w = 10\,\mathrm{m^3/s/m}$).

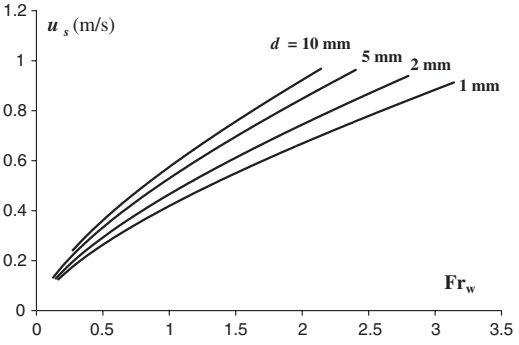

Figure 3. Evolution of the sediment-layer velocity u_s (computed with the two-layer model) with Froude number $\mathbf{Fr}_w$ ($d = 1$ to 10 mm) ($q_w = 10\,\mathrm{m^3/s/m}$).

with increasing Froude number (thus with increasing bottom slope S_0, decreasing water depth h_w, and increasing water velocity u_w). The resulting increase of solid discharge q_s is due, for a part, to the increase of sediment velocity u_s, but mainly to the development in depth of the sediment layer h_s.

Computing the solid discharge from (14) yields a result very close to the Meyer-Peter–Müller formula (Fig. 4). The latter formula was used to calibrate the two-layer model for $\mathbf{Fr}_w = 2$. The three curves on Figure 4 represent three ways to compute q_s for other Froude numbers. One is calculated with the two-layer model, another is obtained applying Meyer-Peter–Müller formula to the water depth h_w calculated with the two-layer model and the last is calculated completely independently with Manning and Meyer-Peter–Müller formulae. That means that the two-layer model and its closure equations (1–9) are at least consistent with the predictions of Meyer-Peter and Müller. As the curves on Figure 4 are quite close, the value of Froude number chosen to calibrate the

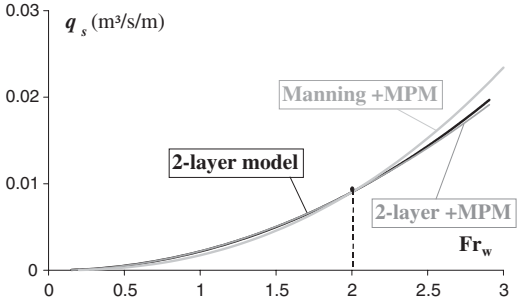

Figure 4. Evolution of solid discharge q_s with Froude number $\mathbf{Fr}_w$: comparison between two-layer model and Meyer-Peter–Müller formula ($d = 1$ mm, $\tau_{crit} = 0.76$ N/m^2, $q_w = 10$ m^3/s/m, $C_{fw} = 0.0016$, $C_{fs} = 0.069$).

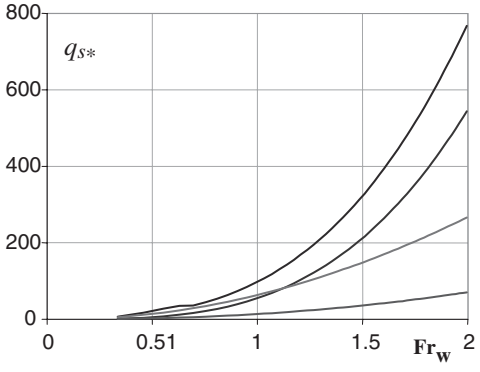

Figure 5. Dimensionless solid discharge in uniform flow conditions – $d = 1$ mm; $q = 10$ m^3/s/m; VR = van Rijn formula (bed load and total load), AW = Ackers-White formula (total load), MPM = Meyer-Peter–Müller formula (bed load).

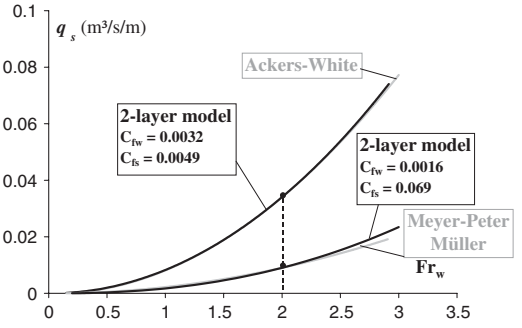

Figure 6. Solid discharge: comparison between two-layer model, Meyer-Peter–Müller formula and Ackers White formula ($d = 1$ mm, $\tau_{crit} = 0.76$ N/m^2, $q_w = 10$ m^3/s/m, $C_{fw} = 0.0016/0.0032$, $C_{fs} = 0.069/0.0049$).

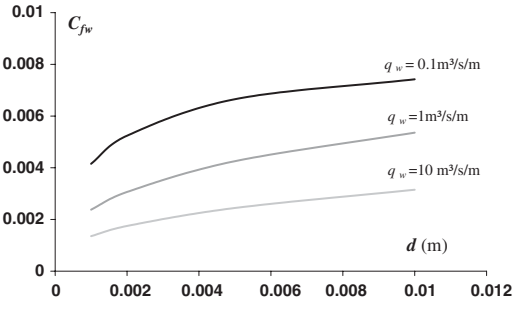

Figure 7. Evolution of the friction coefficient C_{fw} with grain diameter d and water discharge q_w (calibration based on the Meyer-Peter–Müller formula, $\mathbf{Fr}_w = 2$).

friction coefficients is not very important. A Froude number corresponding to the flow is chosen, for example, the mean Froude number in the part of the flow where sediment transport is observed. This consistency is confirmed for other grain diameters ($d = 2$, 5 and 10 mm) and other unit discharges ($q_w = 1$ m^3/s/m), at least if the calibration conditions are not too close to the threshold τ_{crit} under which no transport is expected.

Even if the differences between the common sediment transport formulae are important (Fig. 5), the model seems able to be consistent with several laws.

The Meyer-Peter–Muller relation (17) used to estimate the solid discharge could be replaced by another sediment transport formula like the one proposed by Ackers-White (1980) for example. The calibrated values of the friction coefficientsC_{fs} and C_{fw} depend on the estimation of the solid discharge, which depends in turn on the sediment transport formula used.

If Ackers-White formula is used instead of Meyer-Peter–Muller formula in the previous example ($q_w = 10$ m^3/s/m, $d = 1$ mm; $\rho_s/\rho_w = 2.65$, $\varphi = 30°$, $\mathbf{Fr}_w = 2$), the obtained frictions parameters are significantly different. The calibrated friction coefficients obtained on base of Meyer-Peter–Müller formula are $C_{fw} = 0.0016$ and $C_{fs} = 0.069$, they become $C_{fw} = 0.0032$ and $C_{fs} = 0.0049$ in the case Ackers-White formula is used. For other flow conditions (various slopes for a constant discharge) the solid discharge is calculated by the model and compared with the formulae of Meyer-Peter–Müller and Ackers-White in Figure 6, each computation is in good agreement with the corresponding formula. As the parameters C_{fs} and C_{fw} depend significantly on the chosen formula, it is important to select a formula adapted to the problem, the range of application of the formula has to be respected.

Figures 7 and 8 illustrate the way the friction coefficients C_{fw} and C_{fs} evolve depending on the sediment diameter d and the water discharge q_w. Actually, these figures allow to have a quick idea of which value to

Copyright © 2006 Taylor & Francis Group plc, London, UK

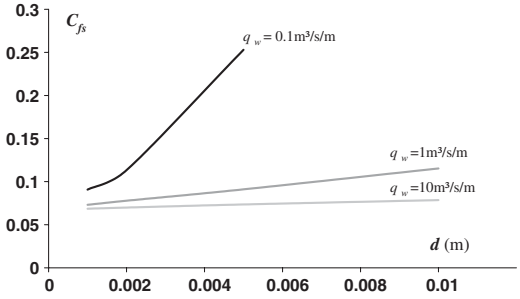

Figure 8. Evolution of the friction coefficient C_{fs} with grain diameter d and water discharge q_w (calibration based on the Meyer-Peter–Müller formula, $\mathbf{Fr}_w = 2$).

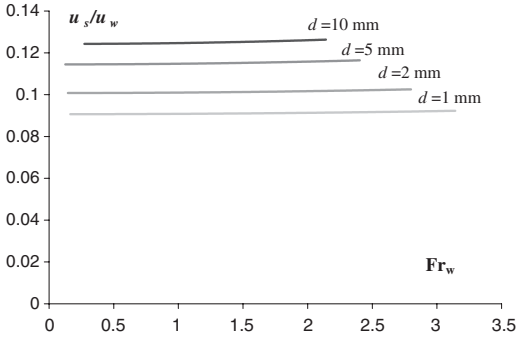

Figure 9. Evolution of the ratio of velocity u_s/u_w in each layer with Froude number $\mathbf{Fr}_w$ (calibration based on the Meyer-Peter–Müller formula, $\mathbf{Fr}_w = 1$).

chose for these coefficients knowing only few parameters of the flow (the grain diameter d and the water discharge q_w). The two coefficients seem to increase with the diameter d and to decrease with the water dischargeq_w. In these figures, the coefficients are calibrated with one specific sediment transport formula for a single Froude number. The important rise of C_{fs} with the diameter for the smallest water discharge ($q_w = 0.1\ m^3/s$) is due to the proximity of the sediment transport threshold. If the grain diameter d is too important and the discharge q_w is too low, the sediment transport is close to zero and the formula is out of its application field.

The ratio of the velocity in each layer u_s/u_w is quite constant with the water Froude number (Fig. 9), only depending on the diameter and the water discharge (Fig. 10). The velocity ratio decreases with the discharge and increases with the diameter to reach asymptotically a near steady value. Once more, when the calibration conditions are too close to the sediment movement threshold ($q_w = 0.1\ m^3/s$, $d > 2$ mm in Fig. 10), the transport formula is no more appropriate.

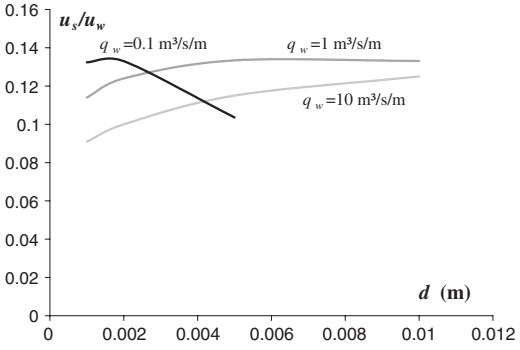

Figure 10. Evolution of the ratio of velocity u_s/u_w in each layer with grain diameter d and water discharge q_w (calibration based on the Meyer-Peter–Müller formula, $\mathbf{Fr}_w = 2$).

These observations underlines the fact the calibration conditions have to be adapted to the flow, avoiding too low sediment transport conditions.

4 TWO-CONCENTRATION MODEL

To take into account different concentrations in the transport layer and in the fixed bed, the source terms of Equations 1–5 are modified (Spinewine, 2005). However, in case of uniform flow, equations 10 and 11 are not modified, as far as ρ_s' is adapted. Thus, the friction coefficients C_{fw} and C_{fs} are calibrated as formerly.

The two models (equal versus distinct concentrations) are compared. In the model assuming identical concentrations, the concentration of the transport layer is set to 0.6 as in the fixed bed, while in the distinct-concentration model, the concentration of the transport layer is set to 0.2, according to Sumer et al. (1996) results.

The parameters are calibrated for $\mathbf{Fr}_w = 1$. For one- and two-concentration model, respectively C_{fw} was found nearly identical (0.0014 vs. 0.00134), while C_{fs}, is significantly distinct (0.068 vs. 0.1166).

Unsurprisingly, the transport layer thickness (Fig. 11) is a little more than 3 times higher in the two-concentration model when the concentration is 0.2 instead of 0.6 in the transport layer. The velocity in the transport layer (Fig. 12) decreases a little in the two-concentration model. The difference in concentration influences mainly the depth of the transport layer. The solid discharge (Fig. 13) remains quite close to Meyer-Peter–Müller predictions for both models. Nevertheless, for large Froude numbers, the solid discharge calculated by the two-concentration model is slightly greater than the predictions by the two other models.

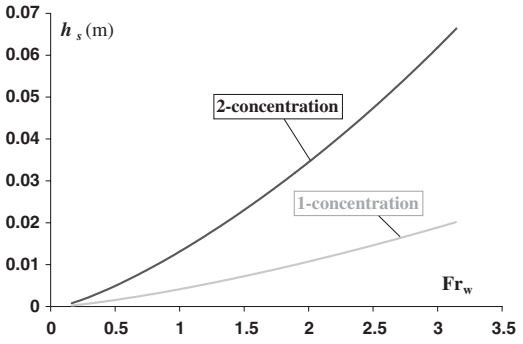

Figure 11. Evolution of the sediment-layer depth h_s with Froude number $\mathbf{Fr}_w$: comparison between the one-concentration model (concentration of the transport layer = 0.6) and the two-concentration model (concentration of the transport layer = 0.2) ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

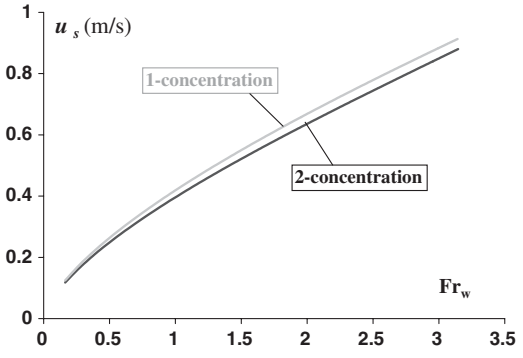

Figure 12. Evolution of the sediment-layer velocity u_s with Froude number $\mathbf{Fr}_w$: comparison between the one-concentration model (concentration of the transport layer = 0.6) and the two-concentration model (concentration of the transport layer = 0.2) ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

5 ONE-VELOCITY MODEL

If the velocity in the water layer and in the transport layer is the same, the five-equation system 1–5 reduces to four equations (Capart 2000, Fraccarollo et al. 2003).

We define the total transport depth $h_m = h_w + h_s$, the common velocity $u_m = u_w = u_s$ and a correction factor $r = C\,[(\rho_s - \rho_w)/\rho_w]$ accounting for the additional mass in the sediment layer compared to the water layer ($\rho_s'/\rho_w = 1 + r$).

In uniform steady flow conditions, the four equations simplify

$$g\frac{\partial z_b}{\partial x} = \frac{-\tau_m}{\rho_w(h_m + r h_s)} \tag{20}$$

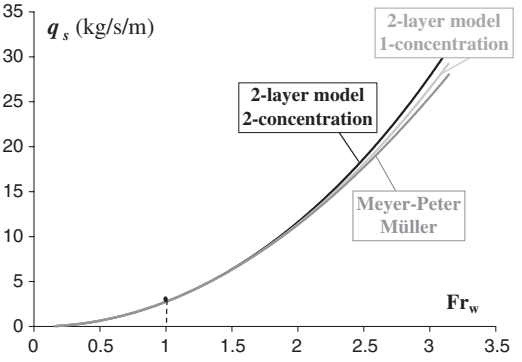

Figure 13. Evolution of sediment transport q_s with Froude number $\mathbf{Fr}_w$ comparison between the one-concentration model (concentration of the transport layer = 0.6), the two-concentration model (concentration of the transport layer = 0.2) and the Meyer-Peter–Müller formula ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

The sediment transport is in equilibrium, which means that neither erosion nor deposition occurs; thus Equation 12 reduces to the condition

$$\tau_b = \tau_m \tag{21}$$

where

$$\tau_m = \rho'_s C_{f,m} |u_m| u_m \tag{22}$$

As the velocity is the same in the two layers, there is no friction shear stress τ_w between the two layers.

If we now define the unit liquid and solid discharges

$$q_m = q_w + q_s = u_m h_m \tag{23}$$

$$q_s = u_m h_s, \tag{24}$$

equations (20–24) and (9) form a set of 6 uniform-flow equations linking 10 parameters: S_0, q_m, q_s, h_m, h_s,u_m, τ_m, τ_b, C_{fm} and τ_{crit}. In opposition to the two-velocity model, only one friction coefficient C_{fm} remains. The critical shear-stress τ_{crit} has to be calibrated in the same way as the friction coefficient, if it is estimated with an external expression (Meyer-Peter–Müller for example), the problem is over-determinate and no solution exists.

Identically to the two-velocity model, it is possible to calibrate the friction coefficient C_{fm} and the critical shear-stress τ_{crit} either from measurement or from estimation of only four parameters (S_0, q_w, h_w, q_s).

The calibration of C_{fm} and τ_{crit} was done for a bottom slope S_0 corresponding to the value of the Froude number $\mathbf{Fr}_w = 1$. During the calibration stage, the water depth h_w was estimated with Manning relation and the corresponding sediment transport q_s was evaluated with Meyer-Peter–Müller formula.

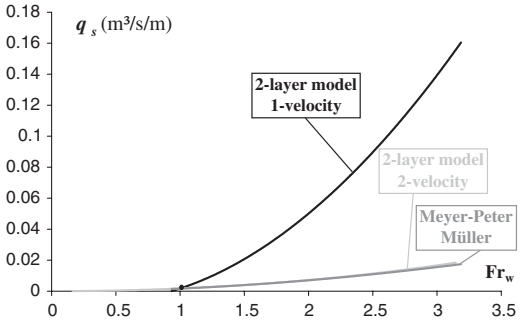

Figure 14. Evolution of sediment transport q_s with Froude number $\mathbf{Fr}_w$ comparison between the one-velocity model, the two-velocity mode and Meyer-Peter–Müller formula ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

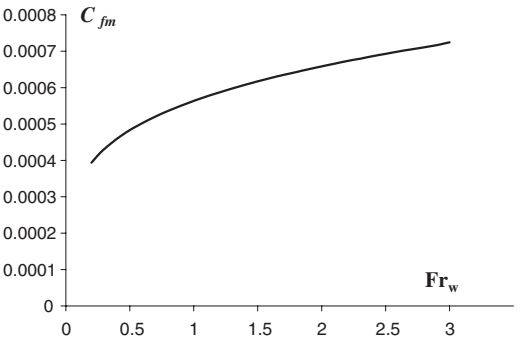

Figure 15. What should be the variation of coefficient C_{fm} with Froude number $\mathbf{Fr}_w$ to make the one-velocity model match Meyer-Peter–Müller ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

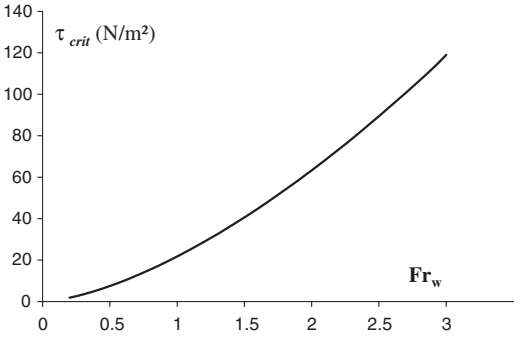

Figure 16. What should be the variation of critical shear stress $\tau_{m,crit}$ with Froude number $\mathbf{Fr}_w$ to make the one-velocity model match Meyer-Peter–Müller ($d = 1$ mm, $q_w = 10\,\mathrm{m}^3/\mathrm{s/m}$).

The solid discharge computed from Equations 20–24, 9 with the calibrated friction coefficient C_{fm} and critical shear stress τ_{crit} is compared with the Meyer-Peter–Müller formula in Figure 14. In case of $\mathbf{Fr}_w > 1$ (supercritical flow), the computed solid discharge highly overestimates the solid discharge calculated by the Meyer-Peter–Müller formula. In case of $\mathbf{Fr}_w < 1$, the computed solid discharge underestimates the Meyer-Peter–Müller formula, too quickly reaching zero with decreasing Froude number. The only Froude number for which the two ways to calculate the solid discharge are identical is $\mathbf{Fr}_w = 1$ corresponding to the calibration point. In opposition with the previous models, no matches with the classical formulae is observed for constant parameters C_{fm} and τ_{crit}.

The velocity in the sediment layer $u_s = u_m$ is overestimated (close to u_w), thus for a given solid discharge the thickness of the transport layer h_s is underestimated. According to (22) and (9), the shear stress applied to the bed τ_m is overestimated and the part of the resistance shear stress τ_b linked to h_s is underestimated. At equilibrium conditions, these two shear stresses have to be equal (21). The deduced critical shear stress τ_{crit} is excessive in comparison with the one proposed by Meyer-Peter–Müller. It explains why the one-velocity model reaches the sediment motion threshold for higher Froude number than the one corresponding to Meyer-Peter–Müller observations. The inappropriate estimation of the shear stresses also explains the overestimation in sediment transport for high Froude numbers.

The values of the parameters C_{fm} and τ_{crit} deduced from the calibration point cannot be extended to other flow conditions. Figures 15 and 16 illustrate how the parameters C_{fm} and τ_{crit} should vary with Froude number (instead of being constant) to match with the Meyer-Peter–Müller formula. This implies the one-velocity model is not able to correctly approach non-uniform flows, except in extreme situations where the assumption of identical velocity in sediment and water holds (e.g.: dam break wave).

This variability of parameters supposed to be constant underlines the expressions of the shear stresses τ_m (22) and τ_b (9) are not appropriate under these assumptions. The correct expression of τ_m (22) should refer to the real velocity $u*$ at the interface between mobile and fixed bed, which is smaller than the mean velocity u_m:

$$\tau_m = \rho_w (1+r) u^{*2} \tag{25}$$

The expression (22) makes use of the assumption $u*^2 = C_{fm}\, u_m^2$ where C_{fm} is a constant. According to the formula of Meyer-Peter–Müller, the shear stress applied to the bed τ_m is expressed

$$\tau_{m,MPM} = \gamma_w R_b S_0\,, \tag{26}$$

which becomes using the Manning formulation

$$\tau_{m,MPM} = \gamma_w n^2 \frac{u^2}{h^{1/3}} = \alpha \frac{u^2}{h^{1/3}} \tag{27}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where α g s a constant, or using the Chézy formulation

$$\tau_{m,MPM}=\gamma_w\frac{1}{C^2}u^2=\beta u^2 \quad (28)$$

The variation of the friction coefficient C_{fm} with water Froude number illustrates the difference between Manning and Chézy formulation. To calibrate, the Manning formula is used, but the expression (22) is Chézy-like. The solution to obtain a constant coefficient C_{fm} would be to unify the way to calculate the shear stress applied to the bed both in the model and in the calibration.

However, the main problem remains the important variation of the critical shear stress with the Froude number. Instead being constant the critical shear stress should rise sharply with the Froude number (Fig. 16). As the critical shear stress is set constant, the resistant shear stress τ_b is underestimated for high Froude number inducing too much transport and overestimated for low Froude number. An artificial correction of the critical shear stress depending on the Froude number would allow the model to fit better with the classical formulation of sediment transport as the one proposed by Meyer-Peter–Müller.

6 CONCLUSIONS

More and more often, two-layer approaches are used as an alternative to common sediment-transport models. The purpose of the paper was to check if these models could compete with those common approaches in the simple case of uniform flow.

Using either experimental data or results of classical approach for one situation, a calibration procedure of the friction parameters is proposed.

Models based on different assumptions were compared: distinct velocities or not in the water and the transport layer, distinct concentrations or not in the bed and the transport layer. The one-velocity model appears to fail in matching the common sediment-transport formulae results, while the solid discharge predicted by a two-velocity model is closer to those. Looking more precisely to the thickness and velocity of the transport layer, the model where also the concentration is distinct reveals to be the more appropriate.

Laboratory experiments are required to generalise the above results and to define a range of applicability of the method.

Our experience of the proposed model seems to show a wide applicability in term of solid discharge, while the thickness of the transport layer is sometimes more difficult to interpret in the case of low transport rates.

ACKNOWLEDGEMENTS

The authors would like to thank H. Capart for the access to his two-layer software.

ABSTRACT: Observations in rivers or flumes have shown that for low water discharge, sediment transport is a very intermittent process. To understand the physical origins of the solid-discharge fluctuations, we investigated the motion of coarse spherical glass beads entrained by a steady shallow turbulent water flow down a steep two-dimensional channel with a mobile bed and steady bead supply at the inlet. Flows were filmed from the side by a high-speed camera. We also revisited Einstein's theory on sediment and derived the statistical properties of the key flow variables. Analyzing the autocorrelation functions and the probability distributions of our measurements revealed the existence of long-range correlations. These frequent wide fluctuations stemmed particle entrainment and motion being collective phenomena rather than individual processes, contrary to what is assumed in most theoretical models.

1 INTRODUCTION

The objective of this paper is to characterize and understand the physical origins of wide fluctuations in the solid discharge for sediment transport in gravelbed rivers and mountain torrents. Sediment is assumed to be made up of coarse particles driven by gravity and drag exerted by a water turbulent flow.

Despite substantial progress made over the last two decades in the physical understanding of the motion of coarse particles in a turbulent stream, the ability to compute sediment flux in rivers remains poor. For instance, the sediment flow rates measured in gravel-bed rivers differ within one to two orders of magnitude from the bed-load transport equations (Wilcock 2001; Martin 2003; Barry et al. 2004), even though these equations have been established from flume experiments using regression techniques and are believed to provide a proper evaluation of sediment transport in a well-controlled laboratory environment.

Impediments to a full analytical approach to twophase flows are many: complex interplay between the particles and the carrying fluid, particle exchanges between the bed and the flow, turbulence effects (bed friction, advection of turbulent structures), etc. That is why most models are based on substantial approximations of the interplay between the solid and fluid phases.

Einstein (1950) realized how important it is to account for the episodic nature of particle transport in computing the solid discharge. In Einstein's view, sediment transport does not result from an equilibrium in the momentum transfers between solid and liquid phases (Bagnold's assumption), but rather from the difference between the entrainment and deposition rates. Einstein's stochastic approach raises a number of issues that have received few responses to date. For instance, since particles move sporadically and in different groups, the solid flow rate is made up of a series of pulses and is highly fluctuating, which makes it difficult to define and measure it properly, even under steady flow conditions (Bunte & Abt 2005). Both field and laboratory experiments have revealed that instances in which the instantaneous solid discharge is four times higher than its mean value are frequent (Kuhnle & Southard 1988; Lisle 1989; Böhm et al. 2004). Translated statistically, this observation means that the probability density functions of the transportrate records have a thick tail and depart from the expected Gaussian behavior. This departure can be seen as the hallmark of collective motions (Sornette 2000); if so, this also implies that any mean-field

Copyright © 2006 Taylor & Francis Group plc, London, UK

approximation runs into difficulty since cooperation between particles is not accounted for.

Our idea was to run experiments in an inclined, two-dimensional flume with a continuous particle supply and steady flow rate. This two-dimensional flume is assumed to be the simplest representation of sediment transport on the laboratory scale and presents overwhelming advantages: the boundary conditions can be controlled and most of the flow variables can be measured using image processing. Since a quantitative comparison between theory and experiment is biased by any parameter fitting, we tested Einstein's theory by analyzing the probability distributions and correlations of the signals measured.

2 EINSTEIN'S THEORY REVISITED

Using *ad hoc* arguments, Einstein (1950) derived a bed-load equation, which has been considered as the cornerstone of probabilistic theories of bed-load transport. Taking inspiration from the work done by Lisle et al. (1998) and Papanicolaou et al. (2002), we assume that sediment transport at low flow rates can be described using a birth-death process.

The solid discharge can be defined as the flux of particles through a flow cross-section $\mathcal{S}$. Equivalently, we can define the flow rate $\dot{n} = q_s/v_p$ as the number n of particles in motion within a control volume of length L times their respective velocity u_i

$$\dot{n} = \frac{1}{L}\sum_{i=1}^{n} u_i, \tag{1}$$

(Böhm et al. 2004). In order to compute the discharge equation, we need to establish (i) the number n of particles in motion and (ii) their velocities depending on the control parameters (water discharge q_w, θ, particle radius a, particle density ρ_p.

In order to compute the number of particles in motion, we can draw an analogy with chemical reactions. If the particles resting on the bed surface are denoted by B, the moving particles by M, we can represent the exchanges between the two phases in the following way: $B \rightleftarrows M$: From these equations, we can establish a kinetic equation, which tells us the rate at which exchanges occur between the species B and M. The time variation in the number of moving particles is

$$\frac{dn}{dt} = \frac{n_{b\to m}}{t_b} - \frac{n_{m\to b}}{t_m}, \tag{2}$$

where $n_{b\to m}$ is the number of particles dislodged from the bed and $n_{m\to b}$ is the number of moving particles that are left to rest within the observation window. These population exchanges are associated with the characteristic times t_b and t_m, which are in turn related to the mean times during which a single particle stays

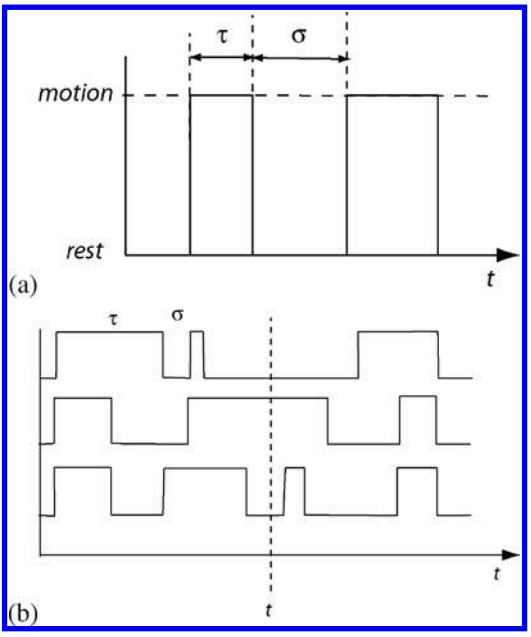

Figure 1. (a) Succession of resting and moving phases for a single particle. (b) The solid discharge is related to the sum of the state variables.

at rest or moves, respectively σ and τ [see Fig. 1(a)]. We can also use Eq. (1) to define the entrainment rate (first term on the right-hand side) and the deposition rate (second on the right-hand side).

Transitions between the moving/resting states occur randomly. Following Lisle et al. (1998) and Papanicolaou et al. (2002), we assume that the particle motion is influenced only by its present state and has a fade memory of its previous states. In other words, the state transitions are governed by a continuous-time Markov process of order 1, with two discrete states (moving/resting). If we further assume that there is time and space invariance in the erosion/deposition process, the Markov transitions occur with constant probability per unit time. For any small time increment δt, we have

$$\text{Prob(moving at time } t+\delta t) = \sigma^{-1}\delta t + o(\delta t),$$
$$\text{Prob(resting at time } t+\delta t) = \tau^{-1}\delta t + o(\delta t),$$

where the characteristic times σ and τ are constant. This two-state Markov process is known as a telegrapher's process (Gardiner 1983). With these assumptions, it can be shown that the resting and moving times are exponentially distributed with means σ and τ, respectively. If $T_{b,i}$ and $T_{m,i}$ represent the durations of the ith periods of rest and motion since observation has started, then $\text{Prob}(T_m) = \tau^{-1}\ \exp(T_m/\tau)$ and $\text{Prob}(T_b) = \sigma^{-1}\ \exp(T_b/\sigma)$; said differently, the waiting time $\Delta t_{b\to r}$ between two entrainments is

Copyright © 2006 Taylor & Francis Group plc, London, UK

exponentially distributed with a mean time equal to σ: $\text{Prob}(\Delta t_{b\to r}) = (\sigma+\tau)^{-1}\exp(\Delta t_{b\to r}/(\sigma+\tau))$. Using the correspondence between the Poisson and exponential distributions, we also deduce that the number of events (deposition/entrainment) that occur per unit time is distributed according to a Poisson distribution: the probability that we observe k entrainments of the same particle within the time interval δt (of any duration) is given by $\text{Prob}(k;\ \delta t) = \nu^k \exp^{-\nu}/k!$, with $\nu = \delta t/\sigma$. The autocorrelation function is $\rho(s) = \exp(-(1/\tau + 1/\sigma)s)$ (Gardiner 1983).

This description is a simplified probabilistic Lagrangian description of a single particle's motion. We generalize it to obtain a Eulerian viewpoint, where we describe the motion of n particles within an observation window. Within our observation window of length $L = 2\lambda a \gg a$ (λ being a free parameter that can take any value), we assume that on average, the particle flux is steady, which means that the particles that leave the window are replaced by other particles coming from upstream. Within this window, there are approximately $N = \lambda$ particles lying over the bed surface, either at rest or in motion. The number n of particles in motion is then the sum of N variables independently distributed and governed by a telegraph process [see Fig. 1(b)]. Since each particle is governed by a telegraph process, the probability of observing it in motion is $\xi = \tau/(\tau+\sigma)$, i.e., it follows a Bernoulli distribution. Now, summing N particles following a Bernoulli distribution leads to a binomial distribution with mean ξN and variance $\xi(1-\xi)N$. We then conclude that with our assumptions, the number n of moving particles is distributed according to a binomial distribution, which means that if ξ stays constant independently of the number of particles N when $L \to \infty$, then the probability distribution of n tends toward a Gaussian distribution. If we further assume that whenever a particle is set in motion, it reaches a fairly constant velocity u_p (Ancey et al. 2003), then using Eq. (1) leads to concluding that the probability distribution of the solid discharge is the binomial distribution Bi, with mean $\xi N u_p$ and variance $\xi(1-\xi)N u_p^2$

$$\text{Prob}(\dot{n}) = \text{Bi}[\xi N u_p,\ \xi(1-\xi)N u_p^2].$$

In the large N limit, this distribution tends to be Gaussian. Since the sum of Poisson-distributed variables also has a Poisson distribution, we infer that the number of deposition/entrainment events per unit time has a Poisson distribution: the probability that we observe k entrainments within the time interval δt is given by

$$\text{Prob}(k;\ \delta t) = \frac{\nu^k}{k!}\exp^{-\nu}, \tag{3}$$

with $\nu = N\delta t/\sigma$. Instead of the Poisson distribution for characterizing the number of events per unit time, we can equivalently use the exponential distribution for specifying the lag times between two events; the mean waiting times between two entrainments within the observation window is $(\sigma+\tau)/N$. The autocorrelation function of N parallel telegrapher's processes is

$$\rho(s) = \exp(-s/\tau_*), \tag{4}$$

with $\tau_* = \sigma\tau/(\tau+\sigma)/N$. It is worth noting that, with our assumptions, the solid discharge and the number of moving particles have the same autocorrelation function.

According to Einstein (1950), the probability of entrainment is the fraction of time $\xi = \tau/(\tau+\sigma)$ that a particle is in a moving state. It also represents, on average, the relative number of particles (i.e., p) that have moved within the observation window for a given time interval (Papanicolaou et al. 2002). Moreover, in Einstein-like theories, particle entrainment results from a loss of stability: when the instantaneous lift and/or drag force exceeds the resisting forces, the particle is dislodged from the bed and starts to roll. By relating the fluid forces to the instantaneous fluid velocity u_f, we can deduce the fluid threshold u_c corresponding to incipient motion (Papanicolaou et al. 2002; Marsh et al. 2004). The probability p is then defined as $p = \xi = \text{Prob}(u_f > u_c)$. Over the time interval t_b, the number of particles that are entrained is then $n_{b\to m} = N_p$, while the number of particles that come to a halt is $n_{m\to b} = n(1-p)$ over the period t_m. In steady flow conditions, Eqs. (2) and (1) lead to

$$q_s = \frac{p}{1-p}\frac{t_m}{t_b}\frac{N}{L}u_p = \frac{p}{1-p}\frac{t_m}{t_b}\frac{u_p}{2a}, \tag{5}$$

which is formally similar to the solid-discharge equation derived by Einstein (1950), except that the solid discharge is now explicitly dependent on the particle velocity.

3 EXPERIMENTAL FACILITIES

3.1 *Overview*

In order to test the influence of fluid velocity (or, equivalently, Shields number) on bed-load transport, we ran six experiments with different flow rates in a twodimensional channel (see Sect. 3.2). The features of each run are summarized in Table 1. The hydraulic conditions are specified using classic dimensionless numbers. The flow Reynolds number is defined as $Re = 4R_h\overline{u}_f/\nu$, where $Rh = Wh/(2h+W)$ denotes hydraulic radius, $\overline{u}_f = q_w/(Wh)$ mean fluid velocity, ν kinematic viscosity of water, and h the time-averaged water depth. The Froude number $Fr = \overline{u}_f/\sqrt{gh}$ varied significantly over the duration of the experiment and along the main stream direction. The mean Fr values are reported in Table 1. The Shields number is defined as $Sh = \rho_f\overline{u}_f^2/((\rho_p-\rho_f)gh)$ and reflects the ratio of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 1. Flow characteristics and time-averaged values of dimensionless numbers characterizing bed load and water flow. The slope is kept constant: $\tan\theta = 10\%$, while the solid discharge at the inlet $\dot{n}_0$ is altered. The notation E10-6 means: $\tan\theta = 10\%$ and $\dot{n}_0 \approx 6$ beads/s. The measured solid discharge within the observation window is denoted by $\dot{n}$. *Re*, *Fr*, and *Sh* are the Reynolds, Froude, and Shields dimensionless numbers. The time-averaged particle velocity in the rolling (saltating, respectively) regime is denoted by $\overline{u}_r$ ($\overline{u}_s$, respectively), while n_r (n_s, respectively) represents the mean number of rolling (saltating, respectively) particles; the variance (Var) of n_r and n_s is provided. We have also reported the autocorrelation time t_e of the rolling-particle number $n_r(t)$.

water driving force to the friction resistance force on the bed (Böhm et al. 2004). The solid concentration is defined as the ratio of the solid and water discharges $C_s = q_s/q_w$. Values reported in Table 1 are low, which indicates that particle flow was dilute. The h/d ratio is low, typically in the range 1.7–3.2.

3.2 *Channel*

Experiments were carried out in a tilted, narrow, glass-sided channel, 2 m in length and 20 cm in height. Figure 2 shows a sketch of the experimental facility. The channel width W was adjusted to 6.5 mm, which was slightly larger than the particle diameter (6 mm). In this way, particle motion was approximately two-dimensional and stayed in the focal plane of the camera. The channel slope $\tan\theta$ was 10%.

3.3 *Channel base and mobile bed*

The channel base consisted of half-cylinders of equal size ($a = 3$ mm), but they were randomly arranged. Disorder was essential, as it prevented slipping of entire layers of particles on the upper bed surface.

3.4 *Solid and water supplies*

Colored spherical glass beads with a nominal diameter $2a$ of 6 mm and a density ρ_p of 2500 kg/m^3 were used. They were injected from a reservoir into the channel using a wheel driven by a direct current motor and equipped with 20 hollows on the circumference, as depicted in Fig. 2. For the experiments presented here, the injection rate $\dot{n}_0$ ranged from 5 to 20 beads per second, with an uncertainty of less than 5%. This corresponded to a solid discharge per unit width q_s/W of $9-38 \times 10^{-5}$ m^2/s. The water supply at the channel entrance was controlled by an electromagnetic flow meter. The discharge per unit width q_w/W ranged from 4 to 10×10^{-3}m^2/s. The hydraulic conditions (velocity profile, bed friction, etc.) have been specified in earlier papers (Ancey et al. 2002; Böhm et al. 2004).

3.5 *Experimental procedures*

Once bed equilibrium was reached, the particles and the water stream were filmed using a Pulnix partial scan video camera (progressive scan TM-6705AN). The camera was placed perpendicular to the glass panes at 115 cm away from the channel, approximately 80 cm upstream from the channel outlet. It was inclined at the same angle as the channel. Lights were positioned in the backside of the channel. An area of $L = 22.5$ cm in length and 8 cm in height was filmed and later reduced to accelerate image processing.

The camera resolution was 640×192 pixels for a frame rate of $f = 129.2$ fps (exposure time: 0.2 ms, 256 gray levels). Each sequence was limited to 8000 images due to limited computer memory; this corresponded to an observation duration of approximately 1 minute.

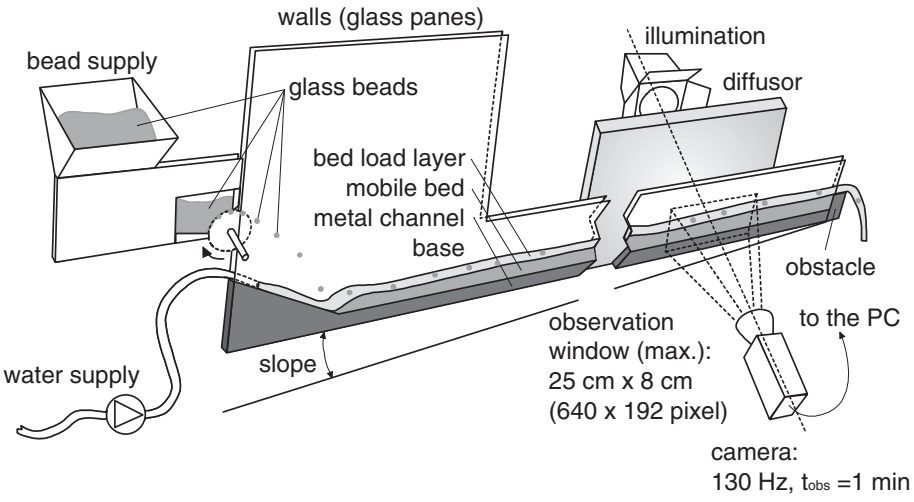

Figure 2. Sketch of the experimental setup.

Each experiment was repeated at least twice in order to spot possible experimental problems and to get an idea of the data scattering. Images were analyzed using the WIMA software, provided by the *Traitement du Signal et Instrumentation* laboratory in Saint- Etienne (France). For more details, the reader can refer to (Böhm 2005).

4 EXPERIMENTAL RESULTS

As we shall see below (Sect. 4.1), the generalized Einstein theory predicts a number of features such as the nearly Gaussian distribution of the solid discharge, the Poissonian character of the occurrence of entrainment/deposition over time, and the exponential decrease in the autocorrelation function of the number of particles moving within the observation window. There are also a number of features that conflict with the fundamental assumptions underpinning this theory. In Sect. 4.2, we will see that the probability distributions of the key variables have much thicker tails than expected. This will be interpreted as the hallmark of cooperation processes between particles when they are entrained or when they move.

4.1 *Solid-discharge time series*

Figure 3 shows the time variations in the solid discharge $\dot{n}$, the number of particles n_r in a rolling regime, the number of particles that passed from a resting state to a rolling state ($r \rightarrow b$) and conversely ($b \rightarrow r$). This diagram represents the results obtained for a mean bed slope of 0.1 and a solid discharge at the flume inlet $\dot{n}_0 = 8$ beads/s (experiment 10-8 in Table 1); these plots are typical of the results that we obtained for other solid discharges $\dot{n}_0$.

Note that in these state transitions [see Fig. 3(d–e)], more than one particle can be involved; because of the limitation of the acquisition rate of our highspeed camera (130 images per second), we could not resolve two events that occurred over very short time intervals. This limitation may pose problems when interpreting the Markovian properties of our time series.

A striking point in Fig. 3 is the wide fluctuations that all the time series exhibit. Typically, the solid flow rate ranged from 0 to 22 beads/s, while the mean flow rate imposed at the inlet was $\dot{n}_0 = 8$ beads/s. For the rolling regime, the fluctuation range was 0–40 beads within the observation window, whereas the mean number was $\overline{n}_r = 9.7$ beads.

As shown in Fig. 4(a), the empirical probability distribution of solid discharge is closely approximated by a Gaussian distribution, although, in places, there are spikes departing from the Gaussian trend. These spikes reflect the existence of a finite number of particles within the observation window (Böhm et al. 2004). This Gaussian behavior is expected since the solid discharge is defined as the product of the number of moving particles and of their velocities [see Eq. (1)]. Indeed, if the particle velocities are sufficiently agitated (resulting in a random velocity distribution) and the number of moving particles within the observation window varies significantly with time, the law of large numbers supports this expectation.

As expected, the autocorrelation functions ρ of the measured signals $\dot{n}(t)$, $n_r(t)$, and $n_s(t)$ are similar. As shown by Fig. 4(b), the typical behavior is the same: (i) we observe a fairly slow exponential decrease, i.e. for short times, we have $\rho(s) \approx \exp(-t/t_e)$ with t_e a

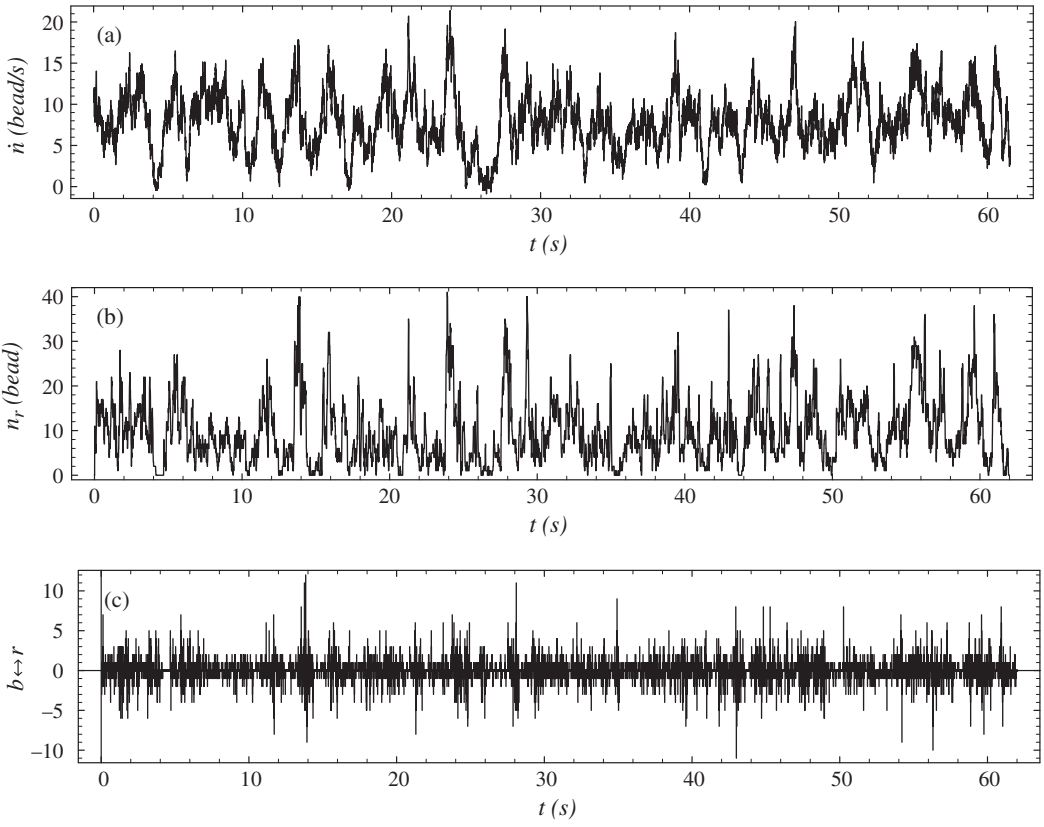

Figure 3. Experiment 10-8: mean solid discharge at the channel inlet $\dot{n}_0 = 8$ beads/s; mean bed slope $\tan\theta = 0.1$. (a) Solid discharge $\dot{n}$ as a function of time. (b) Variation in the number of rolling particles n_r. (c) Exchanges between the bed and the rolling phases: each bar oriented upward indicates the number of beads that passed from the resting state to the rolling regime over a given time interval $\Delta \approx 1/130$ s; downward-oriented bars represent the number of rolling particles coming to a halt.

typical time scale; (ii) the typical time scales t_e related to each signal are very close. For experiment E10-8, we found $t_e \approx 230$ ms. The autocorrelation times for other experiments are reported in Table 1.

In an earlier paper (Böhm et al. 2004), the timescale t_e was interpreted as the typical travel time of the moving particles through the observation window. While this interpretation seems reasonable for the solid discharge, there is at first glance no clear reason why this should be so for the number of rolling/saltating particles. One could call on the following explanation for the similarity in the autocorrelation functions: once a particle experiences a transition into another regime, it moves at approximately the same velocity as the mean phase velocity and hence one expects that the autocorrelation time $n_r(t)$ and $n_s(t)$ is somehow related to a travel time. However, since their mean phase velocity was quite different (see Table 1), their autocorrelation times should also be different.

In Sect. 2, we have also shown that for particle entrainment, the waiting-time distribution should follow an exponential distribution of rate $r = N/(\sigma + \tau)$. A particular problem encountered here in evaluating the parameter r is that we could not resolve successive events when they occurred within a very short time interval (less than the acquisition rate of our camera, i.e. for lag times shorter than $2/130 = 0.015$ s); this means that we should censor the lag-time sample to remove the lowest values if we want to properly evaluate the sample distribution. For the sake of simplicity, however, we did not proceed in this way. Figure 5(a) shows the empirical probability distribution function of the lag times Δt for the different classes of events (entrainment or deposition, transition to a rolling or a saltating regime). We have superimposed the exponential distribution, the coefficient of which has been adjusted using the method of moments on the whole sample. As expected, the exponential distribution is a fairly good representation of the lag-time distribution whatever the type of exchange except at low values of Δt, for which the empirical distribution departs significantly from the exponential

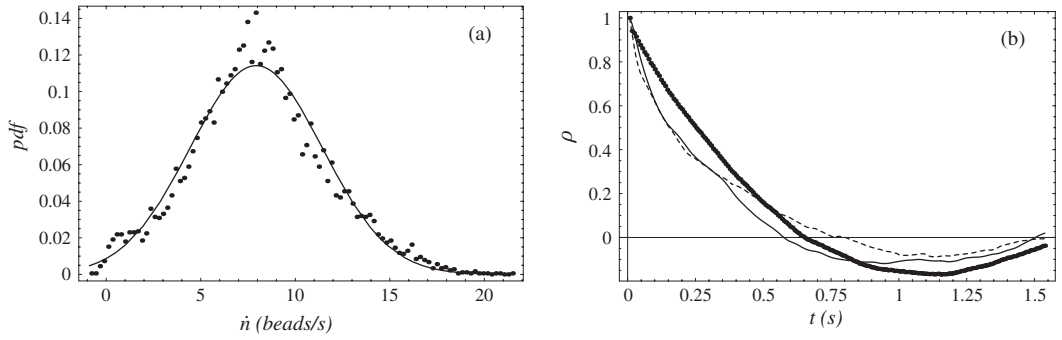

Figure 4. (a) Probability distribution function (pdf) of the solid discharge for experiment E10-8 ($\dot{n}_0 = 8$ beads/s; mean bed slope $\tan\theta = 0.1$): the dots represent the empirical pdf, whereas the solid line is a Gaussian distribution adjusted on the data (mean: 7.93, standard deviation: 3.49). (b) Autocorrelation function for experiment E10-8: the thick dotted line corresponds to the solid discharge $\dot{n}$, the thin solid line to the number of rolling particles n_r, and the dashed line to the number of saltating particles n_s.

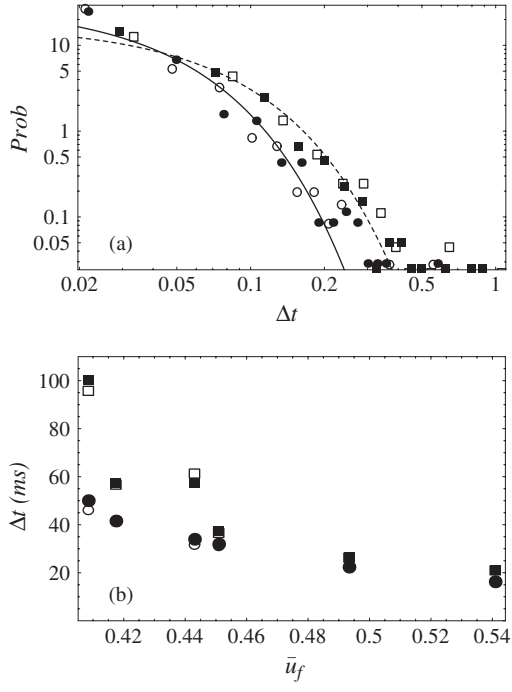

Figure 5. Probability distribution of the time lag Δt between two events (change in state): the filled disks represent the state transition $b \to r$ (entrainment, $\tau_{b\to r}$), while the empty disks represent the state transition $r \to b$ (deposition, $\tau_{r\to b}$); the solid line provides the exponential probability distribution adjusted on the data $b \longleftrightarrow r$ (using the method of moments). The filled boxes represent the state transition $r \to s$, while the empty boxes represent the converse transition $s \to r$; the dashed line is the exponential probability distribution adjusted on the data $r \longleftrightarrow s$. (b) Variation in the lag times $\Delta t_{b\to r}$ (filled disks), $\Delta t_{r\to b}$ (empty disks), $\Delta t_{r\to s}$ (filled boxes), and $\Delta t_{s\to r}$ (empty boxes).

trend. Adjustment provides the following characteristic times for each transition type for experiment E10-8: $\Delta t_{b\to r} = 33.9$ ms, $\Delta t_{r\to b} = 31.7$ ms, $\Delta t_{r\to s} = 57.4$ ms, and $\Delta t_{s\to r} = 61.3$ ms. For all experiments, the mean lag times are reported as a function of the mean fluid velocity in Fig. 5(b).

Up to this point, the generalized Einstein theory is qualitatively consistent with our laboratory experiments. A discrepancy is, however, noticeable. In Sect. 2, we found that the autocorrelation time t_e was $\tau_* = \sigma\tau/(\tau+\sigma)/N$ and the waiting time was $\Delta t_{b\to r} = r^{-1} = (\sigma + \tau)/N$. From these relations, we deduce that the ratio

$$\frac{\tau_*}{\Delta t_{b\to r}} = \frac{\tau/\sigma}{(\tau/\sigma+1)^2} < 1,$$

in contradiction with our experimental results, since for instance for E10-8, we have $\tau_*/\Delta t_{b\to r} = 6.9$. The autocorrelation time is much longer than expected. As we shall see in the next subsection, this result is not fortuitous and illustrates the existence of long-range correlations in the physical processes governing sediment transport.

4.2 *Probability distribution of the number of moving particles*

Analyzing the probability distribution of the number of moving particles is richer than examining that of the solid discharge because the latter combines two sources of fluctuations: the number of particles and their velocities, which makes it difficult to properly interpret them. Here, we will focus on the probability distributions of the number of rolling particles n_r (see Fig. 6).

Figure 6 shows how the probability distribution of n_r changes when the fluid velocity is increased. At low

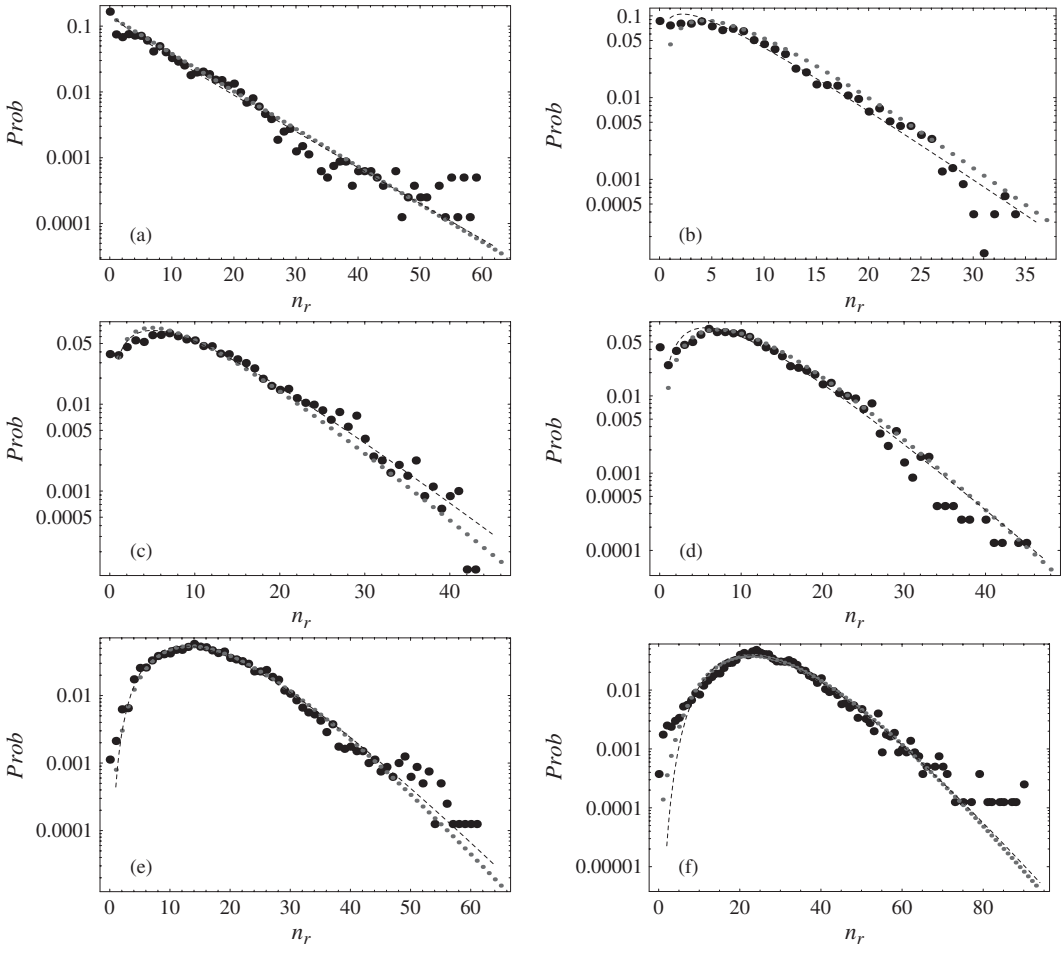

Figure 6. Probability distributions of the number of rolling particles. The dots represent the empirical probability mass functions. The dotted lines represent the negative binomial distribution, while the dashed lines represent the gamma distribution. (a) experiment E10-6, (b) experiment E10-7, (c) experiment E10-8, (d) experiment E10-9, (e) experiment E10-16, (f) experiment E10-21.

fluid velocities, the probability distribution is close to a straight line in a log-linear diagram, revealing a power-like behavior. At higher fluid velocities, the probability distribution takes the shape of an asymmetric bell, with its maximum moving from left to right. At first sight, the prominent impression is that increasing the solid discharge leads to making the probability distribution of n_r more Gaussian.

In the generalized Einstein theory presented in Sect. 2, we inferred that the number of moving particles should be distributed according to a binomial law, with mean ξN and variance $\xi(1-\xi)N$ where N is the density number of particles lying on the bed and $\xi = \tau/(\sigma+\tau)$ is the mean relative time during which a particle is maintained in motion by the stream. A particularity of the binomial law is that its variance must be lower than its mean. For all our experiments, we found that the sample variance exceeded the sample mean. For instance, for experiment E10-8 [see Fig. 6(c)], the mean number of particles is $\overline{n}_r = 10.4$, whereas the variance is $\mathrm{Var}(n_r) = 55.8$. For all probability distributions, the distribution tail is much thicker than expected.

Since thick tails are often associated with collective phenomena (Sornette 2000), it is worthwhile characterizing these distributions more accurately.We found that the negative binomial distribution provides a fairly proper representation of the empirical distribution, as shown in Fig. 6. Small departures are observed in the distribution tail (insufficient number of data) and when $n_r \to 0$. Note that it was not always very easy to distinguish between incipient motion and oscillations of

Copyright © 2006 Taylor & Francis Group plc, London, UK

bed particles and consequently our image-processing algorithm failed at times to count the exact number of moving particles. The small deviations between the theoretical and empirical probability distributions may result from this uncertainty on n_r. Except for the behavior close to the boundaries, the whole trend is well represented by the negative binomial distribution. Instead of a discrete distribution, we can use a continuous probability distribution to approximate the empirical distribution of n_r. A natural candidate is the gamma distribution, which can be fairly well adjusted on data, as shown in Fig. 6.

This observation is of fundamental importance since it conflicts with the assumptions underlying the birthand- death process used in the theoretical derivation. Indeed, if the particles are independent and identical, then one obtains a binomial distribution whatever the model taken for rest/move, provided that the flow is steady and there is bed equilibrium. The only way to obtain a non binomial behavior would be to have (i) unsteady flow conditions or (ii) non identical or dependent particles. Assumption (ii) is the most plausible. Taking a closer look at the resting and moving states showed that on many occasions, particles moved in well-separated groups (Böhm et al. 2004). Collective displacement and entrainment of particles explained why the particles were to some extent dependent and thus why the autocorrelation time was much longer than expected. One might think that aggregate transport was promoted by particle sphericity and equal size. Our observations are, however, well supported by field measurements, which documented similar processes in gravel-bed rivers (Drake, Shreve, Dietrich, & Leopold 1988). The wide range of fluctuations exhibited by laboratory or field measurements (Wilcock 2001; Martin 2003; Barry, Buffington, & King 2004) also confirmed the existence of thick-tailed probability distributions for sediment transport involving irregular particles.

5 CONCLUSION

Our experimental results provided evidence that, although some statistical properties (such as the autocorrelation function of the solid discharge) predicted by Einstein's theory were consistent with our data, the autocorrelation functions of the number of moving particles and their mass distribution functions violated the assumptions underpinning Einstein's theory. Typically, the autocorrelation time was much longer than expected and the mass distribution function had a much thicker tail than predicted using Einstein's arguments. For instance, from the theoretical standpoint, the number of moving particles within any observation window is a random number distributed according to a binomial distribution; in the large-number limit, the theoretical distribution should tend very quickly toward a Gaussian limit. In contrast, our experiments showed that the sample variance outweighed the sample mean and a negative binomial distribution fits the data better. This means that extreme events (i.e., a large number of moving particles) are much more frequent than expected. Furthermore, our experiments showed that the convergence toward the Gaussian limit is slow. At the lowest solid discharges achievable with our system, the probability distribution of the particle number is closer to a power-law distribution. When increasing the solid discharge, the variance/ mean ratio decreases and the probability distribution becomes increasingly bell-shaped.

The present study has many important implications. First, it provides a plausible explanation about the failure of all mean-field theories on bed-load transport, which ignore any cooperation effects between particles. It thus motivates further research with a clear focus on collective effects in entrainment and displacement of coarse particles as a result of fluid action. Second, this work sheds some light in the critical issues concerning bed-load measurement in rivers (Bunte & Abt 2005). Hydraulicians and geomorphologists use various systems (Helley-Smith sampler, bed-load trap) to measure the solid discharge by capturing sediment over a given time interval. The crux of the issues lies in the proper selection of the sampling time (ranging from a few seconds to several minutes), and this dif- ficulty of selecting a proper timescale is illustrated by the large differences among various measurement systems.

SETRAC – A sediment routing model for steep torrent channels

D. Rickenmann, M. Chiari & K. Friedl
University of Natural Resources and Applied Life Sciences, Vienna, Austria

ABSTRACT: A sediment routing model for steep torrent channel networks called SETRAC has been developed. SETRAC is the acronym for sediment transport in Alpine catchments. In SETRAC the water runoff is given as input hydrographs at discrete points. A kinematic flow routing of the flood hydrograph is performed in the channel network. Different sediment transport formulae and flow resistance approaches can be selected in SETRAC. The sediment is transferred through the channel network considering a reachwise sediment budget. Initial sediment stock can be assigned for each channel reach. SETRAC is applied to a well documented case study on a flood event with substantial sediment transport which occurred in a torrent catchment in the Austrian Alps. Using a rough correction procedure to account for form roughness losses which reduce the energy slope available for bedload transport, a reasonable agreement has been obtained between simulated and observed sediment loads. Considering the uncertainty of the input data, the results are encouraging.

1 INTRODUCTION

In contrast to studies on lowland gravel-bed rivers, relatively few have been made on sediment transport in steep headwater channels, with stream gradients steeper than about 0.05. Sediment transport dynamics in these channels may be quite different from low-gradient channels. There is often a strong interaction between hillslope processes and the channel network. Sediment transport may be supply limited rather than controlled by the sediment transport capacity under given discharge and channel conditions. Steep headwater streams are characterized by a wide range of sediment sizes and temporally- and spatially-variable sediment sources. Bed morphology and channel structures may be influenced by the presence of large boulders, woody debris and bedrock constrictions. This can result in large variations in channel geometry, streamflow velocity and roughness, and thus the application of theoretical sediment transport equations may be problematic (Gomi & Sidle 2003). Quantitative measurements of sediment and bedload transport in steep streams are very limited (Rickenmann 2001).

Many bedload transport formulas for gravel-bed rivers were developed or calibrated based on experiments in laboratory flumes. Measured transport rates in natural streams may differ substantially from values predicted with such formulas (e.g. Bathurst et al. 1987, Gomez & Church 1989). Also, measured transport rates in gravel-bed rivers and boulder-bed streams may vary by several orders of magnitude at similar (mean) flow conditions (e.g. Bathurst et al. 1987, Gomez 1987, Reid & Laronne 1995, Hegg & Rickenmann 1999, Rickenmann 2001). In very steep streams and at high transport intensities (e.g. "immature" debris-flow conditions) the distinction between bedload and suspended load transport becomes blurred (Takahashi 1987, Rickenmann 1990a).

For boulder-bed channels, which are typical for torrents and mountain streams steeper than a few percent, a two-phase model as described by Beschta (1987) and Bathurst (1987) can provide a conceptual framework for the description of sediment transport behaviour. In "phase 1 transport" there is basically no destruction of the coarse surface layer, and the transported sediment is generally made up the finer fractions (sand and fine gravel); transport rates largely depend on fine material available in pools and behind channel obstructions, or on external sediment supply which can vary by orders of magnitude. In "phase 2 transport" the surface or armour layer is broken up and there is essentially equal mobility of all size fractions, i.e. the size distribution of the bedload is similar to that of the subsurface material. Several studies have applied different bedload transport formulas to field measurements in gravel-bed rivers and tried to assess their performance. For example, Bathurst et al. (1987) compared six bedload transport formulas with field and flume data at bed-slopes up to 0.09, and found that the best predictions were given by Schoklitsch's (1962) equation.

Flow resistance in steep mountain streams with irregular bed topography includes both grain friction

Copyright © 2006 Taylor & Francis Group plc, London, UK

and form drag. Flows are typically characterized by low relative flow depths. Recent investigations and discussions of such flow conditions were made by Aberle & Smart (2003), Bathurst (2002), Lee & Ferguson (2002), and Smart et al. (2002).

For flows in natural streams with values of h/d_c (with coarse grain size $d_c = d_{84}$ or d_{90}) smaller than about 4 to 6 a marked increase in flow resistance has been observed (Pitlick 1992, Rickenmann 1996, Bathurst 2002). Jarrett (1990) reported that flow resistance may be substantially larger and more variable in steep boulder-bed channels at smaller values of relative flow depths, i.e. when the ratio of the hydraulic radius to the medium grain diameter is less than about 5. Bathurst (1993) discussed the development of a roughly S-shaped velocity profile in boulder-bed channels, at relative flow depths h/d_{84} of about 1 to 4. Compared to a logarithmic velocity profile, the flow in the lower zone near the boulders is retarded while there is a higher velocity zone near the flow surface. The additional drag caused by the boulders in this range may be partly responsible for the lower bedload transport "efficiency" as compared to flows with higher relative flow depths (Rickenmann 2001).

In principle two different approaches may be taken to consider sediment routing in steep streams. The first approach consists in using a hydraulic simulation model including sediment transport and accounting for variations in bed geometry due to erosion or deposition. These models typically include the full Saint Venant equations for one- or two-dimensional flow. A sediment transport equation is used in combination with the so-called Exner equation to account for sediment transport and storage effects in the riverbed. Examples are the MORMO model (Schilling & Hunziker 1995) and the FLUMEN model (Beffa 2005); in both models, armouring of the river bed can be considered.

A second group of hydrosedimentologic models considers sediment transfer processes at the catchment scale, including channel sediment transfer with different degrees of details. These models can typically be linked to a rainfall-runoff module and a module to account for sediment transfer from hillslopes into the channel network. Examples are the ETC rainfall-runoff-erosion model (Mathys et al. 2003), and the SHESED model (Wicks & Bathurst 1996).

The objective of this paper is to present the framework of equations to predict flow resistance and sediment transport in steep torrents and to introduce the new sediment routing model for steep torrent channel networks, called SETRAC, where these equations have been implemented. In addition, an application of the SETRAC model is discussed for the case of a flood event in an Austrian torrent which occurred in August 2005 and transported about 30,000 m^3 of debris to the fan area.

2 FLOW RESISTANCE

2.1 *Flow resistance approaches*

For steep streams with gradients larger than about 0.1 there are only few velocity measurements, and in most cases no information is available on flow depth. However, the well known Manning-Strickler equation is also used in torrents, due to the lack of other approaches.

$$v = \frac{1}{n} R^{0.67} S^{0.5} \tag{1}$$

where v is the mean flow velocity, n *is* Manning's roughness coefficient ($1/n = k_{St}$, where k_{St} is Strickler's coefficient of roughness), R is the hydraulic radius and S is the channel gradient.

Due to the lack of flow depth data in steep streams, Rickenmann (1994, 1996) developed a set of empirical equations where the mean flow velocity, the Strickler or Manning's coefficient and the surface width of the flow, respectively, can be expressed as a function of discharge, channel gradient, and a characteristic grain size of the surface bed material. All the equations are dimensionally homogeneous; they are based on more than 300 measurements in torrents and gravel-bed rivers. The equations to estimate Manning's roughness coefficient n are (Rickenmann 1996):

$$\frac{1}{n} = \frac{0.97 g^{0.41} Q^{0.19}}{S^{0.19} d_{90}^{0.64}} \quad for \quad S > 0.008 \tag{2}$$

$$\frac{1}{n} = \frac{4.36 g^{0.49} Q^{0.02}}{S^{0.03} d_{90}^{0.23}} \quad for \quad S < 0.008 \tag{3}$$

where g is the acceleration due to gravity, Q is the discharge and d_{90} is the grain size of the surface bed material for which 90% of the bed material is finer. The equations are based on stream flow velocity observations covering a wide range of flow conditions, including mountain streams with channel gradients of up to 0.2 and relative flow depth as small as about 0.4. The original regression equations were derived using dimensionless parameters. Figure 1 compares the two equations with the field data. For most of the data points, the difference between predicted and observed values is less than about +/−50%.

Alternatively the mean flow velocity can also be expressed as a function of discharge instead of flow depth (Rickenmann 1991, 1994):

$$v = \frac{1.3 g^{0.2} q^{0.6} S^{0.2}}{d_{90}^{0.4}} \tag{4}$$

where q is the flow rate per unit width. Equation (4) was originally proposed by Takahashi (1978) based on

Copyright © 2006 Taylor & Francis Group plc, London, UK

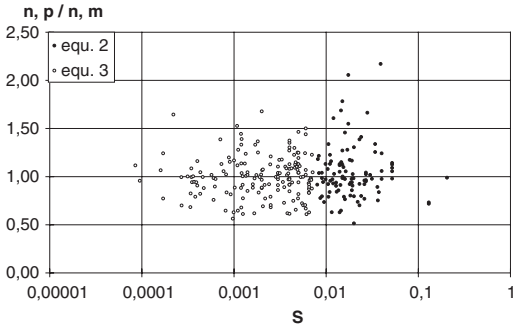

Figure 1. Ratio of predicted to measured Manning roughness coefficient, n_p/n_m, against the slope, S for the equations (2) and (3).

laboratory experiments on debris flows, and successfully applied by Rickenmann (1991) to experimental sediment transporting flows. Like equation (2) and (3) equation (4) is dimensionally homogenous.

Equation (4) was applied to field data by Rickenmann (1996), resulting in a similar scatter between predicted and observed velocities, as when applying equation (2) in combination with equation (1). With $q = vh$ equation (4) can be transformed to:

$$v = \frac{1.93 g^{0.5} h^{1.5} S^{0.5}}{d_{90}} \tag{5}$$

where h is the flow depth.

Another flow resistance equation for steep channels was introduced by Smart & Jäggi (1983). The formula is based on their laboratory data of sediment transporting flows. The increasing flow resistance at low relative flow depths is expressed by:

$$v = 2.5 v^* \left(1 - e^{\frac{-0.05 h_m}{S^{0.5} d_{90}}}\right) \ln\left[\frac{12.3 h_m}{1.5 d_{90}}\right] \quad \text{for } S \le 0.20 \tag{6}$$

where the shear velocity is defined as $v^* = (g h_m S)^{0.5}$, and the expression in the first brackets accounts for increasing flow resistance at low relative flow depths. The mixture flow depth h_m accounts for the space occupied by moving particles. The increase compared to the fluid flow depth, $h_f = q/v$, was found to be important for channel gradients steeper than about 0.1 in the laboratory experiments. In SETRAC, the following empirical relation for the ratio h_f/h_m is used (Rickenmann 1990a):

$$\frac{h_f}{h_m} = 1 - 1.64 S^{0.42} \left(\frac{q_b}{q}\right)^{0.63} \tag{7}$$

where q_b is the bedload transport rate per unit channel width. The experiments for the development of (7) covered channel gradients up to 0.2. To avoid unrealistic extrapolations, the minimum value of h_f/h_m is set as 0.2, which approximately corresponds to the maximum packing density of natural sediment.

2.2 *Flow resistance due to form roughness*

In steep mountain streams with irregular bed topography, form roughness is an important contribution to total grain friction. Flows are typically characterized by low relative flow depths and substantial form drag.

Wong & Parker (in review) proposed an expression for the roughness coefficient n_r associated with skin friction only, in the context of reanalysing the bedload relation of Meyer-Peter & Müller (1948):

$$\frac{1}{n_r} = \frac{23.2}{d_{90}^{1/6}} \tag{8}$$

A similar equation for n_r has also been reported by Jäggi (1984). Following a procedure proposed by Palt (2001), the relative proportion of grain roughness to total roughness can be expressed by dividing (8) by (2):

$$\frac{n_r}{n} = \frac{0.131 g^{0.09} Q^{0.19}}{S^{0.19} d_{90}^{0.47}} \quad \text{for } S > 0.008 \tag{9}$$

In (9) the contribution of form resistance to the total resistance is represented by $(1 - n_r/n)$. A slightly different expression for n_r/n can be obtained by using (8) in combination with the empirical equations for velocity and flow width (equations (2a) and (4) in Rickenmann 1994), resulting in:

$$\frac{n_r}{n} = 0.185 S^{-0.22} \left(\frac{h}{d_{90}}\right)^{0.55} \quad \text{for } S > 0.008 \tag{10}$$

A comparison of (9) and (10) is made in Figure 2 where they are applied to the data set of flow velocity measurements used by Rickenmann (1994, 1996). A large variation of the n_r/n values is observed for channel gradients up to about 0.1. For steeper channels form roughness appears to be more important than grain roughness, based on the limited data available.

The slope of the energy line S can now be partitioned into a fraction S_{red} associated with skin friction only:

$$\frac{S_{red}}{S} = \left(\frac{n_r}{n}\right)^2 \tag{11}$$

Using a similar procedure, Palt (2001) accounted for form losses and found much better agreement with his bedload measurements in Himalayan rivers and

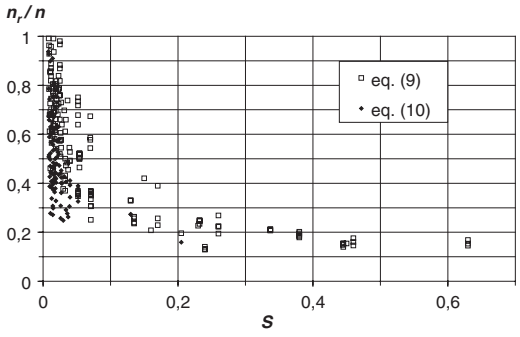

Figure 2. Comparison of two approaches to estimate the proportion of form and grain roughness in steep streams.

the bedload transport data of Meyer-Peter and Müller (1948).

The exponent of 2 in equation (11) is based on the Manning-Strickler equation. However Meyer-Peter & Müller (1948) argued that the exponent in the following equation (12) may be different from 2, and from their experiments they empirically determined a value $a = 1.5$ (Meyer-Peter & Müller 1948), as is also discussed by Wong & Parker (in review). A more general form of equation (11) is therefore:

$$S_{red} = S\left[\frac{n_r}{n}\right]^a \tag{12}$$

where plausible values of a are probably in the range $1 \le a \le 2$.

3 SEDIMENT TRANSPORT

The sediment transport module includes formulae for the determination of the total and grain resistance, the determination of incipient motion conditions in high gradient streams and the calculation of the sediment transport capacity. These interacting components can be combined within SETRAC.

Only a very limited number of bedload transport formulas have been developed for steep gravel bed streams. At ETH Zurich, a total of 252 experiments on bedload transport in gravelbed channels were performed both for gradients of 0.0004 to 0.023 (Meyer-Peter & Müller 1948) and for gradients of 0.03 to 0.20 (Smart & Jäggi 1983, Rickenmann 1990a).

Smart & Jäggi (1983) performed flume experiments to estimate the maximum transport capacity in steep channels:

$$q_b = \frac{4}{s-1}\left(\frac{d_{90}}{d_{30}}\right)^{0.2} qS^{1.6}\left(1-\frac{\theta_{cr}}{\theta}\right)$$

$$\text{for } 0.002 \le S \le 0.20 \text{ and } d_{90}/d_{30} \le 10. \tag{13}$$

where $s = \rho_s/\rho$ is the ratio of solid to fluid density and θ is the dimensionless bed shear stress. They estimated the dimensionless critical shear stress at initiation of bedload transport, θ_{cr}, with:

$$\theta_{cr} = \theta \cos\arctan S\left(1-\frac{S}{\tan\varphi}\right) \tag{14}$$

where ϕ is the angle of response.

For the entire slope range, including a total of 252 experiments, the following dimensionless bedload transport equation was developed (Rickenmann 1991):

$$\Phi_b = 3.1\left(\frac{d_{90}}{d_{30}}\right)^{0.2} \theta^{0.5}(\theta-\theta_{cr})Fr^{1.1}(s-1)^{-0.5} \tag{15}$$

where $\Phi_b = q_b/[(s-1)gdm^3]^{0.5}$ is the dimensionless bedload transport rate, d_m is the mean grain size and the dimensionless shear stress is $\theta = h_m S/[(s-1)d_m]$, and the Froude number is $Fr = v/(gh)^{0.5}$.

For the steep slope range only, i.e. $0.03 \le S \le 0.20$, a slightly more accurate representation of the data on bedload transport is given by the following equation (Rickenmann 1990a):

$$q_b = 12.6\left(\frac{d_{90}}{d_{30}}\right)^{0.2} (q-q_c)S^{2.0}(s-1)^{-1.6} \tag{16}$$

where q_c is the critical discharge for beginning of bedload transport.

Rickenmann (2001) slightly modified equation (15) by setting $Fr = 1$ and transforming it into a form similar to (16).

$$q_b = 3.1\left(\frac{d_{90}}{d_{30}}\right)^{0.2} (q-q_c)S^{1.5}(s-1)^{-1.5} \tag{17}$$

This form facilitates a comparison with other sediment transport formulae specifically developed for streams with gradients steeper than about 0.03. For a typical value of $s = 2.65$ and setting $d_{90}/d_{30} = 1.05$ for a uniform grain size distribution (Smart & Jäggi 1983), a comparison is made between equation (13), (16), and (17) with experimental data from the steep flume studies at ETH Zurich (Figure 3). For this purpose, (13) has been slightly modified to substitute θ_{cr} by q_c (Rickenmann 1990a).

The formulae (16) and (17) can be combined with an equation for the critical discharge.

$$q_c = 0.065(s-1)^{1.67} g^{0.5} d_{50}^{1.5} S^{-1.12} \tag{18}$$

$$q_c = 0.143(s-1)^{1.67} g^{0.5} d_{90}^{1.5} S^{-1.167} \tag{19}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

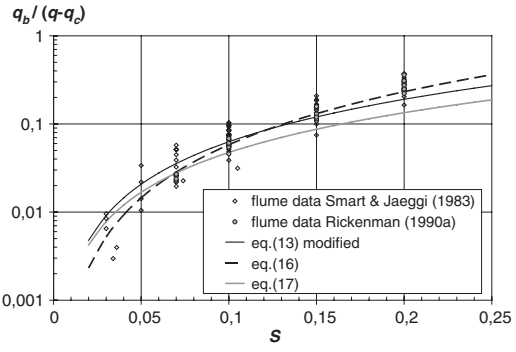

Figure 3. Comparison of bedload transport equations implemented in SETRAC with steep flume data of ETH Zurich.

Equation (18) was proposed by Bathurst et al. (1987) based on field data, and was slightly modified by Rickenmann (1990a). It represents bed conditions without an amour layer. Equation (19) is based on block ramp experiments by Whittaker & Jäggi (1986), and by using d_{90} as characteristic grain size it may be considered to represent the critical discharge required to break up an amour layer in steep streams.

4 SETRAC MODEL

4.1 *Modelling concept*

A one-dimensional sediment routing model for steep torrent channel networks called SETRAC has been developed at the University of Natural Resources and Applied Life Sciences, Vienna (Friedl 2004, Fuchs & Friedl 2002). SETRAC is the acronym for Sediment Transport Model in Alpine Catchments.

The channel network and longitudinal channel profile may be determined by means of a GIS. The channel cross-sections may have irregular shapes, representing a terrestrial bed survey. For the computations, the cross-sections may be represented with different degrees of simplification. A rainfall-runoff model may be used to determine the lateral input into channel sections in SETRAC, or input hydrographs may be defined at discrete points of the channel network.

The model uses a kinematic flow routing of the flood hydrograph through the channel network, neglecting diffusive and convective terms of the full Saint Venant equations.

Typically, the flow resistance approaches (1) or (4) are combined with the sediment transport formulae (16) and (17) and with the critical discharge (18) and (19). The flow resistance approach (6) can be combined with the sediment transport formulae (13) or (15). The flow resistance losses due to form drag (9) and (12) may or may not be taken into account with a sediment transport equation.

4.2 *Graphical user interface*

The SETRAC graphical user interface provides a clearly arranged tool for data handling. The input files can be selected and stored as projects. The channel network and the cross-sections including information about the discretization for calculation can be visualized. The parameters can be set and the formulae for the simulation can be selected. During the simulation the hydrographs and sedigraphs for the outlet and for selected locations can be monitored.

At any point in the channel network, the following output can be generated: Hydrograph and sedigraph as well as a sediment transport diagram showing reaches with erosion, “equilibrium” transport, and deposition of sediment. The longitudinal section can be exported as DXF (to be opened with CAD Software). The results of the simulation can also be stored as ASCII files.

4.3 *Geometric data*

The channel network is represented by nodes, sections and cross-sections. The longitudinal profile and the cross-sections need to be surveyed in the field, because the resolution of DEMs is commonly of the order of 25 m by 25 m. These may not be accurate enough to produce data expected by numerical models in river hydraulics and morphology. Data from laser scan flights or terrestrially scanned DEMs can also be used to generate the input data needed.

The channel geometry has to be defined by points. These points are defined by x and y coordinates and are connected by sections. Each node needs a related cross-section.

The sections include information about how the points are connected and the distance between the points. The reach lengths between the cross-sections should consider the flows in the main channel that can be longer than the thalweg. Initial sediment stock can be assigned for each section.

Cross-sections are defined through a series of points of known elevation, which may include optional floodplains. Bed and bank sediment properties are considered as part of cross-sectional data. The characteristic grain sizes d_{90}, d_{50} and d_{30} are required. The Strickler’s roughness coefficient k_{St} is required for bed, bank and floodplain, if it is not determined by equation (2) or (3). A specify variable hydraulic roughness across the channel bed can also be defined for the bank and the floodplain. For calculation the cross-section is divided into strips to get a representative discretization of the profile. The number of strips depends on the number of points that were recorded in the field. That means the number of strips increases with the complexity of the cross-section (Figs 4 and 5).

Copyright © 2006 Taylor & Francis Group plc, London, UK

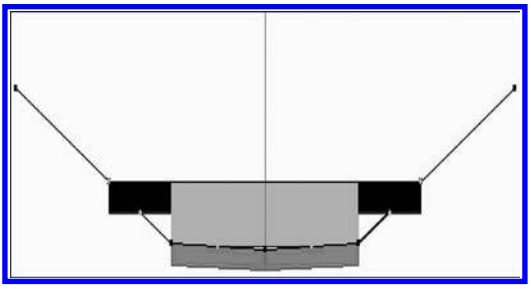

Figure 4. Simple cross-section with approximation by strips.

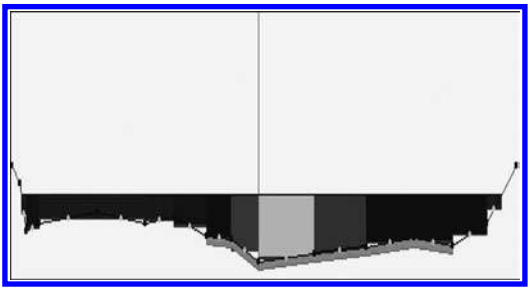

Figure 5. Structured cross-section with approximation by strips.

4.4 *Flow data*

In SETRAC, the water runoff is given as input hydrographs at discrete points. Inflow discharge should be specified as time series.

Sediment can also be fed as sedigraph at nodes (time series).

4.5 *Applications*

The model is designed to calculate sediment transport in steep headwater catchments, i.e. torrent streams. Depending on the formulae set used it can be applied to channel gradients up to 0.63. It can only be used for sediment transport. For steeper channel gradients sediment concentrations comparable to hyperconcentrated flow or debris flows can be achieved. However, debris flows are not explicitly considered.

5 CASE STUDY

For comparison between observed and modeled sediment transport SETRAC is applied to well documented extreme events that occurred in the Austrian Alps. The erosion and deposition of bedload was mapped in the field. The longitudinal profile and representative cross sections were also surveyed. Grain size analyses were made with line by number sampling and evaluated after Fehr (1987).

Table 1. Formulae combinations used for the simulations.

Case	v	n	q_b	q_c	n_r/n	a in (12)
A	(1)	(2)	(16)	(18)	–	–
B1	(1)	(2)	(16)	(18)	(10)	1.0
B2	(1)	(2)	(16)	(18)	(10)	1.5
B3	(1)	(2)	(16)	(18)	(10)	2.0

5.1 *Sessladbach*

After the extreme events from August 2005 several torrents were documented by a team of our University. One oft these torrents is the Sessladbach in Tyrol, Austria (Hübl et al. 2005). The catchment area is about 9.9 km^2 and the main channel is 4 km long. The mean slope is 0.25, the steepest parts are in the middle reaches with channel gradients up to 0.4. The slope of the fan is 0.18. About 32,000 m^3 of sediment were mobilized. The sediment erosion and deposition was mapped in the field in order to be compared with SETRAC calculations.

The input hydrographs needed for SETRAC were generated with the Hydrologic Modelling System HEC-HMS (Version 2.2.2). Data from a precipitation gauge situated in the catchment, which delivers data in one minute resolution, were used. The simulated peak discharge was calibrated with reconstructed values of the peak discharge at several appropriate cross sections. The catchment was separated into four sub catchments. The resulting hydrographs were attached to the related nodes in the SETRAC model. The duration of the whole event was 24 hours with a peak discharge of about 25 m^3/s at the fan apex. No streamflow measurements are available for this channel.

5.2 *Simulation*

Depending on the field investigations, different cases can be computed with SETRAC. If information about sediment stock is available, it is possible to model a so-called supply limited case. That means that sediment can only be eroded if the stock has not been depleted. If there is no information about reach wise sediment availability, a uniform sediment stock in m^3/m can be assumed. If the sediment availability is set at a very high value, the so-called transport limited case can be modeled.

Four simulation runs were computed with the formulae as indicated in Table 1. In the first simulation flow resistance due to form roughness was not considered. The other runs considered a reduced energy Slope according to formulae (8) and (11) with a variation of the exponent a. The exponent was set as 1.0, 1.5 and 2.0. The different cases are described in table 1.

For the discretization in space and time 50 meters and 60 seconds were chosen to limit the discretization error as well as the computing time.

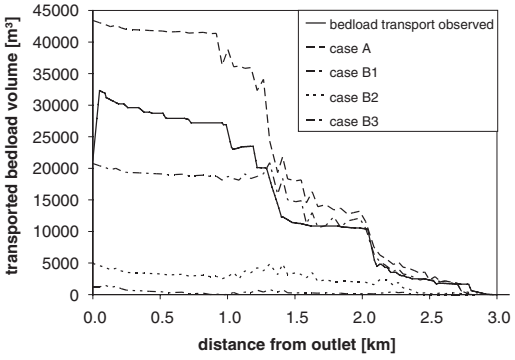

Figure 6. Observed versus simulated bedload transport for the supply limited case.

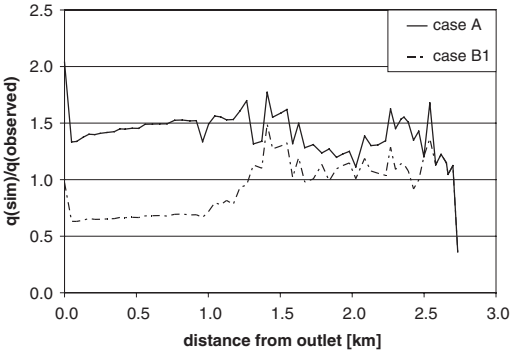

Figure 7. Variation of the ratio between simulated and observed bedload transport for the supply limited case along the torrent channel.

The presented simulation results were computed with SETRAC version V20060127 (Version of 27 January 2006).

Figures 6 and 8 show bedload volumes integrated over the flood duration for any cross-section along the torrent channel.

For the supply limited case (Fig. 6) sediment stock in reaches was considered. The availability varied between 1.0 m^3/m for channel reaches mainly in bedrock and up to 100 m^3/m for channel reaches where intensive erosion was observed. The sediment stock in the reaches was assumed as it might have been estimated by a channel survey before the extreme event occurred. Simulation A slightly overestimates the sediment transport due to the higher availability of sediment. The case B1 also shows a good agreement with the observed sediment transport. The least discrepancies result for the upper and middle reaches of the Sessladbach. The different behaviour of the simulations for A and B1 in the reaches from km 1.0 to km 1.4 may be related to the fact that massive lateral erosion occurred of finer material from the banks and the main channel changed its bed. Changes in the cross-sections geometry can not be modeled with the actual version of SETRAC. On the lowest 100 m of the fan about 10,000 m^3 of sediment were deposited outside of the channel. This two-dimensional problem can not be reproduced by the one-dimensional simulations in SETRAC. Considering the sediment transport simulations along the entire channel, it is found, that for the cases B2 and B3 there is a too strong reduction of the energy slope for the Sessladbach (Fig. 6).

Figure 7 shows the ratio between simulated and observed bedload transport for the supply limited case for the simulation without a reduction of the energy slope and for the simulation considering an exponent $a = 1.0$ in equation (12) for the reduced energy slope.

For the transport limited case (Fig. 8) a constant sediment availability of 100 m^3/m along the entire channel bed was assumed. The simulation A represents

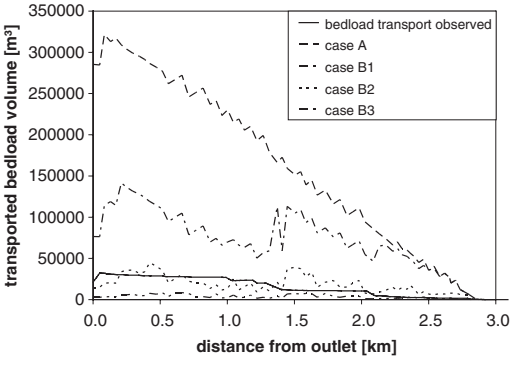

Figure 8. Observed versus simulated bedload transport for the transport limited case.

the transport capacity and clearly overestimates the observed sediment transport by a factor of ten. The best agreement between observed and computed sediment transport was found for B1, whereas B2 and B3 result in a too weak sediment transport. The discrepancy between simulated and observed bedload transport in the reaches from km 2.1 to km 2.4 (Fig. 9) is a result of the "unlimited" availability of sediment. In reality, this reach has a very rough channel bed, and probably a higher critical discharge is necessary for the beginning of motion than estimated by equation (18). This shows the necessity of detailed field investigations on sediment availability for the calculation of sediment transport in torrents.

6 DISCUSSION

To evaluate the performance of a sediment transport model in torrent channels, the observations on bedload transport in steep experimental flumes are taken as a reference condition; these conditions define maximum

Copyright © 2006 Taylor & Francis Group plc, London, UK

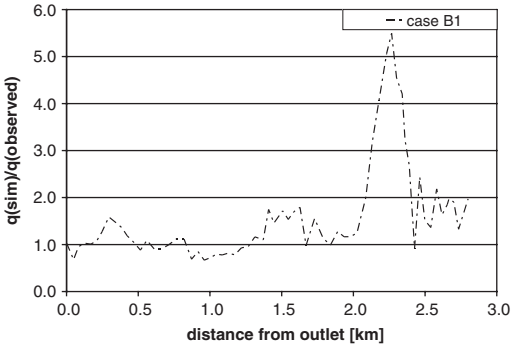

Figure 9. Variation of the ratio between simulated and observed bedload transport for the transport limited case along the torrent channel.

transport rates for the idealized case of rather uniform bed material, essentially no morphological features and hence no significant form roughness effects. Rickenmann (2001) found that observed sediment transport in the steep and small streams was one to three orders of magnitude smaller than values predicted by a sediment transport capacity formula. Apart from limited sediment supply, this discrepancy may be partly due to substantial bedform roughness reducing bedload transport efficiencies. A tendency for over prediction of sediment loads using a bedload transport capacity formula was also found in case studies on sediment transport during flood events in Swiss torrents: Rickenmann (1990b) applied equation (16) and used a relatively high critical discharge to move the coarsest bed particles to obtain reasonable agreement of the calculated sediment load with field observations. For the transport-limited case (i.e. unlimited sediment availability), bedload volumes are overestimated by about a factor of ten for the case study examined with the SETRAC model. Applying two sediment transport models to a river reach with a channel gradient of about 0.02, Rathburn & Wohl (2001) found that predicted bedload discharges were overestimated by up to several orders of magnitude.

7 CONCLUSION AND OUTLOOK

The SETRAC model is a new one-dimensional simulation program for torrent channels. Three flow resistance approaches appropriate for steep channel gradients have been implemented. A formula is established to take into account the effect of flow resistance due to form roughness on sediment transport in channels with stable structures by modifying the energy slope. The extent of the reduction can be related to different roughness structures. These formulae can be combined with different bedload transport equations.

The presented case study of an extreme event in the Austrian Alps demonstrates the models capability to compute sediment transfer in steep headwater torrents. Using a rough correction procedure, a reasonable agreement has been obtained between simulated and observed sediment loads. Considering the uncertainty of the input data, the results are encouraging. Further improvement and validations of the model are necessary and are continuing to develop a reliable software tool for the prediction of sediment transport in torrents.

The SETRAC model will be further developed to take into account both bed armouring effects and transport by size fractions, and to take into account bed level variations during the simulations.

8 NOTATION

The following symbols are used in this paper:

a	variable exponent
d_m	mean grain size (m)
d_{30}	characteristic grain size for which 30% of the sediment is finer by weight (m)
d_{50}	characteristic grain size for which 50% of the sediment is finer by weight (m)
d_{84}	characteristic grain size for which 84% of the sediment is finer by weight (m)
d_{90}	characteristic grain size for which 90% of the sediment is finer by weight (m)
Fr	Froude number
g	acceleration due to gravity (m/s^2)
h	flow depth (m)
h_f	fluid flow depth (m)
h_m	sediment mixture flow depth (m)
k_{St}	Strickler coefficient of roughness (m$^{1/3}$/s)
n	Manning's coefficient of roughness (s/m$^{1/3}$)
n_r	roughness coefficient associated with skin friction only (s/m$^{1/3}$)
Q	discharge (m^3/s)
q	volumetric water or fluid discharge per unit width (m^3/sm)
q_b	volumetric bedload transport rate per unit width (m^3/sm)
q_c	critical flow discharge at the beginning of bedload transport (m^3/sm)
R	hydraulic radius (m)
S	slope of the energy line
S_{red}	component of the energy line related with skin friction
s	ratio between grain and fluid density
v	velocity (m/s)
v^*	shear velocity (m/s)
θ	dimensionless bed shear stress
θ_{cr}	critical value of θ at initiation of motion
ρ	fluid density (kg/m^3)

ABSTRACT: Generally, sand particles, which are used in Distinct Element Method, are modeled using spheres or circle elements in a movable bed simulation. However, because actual beds are composed of many shapes of sand particles, it is important to investigate the influence of sand shape on characteristics of sediment transport. In this study, numerical simulation was performed for the sorting process under sheetflow conditions using a vertical two-dimensional granular material model based on the Distinct Element Method. Thereby, we investigated the influence of sand shape on the sorting process.

1 INTRODUCTION

Uneven bed form is the key to numerical simulation of sediment transport. From such a perspective, granular material model based on the Distinct Element Method proposed by Cundal & Strack (1979) is an effective tool because the inter-elemental force among particles can be tracked directly. Generally, circle or sphere elements are used in the granular material model because of limited computational capability and the relative ease of handling. On the other hand, numerical simulation, which has treated non-circle or non-sphere elements, has been attempted to support improvements in computer performance. For example, Latham & Munjiza (2002) simulated the collision process of rocks using the elements, with surface details. The resistance against motion of the circular or spherical elements is less than that of actual sand. Furthermore, the pores of the particle arrangement made using circles and spheres differ from those of actual sand. Consequently, in the present study, the vertical sorting process of two shapes and two sizes of elements (squares and circles) were investigated numerically using the improved movable bed simulator code, which was developed by Gotoh & Sakai (1997).

2 OUTLINE OF THE SIMULATION MODEL

2.1 *Distinct element method*

The movable bed was evaluated by the granular material model based on the Distinct Element Method.The motion of each particle was governed by the translational and rotational equations as follows:

$$\rho\left(\frac{\sigma}{\rho}+C_M\right)V_i\frac{d\boldsymbol{u}_{pi}}{dt}=\boldsymbol{F}_{p\,\mathrm{int}}+\boldsymbol{F}_D+\boldsymbol{F}_{gr} \tag{1}$$

$$I_i\frac{d\boldsymbol{\omega}_{pi}}{dt}=\boldsymbol{T}_i \tag{2}$$

$$\boldsymbol{F}_D=\frac{1}{2}\rho C_D S_i\left|\boldsymbol{U}-\boldsymbol{u}_{pi}\right|\left(\boldsymbol{U}-\boldsymbol{u}_{pi}\right) \tag{3}$$

$$\boldsymbol{F}_{gr}=-\rho\left(\frac{\sigma}{\rho}-1\right)V_i\boldsymbol{g} \tag{4}$$

where, $\boldsymbol{F}_{pint}$: vector of the inter-particle force, $\boldsymbol{F}_D$ vector of the drag force, $\boldsymbol{F}_{gr}$: vector of the gravitational force, $\boldsymbol{u}_{pi}$: vector of the i-th particle velocity, C_M: added mass coefficient, $\boldsymbol{U}$: vector of the flow around the i-th particle, V_i: volume of the i-th particle, I_i: moment of inertia of i-th particle, S_i: projection area to the flow direction, T_i: torque acting on the i-th particle, $\boldsymbol{\omega}_{pi}$: angular velocity of the i-th particle, C_D: drag coefficient, σ: density of the particle and ρ: density of the water.

Each inter-particle force was expressed by the spring and dashpot system (see Fig. 1). Between two contacting particles, Voigt model is assumed in both of the normal and tangential directions, to describe the dynamic interparticle relation. The acting forcer between i-th and j-th particles in normal and tangential direction, f_n and f_s, can be written as follows:

$$f_n(t)=e_n(t)+d_n(t) \tag{5}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

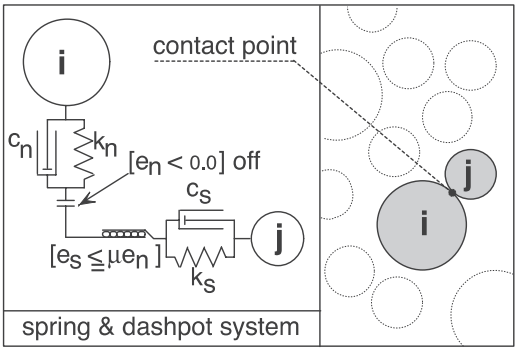

Figure 1. Spring and dashpot system between contacting particles.

$$f_s(t) = e_s(t) + d_s(t) \tag{6}$$

$$e_n(t) = e_n(t - \Delta t) + k_n \cdot \Delta\xi_n \tag{7}$$

$$d_n(t) = c_n \cdot \Delta\dot{\xi}_n \tag{8}$$

$$e_s(t) = e_s(t - \Delta t) + k_s \cdot \Delta\xi_s \tag{9}$$

$$d_s(t) = c_s \cdot \Delta\dot{\xi}_s \tag{10}$$

in which e_n,e_s:forces working on springs, d_n,d_s:forces working on dashpots, $\Delta\xi_n$, $\Delta\xi_s$:displacement of particles during the time Δt(Δt = time step of the calculation), k_n,k_s:spring constants and c_n,c_s:damping coefficients. In this simulation model, particles are non-cohesive, hence the joint, which has no resistance to the tensile force, is assumed in the normal direction. While, in the tangential direction, the frictional force works. To describe this characteristics, the joint, which slips at the limit of the shear stress, is assumed in the tangential direction. These joints can be formulated as follows:

$$f_n(t) = f_s(t) = 0 \quad when \quad e_n(t) < 0 \tag{11}$$

$$f_s(t) = \mu \cdot SING(e_n(t), e_s(t)) \quad when \quad |e_s(t)| > \mu \cdot e_n(t) \tag{12}$$

$$SIGN(a,b) = \begin{cases} |a| & when \quad b \geq 0 \\ -|a| & when \quad b < 0 \end{cases} \tag{13}$$

in which μ:coefficient of friction. The spring constants to the normal (k_n) and the tangential direction (k_s), the damping constants to the normal (c_n) and the tangential (c_s) and the friction coefficient (μ) were determined as the relationship between bottom shear-stress and sediment transport rate could be reproduced in the uniform circle elements bed according to the optimization procedure proposed by Gotoh et al. (2001).

The outline of the optimization procedure is as follows. In the ordinary Distinct Element Method, the condition for the stability for the simple mass-spring system:

$$\Delta t \leq 2\sqrt{m / k_n} \tag{14}$$

in which m:mass of the element, is frequency considered to estimate the time step of the calculation under the given spring constant. Here, the time step of the calculation is determined by considering the natural period, or T, of the simple mass-spring system as follows:

$$\Delta t = T / 20 \ ; \ T = 2\pi\sqrt{m / 2k_n} \tag{15}$$

This relation was proposed by Masuya & Kajikawa (1991), as the more stable condition than the usual stability condition. The relation between the normal and tangential spring constants are given as follows:

$$k_s = \frac{k_n}{2(1+\nu)} \tag{16}$$

in which ν:Poisson rate (=0.3). The critical damping condition for the Voigt model gives the relation between spring and damper constants as follows:

$$c_n = \alpha_{cn} \cdot 2\sqrt{m \cdot k_n} \ ; \ c_s = c_n / \sqrt{2(1+\nu)} \tag{17}$$

When the constants $\alpha_{cn} = 1.0$, this equation is coincide with the standard stability condition of Voigt system. This parameter is tuned to fit the calculated sediment transport rate to the experimental data. For the irregularly arranged particles, $\alpha_{cn} = 1.3$ is the appropriate value.

2.2 *Judgment of contacting elements*

Two kinds of elements' geometric shapes, or circle and square, were used in the present simulation. Hence, three kinds of the judgment of contact conditions between elements: 1) circle–circle, 2) circle–square, 3) square–square are required.

The judgment of contact condition between circle and circle elements is as follows:

$$\frac{d_i + d_j}{2} \geq \sqrt{\left(x_i - x_j\right)^2 + \left(y_i - y_j\right)^2} \tag{18}$$

where, d_i,d_j: diameter of the i-th and j-th elements respectively and (x_i,y_i),(x_j,y_j): coordinate of the center of the i-th and j-th elements respectively(see Fig. 2).

The judgment of contact condition between circle and square elements is defined as the condition that the coordinate of the center of the j-th element is in

Copyright © 2006 Taylor & Francis Group plc, London, UK

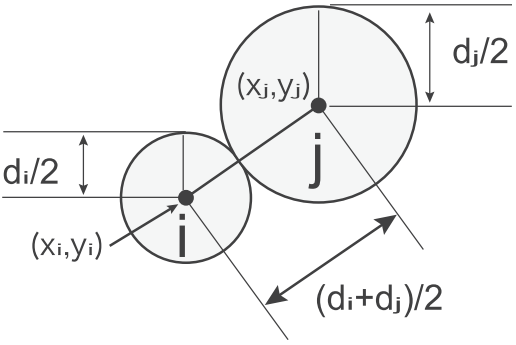

Figure 2. Judgment of contacting elements between circle & circle.

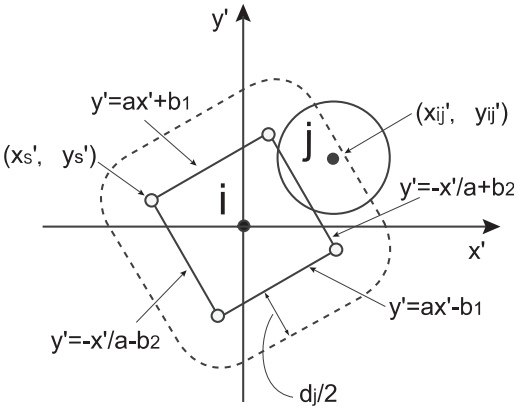

Figure 3. Judgment of contacting elements between circle & square.

the range surrounded the i-th square element in the width of $d_j/2$:

$$\left.\begin{aligned} & ax_{ij}' + b_1 \geq y_{ij}' \geq ax_{ij}' - b_1 \quad and \\ & -x_{ij}'/a + b_2 \geq y_{ij}' \geq -x_{ij}'/a - b_2 \quad and \\ & d_j/2 \geq \sqrt{\left(x_s' - x_{ij}'\right)^2 + \left(y_s' - y_{ij}'\right)^2} \end{aligned}\right\} \tag{19}$$

where, (x'_{ij}, y'_{ij}): relative distance of the coordinate of the center between the i-th square element and the j-th circle element, a, b_1, b_2: parameters defined by the relative position between the circle and square elements and (x'_s, y'_s): four coordinates of the corner of the square element (see Fig. 3). And x'–y' coordinate is thelocal coordinate, the origin of which is the coordinateof the center of the square element.

The judgment of contact condition between square and square elements is defined as the condition that

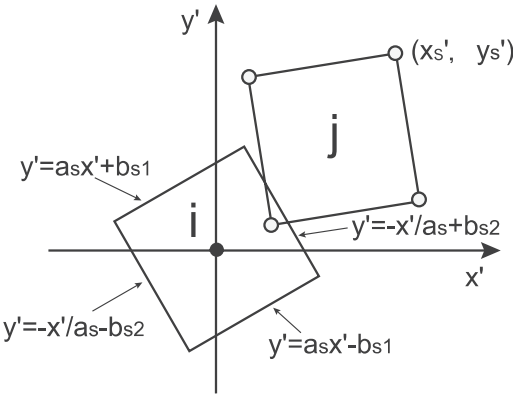

Figure 4. Judgment of contacting elements between square & square.

any corner coordinates of the j-th square is in the i-th square element:

$$\left.\begin{aligned} & a_s x_s' + b_{s1} \geq y_s' \geq a_s x_s' - b_{s1} \quad and \\ & -x_s'/a_s + b_{s2} \geq y_s' \geq -x_s'/a_s - b_{s2} \end{aligned}\right\} \tag{20}$$

where, a_s, b_{s1}, b_{s2}: parameters defined by the relative position between square elements(see Fig. 4).

2.3 *Model of flow phase*

The modeling of the flow phase is necessary for the appropriate evaluation of the driving force acting on sand elements. There are not a few items to modeling of the flow phase in detail, such as turbulent fields and sediment laden flow and so on. Here, we focused on the motion of the elements especially, and the modeling of flow phase was treated simplified.

The mean flow velocity is given by logarithmic law as follows:

$$\frac{U}{u_*} = \frac{1}{\kappa}\ln\left(30.1\frac{y + 0.25d}{k_{sr}}\right) \tag{21}$$

where, u_*: shear velocity, κ: von Karman constant and ksr: roughness (mean diameter). The time series of the flow turbulence is simulated by the simple Monte Carlo method. The fluctuating velocity components of the flow can be written as follows:

$$u(t) = r_u \cdot \sqrt{u^2} \;\; ; \;\; v(t) = r_v \cdot \sqrt{v^2} \tag{22}$$

where, r_u,r_v: random numbers following to the standard Gauss distribution in x and y directions and $\sqrt{u^2}$, $\sqrt{v^2}$: turbulent intensities in x and y directions. The two

Copyright © 2006 Taylor & Francis Group plc, London, UK

series of random numbers satisfy the two dimensional Gauss distribution as follows:

$$f_r(r_u,r_v)=\frac{1}{2\pi}\exp\left(-\frac{r_u^2}{2}\right)\frac{1}{\sqrt{2\pi}\sqrt{1-\gamma^2}} \times\exp\left\{-\frac{(r_v-\gamma\cdot r_u)^2}{2(1-\gamma^2)}\right\} \quad (23)$$

where, γ: cross correlation coefficient of two series of the random numbers. Eq. 10 can be re-written through an simple variable transformation as follows:

$$r_u=\xi_r \;;\; r_v=\gamma\cdot\xi_r+\sqrt{1-\gamma^2}\cdot\zeta_r \quad (24)$$

Turbulent intensities is given by the semi-empirical formulation as follows:

$$\frac{\sqrt{\overline{u^2}}}{u_*}=2.30\exp\left(-\frac{y}{h}\right)\;;\;\frac{\sqrt{\overline{v^2}}}{u_*}=1.27\exp\left(-\frac{y}{h}\right) \quad (25)$$

where, h: water depth, u_*: shear velocity. The cross correlation coefficient of two turbulent velocity components can be related to the Reynolds stress as follows:

$$\gamma=\frac{-\overline{uv}}{\sqrt{\overline{u^2}}\sqrt{\overline{v^2}}}=0.342\left(1-\frac{y}{h}\right)/\exp\left(\frac{2y}{h}\right) \quad (26)$$

The detailed information of modeling of flow is shown in Gotoh & Sakai(1997).

3 VERTICAL SORTING PROCESS

3.1 *Calculated condition*

The model constants using in the granular material model based on the Distinct Element Method were determined by following the optimization procedure proposed by Gotoh et al.(2001). The model constants are as follows: $k_n=314.01$ N/m, $k_s=120.77$ N/m, $c_n=0.66$ Ns/m, $c_s=0.41$ Ns/m and $\Delta t=0.0002$ s. The predicted sediment transport rate shows the good agreement with the previous experiment. Two kinds of geometric shapes and size elements, or circle and square, were used. The calculated conditions are shown in tab. 1. The number in tab. 1 shows the number of the elements, which was determined as correspondence with the total number of elements in each case. And the specific density of all kinds of geometric shapes of elements are the same specific density. And also, both sides of the calculated domain are periodic boundaries to save the calculation time. In addition, the simulation was conducted under the dimensionless bottom shear stress $\tau_*=0.1$ for 95.0 seconds.

Table 1. Calculated condition of case1 & case2.

case No.	D	d	L	l
case1	199	526	–	–
case2	–	–	199	526

[unit : num.]

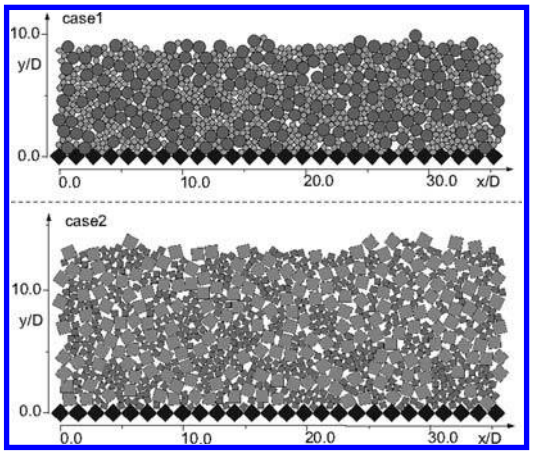

Figure 5. Initial condition of movable bed [upper: case1, lower: case2].

Initial arrangement of both simulations are shown in Fig. 5. The bottom boundary is formed by using large square elements. The calculated total area of the square element is larger than that of the circle element in the same calculated bottom length. Because the square element is squarish shape. Hence, the volume of the square case is larger than the circle case in spite of using the same number of elements in both simulations.

3.2 *Influence of square elements*

The snapshots of both cases are shown in Fig. 6. To show the developing process of the armor coat clearly, the motion of the element in the vicinity of the exchange layer is focused. The active motion of elements are confirmed in both cases. However, the rising process of the large elements to the surface of the sand layer and the descent process of the small elements, or percolation, can be seen in case1, while, such that tendency cannot be seen in case2(see the time $t=20.0$–40.0 s). The difference of the geometric shape between both cases, or the difference of the moving resistance of the square element is larger in comparison with the circle element, would be the cause of that. At the time $t=95.0$ s, the significant armoring around

Copyright © 2006 Taylor & Francis Group plc, London, UK

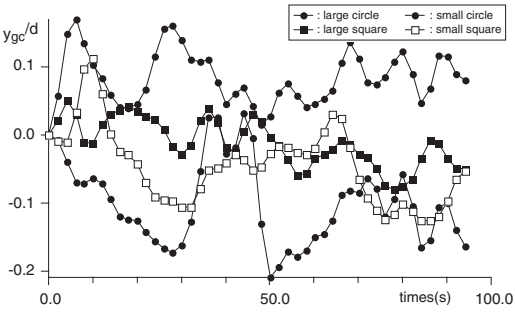

Figure 7. Time series of gravity center in each case.

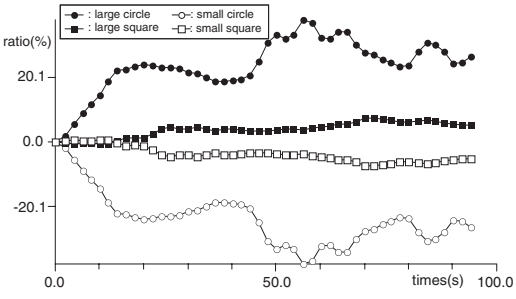

Figure 8. Time series of ratio around exchange layer in each case.

the sand surface is confirmed in case1, while, such a phenomenon isn't confirmed in case2, the effect of the difference geometric shape to the vertical sorting is shown clearly.

Figure 7 shows the time series of the gravity center of each form. And the y-axis indicates the relative gravity center to initial condition of each element. The decrease of the gravity center of the small element and the increase of gravity center of the large element is shown in case1. While, in case2, although the fluctuating of the gravity center is seen, a difference in the small and large elements isn't clear and the gravity center keeps about same level. The effect on the geometric shape of element to the vertical sorting can be confirmed in the time series of the gravity center as well as the snapshots.

Figure 8 shows the time series of the ratio of each element around the exchange layer. And the y-axis shows the relative share to the initial condition. The increase of the share of the large circle and the decrease of the that of the small circle is shown clearly just after the acting of the shear stress. This indicates the developing of the armor coat around the surface of the movable bed. While, only a little difference is seen by the time $t = 20.0$ s in case2. Although, after the time $t = 20.0$ s, slight increase of the share of the large square element is shown, the significant developing process of the armor coat isn't confirmed in comparison with case1.

3.3 *Inner structure of movable bed*

The effect of the geometric shape to the sorting is shown through the snapshots, time series of the gravity center and the time series of the share. To show the inner structure of the movable bed, the distribution of the inter-element force is shown in Fig. 9. The interelement force is represented by using the pass line called stress chain connected between the center of the elements, the direction of which indicates the acting direction of inter-element force, and the level of the inter-element force is in proportion

Copyright © 2006 Taylor & Francis Group plc, London, UK

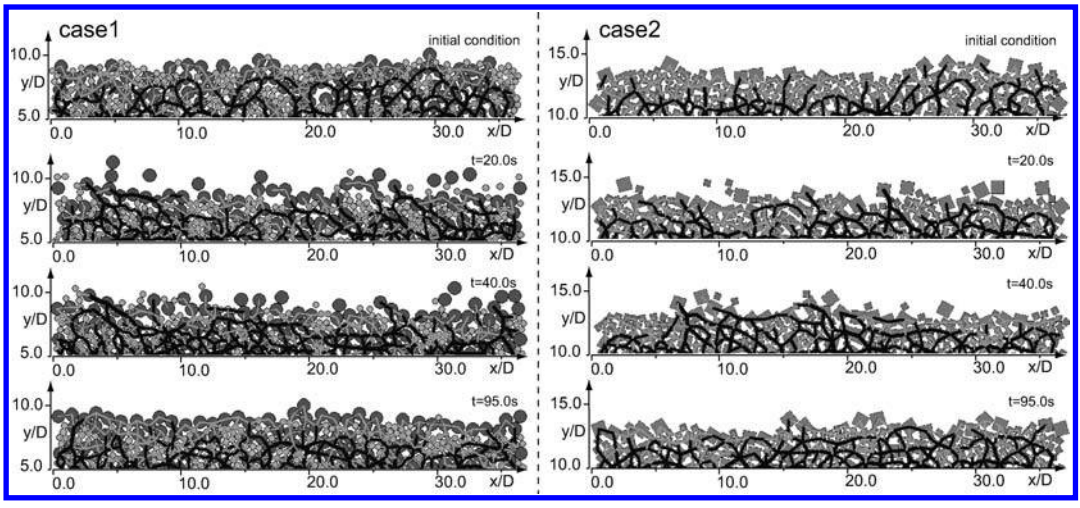

Figure 9. Snapshots of inter element force by stress chain around exchange layer in sheetflow regime [left: case1, right: case2].

to thickness of the pass line. And also, to show the inner structure of the movable bed clearly, the color of the pass line changes according to the level of the inter-element force, or Black line indicates the comparatively high inter-element force, and Gray line indicates the comparatively low inter-element force.

The high inter-element force is distributed in the large area around the surface of the movable bed in case2 in comparison with case1. The difference of the effect of the engagement between elements due to the difference of the geometric shape would be one of the cause. In other words, the moving resistance of the square element is larger than that of circle element because of its squarish shape.

4 CONCLUSIONS

In this study, the influence of sand shape on vertical sorting under uniform flow conditions was investigated from a numerical simulation using the granular material model based on Distinct Element Method. Furthermore, the differences according to the element shape were investigated from the viewpoint of snapshots, the time series of the center of gravity, and the ratio in the exchange layer. Moreover, the inner structure of the movable bed was investigated using the distribution of the inter-elemental forces. Although investigation of the vertical sorting process in consideration of the elements' geometric shape is important, the representation of all geometric shapes of the actual movable bed in the simulation code is extremely difficult. In the near future, the effect of geometric shape should be evaluated in consideration of some indexes.

Investigation of flow hydrodynamics under equilibrium bedload transport conditions using PIV

F. Bigillon, G. Couronné & J.Y. Champagne
Laboratoire de mécanique des fluides et d'acoustique, Lyon, France

A. Recking & P. Frey
Cemagref Grenoble, UR ETNA, Domaine Universitaire Saint-Martin-d'Hères Cedex, France

ABSTRACT: We present results of velocity, turbulence intensities, and Reynolds stress distribution in presence of bed load transport obtained from flume experiments carried out under equilibrium bed load transport conditions. Measurements of those quantities were obtained using Particle Image Velocimetry. They are compared with trends typically found in classical turbulent flow with no sediment load: a logarithmic law, exponential laws, and a linear trend respectively. Our results show a more complex behaviour than the one predicted by classical laws as sediment transport increases. The general trend shows that increasing bed load transport results in lower longitudinal velocities, larger turbulence intensity, and larger Reynolds stress values compared to conditions without sediment load. However, we observe a critical point, corresponding to mid transport rate, for which this general trend fails. This behaviour may be explained by changes in bed roughness and relative flow depths.

1 INTRODUCTION

There is uncertainty regarding the effect of sediment transport on mean flow and turbulence characteristics. In general, increasing sediment transport enhances flow resistance (Song et al. 1998), reduces longitudinal velocities, and increases turbulence intensities (Campbell et al. 2005, Carbonneau & Bergeron 2000). However, recent work suggests that bed load transport can also reduce flow resistance (Recking et al. 2005) and produce higher longitudinal velocities (Campbell et al. 2005). This complex behaviour seems related to the size of sediments (Campbell et al. 2005), bed roughness, and sediment transport itself (Recking et al. 2005, Carbonneau & Bergeron 2000).

Few investigations have been done concerning the effect of bed load transport on flow characteristics. Most of them concern flow resistance and few attempt to describe velocity and turbulence characteristics. This may be due to the difficulty of performing measurements in presence of sediments. In addition, previous work focused on gentle slopes and relatively low transport rates.

In this paper we investigate the effect of bed load transport rate on longitudinal velocity distribution and turbulence characteristics under steep slopes and equilibrium bed load transport conditions. The flume experiments we carried out, as well as the Particle Image Velocimetry (PIV) technique we used to measure flow velocity, are described in section 2. In section 3 we present the results of our flume experiments that are compared with distributions generally found in turbulent flow with no sediment load: a logarithmic law for the velocity, exponential laws for the turbulence intensities, and a linear trend for the Reynolds stress.

2 EXPERIMENTS

2.1 *Experimental setup and conditions*

We conducted experiments in a tilting flume 8.0 m long and 0.05 m wide. The bed of the flume was formed of sediments of mean diameter $d = 2.25$ mm and its sidewalls were made of glass.

Table 1 summarizes the experimental conditions of the tests. The slope S corresponds to the equilibrium slope of the bed and to the channel slope and was set at 3% and 5%. We measured the flow rate q_l with an electromagnetic flow meter and the solid discharge q_s using GDS, a visualisation based technique described in Frey et al. (2003). Sediments concentration, defined as the ratio of solid discharge over flow rate, was between 0 and 4%. We used the visualization method developed by Recking et al. (2005) to obtain the bulk mean flow velocity U_q. The flow depth h_q computed from q_l and U_q, was small enough to have a

large channel aspect ratio (i.e. $B/h_q > 3$) that prevented the formation of significant secondary flows. For all tests, the Froude number defined as $Fr = U_q/(gh_q)^{0.5}$ was larger than one, and the Reynolds number defined as $Re = U_q h_q/\nu$, where $\nu = 10^{-6}$ m^2/s is the kinematic viscosity of the water at 20°C, was larger than 2000 so that all flow conditions correspond to supercritical and turbulent flows. We computed the shear velocity u_{*q} as $(gR_hS)^{0.5}$ where R_h is the hydraulic radius.

We performed all tests under equilibrium bed load transport conditions using uniform natural sediments of mean diameter $d = 2.25$ mm and density $\rho_s = 2650$ kg/m^3. To ensure bed load transport equilibrium conditions, we compared the measured solid discharge to the one estimated using Smart & Jaeggi (1983) bed load transport formula. This formula is valid for slopes ranging from 3% to 20% and can be written for uniform sand distribution as:

$$\frac{q_s}{q_l} = 4\frac{S^{1.6}}{s-1}\left(1-\frac{\tau^*_{cr}}{\tau^*}\right) \quad (1)$$

where s is the relative sediment density and τ^* is the dimensionless shear stress defined as:

$$\tau^* = \frac{\rho u_*^2}{(\rho_s - \rho)gd} \quad (2)$$

and ρ is the water density.

Figure 1 represents the solid discharge as a function of the dimensionless shear stress. We observe a good agreement between measured and predicted values (Eq. 1–2), which corroborates that our tests correspond to equilibrium bed load transport conditions.

2.2 *Particle Image Velocimetry measurements*

We measured the instantaneous velocity field along the flume centreline of a test section for different flow conditions specified in Table 1 (Fig. 2). The test section was located 4 m downstream from the entrance, and its

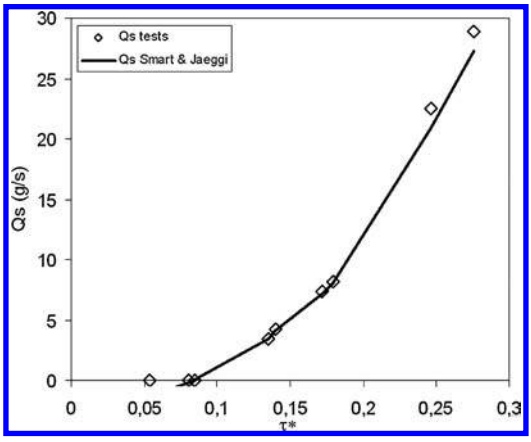

Figure 1. Solid discharge measured from GDS (diamonds) and computed from Smart & Jaeggi formula (solid line).

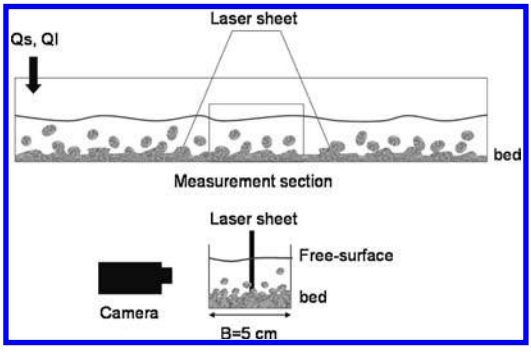

Figure 2. Side view and front view of the experimental setup.

size was about 25 × 25 mm. It was made dark in order to preserve the uniformity of the recording conditions.

We performed the velocity measurements using a PIV system from *Dantec* that includes illumination, image capture, and data acquisition components. We used a dual-pulsed 15 Hz Solo PIV I Nd:YAG laser manufactured by *New Wave Research* for illumination. This laser system gives 15 mJ per pulse over 5 ns pulse width and has a wave length of 532 nm. We used neutral, buoyant particles about 10 μm in diameter as water tracers.

The use of the PIV technique is not typical for the study of sediments laden flows. To utilize it in our experiments we had to solve the following issue. Since sediments do not follow the fluid velocity, we had to eliminate them in the estimation of velocity vectors. To do so, we used fluorescent tracer particles (orange vinyl pigment, water soluble, by Lefranc and Bourgeois, see Nogueira et al. 2003). Those particles when excited by the laser emit light at higher wavelengths

Copyright © 2006 Taylor & Francis Group plc, London, UK

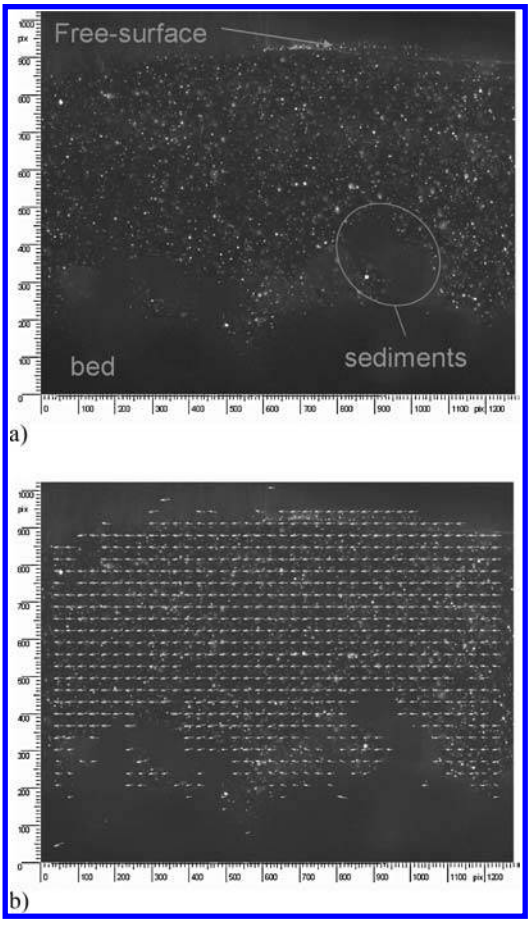

Figure 3. a) PIV image. b) Computed velocity field (test S5T4).

than the laser. We added a 540 nm high pass filter to the camera to capture only signals emitted by tracer particles. As result, sediments are eliminated from images (Fig. 3a).

We captured images using a HighSense camera mounted with an objective Nikkor 60 mm/2.8. The camera resolution was 1024 × 1080 pixels, with each pixel measuring 6.7 μm^2, and a maximum frame rate of 9 Hz. We controlled the camera using *Flowmap* software. We recorded image pairs at 2 Hz and sent them to a PC through a frame-grabber board. We recorded and stored about 800 image pairs for each flow case. We collected four series of 200 image pairs (50 s per realization) over 5 minutes in order to randomly sample the flow. The time between recordings was needed to transfer the images to the computer.

We processed image pairs using a correlation technique available in *Flowmap* software. Each frame was split up into a grid of small interrogation areas of

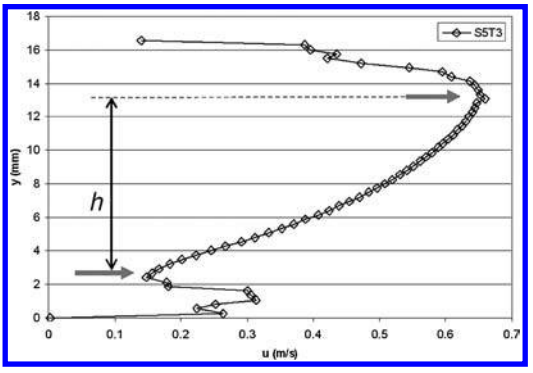

Figure 4. Computation of flow depth from velocity profiles.

32 × 32 pixels with 50% overlap. We computed the mean displacement of the tracer particles in each interrogation area using a two dimensional cross-correlation algorithm. That procedure gave spurious vectors that we eliminated applying sequentially a signal/noise and a range filter to the vectors fields.

2.3 *Difficulties of data analysis*

Figure 3 displays a typical image and the corresponding instantaneous velocity field obtained in the tests using PIV. Figure 3b shows that vectors were eliminated in areas located above the free surface, at the bed, and in regions with sediments. Those locations in Figure 3b coincide with zones in Figure 3a containing few tracers. Figure 3 shows that there were few velocity measurements into the bed load layer. However, velocity measurements were possible over the bed load layer that is in the clear water part of the flow.

As instantaneous velocity fields measured in such conditions were very irregular, data analysis and computation of mean quantities were very difficult. The main difficulty was to determine the average flow depth *h* because of bed load transport and free surface waviness. This quantity was necessary to compare dimensionless vertical profiles between different tests. We chose to compute the flow depth based on the average profile of the longitudinal velocity (Fig. 4). The flow depth was defined between the maximum velocity and the first inflection point encountered moving towards the bed. With this procedure, flow depth corresponded to the clear water flow depth that did not take into account the bed load layer.

3 EXPERIMENTAL RESULTS

This section focuses on the description of the flow located mainly above the bed load layer that does not have sediment load. This part of the flow is denoted as

Table 2. Hydrodynamics of the clear water flow.

Tests	U [m/s]	h [mm]	u_* [m/s]	$y/h(U)$ [−]
S3T1	0.32	6.4	0.039	0.41
S3T4	0.49	13.9	0.051	0.46
S3T6	0.49	15.2	0.053	0.40
S3T7	0.62	15.5	0.053	0.36
S5T1	0.3	7.47	0.053	0.57
S5T2	0.42	12.3	0.064	0.54
S5T3	0.48	10.7	0.061	0.7
S5T4	0.66	13.9	0.066	0.5
S5T5	0.78	15.5	0.068	0.5

clear water flow in the following. The origin of the bed $y = 0$ is located at the bottom of the clear water flow, i.e. at the stationary bed for the tests without bed load, and at the top of the bed load layer for the tests with bed load.

3.1 *Hydrodynamics of the clear water flow*

Table 1 presents the bulk hydrodynamics of the total flow, taking into account the flow in the bed load layer. Table 2 summarizes the hydrodynamics of the flow over the bed load layer calculated using PIV measurements. As bed load transport increases, we observe larger differences in hydrodynamics computed using both methods. In particular, values of flow depth, h, and shear velocity, $u_* = (gR_hS)^{0.5}$, are smaller in the clear water flow than the ones corresponding to the total flow as bed load transport increases. Values of the mean velocity, U, computed from the velocity profile, show that mean velocity for the clear water flow is very close to the mean velocity of the total flow. In general, U is found at y/h in the range 0.4–0.5.

3.2 *Vertical distribution of the longitudinal velocity*

We computed the vertical distribution of the average longitudinal velocity, $u(y)$, using a double-averaging procedure: first we calculated the time (or ensemble) average field, and then the spatial average of time-averaged field in the longitudinal direction.

In general, the vertical distribution of the longitudinal velocity in a fully developed turbulent open channel flow is well represented by a logarithmic distribution (e.g. Bigillon et al. in press). However, there is no evidence that the velocity profile remains logarithmic in presence of bed load transport. Figure 5 shows the vertical distribution of double-averaged longitudinal velocity plotted in a semi-logarithm scale as function of $y^+ = yu_*/\nu$. This figure displays the experimental data as well as the logarithmic velocity distribution obtained for smooth and rough wall

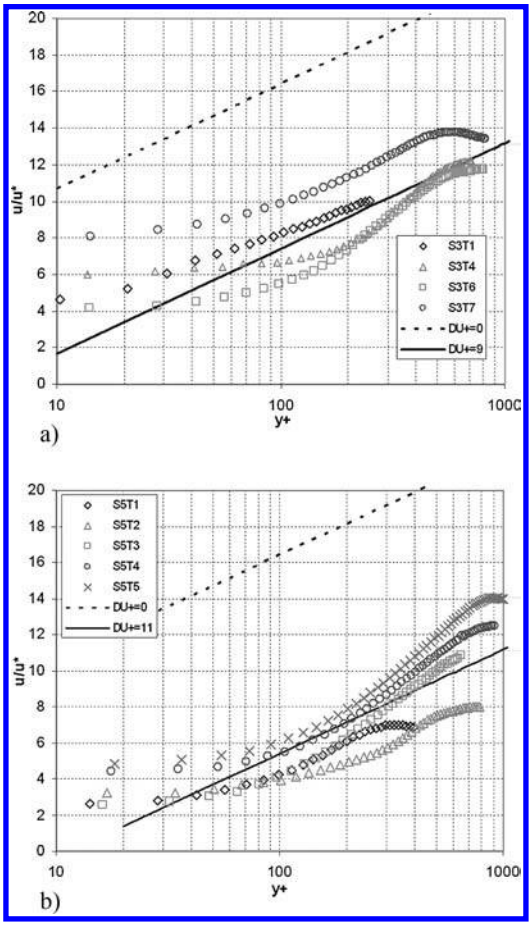

Figure 5. Vertical distribution of the longitudinal velocity above the bed: a) S = 3%; b) S = 5%. Experimental data and distribution computed from Eq. (1).

given by (e.g. Nezu & Nakagawa 1993, Bigillon et al. in press):

$$u^+ = \frac{1}{\kappa} \ln y^+ + B - \Delta U^+ \qquad (3)$$

where $u^+ = u/u_*$, $\kappa = 0.41$ is the von Kármán constant, $B = 4.9$, and ΔU^+ represents the shift of the log-law due to roughness effect. In our study, ΔU^+ is between 7 and 11 for S = 0.03, and between 11 and 13 for S = 0.05. Figure 5 illustrates that velocity profiles have a thin logarithmic zone for values of y^+ between 80 and 200, corresponding to values of y/h smaller than about 0.25. This result corroborates that velocity outside of the bed load layer satisfy a log-law like it was previously found over a sheet-flow (Summer et al. 1996).

Figure 5 indicates a complex behaviour as sediment transport increases. In absence or for small transport rates (tests S3T1, S3T4, S3T6, S5T1, S5T2),

Copyright © 2006 Taylor & Francis Group plc, London, UK

increasing sediment transport shifts velocity profiles towards smaller values of the dimensionless velocity u/u_*. This result was previously found by Carbonneau & Bergeron (2000). It is also consistent with the fact that drag and sediments collision extract kinetic energy from the mean flow. On the other hand, for large transport rates (tests S3T7, S5T3, S5T4, S5T5), the shift occurs towards higher values of the velocity. We think that this complex behaviour is related to roughness effect. When there is not sediment transport, roughness is due to static sediments forming the bed. As sediment transport increases, sediments start moving on the bed which results in a more irregular bed. Thus, the bed appears rougher to the flow that dissipates more energy and slows down compare to case without transport. As sediment transport continues increasing, more sediments move on the bed. The bed load layer becomes more concentrated and, at the limit, turns into a sheet-flow layer. In such condition, the bed appears somehow regular to the clear water flow that consumes less energy and accelerates compared to the mid-transport case. This roughness effect is supported by recent work on flow resistance obtained in the same experimental setup (Recking et al. 2005).

3.3 *Turbulence intensities*

Figures 6–7 display the longitudinal and vertical turbulence intensities, u_{rms}/u_* and v_{rms}/u_*, where u_{rms} and v_{rms} denote the root mean square of velocity fluctuations u' and v' respectively. We computed velocity fluctuations using a classical Reynolds decomposition i.e. by removing the time-averaged velocity field from the instantaneous velocity field.

Figures 6–7 show a very complex behaviour of turbulence in presence of bed load transport. We observe that, in general, higher sediment transport rates enhance longitudinal turbulence intensity as shown in Figure 6. This tendency agrees with previous research (e.g. Campbell et al. 2005) and supports the idea that bed load extracts momentum from the mean flow. However, this trend reverses in tests that correspond to moderate bed load transport (tests S3T4 and S3T6, S5T2 and S5T3) and a ratio of the flow depth to the grain diameter of about 5.

Figures 6–7 demonstrate that turbulence intensities are reasonably well represented by typical exponential laws previously found for smooth and rough beds such as (e.g. Nezu & Nakagawa 1993, Song et al. 1994, Bigillon et al. in press):

$$u^+_{rms} = 2.3\exp(-\frac{y}{h}) \quad (4)$$

$$v^+_{rms} = 1.14\exp(-0.76\frac{y}{h}) \quad (5)$$

However, for tests corresponding to low bed load transport and ratio of the flow depth to the grain diameter smaller than 6 (tests S3T1, S3T4, S5T1, S5T2, S5T3), vertical turbulence intensity is more homogenous (Fig. 7).

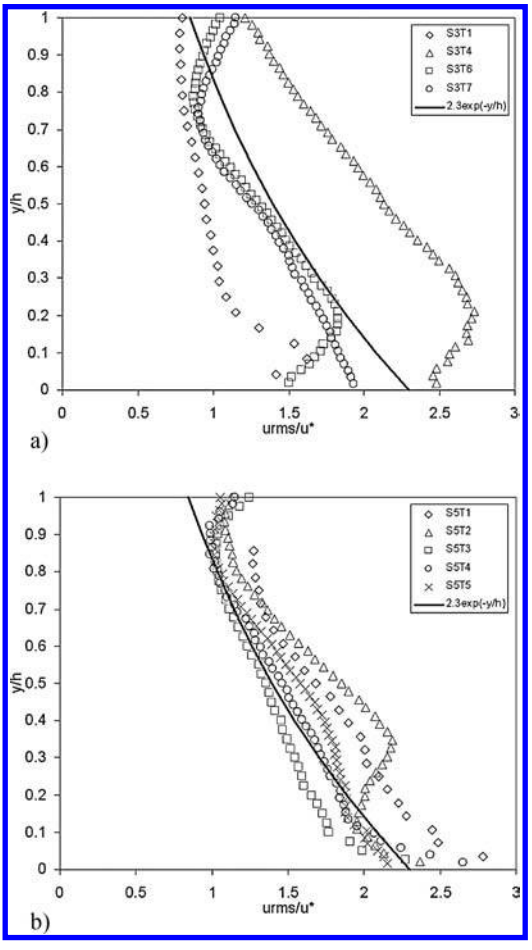

Figure 6. Vertical distribution of the longitudinal turbulence intensities. a) S = 3% b) S = 5%.

3.4 *Reynolds stress*

Figure 8 displays the vertical distribution of the Reynolds shear stress normalized with u_*^2, denoted by $u'v'$, plotted versus y/h.

Reynolds stress profiles indicate that turbulence production is enhanced by increasing bed load transport. This trend is evident for tests preformed with a slope S = 5% (Fig. 8b), but it should be mentioned, however, that the Reynolds stress curve corresponding to test S3T7, is under the one corresponding to test S3T6, contradicting the previous argument. This may be caused by an underestimation of the shear velocity.

Copyright © 2006 Taylor & Francis Group plc, London, UK

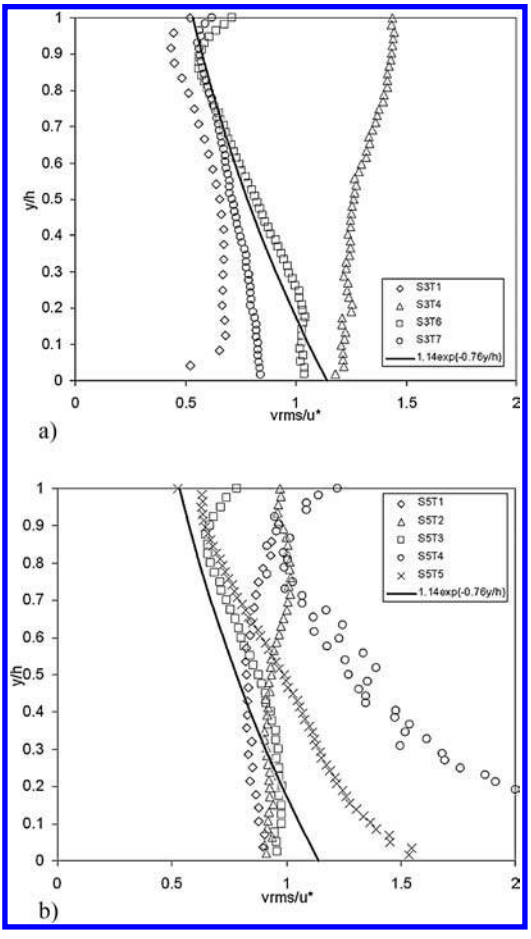

Figure 7. Vertical distribution of the vertical turbulence intensities. a) S = 3% b) S = 5%.

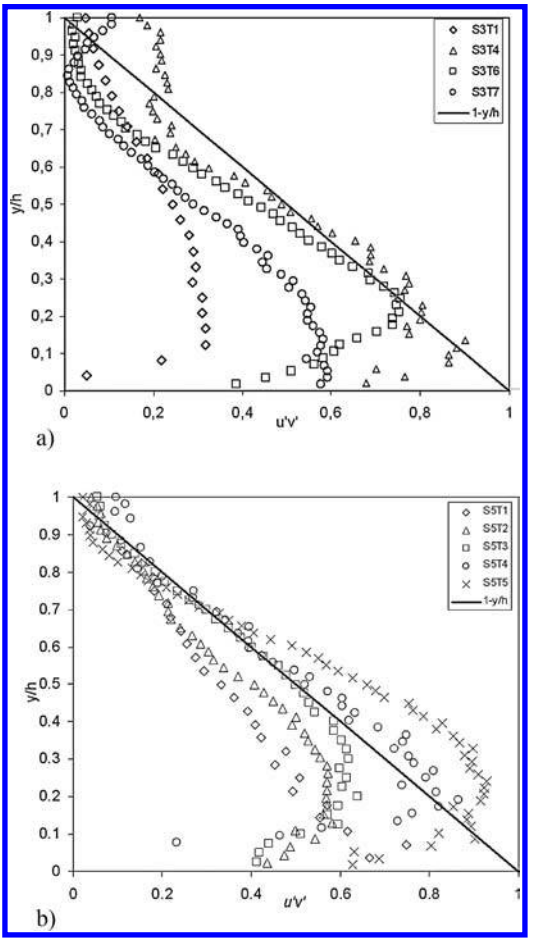

Figure 8. Vertical distribution of the dimensionless Reynolds shear stress $u'v'$: a) S = 3% b) S = 5%.

Reynolds stress profiles present a similar shape for all tests. They demonstrate a linear trend around the one given by (e.g. Bigillon et al. in press):

$$u'v' = 1 - y/h \quad (6)$$

However many tests deviate from (6) and display a different slope. This could be due to secondary currents that yield to different values of the shear velocity than the one estimated by the method described in section 3.1.

As previously found by Campbell et al. (2005), Reynolds stress deviates from a linear trend near the bed. In particular, we observe that the fluid shear stress decreases towards the bed indicating the existence of a roughness sublayer. This layer extends from the top of the bed to the level of maximum Reynolds stress and it is one to two diameters thick in all tests. The existence of this layer demonstrates that additional momentum extraction mechanisms appear in this region. In particular, some shear stress is extracted from the fluid and given to the sediments via drag. At the limit, according to Bagnold hypothesis (e.g. Seminara et al. 2002), the fluid shear stress at the bed should reduce to the threshold value associated with incipient motion.

4 CONCLUDING REMARKS

This study provides new information about the effect of bed load transport on flow velocity and turbulence. We collected velocity measurements using PIV in flume experiments performed under equilibrium bed load transport conditions. PIV data provided instantaneous and average hydrodynamics fields over the bed load layer. Results from our experiments show

Copyright © 2006 Taylor & Francis Group plc, London, UK

that bed load transport has a complex effect on hydrodynamics corroborating previous results (Campbell et al. 2005, Carbonneau & Bergeron 2000). Our data indicate that bed load transport causes opposite effect depending on bed load rate. In general, we observe that increasing bed load transport results in lower longitudinal velocities, larger turbulence intensity, and larger Reynolds stress values compared to conditions without sediment transport. However, an increase of bed load transport results in larger longitudinal velocities and smaller longitudinal turbulence intensity in tests corresponding to moderate sediment transport rates. We think that this behaviour is related to changes in bed roughness and relative flow depths, as it was recently proposed by Recking et al. (2005). Those changes may be related to a transition from a bed load transport to a type of sheet flow transport. Further work is required to develop a better understanding of bed load effect on flow hydrodynamics. Future work should focus on the study of moderate sediment transport conditions for which it seems that the bed load produces sudden changes on hydrodynamics.

The resistance of transported sediment

Graeme Smart
Nat. Inst. of Water & Atmospheric Research, Christchurch, New Zealand

ABSTRACT: In the 1980s the author undertook flume experiments that extended the 1940s Meyer-Peter & Mueller sediment transport data to higher transport rates and to steeper slopes. This paper investigates these data for friction losses associated with sediment transport, by measuring water velocity within the flow mixture and by breaking down the mixture depth into water depth (h_w) + sediment depth (h_s). Interrelationships between the mean fluid velocity, mean sediment velocity, water depth, sediment depth, mixture depth and energy gradient are evaluated. The lag between sediment velocity and water velocity for the steep flume data is shown to be a function of $\sqrt{(gd(\rho_s/\rho - 1))}$, h_s/d, and $(h_w + h_s)/d$. Resistance coefficients that incorporate sediment behavior were introduced and reasonable quantitative predictions of the sediment and water components of the flow were achievable.

1 INTRODUCTION

Correct prediction of the depth of floodwaters is necessary to design riparian structures and to define flood hazard zones. As many floods carry high sediment loads any influence of transported sediment on flow resistance should be understood. Many contemporary flow resistance equations are derived assuming a logarithmic or power law velocity profile above the bed. Where the bed boundary is mobile (Fig. 1) these equations may still be applicable, albeit with altered boundary roughness and/or depth of flow. When there are particles in transport over much of the flow depth (Fig. 2) the theoretical, clear-water velocity profiles may not apply and conventional resistance equations may not be suitable.

This concern is overcome if a simple friction coefficient is used to quantify flow resistance. The problem then becomes one of how to calculate the correct coefficient.

Since the work of Meyer-Peter & Mueller (MPM) in the 1940s there has been debate over friction losses associated with transportation of sediment. Bagnold (1973) described how particle velocity was less than fluid velocity but he encountered problems in quantifying the difference. Muste & Patel (1997) measured the difference to be up to 4% for sand particles in water. More recent studies are described by Cheng (2004). These investigations did not consider sediment sizes larger than sand and Cheng concluded by calling for further research.

In the 1980s, Smart (1984a) undertook sediment transport experiments in an adjustable slope flume in MPM's laboratory, which extended the MPM data to

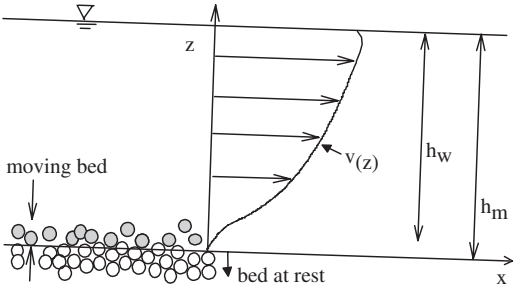

Figure 1. Conditions for application of conventional flow resistance equations, v = water velocity, c = sediment concentration, h_w = depth of water, h_m = depth of mixture.

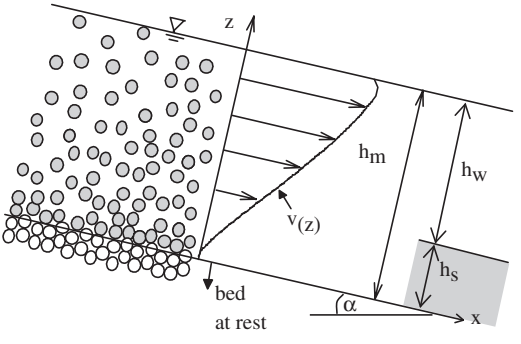

Figure 2. Typical conditions assessed in this investigation, h_s = depth of moving sediment excluding porosity, α = slope angle.

Table 1. Sediment materials used in the steep flume experiments. d = mean particle size, other symbols are defined in the notation section.

Material	ρ_s [kg/m^3]	d [mm]	d_{30} [mm]	d_{90} [mm]
I	2670	4.3	1.3	11.0
II	2670	4.2	3.6	5.2
III	2680	2.0	1.0	4.6
IV	2680	10.5	9.0	12.1

higher transport rates and steeper slopes. The flume was 6 m long, 0.2 m wide and sediment transport data were measured for slopes ranging from 3% to 25%. Four sediment materials were used in the experiments. Their properties are given in table 1.

As part of the experiments the fluid velocity was measured independently from that of the fluid/sediment mixture. This fluid velocity ranged from 0.6–2.8 m/s while the bulk flow velocity ranged from 0.6–2.4 m/s. Until now these measurements have not been fully analyzed. As mean sediment particle velocity can also be calculated from the measurements, the data should provide insight into factors influencing flow resistance in situations similar to the Figure 2 – type conditions. This paper presents these data and analyses interrelationships between the fluid velocity, sediment velocity, flow resistance coefficient, water depth, sediment depth, mixture depth and energy gradient. Potential ways to improve prediction of flow depth in Figure 2 – type conditions are: (a) develop a flow resistance coefficient that incorporates sediment drag or bulking effects or (b) predict water depth and sediment depth separately and add these to give the overall mixture depth.

2 MEASUREMENT METHODS

2.1 *Water and sediment discharge*

The steady water discharges in the experiments were determined from calibrated pressure differentials measured across an orifice plate in the flume supply pipe. Steady sediment discharges were regulated by an upstream conveyor belt and weighed in a collection hopper downstream of the flume. Details of the experimental setup were given by Smart & Jaeggi (1983).

2.2 *Mixture depth*

The depth of the flowing sediment/water mixture (h_m) was read from millimeter scales fixed to the outside of plexi-glass walls on the sides of the flume. At higher sediment transport rates the water surface was fluctuating and the bed surface was mobile, thus making it difficult to define the exact location of the non-mobile bed. For such extreme conditions the mixture depth measurement error could be of the order of ±10 mm.

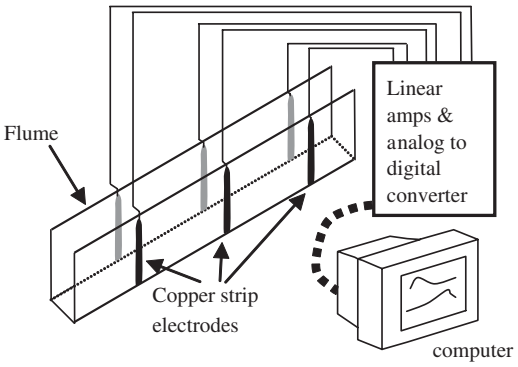

Figure 3. Diagram showing water velocity measurement apparatus.

2.3 *Water velocity*

The velocity of water (v_w) within the sediment/water mixture was recorded by measuring the travel time of salt slugs injected instantaneously into the flow. Water travel time was indicated by monitoring the conductivity between pairs of electrodes mounted on the flume walls as shown diagrammatically in Figure 3.

Each pair of electrodes indicated the conductivity of the water cross-section between them. Slugs of sodium carbonate were injected near the upstream flume end and as these slugs advected and dispersed down the flume the conductivity between the electrodes changed. Mean velocity was defined as the distance between two pairs of electrodes divided by the time difference between the centroids of the peaks in conductivity at each electrode pair. Technical details of the automated velocity measurement setup are given by Smart (1984b). Three pairs of electrodes were used so that the velocity could be determined independently over two reaches of the flume, thus enabling verification of flow uniformity.

3 CALCULATED PARAMETERS

3.1 *Water depth and velocity, sediment depth and sediment velocity*

The mean velocity of the sediment water mixture is:

$$v_m = (q_w + g_s/\rho_s)/h_m \quad (1)$$

where q_w is the measured water discharge divided by the flume width, g_s = measured mass transport rate

Copyright © 2006 Taylor & Francis Group plc, London, UK

per unit width and ρ_s = sediment density. The mean velocity of water over the mixture depth is:

$$v_{mw} = q_w/h_m \quad (2)$$

The depth (h_w) of clear water within the mixture is calculated from the continuity equation:

$$h_w = q_w / v_w \quad (3)$$

where v_w can be measured as described in 2.3 above.

The equivalent sediment depth h_s with no porespace, is:

$$h_s = g_s / (\rho_s v_s) \quad (4)$$

where v_s = sediment velocity along the flume. From conservation of volume, the mixture depth is the sum of the water depth and the sediment depth:

$$h_m = h_s + h_w \quad (5)$$

With mixture depth measured as described in section 2.2, the sediment depth can be calculated using (3) and (5). Eq. (4) then gives the sediment velocity:

$$v_s = g_s / (\rho_s (h_m - h_w)) \quad (6)$$

Using this breakdown of the flow components, in order to predict h_m given q_w, g_s, S and d_m, it will be necessary to calculate v_w and v_s. For low sediment loads v_w should be predictable by the usual clear water resistance equations such as Manning's Eq. or a log law equation. As sediment load increases, v_w may decrease due to the drag of suspended particles.

3.2 *Drag force balance*

For a single suspended sediment particle diameter d, traveling downstream at v_s, the streamwise drag force is $(C_d/2)\ \rho\ (v_w\text{-}v_s)^2\ \pi\ d^2/4$ where C_d is a drag coefficient that depends on particle shape and flow turbulence. The number of identical, spherical, moving particles above area A of bed is $(h_s A)/(\pi\ d^3/6)$. Introducing C_p to correct for differences in the sediment and water velocity profiles and particle interaction, the total streamwise particle drag F_s above the area A of bed is the sum of the drag on individual particles times the number of particles:

$$F_s = 3\ C_d\ C_p\ \rho\ (v_w\text{-}v_s)^2\ \ h_s\ A\ /\ (4\ d) \quad (7)$$

Assuming the weight of suspended particles is eventually supported by the bed, the transfer of particle drag force to the bed can be described using a coefficient of dynamic friction μ and the normal force:

$$F_s = \mu\ (\rho_s\text{–}\rho)\ h_s\ A\ g\ \ \cos\alpha \quad (8)$$

Equating (7) and (8) gives:

$$\mu\ /\ (C_d\ C_p) = .75\ (v_w\text{-}v_s)^2\ \ \rho\ /\ [(\ \rho_s\text{–}\rho\ )\ g\ d\ \cos\alpha] \quad (9)$$

All parameters on the right hand side of (9) can be measured or derived from the flume data allowing calculation of $\mu/(C_d\ C_p)$. Such calculated values will contain any errors introduced by the above assumptions and by measurement inaccuracies. The equation does not differentiate between the case where water moves faster than the sediment and the potential case of sediment moving faster than the water.

3.3 *Energy head loss*

For the uniform flow conditions investigated here the energy loss per unit weight per unit channel length is given by the channel slope (S).

Without sediment load, according to Meyer-Peter & Mueller (1949), the energy gradient required to produce a depth h_w in the flume would be:

$$S_b = v_w^2\ n^2\ /\ h_w^{4/3}, \qquad n = d_{90}^{1/6}/26 \quad (10)$$

where d_{90} is the sediment sieve diameter for which 90% of a sediment sample is finer. As there were no bedforms other than antidunes in the flume, an approximate indication of the energy gradient (S_s) associated with the sediment load component of a mixture (with water depth h_w) is therefore:

$$S_s = S - S_b \quad (11)$$

The relation is approximate because of the different flow structure when sediment is present and the different weight of flow carrying a sediment load compared to flow without a sediment load.

3.4 *Friction coefficient*

Friction coefficients represent a ratio of driving force and frictional resistance force. To modify friction parameters to allow for sediment drag it is necessary to understand the physical composition of friction coefficients like Chézy C or friction factor. The driving force for unit bed area and flow depth h, is the down-slope weight of the flow $\tau_o = \rho\ h\ g\ \sin(\alpha)$ where g = gravitational force per unit mass. The retarding frictional drag force over unit bed area is considered as skin drag: $\tau_b = C_b\ \rho\ v_b^2/2$ where C_b is a bed drag coefficient and v_b is the effective flow velocity at the bed. The effective bed velocity is some function of mean velocity, say $v_b^2 = v^2/(C_a/2)$. Equating the driving and retarding forces gives:

$$v^2/(gh\ \sin\alpha)\ = C_a\ /\ C_b \quad (12)$$

Even at the moderate slopes of these experiments, little error is introduced by assuming $\sin\alpha = S$ and the left side of (12) is seen to be $(v/v^*)^2$ where

Copyright © 2006 Taylor & Francis Group plc, London, UK

$v^* = \sqrt{(ghS)}$. The correspondence between v/v* and friction factor, Manning's n and Chézy C is described by Smart (2002). The right side of (12) is not constant and in rough turbulent flow, the factor C_a/C_b may depend on flow depth, bed roughness height, particle shape and particle packing. When sediment is introduced into the flow the downslope weight component increases and other forces come into play. Sediment weight can be incorporated if v* is redefined as:

$$v^*_{ws} = \sqrt{(g(h_w+(\rho_s/\rho-1)h_s)\,S)} \qquad (13)$$

Various guises of v/v* can be considered and the following friction coefficients are proposed:

$$c_m = v_m/\sqrt{(gh_m\,S)} \quad \text{mixture coef.} \qquad (14)$$

$$c_{mw} = v_{mw}/\sqrt{(gh_m\,S)} \quad \text{mixture water coef.} \qquad (15)$$

$$c_{mg} = v_m/v^*_{ws} \quad \text{mixture coef. using (13)} \qquad (16)$$

$$c_w = v_w/\sqrt{(gh_w\,S)} \quad \text{water coef.} \qquad (17)$$

$$c_s = v_s/\sqrt{(gh_s\,S)} \quad \text{sediment coef.} \qquad (18)$$

3.5 *Wall effect correction*

In the experiments, the flume-width to flow-depth ratio varied from 2.2 to 6.9 and there is no consensus on the best technique for correcting for flow resistance effects associated with drag caused by the flume walls. As the roughness of sediment on the flume bed was an order of magnitude greater than the equivalent roughness height of the smooth flume walls, no sidewall correction is applied to the present data analyses. In the original investigations (Smart & Jaeggi, 1983) it was found that the use of a wall drag correction procedure did not improve the correlation between predicted and measured transport rates.

4 RESULTS

Water velocities were measured in 71 experiments. Inaccuracies in measurement of mixture depth indicated negative, zero or infinite sediment velocities in 6 cases and these data were excluded in the following analyses.

4.1 *Energy head loss*

An indication of the energy gradient associated with the sediment load, as discussed in section 3.3, is given in Figure 4. It appears that for these steep flume experiments up to almost 100% of the available energy may be spent on transporting sediment. Figure 4 shows a log function fits the data reasonably well:

$$(S-S_b)/S = .038*\ln(h_s/d) + 0.90 \qquad (19)$$

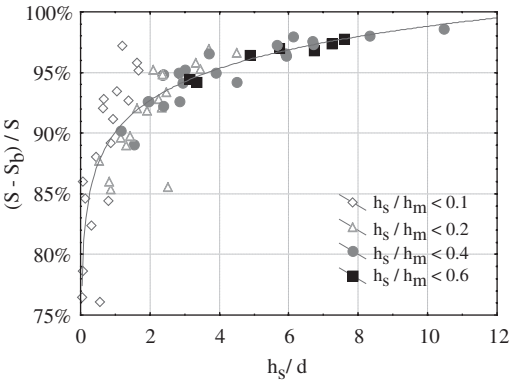

Figure 4. Indication of fraction of energy spent on sediment transport as a function of relative sediment depth. Symbols showing h_s/h_m illustrate the effect of sediment concentration.

but, as explained in section 3.3, this approach is not particularly robust on a theoretical basis.

4.2 *Velocity lag*

Widely used in investigations of fine sediments, the lag between mean sediment velocity and mean water velocity can be misleading where there are coarser particles, especially when these are transported as bedload. In the case of no sediment movement the lag would be 100%.

Figure 5 shows velocity lag as fraction of water velocity. Negative lags occur at moderate slopes indicating that sediment is moving faster than the interstitial water or that there is measurement error. Figure 5 shows the sediment concentration (h_s/h_m) ranges from near zero to more than 50%, indicating that there can be more sediment than water in the flow mixture. Figure 5 shows that the relative velocity lag is a function of the sediment concentration and channel slope.

Further analysis of relative velocity lag is not straightforward and the velocity lag is studied using the drag force balance of Equation (9).

Figure 6 shows calculated values of the parameter $\mu/(C_d\,C_p)$ according to Eq. (9). The main variation in this parameter should come from C_p which relates the effective water velocity moving the sediment to the mean water and sediment velocity. A decrease in C_p is expected as sediment transport rate increases and bedload becomes suspended load.

Figure 6 shows that $\mu/(C_d\,C_p)$ increases with mixture depth to grain size ratio and increases with sediment depth to grain size ratio.

The relation can be described by the equation

$$\mu/(C_d\,C_p) = 0.6\,(h_m/d)\sqrt{(h_s/d)} \qquad (20)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

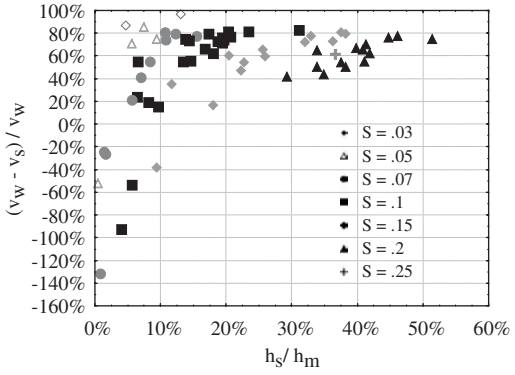

Figure 5. Sediment velocity lag as fraction of water velocity compared with sediment to water volume ratio (h_s/h_m) and channel slope S.

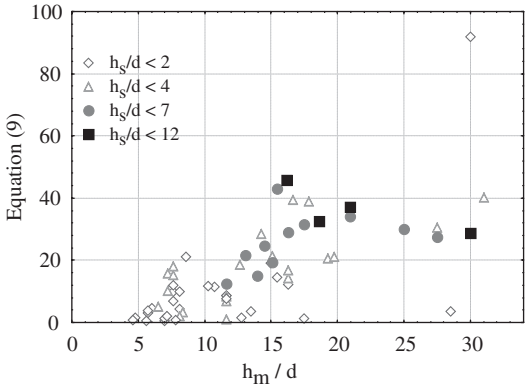

Figure 6. Coefficient of drag force balance (Eq. 9) as a function of relative mixture depth and relative sediment depth.

and, taking into account that measurement errors in ($v_w - v_s$) are squared in calculation of $\mu/(C_d\ C_p)$, the goodness of fit is reasonable as shown in Figure 7.

4.3 *Friction coefficient v/v**

For clear water, the friction coefficient can be explained as a function of the flow depth to roughness height ratio. Parameters explaining the sediment influenced coefficients of equations (13) to (18) are investigated in the following sections. An increase in the coefficient indicates a decrease in flow resistance. Each coefficient was examined for dependence on experimental variables such as relative depth, sediment concentration, d_{90}/d_{30} and energy gradient. Results are not given where no relation was evident. The relations are not applicable when there is no sediment load and were not investigated for slopes flatter than 3%.

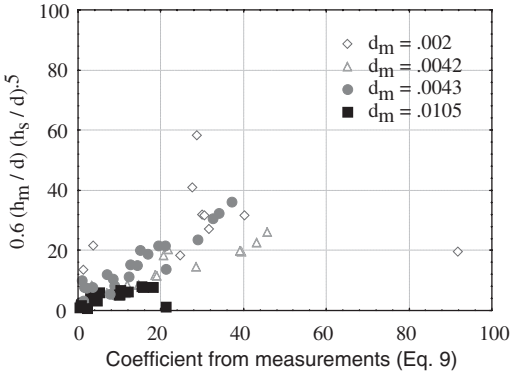

Figure 7. Measured coefficient $\mu/(C_d\ C_p)$ compared with value calculated by Eq. (20).

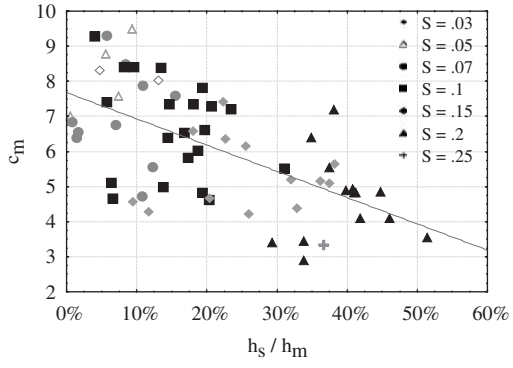

Figure 8. Mixture coefficient c_m decreases with increasing sediment concentration (h_s/h_m).

4.3.1 *Mixture coefficient c_m (Eq. 14)*

Values of c_m in the steep flume experiments, range from around 2.9 for the coarsest sediment to 9.5 for the finest sediment. No straightforward description of c_m in terms of clear water parameters such as $\log(h_m/d_{90})$ was evident. There is a decrease in c_m with increasing sediment concentration as shown in Figure 8. The relation is $c_m = 7.75 - 7.73\ (h_s/h_m)$. Considering $h_s/h_m = 1 - h_w/h_m$ this may be written:

$$c_m = 7.7\ (h_w/h_m) \tag{21}$$

4.3.2 *Mixture water coefficient c_{mw} (Eq. 15)*

The range of c_{mw} values was similar to the c_m range but a stronger relation explaining the decrease in c_{mw} with h_s/h_m was evident. The line fitted to Figure 9 has the equation: $c_{mw} = 7.51–9.15*(h_s/h_m)$ $r^2 = 0.5$.

Re-arranging to a form similar to (21) gives:

$$c_{mw} = 9.15\ (h_w/h_m) - 1.64 \tag{22}$$

A relation is also evident between c_{mw} and $\log(h_m/d_{90})$ as shown in Figure 10. A different log law

Copyright © 2006 Taylor & Francis Group plc, London, UK

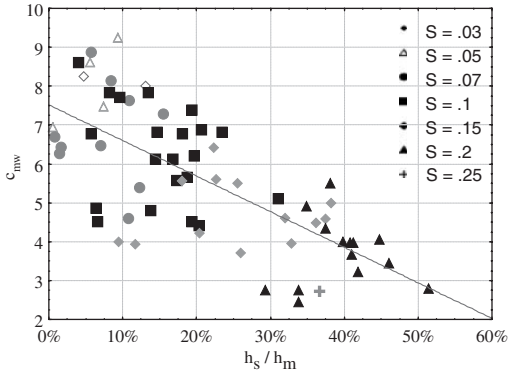

Figure 9. Mixture water coefficient as a function of sediment concentration showing flume slope S.

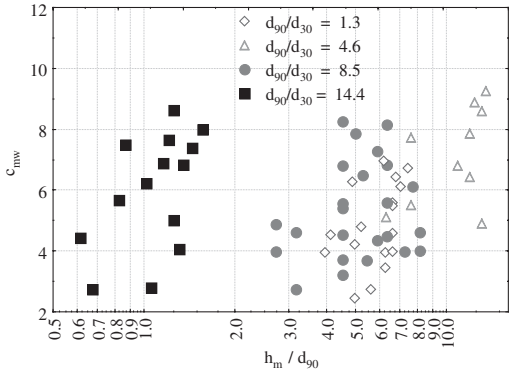

Figure 10. Mixture water coefficient as a function of $\log(h_m/d_{90})$.

is indicated for the sediment with $d_{90}/d_{30} = 14.4$ than for the other sediment types. From the present data set it was not possible to find a variable that improved on the data grouping and a general log law equation could not be found.

4.3.3 *Mixture coefficient corrected for weight c_{mg} (Eq. 16)*

The c_{mg} coefficient behaved similarly to c_m and c_{mw}. A stronger relation explaining the decrease in c_{mg} with h_s/h_m was evident compared to c_m but the correlation was similar to that between c_{mw} and h_s/h_m ($r^2 = 0.5$).

4.3.4 *Water coefficient c_w (Eq. 17)*

The c_w coefficient shows no significant relation to sediment concentration. A relation with log (h_m/d_{90}) was discernable for some sediment materials but it was not possible to formulate a general log law.

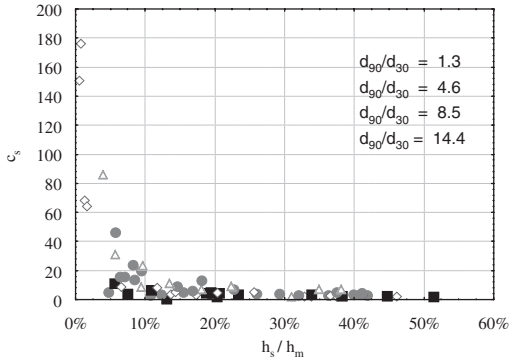

Figure 11. Sediment resistance coefficient c_s as a function of sediment concentration.

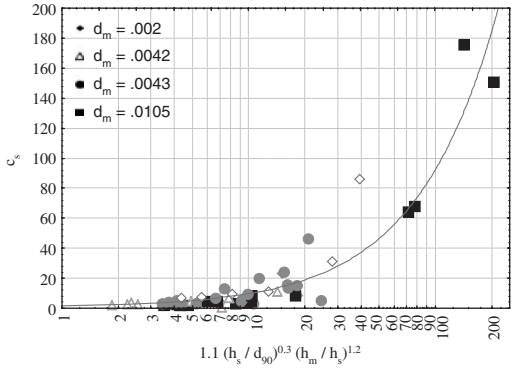

Figure 12. Measured c_s coefficient compared with value calculated by Eq. (23). Line shows $y = x$.

4.3.5 *Sediment coefficient c_s (Eq. 18)*

This coefficient has a large range in values from near 200 to almost zero. The value falls quickly (resistance increases) as sediment moves from bedload to suspended load and concentration increases as shown in Figure 11.

The coefficient can be explained by a relation incorporating relative sediment roughness depth (h_s/d_{90}) and sediment concentration:

$$c_s = 1.1\ (h_s/d_{90})^{0.3} / (h_s/h_m)^{1.2} \qquad (23)$$

The high correlation of this relation ($r^2 = 0.87$) is evident in Figure 12 where the x-axis is given on a log scale to show the spread of low c_s values.

5 DISCUSSION

Recalling that the goal of the investigations is to investigate sediment resistance and improve prediction of flow depth, the results are now analyzed to determine whether this can be achieved.

Copyright © 2006 Taylor & Francis Group plc, London, UK

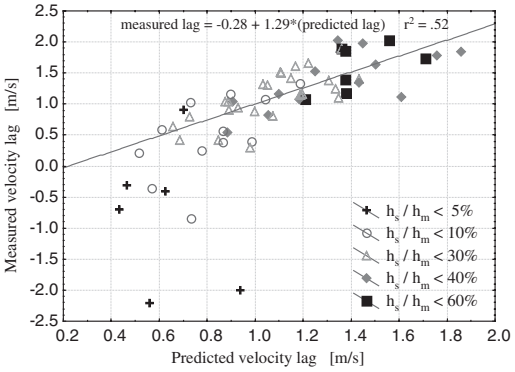

Figure 13. Comparison of predicted and measured velocity lag.

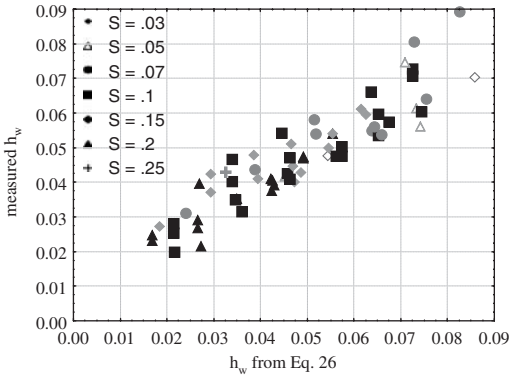

Figure 14. Measured water depths compared with values predicted by Equation (26).

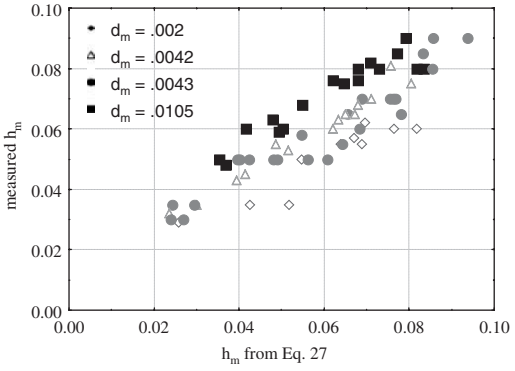

Figure 15. Measured flow mixture depth compared with values predicted by Equation (27).

5.1 *Velocity lag*

Substituting the empirical prediction of the $\mu/(C_d\ C_p)$ coefficient from Eq (20) into the drag force balance equation (9) and using $\cos\alpha = 1$ gives: $v_w - v_s = \pm 0.9\ (h_s/d)^{0.25}\ [(g(\rho/\rho_s - 1)\ h_m]^{0.5}$. The equation does not identify whether sediment velocity lags water velocity or *vice versa*. Figure 13 shows this predicted velocity lag versus measured velocity lag. It appears that, at lower sediment concentrations on moderate slopes, the sediment may travel faster than the water. It was noted during the experiments that some particles were entrained with such vigor that they were ejected through the water surface. This vigorous entrainment by turbulence may explain these high sediment velocities at low transport rates.

Using only positive lags to correct the coefficient for best fit (Figure 13) and grouping logically gives:

$$v_w\text{-}v_s = 1.2(h_s/d)^{0.25}(h_m/d)^{0.5}[(g(\rho/\rho_s)\text{-}1)d]^{0.5} - 0.28 \quad (24)$$

This relation is not applicable when there is low sediment load or no sediment load.

5.2 *Predicting* h_m *from components* $h_w + h_s$

The mixture friction coefficient equation (21), may be written as:

$$h_w = 0.13\ (q_w + g_s / \rho_s\ ) / \sqrt{(g h_m S)} \quad (25)$$

Similarly the mixture water coefficient equation (22), indicates:

$$h_w = 0.11\ (\ q_w / \sqrt{(g h_m S)}) + 0.18\ h_m \quad (26)$$

In comparison with measured data, Equation (26) gives better results. It is shown in Figure 14 compared with the measured values of h_w.

Equating (25) and (26) to eliminate h_w gives:

$$h_m = (0.11\ q_w + 0.72\ g_s / \rho_s\ )^{2/3} /\ (g\ S)^{1/3} \quad (27)$$

This prediction of overall flow depth is shown in Figure 15.

The figure indicates that the reasonable prediction of mixture depth may be improved upon by incorporating a grain size indicator. In the case when there is no sediment transport Equation (27) implies $c_w = c_m = 12$. The form of clear water flow resistance equations (e.g. Keulegan, 1938) implies that this "constant" should be a log or power law function of depth and bed roughness. Further work is therefore required to develop a general purpose equation.

5.3 *Sediment resistance coefficient*

The sediment resistance coefficient of Equation (23) can also be arranged to a form similar to (25) indicating:

$$h_s = .85\ ((g_s / \rho_s)/\sqrt{(g\ h_m\ S)})^{1.67}\ \sqrt{(d_{90} / h_m)} / h_m^{0.67} \quad (28)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

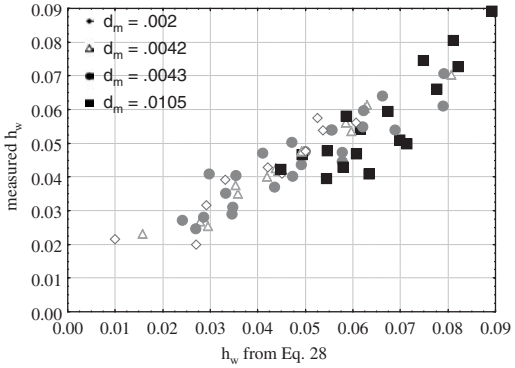

Figure 16. Measured water depths compared with values predicted by $h_w = h_m - (h_s$ from Equation 28).

In Figure 16 this is plotted as h_w $(=h_m - h_s)$ for comparison with previous results.

The goodness of fit is excellent ($r^2 = .84$) and is equivalent to that achieved using c_{mw} (Figure 14).

6 SUMMARY AND CONCLUSIONS

Resistance properties of steep slope flows with high sediment loads were investigated by measuring water velocity within the mixture and by breaking down the mixture depth into water depth + sediment depth. The drag of transported sediment was studied in terms of force balance, from an energy loss perspective and from a velocity lag point of view. The physical meaning of the classical (clear water) friction coefficient v/v* was explained and five variants were introduced to incorporate sediment effects. These conceptual approaches were then investigated with the experimental data.

The questionable energy loss approach indicated that for high sediment loads more than 90% of the available energy may be spent on transporting sediment. The relative energy loss due to sediment could be predicted by Equation (19).

The lag between sediment velocity and water velocity for the steep flume data was shown (Equation 24) to be a function of $\sqrt{(gd(\rho_s/\rho - 1))}$, h_s/d, and h_m/d. Several situations with negative velocity lags were also evident which may indicate vigorous entrainment by turbulence.

For the 5 variants of friction coefficient, predictive equations for c_m, c_{mw} and c_s could be found. These were evaluated by comparing measured and predicted water depth and measured and predicted mixture depth (Figures 14–16). Reasonable quantitative predictions of the sediment and water components of the flow were achievable.

The equations presented above were not verified against independent experiments and consequently they should be used as a starting point for further research rather than as a design tool.

Development of a hybrid adaptive neuro-fuzzy system for the prediction of sediment transport

ABSTRACT: In natural streams, turbulent flow is considered as the forcing mechanism responsible for particle dislodgement. A hybrid approach is presented here for predicting the movement of individual grains. To effectively manage the uncertainties that rise because of the dynamic, non linear and complex nature of the highly interrelated variables of the system, an Adaptive Neuro Fuzzy Inference System (ANFIS) is utilized. This system combines the ability to model human reasoning, by means of fuzzy inference (if-then rules) and linguistic variables with the power of learning and adaptation inherited from neural networks. Thus the tuning of the fuzzy system is performed automatically using experimental data, instead of heuristics, which is a tedious process and requires extensive insight and expertise of the studied phenomenon. The experimental data are obtained via the use of a laser Doppler velocimeter (LDV) for the velocity measurements and visual techniques (video capturing) for identifying grain movement in an existing research flume. The experimental setup involves a mobile spherical particle, which is only allowed to be subjected to small displacements. The total velocity measurements obtained with the LDV signal, are treated as fuzzy input sets while the captured video, supplies the time history of the incidents of displacement of isolated particle representing the fuzzy output set. Different architectures of the model are evaluated, and compared with a previously studied artificial neural network model. The model is capable of good prediction of the dislodgment events.

1 INTRODUCTION

Sediment transport is an environmental problem of high concern to the civil and environmental engineer; either it is related to the bank erosion or deposition, the scour around bridge piers or even the transportation of contaminants and pollution of the downstream ecosystems. To be able to understand such a complex phenomenon, we have to first identify the major underlying factors that significantly affect it. Under that context, the study of the initiation of particle movement in relation to variables which have the greater impact upon it such as the instantaneous local velocity field is considered here. A plethora of researchers have pursued this issue. For instance Papanicolaou et al. (2001) as well as Shvidchenko and Pender (2001) employed a visualization technique to investigate the effect of near bed turbulence in rough beds. Nino et al. (2003) studied both rough and smooth boundaries investigating particle suspension via a theoretically approached threshold of particles motion criterion.

However, the existence of near bed turbulence from which it inherits a highly nonlinear behavior, makes it difficult to be accurately resolved by time deterministic averaging (Shields 1936) or stochastic (Papanicolaou et al. 2002) approximations. The strong non-linearity and chaotic structure of turbulence (Gallavotti 2000) and the hydrodynamic instantaneous forces on which it depends (Einstein & El-Samni 1949), render the above approaches unable to be characterized as universally superior models.

Recently soft-computing techniques such as artificial neural networks (ANNs) and fuzzy inference systems (FIS) have demonstrated a unique ability in dealing successfully with nonlinearity over a wide range of applications and disciplines related to forecasting. Thus the use of such sophisticated algorithms is thought as an appropriate methodology to address the problem of particle entrainment.

In this paper we present a state of the art neuro-fuzzy approach as a predictive tool in an attempt to investigate the dynamics of single particle dislodgement.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The proposed adaptive neuro-fuzzy inference system (ANFIS) is a well established algorithm which combines the features of neural networks such as the data driven process of learning, with the fuzzy logic concept which accounts for imprecision and vagueness in the data.

In the following we present the use of the developed ANFIS model in predicting the initiation of a particle sediment motion. Firstly a discussion of the experimental setup, the algorithm's architecture and preparation of data is provided. Next the results from the analysis are shown along with respective results from a previous ANN model so that a constructive comparison will be drawn. Finally the outcomes of the model are further analyzed complemented by conclusions and evaluation of the model in respect to its performance in computational resources and accuracy.

2 METHODOLOGY

2.1 *ANFIS overview*

Since their discovery ANNs have been used in many applications. Recently their implementation in sedimentation prediction (Ariffin 2004), scour (Azmathullah et al. 2005) and river discharge forecasting (Sahoo & Ray 2006) has been reported. ANNs are data driven algorithmic structures which are able to accurately predict the evolution of a nonlinear system by adapting to it. In contrast to conventional numerical or analytical solutions they do not require a priori knowledge of the system or construction of rigorous approximating relationships. However they are considered as "black boxes" since they are unable to reveal the way the variables interact with each other. On the other hand fuzzy logic is able to provide rules for the underlying dynamics of the studied system dealing also effectively with impreciseness of the utilized data (Zadeh 1973). For this reason ANFIS is thought to integrate the mentioned virtues of both ANNs and FL into a powerful computational hybrid model (Jang 1993). It has successfully been implemented in numerous applications such as fault detection and diagnosis (Awadalah et al. 2005, Kazeminezhad et al. 2005), modeling (Hasiloglu 2004), prediction (Chang and Chang 2006) and signal processing (Valsan et al. 2002). Thus ANFIS has a high potential as a predictive tool for the study of the initiation particles entrainment.

2.2 *ANFIS architecture*

ANFIS has a structure that resembles a multilayer feed-forward ANN, which uses fuzzy inference to map an input to an output space (Sugeno 1995). For instance if we consider a first order Takagi-Sugeno fuzzy inference type, with two inputs (x, y), an output ($f(x)$) and a typical fuzzy rule base of two "If-Then" rules, then we can express them as follows (Jang 1993):

Rule 1: If x is A_1 and y is B_1, Then $f_1 = p_1x + q_1y + r_1$
Rule 2: If x is A_2 and y is B_2, Then $f_2 = p_2x + q_2y + r_2$

where A_i, B_i are values of membership functions for x, y respectively, in the premise (If) part and p_i, q_i, r_i are the linear parameters of the consequent (Then) part. The subscript i is used as a notation for each of the rules.

Each layer of ANFIS has different nodes as described below for the general case of N_{in} number of inputs (x_i, $i = 1, \ldots, N_{in}$), N_{xi} fuzzy numbers (or linguistic labels $A_{i,j}$) for each input and N_R number of rules (Figure 1).

Layer 1: This layer consists of a total of N adaptive nodes ($N = \Sigma N_x$) – one for every linguistic label $A_{i,j}$ – with a membership function ($\mu A_{i,j}$), which maps the input x_i, to a certain output value:

$$O_{i,j}^1 = \mu_{A_{i,j}}(x_i) \tag{1}$$

Widely used are bell shaped functions bounded from zero to one from which the most popular is the Gaussian:

$$\mu_{A_{i,j}}(x) = \exp\left[-\left(\frac{x - c_{i,j}}{2\sigma_{i,j}}\right)^2\right] \tag{2}$$

defined by $c_{i,j}$, $\sigma_{i,j}$ named as premise parameters.

Layer 2: Each node in this layer (Rule node) combines the transmitted signals by using membership functions of different input variables. Thus the output of each node is analogous to the firing strength of the rule it represents. The operator used to combine the signals is the multiplication (AND) T-norm fuzzy operator (Tanaka 1996):

$$O_k^2 = w_k = \prod \mu_{A_{i,j}}(x) \tag{3}$$

meaning that the antecedent part of *kth* rule which involves one membership function $\mu_A(x)$ for each input, is satisfied proportionally to w_k.

Layer 3: In this layer we calculate the ratio of each rules firing strength to the sum of them for all rules. In a way a normalization of the firing strengths for each rule is performed:

$$O_3^k = \overline{w_k} = \frac{w_k}{\sum_{i=1}^{N_R} w_i} \tag{4}$$

where w_k is the normalized firing strength for *kth* rule.

Layer 4: The consequent part of fuzzy reasoning is represented by this layer where the contribution of each of the rules ($k = 1, \ldots, N_R$) in the final output is given by:

$$O_k^4 = \overline{w_k} f_k = \overline{w_k}\left(\sum_{i=1}^{N_R} p_{i,k} x_i + r_k\right) \tag{5}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

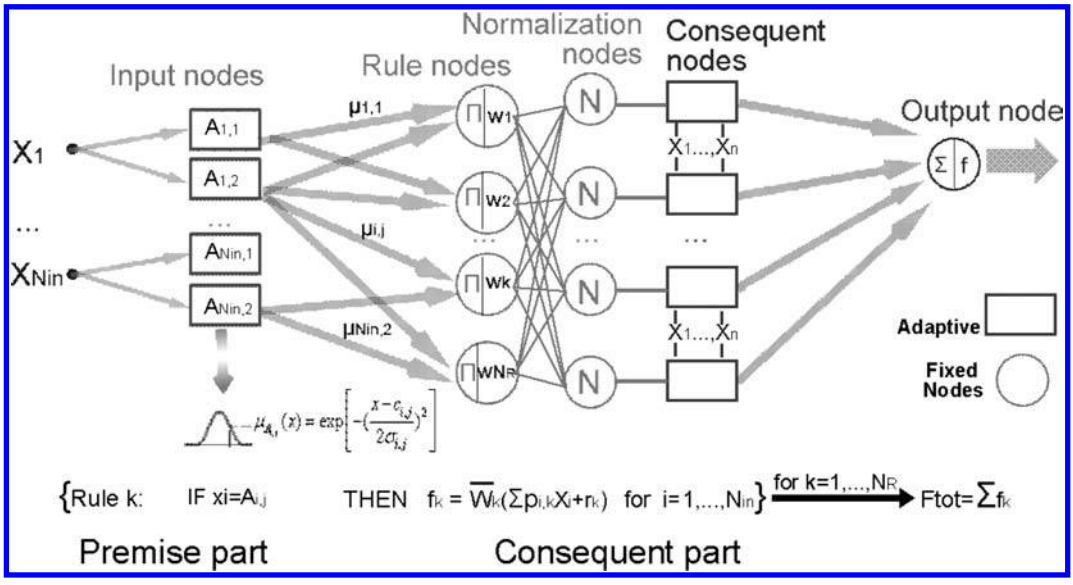

Figure 1. ANFIS architecture for $N_{i,j}$ number of inputs, $N_x = 2$ linguistic labels ($A_{i,j}$) for each input and N_R number of rules.

with $p_{i,k}, r_k$ the consequent parameters as mentioned before.

Layer 5: In the final layer the total output is calculated by adding all the transferred signals from each rule:

$$O^5 = \sum_{i=1}^{N_R} \overline{w}_i f_i \qquad (6)$$

Above we have described the forward pass of the input signal which provides the respective result. The hybrid learning procedure proposed by Jang (1993), involves tuning or calculating the consequent linear parameters $p_{i,k}$, and r_k in the forward pass of the transmitted signal with the least square method. Moreover ANFIS is trained with supervised learning which means that the model adjusts its parameters according to the error, which is the difference of calculated output from the desired output taken from the respective input-output pair. Thus the above error has to be back-propagated to adjust the premise parameters$c_{i,j}$, $\sigma_{i,j}$ with a nonlinear optimization method such as gradient descent.

There exists no guiding rule in defining a priori the model's architecture since it is highly dependent on the nature of the studied problem. In general a complex structure with many nodes attains high accuracy (small training error) but poor generalization ability (higher testing error). In contrast a simple, relatively to the size of the training data set, architecture exhibits the worse approximation and good generalization. Thus in our case a trial and error analysis was undertaken to find the optimum number of parameters that define ANFIS model. The selected architecture is not of high complexity and is limited by the huge size of the data pairs compared to the available computational resources.

The maximum number of lagged variables in the input vector was three representing the local velocities. The number of utilized membership functions determines the granularity (or level of detail) of the model (Zadeh 1997), and in our case did not seem to significantly affect models performance.

2.3 *Experimental setup*

The input to our ANFIS model consisted of laser Doppler velocimetry measurements obtained simultaneously with data from a camcorder which provided the time and duration of particle movement. Similar experiments for the study of initiation of particles motion, have been reported (Smcheeckle et al. 2003, Dancey et al. 2002, Papanicolaou et al. 1999).

The experiments for the initiation of motion of a single spherical particle were performed in a research flume located at the Kelso S. Baker Environmental Hydraulics Laboratory, Virginia Tech. The flume has dimensions of 20.5 m, 0.6 m and 0.3 m for its length, width and depth respectively. A Viton® sphere of 8.0 mm diameter was used as a mobile particle exposed to a fully-rough turbulent open channel flow of average stream-wise local velocity of 0.21 m/sec. The Viton® sphere of 8.0 mm diameter was used as a mobile particle exposed to a fully-rough turbulent open sphere is placed over a bed made of four layers of packed glass beads of the same diameter (Figure 2). The particle's displacement is retained by a fixed pin. Thus

Copyright © 2006 Taylor & Francis Group plc, London, UK

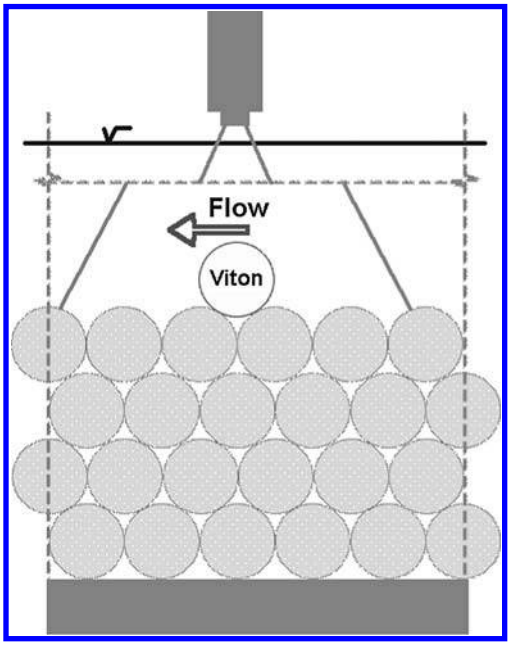

Figure 2. Profile of the study area.

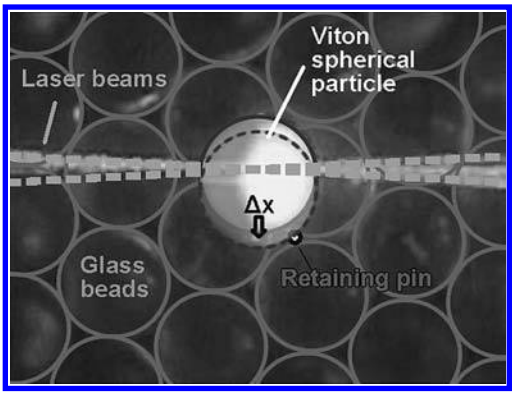

Figure 3. A planar view of the study area. The dashed circle indicates the position of the displaced sphere by Δx.

the particle can only be displaced for a certain small distance (Δx), and then return to its initial position (Figure 3).

Thus only a small dislodgment of the particle from its pocket is allowed, enabling the continuous monitoring of a series of sphere movement events. The particle's displacement events are recorded with a commercial camcorder, mounted on top of the flume above the free surface of the flow (Figure 2). The camera is looking downwards capturing the area of interest at a rate of thirty frames per second. The recorded movie is then digitized in a computer and a digital video file is produced from which the time series of

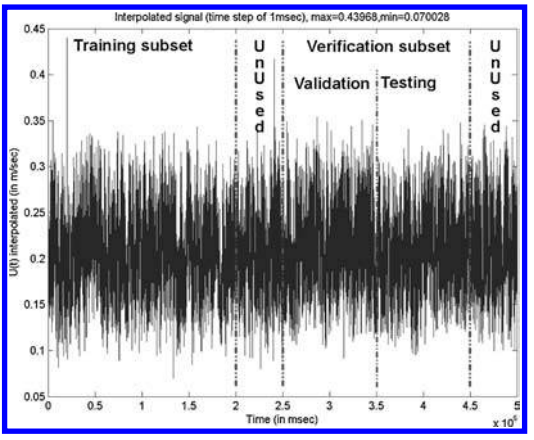

Figure 4. Interpolated values of stream-wise velocity measurements, divided into training and verification input subsets.

those events is manually generated by observation to be used as an output for the ANFIS model.

The time series of velocity measurements were acquired by laser Doppler velocimetry (LDV). A two-component color separated LDV system with frequency-domain signal processing was employed to measure the stream-wise component of velocity. The LDV system was oriented in direct backscatter mode. It was mounted along side of the flume and tilted approximately 4.8 degrees from the horizontal. According to this technique measurements are obtained randomly only when seeding particles cross the measurement area formed by the laser beams (denoted by the green dashed lines in Figure 3). Thus the seeding density and the quality of the seeding material are major factors that significantly affect the experiment's outcome. The seeding material was SiC (silicon carbide) with a mean particle diameter of 4 microns. The stream-wise velocity was measured directly with a sufficient average data rate of approximately 450 measurements per second.

2.4 *Data preparation*

The available LDV measurements are unevenly spaced in the time domain (due to the fact that seeding particles cross the measurement area in randomly distributed time instances), which means that a reconstruction of the time series with a constant instead of a varying time step is required. Thus the data were interpolated (Figure 4), to a constant time step of one millisecond. We also implement a reconstruction of the observed output to the same constant time step (Figure 5). The output data set is built by considering a Gaussian function for each of the observed displacement events, of width (σ) equal to the duration of the displacement.

Copyright © 2006 Taylor & Francis Group plc, London, UK

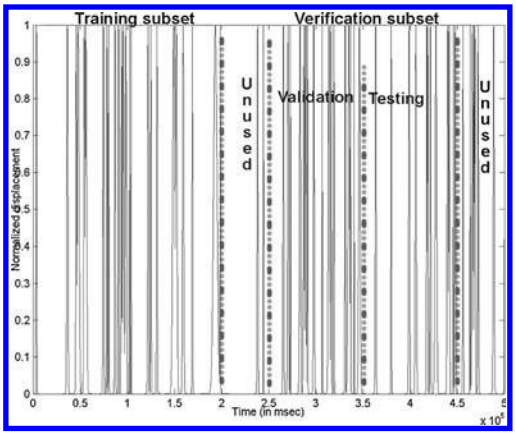

Figure 5. Distribution of displacement events in training and verification output subsets.

Table 1. Characteristics of the chosen subsets.

		Verification set	
	Training set	Validation	Testing
From [msec]	1	250000	350001
To [msec]	200000	350000	450001
Observed events	5	17	12
Data points	200000	100000	100000
Mean	0.2079	0.2163	0.2108
Standard deviation	0.0393	0.0399	0.0377

The available data are divided into two sets which are totally independent. As it can be seen in Figures 4–5, these are the training and verification subsets. The role of the training set is to build the model by tuning the adaptive nodes in the consequent and premise part of each fuzzy rule. The validation subset is utilized to simulate the network and provide a model with good generalization ability. Finally the testing data set is employed to check the model's response to newly fed data. In order to sufficiently train the model without compromising the validation and testing procedure we choose a ratio of length of our data subsets of 2: 1: 1. These data sets must not have any overlapping data points so data from one subset are unseen from the others. Under this context it is ensured that the models performance is not overestimated. The corresponding number of data points and displacement events per subset is shown in Table 1.

When choosing the training input data, it is important to include a wide range of data which will be descriptive of the solution domain. In a different case the model will extrapolate returning probably poor results (Kazabof 1998).

We also calculate the statistical properties of the subsets, which is indicative of their same representative ability. A slight difference between the means of the subsets is eliminated after de-trending our data sets. Removing any existing trend or seasonality improves the effectiveness of the model (Nelson et al. 1999).

We utilize the horizontal component of the instantaneous velocity, assuming that it contains a high degree of information for discovering the dynamics of the phenomenon. Using time delays of this input variable, we construct a lagged in time input vector to predict future values of the dislodgment events:

$$D_{(t+\tau)} = f(U_{(t)}, U_{(t-1)}, \ldots, U_{(t-n+1)}) \quad (7)$$

were $D_{(t+\tau)}$ is the output variable which we want to predict τ steps ahead and $U_{(t-i)}$ is the i input vector representing the stream-wise velocity $i-1$ time steps before the time instant $t \cdot f$ is the transfer function of ANFIS model mapping a sequence of previous observation of inputs $U_{(t-i)}$ to outputs $D_{(t+\tau)}$. The accuracy of the model was found to strongly depend on the size of the time step. Thus a right selection of this variable will provide data sets with "richer information" and better predictability (Mencar 2005). A sensitivity analysis for the effect of the time lag on the reliability of the model was carried, and the results are shown in Figure 8.

Moreover, Abarbanel has proposed that working with a higher embedded dimension than the one of the studied system introduces noise contamination deteriorating the predictability of the forecast model. (Abarbanel et al. 1993). Therefore choosing the appropriate lag time is required so that the input vector will include only useful information. This forecast method is the same as the one implemented by a previously developed time-delay Artificial Neural Network (Valyrakis et al. 2006), which we use to compare the obtained results.

We observe that the optimum lag time for which our model performs relatively better, is at about 150 milliseconds. This is in agreement with the findings of Nelson (Nelson et al. 1995), who used a similar experimental setup and showed that the stream wise velocity measured about 0.1 sec before a sediment grain movement highly correlates with the measured sediment flux (Nelson et al. 1995).

3 RESULTS

3.1 *Performance indices*

To evaluate the overall performance of each of the developed models and be able to compare them, we adopt the accuracy criteria and error metrics which follow (Twomey & Smith 1996).

– Normalized mean squared error (NMSE):

$$NMSE = \frac{\sum_{i=1}^{N}(o_i - t_i)^2}{\sum_{i=1}^{N}(t_i - t_{mean})^2} \quad (8)$$

ANFIS1	2	36	50000	292.33	0.45	0.80	0.84	0.069	0.064
ANFIS2	2	24	200000	4237.14	0.48	0.80	0.78	0.073	0.067
ANFIS3	2	36	200000	5438.39	0.52	0.75	0.74	0.069	0.064
ANFIS4	3	63	200000	9539.40	0.53	0.71	0.71	0.056	0.057

where o_i, t_i are the computed and the observed (target) output the for each (i) of the N data points, while t_{mean} is the mean of the observed values.

– Root mean square error (RMSE):

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(o_i - t_i)^2}{N}} \quad (9)$$

– Correlation coefficient (CC):

$$CC = \frac{Cov(o_i, t_i)}{\rho_{o_i}\rho_{t_i}} \quad (10)$$

where ρ_{o_i}, ρ_{t_i} are the standard deviations of the model's output and the target respectively. Their covariance is (11)

$$Cov(o_i, t_i) = \sum_{i=1}^{N}\left[(o_i - o_{mean})(t_i - t_{mean})\right]/N \quad (11)$$

– Mean average error (MAE):

$$MAE = \frac{\sum_{i=1}^{N}(o_i - t_i)^2}{N} \quad (12)$$

All of the above performance indicators are dependent on the residuals (e) of the predicted minus the observed values ($e_{(i)} = o_{(i)} - t_{(i)}$). Generally the smaller the *MAE, NMSE* or *RMSE* metrics are the better the model's accuracy is, while high covariance values indicate the degree to which the predicted results coincide with the observed ones. *MAE* is also dependent on the size of data. This is the reason why for the same model but larger size of data sets (N) we may observe a smaller *MAE* (Table 2).

3.2 *ANFIS simulation results*

All of the simulations were carried out on a 3.20 GHz Pentium®4 processor with 1.25 GB of RAM, running under Microsoft Windows XP v.2002 SP2.

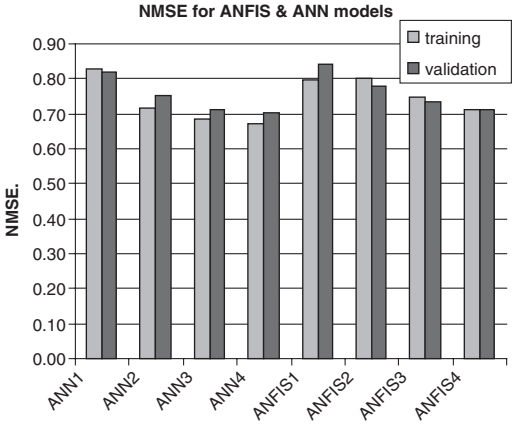

Figure 6. Minimum values of RMS errors for each ANN and ANFIS structure.

The computational code of both ANN and ANFIS was written in Matlab v.6.5, release 13.

We studied four architectures for the ANFIS model, with different size of shifted input vectors or number of membership functions per input variable, in order to assess the sensitivity of our model to that parameter (Table 2). A comparison between the first two models (ANFIS1 and 2) illustrates that the more data utilized the better the obtained accuracy. The same occurs for increasing complexity of the model's architecture as verified from the error indices (Figure 6). However if a certain level of complexity for a given size of data set, is exceeded, the model will not be able to generalize and will be over-trained, by memorizing the training subset. A result of this "over fitting" phenomenon is that the model performs awkwardly in unseen data (Twomey 1996). None of the studied models was over-trained according to Figure 6.

Due to the data size, as the complexity of structure increases, the computational time increases exponentially, with a relatively small improvement in accuracy (Table 2).

Copyright © 2006 Taylor & Francis Group plc, London, UK

Thus there exists a trade off between accuracy and computational effectiveness, which will eventually affect our choice for the optimum model.

The predicted versus the observed values are given for the model with the best performance (Figure 7). To evaluate the generalization ability of the chosen model, we plot the error curves for each of the aforementioned error metrics (Figure 8). The optimum time lag is the one which gives the minimum error for the validation set. Additionally we observe that the randomly initiated membership functions (Figure 9) significantly

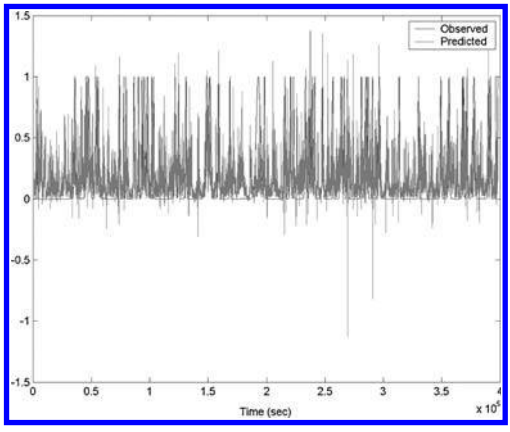

Figure 7. Predicted and observed displacement event values for the minimum validation error of the chosen ANFIS3 architecture (150 msec of time lag).

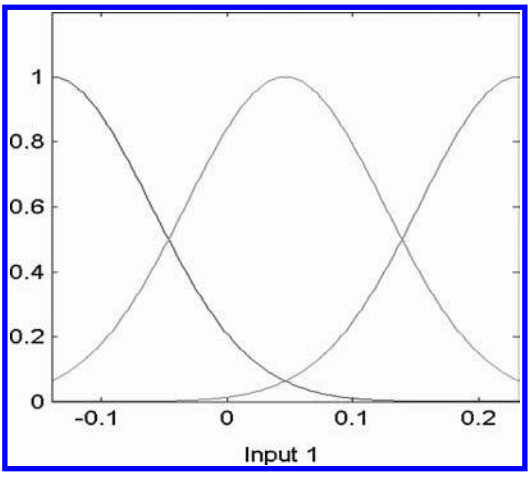

Figure 9. Initial membership functions (same for each of the lagged input vectors of local velocity U_i, in m/sec).

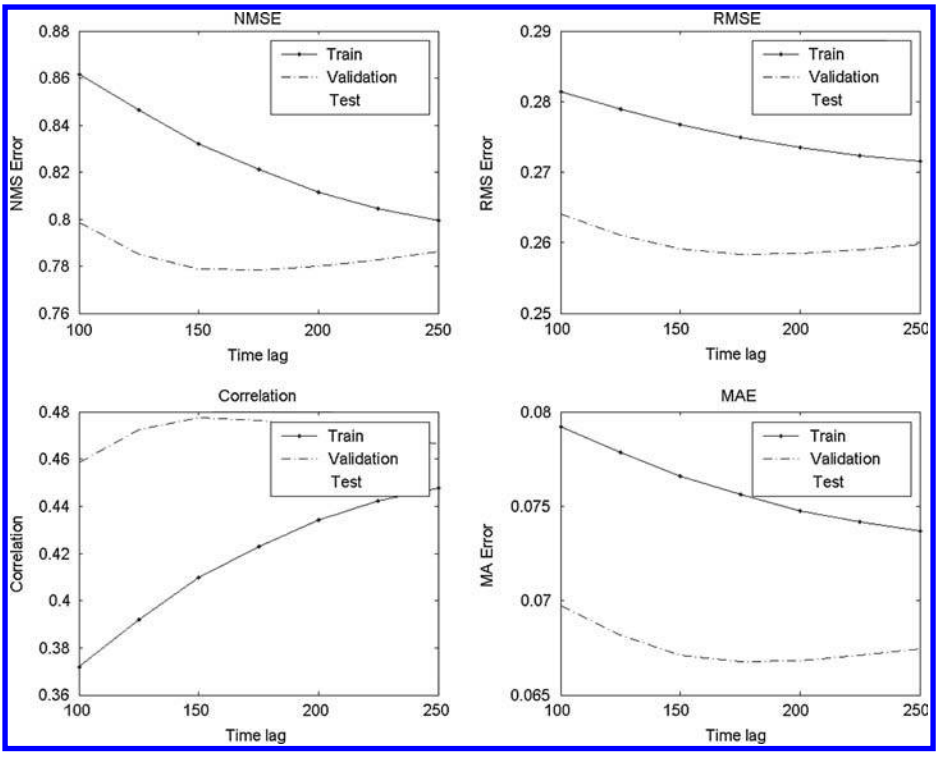

Figure 8. Performance evaluation of ANFIS3 (2 input vectors) for time lag values varying from 100 to 250 msec.

change in shape and position indicating the effect of the training process (Figure 10).

3.3 *ANFIS-ANN comparison*

To better understand the performance of the built ANFIS models, a comparison is made with ANN models with the same forecasting technique and data sets (Table 2). We observe that the ANFIS model is able to make a better prediction for the same size of input vectors. ANFIS models were trained for 50 epochs (Figure 11), while ANNs for 100 training cycles. Figure 11 suggests that training and validation errors do not improve over the training cycles, which means that computational time may be significantly reduced if the model is trained for fewer epochs without loss in accuracy.

However a compelling advantage of ANFIS as opposed to ANNs is that they are more transparent, enabling the derivation of input-output relations for every "If-Then" rule, as described in the model's architecture section. ANFIS can also incorporate expert knowledge in initiating the rule construction or complementing the training procedure, a procedure which may be easily embedded in a later model and might significantly improve its efficiency.

4 CONCLUSIONS

This study was conducted to illustrate the potential effectiveness of ANFIS with hybrid learning, for the prediction of initiation of particle movement.

The performance of ANFIS was evaluated using standard error measurements which revealed that a right choice of the embedded dimension is necessary for better predictability. The generalization ability and accuracy was assessed by checking the performance indices of the training and testing data subsets.

As data driven methods, their performance is highly depended on the architecture and the quality and quantity of the training data. Thus model performance might have been better if a more complex structure was employed. Furthermore, the relative scarcity of the observed output events (Table 1) may have deteriorated the situation. The performance was found to strongly depend on the way we constructed the output data (using a Gaussian function to resemble the particle's movement in time). Thus better performance may be attained if a more precise technique for obtaining the output is followed.

Moreover if we also utilize the vertical component of the instantaneous velocities we may acquire a better understanding of the system's dynamics.

The magnitude of time lag for which we observe the optimum results, is directly related to the mass of the sediment particle. In a different case the particle's dislodgment events would correlate well with local velocities, with a zero time lag.

Thus we should expect that the length of window in time or time history of velocities required for a certain level of prediction is analogous to the mass of the particle.

Observing the forecasted and output events we can say that the model is able to predict when the particle will move out of its pocket. However this is not always the case since we also observe events of lower magnitude which we may neglect if we set a threshold for when we should consider that the particle fully dislodged or just slightly moved. Using the same concept we could denote that the low level "noise" is due to small vibrations of the particle which however our visualization technique was not able to follow.

ANFIS method would work well in comparison to other averaging techniques since the density of entrainment events is well predicted. However it may be very expensive in computational time.

In general the model predicts a higher possibility of particle entrainment for a sequence of increasing velocities, which is also verified by plotting the phase portrait of the experimental time series just prior to a dislodgment event (Figure 12). This may be accessed if we also plot the piecewise linear relations provided by the model (Figure 13).

In those plots the inputs are mapped to a certain output which is weighted according to the activated rules to return the overall possibility of displacement.

A comparison with a feed-forward artificial neural network (FF-ANN) trained with back-propagation and the same data set, demonstrated that the combination of FIS and learning with NN provided a relative advantage, allowing for rules extraction which facilitates interpretation of the interconnecting relations between them. Although the study is still in an early stage the fusion of ANNs with fuzzy inference systems is quite promising in unveiling the nonlinear interaction of the salient variables which trigger the sediment entrainment in the near bed flow.

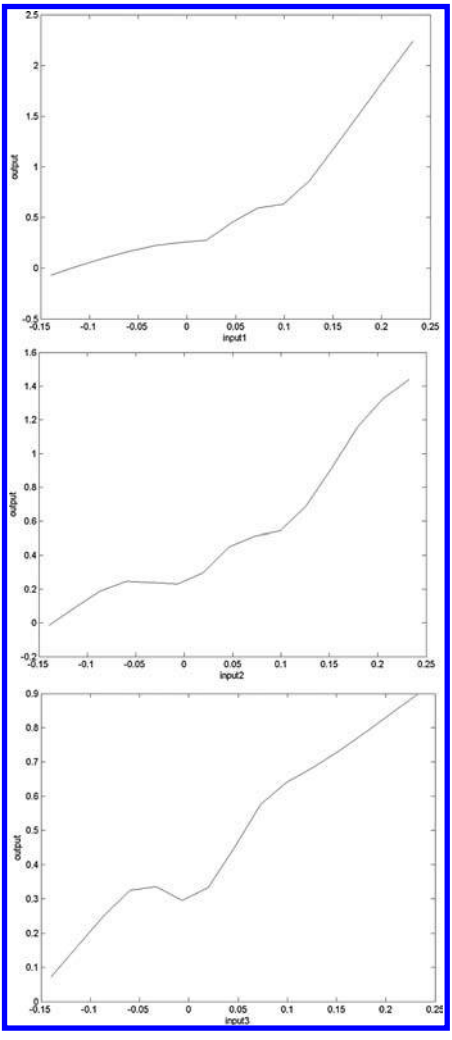

Figure 13. Piecewise linear Input-Output relations for ANFIS4.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In order to access more generic results and rules, we need a plethora of runs with different flow or particle properties, which will be pursued in a future study.

Experimental study of bed load on steep slopes

Philippe Frey, Matthieu Dufresne, Tobias Böhm & Magali Jodeau

Christophe Ancey
Ecole Polytechnique Fédérale de Lausanne, Ecublens, Lausanne, Switzerland

ABSTRACT: An important issue in the study of bed load transport in gravel-bed rivers is related to the physical mechanisms governing the bed resistance and particle motion. In order to better understand the physical processes ruling bed load solid transport at the grain scale, an experimental study of the motion of coarse spherical glass beads entrained by a turbulent and supercritical water flow down a steep channel with a mobile bed was set up. The initial width was 6.5 mm slightly larger than the particle diameter of 6 mm to create a two-dimensional particle flow allowing recording from the side all particles with a high speed camera. The overall aim of this research is to measure the trajectories of all particles and to analyze the fluctuations of the solid discharge as well as the state of movement, rolling or saltation. This paper is focussing on global hydrodynamic and equilibrium solid transport results. The channel inclination ranged from 7.5% to 15% and a doubled width of 12.7 mm was also studied. Data were corrected with the Einstein's method to account for side-wall effects. Non-dimensional solid discharge vs. Shields numbers results are in good agreement with classical incipient motion Shields numbers and compare favorably with two specific semi-empirical bed-load formulae. Those results show that upscaling of data obtained at the particle scale to the reach scale is possible despite the unusual hydraulic configuration of this narrow channel.

1 INTRODUCTION

Despite substantial progress made over the last two decades in the physical understanding of the motion of coarse particles in a turbulent stream, the ability to compute bulk quantities such as the sediment flux in rivers remains poor. For instance, the sediment flow rates measured in gravel-bed rivers differ within one to two orders of magnitude from the bed-load transport equations (Wilcock 2001; Martin 2003; Barry et al. 2004). In order to better understand the physical processes ruling bed-load solid transport at the grain scale, an experimental study of the motion of coarse spherical glass beads entrained by a turbulent and supercritical water flow down a steep channel with a mobile bed was set up. The initial width was 6.5 mm slightly larger than the particle diameter of 6 mm to create a two-dimensional particle flow allowing recording from the side all particles with a high speed camera. The overall aim of this research is to measure the trajectories of all particles and to analyze the fluctuations of the solid discharge as well as the state of movement (rolling or saltation). First the trajectory of a single saltating or rolling particle was analyzed (Ancey et al. 2002; Ancey et al. 2003). Secondly, the aim was to measure the trajectories of all particles and to analyze the fluctuations of the solid discharge as well as the state of movement, rolling or saltation (Boehm et al. 2004; Boehm 2005; Boehm et al. 2006). More recently a doubled width of 12.7 mm was also investigated. The objective of this paper is to present data focusing on global time-averaged hydrodynamic and bed load results. Results will first be discussed for each width taking account of wall effects. Non-dimensioned solid discharge vs. Shields numbers will be analyzed and compared with classical formulae.

2 EXPERIMENTAL FACILITIES AND TECHNIQUES

2.1 *Channel*

Experiments were carried out in a tilted, narrow, glass-sided channel, 2 m in length. Figure 1 shows a sketch of the experimental facility. The channel width W was initially adjusted to 6.5 mm, which was slightly larger than the particle diameter (6 mm). In this way, the particle motion was approximately two-dimensional and stayed in the focal plane of the camera. The channel slope $\tan\theta$ ranged from 7.5% to 15% (i.e., channel representative of steep gravel-bed rivers as

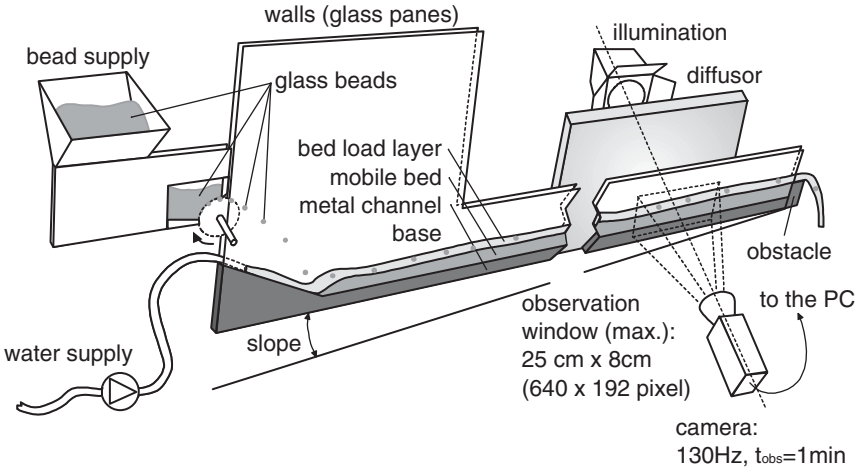

Figure 1. Sketch of the experimental setup.

Table 1. Flow characteristics and time-averaged values of dimensionless numbers characterizing bed load and water flow for width 6.5 mm. Varying parameters: Channel inclination $\tan\theta$ and solid discharge $\dot{n}$. The notation E7-6 indicates: $\tan\theta \approx 7\%$ and $\dot{n} \approx 6$ beads/s. Not all experiments made at $\tan\theta = 10\%$ are reported here, see (Boehm et al. 2004; Boehm 2005) for further information.

Experiment	E7-6	E7-8	E7-9	E10-16	E12-9	E12-16	E12-21	E15-16	E15-21

encountered in mountain areas). In order to test the influence of the channel slope on bed load, 15 experiments with different inclinations and various flow rates (see Table 1) were first set up. The channel base consisted of half-cylinders of equal size ($r = 3$ mm), but they were randomly arranged on different levels, from 0 to 5.5 mm, by increments of 0.5 mm. These levels were generated using a sequence of uniformly distributed random numbers. Disorder was essential as it prevented slipping of entire layers of particles on the upper bed surface, which would have induced artificial erosion conditions. Maintaining disorder in monosized spherical particles is difficult, with severe constraints (Bideau and Hansen 1993), here involving mainly how to create disorder in the packing and the bed thickness. For thick beds (typically, whose thickness exceeded 5–6 particle diameters), a regular, crystalline arrangement was observed along the upper part of the bed. This is expected since it is well-known that the disorder range induced by a defect in a crystalline arrangement of monosized spherical particles is a few particle diameters (Bideau and Hansen 1993). Therefore, in order to be able to control the order in the particle arrangement, we built beds whose thicknesses did not exceed 5 particle diameters. The effects of disorder on bed-load transport features have been presented in another paper (Boehm et al. 2004). An obstacle was set at the channel outlet to enable bed formation and prevent full bed erosion; its height could be adjusted.

More recently, 33 new experiments were performed with a width of 12.7 mm about two bead diameters

$2h/W$	2.2–4.1	1.5–2.2	1.4–1.8	1.6–1.7

(see Table 2). In that case, there is no more problems in creating disorder as there is an added widthwise degree of freedom. The first objective was to adapt the image analysis algorithms preparing for studying two-size mixtures. the second objective whose results are reported in this paper was to assess the influence of the width and wall effects of this unusually narrow channel.

2.2 *Solid and water supplies*

Black spherical glass beads with a nominal diameter d of 6 mm and a density ρ_p of 2500 kg/m^3 (provided by Sigmund Lindner GmbH, Germany) were used. They were injected from a reservoir into the channel using a wheel driven by a direct current motor and equipped with 20 hollows on the circumference, as depicted in figure 1. For the experiments presented here, the injection rate $\dot{n}$ ranged from 5 to 26 beads per second, with an uncertainty of less than 5%. This corresponded to a volumic solid discharge per unit width q_s of $7 - 38 \times 10^{-5}$ m^2/s. The water supply at the channel entrance was controlled by an electromagnetic flow meter provided by Krohne (France). The discharge per unit width q_w ranged from 3 to 15×10^{-3} m^2/s. The values for 6.5 mm wide runs (labelled E) are summarized in Table 1 and ranges of values for 12.7 mm wide runs (labelled F) appear in Table 2.

2.3 *Dimensionless numbers*

The hydraulic conditions can be specified using classic dimensionless numbers. In tables 1 and 2, h is the time-averaged flow depth. To make the particle rate $\dot{n}$ more palpable, we express it in beads/s instead of m^3/s. The flow Reynolds number is defined as $\mathrm{Re} = 4R_h\bar{u}_f/\nu$, where $R_h = Wh/(2h+W)$ denotes hydraulic radius, $\bar{u}_f = q_w/h$ fluid velocity (averaged in the y- and z-directions), ν kinematic viscosity of water. The Froude number $\mathrm{Fr} = \bar{u}_f/\sqrt{gh}$ (where g denotes gravity acceleration) varied significantly over the experiment duration and along the main stream direction. The mean Fr values are reported.

The Shields number is defined as the ratio of the bottom shear stress ($\tau_0 = \rho_p g R_h \tan\theta$) to the stress equivalent of the buoyant force of a particle lying on the bottom (Julien 1994): $\tau* = \tau_0/(gd(\rho_p - \rho_f))$. The solid concentration is defined as the ratio of the solid and the water discharge $C_s = q_s/q_w$. The ratio h/d is low, typically in the range 0.8–4. A few aspects of the free-surface line and the bed configuration are shown in the tabulated figure 2 for the experiments in the 6.5 mm wide channel. Figure 3 shows a typical image obtained in the 12.7 *mm* wide channel compared to an image at a width of 6.5 *mm* where trajectories of all beads are two-dimensional. Disorder induced by the doubled width appears quite obviously.

Note that the dimensionless number values differ substantially from the values usually found in the hydraulics literature. The reason is twofold: first we used a short and narrow channel, which led to studying low Reynolds number regimes, whereas in most experiments on bed load transport, one takes care to avoid such regimes; this is the price to pay to have access to the details of particle movements. Since we used coarse particles, particle motion was weakly dependent on the actual value of the flow Reynolds number and turbulence structure. Therefore we think that the small size of the experimental setup is not a handicap. Second we mostly studied supercritical flows because of the steep slopes investigated. However, in a supercritical regime, flow depth was low: on the order of the particle size, meaning that particle motion was affected by the water free surface.

2.4 *Experimental procedures*

The preliminary procedure can be split into three major steps. First of all, a particle bed was built along the

Copyright © 2006 Taylor & Francis Group plc, London, UK

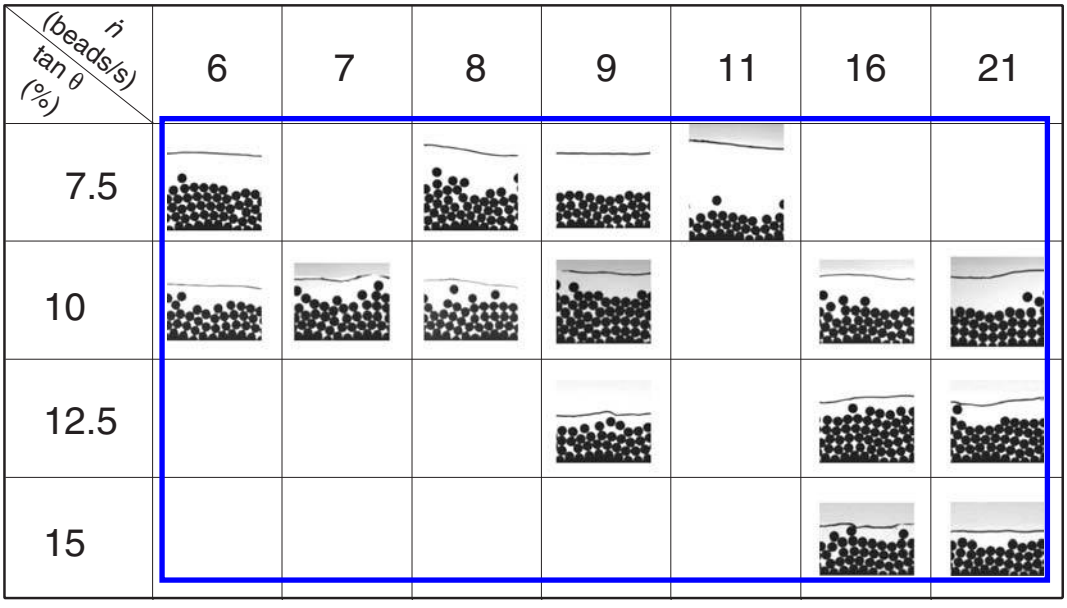

Figure 2. Overview of the experiments conducted for width 6.5 mm at various solid discharges $\dot{n}$ and slopes $\tan\theta$. For each experiment, a detail of one filmed image is shown. See Table 1 for the experimental conditions.

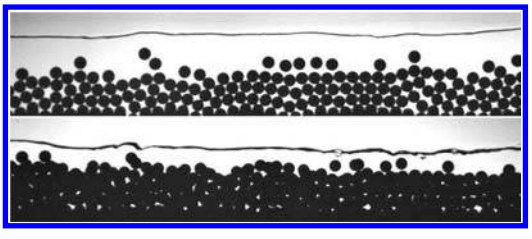

Figure 3. Typical images obtained respectively in the 6.5 *mm* (above) and 12.7 *mm* (below) wide channel.

channel base, which remained stationary on average. To that end, an equilibrium between the water discharge, solid discharge, bed elevation, and channel slope was sought. This equilibrium was reached by using the following procedure:

1. The water discharge q_w was set to a constant value.
2. An obstacle (approximately 20 mm in height) was positioned at the downstream end of the channel. The solid discharge $\dot{n}$ at the channel entrance was set to a constant value. The solid discharge per unit width q_s was calculated by the relation $q_s = \pi d^3 \dot{n}/(6W)$. The first beads supplied by the feeding system were stopped by the obstacle at the channel outlet and started to form a bed. The bed line rose to the level of the obstacle and beads began to leave the channel. After approximately 10 minutes, the system arrived at bed load equilibrium, i.e., there was no more bed deposition or erosion over a sufficiently long time interval.
3. In order to make the bed line parallel with the channel base, the water discharge was then adjusted. After several iterations, we arrived at the configuration of a bed that consisted of two to three almost stationary bead layers along the channel, for which the bed line slope matched the channel base inclination. Average equilibrium conditions were sustained over long time periods, basically as long as 30 minutes.

Once bed equilibrium was reached, the particles and the water stream were filmed using a Pulnix partial scan video camera (progressive scan TM-6705AN). The camera was placed perpendicular to the glass panes at a distance of 115 cm from the channel, approximately 80 cm upstream from the channel outlet. It was inclined at the same angle as the channel. Lights were positioned in the backside of the channel. An area of approximately 25 cm in length and 8 cm in height was filmed and later reduced to accelerate image processing.

The camera resolution was 640×192 pixels for a frame rate of $f = 129.2$ fps (exposure time: 0.2 ms, 256 gray levels). Each sequence was limited to 8000 images due to limited computer memory; this corresponded to an observation duration of approximately 1 minute.

Copyright © 2006 Taylor & Francis Group plc, London, UK

Each experiment was repeated at least twice in order to spot possible experimental problems and to get an idea of the data scattering.

2.5 *Image and data processing*

Images were analyzed using the WIMA software, provided by the *Traitement du Signal et Instrumentation* laboratory in Saint-Etienne (France). Positions of the bead mass centers were detected by means of an algorithm combining several image-processing operations. It compared the filmed images with the image of a model bead and calculated the correlation maxima to obtain the bead positions. Data obtained from the image sequences were analyzed to obtain the particle trajectories. For this purpose, we developed a particle-tracking algorithm. This algorithm compared the bead positions of two consecutive images to determine the trajectory of each bead step by step. Since the particle movement was nearly two-dimensional and the displacement of a particle between two images was always smaller than a particle diameter, the trajectories (approximately 700 per sequence) could be calculated with no significant error. The state of movement of a particle was also defined by considering that each bead was always either in a resting, rolling, or saltating regime (Boehm et al. 2006; Boehm 2005). In this paper image analysis was only used to measure the water depth. Since the experiments involved a mobile bed, the water depth was defined as the difference between the free surface and the bed surface elevation. The water free surface (averaged in the direction perpendicular to the channel walls) was detected using its slim form; missing portions were inter- or extrapolated. For the 6.5 mm width the bed surface profile was taken as the line linking the top points of the uppermost resting or rolling beads. For the width 12.7 mm, a different algorithm was used to derive the bed line combining derivative and morphological operators (Dufresne 2005).

3 RESULTS

3.1 *Analysis of uncorrected data*

A widespread way of representing bed load transport rates for different flow conditions is to plot the dimensionless solid discharge ϕ as a function of the Shields number $\tau*$. The solid discharge was made dimensionless by the definition

$$\phi = q_s/\sqrt{(\rho_p/\rho_f - 1)gd^3},$$

where q_s is the bed load transport rate per unit width, $q_s = \pi d^3 \dot{n}/6W$.

First, the Shields number $\tau*$ was calculated with the global hydraulic radius.

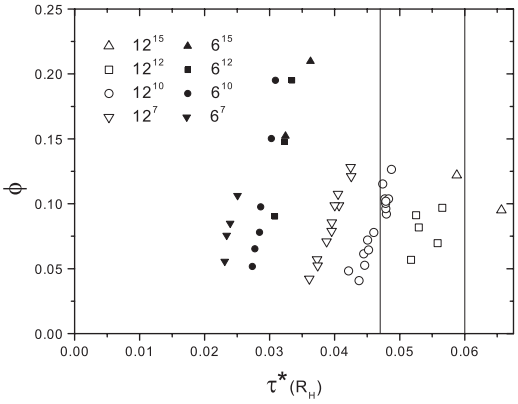

Figure 4. Relations between dimensionless solid discharges and uncorrected Shields numbers. Black lines correspond to incipient motion thresholds: $\tau* = 0.06$ or $\tau* = 0.047$.

Although the dimensionless solid discharge increases with the Shields number on figure 4, most of the values of Shields number are lower than widely accepted incipient motion thresholds ($\tau* = 0.06$ or $\tau* = 0.047$). Moreover experiments at width 6.5 mm and 12.7 mm are separated in two groups and it seems that data are scattered depending on the slope value. A closer look on data within tables shows that the lowest values of $\tau*$ are obtained for the highest values of the aspect ratio $2h/W$. This behavior is then clearly due to side-wall effects.

3.2 *Side-wall correction procedure*

The purpose of this section is to present the method used to calculate a bottom hydraulic radius. The method used is the well-known Einstein's method (Cao 1985).

This method is based on three hypotheses:

- three Darcy–Weisbach equations can be written:

$$\sqrt{\frac{8}{f}} = \frac{u_f}{\sqrt{gR_h sin\theta}} \quad (1)$$

$$\sqrt{\frac{8}{f_b}} = \frac{u_f}{\sqrt{gR_{h_b} sin\theta}} \quad (2)$$

$$\sqrt{\frac{8}{f_w}} = \frac{u_f}{\sqrt{gR_{h_w} sin\theta}} \quad (3)$$

- the energy slope is the same for each area,
- the flow velocity is the same for each area.

With theses hypotheses, we can write the following equations:

$$\frac{f}{R_h} = \frac{f_b}{R_{hb}} = \frac{f_w}{R_{hw}} \quad (4)$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

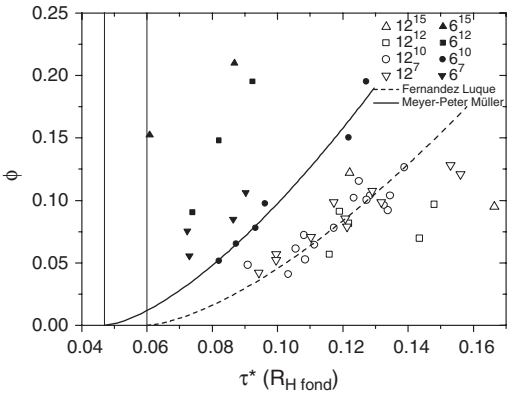

Figure 5. Relations between dimensionless solid discharges and Shields number calculated with the bottom hydraulic radius. Black lines correspond to incipient motion thresholds: $\tau* = 0.06$ or $\tau* = 0.047$.

$$\frac{Re}{f} = \frac{Re_b}{f_b} = \frac{Re_w}{f_w} \tag{5}$$

$$f_b = f + \frac{2h}{W}(f - f_w) \tag{6}$$

f_w is calculated with the following turbulent and smooth formula (Graf and Altinakar 1993):

$$\frac{1}{\sqrt{f_w}} = 2log(Re_w\sqrt{f_w}/4) + 0.32 \tag{7}$$

f_b is then calculated by using *eq.* 6 and knowing f and $2h/W$. R_{h_b} is calculated with the help of eq 4.

It must be stressed that the Einstein's method is usually applied to account for minor side-wall effects. In our case, the $2h/W$ ratio is always above 1 meaning that the water depth is always superior to the width. The side-wall effects are then important and it can be questioned whether the Einstein's method would be relevant in our case. Results are presented on figure 5. By comparing with figure 4, we can see that results are relevant with incipient motion thresholds because all points are above these levels. We notice too that the two groups of points (width 6.5 mm and width 12.7 mm) are nearer than on figure 4. Although more than a mild correction the Einstein's method proved in our case relatively efficient in so far as corrected data appear to agree with classical results.

In addition both the two widely used Meyer-Peter Müller (Meyer-Peter and Muller 1948) and Fernandez Luque semi-empirical formulae (Fernandez Luque and van Beek 1976) are plotted on figure 5. Note that these empirical formulas were established for slopes much lower than in our case, but this should not be a major issue since the physics should remain essentially the same.

Our data lie relatively near incipient motion as our maximum Shields Number is only about three times critical incipient motion Shields Numbers. Although it is well known that empirical formulae do not perform well near the threshold of motion, our data, most surprisingly, relatively agree with those formulae which again shows that the Einstein's method is relevant. A closer look to figure 5 reveals that data for the steepest slopes (12.5% and 15%) agree the least with the formulae. As already discussed, at the lower width, these data have the lowest h/d submergence ratio approaching 1 which means that the free surface acts as a physical barrier truncating the saltation trajectories and forcing most particles to move in the rolling regime. As the saltation of a single particle has been used as a theoretical basis to establish semiempirical bed-load formulae (Bagnold 1973; Wiberg and Smith 1985; Wiberg and Smith 1989; Bridge and Bennett 1992), it is not surprising that those formulae are not in good agreement with data presenting the lowest h/d ratios (Ancey et al. 2005).

4 CONCLUSIONS

In this paper, global time-averaged hydrodynamic and bed load results obtained on an idealized very narrow channel are presented. This channel was primarily designed for studying bed load from a physical viewpoint at the grain scale, the width of the channel being the same as the particle diameter. To analyze results from the fluid mechanics viewpoint and to study the wall effects, a double width was investigated. Nondimensional bed load solid discharges vs. uncorrected Shields numbers appeared quite scattered depending on width and slope but more precisely on the aspect ratio. The classical use of the Einstein's method to account for side-wall effects proved efficient although in our case hypotheses behind this method could be questionable. Corrected results were in good agreement with classical incipient motion Shields numbers and compared favorably with two specific semiempirical bed-load formulae. For steeper slopes with low submergence of the order of the particle diameter more deviation was observed probably because the assumptions underlying the classical bed load formulae do not hold any more.

The experimental set-up was designed to be as simple as possible to gain access to the trajectories of all particles for studying solid discharges fluctuations and motion regimes. In particular analysis of probability distribution functions are thought to help better modelling of bed-load especially near incipient motion. However the crucial question is whether upscaling from the grain scale to the reach scale would be possible with results obtained in this narrow channel. The global results presented in this paper are encouraging

Copyright © 2006 Taylor & Francis Group plc, London, UK

in that perspective. The use of the simple Einstein's correction to account for side-wall effects appears enough to yield results comparable to data obtained with classical large tilting flumes and natural materials. In short, our experimental set-up makes it possible to bridge the gap between the physics and the fluid mechanics approaches in bed load research.

Downstream fining of sediments in the Meuse River

R. Murillo-Muñoz
School of Civil Engineering, University of Costa Rica, San Jose, Costa Rica

Gerrit J. Klaassen
UNESCO-IHE Institute for Water Education, Delft, Netherlands

ABSTRACT: The available information on the river characteristics of the Meuse River in combination with the geological conditions are assessed and analyzed in an attempt to understand the occurrence of a transition from a gravel-bed to a sand-bed river. This transition is characterized by a reduction in D_{50} of the bed material from about 16 to about 2.6 mm whilst the bed slope changes from about 0.5 to 0.10 m/km. From the analysis it is concluded that neotectonic subsidence provides an adequate environment for deposition of coarser sediments triggering the selective transport of particles. The combined action of this selective transport and the abrasion of sediment particles result in an increase of the sand content on the bed material. After some distance a threshold point is reached where the sand content starts to govern the behavior of the sediment mixture; at this point the sand overwhelms the gravel and the river starts to behave as a sand-bed river; consequently the gravel-sand transition is formed.

1 INTRODUCTION

The Meuse River (Maas River) is the second largest river in The Netherlands and it has an international basin that spreads over four countries. It enters The Netherlands in Southern Limburg near Maastricht from where it flows to the North forming the border with Belgium in the reach known as the Common Meuse. In this reach major nature restoration projects are planned (Helmer et al, 1991; Klaassen et al, 1999), which has generated substantial interest in the morphological phenomena occurring in this gravel bed river.

Near the city of Roermond (Figure 1), the Meuse River shows a sharp transition from a gravel-bed to a sand-bed river. Over this transition the D_{50} of the bed material changes from about 16 to about 2.6 mm whilst the slope also decreases from about 0.5 to about 0.10 m/km. Several possible explanations can be proposed for this sudden change on the granulometric composition of the bed material. Most of them centre around three possible causes: abrasion, break down and selective transport. Authors like Holly & Rahuel (1990), Parker (1991a,b), Hoey & Ferguson (1994) among others have studied these phenomena and they reported that downstream fining of sediments is linked to aggradation. However, aggradation has not been observed in the Meuse River in the past; on the contrary, the riverbed seems to have degrade over the last century. This seeming contradiction might be explained by subsidence due to tectonics. Therefore, this contribution explores the role of abrasion, break down, selective transport and subsidence on the observed gravel-sand transition.

2 WATERSHED CHARACTERISTICS

2.1 *Hydrological conditions*

The Meuse River drains an area of about 33,000 km^2 distributed over France (30%), Belgium (40%), Netherlands (18%) and Germany (12%). Available hydrological data includes discharges and water levels from 1911 onwards. The basin response to precipitation is fast, chiefly due to the presence of large tributaries together with relative impervious subsoils in Belgium. On the long term, the yearly average discharge in the Meuse River at Borgharen is about 250 m^3/s. Discharge records go from less than 70 m^3/s in 1976 up to 3047 m^3/s in 1993, indicating that the river has a great variation in its flows.

2.2 *Geological setting*

The watershed of the Meuse covers several geological formations and therefore, it is a complex combination of morphotectonic units. The area of interest is localized in the Lower Rhine Embayment, a tectonic depression localized between the southern North Sea Basin, the uplifting areas of Ardennes and Rhenish Shield and the London-Brabant Massif. This depression is composed of several north-eastward tilted blocks which are determined by a set of faults with NW-SE orientation (Figure 2). These blocks have differential movements between them and Figure 3 shows a schematic representation of the vertical displacement rates of these blocks along the river course. From this figure, it is clear that the movements are not uniform and the Feldbiss fault separates the uplifting blocks from the subsiding blocks.

2.3 *Bed level and bed slope*

Bed levels along the Meuse have changed significantly in the upper part of the river. These changes are due to

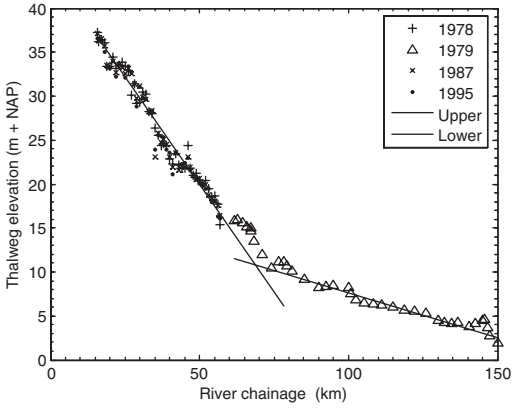

Figure 4. Trend of the thalweg elevation along the Meuse River.

the impressive degradation process that the river has suffered during the last century as a result of training works and subsurface mining. In the area near Maasband this has resulted in degradation of some 5 m while in others reaches the degradation is less severe but still considerable. On the contrary, minimum degradation has been observed in the lower parts of the river, with a number of reaches experiencing some aggradation.

Measured bed levels along the Meuse are shown in Figure 4. From these levels the slope of the river bed is estimated and the resulting lines represent the trend of the bed elevation. The trend of the data in the upper part of the river indicates a slope of 0.5 m/km whilst for the lower reach a value of 0.10 m/km is found. It is possible to observe also that the change in the slope occurs between km 60–80. However, a close inspection of the bed levels indicates that in period 1909–1916 the change in slope was more gradual with a sharper transition near the km 95, where probably the gravel-sand

Copyright © 2006 Taylor & Francis Group plc, London, UK

transition was formed (Murillo-Muñoz, 1998). This suggests that the current location of the transition in the bedslope is probably the results of the intensive degradation process induced by the human interference in the system.

2.4 *Sediment transport rates*

Regarding the sediment transport rates there is great variability of data reported in the literature. Waterloopkundig Laboratorium (1994) reports that the average sediment transport rate of the Meuse River is approximately 35×10^3 m^3/y; but at Linne it is reported to be about 26×10^3 m^3/y, while 19×10^3 m^3/y at Kessel and 70×10^3 m^3/y at Ravenstein are mentioned for the more downstream reach (Gerretsen, 1968).

Furthermore, it has been observed in the Meuse River that the transported sediment load depends on whether or not the armour layer has been mobilized during a previous flood. Klaassen (1986) indicated that if the armour layer remains stable when the smaller floods are passing little sediment is transported. Once the armour layer is mobilized the substratum material is available and the sediment load increases rapidly. This phenomenon has been estimated to occur at discharges higher than 1250 m^3/s (Klaassen, 1981), which coincide with the present estimated bank-full discharge. During the receding part of the flood the armour layer is built up once again but at a lower level, and on top of the eroded layer sediments are deposited. These deposited (and often finer) sediments are available for transport and therefore after a flood period this material can be transported at smaller discharges until the armour layer is exposed again. Hence, the composition of the armour layer and the sediment transport is a function of the magnitude of previous floods (Duizendstra, 1999). A high flood will give a finer armour layer and more eroded sediment on top of the restored armour layer after the flood (Klaassen, 1986).

2.5 *Human interference*

Human impact on the Meuse River is extensive and it includes changes in land use, water withdrawal for irrigation and human consumption, mining, hydropower production as well as extensive river training works for navigation and flood control. At the same time, the sediment supply to the downstream river reaches has been reduced considerable to the extent that the river hardly transports any bed material load across the border; however, the wash load content of the river has increased substantially (Micha & Brolee, 1989). In fact, due to the reduced upstream sediment supply and the degradation of the river over the last century the armouring of the river might have increased. For this, however, no evidence is available. It can be stated that the overall effect of human interference has resulted in the Meuse River being an incised river which only floods occasionally its floodplain. Furthermore, the morphological processes in the Meuse River are extremely slow (de Vries, 1975). The very long morphological time scale implies that the Meuse River responds very slowly to changes and should not be considered to be "in equilibrium". Even without further human interference, for a long period to come the river will continue to adjust to changes in the past.

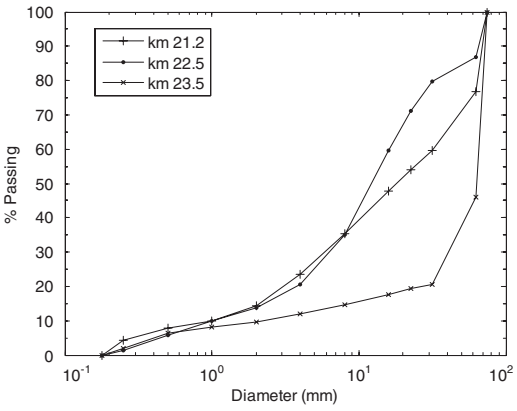

Figure 5. Spatial variation of the bed material in the Meuse River.

3 ANALYSIS OF THE BED MATERIAL CHARACTERISTICS

The Meuse is a gravel-bed river and therefore it is not easy to characterize it by the few statistical parameters often used for other rivers, notably median diameter, standard deviation and D_{50}. Spatial and temporal variation of the deposited sediments is important. In dry periods, the Meuse presents an armour layer while during floods this layer becomes unstable and the underlying material is mobilized. Thus, depending when and where the samples are taken and the frequency of the sampling, the characterization could lead to substantially different results. As an example of such variations, Figure 5 presents the variability of the bed material composition in longitudinal direction. In addition, reworking of the bed material due to training works is extensive making it even more difficult to characterize the bed material by means of a few statistical parameters. The reader should be aware of this large variability.

3.1 *Characteristic parameters*

The variation of the D_{50} in the bed material and its geometric standard deviation are shown in Figures 6 and 7, respectively. It can be observed that until the km 90 the D_{50} approximately is mainly in the coarse gravel range, with an average value of 16 mm shown

Copyright © 2006 Taylor & Francis Group plc, London, UK

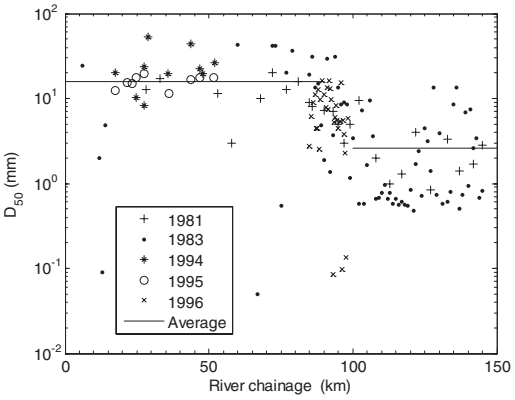

Figure 6. Variation of the D_{50} in the bed material along the Meuse River.

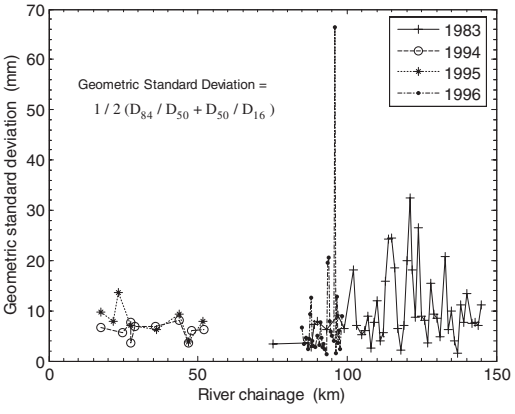

Figure 7. Geometric standard deviation of the bed material samples in the Meuse River.

as a straight line in Figure 6. There are a few points in this reach which are in the medium sand range but they may be due to problems related to the sampling. Furthermore, the Meuse is characterized by armour layers in its upper reaches. This may be linked to the fact that sediment supply is insufficient and that the river is degrading but it can also be explained as a normal phenomena for a gravel-bed river. From about km 105 onwards, the D_{50} is significant smaller and the average value is about 2.6 mm. In this zone, there is a lot of scatter in the data and this is reflected by higher values in the geometric standard deviation (Figure 7), probably produced by sediment bimodality in combination with lateral sorting. Between km 90 and 105 approximately, a gradual transition in the values of D_{50} is observed. An important point is the large values of the geometric standard deviation, especially from km 90 onwards. This implies that the correct collection of samples is particularly important in this reach. It also

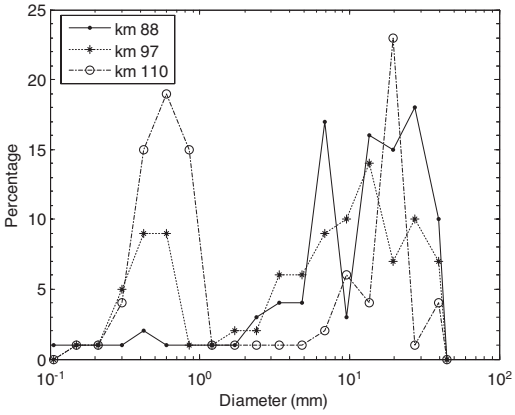

Figure 8. Development of the bimodal composition in the bed material.

indicates the necessity of more samples, which might not reduce the variability but it would improve the estimate of the average value. It may very well be that the large variation is caused by physical phenomena and is inherent to this type of mixed gravel-sand bed river.

3.2 *Bimodal composition of the bed material*

One of the characteristics observed in many transitions from gravel to sand-bed rivers is the development of a bimodal composition of the bed material. The Meuse is no exception; Figure 8 shows the grain size distribution at three locations, the development of a gap in the range of 1–5 mm is clearly observed. The gap in size material has been related to the break down of gravel particles into sand (Yatsu, 1955; Sambrook Smith & Ferguson, 1995).

3.3 *Median diameter*

A bimodal composition of the bed material makes the D_{50} a sensitive parameter in the characterization of the sediments. Especially if the D_{50} is within the flat zone of the granulometric curve (1–5 mm approximately). In such a case of bimodal composition, the median diameter (D_m) is more representative for the bed material. Figure 9 shows the available D_m values. This picture is less complete than Figure 6 but appears to be more consistent. Furthermore, the relation between D_{50} and D_m for the all data ensembles yields a ratio of $D_m/D_{50} = 1.52 \pm 0.42$ mm.

3.4 *Gravel-sand content of the sediments*

The gravel-sand content of the sediments is another way to represent the spatial variation of the sediments. Figure 10 gives the percentage of gravel ($D_j \geq 2$ mm) content along the Meuse River. In this

Copyright © 2006 Taylor & Francis Group plc, London, UK

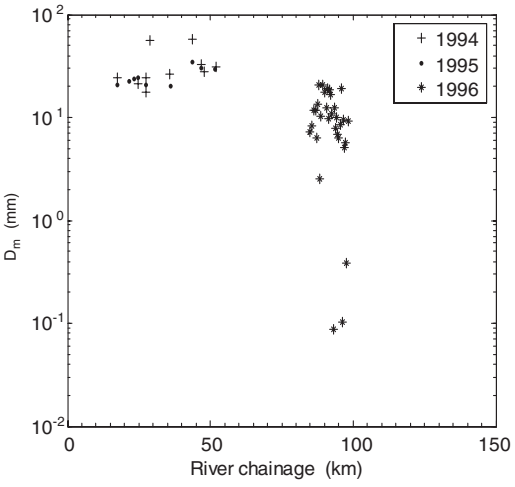

Figure 9. Median diameter of the bed material.

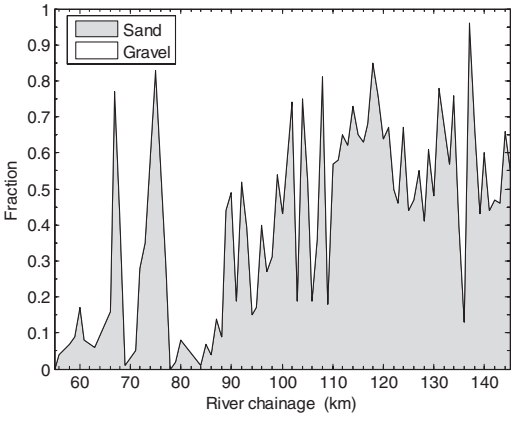

Figure 10. Gravel and sand content along the Meuse River.

figure is possible to notice that the average sand content exceeds the 50% around km 100 approximately, which is also the reach where the gravel-sand transition occurs. Inspection of the spatial variation in D_{16}, D_{50} and D_{84} confirmed such location (Murillo-Muñoz, 1998). In Figure 10, two peaks in the sand content are observed, notably around km 67 and 75. These peaks may be produced by the barrages of Linne and Roermond respectively, which induce sedimentation of sand during low flow conditions.

4 QUALITATIVE ASSESSMENT OF THE DOWNSTREAM FINING

Along the river course the Meuse sediments are subjected to different factors that contribute to the overall fining in downstream direction. These factors are: abrasion, break down of particles, subsidence, and selective transport. In principle also other factors can be considered (like the presence of ancient Rhine deposits and the input of finer sediments from a minor tributary of the Meuse River, notably the Roer River) but in Murillo-Muñoz (1998) it was shown that these have a negligible effect and hence they are not discussed here.

4.1 *Abrasion process*

The abrasion process causes a slow reduction in the particle size and produces mainly sands and silts, thus the sand content and the wash load increase while the total bed load decreases. The rate of reduction depends on the rock type. Van Straaten (1946) provides a general classification of the rock fragments present in the South Limburg area. Van Straaten classified the rocks into four groups and sized them into six fractions. From this work it is possible to infer that the dominant rock group in the gravel fraction corresponds to common sandstones like arkose, quartzite and phyllite; follow by rock fragments containing quartz like gneiss.

Furthermore, Edelman & Van Baren (1935) reported on the mineralogical composition of the Meuse deposits. A re-examination of their findings suggests that the gravel and coarse sand deposits present in the whole area are likely to come from fragments of metamorphic rocks and to a lesser extent from igneous rocks. The metamorphic rock fragments present in the deposits probably come from gneiss and schist. From the above mentioned rocks, the two weaker ones are phyllite and schist; which have similar internal structure and therefore comparable resistance to weathering.

To assess the relevance of abrasion, not only the rock type should be selected but also the particle's velocity should be assessed. Rijkswaterstaat has filmed the movement of the bed-load particles using a video camera attached to a Helley-Smith sampler (Duizenstra et al, 1994). From these movies, it was possible to observe that particles do not move for quite some time but when they move velocities reaching about 1 m/s can occur. If this velocity is considered, the loss of weight over the 15 km of the transition is about 5% using the abrasion rates reported by Abbott & Peterson (1978). This corresponds to a change in particle diameter from 16 to 15.7 mm approximately. Furthermore, if the particle velocity would be as low as 3 cm/s the loss of weight would be about 15%, which corresponds to a reduction of only 0.8 mm in particle diameter. Hence, abrasion per se does not explain the formation of the gravel-sand transition in the Meuse River though it would contribute to the production of sand. Here it is assumed that abrasion occurs only when the particle is moving. However, a particle at rest suffers abrasion by

Copyright © 2006 Taylor & Francis Group plc, London, UK

the blows of other particles, by sandblasting and even by chemical attack. These mechanisms are difficult to incorporate into the available methodologies.

4.2 *Break down of particles*

Break down refers to the breaking of a particle into two or more parts of roughly equal size. It produces a discontinuity in the grain size of the bed-load material but it does not affect the total load. It occurs when the particles reach a certain cut-off diameter and this happens along the river course rather than at certain locations (Parker & Cui, 1998).

The break down of particles mainly depends on the lithology of sediments. In the case of the Meuse River likely sediments are quartzite, sandstone and phyllite. Quartzite has an internal structure, which is compact, with no defined structural planes of weakness and therefore break down is unlikely to occur as principal mechanism of the abrasion process although it will produce big quantities of sand. On the other hand, sandstone particles may have planes of weakness depending on the environment of deposition and the degree of cementing between the grains; thus sandstone might suffer break down. Finally, the elements of phyllite are grouped in plates (or in laminar layer) and therefore the phyllite is more likely to break down and produce fine gravel and sand. However, there are no sufficient field evidences to reject or to accept the break down as an important process in the case of the Meuse River. There is still the evidence of the bimodal composition of the bed material, with a gap in the range of 1–5 mm. Yatsu (1955), Moss (1972) as well as Sambrook Smith & Ferguson (1995) indicate that particles in this range show tendency to break down into smaller sizes. Nevertheless, field surveys are needed to further study the importance of break down in the Meuse River.

4.3 *Tectonic movement, simplified approach*

In the past, the Meuse was a free system. The river meandered within its floodplains and the location of the main channel shifted slowly over time. Thus, if sedimentation of coarse grains occurred only at the main channel the location of the deposited sediments was governed by the meandering process. This process is time dependant and if long-term average conditions are sought, the total deposition width over which sedimentation occurred should be considered, i.e., all locations where the main channel was during a whole meander cycle.

Considering the above, an initial assessment of the relevance of tectonic movements can be made using the sediment mass balance equation expressed in finite differences as (see Figure 11)

$$B\Delta Z\Delta x = -\left(S_d - S_u\right)\Delta t \qquad (1)$$

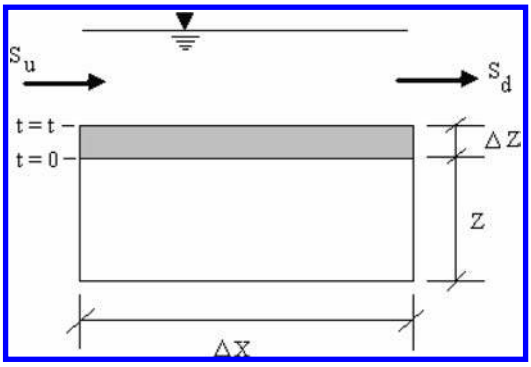

Figure 11. Definition sketch for the sediment mass balance.

where B is the total deposition width, ΔZ the uniform thickness of the deposition layer, Δx the reach length and S the total sediment transport; sub-index u and d refers to upstream and downstream.

Equation 1 does not include the effects of longitudinal sorting. If subsidence is taking place in the reach under consideration it is possible to assume that ΔZ is uniform and equal to the subsidence magnitude over a certain period of time. Hence, the bed level would remain stable and Equation 1 can be written in the following way:

$$S_d = S_u - B\Delta x\frac{\Delta\Gamma}{\Delta t} \qquad (2)$$

where the term $\Delta Z/\Delta t$ was substituted by the subsidence rate $\Delta\Gamma/\Delta t$ in the area. The second term on the right side of Equation 2 represents the volume of material V that is deposited in the reach during the time interval Δt. This volume depends on the length of the subsidence reach, on the rate of subsidence and on the assumed deposition width. Moreover, under the above mentioned assumptions, Equation 2 shows that the sediment transport within the reach of interest depends on the incoming sediment, the deposition width, and the subsidence rate.

If the volume V represents the amount of material deposited on the subsiding reach, and this volume is removed from the coarser fractions of the sediment load entering the reach, the remaining grain size distribution would give an indication of the effects that subsidence has on the sediment composition. Figure 12 presents the results of applying such an idea on an average granulometric curve. Figure 12 shows a fair agreement in the fine part of the curves at km 110. It is also possible to observe that at this location, the bed material already has a bimodal composition with a gap between 1–5 mm. The coarse part of the bimodal composition is not correctly reproduced by this simplified approach, probably because particle break down is not considered and there may be some deposition

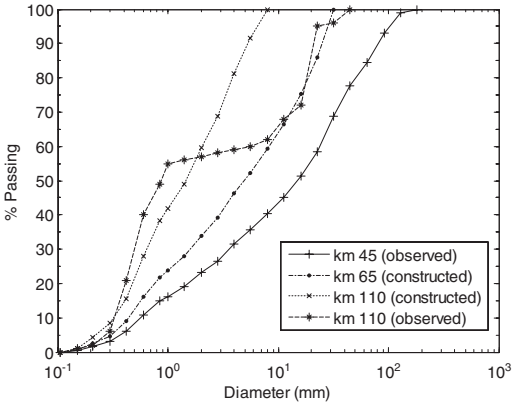

Figure 12. Granulometric composition of the bed material at different locations, B = 750 m, S = 35×10^3 m^3/y (incoming sediment load).

of the finer fractions. In using the above methodology two differential rates of subsidence were considered, the first one between Feldbiss and Stevensweert faults (see Figure 3) at an average rate of 0.6 mm/y and the second one between Stevensweert and Tegelen faults at 0.3 mm/y.

In addition, several combinations of deposition width ($100 \leq B \leq 2500$ m), upstream sediment supply ($15 \leq S \leq 75 \times 10^3$ m^3/y) and granulometric curves were analyzed. The results of this sensitivity analysis indicate that the deposition width should be between 500–750 m in order to properly estimate the observed $D_{50} = 2.6$ mm of lower Meuse reaches. In addition, these results suggest that the agraddation process which accompanies the downstream fining can be effectively counteracted by a similar subsidence rate preserving always the bed elevation and the reduction in size of the bed material. The reduction in size depends on the incoming sediment load and the deposition width, the latter parameter being the more important one.

5 NUMERICAL SIMULATION

In the previous section an individual assessment of the different potential causes was given. The present section presents an assessment in which the processes of abrasion, break down, subsidence and selective transport are combined via a numerical model. The selected model is Acronym5 which was developed by Cui & Parker (1998). This is a 1-dimensional steady state model that computes the long-term profiles by applying on the gravel reach the selective transport approach of Parker (1990) on the full grain size distribution. On the sandy reach only one diameter represents the sediment and the Engelund-Hansen expression is used to predict the sediment load. Acronym5 allows for three types of gravel-sand transition: 1) the gravel can run out; 2) all the gravel can reach the cut-off size and break into sand or 3) the sand can overwhelm the gravel. This last type of transition occurs when the capacity condition for sand transport is reached before the gravel transport has drop to zero, and thus, leaves a residual load of gravel in the sand-bed reach that is typically a very small fraction of the sand load. Further details on the model can be found in Sinha & Parker (1996), Parker & Cui (1998) as well as in Cui & Parker (1998).

5.1 *Model schematization*

Since Acronym5 does not simulate differential vertical movements, only the subsidence area of the Roer Graben Rift system is taken into consideration, i.e. only from km 45 onwards subsidence is modeled. The discharge considered during the simulations is the bankfull discharge, which is approximately 1250 m^3/s and occurs about 1% of the time. The sediment load entering at km 45 is estimated from Wilbers (1996) and corresponds to about 36×10^3 m^3/y. This amount was divided into gravel (80%) and sand (20%) according to the percentage found in Wilkens & Lambeek (1997). The grain size distribution of the gravel load is assumed to be equal to the surface layer distribution at Koeweide (km 46.9) as reported by Van Manen et al. (1994).

The subsidence rate considered is the average between km 45 and 102.5; this average value is 0.5 mm/y. Similarly, an average abrasion coefficient of 2×10^{-5} m^{-1} is used. Moreover, the sinuosity of the Meuse is set at 1.46 and the main channel width at 100 m. For the deposition width a value of 650 m is employed. The grain size cut-off is estimated in 4.8 mm whilst bed porosity at 0.4. Finally, due to limitation of the model the sand diameter in the sandy reach is set at 2 mm instead of the better estimate of 2.6 mm.

5.2 *Results of the simulation*

Results of the application of the model are presented in Figure 13. In this simulation the gravel-sand transition occurs at km 98, which is nearly the middle of the defined transition zone (km 90–105). In this simulation the D_m obtained by the model fairly agrees with the behaviour of the field and average values. The gravel-sand transition occurs because the gravel load drops to almost zero allowing the sand to "overwhelm" the remaining gravel particles.

Important is the fact that the field values shown in Figure 13 are obtained by the relation $D_m = 1.52\, D_{50}$ previously mentioned. Remarkable is the gradual variation of the D_m in the gravel reach due to abrasion. The D_m in the sandy reach is equal to 2 mm due to limitations of the program.

Copyright © 2006 Taylor & Francis Group plc, London, UK

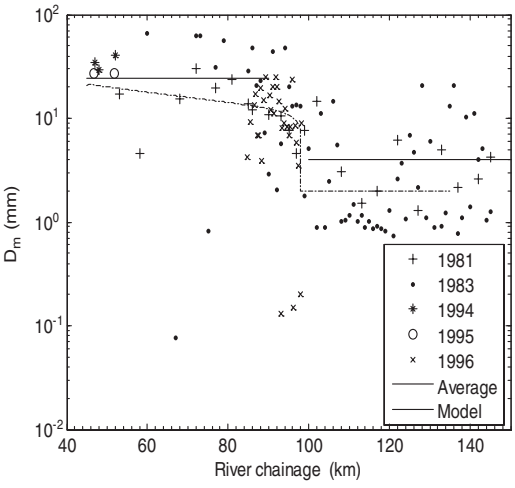

Figure 13. Variation of the median diameter on the Meuse River according to the simulation.

5.3 *Sensitivity analysis*

A sensitivity analysis of the findings indicates that an increment on the subsidence rate moves the location of the transition in upstream while the D_m increases moderately. Conversely, when the subsidence rate is lower the transition moves in downstream direction, but the rate of change in location and in D_m is higher than in the case of higher subsidence rate. In the case of pure abrasion (no subsidence) there is no gravel-sand transition in the area of interest. This case also demonstrates the effect of abrasion in the reduction of the grain diameter. Over 100 km the D_m reduces from 20 to 7 mm, which corresponds to a reduction in volume of 90%, only 10% of the volume remains.

Moreover, changes in the sediment load produce only slight variations on the location of the gravel-sand transition, suggesting that the location is not sensitive to changes in total value of sediment load. On the other hand, the deposition width affects the location of the transition; a reduction of the width moves the location in downstream direction. The deposition width has only a slight effect in the reduction of the grain diameter.

Regarding the abrasion coefficient, a reduction of its value shifts the transition in downstream direction. In the case of pure abrasion (no subsidence), all the available sand is deposited in between gravel grains and there is no sand left at the transition point and therefore, it cannot form. This confirms that although abrasion does not explain completely the presence of the transition, it plays an important role. It provides sand to fill the voids between the gravel particles and thus allows the formation of a transition.

Finally, in all the cases with the exception of pure abrasion and pure subsidence, the transition is formed because the gravel load drops to almost zero allowing the sand to overwhelm the remaining gravel particles. Moreover, the cut-off diameter for break down is not reached in any of the simulations. Thus, according to the simulations break down does not occur in the Meuse River.

5.4 *Effect of river training in the 19th century*

The results previously presented are obtained using a deposition width of 650 m, which was probably the situation when the Meuse River was a free meandering system. However, during the last two centuries the river has been trained and currently the planform of the river is fixed. This makes the deposition width similar to the main channel width, which is 100 m approximately. Simulations using this value suggest that the gravel-sand transition in the Meuse River is probably moving in downstream direction due the reduction of the deposition width. This movement is probably taking place very slowly and because of many human interference in the river and the spatial and temporal variation of the bed material data is difficult to detect in the field.

6 DISCUSSION OF RESULTS

The analysis of the field data reveals that there is an appreciable variability of the bed material characteristics in space and time. The variability in space is amongst others caused by armouring and by lateral and longitudinal sorting. Probably the latter variation occurs at the length scale of bends. Variability in time has two main causes. The passage of floods, which causes instability of the armour layer, generates much sediment and affects the armour layer composition. The second cause is the delayed response of the river system to human interference. This reflects that the river cannot be considered to be in "equilibrium condition"; most probably this condition of non-equilibrium is the result of the many training works, dredging and other human interferences with the Meuse river system since the 19th century. In addition, there might be also changes in lithology that introduce additional difficulties to the bed material characterization. Therefore, to characterize the Meuse River by means of simple statistical parameters is probably too much a schematization and might not represent the real conditions of the river.

The variability of the bed material has implications on the data collection. Specifically, the use of bucket sampling is not advisable since special care should be taken to differentiate between the armour layer and the substratum material. Similarly, separate description of

Copyright © 2006 Taylor & Francis Group plc, London, UK

the banks and channel should be done. Furthermore additional bed material samples are needed, especially in the ranges 50–88 km and 100–150 km. Additionally, the presence of armour layers along the Meuse also requires that field measurements of sediment load should be done not only during flood conditions but also before and after such an event. In particular, after a large flood, substantial quantities of sediments are still transported at lower discharges.

Nevertheless, the changes in the average value of the bed material and the bed slope show that a fairly sudden transition is present. Furthermore, the development in downstream direction of a bimodal bed material composition was confirmed. This bimodal composition is especially appreciable in the gravel-sand transition (km 90–105) and it is likely produced by the break down of particles. The results suggest that the diameter at which the particles are breaking is about 5 mm; this diameter though depends on the lithology of the bed material. Further studies into this aspect are appropriate.

Looking at the abrasion process, the principal rock in the Meuse River deposits is likely to be sandstone. Solely, abrasion does not explain the sudden transition to a sand-bed river; however, the sand content increases in downstream direction due to abrasion and as suggested by the simulations, this increase is important in the development of the transition. On the other hand, break down of particles is probably the dominant process in the development of the bimodal composition of the bed material, but field data should be collected in order to verify this hypothesis.

The vertical tectonic movements (uplift and subsidence) within the basin play an important role in the long-term morphological behavior of the Meuse River. The uplift process in the South Limburg block is likely to encourage an incision of the river bed. Probably the current Meuse terraces are the product of this incision. Conversely, the subsidence in the Roer Graben imposes changes in the river slope and thus, it provides a depositional environment in which the coarser particles can deposit due to selective transport. If deposition and subsidence rates were in equilibrium, the bed level would not change in time but downstream fining would still occur.

In the Meuse River the gravel-sand transition occurs between km 90–105; in this reach the gravel and sand contents are about 50% each. This sand content in the studied case is reached by the selective transport triggered by the subsidence within the Roer Graben as well as the abrasion process. Hence, the gravel-sand transition in the Meuse River is the result of the combined action of selective transport (induced by subsidence) and the abrasion of particles.

However, the transition of the bed slope takes place between km 60–80 and not in the vicinity of the change in D_{50} as expected. If only the surveys of the beginning of the 20th century are considered, the change in slope used to be located near the transition of the grain size. The present location of the bed slope transition is probably the results of the many human interferences that have taken place since the middle of the 19th century.

The width over which deposition is taking place in the subsiding reach was shown to be an important factor in the overall process of the downstream fining. However, its consideration depends on the time scale of the problem; in the case of long-term profiles the deposition width should be considered as the width over which the river has been meandering. This width depends on factors like floods, bank erosion rates and soil type among others. The simplified approach and the numerical simulations suggest that in the case of the Meuse River the representative deposition width is about 650 m. Probably though a more complicate picture should be drawn. During the meandering process the channel is mostly present in a narrow band around the valley axis. Occasionally the meandering extends farther away from this axis. This implies that in the floodplain areas away from the axis conditions are different. There finer material is also stored, and hence these far-away reaches contribute less to the preferential settling of the coarser sediments. The value of 650 m should therefore be considered as the result of a weighting procedure of probability of occurrence of a channel and the effectivity of the selective transport.

The results using a deposition width of 100 m indicate that due to fixation of the planform the gravel-sand transition would shift in downstream direction. This shifting in position could be the explanation of why the field data suggest that the gravel-sand transition is between km 90–105. Perhaps in the past, the transition was arrested near km 90 but since the Meuse River has been trained and its planform fixed, the transition may have moved slowly towards a more downstream location, which could be at this moment, near km 105. This dynamic process is likely to be happening now as well and it might explain some of the scatter in the data. Unfortunately at the present moment, there is no morphological time scale to predict how long the shifting process would take.

Given these results, it is important that abrasion, differential vertical movements and the actual deposition width are incorporated into a potential mathematical model of the Meuse River. This model should not use parameters that are sensitive to the bimodal composition of the bed material. Furthermore, it should be able to distinguish whether the armour layer has been mobilized or not. Finally, it should be realized that a complete numerical model of the Meuse River will never be possible. Too many uncertainties and limitations of the available data as well as the fact that the Meuse is never in "equilibrium condition" preclude this. It seems preferable to concentrate on a model that predicts the present conditions at an acceptable level.

7 CONCLUSIONS

The Meuse River can be characterized as a gravel-bed river upstream of km 90 and as a sand-bed river downstream of km 105. Thus, a gravel-sand transition occurs between km 90–105 where the D_{50} of the bed material changes from about 16 to 2.6 mm. There is also a pronounced and fairly sharp transition in the bed slope. This slope changes from about 0.5 m/km to about 0.10 m/km around km 70.

The gravel-sand transition takes place fairly smoothly as a result of the abrasion process and the action of selective transport triggered by tectonic subsidence. These two mechanisms allow the sand content to increase in downstream direction until the point that it overwhelms the gravel fraction. This phenomenon is well simulated by Acronym5, allowing a better assessment of the relevant processes.

The assumed deposition width plays a major role in the assessment. There is however only limited understanding of this concept as used in this contribution. This deposition width is much larger than the channel width, and although some support is available for this assumption, more studies are needed to clarify the concept and to make a good choice of it based on the meandering characteristics of the river and the lateral sorting on point bars.

In addition, there is a large variability both in space and probably in time of the particle distribution of the bed material in the Meuse River. This variability is linked to the physical processes in the river. Also the transient phenomena induced by human interference in the system since the 19th century might be important on this respect. It is clear however, that the Meuse River shows the development of a bimodal grain size distribution with a gap between diameters of 1–5 mm. Nevertheless there is still not sufficient data and insight to fully characterize the bed material of the Meuse River. More studies may shed additional light on this aspect.

Finally, sediment transport processes in the Meuse River are quite complicated and difficult to understand because of (1) the occurrence of an armour layer in the Common Meuse; (2) the poorly understood effect of floods on the armour layer; (3) the occurrence of the gravel-sand transition; (4) the effects of human interference which has induced transient phenomena and (5) the limited availability of field data on bed material and sediment transport.

Cohesive sediment removal from a fixed bed

R. Della Morte
Faculty of Engineering, University of Naples, Naples, Italy

Department of Hydraulic and Environmental Engineering, Federico II University, Naples, Italy

ABSTRACT: A few experiments were carried out, in a 1:1 scale laboratory flume, to evaluate, by the acquisition and processing of photographic images, the capability of currents flowing in a stream to remove cohesive sediments deposited on the bed of a river. The results of the experiments, expressed in terms of area and volume eroded, and changes in the concentration of suspended sediments carried by water, were consistent with the physical phenomenon, and congruous with others results already reported in the literature. Considering the goodness of the results obtained by the experiments carried out, it was possible to assert that the procedure adopted for the evaluation of sediment removal is suitable for studying the erosion and transport phenomena involving most kinds of granular or cohesive sediments.

1 INTRODUCTION

Starting from the XIX century, the study of sediment transport in both rivers and channels is a very important topic in hydraulic engineering and a challenging task in the research. Most of the analyses carried out were focused on deposit/erosion phenomena involving granular sediments, whereas there is poor experience on the behaviour of cohesive sediments. Indeed, cohesive sediments exhibit different capability to resist to the flow actions, strongly depending on the composition of sediment itself and, then, on the strength of electrical attraction forces among particles. Besides, it is practically impossible to reproduce these forces in a smaller scale: as a consequence, when a problem arises involving the evaluation of erosion/deposit behaviour of cohesive sediments subject to a flow, it is usually impossible to bring useful information from the literature.

Starting from these considerations, some experiments were carried out at the laboratory of the Department of Hydraulic and Environmental Engineering *Girolamo Ippolito* of the University of Naples *Federico II*, aiming to reproduce, in a 1:1 scale flume, the capability of currents flowing in a natural river (the Bagnoncino Creek, Tuscany, Italy) to remove cohesive sediments deposited on the river bed.

In particular, the cohesive sediments specifically considered in this study were *aluminum hydroxide flocs*, diffusely found on the river bed, with layers up to 0.40 m thick. These flocs were discharged into the river, for a very long time (about 1 year), because of malfunctioning of a few water treatment plants, whose goal was to remove, by adding aluminum salts, the sediments present in the water coming from some tunnel digs and containing high level of suspended solids.

The flocs covered the river bed, at first destroying the fluvial vegetation, and then provoking the disappearance of fish, riparian fauna and vegetation.

As a consequence, in order to evaluate the possibility that the sediments were *naturally* removed, and transported until prefixed "sediment traps" to locate along the creek, it was important to individuate the hydraulic conditions needed to have sediment removal by the currents flowing in the stream.

For this reason, some laboratory activities were carried out to evaluate: i) the capability of flow to remove cohesive sediment from a fixed bed; ii) the mechanic of transport of this kind of sediment; iii) the time required for complete sediment removal.

The experiments have regarded five different aspects: i) the evaluation of the optimal conditions to artificially produce aluminum hydroxide flocs; ii) the massive production of aluminum hydroxide flocs and their subsequent transfer into the laboratory flume; iii) the acquisition of the flow velocity profiles by an Acoustic Doppler Velocimeter Profiler (*ADVP*); iv) the acquisition and processing of photographic images taken during the sediment removal; v) the evaluation of the capability of flows to remove the sediments.

It could be important to observe that the work presented here could be considered of some importance not only because it aims to solve a few specific problems, such as the determination of critical flow

Copyright © 2006 Taylor & Francis Group plc, London, UK

conditions for starting erosion of a given cohesive sediment or the evolution in time of erosive phenomena, but also because it proposes a new kind of laboratory approach, that could be useful even for studying the behaviour of other kinds of cohesive or granular sediments.

2 LABORATORY SET-UP

The experimental work aimed to reproduce natural phenomena that could be observed, both during low discharge periods and in consequence of floods events, in the *Bagnoncino Creek* (Tuscany, Italy), that was interested, a few years ago, by large deposit phenomena of cohesive sediments. Because of the impossibility to know and scale the inter-particles attraction forces originating the flocs, and the strength of links among the flocs themselves, it was decided to try to reproduce, in a 1:1 scale channel, the actual conditions that could be usually observed in a central region of the creek cross-sections. As a consequence, a Perspex channel 18.0 m long, 0.76 m wide and 0.60 m deep, having a fixed slope $i = 0.001$ m/m, was used for the experiments (Fig. 1). To adequately reproduce the field conditions, the bed of the experimental flume was covered with a single layer of stones. The grain size distribution of sediments used in the experiments fitted quite well that of sediments observed at the bottom of the Bagnoncino Creek (Fig. 2). In particular, the d_{50} diameter of the stones used in the experiments was equal to 30 mm.

In the middle of the channel, a removable wood tablet, 0.45 m long and 0.76 m wide, with fixed stones was arranged (Fig. 3). The tablet was covered with aluminum hydroxide flocs produced inside a 1 m^3 tank and then positioned in the channel.

It was decided to produce cohesive sediment into the tank to avoid water contamination in the general laboratory circuit.

2.1 *Procedure used to obtain the optimal chemical dosage for pollutant production*

The first phase of the experiments was focused to establish the optimal conditions to produce aluminum hydroxide flocs. To achieve this purpose, a great number of *Jar-Tests* were carried out, adding in the water samples variable dosages of lime, polyelectrolyte and aluminium chloride and changing the environmental conditions. The procedure used in the tests is made of the following steps: 1) addition of lime in the water (to correct the *pH* value) and its rapid mixing for 10 minutes; 2) addition of the polyelectrolyte solution, and its rapid mixing for at least 10 minutes; 3) addition of powdered aluminium chloride, and its slow mixing until the flocs are done.

Figure 1. View of the experimental channel.

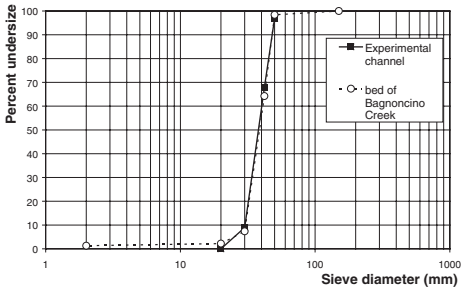

Figure 2. Grain size distribution of the sediments at bed of the Bagnoncino Creek and of the sediment used in the experiments.

Figure 3. Plain view of the removable tablet.

Copyright © 2006 Taylor & Francis Group plc, London, UK

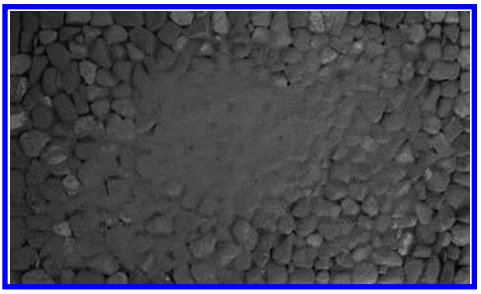

Figure 4. A top view of the contaminant on the table.

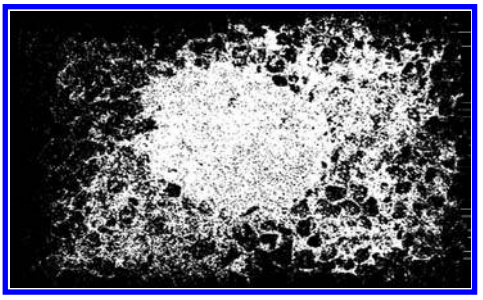

Figure 5. The output of the software.

The optimal conditions resulting from *Jar-Test* were the following: $pH = 9$; lime dose = 0.15–0.25 g/l; polyelectrolyte dose = 0.125 ml/l; aluminium chloride dose = 0.01 g/l.

2.2 *Pollutant production*

As above mentioned, the massive flocs production have taken place in the 1 m^3 tank, using the optimal conditions resulting from *Jar-Tests*. The procedure was carried on until the removable tablet was totally covered with flocs (Fig. 4). In addition, blue of methylene was added to colour the flocs, in order to be able to optically scan the variation of their concentration at bed.

2.3 *The photographic image acquisition*

At the end of the flocs production step, the wood tablet was removed from the tank and positioned at bed of the experimental flume. A digital camera was positioned at the top of the channel and snap shots were taken at regular time steps. Then, the pictures taken during each experiment were processed, by using a specific software, to identify the blue pixels associated with the pollutant presence. Given the dimensions of the pictures, it was possible to calculate both the pollutant quantity on the tablet and its variation in time due to the erosion processes originated from the shear stresses transmitted by the flow. Picture definition and luminosity were essential to be able to correctly process them by using the software. Some problems were encountered due to the presence of light reflections, the non uniformity of the water surface and the non homogeneous luminosity in the room. Thus, a correct alignment of the camera was necessary to avoid errors due to perspective. Furthermore, a black screen was positioned over the entire area to eliminate reflected light.

2.4 *The software*

The software determined the variations in blue from one shot to the following one, by comparing the corresponding pixels on the pictures. The colour information for each pixel is a 24 bit datum, ranging from black (value = 0) to very light blue (value = 255). The area with non zero values was calculated and monitored in time. A software filter was utilized to compare the single pixel datum with the adjacent ones in order to remove isolated black pixels due to light reflections or water waves at the surface, thus obtaining homogeneous areas of contaminant.

Afterwards, the value of each pixel was compared against a threshold value in order to obtain an output with only two colours. All pixels with values below the threshold value became black, and the rest were white. The threshold value falls in the range 25–28, and could be considered low enough to include also dark blue.

It is possible to show that the white area obtained by the procedure proposed perfectly corresponds to the area of the contaminant (Fig. 5).

2.5 *Hydraulic flow characteristics*

An *ADVP* was used to acquire the vertical distribution of mean local velocities along the channel axis. The number of longitudinal sections considered for measurements was 8, 20 cm spaced (Fig. 6). The range of the discharges used in the experiments was 20–85 l/s. Flow depths were also measured by using a point gauge with a *vernier scale*.

For *large-scale roughness* conditions, like those observed during the experiments, the shape of the flow velocity profile is affected by local phenomena developing near the bed. According to the experimental data of Bathurst (1988) and Marchand et al. (1984), velocity profiles could be considered *S-Shaped* when the velocities measured near the free water surface are noticeable greater than the ones measured near the bed.

The particular shape of the velocity profile is due to the existence of two different regions (Bathurst 1988): a *lower zone*, immediately over the boulders, in which the flow is delayed by drag effects due to the coarser elements; an *upper zone*, located above the boulders up to the free water surface, in which a quasi-smooth flow occurs (Morris 1959; Marone 1970).

According to Bathurst (1988), the development of a *S-Shaped profile* can be observed if: i) the value of the depth/sediment ratio is $1 \leq h/d_{84} \leq 4$; and ii) the size distribution of the bed materials is non uniform,

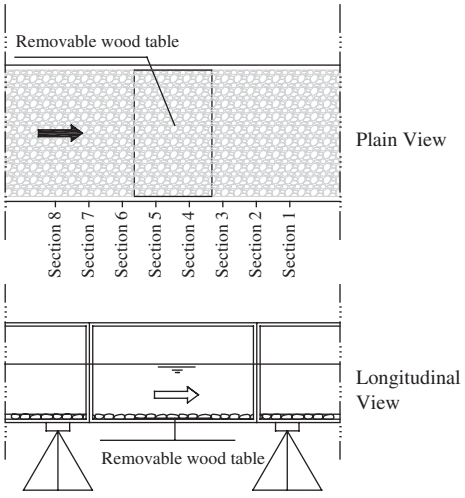

Figure 6. Schematic representation of experimental flume carrying the position of measurement cross-sections.

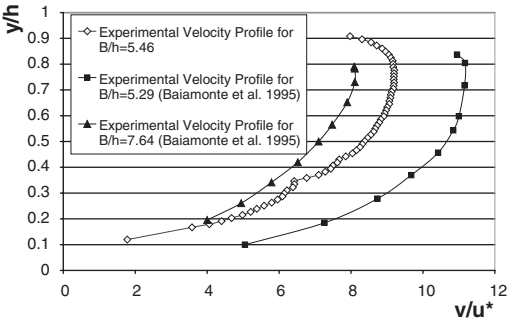

Figure 7. Experimental Velocity Profile in Section 1.

in order to allow the development of the lower zone flow (Baiamonte et al.1995).

In the cases examined, $d_{84} = 45$ mm and $h/d_{84} = 1.9 \div 3.2$.

As a matter of fact, the local velocity profiles were characterized mainly by the presence of a progressive transition to the *S-Shaped* form that is peculiar to gravel bed streams (Baiamonte et al. 1995; Nikora & Smart 1997).

With reference to the experimental data, the velocity profiles show a progressive transition to the *S-Shaped form*. This behaviour is confirmed by the observations.

As an example of experimental results, in Figure 7 is represented the vertical profile of local mean velocity at the cross-section n.1, corresponding to a flow rate $Q = 80$ l/s and a ratio $B/h = 5.46$. For comparison, the experimental results obtained in these conditions are plotted, in dimensionless form, together with those reported, by Baiamonte et al. (1995), for $B/h = 5.29$ and $B/h = 7.64$, respectively.

Table 1. Values of $q = Q/B$, Ks, u_*., τ_o, h

Q (l/s)	q (m^2/s)	K_s (m)	u_* (m/s)	τ_o (N/m^2)	h (m)
20*	0.0263	–	–	–	0.084
30	0.0395	0.055	0.0289	0.8328	0.097
40	0.0526	0.084	0.0495	2.4547	0.107
55	0.0658	0.098	0.0640	4.0956	0.116
60	0.0789	0.068	0.0796	6.3362	0.125
70	0.0921	0.081	0.0881	7.7605	0.134
80	0.1053	0.096	0.0944	8.9087	0.139
85*	0.1118	–	–	–	0.143

*For $Q = 20$ l/s and 85 l/s the velocity profiles are not available.

It seems evident that the vertical profile of local mean velocity is actually *S-Shaped*.

For large-scale roughness, the velocity distribution in the lower zone can be described by the following logarithmic profile:

$$\frac{u(y)}{u_*} = \frac{1}{k}\ln\frac{h}{K_s} + a \tag{1}$$

where y is the distance from the top of the bed, h is the flow depth, u_* is the shear velocity, $u(y)$ is the local mean flow velocity, K_s is the roughness height, $a = 8.48$ is the value frequently used for rough bed, and k is the Von Karman's constant, that can be assumed equal to 0.4 for low concentration field. Note that the values of u_* and K_s in the Eq. (1) are unknown, that have to be determined by experimental data.

Substituting the values of the constants a and k in the Eq. (1), it is possible to write:

$$\frac{u(y)}{u_*} = 5{,}75\log\frac{h}{K_s} + 8{,}48 \tag{2}$$

Referring to the present data, the velocity distribution (2) could be considered valid for $y\,u_*/v \geq 30$ and $y/h < 0.2$.

The best fit of the lower part of the velocity profiles along the channel axis and along each vertical was obtained by using the least square method.

The u_* and K_s values found by using this approach are listed in the Table 1. The K_s values are congruous with the ones reported in literature, included in the range 2-3 d_{50} (Becchi 1978).

The shear stress values τ_o were obtained considering the average of the u_* values, through the expression:

$$\tau_0 = \rho\, u_*^2 \tag{3}$$

where $\rho =$ density of the water at 20° C.

In Figure 8 are reported the τ_o and $q = Q/B$ values, where $B =$ width of experimental channel.

Copyright © 2006 Taylor & Francis Group plc, London, UK

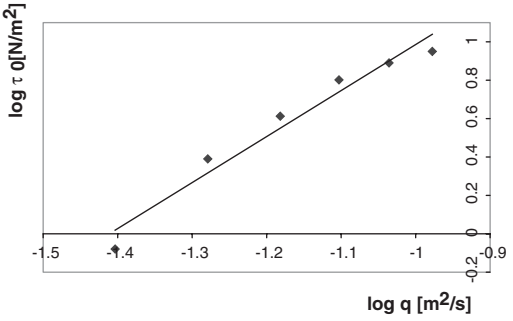

Figure 8. Relationship between τ_o and q.

The experimental relationship obtained between τ_o and q was:

$$\tau_o = 2404.4q^{2.3955} \cong 2400\ q^{2.4} \quad (4)$$

The τ_o values for $Q = 20$ l/s and $Q = 85$ l/s were obtained from the equation (4).

3 EVALUATION OF THE EROSION RATE

By using the technique described before, the erosion process of cohesive sediment vs time was evaluated for discharges $Q = 20$, 40, 55, 70 and 85 l/s (Fig. 9).

It appeared that the resistance to the erosion increases with decreasing bulk density of the pollutant. In fact, the initial erosion rate of sediment at the bed is high and it concerns the first layer, where the bulk density of the contaminant is low. Then, after a time t_c that could be considered to be constant for all the experiments, the erosion rate decreases. This behaviour could be explained considering that the lower layers, after compaction and loss of water, oppose higher resistance to the action of flow.

Vice versa, in the layers near the bed the strength of the flocs might be more and, thus, the erosion could be more difficult.

In the first phase, the erosion could be considered as exponentially decreasing with time, while in the second phase it seems to be linear.

Between the two phases, there is a kind of plateau, that might be explain as a stabilization phase where the flocs, notwithstanding the stresses induced by flow, are not removed. After a few time, the steady action of the flow weakens the links between the flocs (Partheniades 1965), and erosion can start again, though with lower rate.

It appears that the area of contaminant decreases with increasing of the value of discharge and at 85 l/s almost all the contaminant is eroded.

At the discharge $Q = 20$ l/s, the contaminant eroded was very little and, therefore, this condition was taken

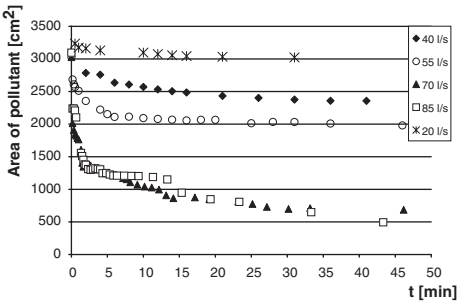

Figure 9. Area of cohesive sediments remaining on the tablet vs time.

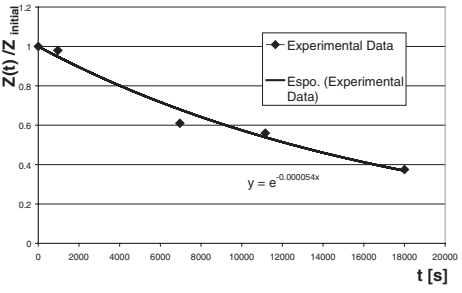

Figure 10. Variation of $Z(t)$ vs time.

as the value of the critical discharge, or condition for the *first breakaway*. The corresponding shear stress value is $\tau_{o,cr} = 0.39$ N/m^2.

To obtain the variation in concentration over time, it was necessary to calculate the volume eroded in time:

$$V(t) = A(t) \cdot Z(t) \quad (5)$$

where $V(t) =$ volume of pollutant eroded in time; $A(t) =$ area of pollutant eroded in time; $Z(t) =$ pollutant thickness.

The following law was chosen to represent the area variation in time:

$$A(t) = \frac{A_0}{(1 + t/t_\alpha)^\beta} \quad (6)$$

where $A_o =$ area of pollutant at the time zero, t_α and β are unknown parameters.

The parameters t_α and β were calculated using the experimental values of $A(t)$ evaluated in the time interval $[t = 0,\ t = t_c = 50$minutes], when the erosion rate is greatest.

According to the experimental results of Winterwerp & Kranenburg (1997), which used suspensions of kaolin, the behaviour of $Z(t)$ was considered to be a decreasing exponential function. The trend considered for following evaluations is represented in Figure 10, where the dimensionless ratio $Z(t)/Z_{initial}$ vs. time is plotted, together with a few experimental values.

Copyright © 2006 Taylor & Francis Group plc, London, UK

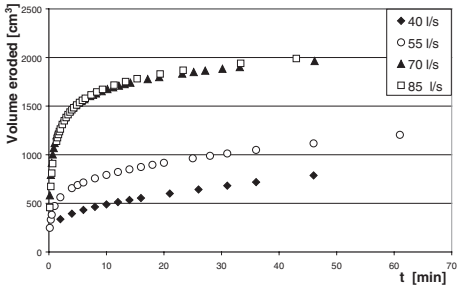

Figure 11. Variation of volume eroded vs. time.

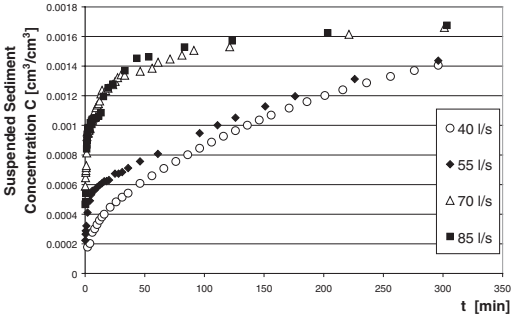

Figure 12. Suspended sediment concentration C vs time.

By comparing these results with those of Winterwerp & Kranenburg (1997), it is possible do observe that the aluminum hydroxide flocs show an erosion rate significantly lower than the kaolin, due to the differences existing in interacting forces between the particles.

In Figure 11, the variation of the calculated volume V vs time is represented for the present data:

The trend is similar to that given by Kuti & Yen (1976) for kaolin.

In order to compare to the results obtained from the experiments with those by Patheniades & Metha (1965) and of Metha & Parchure (1985), it was also evaluated the concentration of eroded material with time (Fig. 12).

It is possible to observe that the suspended sediment concentration increases with time. The rate of increasing is greater in the first phase; then, the curve tends to a constant value, because the shear stress of the flow doesn't overcome the shear stress of the cohesive soil. In particular, for $Q = 70$–85 l/s, at the end of the test, all the contaminant initially present at bed of the flume was eroded.

4 CONCLUSIONS

The main objective of this work was the evaluation of the hydraulic conditions needed to have removal, by currents flowing in a stream, of a specific cohesive sediment (*aluminum hydroxide flocs*), for which seem not available literature data.

The first difficulty was the lack of solidity of the *flocs* considered in the experiments. For this reason, it was not possible to utilize the traditional procedures of measurement. So, a new procedure was used, based on the acquisition and processing of photographic images during sediment removal. The results of area eroded, volume eroded and suspended sediment variation of concentration were consistent with the physical phenomenon and congruous with the results of literature.

However, in order to evaluate in a more rigorous way the cohesive sediment erosion, it is necessary to reproduce a greater number of experiments. Moreover, it can be interesting to repeat the tests with other types of flocs at different time of consolidation to evaluate the relationship between the time of consolidation and the capability of erosion of the flow.

By comparison with the results obtained by other researchers, it is possible to assert that the new procedure proposed, based on the acquisition and subsequent processing of photographic images taken during sediment removal processes, gives solutions consistent with the results reported in literature, and then seems suitable for studying the removal of both cohesive and granular sediments at bed of rivers and channels.

Modeling granular sediment transport over water worked gravels within a CFD framework

R.J. Hardy
Department of Geography, Science Site, South Road, Durham, UK

ABSTRACT: A numerical description of the hydraulics and sediment transport processes operating in a fluvial environment is far from complete due to the complex interactions between form, flow and sediment transport. Near bed turbulence determines the dynamics of sediment transport, however an analytical description of turbulent flow and sediment transport is subject to significant errors due to the poor parameterization of physical processes and that mean boundary shear stress is frequently determined from velocity profiles. This paper reports a numerical model that calculates the transport paths of individual granular particles over a natural water worked gravel surface. Surface topography is measured using digital photogrammetry and incorporated into a computational fluid dynamics (CFD) scheme by the application of a porosity algorithm. The predicted hydraulics determines the forces acting on each particle enabling the particle trajectory to be solved by Langrangian transport equations. The methodology demonstrates the importance of including complex topography in the numerical scheme as topographically induced hydraulic acceleration and deceleration affect both the transport mechanism and subsequent trajectory of the particle.

1 INTRODUCTION

A numerical description of the high spatial resolution hydraulics and sediment transport processes operating in a gravel bed river is far from complete due to the complex interactions between form, flow and sediment transport. The heterogeneous structure of the gravel bed determines both the turbulence and sediment transport dynamics and subsequent development of bed forms through a series of complex feedback processes (Clifford et al. 1992; Ashworth, 1996). An analytical description of turbulent flow and sediment entrainment, transport and deposition is subject to significant errors due to the poor parameterisation of physical processes (McEwan & Heald, 2001). One reoccurring limitation is that velocity profiles are frequently used to determine the mean boundary shear stress (McLean et al. 1999) which may be inadequate to describe the effect of bed roughness on flow characteristics (Papanicolaou, 2001). Such averaging obscures the complex, nonlinear interaction of wake decay, boundary-layer development and topographically induced acceleration and deceleration which leads to an inaccurate estimate of boundary stress, particularly skin friction, which is essential in sediment transport. This is especially true for gravel bed rivers which have complex surfaces (Clifford et al. 1992; Butler et al. 2002; Lane et al. 2004), where the flow depth is unusually shallow in relation to the height of the morphological form. In such shallow flows the detailed micro-topography of the bed exerts a significant effect on the flow (Wiberg & Smith, 1991). Moreover, entrainment and motion of sediment grains are driven by fluctuating instantaneous lift and drag forces. These events depend on the flow structures acting on the particle, in as much as they correlate poorly with measurements made upstream of, or over the particle (Nelson et al. 2001). Thus, they are determined by both the particle exposure to the flow and the pocket geometry of the particle.

Granular material can be transported either by: (1) suspension, an advanced stage of transport (Graf 1988) where the particles are rarely in contact with the bed; (2) saltation, the unsuspended transport of particles in the form of consecutive hops within the near bed region which is generally considered the dominant mode of bed load transport (Nino & Garcia, 1994) and; (3) rolling and sliding which occur to a lesser extent mainly near the threshold of entrainment and in between individual saltation events (Bridge & Dominic, 1984). Previous research has indicated that saltation dominates the majority of bed load transport (Sekine & Kikkawa, 1992; Wiberg & Smith 1989) and flume experiments using photogrammetric techniques have been used to understand saltation processes and determined saltation characteristics (e.g. Sekine &

Copyright © 2006 Taylor & Francis Group plc, London, UK

Kikkawa, 1992; Abbot & Francis, 1977; Drake et al. 1988; Nino et al. 1994). Through this processes understanding semi-empirical relationships of saltation characteristics have been calculated (Bagnold 1973; Bridge & Domic, 1984; Bridge & Bennett, 1992), enabling the development of generalised bed load equations. These have been used in the development of numerical models to predict particle saltation in water (Wiberg & Smith, 1989; Sekeine & Kikkawa, 1992). The most frequently used approach has been the application of Langrangian equations to predict particle motion (e.g. Van Rijn, 1984; Wiberg & Smith, 1985, 1989; Nino & Garcia, 1994; Lee & Hsu, 1994; Sekeine & Kikkawa, 1992). These have previously been applied to gain an understanding of the kinematic and geometric characteristics of the particle saltation process, including saltation length, height and particle velocity, which have all agreed well with experimental results.

The reoccurring limitation with all these individual particle based transport models is that the hydraulic representation is calculated by averaged velocity profiles over a homogenous bed. The topographically forced flow introduces a random element into sediment entrainment which in the past has required a probabilistic approach to problem (Grass, 1970).

However, if the complex topography can be included in the numerical model the probabilistic nature of sediment transport may be reduced. Recent research in computational fluid dynamics (CFD) has developed a mass flux scaling algorithm based upon a cell porosity approach (Lane et al. 2004; Hardy et al. 2005) that enables the prediction of both the time averaged hydraulics over a water worked gravel surface (Lane et al. 2004) and the prediction of time dependent flow by the application of Large Eddy Simulation (Hardy & Lane, 2004). The development of this method has allowed an understanding of the way in which a complex gravel-bed surface interacts with the associated 3D flow field. Furthermore it provides a high resolution prediction of the hydraulic forces acting on each individual particle. Here a sediment transport model is described where individual particle motion is mathematically modelled through trajectories based on Langrangian equations driven by hydraulic forces calculated from a CFD scheme.

2 METHODOLOGY

2.1 *The hydraulic scheme*

The numerical solution is three dimensional and based upon a finite volume approach. The incorporation of complex micro-topographies (individual particles) within such a CFD scheme has been problematic to date as the representation of large-scale topographic features has required the application of boundary fitted co-ordinates (BFCs). Here we apply an alternative approach which has recently been developed for incorporating complex river-bed topographies into regular structured meshes, without the need to use boundary fitted co-ordinates (Lane et al. 2004; Hardy et al. 2005). It uses a porosity based method based upon the methodology proposed by Olsen & Stokseth (1995) and involves the use of regular structured grid, in which all control volumes are orthogonal in both computational and Cartesian space, with the bed topography specified using cell porosities. The porosity algorithm for the flow treatment used has previously been reported, demonstrated and validated against Acoustic Doppler Velocimetry (ADV) for the case of time-averaged flow over rough gravel beds (Lane et al. 2004) and digital Particle Imaging Velocimetry (DPIV) data as applied to an irregular arrangement of cuboidal roughness elements (Hardy et al. 2005). The hydraulics calculated using this approach are then applied to drive a sediment transport scheme which is outlined below.

2.2 *The sediment transport scheme*

The model determines the particle transport trajectory and velocity, in a Lagrangian framework, by:

$$\frac{\partial x_p}{\partial t} = U_p \tag{1}$$

where x_p = particle position; and U_p = particle velocity. The particle velocity is calculated by a particle momentum equation:

$$m_p \frac{\partial U_p}{\partial t} = D_p(U - U_p) + m_p g - V_p \nabla_p \tag{2}$$

where m_p = particle mass; D_p = drag function; U = the continuous-phase instantaneous velocity ($U = U_c + U_c'$, where U_c = continuous-phase average velocity; and U_c' = turbulent fluctuation component), g = gravity; V_p = particle volume and; ∇_p = continuous-phase pressure gradient. The drag function (D_p) assumes that the particles are spherical and calculated by:

$$D_p = \frac{1}{2}\rho A_p C_D |U - U_p| \tag{3}$$

where A_p = particle projected area and; C_D = the drag coefficient.

The effect of turbulent fluctuations on a particle's trajectory is calculated with a stochastic turbulence model which applies a Reynolds decomposition approach. The fluctuating component is calculated assuming a normal distribution with a mean of zero and a standard deviation of $\sqrt{2k/3}$, where k is the

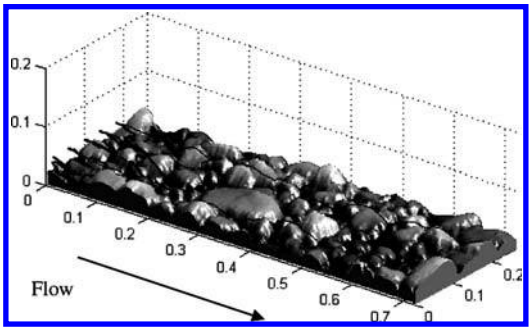

Figure 1. The trajectories for particles with 0.5 mm and 2 mm diameters for a flow velocity of 0.435 ms^{-1}.

turbulence kinetic-energy. The fluctuating component U_c' acts over a time interval which is defined as the minimum lifetime of the local eddy which the particle is traversing (Ludwig et al. 2004).

Interaction with bed topography is presently based upon the application of a restitution coefficient. In this application a value of 0.5 is used as it the mid value of the data of Wiberg and Smith (1985). Finally a stagnation criterion is applied where the particle trajectory will stop being calculated if the particle has fallen into a hydraulically stagnant region which is based on a pre-defined criterion based on zero movement over a number of iterations. The bed topography (through the porosity algorithm) is then modified as it is assumed that the particles have been deposited. At present only spherical particles are considered and the Basset and the Magnus forces are not resolved.

2.3 *Experimental set-up*

The topography and hydraulic predictions used here are based upon unpublished flume experiments. A bulk sample of sediment from the River Wharfe, northern England was placed in the flume and water worked until a stable bed (no sediment transport) was obtained. The surface morphology was measured using digital photogrammetry. Figure 1 shows the final DEM, a 0.76 m by 0.26 m gravel surface with a vertical precision of ±0.002 m. The gravel DEM is incorporated into a computational mesh on a resolution of 0.002 × 0.002 × 0.002 meters (361 × 130 × 100 = 4 693 000 grid cells).

For the experiments a water depth of 0.2 meters was maintained above the bed of the flume. Three different flow conditions were considered with the downstream velocity at 0.4 z/h being 0.155 ms^{-1}, 0.3 ms^{-1} and 0.435 ms^{-1}. Table 1 summarizes the hydraulic conditions used in the study. Velocity measurements were obtained using a two-dimensional digital Particle Imaging Velocimetry (2D DPIV). The DPIV methodology applied here is identical to that applied by Hardy et al. (2005) and is used to provide inlet boundary conditions as well as to validate the hydraulic scheme.

Table 1. The hydraulic condition used in the experiments.

Flow velocity (ms-1)	0.155	0.300	0.435
Flow depth (m)		0.200	
Flume width (m)		0.300	
Froude number (–)	≈0.11	≈0.21	≈0.31
Reynolds number (–)	≈13 000	≈25 000	≈37 000

Particles enter the domain at the inlet at prespecified locations where the initial particle velocity is dependent upon the hydraulic inlet boundary conditions. In each case the particle is assumed to be spherical and quartz (density 2650 kgm^{-2}). Each particle trajectory is tracked until it either leaves the domain through the outlet or is deposited. If the particle is deposited the bed elevation is modified through the porosity algorithm.

3 RESULTS

As discussed above the hydraulic methodology has previously been applied on several different examples. Therefore, in this paper only the sediment dynamics are reported.

Figure 1 demonstrates 10 predicted particle trajectories released from 5 locations for the 0.435 ms^{-1} experiment. Two separate experiments were undertaken, the first with a particle size of 2 mm and the second with a particle size of 0.5 mm. Each particle was assigned an initial velocity associated with the inlet velocity at the x, y, z-location. In this experiment only two particles reach the end of the domain, both 0.5 mm particles, with none of the 2 mm particles traveling more than 0.25 cm (0.36 x/l). The two particles which reach the end of the domain show very similar transport characteristics. The particles are transported by the combination of two processes; initially the particle bounces through a saltation process which then lifts the particle into a skimming flow formed above the largest protruding bed particles. The product of these processes are elongated hydraulically induced hops. For example, 0.4 meters down the domain from the inlet both particles move into separate hollows behind a large clast, the particle bounces on impact with the bed and is then entrained over the clast by a primary vortex (Hunt et al. 1978) and incorporated into a hydraulically skimming flow over the largest bed form. A more classical saltation processes can be observed for the particle at ≈0.2 across the domain where the particle saltates down the bed form. In this case the particle does not rebound high enough in the flow, or the hydraulics are not sufficient, to induce one of the hydraulically induced hops, as observed earlier.

Copyright © 2006 Taylor & Francis Group plc, London, UK

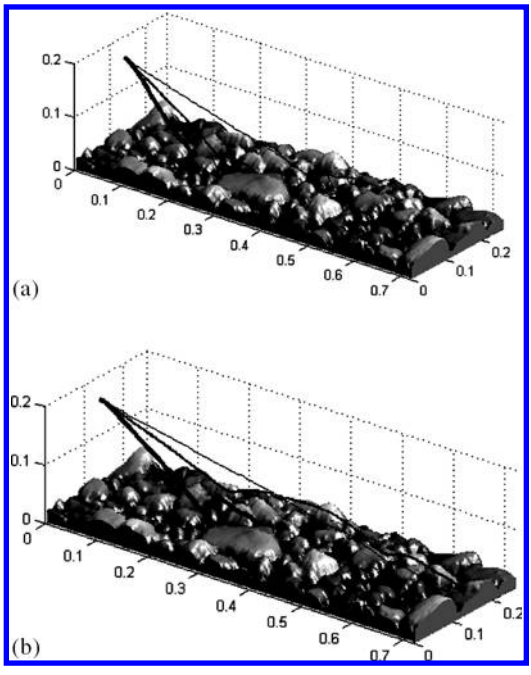

Figure 2. The trajectories for 0.5 mm, 1 mm and 2 mm particles for flow velocity of (a) 0.30 ms^{-1} and (b) 0.435 ms^{-1}.

The 2 mm particles show similar characteristics by entrainment into primary vortices at 0.1 m (0.14 x/l) location where the particles are lifted, with a sharp vertical gradient, up and over the bed form (micro topography). However, these two particles, as with the other 2 mm particles they are deposited in a short space within a hydraulically sheltered region. Although the transport distance is not that significant, the hydraulically induced hop shows the importance of including complex topography within an integrated hydraulic-sediment transport scheme.

Figures 2a & b demonstrate the predicted trajectories from a single point for the 0.5, 1 and 2 mm particles for both the 0.3 and 0.435 ms^{-1} experiments. It is acknowledged that the starting point for the particle is unnaturally high in the flow, however the results in Figure 1 demonstrated that transport distances were not that great if the particle starting point was in the bottom 25% of the flow depth. This starting point was deemed necessary to test the different transport mechanisms. For all 6 particles the initial trajectories are the particles tending towards an equilibrium height with the surrounding hydraulics. Therefore, the transport mechanism is a reflection of the initial conditions. If the 2 mm particles are studied (thick lines), considerable differences between the particle trajectories for 0.435 ms^{-1} and 0.3 ms^{-1} experiment can be observed. As would be expected the particle in the 0.435 ms^{-1} experiment collides with the bed further downstream than the 0.3 ms^{-1} experiment. In both cases the particles fall into hydraulically sheltered regions between large clasts. Both particles have the same restitution coefficient so their outward post collision velocity is of the same order of magnitude. However, the subsequent particle transport mechanism depends dramatically depending on the flow velocity. For the 0.435 ms^{-1} the particle is entrained by a tertiary vortex into a shear flow and over a clast before being deposited within another hydraulically sheltered region. However, in the 0.3 ms^{-1} experiment the hydraulics are not sufficient to induce the hydraulic hop and the particle is forced around the clast, potentially by a horseshoe vortex, in a hydraulically driven saltation process. The particle trajectories for the 1 mm particles show some similarities to the 2 mm particles. For example, the 1 mm particle in the 0.3 ms^{-1} experiment follows a similar mode of transport to the 2 mm particle in the 0.435 ms^{-1} experiment, the particle initially falls in a hydraulically sheltered region and then is transported by a hydraulically induced hop. The particle then falls into another hydraulically sheltered region, rolls back down the slope of the particle and is deposited. However, the 1 mm particle in the 0.435 ms^{-1} experiment takes a completely different transport path, where after an initial collision the bed the particle travels in a long elongated hop ($\approx$0.4 meters) in the skimming flow over the bed. Then after a final collision the particle leaves the domain. For the 0.5 mm particle in the 0.435 ms^{-1} experiment the initial starting point is such that it travels completely out the domain with only minimal contact with the bed at 0.6 m downstream (0.85 x/l). For the 0.5 mm particle in the 0.3 ms^{-1} experiment the particle, after its first contact with the bed is entrained by localised flow structures before being deposited.

The particle trajectories are explored further by dissecting them into the particle height and the particle's vertical (w-) velocity component for the 1 mm and 2 mm particles. These are shown in Figure 3. If the 2 mm particles are considered first both particles can be seen to be falling towards the bed with a vertical velocity of -0.4 ms^{-1} until each particle collides with the bed. At this point, both particles show an instantaneous change in the particle w-component as they bounce off the gravel surface. For the 0.3 ms^{-1} experiment the particle, as observed in Figure 2, is transported around in a confined hydraulically sheltered region, with the particle transport characteristics showing rapid changes in both velocity and transport distance. This is expanded further in Figure 4. The particle in the 0.435 ms^{-1} experiment impacts the bed and there is a dramatic increase in the w-component. This momentum is sufficient to lift the particle into a region where the hydraulic forces are sufficient to continue particle motion downstream. This is in a series of hydraulically induced hops which can be

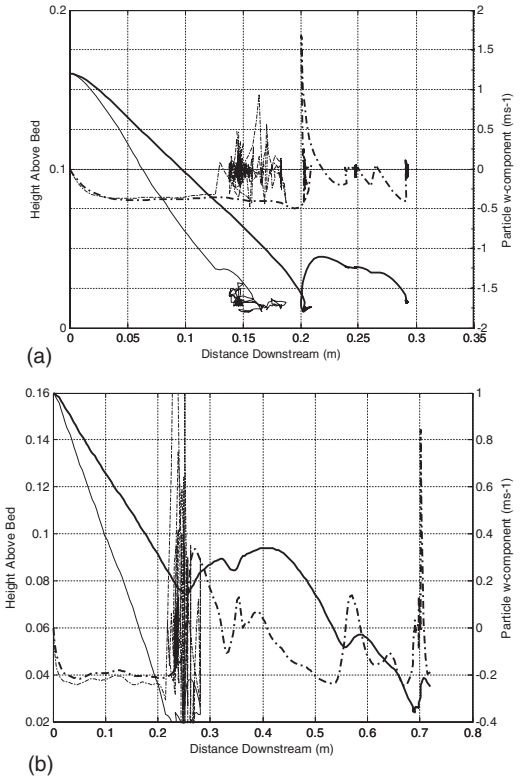

Figure 3. The particle trajectories represented through particle height and particle vertical velocity. Thick lines represent 2 mm particles while the thin lines 1 mm particles. Solid lines represent particle height while dashed lines represent particle velocity. (a) The particle trajectories for the 0.435 ms^{-1} experiment. (b) The particle trajectories for the 0.3 ms^{-1} experiment.

observed in both the height above the bed and in the *w*-velocity component. There is no consistent pattern in the profile of these saltation hops in terms of height above the bed or particle velocity due to the changing local hydraulics. A similar pattern is observed for the 1 mm particle, the particle trajectories for the 0.3 ms^{-1} experiment reflect that of the 2 mm particle and the same is true for the 0.435 ms^{-1} experiment. Although no definite conclusions can be drawn on the pattern of sediment transport from the examination of one particle there possibly could be a change in processes observed in sediment transport between the 0.3 and 0.435 ms^{-1} experiments.

Figure 4 demonstrates some more localised processes of granular sediment transport that has been observed above. The figure shows a view down the DEM from the inlet. The particle is transported in a localised area of low flow and a region of possible deposition in front of a large pebble. However the

localised hydraulics in front of the particle, a possible suppressed saddle point vortex (Hunt et al. 1978), transport the particle within a confined area until a tertiary vortex (Hunt et al. 1978) entrains the particle into the shear flow over the particle into a hydraulically induced hop. This demonstrates the spatial variability and the processes gradients operating in these environments. It is demonstrated that a spatial difference of millimetres can affect the forces acting on the particle and the possible transport mechanism. Once the particle transported over the large clast the transport mechanism changes to saltation and the particle moves down slope.

4 DISCUSSION

The results demonstrate the importance of microtopography for the generation of localised flow structures, which in turn determine the transport direction of the particles as well as the associated transport mechanisms. In none of the experiments did a particle travel the full length of the experiment by saltation. This is not that surprising due to the difference in size between the transported particles and the particles on the bed. However, transport paths are observed which have similar trajectories to saltating particles although they are driven by different mechanisms. In this transport mechanism the particle collides with the bed and bounces, or local vortex structures lift the particle until it is entrained into a shear layer over an individual particle. They are therefore hydraulically induced. This mechanism can not be defined as saltation, which Bagnold (1973) described as the unsteady suspended transport of particles by fluid flow, in the form of consecutive hops, in which no upward impulses are imparted to the particle other than those attributed to successive contacts between them and the

Copyright © 2006 Taylor & Francis Group plc, London, UK

bed. This implies that hydrodynamic lift is not important in the saltation process and rules out the effect of turbulence as the mechanism to sustain saltation (Nino et al. 1994). However, these results have demonstrated that the saltation process can be re-started by localised hydraulic forces in that after a hydraulically induced hop, the particle can saltate if the bed topography is smooth enough.

The model presented herein provides a new methodology to determine the role of micro-topographical forcing of flow and turbulence in a fluvial environment. The localised interactions have been demonstrated to determine both the transport mechanism and its dynamics.

The beginning of sediment transport – A different approach

R. Aleixo & R. Maia
Departamento de Engenharia Civil, Faculdade de Engenharia da Universidade do Porto Rua, Porto, Portugal

ABSTRACT: The beginning of motion of particles at the bottom of a water channel is a result of a rather complex interaction between the flow and the particles. Using a simplified bed model it is possible to easily study and isolate the interactions between the flow and the bed and to better define the conditions leading to the beginning of bed particles motion. A theoretical approach that takes into account the different parameters such as support angle and turbulence intensity, is presented and compared with the Shields diagram and experimental results. This study is the first phase of a broader research project in course who aims to better understand and explain the beginning of sediment particles motion.

1 INTRODUCTION

Aiming to study the interaction between the flow and the channel bed, a simple model was developed in order to allow a proper description of that interaction in terms of its physics. Some assumptions were made and based on the known results of the boundary layer theory.

This work summarizes the first stage of a broader research project in course at the Hydraulics Laboratory of Faculty of Engineering of Porto University, currently focused at the study of the flow around a single particle, aiming to be used in future work to characterize the interaction between particles.

2 CONCEPTUAL MODEL

The bed model studied consists on a flat and horizontal plate in which a localized two-particles' width bed, with the full transverse length of the water channel was provided, as depicted in Figure 1. Over this bed of particles, at the channel axis, a single particle was placed. The particles that support that single particle will be from now on referred as supporting particles and the single particle will be designated as test-particle. This model consists in a simplification of one presented by (Nezu and Nakagawa 1993).

There are two possible 3D configurations to support the test-particle: a three- or a four-particles bed arrangement. For this analysis the test-particle is assumed to be supported by a four particles bed arrangement with the centres of the five spheres forming a square-based pyramid as shown in Figure 2. It can be shown that the maximum height of the sphere is $h_{1t} = d/\sqrt{2}$ and that the support angle is $\theta = \text{atan}\,\sqrt{2}/2 = 35.26°$ (as depicted on Fig. 2).

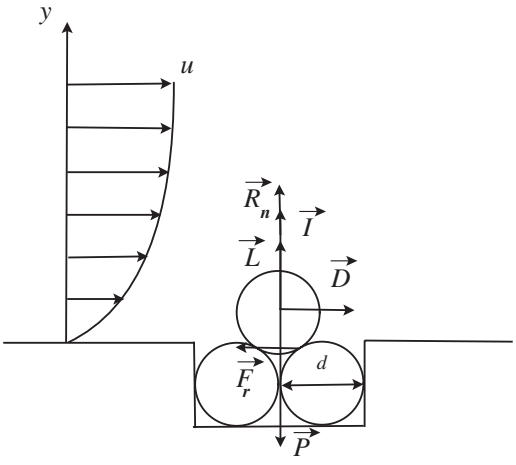

Figure 1. Simplified bed model. A test-particle, with the same diameter as the ones of the bed is immersed on a flow with a velocity profile $u = u(y)$. The forces acting on a particle (referred as test-particle) are the weight $\vec{P}$, the drag $\vec{D}$, the lift $\vec{L}$, the buoyancy $\vec{I}$, the normal reaction $\vec{R}_n$, the friction force $\vec{F}_r$, and d is the particle's diameter.

For this simple model theoretical hypothesis regarding the beginning of motion were assumed:

1. the flow is processed over a flat smooth bed until it reaches the test-particle.
2. the flow is bidimensional and developed, so that the longitudinal component, u, is much larger

Copyright © 2006 Taylor & Francis Group plc, London, UK

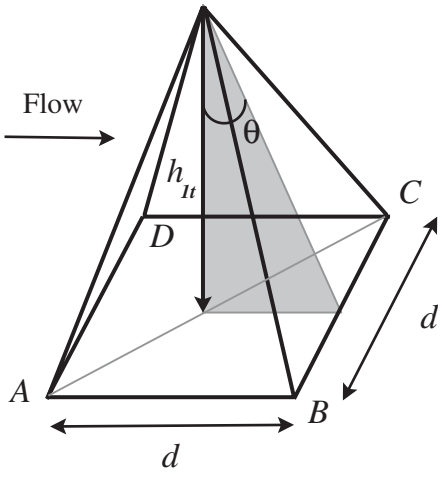

Figure 2. A squared based pyramid results from the four-spheres support arrangement considered in this study, being θ the supporting angle. Flow direction is perpendicular to the segment AD.

than the vertical and transversal components v and w, respectively;

3. the boundary-layer is limited to a narrow region near the bed, so that the test-particle may be considered, in this approach, immersed in a uniform stream, of velocity U_∞;
4. outside the boundary layer, the turbulence intensity profile will be assumed constant (Hinze 1975);
5. the flow is fully established;

2.1 *Analysis of the forces acting on the test-particle*

The forces acting on the test-particle are the following (considering an horizontal plate) are:

– The immersed weight force, $\vec{P} - \vec{I}$:

$$P - I = \frac{\pi}{6}(\rho_s - \rho)gd^3 \tag{1}$$

where $\rho_s =$ density of the particle; $\rho =$ density of the water; $g =$ acceleration of gravity; and $d =$ particle's diameter.

– The drag, $\vec{D}$, and lift, $\vec{L}$, forces (Goldstein 1965):

$$D = \frac{1}{2}\rho U_\infty^2 S C_D \tag{2}$$

$$L = \frac{1}{2}\rho U_\infty^2 S C_L \tag{3}$$

where $U_\infty =$ velocity of the flow far from the bed; $S =$ particle's section exposed to the flow; $C_D =$ the drag coefficient; and $C_L =$ lift coefficient.

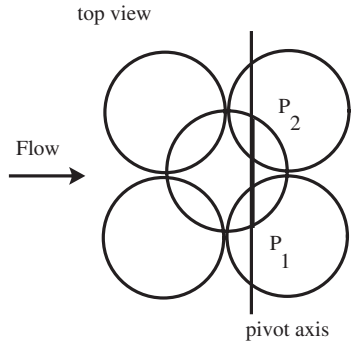

Figure 3. Top view of the particle arrangement and representation of the pivot points (P_1 and P_2) and axis formed by those points. Flow direction is perpendicular to the segment P_1P_2.

– The resistance force, $\vec{F}_r$ which can be expressed as (Halliday et al. 2001):

$$F_r = \mu_e R_n \tag{4}$$

where $\mu_e =$ static friction coefficient; and $R_n =$ normal reaction.

From the equilibrium conditions, $\sum \vec{F} = 0$ and $\sum \vec{M} = 0$, where $\vec{F}$ represents the resultant force and $\vec{M}$ the resulting torque, one obtains respectively for the force balance:

$$\frac{U_\infty^2}{(s-1)gd} = \frac{4}{3C_D}\left(\frac{\mu_e}{1 + \frac{C_L}{C_D}\mu_e}\right) \tag{5}$$

and for the torque balance:

$$\frac{U_\infty^2}{(s-1)gd} = \frac{4}{3C_D}\left(\frac{\tan\theta}{1 + \frac{C_L}{C_D}\tan\theta}\right) \tag{6}$$

where $\theta =$ support angle, as represented in Figure 2; and $s = \rho_s/\rho$. According to observations for the studied case conditions and considering current values of static friction coefficients for glass and *perspex* (0.7 to 0.9), equation (6) was taken as the critical reference in the following analysis.

The first member of equation (6) can be identified as a Froude number, and so the following relation can be written:

$$\mathrm{Fr} = f(C_D, C_L, \theta, \phi) \tag{7}$$

where C_D and C_L are functions of the particle Reynolds number, defined as $Re_p = U_\infty d/\nu$ and of the shear rate defined as $\partial u/\partial y$ (Saffman 1964). For C_D and C_L, formulations corresponding to the situation of a sphere in a shear flow should be used, if available.

Copyright © 2006 Taylor & Francis Group plc, London, UK

In accordance with the model's theoretical hypothesis referred (as 3.) before, it was assumed that C_L was zero (Goldstein 1965), corresponding to, on a first approach, not taking into account lift force effects. That simplification was assumed although having in mind that, accordingly to (Saffman 1964), a sphere in a slow shear flow is submitted to a lift force. Therefore equation (6) can be written:

$$\frac{U_\infty^2}{(s-1)gd} = \frac{4}{3C_D}\tan\theta \tag{8}$$

or, multiplying both terms by the squared shear velocity, $u_*^2 = \tau_w/\rho$:

$$\frac{u_*^2}{(s-1)gd} = \frac{4}{3U_\infty^{+2}C_D}\tan\theta \tag{9}$$

where $U_\infty^+ = U_\infty/u_*$. For turbulent boundary layer flows, and using the skin friction coefficient definition, it is possible to demonstrate that $u_*/U_\infty \approx 1/20$. The left hand side of equation (9) may be identified as the Shields parameter (Shields 1936) and will be denoted by Sh (sometimes referred in the literature by θ or Y), and referred from now on as the Shields number.

The behavior of the C_D can be expressed as a function of the particle Reynolds number (Cliff et al. 1978). Some of those expressions, which are particle Reynolds number range dependent, are:

- for $0.01 \le \mathrm{Re}_p \le 20$:

$$C_D = \frac{24}{\mathrm{Re}_p}\left(1 + 0.1315\mathrm{Re}_p^{0.82-0.05\log\mathrm{Re}_p}\right) \tag{10}$$

- for $20 \le \mathrm{Re}_p \le 260$:

$$C_D = \frac{24}{\mathrm{Re}_p}\left(1 + 0.1935\mathrm{Re}_p^{0.6385}\right) \tag{11}$$

- for $260 \le \mathrm{Re}_p \le 1.5\times10^3$:

$$\log C_D = 1.6435 - 1.1242W + 0,1558W^2 \tag{12}$$

- for $1.5\times10^3 \le \mathrm{Re}_p \le 1.2\times10^4$:

$$\log C_D = -2.4571 + 2.5556W - 0.9295W^2 + 0,1049W^3 \tag{13}$$

with $W = \log \mathrm{Re}_p$.

Taking into account the referred expressions (10 to 13) for the C_D evaluation, equation (9) can be plotted and compared with the Shields diagram (correspondent to granular mixtures), considering the Reynolds number range variation (using $u_* \approx U_\infty/20$), and different support angles (Fig. 4).

For the turbulent regime, $\mathrm{Re}_* > 80$, and considering $\theta = 35.26°$, the Shields number Sh, as calculated by equation (6) is approximately 0.006, which is about 10 times less than the value usual accepted for the Shields

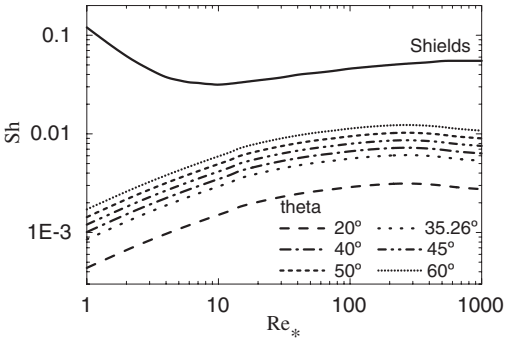

Figure 4. Comparison of Shields diagram with curves obtained for an isolated sphere, for different support angles (theta means θ).

diagram in the same conditions, $Sh \approx 0.06$, (Cardoso 1998). In experiments carried out by (Fenton and Abbott 1977) a value of $Sh \approx 0.01$ was obtained, for large values of Re_*. Moreover, this last result is in good agreement with the ones obtained by (Coleman 1967).

In addition to the previous considerations one should also take into account the existence of turbulence forces, namely a turbulent drag and a turbulent lift. Starting from the definition of drag force, and expressing the velocity in terms of a mean value and of a fluctuation component:

$$D = \frac{1}{2}\rho(u+u')^2 SC_D \tag{14}$$

or:

$$D = \frac{1}{2}\rho(u^2 + 2uu' + u'^2)SC_D \tag{15}$$

Applying the Reynolds average in order to eliminate the term uu' and taking into account the simplified theoretical hypothesis 3 referred before, one has:

$$\overline{D} = \frac{1}{2}\rho(U_\infty^2 + \overline{u'^2})SC_D \tag{16}$$

expressing that the drag force has a contribution from the mean as well as from the fluctuating velocity components and it can be seen that the drag force has a contribution from the mean value of the flow and from the fluctuating component. A similar reasoning is valid for the lift force. It is then possible to individualize drag and lift turbulent forces, $\overline{D_t}$ and $\overline{L_t}$, with:

$$\overline{D_t} = \frac{1}{2}\rho\overline{u'^2}C_D S \tag{17}$$

$$\overline{L_t} = \frac{1}{2}\rho\overline{u'^2}C_L S \tag{18}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

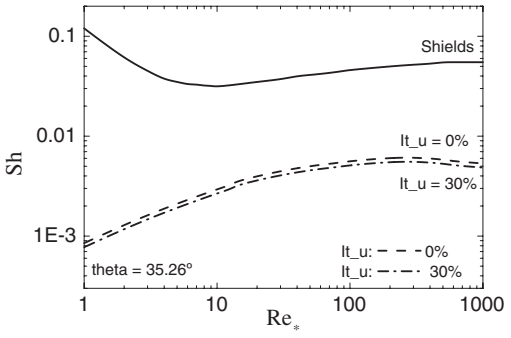

Figure 5. Variation of the Shields number with the turbulence intensity of the longitudinal velocity component (u) on the Shields number, for a support angle of $\theta = 35.26°$ (It_u stands for It_u).

where $u' =$ fluctuation of the longitudinal velocity.

Conducting a similar approach as before (neglecting the lift component), and again from the torque analysis equation (9) turns now into:

$$Sh = \frac{4}{3C_D}\tan\theta \frac{1}{U_\infty^{+2}}\left(\frac{1}{1+It_u^2}\right) \tag{19}$$

where $It_u^2 = \overline{u'^2}/U_\infty^2$, is defined as the turbulence intensity for the u component. If It_u is small compared with unity, equation (19) can be written as:

$$Sh = \frac{4}{3C_D}\tan\theta \frac{1}{U_\infty^{+2}}\left(1-It_u^2\right) \tag{20}$$

The plot of this function is depicted in Figure 5 considering $\theta = 35.26°$ for two different values of It_u. One can observe that the contribution of turbulence, although not relevant, shall be envisaged and taken into account, the most as more turbulent the flow is.

3 EXPERIMENTAL SETUP

The experiments were made on the flume channel of the Hydraulics Laboratory at FEUP. The channel is 0.4 m wide by 0.6 m high and has a length of 17 m.

On this channel a model similar to the one described before (Fig. 1) was built in a *perspex* plate placed on the bottom of the water channel and the 5 mm diameter spherical particles used were made of glass ($\rho_s = 2.65\,\mathrm{kgm^{-3}}$).

In order to measure the mean and turbulent velocities of the flow a one component laser Doppler velocimeter (LDV) system from DANTEC was used. The characteristics of this system are shown in Table 1.

The measurement grid used is depicted in Figure 6 and shows the plant view of the measured profiles.

Table 1. Parameters of the LDV (m.c.v. stands for measurement control volume).

Parameter	Value	Comment
λ	514 nm	wavelength
θ	6.834°	angle of laser beams
δ_x	2.53 mm	major axis of m.c.v.
δ_y	162 μm	minor axis of m.c.v.
D_f	4.318 μm	fringe spacing
f_s	0.6 MHz	frequency shift

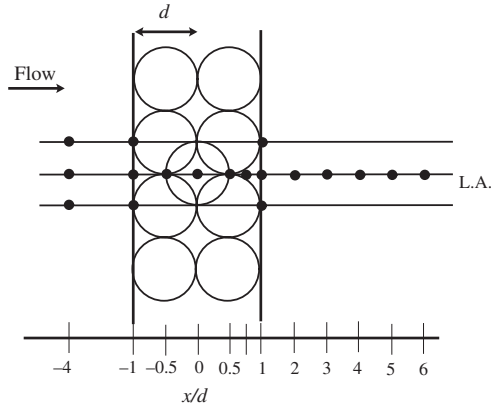

Figure 6. Top view of the measurement grid used in the measurements (L.A. stands for Longitudinal Axis).

4 EXPERIMENTAL RESULTS

In order to determine the conditions for the detachment of the test-particle (hereafter referred as critical conditions) several tests were carried out in order to obtain a narrow band of flow rate values for which the single test particle was removed, hereby referred as critical flow rate, Q_c. It was observed in the laboratory that the obtained interval for the critical flow rate was:

$$Q_c = [15.85;\ 17.25]\ \mathrm{(L/s)} \tag{21}$$

The average flow rate obtained was 16.16 L/s and that was the flow value used as the critical flow case.

4.1 *Studied flow characteristics*

In order to allow the measurement for velocity fields characterisation in the critical condition to be made, the glass sphere was replaced by a steel sphere with the same diameter. The mean and turbulent velocity fields over and close to the test-particle were also characterised for two other flowrate values in the range below the critical one.

Table 2 summarizes the characteristics of the studied flows in terms of flow (Q), Reynolds number

Copyright © 2006 Taylor & Francis Group plc, London, UK

Table 2. Parameters of the flows considered.

Re_h	Height h (m)	Q (L/s)	τ_w (Nm^{-2})
3.1×10^4	0.055	4.04	0.120
7.0×10^4	0.085	10.10	0.224
1.0×10^5	0.120	16.16	0.323

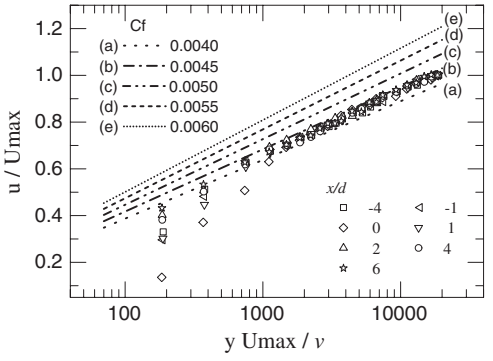

Figure 7. Application of the Clauser method to obtain the shear stress values on different longitudinal sections of the channel for $Re_h = 1.0 \times 10^5$ (take $U_{max} = U_\infty$).

($Re_h = UR_h/\nu$, where R_h is the hydraulic radius, U is the cross sectional mean velocity and ν is the kinematic viscosity) and shear stress (τ_w). The latter was evaluated by applying the Clauser method to the measured velocity profiles.

The flow fields characterization for any of those flows was carried for two situations: one with and the other without the test-particle placed in the flow. The last ones enabled the application of the Clauser's method. In fact, according to (Young 1989) from the log velocity law it is possible to demonstrate that the following relation holds:

$$\frac{u}{U_\infty} = \frac{1}{\kappa}\sqrt{\frac{C_f}{2}}\ln\left(\frac{U_\infty y}{\nu}\right) + \sqrt{\frac{C_f}{2}}\left(B + \frac{1}{2\kappa}\ln\left(\frac{C_f}{2}\right)\right) \quad (22)$$

where $C_f = 2\tau_w/\rho U_\infty^2$ is the skin-friction coefficient, $\kappa = 0.4$ is the von Kármán's constant and B is a constant. Choosing several values of C_f it is possible to determine a family of curves, and choose the one who better fits the obtained experimental data. In Figure 7 the Clauser method is illustrated for the critical condition, $Re_h = 1.0 \times 10^5$.

As it can be seen the obtained values for C_f at different longitudinal sections, for the fitting range, are constant.

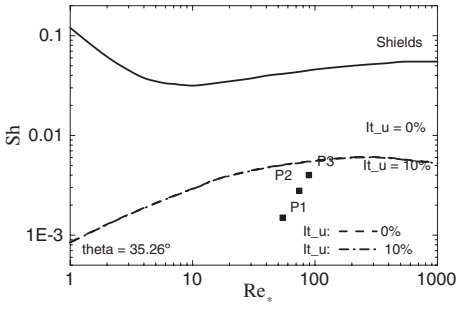

Figure 8. Comparison of the experimental results with the proposed conceptual model. Particle detachment situation corresponds to point P3 (obtained for the critical flow, $Re_h = 1.0 \times 10^5$). Points P1 and P2 correspond to the two other flows considered ($Re_h = 3.1 \times 10^4$ and $Re_h = 7.0 \times 10^4$, respectively).

Table 3. Experimental data points obtained in the channel flume.

Point	Re_h	Re_*	*Sh*	*Sh* (Predicted)
P1	3.1×10^4	54	0.0015	—
P2	7.0×10^4	74	0.0028	—
P3	1.0×10^5	89	0.0040	0.0055

4.2 *Analysis of the conceptual model*

The conceptual model presented in the beginning of this paper is analyzed here in the light of the experiments. Using the flow characteristics (referred on Table 2), the correspondent Shields numbers (*Sh*) and Re_* could be obtained and are plotted in Figure 8 and listed on Table 3.

Comparing those values with the classical Shields diagram, also depicted on Figure 8, it is clear that, even for the determined critical condition, Shields' theory does not predict the beginning of particle motion. This is recognised to be due to the fact that the Shields' criterion was derived considering the erosion of a granular bed of sediments and not only a single particle. Nevertheless the comparison is made since the Shields diagram is one of the important tools to assess the beginning of sediment motion and it is a very widely used reference for granular mixtures. It can be seen that (i) all the experimental points obtained present a consistent and crescent trend and (ii) the point correspondent to the critical flow (P3) is quite close to the line obtained by application of the simplified conceptual model, but still below the predicted critical value.

As referred before, the model assumes that there is no lift force contribution. It can be expected that if lift force is taken into account, the prediction of the critical value may be improved. In fact by considering the lift component, by adopting in equation (6) the

Copyright © 2006 Taylor & Francis Group plc, London, UK

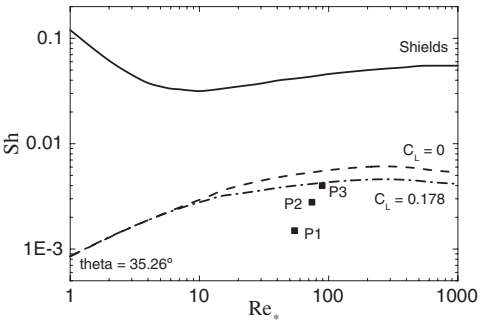

Figure 9. Comparison of the experimental results with the proposed conceptual model considering $C_L = 0$ and $C_L = 0.178$ as proposed by Einstein and Samni. Considering the lift coefficient the conceptual model gives results closer to the experimental ones.

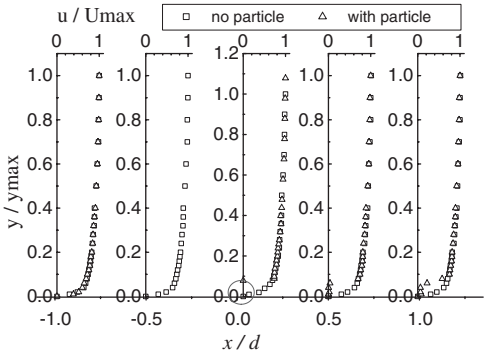

Figure 10. Mean velocity profiles of the u component on the test-particle for $\mathrm{Re}_h = 1.0 \times 10^5$, at the longitudinal axis (take $U_{max} = U_\infty$ and note that the circle is only to indicate the test-particle height).

value of $C_L = 0.178$ proposed by (Einstein and Samni, 1949), a new conceptual model curve may be obtained as depicted on Figure 9.

Figure 9 indicates that by considering the lift contribution the predicted critical values will be still in better agreement with experimental ones, and so the use of formulations for both C_L and C_D on the conceptual model is recommended.

4.3 *Flow field over the test-particle*

The use of the LDV, as referred, allowed to characterize mean velocity and turbulence intensity values on both longitudinal (u) and vertical (v) directions. Those measurements were carried out in the perspective of investigating the influence of the turbulence fluctuations and also the kinetic energy in the detachment process of the particle. Of course, that in addition of the characterization of the flow field for the critical condition case.

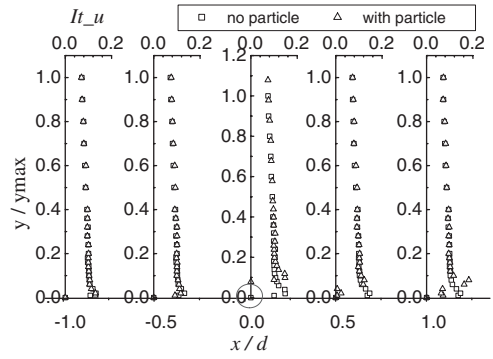

Figure 11. Turbulence intensity for the longitudinal component (u) over the test-particle for $\mathrm{Re}_h = 1.0 \times 10^5$, at the longitudinal axis (take $U_{max} = U_\infty$, It_u = It_u and note that the circle is only to indicate the test-particle height).

The velocity profiles corresponding to the critical condition ($\mathrm{Re}_h = 1.0 \times 10^5$) are depicted in Figures 10 to 13 and compare the behavior of the velocity field with and without test-particle along the longitudinal axis (see Fig 6).

Figure 10 shows that immediately upstream of the test-particle there is a reduction on the value of the longitudinal velocity (u) due to the deceleration of the flow. It is also clearly seen that over the test-particle there is an acceleration of the flow, with a high velocity gradient; on the other hand the wake region is characterized by a low velocity zone (with velocities about zero). The turbulence intensity (Fig. 11) has a similar behavior but, in the wake region the higher values are located at a distance of the wall of about one diameter ($y/d \approx 1$). Over the test-particle turbulence intensity, It_u is about 18% (Fig. 10).

For the v component, due to geometric limitations, it was not possible to make the measurements near the bottom. Nevertheless, it was possible to measure at a distance of 0.75 mm from the top of the sphere. The correspondent results are shown in Figures 12 and 13.

In terms of order of magnitude it can be concluded that the longitudinal mean component, u, is much larger than the correspondent vertical component v. It is also possible to note that the turbulence intensity associated to the vertical velocity component (v) is of the same order of magnitude of the correspondent mean component.

4.4 *Kinetic energy evaluation*

Using the information available from the measured velocity profiles it is possible to determine the kinetic energy of the flow. In order to study the effect of the test-particle on the kinetic energy of the flow an analysis was made concerning sections $x/d = -1$ and $x/d = +1$ (along the axis of the test-particle) by calculating the kinetic energy difference between those

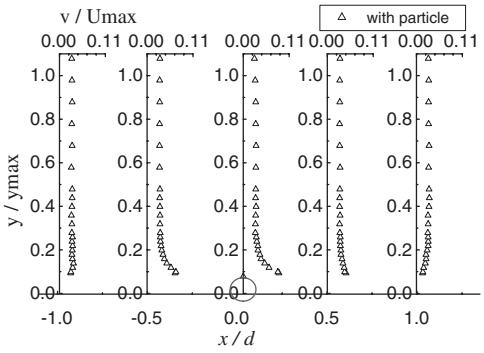

Figure 12. Velocity profiles of the mean v component on the test-particle for $\mathrm{Re}_h = 1.0 \times 10^5$, at the longitudinal axis (take $U_{max} = U_\infty$ and note that the circle is only to indicate the test-particle height).

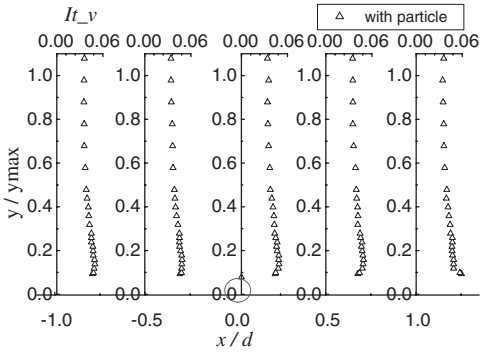

Figure 13. Turbulence intensity for the v component on the test-particle for $\mathrm{Re}_h = 1.0 \times 10^5$, at the longitudinal axis (take $U_{max} = U_\infty$, It_v $= It_v = \overline{v'^2}/U_\infty$ and note that the circle is only to indicate the test-particle height).

sections. The kinetic energy of the flow is given by (Hinze 1975):

$$k = \overline{k} + k' \tag{23}$$

where $\overline{k} = (\overline{u}^2 + \overline{v}^2 + \overline{w}^2)/2$ is the kinetic energy due to the mean components and $k' = (\overline{u'^2} + \overline{v'^2} + \overline{w'^2})/2$ is the kinetic due to the turbulent fluctuations of the flow. Due to experimental limitations the transverse w component was not measured and so the following approximation was made:

$$k \approx \frac{1}{2}(\overline{u}^2 + \overline{u'^2} + \overline{v}^2 + \overline{v'^2}) \tag{24}$$

The difference between the kinetic energy of the flow measured at $x/d = +1$ and at $x/d = -1$ is then given by:

$$\Delta K = K_{+1} - K_{-1} \tag{25}$$

where $K_{+1} =$ total kinetic energy at section $x/d = +1$; and $K_{-1} =$ total kinetic energy at section $x/d = -1$. By

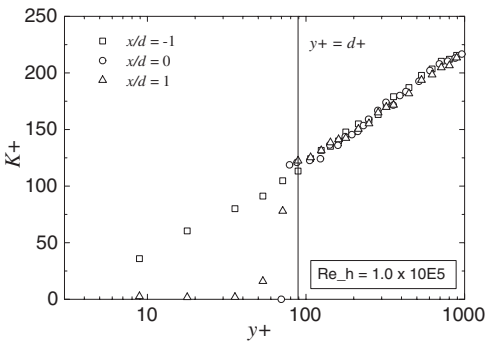

Figure 14. Total non-dimensional kinetic energy profiles measured at $x/d = -1{,}0$, and $+1$ for the critical flow situation. Note that at $x/d = +1$ the total turbulent kinetic energy decreases significantly when compared with the one measured at $x/d = -1$.

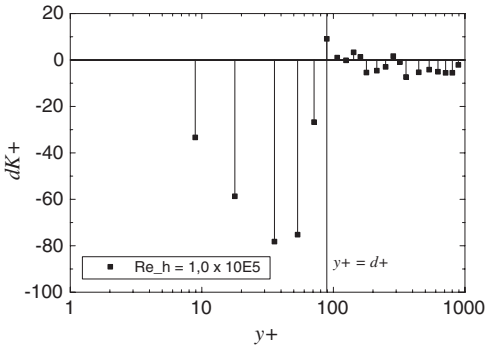

Figure 15. Total non-dimensional kinetic energy difference between profiles measured at $x/d = -1$ and $x/d = +1$ ($dK^+ = \Delta K^+$).

dividing by u_*^2 equation (25) is made non-dimensional, which may be expressed by writing:

$$\Delta K^+ = K_{+1}^+ - K_{-1}^+ \tag{26}$$

Figure 14 shows the profiles of the total non-dimensional kinetic energy in $x/d = -1{,}0$, and $+1$ for the critical flow situation ($\mathrm{Re}_h = 1.0 \times 10^5$) at the longitudinal axis.

The correspondent quantitative changes between the profiles at $x/d = -1$ and $x/d = 1$ are expressed in Figure 15.

In order to characterize the test-particle influence in the kinetic energy longitudinal variations it is possible to define the average kinetic energy between the bed and the particle's top. This averaged value can be expressed in a non-dimensional form as:

$$\epsilon = \frac{1}{d^+}\int_0^{d^+} \Delta K^+ dy^+ \tag{27}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

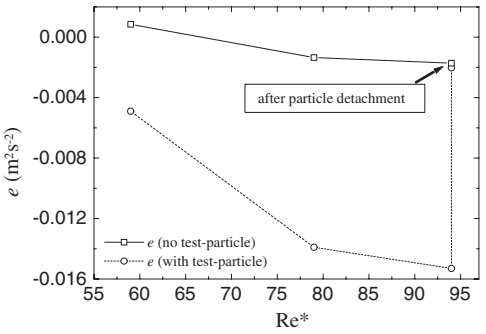

Figure 16. Variation of the e parameter with the shear Reynolds number considering two situations: with no test-particle and with test-particle. It can be seen that the test-particle acts as an energy dissipater.

where $d^+ = u_* d/\nu$ is the non-dimensional height of the particle. ϵ may be interpreted as the mean value of the total kinetic energy difference between the bottom and d^+.

In dimensional form, the average value of the total kinetic energy difference may be expressed by:

$$e = \epsilon u_*^2 \tag{28}$$

On Figure 16 the variation of e is plotted against the variation of the shear Reynolds number Re_* for two cases: one considering the presence of the test-particle in the flow and other not considering it. From the case with test-particle it can be seen that the test-particle acts naturally as a kinetic energy dissipater, and it can be guessed that the particle will be detached if the flow has enough kinetic energy to remove it from its place. Further developments of this energy based method to assess the beginning of sediment motion are to be studied.

5 CONCLUSIONS

A conceptual model for the beginning of motion of a singular test-particle was presented that considers the influence of the drag and of turbulent drag forces.

The improvement of the model by considering the lift force contribution proved to enhance model accuracy, as should be expected. Although the complete form and adequacy of the conceptual model to the full range of shear Reynolds number has still to be validated, the obtained results of the model showed a good agreement with the ones obtained experimentally for the beginning of motion. In order to avoid approximations and use of inadequate data, the values of lift and drag coefficients should be calculated considering the particle Reynolds number and the shear rate ($\partial u/\partial y$) near the wall.

It is known that turbulence is an important mechanism regarding the beginning of sediment motion. The presented model showed also that turbulence intensity contributed to influence particle detachment, but the formulation used, based on time averaged values, did not reveal that effect as mostly significant in current turbulent flows, as it could be expected. Improvements on this model should also be implemented in order to deal properly with the turbulence effects, namely by considering all velocity components, based on laser Doppler anemometry measurements.

Using the velocity profiles it was possible to study the flow field for the critical condition and estimate the kinetic energy of the flow (mean and fluctuation component). It is clear that the test-particle acts as a kinetic energy dissipater and that there is a threshold for which the test-particle is removed. That should be explored in order to better assess the beginning of particles motion.

ABSTRACT: An oil flume in combination with a 100 Hz Particle Image Velocimetry system has been used to study entrainment of 11 mm diameter spherical Nylon particles. The flow field near the bed and around sediment particles holds essential information for studying entrainment mechanics, but measurements in water are often hampered by a lack of adequate resolution, particularly for smaller particle sizes. The higher viscosity of oil compared to water increases length scales, allowing water flows to be modelled with much larger sediment sizes and deeper near-bed flow layers. The 11 mm diameter particles used in the present oil flow experiments are dimensionally equivalent to 0.74 mm diameter quartz particles in water flow. Analysis of the flow field at the instant of bed particle movement indicates that sweep structures (higher than averaged streamwise velocity combined with bed-directed vertical velocity) are the dominant mechanism of entraining particles for the bed geometry and flow regimes studied.

1 INTRODUCTION

Subaqueous granular movement is presently analysed based on the premise that granular material is moved by an average flow property, typically a depth-averaged velocity or an average shear stress exerted by the bulk flow on the surface of the granular mass. This premise, which is inadequate for real (e.g. non-uniform or 3-D) flows, limits understanding, analysis and prediction of granular material motion in nature, numerical modelling of loose-boundary processes being restricted to empirical approximations.

Recent research has focused on relating grain entrainment to local flow conditions, particularly coherent flow structures such as hairpin and funnel vortices. García et al. (1996) used a liquid tracer injected into the flow combined with high-speed photography to visualise a range of particle sizes (0.038–0.53 mm) in both hydraulically smooth and transitional flow regimes (grain Reynolds number $R_* = 0.7$–20) being entrained into suspension. They concluded that ejection events downstream of shear layers are primarily responsible for lifting particles from the bed, even for particles that are immersed within the viscous sub-layer.

Hofland & Booij (2004) used Particle Image Velocimetry (PIV) to measure the flow field over a gravel bed (median sediment size $d_{50} = 17.8$ mm, $R_* = 1200$), with a single moveable light-weight target particle. Their findings suggest that a small-scale ejection creates the initial uplift of the target particle followed by a larger sweep event that dislodges the stone completely. They conclude that sweep events by themselves are less effective than the ejection-sweep combination for moving bed material because the downwards-directed flow associated with sweep events reduces the lift force acting on the particle.

Nelson et al. (2001) found a strong coupling between instantaneous drag force and streamwise flow velocity, but suggest instantaneous lift force is poorly correlated with local velocity either above or in front of the test particle. Horizontal and vertical force components were measured using a force transducer attached to a 19 mm diameter sphere with simultaneous PIV measurements of the flow field. They suggest the optimal conditions for high-lift events are a combination of high velocity (and associated low pressure) over the top of the particle and lower than average velocity (with a high pressure) beneath the particle, maximising pressure differential.

2 DIMENSIONAL ANALYSIS

2.1 *Improving effective measurement resolution*

Resolving the flow field around individual particles, detecting and controlling bed geometry, and

Copyright © 2006 Taylor & Francis Group plc, London, UK

measuring particle movement are all essential for studying particle entrainment at the grain scale. Flows of interest in the $R_* = 5$–50 range (typical sand-size sediments with 0.5–2 mm diameter), where Shields curve describing entrainment shows significant variation with R_*, are difficult to study at the grain scale using conventional techniques due to the small scales involved.

Such flows can be modelled using larger particles by reducing sediment density (effectively decreasing u_* for entrainment) and/or by increasing fluid viscosity ν. Maintaining similarity of the Shields' parameter (θ_c) and the grain-size Reynolds number R_* to ensure correct simulation of particle entrainment under viscous, gravity and fluid shear forces, we can write Equation 1 and Equation 2, which reduce to Equation 3.

$$\lambda_{\theta_c} = \frac{\lambda_{u_*^2}}{\lambda_{(S_s-1)}\lambda_g\lambda_d} = 1 \quad (1)$$

$$\lambda_{R_*} = \frac{\lambda_{u_*}\lambda_d}{\lambda_\nu} = 1 \quad (2)$$

$$\lambda_d = \left[\frac{\lambda_\nu^2}{\lambda_g\lambda_{(S_s-1)}}\right]^{1/3} \quad (3)$$

where λ is the ratio between model and prototype scales, S_s = submerged sediment density, d = particle diameter, g = acceleration due to gravity and u_* = shear velocity. Using oil of higher viscosity than water, the sediment size needs to be increased according to Equation 3 to correctly replicate fluvial sediment processes. Improved resolution of near-boundary flow and entrainment mechanics in this manner using oil flows is the focus of the present study.

3 HIGH-VISCOSITY CONDUITS

3.1 *Previous flumes*

Einstein & Li (1958) and Eckelmann (1974) both used oil flumes to study the viscous sublayer region of turbulent flows. The former study used relatively shallow flows (0.044 m) and high velocities (2 m/s) in a 0.292 m-wide flume to achieve flow Reynolds numbers of around R = 4000. Eckelmann in contrast used comparatively slow flows (0.225 m/s) in a larger 0.5 m-wide and 0.85 m-deep flume with Reynolds numbers around R = 7000. Einstein & Li (1958) used oil with a kinematic viscosity of 66×10^{-6} m^2/s, while Eckelmann used a less viscous paraffin oil with a viscosity of 6×10^{-6} m^2/s, 6 times more viscous than water.

Bechert et al. (1992) constructed an oil flume 11 m long, with a cross section measuring 0.25 m wide by 0.85 m deep. The flume had a racetrack design with two propellers driving the 12×10^{-6} m^2/s white paraffin oil at velocities up to 1.2 m/s, giving flow Reynolds numbers up to R = 45,000. Coleman & Eling (2000) used a small-scale oil flume to study sand-wave generation in laminar flows. Flow depths ranged from 0.038 m to 0.068 m in the 0.1 m-wide flume, with Reynolds numbers typically less than 2000. Both Bechert et al. (1992) and Coleman & Eling (2000) highlight potential problems with air bubble generation, air bubbles tending to remain suspended in the flow, reducing visibility and affecting measuring equipment. Pilotti & Menduni (2001) also studied sediment transport in laminar and hydraulically-smooth turbulent flows using a 2 m long and 0.15 m wide flume, with a maximum flow depth around 0.02 m. The fluid used was a water-glucose solution, with kinematic viscosity adjustable in the range 1×10^{-6} to 281×10^{-6} m^2/s.

3.2 *University of Auckland oil flume*

A new flume has been constructed at The University of Auckland (Figure 1 capable of circulating viscous fluids at flow rates up to 80 litres/second. The glass-sided tilting flume has a width of 0.4 m, maximum fluid depth of 0.2 m and an open-channel section length of 10 m. A tank measuring 1.5 m long, 0.65 m wide and 1.6 m deep collects fluid at the downstream end of the open-channel section, and a twin-screw positive-displacement pump returns the fluid via a 250 mm diameter pipe to the top end of the flume. The oil used is Shell Ondina 15, a white mineral oil with a density of $\rho = 850$ kg/m^3 and a kinematic viscosity of 36×10^{-6} m^2/s at 20°C. The flume is covered at all times to reduce contamination of the colourless and odourless oil. Heating elements in the tank connected to a thermostat allow the oil temperature to be varied between ambient (~20–24°) and 40°C, the kinematic viscosity varying according to Figure 2.

Initial trials with the flume showed that air bubble entrainment would be problematic when higher flow rates were used. The air bubbles were predominantly generated by strong surface turbulence in the collection tank where the flow reaches the end wall. The problem was sufficiently mitigated by installing a series of vanes (running parallel to the flow) in the tank in order to create drag and reduce flow velocity. At the end of the vanes, a double-cup-shaped curved section was installed to turn the flow away from the end wall and back down the sides of the tank, where it was separated from the incoming flow by the outer guide vanes. The writers note that Acoustic Doppler Velocimeters do not function in this oil, possibly because of attenuation of the 16 Mhz signal due to fluid compressibility.

4 PARTICLE IMAGE VELOCIMETRY

Particle Image Velocimetry is a non-intrusive velocity measurement technique where a video camera is used to capture images of small seeding particles added to the flow, the particles typically illuminated by a thin sheet of laser light. The recorded images are broken up into smaller interrogation regions, with particle motion between successive video frames analysed to provide an estimate of velocity at each interrogation region.

Light sheets can be produced by diverging a laser beam with a cylindrical lens when using pulsed lasers, where the light energy is confined to short duration pulses at regular intervals. When using continuous wave lasers however, a diverged light sheet often has insufficient intensity to capture flows of higher velocity, the comparatively longer exposure time required leading to blurring of the particle images. In the case of continuous wave lasers, the available light energy is more efficiently used by scanning the laser beam across the area of interest (Gray et al. 1991), confining the effective exposure time for a seeding particle to the time it takes for the beam width to scan across the particle.

Single-pulsed and double-pulsed lasers have limited flexibility in the range of inter-pulse times that they can produce, essentially limiting the range of flow velocities that can be resolved. This problem is often addressed by using two pulsed lasers, the time between successive laser pulses then easily adjusted to suit the flow conditions. Commonly-available pulsed lasers, however, typically have pulse repetition rates <50 Hz, which can be insufficient to resolve the smaller time scales in turbulent flows. When using a scanning beam system, higher sampling frequencies are possible, while maintaining the flexibility of more costly twin pulsed laser setups.

The University of Auckland PIV system uses the scanning beam technique to generate up to 200 PIV images per second. The beam is scanned using a GSI Lumonics VM500 galvanometer with a 6 mm clear aperture silver-coated mirror in combination with a parabolic mirror as shown in Figure 3. A Miniature Single Axis (MiniSAX) servo amplifier drives the galvanometer, continuously monitoring and updating the mirror position (within an angle of $\pm 10°$ relative to the reference position) to match the command waveform generated by an SC2000 Digital scanning controller, which connects to a computer via an RS-232 serial interface.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The computer-created command waveform is generated using simple control statements such as "Slew 16383 130", which tells the scanner mirror to move to position 16,383 angle units (approximately 10°) over time period 130 time units (approximately 3 ms). A complete waveform is generated by combining a series of commands, which can then be uploaded to the SC2000 controller, where it continuously loops the commands without further interaction with the computer. Commands can also be used to set sync pins on the SC2000 controller to high or low at particular positions in the scan cycle, or the galvanometer can be commanded to wait for a change in state of a sync pin before continuing the scan cycle. These sync pin commands are used in the present system to synchronise the scanning mirror to the camera system.

The camera system consists of a Basler A504k camera, a Coreco X64-CL frame grabber, and Streampix image-capture software. The camera is a 1280 × 1024 pixel, 8bit, monochrome digital camera, with a CMOS sensor capable of capturing a maximum of 500 full resolution images per second. The frame grabber has 128 MB of on-board frame buffer memory and sits on a 64bit/66 MHz PCI bus that supports data rates of up to 528 MB/s. The Streampix software, developed by Norpix, allows image data to be streamed directly to hard disk drives (6 × 18 GB 15 k RPM SCSI drives attached to an Intel SRCU42X PCI-X raid controller for the present system) in the host PC. The present drives, configured as a Raid-0 array, support a sustained transfer rate of 200 MB/s across the entire 108 GB of storage space. When operating at a resolution of 960 × 960 pixels and a frame rate of 200 frames per second (fps), there is sufficient storage space to allow for over 8 minutes of continuous recording.

To capture single-exposure images for cross-correlation, it is necessary to have a single scan of the galvanometer for each camera frame, with the galvanometer retrace positioned between camera exposures. Two synchronisation options are available depending on the time required between successive exposures, which is a function of flow velocity. For interframe times equal to the inverse of the camera frame rate, the "galvanometer master" timing shown in Figure 4a is adopted, which allows for interframe times down to 5 ms (for a maximum video streaming rate of 200 fps). For higher flow velocities, the "camera master" timing shown in Figure 4b is adopted, which uses frame straddling to give an effective interframe time of 2.5 ms.

The "galvanometer master" timing uses a sync pulse generated by the scan controller to trigger the camera. As illustrated in Figure 4a, the position of the galvanometer mirror lags the command waveform by 0.5 ms due the finite torque of the galvanometer and the rotational inertia of the mirror. To compensate for this lag, the sync pulse is delayed from the start of

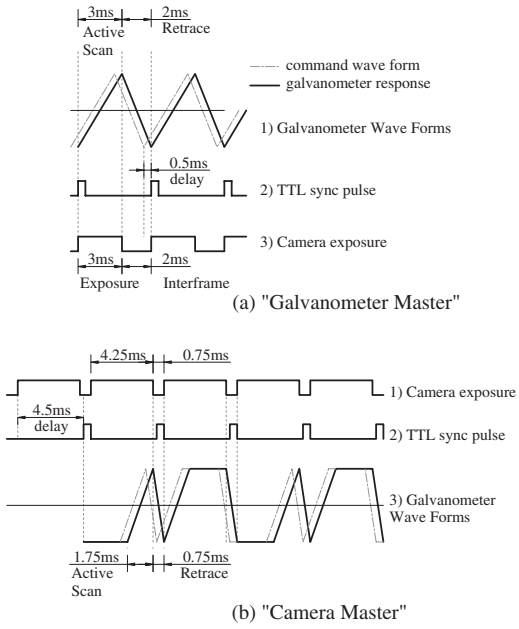

Figure 4. Lightsheet-camera synchronisation options.

the command waveform by 0.5 ms using the built in command set for the scan controller. For the present work, a typical example of this timing (which can be varied to suit the measured flow field) is for the camera to run in an external sync mode, capturing a 3 ms exposure (corresponding to the active scan time of the galvanometer) at each sync pulse.

The "camera master" timing uses a sync pulse generated by the frame grabber to trigger the galvanometer. The camera is set in a 200 fps free-run mode with an exposure time of 4.25 ms. The sync pulse is positioned 4.5 ms after the start of a camera frame or 0.5 ms before the start of the next frame (accounting for the lag of the galvanometer). After receiving the sync pulse, the galvanometer runs a sequence of "idle-active scan-retrace", waits for another sync pulse, and then runs the sequence "active scan-idle-retrace", positioning one active scan at the end of one frame and another at the start of the next. The idle setting corresponds to the galvanometer mirror being parked at either extreme of the scan range where the laser beam is blocked from leaving the scanning beam box (Figure 3). Galvanometer retraces are positioned between camera exposures.

5 PARTICLE-ENTRAINMENT STUDIES

For the present study, the length of the flume is covered in a single layer of 11 mm nominal-diameter glass balls in a hexagonal close packed arrangement and

Copyright © 2006 Taylor & Francis Group plc, London, UK

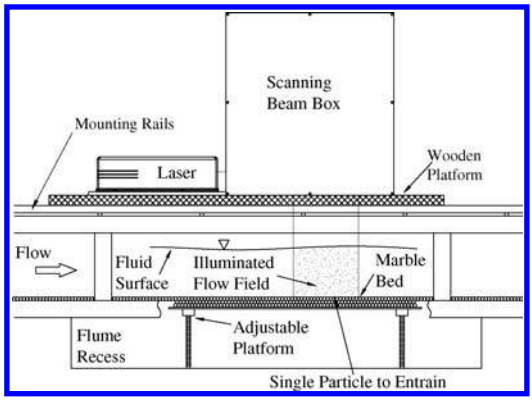

Figure 5. Experimental setup.

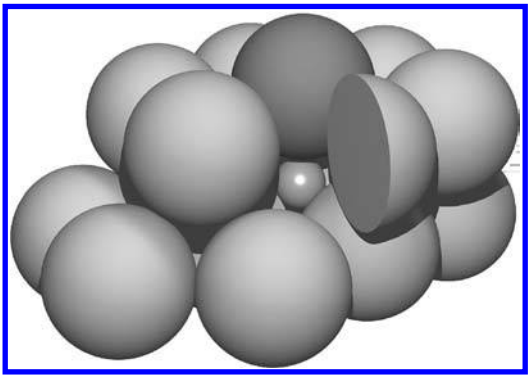

Figure 6. Sphere stacking.

glued to Aluminium sheets along the bed of the flume. Over a length of 1 m in the flume recess (Figure 5), the glass balls are increased to 3 layers deep to more accurately reflect pore flow conditions that might be expected in natural sediments. A removable section 19 ball diameters long, 4 wide and 2 deep in the test section is constructed of precision 11.11 mm black glass spheres. The black glass reduces the reflection and scatter of the laser beam giving more suitable conditions for near-bed PIV measurements. One sphere position in the centre of the removable section is left empty for the target particle of the entrainment experiments to sit. The protrusion of this particle can be adjusted in discreet steps by placing a smaller steel ball into the cavity before placing the target particle on top (Figure 6), the protrusion above the surrounding particles varying according to the diameter of the steel bearing as shown in Table 1. The target particle has a diameter of 11.11 mm and is made of Nylon with a density of 1150 kg/m^3 ($S_s = 1.35$). Equation 3 indicates that entrainment of the 11 mm Nylon particle in the 27×10^{-6} m^2/s oil is equivalent to entrainment of a 0.74 mm quartz ($S_s = 2.65$) sediment in water.

Table 1. Sphere protrusion for different steel-ball diameters.

Steel ball diameter mm	P mm	P_{vb} mm
3.2	1.2	3.4
3.5	1.8	4.0
4.0	2.5	4.7
4.5	3.2	5.4

where: P = protrusion above surrounding particle tops, P_{vb} = protrusion relative to the virtual bed $0.2d$ below particle tops, e.g. Fenton and Abbott (1977).

Each experiment begins by setting the target bed particle at the required protrusion, and adjusting the flume slope to give uniform flow at the expected entrainment flow rate. The flow rate is initially set to just below the threshold level and any transient effects associated with flow rate adjustment allowed to dissipate. The PIV system is then started and the flow rate increased in small increments every 2 minutes until the particle is entrained.

Recorded images are processed using an iterative cross-correlation technique with discrete window shifting. The window-shifting technique, where the location of the second interrogation window is offset with respect to the first, improves correlation peak height, as fewer particles leave the interrogation region between exposures, and permits resolution of larger particle displacements, which are limited to less than half the interrogation region size with basic cross-correlation. Our typical analysis uses a 64×64 pixel interrogation window without window shifting for the first pass, reducing to 32×32 pixel for the second pass with a window shift according to the displacement determined from the first pass.

The position of the target particle is detected at the same time as cross-correlation processing of flow velocities using a technique similar to the intensity-gradient-based Canny Edge Detector (Canny 1986). The first step in the edge-detection process is to apply a Gaussian blur to the source image to reduce background noise (Figure 7a). The horizontal and vertical intensity gradients of the blurred image are then estimated by convolving the image with the Sobel operator defined in two orientations, Gx and Gy (Figure 8), which respond optimally to vertical and horizontal edges respectively. In essence, both orientations of the Sobel operator are swept across all pixels in the image, combining surrounding pixel grey levels to a give a modified value for the central pixel. The absolute magnitude of the intensity gradient (G) and the gradient direction θ can then be approximated at each pixel location using Equations 4 and 5 (Figures 7b, c). Candidate edges, defined by pixels with intensity gradients above a threshold level, are usually several pixels thick

due to the applied Gaussian blur and the width of the Sobel operator. The thickness of these edges is reduced using a process called Non Maximum Suppression (NMS), where pixels having intensity gradients that are not a local maximum in the direction perpendicular to the edge are suppressed, reducing candidate edges to one pixel wide. The final step in the edge-detection process is to remove lower particle edges (assessed from the gradient direction) and to trace along all remaining edges, determining their length and selecting the longest as the top edge of the target particle. A parabola is then fitted to the highest 10 rows of pixels on the edge, and the horizontal and vertical coordinates of the peak point calculated.

$$|G| = |Gx| + |Gy| \tag{4}$$

$$\theta = \tan^{-1}\left(\frac{Gy}{Gx}\right) \tag{5}$$

6 RESULTS

For the four protrusions tested (Table 1), double-averaged (in time and space) streamwise velocity ($\langle\bar{u}\rangle$) profiles at threshold conditions are shown in Figures 9

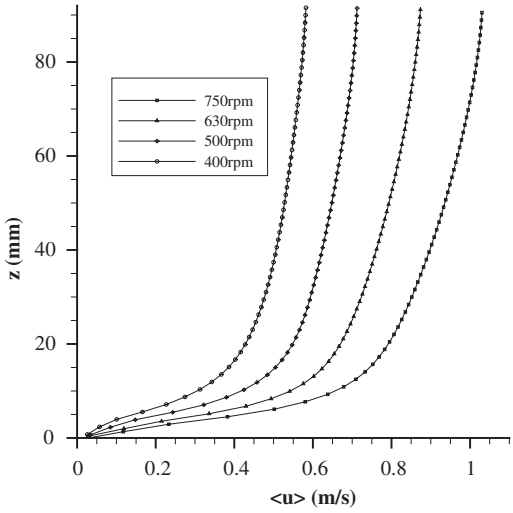

Figure 9. Double-averaged velocity profiles.

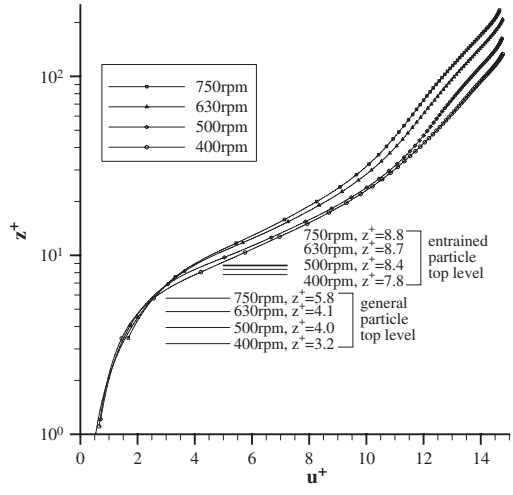

Figure 10. Dimensionless velocity profiles, where: $z^+ = zu_*/\nu$ and $u^+ = \langle\bar{u}\rangle/u_*$

and 10. In each case, the spatial-averaging window used extended over 10 particles, with the vertical origin at the virtual-bed, $0.2d$ below the surrounding particle tops. Below particle tops, $z^+ = zu_*/\nu = 3.2 - 5.8$, averaging was carried out over the fluid volume. Figures 9 and 10 show classic near-bed profiles, with particle tops generally within the laminar sublayer, and the top of the entrained particle at the lower extent of the buffer layer.

Figure 11 illustrates the time-averaged flow patterns for the case of the target particle protruding 3.2 mm above the tops of the surrounding particles ($P_{vb} = 5.4$ mm). Of particular interest is the area of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

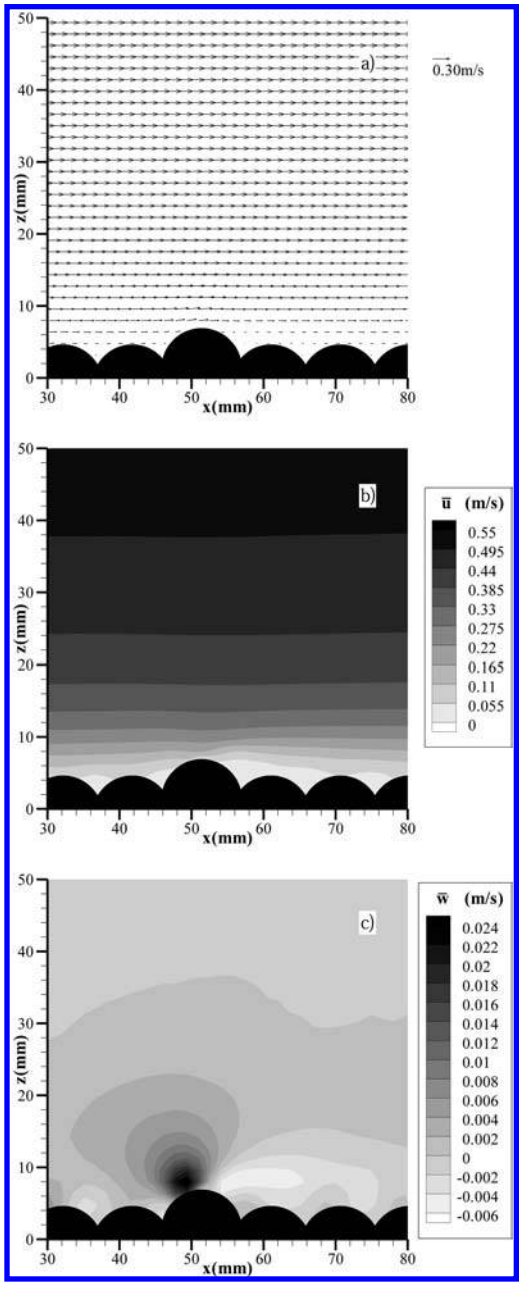

Figure 11. Time-averaged flow field for particle protruding 3.2 mm above tops of surrounding particles ($P_{vb} = 5.4$ mm): (a) velocity vectors, (b) ū contours, (c) and w̄ contours. Bed origin is the image base level.

flow field affected by the protruding particle, extending more than 5 times the protrusion in the upstream and vertical directions and 10 times the protrusion in the downstream direction.

Table 2. Flow properties at threshold protrusion.

Pump rpm	P_{vb} mm	H m	U m/s	R	u_{*c} m/s	u_c/u_{*c}	R_*
750	3.4	0.132	0.91	10690	0.070	10.6	27.7
630	4.0	0.131	0.77	9422	0.059	11.2	24.6
500	4.7	0.129	0.63	7299	0.048	10.8	17.3
400	5.4	0.129	0.50	5793	0.039	10.8	14.4

where: $\nu = 27 \times 10^{-6}\ m^2/s$, P_{vb} = protrusion relative to the virtual bed, H = flow depth, U = depth-averaged velocity, $R = UH/\nu$ = flow Reynolds number, u_{*c} = critical shear velocity, u_c = critical local velocity, $R_* = du_*/\nu$ = particle size Reynolds number.

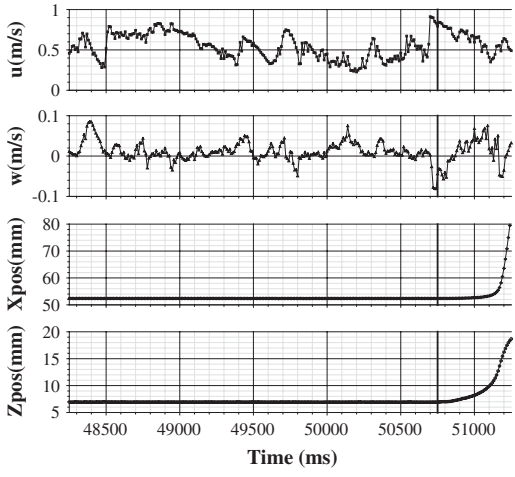

Figure 12. Time series showing velocity components (u & w) and particle position (Xpos & Zpos) for $P_{vb} = 3.4$ mm. Darkened vertical bar at Time = 50,750 ms marks the start of particle movement.

Flow properties for the each of the four tested particle protrusions are summarised in Table 2.

Figure 12 shows time series of streamwise and vertical flow velocities extracted from a point 4.5 mm upstream and 2.5 mm above the top of the target particle, which in this case protrudes 1.2 mm above the tops of the surrounding particles ($P_{vb} = 3.4$ mm). Apparent from the diagram is a period of higher than average streamwise velocity combined with negative vertical velocity (a 4th-quadrant sweep event) peaking just prior to the marked onset of particle motion. The apparent delay (around 50 ms in Figure 12) between peak streamwise velocity and detected particle movement may be accounted for by the upstream/elevated location of the interrogation region and the time it takes for the velocity peak to reach the lower fluid layers closer to the particle. The initial particle displacement between measurement intervals (every 10 ms) is

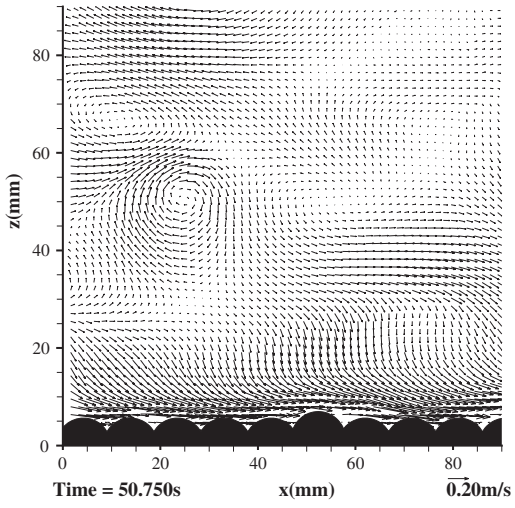

Figure 13. Vectors of $u' = u - \bar{u}$ and $w' = w - \bar{w}$ at the time of entrainment for $P_{vb} = 3.4$ mm. Mean flow is from left to right. 1 mm = 2.6 wall units.

also very small (~0.01 mm) making it difficult to pinpoint the exact, at this fine resolution, moment of the initiation of particle movement.

The u' and w' vector field shown in Figure 13 corresponding to the time of first-detected particle movement (Time = 50,750 ms) for the same experiment as Figure 12 confirms the entraining sweep structure to be present over a bed area greater than the 90 mm window size, and to extend vertically for approximately 10–20 mm (26–52 wall units). The sweep structure may be consistent with down-flow to the side of a streamwise-orientated vortex (e.g. at the outside of the leg of a stretched hairpin-vortex), or between a pair of counter-rotating vortices, but improved interpretation requires full 3d flow-field information, ideally, or in the absence of this, greater numbers of captured particle- entrainment events.

Figures 14 and 15 present velocity time series (aligned with entrainment at Time = 0) averaged over eight repeat runs of the four protrusions tested (Table 2). The series in each figure are offset vertically to aid clarity. These figures highlight a consistent entrainment process, with a positive spike in horizontal velocity and a negative spike in vertical velocity (i.e. a sweep), although the latter is less clear for the entrainments at larger protrusions and lesser R_*.

The path followed by the particle after the initial movement is illustrated in Figure 16a for the case of a 1.2 mm protrusion above the tops of the surrounding particles ($P_{vb} = 3.4$ mm), and in Figure 16b for a 3.2 mm protrusion ($P_{vb} = 5.4$ mm). For the high protrusion case, the particle appears to roll out of the cavity, maintaining contact with the bed until it

bounces off a downstream particle, then gaining elevation and being carried some distance downstream before regaining contact with the bed. The lower protrusion particle, while still rolling out of the cavity, has sufficient lift force and momentum to leave contact with the bed after clearing the cavity.

In future experiments, we plan to extend the current methodology to visualise entrainments over a wide range of grain-size Reynolds numbers by varying particle density, fluid viscosity and particle size. Of particular interest will be whether the sweep structure identified in the experiments to date (Figures 12–15) remains the dominant entrainment mechanism for hydraulically smooth and rough flows. Also of interest is whether particles can be entrained for laminar flows, and implications of this to understanding of entrainment mechanics.

7 CONCLUSIONS

A series of experiments has been conducted in an oil flume to study the flow field near sediment particles leading to particle movement. The higher viscosity of the oil ($\nu = 27 \times 10^{-6}\,\mathrm{m^2/s}$) compared to water ($\nu = 1 \times 10^{-6}\,\mathrm{m^2/s}$) enhances length scales, enabling 0.74 mm quartz sediment in water flows to be modelled with 11 mm diameter nylon particles in the oil, effectively improving measurement resolution for the near-bed flow. A particle image velocimetry (PIV) system employing the scanning-beam technique of light sheet generation was used to measure streamwise and vertical velocities in a 2d slice of the flow field at a frequency of 100 Hz. Experiments focused on the entrainment of a single 11 mm diameter Nylon particle of varying protrusion set in a bed of tightly-packed, co-planar, 11 mm diameter marbles. Time series of near-particle velocity for the four protrusions considered (3.4–5.4 mm above the virtual bed), consistently show a period of high streamwise velocity, often accompanied by downwards flow, immediately prior to entrainment. Flow field vector maps indicate a sweep structure over and around the target particle to be the cause of entrainment. This mechanism is consistent with drag and lift forces both scaling with the square of streamwise velocity. The motion of particles as they are entrained and carried downstream can be tracked from the PIV images using an edge-detection algorithm, potentially enabling measurements of particle velocity and acceleration as it is entrained. Double-averaged (in time and space) streamwise velocity profiles confirm the deepened nature of the near-bed viscous sublayer and buffer regions of the present turbulent flows. Future experiments will extend the same experimental techniques to hydraulically smooth and rough turbulent flows, as well as laminar flows, by varying particle size, particle density and fluid viscosity.

Bed load fluctuations and channel processes in a braided network laboratory model

Walter Bertoldi, Thomas Amplatz, Stefano Miori, Luca Zanoni, Marco Tubino
Department of Civil and Environmental Engineering, University of Trento, Italy

ABSTRACT: Braided networks are characterized by multiple and different temporal and spatial scales. In order to understand their evolution mechanisms and to improve our predicting ability it is relevant to recognize these scales and to relate them to different channel processes. In this work we present the results of detailed observations performed on a braided network scale model within a 2.9 *m* wide laboratory flume, with movable bed made of a well sorted quartz sand. Measurements comprised the survey of bed topography through laser scanning device, the image analysis of the planimetric configuration and the continuum record of sediment transport rate. We focussed our attention on the fluctuations of the sediment transport rate, which are mainly determined in braided streams by the over-reaction of the sediment flux to the bed morphology. Therefore, they may be seen as an indicator of the inherent unsteadiness of the evolution process of the network.

Previous studies pointed out the presence of various temporal scales, which were related to various processes like bedforms migration and network rearrangement (see for example Ashmore 1988 and Hoey and Sutherland 1991). The Fourier analysis of time series of sediment transport data allowed us to provide a detailed measure of the above scales. In particular, three different timescales could be detected in our experiments. The first scale mainly characterizes the initial stage of network development and it is related to the migration of bars in individual distributaries. The other two scales, which correspond to shorter frequencies, seems to be related to the migration of the nodes (bifurcations and confluences) and to the overall rearrangement of the network, which mainly occurs through the lateral shift of the main channel.

1 INTRODUCTION

The relationship of sediment transport and channel morphology is a key feature of braided networks. As pointed out by Murray and Paola (1994) and Paola (2001), the strongly unsteady character of these systems is inherently related to the over-reaction of the sediment flux to bed changes and to the longitudinal variation of the geometrical properties of the network (total free surface width, number of channels, mean bed elevation, …).

Previous experimental works have highlighted the existence of different spatial scales in braided networks. Suitable indexes have been identified (such as the mean width of the belt, the link length, the braiding index,…) through which a static description of the network can be given (Ashmore 2001). Similarly, bed load fluctuations have been widely documented, along with the occurrence of bed waves with different length-scale, and their relationship with the morphology of the channels has been pointed out (see for example Hoey 1992).

Ashmore (1988) has analyzed bedload fluctuations in a laboratory model of a braided network, showing that the autocorrelation of the sediment transport rate may decay relatively fast (about 30 minutes), though in many experiments a peak was detected at higher lags (from 5 to 10 hours). However, the above phenomenon has not been observed to show a high degree of regularity. Therefore it was not clear whether it could be related to morphological characteristics, though a possible relationship of long scale fluctuations with the aggradation and degradation phases of the whole network has been identified, at least qualitatively.

Analyzing the variability of the sediment transport and the possible relationship with channel morphology, Hoey and Sutherland (1991) have found that a correlation can be established in terms of the capacity of the cross section to store sediments. Consequently the occurrence of bed pulses has been qualitatively referred to the three-dimensional structure of the network. Furthermore, through the analysis of 11 experiments starting from the same initial condition, Warburton and Davies (1994) have attempted to relate

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 1. General overview of the laboratory model, flow is from bottom to top (run P7A).

the observed differences in mean bedload transport rate to the braiding index. A weak relationship of braiding intensity and transport rate has been clearly detected only for a timescale of the order of 10 hours, which agrees with the observations of Ashmore (1988).

In this work we have pursued the attempt of defining quantitative relationships of the bed and channel evolutionary processes and the bed load fluctuations measured in a braided network scaled model. Laboratory modelling is a suitable tool to investigate the intrinsic evolutionary scales of braided patterns, since the feeding conditions can be regulated; furthermore, the planimetric and altimetric configuration of branches and the sediment transport flux can be measured with high detail and accuracy. A snapshot of the braided network is given in Figure 1. The records of the outgoing sediment transport flux have been processed through a Fourier transform procedure in order to identify the dominant frequencies of the sediment transport fluctuations. These have been then related to the timescales of the main processes that determine major changes of network morphology, namely the formation and migration of bar fronts, the creation and destruction of bifurcations and confluences, and the shift of the main channels within the braided belt.

The experimental setup and the data analysis procedure are described in the next section, where the dominant frequencies of bed load fluctuations are determined through a Fourier analysis. The resulting timescales are then compared with those typical of the morphological processes occurring in the network.

2 EXPERIMENTAL SET UP AND PROCEDURE

The experiments have been performed on a large laboratory flume, 25 m long and 3.14 m wide, constructed in the Hydraulic Laboratory of the University of Trento. In the flume a 24 m long and 2.90 m wide floodplain of well-sorted quartz sand is set up, characterized by a mean diameter d_s of 0.63 mm and a relative density Δ equal to 1.63. Water and sediment discharges can be automatically regulated by a software, such that both steady and unsteady incoming conditions can be simulated. At the upstream end of the flume the kinetic energy of the incoming flow is dissipated by a 1 m long basin. At the downstream end a chute conveys both the liquid and solid flux in a submerged tank, where the sediment transport rate is measured. The water is recycled by a submerged pump, controlled by an inverter. The sand is supplied by a volumetric sand feeder at the upstream end of the flume through three rotating screws and a diffuser. The open circuit supply system allows one to obtain a precise input, particularly for relatively low sediment rates.

Bed topography has been surveyed by a laser profiler supported by a carriage mounted on a high accuracy rail system. The carriage and the laser are both automatically controlled by software. Bed elevation has been measured on a regular grid, with longitudinal spacing of 10 cm and transverse spacing of 1 cm. Another movable carriage supporting a digital camera located 4 m above the sand bed has been used to provide a regular photographic monitoring of the evolution of the channel planform, through a series of vertical images. Moreover, other digital cameras have been used to get an overall view of the floodplain or to survey specific processes (like node evolution) with higher detail.

The system has been freely run to generate a braided network, subject to a constant water and sediment supply. Each run has been performed starting from a topographic configuration made up by a single straight channel cut on the flat sand surface, which has been initially levelled at a prescribed slope. The geometry of the channel has been selected in order to ensure bankfull conditions, with an initial width to depth ratio equal to 10, i.e. lower than the threshold value for alternate bar growth (see Colombini et al. 1987).

13 experimental runs have been performed, with different values of longitudinal slope S and water discharge Q. The sand has been supplied according to the bed load transport capacity of the channel and ensuring a mass balance between the input and the output. The initial conditions have been chosen in order to reproduce values of the Shields stress typical of gravel bed braided rivers.

In Table 1 the parameters characterizing each run are reported. S is the initial slope, Qs^{IN} is the incoming sediment discharge, b_o is the channel width, D_o is the flow depth, ϑ_o is the Shields parameter, $\Omega = \gamma QS$ is the stream power, where γ is the specific weight of water (the subscript $_o$ denotes the initial reference values of

parameters). Moreover Qs^{OUT} is the mean outgoing sediment transport rate.

The total duration of each run has been set depending upon the morphologic activity of the network. It ranged between 30 and 110 hours. During each run we have monitored the solid discharge at the downstream end of the flume, measuring the weight of the sand cumulated in a submerged tank, held up by four load cells.

The acquisition time interval has been set equal to 1–5 minutes. The minimum recording interval is imposed by the accuracy of the load cell and the amount of transported sand. The planimetric configuration of the network has been reconstructed through 15 vertical images that have been then stitched and scaled. The images have been processed to obtain information on the width of the braid belt and of the single channels, the number of branches, their length, the number and position of the morphological active channels, the characteristics of the bifurcations.

3 DATA ANALYSIS

In order to investigate the timescale of the bed load fluctuations we have used a Fourier transform analysis. In spite of the complexity of the signal and of the presence of irregular time fluctuations such analysis has provided reasonably good results.

A first analysis performed on the rough data has highlighted the existence of dominant harmonics, though the signal displayed a high degree of irregularity. Therefore we have decided to pre-process the data and to select suitable, albeit shorter, data record.

The signal has been smoothed with a moving average procedure based on 5, 10 and 30 minutes intervals. Such procedure returned a more clear signal, where the fluctuations with a timescales of the order of few hours have been detected more easily: the Fourier spectrum shows in this case the presence of more distinguishable dominant harmonics.

These fluctuation frequencies have been then checked and more precisely defined by a further step. The Fourier analysis has been carried out on a 'window' of data, that moves along the whole data set. The length of the window, i.e. the number of data on which the Fourier transform has been applied, has been defined as a n-multiple of the timescale previously found. In this way it has been possible to assess the regularity of the signal and to single out ranges of data characterized by a more clear spectrum, where the oscillation can be more easily detected.

The evaluated timescales for a selection of experiments are reported in Figure 3 (only few values are plotted to keep the readability of the figure). The above analysis provides for each run an evaluation of the wavelength of the dominant harmonics, however a general behaviour can hardly be detected. Figure 3 shows the presence of different fluctuations scales, ranging from tens of minutes to few hours. The question then arises whether the occurrence of different timescales can be the results of a non linear interaction among various processes, such to produce a cascade of oscillations. On the other hand, as the sediment transport is intrinsically related to the altimetric and planimetric development of the channels, distinct fluctuations and precise timescales can be determined by the evolutionary scales of the network. In this respect it is worth noticing that theoretical and experimental research on the unit processes of braiding (Bolla Pittaluga et al. 2001) has pointed out the existence of defined timescales of some of the recurring processes.

For example a well known phenomenon is the occurrence of migrating bed waves. According to the

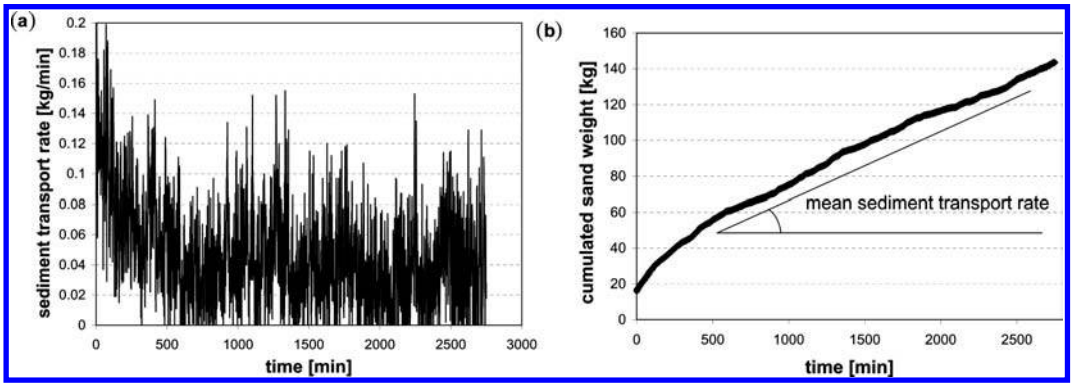

Figure 2. (a) sediment transport rate as a function of time; (b) cumulated weight of transported sand (run P4B).

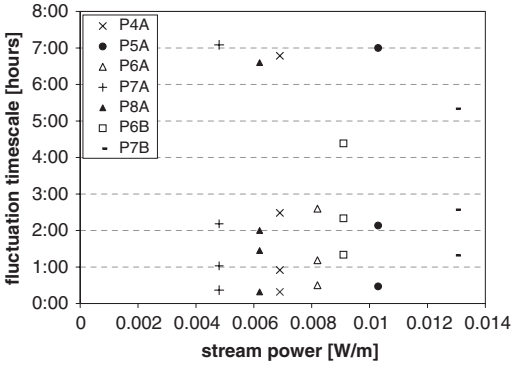

Figure 3. Some examples of different timescales of sediment transport fluctuations.

weakly non linear theory of Colombini et al. (1987) it is possible to determine the migration speed of the alternate bars, that have been invariably observed to form throughout the whole runs. In our experiments, bars have been found to migrate with a period of approximately 30 minutes. Analogous estimates have been obtained in previous experiments where alternate bar developed in a single almost straight channel (see Bertoldi et al. 2005).

The problem of the temporal evolution of a Y-shaped bifurcation has been tackled recently through theoretical (Miori et al. 2006) and experimental works (Bertoldi et al. 2005). They have shown that a bifurcation evolves toward an unbalanced equilibrium configuration, in which the downstream distributaries are characterized by an uneven flow and sediment distribution. Furthermore the process seems to be regulated by an intrinsic timescale, which is typically much smaller than the morphological timescale which is required to adapt to the influence of downstream boundary conditions.

Hence, though the dominant harmonics we have detected can not be accurately resolved, it is reasonable to consider that they reflect different planimetric and altimetric processes that concur in the evolution of the network.

4 BED LOAD TRANSPORT RATE ANALYSIS

Figure 2 shows an example of the measured bed load transport rate (run P4B). In Figure 2(a) the sediment discharge (averaged over 5 minutes interval) is given as a function of time while in Figure 2(b) the cumulated transport rate is reported. The analysis of the bed load transport rate data shows that it is possible to distinguish an initial period in which the sediment transport is more intense. This is due to the higher bed load transport capacity that characterizes the initial straight channel, which decreases when the width and the number of branches increases. The plot of the cumulated sediment transport (Figure 2b) shows that, after the first hours, the total sand weight increases almost linearly, with a constant slope, which changes in each run. In these conditions we can consider the network to be fully developed and in equilibrium with the upstream sand feeding. The mean values and the amplitude of the fluctuations reported in the following plots have been computed with reference to this period of dynamic equilibrium.

In Figure 4 we report the mean sediment transport rate for each experimental run as a function of the stream power. The values follow a power law relationship with an exponent equal to 1.54. Figure 4 also shows the minimum and the maximum transport rate, averaged over an interval of 30 minutes, for each run. The values range from 0 to about 3–4 times the mean value and the amplitude of the fluctuations increases for larger values of the stream power. The high variability highlighted by this analysis, though data are averaged on a quite long interval, points out the complexity and, in some cases, the randomness of field measurements of bed load transport.

Copyright © 2006 Taylor & Francis Group plc, London, UK

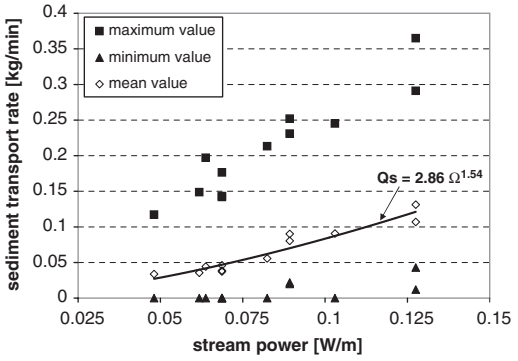

Figure 4. Minimum, mean and maximum sediment transport rate as a function of the stream power for each experimental runs (data are averaged on 30 minutes interval).

In order to compare the data with other experimental results we have introduced two dimensionless parameters, that account for the effect of mean sediment diameter. Both the sediment transport rate and the stream power have been divided by the sediment transport scale and by the flume width B_f as follows:

$$\phi = \frac{Q_s}{B_f\sqrt{g\Delta d_s^3}}, \qquad \omega = \frac{Q \cdot S}{B_f\sqrt{g\Delta d_s^3}}, \tag{1}$$

where g is gravity.

In Figure 5 a comparison between present results and data obtained by Ashmore (1988), Young and Davies (1990), Hoey and Sutherland (1991) and Warburton and Davies (1994) is reported. A similar behaviour is exhibited in all cases, with an average exponent of the power law ranging about 1.8. Some runs display a lower sediment flux, but this could be due to the choice of the flume width B_f as the scale of the experiments, since the active width of each run can not be easily determined in previous works.

As pointed out before, the temporal series display a wide range of fluctuations, characterized by different timescales (see Figures 2a and 3).

In the following plots we report some examples of the bed load transport rate fluctuations and the results of the Fourier analysis in terms of the timescales as a function of the stream power. The main harmonics (reported in Figure 3) can be divided in three groups, with characteristics frequencies and similar amplitudes: a short timescales with a period of 20–30 minutes, two medium fluctuations characterized by a period of 1–2 hours and a longer oscillation with a period ranging about 4 to 8 hours.

The shorter timescale (see Figure 6) is comparable with the autocorrelation time of the sediment transport measures found in previous laboratory investigations (e.g. Ashmore 1988 and Hoey and Sutherland 1991).

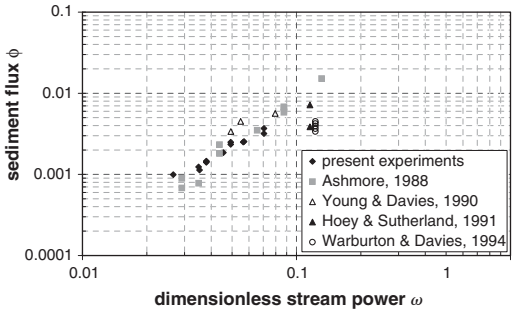

Figure 5. Comparison of mean sediment flux for different experimental works as a function of the dimensionless stream power ω.

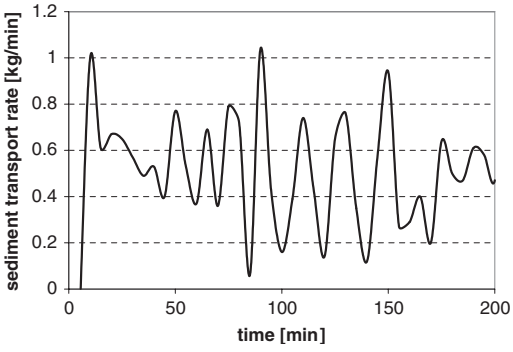

Figure 6. Typical bed load fluctuations determined by the migration of alternate bars (run P4A).

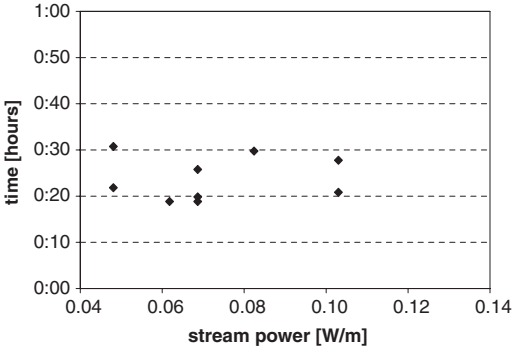

Figure 7. Short term timescale for each experimental runs.

In these series of runs this fluctuation is clearly distinguishable in the first hours, when the planimetric configuration is still characterized by the presence of a single channel, but it is also present during the whole run, superimposed to the other fluctuations.

In Figure 7 we report the computed short timescale for each experimental run. The period is quite constant

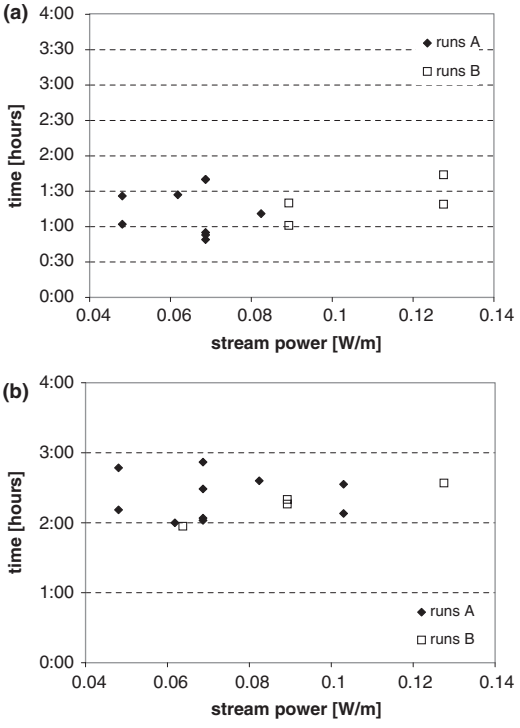

Figure 8. Medium bed load fluctuations timescale evaluated for each run.

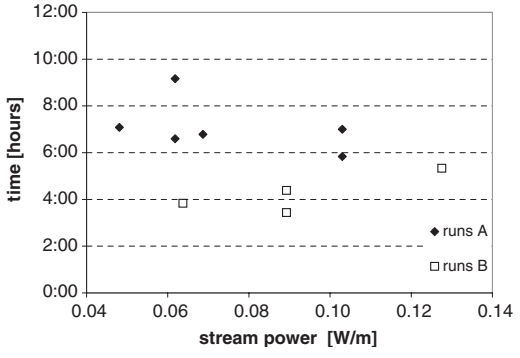

Figure 9. Long bed load fluctuations timescale evaluated for each run.

and does not seem to be strongly affected by the different water and sediment supply.

The two 'medium' timescales range respectively from 1 to 1.5 hours and from 2 to 3 hours. In Figure 8 the obtained values are reported as a function of the stream power Ω. Furthermore Figure 10(a) shows an example of the medium term bed load fluctuations: these oscillations are more clearly detectable on the record of data averaged over 30 minutes interval.

In Figure 10(b) the sediment transport rate is plotted for an interval of about 15 hours. It is possible to notice four subsequent phases of high sediment discharge, characterized by similar frequencies, even if the shape and the amplitude are not regular. This is an example of the long term bed load fluctuations that we have detected through the Fourier analysis. We may notice that the above timescale can be hardly singled out, because of the interference of the other scales on the signal. Figure 9 shows the result of the bed load data records analysis, in terms of the long term dominant harmonic of the Fourier spectrum. This timescale is characterized by a higher variability, since its values range between 4 and 7 hours. This variability can be due to the different configuration of the branches in the runs with a longitudinal slope of 0.7% and 1.3% (see next Section).

5 BED LOAD FLUCTUATIONS AND CHANNEL PROCESSES

In this Section we try to relate the timescales of the bed load fluctuations to the braided network evolution, characterized by the migration of bed forms and by the change in the number and relative position of the branches. The analysis is based both on the detailed topographic data collected in present experiments and on the results of recent investigation carried out on the bifurcation process (see Tubino and Bertoldi 2006).

The short term fluctuations can be related to the formation of migrating bars, that induces regular bed load waves. This phenomenon is more evident in the first phase of the run, when no other channel process influences the sediment transport, but it occurs also when the network is fully developed. In particular we observed the formation of migrating bars when the network is subject to a degrading process. In this case the high erosion rate determines a more intense sediment transport, that gets organized in the form of alternate bars. Moreover, in the degrading phases the network displays a more simple structure, consisting of few branches displaying an almost straight pattern.

The analysis of the vertical images taken on regular intervals allows for an estimate of the migration period of the alternate bars. The measured time step between the transit of two subsequent bars corresponds with high accuracy to the observed short bed load fluctuations timescale. The existence of this short term fluctuation, along with the observation that the correlation time of the sediment transport rate is of the order of 20–30 minutes (Ashmore 1988; Hoey and Sutherland 1991) points out that the movement of sediment in a gravel bed braided stream is generally organized in the form of migrating bars.

The medium and long term oscillations have been related to the planimetric evolution of the network and

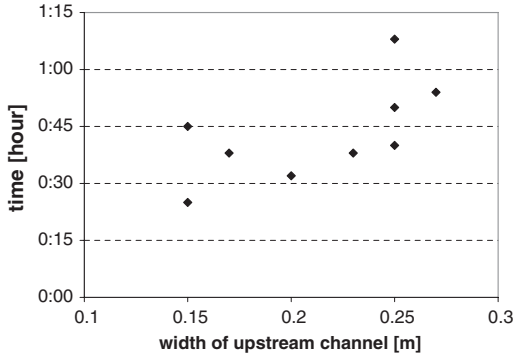

Figure 11. Timescale of bifurcation evolution.

in particular to the processes governing the dynamics of the nodes and of the main branches in the network.

A bifurcation is likely to assume an unbalanced configuration when the upstream channel is characterized by low values of the Shields parameter and relatively high values of the aspect ratio. These conditions are easily found in gravel bed braided networks and, as a consequence, the nodes are subject to a process that leads to the closure of one of the downstream distributaries. A bifurcation undergoing such evolution determines a fluctuation of the sediment transport rate, as far as the bed load capacity of one channel carrying the total discharge is different from that of two branches. In fact, the total sediment discharge of a symmetrical node in which the flow is equally distributed is generally lower than that of a strongly unbalanced bifurcation, with a large part of water and sand flowing in the main branch. Similarly, aggrading phases are associated with a high braiding intensity, whereas degrading periods are characterized by few incised channels.

We have analyzed the evolution of single bifurcations inside the network, measuring the time during which both the distributaries of a newly formed bifurcation are characterized by sediment transport, and consequently can be defined active in a morphodynamic sense. The results of this observation are reported in Figure 11, as a function of the width of the upstream branch. We have found that this scale ranges between 1 and 2 hours, in agreement with the experimental observation on Y-shaped bifurcations of Bertoldi et al. (2005). This timescale is quite close to the medium fluctuations highlighted through the Fourier analysis of the bed load transport rate.

The planimetric timescale of the network can be quantified in a different way taking into consideration the shift of branches inside the network. The lateral evolution of the main channel has been monitored by a detailed photographic survey. We have observed that the channel moves frequently inside the network, changing its position through two different mechanisms. Most of the time the main channel moves slowly, evolving like a weakly meandering channel that increases its axis curvature through the erosion of the outer bank. The second process, which seems to be peculiar of the dynamic rearrangement of braiding systems, is a rapid shift of the position of the main channel, that leads to a markedly different network configuration.

In Figure 12 we give an example of the lateral migration of the main branch just upstream of the downstream tailgate of the flume (run P8A). Experimental data suggest a strong correlation between high sediment transport phases and rapid migration of the main branch. On the other hand, low sediment transport rates are recorded when the active channels move slowly.

We have monitored the transversal location of the main channel in different cross sections along the

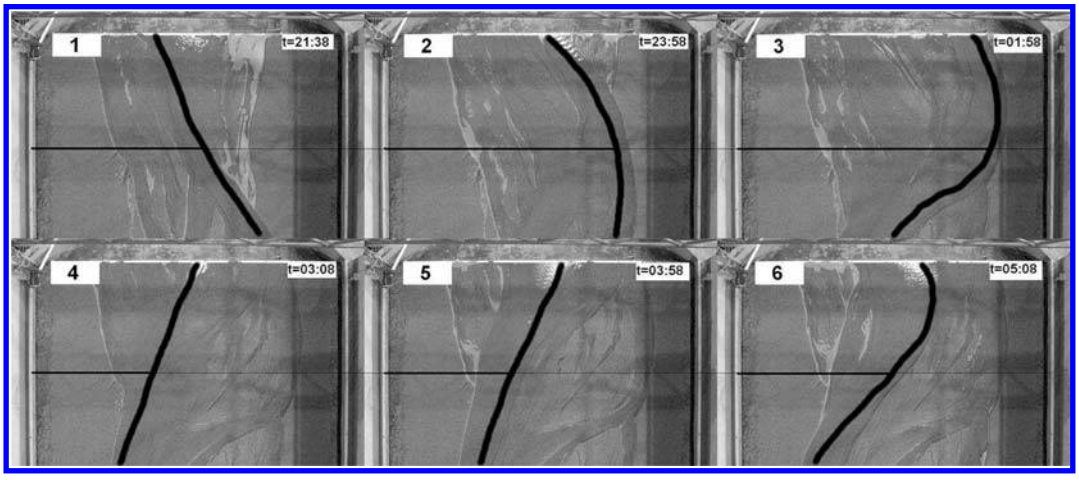

Figure 12. An example of the lateral migration of the main branch, flow is from bottom to top (run P8A).

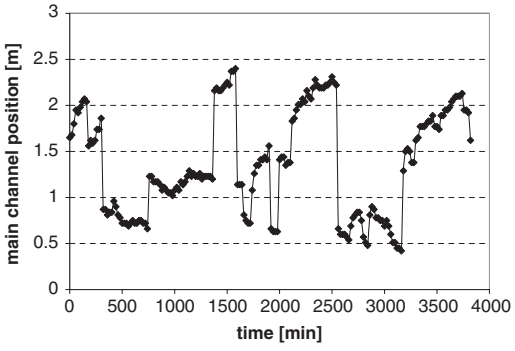

Figure 13. An example of the transversal fluctuations of the main branch (run P8A).

network (an example is reported in Figure 13). The time interval between two subsequent rapid shifts has been analyzed in order to obtain the corresponding timescale. We have found that it can be well represented by a log-normal distribution (reported in Figure 14). In particular we have measured a mean shift interval equal to approximately 100 minutes, that again correspond to the medium bed load fluctuations. The sudden movements of the main channel are actually determined by the modification of the flux distribution in an upstream bifurcation. Moreover, the data in Figure 14 display a not negligible probability of shift characterized by a timescale of 3–4 hours. As a result, the long term oscillations plotted in Figure 9 can be related to the sudden changes that determine a complete rearrangement of the network and the transition of the main branch from one side to the other of the flood plain. This process can be also influenced by the development of an axis curvature in the main channels. The different timescales evaluated for the *A* and the *B* runs (Figure 9) can be explained considering that the runs characterized by a lower value of the longitudinal slope generally showed a higher sinuosity and therefore larger values of the maximum curvature.

6 CONCLUSIONS

In this paper we present the results of an experimental work on braided networks, in which detailed measures of both sediment transport rate and planimetric configuration have been carried out, in order to quantify the characteristic timescales. The main conclusions of the analysis are summarized in the following.

1. Bed load time series show a wide range of fluctuations that can be characterized by few dominant timescales. The variability is not random, but defined modes of oscillation have been recognized, through a Fourier transform analysis of the data records.
2. Three different timescales have been found, that in the model show a period of about 30 minutes, 1–2 hours, 4–7 hours.
3. The shorter fluctuations are determined by the migration of bed forms. They are more clearly visible in the first phase of the runs, when other processes are absent, though we observed the formation and migration of alternate bars during the whole run.
4. The second timescale can be related to the evolution of the bifurcations. The variation of the water and sediment distribution occurring at a node that evolves toward an unbalanced equilibrium configuration affects the sediment transport along the network, determining a sequence of aggrading and degrading phases.

Copyright © 2006 Taylor & Francis Group plc, London, UK

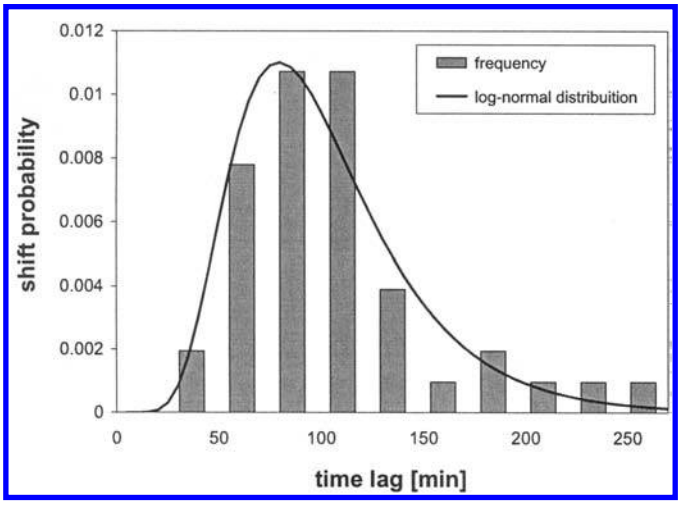

Figure 14. Timescale of the main channel shifts.

5. The longer timescale is controlled by the planimetric rearrangement of the network. We have observed that the main branch shifts its position within the network with a timescale comparable to that of the bifurcation evolution, but longer time lags are possible, in particular when the single channels develop a higher axis curvature.

João G.A.B. Leal
Universidade da Beira Interior, Covilhã, Portugal

António H. Cardoso
Instituto Superior Técnico, Lisbon, Portugal

ABSTRACT: A conceptual model for the morphological and textural evolution of gravel bed rivers is proposed. It is composed of conservation and closure equations. The former are drawn from the shallow-water theory, using a multiple layer framework and the continuum hypothesis for each transport layer. The latter specify flow resistance and phenomena pertaining to the dynamics of gravel transport. Special attention is given to the theoretical formulation of the velocity of the bedload layer and to the experimental characterization of the grain and water velocities. For that purpose, new experimental gravel transport data is presented. The proposed formulation envisages the incorporation of sediment dynamics in the overall momentum conservation equation. The model is applied to a simple test case, strong overfeeding imposed at the upstream end of a mild-sloped mobile bed channel. The numerical results of the proposed model are compared with those of a classic de Vries-type model. It is argued that the inclusion of the dynamics of the transported particles represents a major change in the structure of the morphological models, thus justifying further research efforts.

1 INTRODUCTION

The mathematical modelling of the morphological and textural evolution of gravel bed rivers requires a conceptual model composed of conservation equations and of closure equations. The former are generally drawn from the shallow-water theory. The latter specify, among other aspects, flow resistance and phenomena pertaining to the dynamics of gravel transport.

Since the work of Hirano (1971), the physical domain has been idealized as layered system. Earlier modelling attempts would either conceptualize the entire flow depth as a continuum or simply ignore the dynamic effects of the added density by assigning an infinitely small thickness to the bedload layer (de Vries 1965). In order to include the inertia of the transported sediment, the bedload layer can be idealized as a continuum (in the sense of Atkin and Crane (1976) whose density depends on the sediment concentration.

Ferreira (2005), §2, pursuing objectives earlier stated by Ferreira and Cardoso (2000), developed a multiple-layer model for the transport of poorly sorted mixtures. In that model, the continuum hypothesis was embraced and the problem of the velocity lag between water and sediment was explicitly addressed.

In this paper, the continuum multiple-layer model is further explored. The main objectives are: (i) the derivation of an expression for the velocity of the bedload layer, depending on the grain and water velocities; (ii) the development of a conceptual model incorporating the continuum bedload layer; and (iii) the validation of the model using a simple test case. To pursue these objectives, theoretical, experimental and numerical modeling work was carried out. The main theoretical issues are presented in section 2. The conceptual model is presented with emphasis on the idealization of particle-fluid segregation and respective mathematical treatment.

The experimental work is described in section 3. Grave bed experiments under hydraulically uniform conditions and equilibrium transport (capacity conditions) were carried out in a recirculating flume. The velocity of the gravel size fractions was investigated with the help of a particle tracking algorithm. Water velocity at the upper regions of the bedload layer was measured with Laser Doppler annemometry. The results are shown in section 4.

The validation of the model is carried out in section 5. A simple test case, upstream overfeeding upon an uniform subcritical flow, is proposed in order to

Copyright © 2006 Taylor & Francis Group plc, London, UK

identify the differences between the continuum model and the classical de Vries-type model. The discussion of the performance of the model takes place in the last section of the paper.

2 CONCEPTUAL MODEL

2.1 *Description of the physical system*

A conceptual model for the modelling of the morphological and textural evolution of gravel bed rivers can be derived by means of a control volume analysis within the shallow-water framework.

Two flow layers are identified in figure 1. The uppermost layer transports clear water and, possibly, wash load. It is admitted that the bed material is sufficiently coarse so that no suspended sediment is generated locally.

In a confined layer above the bed, termed bedload layer, sediment particles are transported as contact load. The localization of the boundaries of the bedload layer is a matter of convention. The lower boundary is the bed surface. Following a procedure similar to that of Parker et al. (2000), Ferreira (2005), p. 86–87, defined the bed surface as the elevation above the lowest trough for which the percentage of area occupied by solids is 15. As for the upper boundary, it is assumed that the thickness of the bedload layer should scale with the saltation height.

There exists segregation between the sediment particles transported in the bedload layer and the mean flow: the ensemble average of the path-averaged velocity of the sediment particles (see section 4.1) of any given size fraction is lower than the time- and space-averaged velocity of the water in the bedload layer.

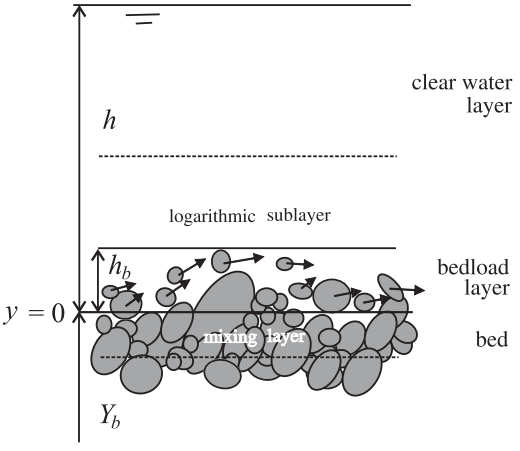

Figure 1. Idealised physical system. The involved variables and parameters are h, the flow depth, h_b, the thickness of the bedload layer, Y_b, the elevation of the bed and y, the vertical co-ordinate.

The upper bed region is the mixing layer (Hirano 1971). The trade-off between the bed and the transport layer is controlled by the dynamics of this layer. Acting like a filter, it controls both the incoming fractions to the bed and the outgoing fractions to the transport layer.

It is hypothesized that the flow is rough turbulent and two-dimensional. Furthermore, Townsend's wall-similarity hypothesis (see Townsend 1976, p. 135–143) is assumed to hold. Hence, there is a region above the bedload layer where the velocity profile is logarithmic and that Reynolds stresses $-\rho^{(w)}\overline{u'w'}$ (where u' and w' stand, respectively, for the fluctuations of the longitudinal and vertical velocity), make up for the totality of the shear stress and are linearly distributed. Above this region, the velocity profile will eventually suffer the effect of the free-surface and deviate from the log-profile.

In the bedload layer, the mean flow interacts with the moving particles and with the wakes of the protruding grains. The structure of the flow is determined by the shape, surface density and arrangement of the roughness elements (protruding grains or clusters or exposed grains) and by the intensity of the bedload transport (Ferreira 2005; Nikora et al. 2001). The overall effect of these interactions to the two-dimensional flow is that of a sink of momentum. As a result, the velocity profile is bound to strongly deviate from the log-law.

Theoretical and experimental results by Nikora et al. (2001) and experimental results by Ferreira (2005), p. 91–92, show that the profile of the time- and space-averaged velocity in the bedload layer should be linear.

2.2 *The continuum approach*

The equation of conservation of the mass of sediment in the bedload layer can be obtained from a control volume analysis for the discrete set of particles actually in motion (details *in* Ferreira 2005, p. 18–41). It reads

$$\partial_t \left(\hat{C}^{(2)} h_b \right) + \partial_x \left(\hat{C}^{(2)} h_b u_b^{(g)} \right) = \phi_{2,3}^{net} \tag{1}$$

where t and x stand for the time and space co-ordinates, h_b is the thickness of the bedload layer, $u_b^{(g)}$ is ensemble average of the path-averaged grain velocity (irrespectively of the class size), $\phi_{2,3}^{net}$ is the vertical net flux of sediment between the bed and the bedload layer and $\hat{C}^{(2)}$ is the depth-averaged concentration. The latter is defined as

$$\hat{C}^{(2)} = \frac{\forall_g^{(2)}}{\forall^{(2)}} \tag{2}$$

where $\forall_g^{(2)}$ is the average volume of the particles moving in any given control volume enclosing the bedload

Copyright © 2006 Taylor & Francis Group plc, London, UK

layer between two vertical cross-sections and $\forall^{(2)}$ is the size of that control volume.

In the wake of de Vries (1965), early mobile bed models would conceptualize the entire flow depth as a continuum or simply ignore the dynamics of the bedload. Under non-equilibrium transport and for sufficiently high sediment concentrations, the inertia of the granular phase, in particular the convective inertia, may play a relevant role in the morphological evolution of the stream. In order to include these inertial terms, the bedload layer can be idealized as a continuum (in the sense of Atkin and Crane 1976) whose density depends on the sediment concentration. The mixture of water and sediment, although idealized as continuous, remains non-homogeneous and fluid-particle segregation must be addressed.

In the continuum approach, the mass flow rate characteristic of the bedload layer must be maintained. It can be defined as $\rho_b q_b$ where $q_b = u_b h_b$ is the total volumetric discharge in the bedload layer, u_b is the layer velocity and $\rho_b = \rho^{(w)}(1 + (s-1)C_b)$ is the layer density. The parameter s is the specific gravity of the bedload grains. The concentration C_b is a flux-averaged layer concentration, defined as

$$C_b = \frac{q_{gb}}{q_b} \tag{3}$$

where q_{gb} is the volumetric bedload discharge.

The idealisation of the physical system within the continuum approach can be seen in figure 2. The layer velocity can be obtained from the integration of the mean longitudinal velocity profile of the water constituent and from the average velocity of grains moving as bedload. The velocity in the clear water layer can also be obtained from the velocity profile. These velocities can be parametrised for the friction velocity, which can be drawn from the $\overline{u'w'}$ profile. Under the shallow-flow hypothesis, the pressure distribution is hydrostatic. It should be noticed (figure 2) that, within the continuum approach, the slope of the pressure diagram must be larger in the bedload layer

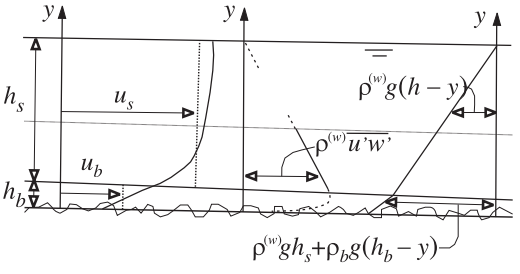

Figure 2. Idealised physical system for the multiple layer approach. The involved previously unspecified variables and parameters are h_s, the thickness of the clear water layer, u_s, the velocity of the clear water layer.

than in the clear water layer due to the greater layer density.

Under the shallow-flow hypothesis and within the continuum paradigm, the equation of conservation of momentum can be obtained for the bedload layer (details *in* Ferreira 2005, p.23–23):

$$\begin{array}{c} \partial_t\left(\rho_b h_b u_b\right) + \\ \partial_x\left(\rho_b u_b^2 h_b + g\left(\frac{1}{2}\rho_b h_b^2 + \rho^{(w)} h_s h_b\right)\right) + \\ g\rho_b h_b \partial_x\left(Y_b\right) = -\tau_b + \tau_s + \rho^{(w)} u_1 \phi_{2,3}^{net} \end{array} \tag{4}$$

In equation (4) the previously unspecified variables ans parameters are τ_b, the bed shear stress, τ_s, the shear stress between the bedload layer and clear water layer and g, the acceleration of gravity. A relation among the variables that describe the discrete system, $u_b^{(g)}$ and $\hat{C}^{(2)}$ (used in equation 1), the fluid velocity and the continuum variables u_b and C_b (employed in equation 4) will be sought next.

2.3 *Bedload layer variables*

The layer velocity can be obtained from mass conservation. The total discharge in the bedload layer is

$$q_b = q_{gb} + q_{wb} = h_b u_b \tag{5}$$

where $q_{gb} = \hat{C}_b^{(2)} h_b u_b^{(g)}$ is the sediment discharge in the bedload layer, $q_{wb} = (1 - \hat{C}_b^{(2)}) h_b u_b^{(w)}$ is the water discharge in the same layer and $u_b^{(w)}$ is the time- and space-averaged flow velocity in the bedload layer. Hence, from the above definitions and from equation (5), the bedload layer velocity can be written as

$$u_b = u_b^{(w)} - \hat{C}^{(2)}\left(u_b^{(w)} - u_b^{(g)}\right) \tag{6}$$

Further elaborating over the relation between the layer velocity and the grain and water velocities, consider a control volume whose length, height and width are, respectively, $u_b^{(w)}\,\mathrm{d}t$, h_b and B, the later being the width of the channel. The size of the control volume is, thus, $\forall^{(2)} = B h_b u_b^{(w)}\,\mathrm{d}t$. Inside the control volume there are N moving particles at a given instant t_0. The number of particles that leave the control volume between t_0 and $t_0 + \mathrm{d}t$ is n. Considering that there is segregation between fluid and sediment and that the particles move slower than the fluid, one has $n \leq N$.

Ensemble-averaging over a large number of control volumes whose length is $u_b^{(w)}\,\mathrm{d}t$ it is obtained

$$\frac{\langle n \rangle}{\langle N \rangle} \cong \frac{u_b^{(g)}}{u_b^{(w)}} \stackrel{def}{=} \frac{1}{\alpha_*} \tag{7}$$

The result expressed in equation (7) requires that the system is ergodic, *i.e.* that the time-averaged velocity

Copyright © 2006 Taylor & Francis Group plc, London, UK

of the particles in the control volume is, in the limit, equal to the ensemble average of the velocities of all particles in the system. Although not strictly necessary, it is also assumed that the moving particles are not organized in bed forms.

Introducing the definition of α_* in equation (6), one obtains

$$u_b = u_b^{(g)} \left(\alpha_* + \hat{C}^{(2)} \left(1 - \alpha_* \right) \right) \tag{8}$$

Equation (8) can be used to re-write the flux of sediment in the bedload layer. It is obtained

$$q_{gb} = \frac{\hat{C}^{(2)}}{\alpha_* + \hat{C}^{(2)} \left(1 - \alpha_* \right)} h_b u_b \tag{9}$$

It is easy to verify that the term $\hat{C}^{(2)}/(\alpha_* + \hat{C}^{(2)}(1-\alpha_*))$ is the flux-averaged concentration of sediment in the bedload layer. For that purpose, let $N \equiv \langle N \rangle$ be the number of moving particles in the control volume and let $n \equiv \langle n \rangle$ be the number of particles that leave the control volume. The bedload becomes

$$q_{gb} = n \forall^{(g)} \tag{10}$$

where $\forall^{(g)}$ is the volume of each particle. The total discharge in the bedload layer is

$$q_b = B h_b \mathrm{d}x - N \forall^{(g)} + n \forall^{(g)} \tag{11}$$

where $\mathrm{d}x = u^{(w)}\, \mathrm{d}t$. The quantities $B h_b \mathrm{d}x - N \forall^{(g)}$ and $n \forall^{(g)}$ are, respectively, the volumes of water and of sediment that leave the control volume during the time interval $\mathrm{d}t$. Introducing equations (10) and (11) in (3), the flux-averaged concentration of sediment becomes

$$C_b = \frac{n \forall^{(g)}}{B h_b \mathrm{d}x - N \forall^{(g)} + n \forall^{(g)}} \tag{12}$$

Introducing the expressions for the volume of sediment and for the total volume, the depth-averaged concentration of sediment in the bedload layer, defined as (2), becomes

$$\hat{C}^{(2)} = \frac{N \forall^{(g)}}{B h_b \mathrm{d}x} \tag{13}$$

Dividing both the numerator and the denominator of equation (12) by $B h_b \mathrm{d}x$, introducing equation (13) and attending to the definition of α_*, equation (7), equation (12) becomes $C_b = \hat{C}_b^{(2)}/(\alpha_* + \hat{C}_b^{(2)}(1-\alpha_*))$, which completes the verification.

For computational convenience, the volume of sediment, per unit bed area, accumulated in the bedload layer, term $\hat{C}_b^{(2)} h_b$ in equation (1), should be written in terms of flux-averaged quantities, for which

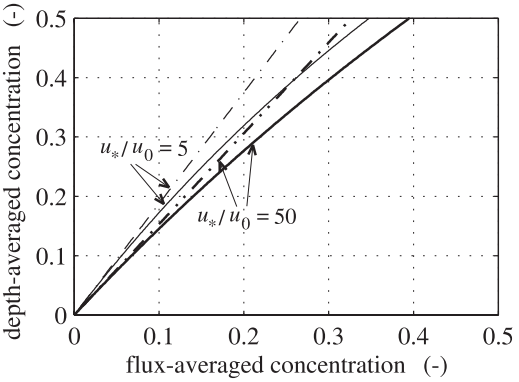

Figure 3. Relation between depth-averaged and flux-averaged concentrations with α_* calculated by equation 14.

purpose α_* must be estimated. The fluid velocity in the bedload layer may be expressed as $u_b^{(w)} = \alpha^{(w)} u_*$ where $\alpha^{(w)} = \alpha^{(w)}(X)$, $X = u_* d_{50}/\nu$ and d_{50} is the median diameter of the bed material. As for the mean velocity of the coarse grains, it will be seen that $u_b^{(g)} = \alpha_c (u_* - u_0)$ where u_0 is a best fit parameter. Hence, from definition (7), one has

$$C_b = \frac{\hat{C}_b^{(2)}}{\alpha_* + \hat{C}_b^{(2)} \left(1 - \alpha_* \right)} \tag{14}$$

Let $\alpha^{(w)} = 7.1$, $\alpha_c = 4.5$ and $u_0 = 0.029\,\mathrm{ms}^{-1}$ (see section 4). Equation (**??**), with α_* calculated by equation (14), can be plotted along with $\hat{C}_b^{(2)} = \alpha_* C_b$. The results can be seen in figure 3.

From figure 3 it is concluded that (i) the depth-averaged concentration of sediment is, for low values of the friction velocity (*eg.* $u_*/u_0 = 5$), about two times the flux-averaged velocity; (ii) the greater the friction velocity (the more intense the bedload) the smaller the difference between the dept-averaged and the flux-averaged velocities and (iii) equation (**??**) is well approximated by

$$\hat{C}_b^{(2)} = \alpha_* C_b \tag{15}$$

provided that the depth-averaged concentrations are less than 0.2; in this case the error between the computed flux-averaged concentrations is less than 10%.

Thus, it will be assumed that the relation between flux- and depth-averaged concentrations on the bedload layer is given by equation (15). Introducing this equation in (1), it is obtained

$$\partial_t \left(\alpha_* C_b h_b \right) + \partial_x \left(C_b h_b u_b \right) = \phi_{2,3}^{net} \tag{16}$$

Equation (16) is the equation of conservation of the total mass of sediment in the bedload layer written in conservative form.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The scope of this study is restricted to flows for which the role of the mixing layer is negligible *eg.* when the bed is composed of well-sorted sediment or if all size fractions are imposed in the bedload. Within this scope, the remaining set of conservation equations is shown next.

2.4 *The complete model*

The complete set of conservation equations comprises (i) the equation of conservation of the total mass

$$\partial_t (h) + \partial_x (hu) = \tfrac{1}{(1-p)} \phi_{2,3}^{net} \tag{17}$$

where u is the mean flow velocity, defined as $(u_b h_b + u_s h_s)/h$; (ii) the equation of conservation of the sediment mass in the bed

$$\partial_t (Y_b) = -\phi_{2,3}^{net} \tag{18}$$

and (iii) the equation of conservation of the momentum of both phases

$$\begin{aligned} &\partial_t (\rho_m hu) + \partial_x \left(\rho^{(w)} u_s^2 h_s + \rho_b u_b^2 h_b + \right. \\ &\left. g \left(\tfrac{1}{2} \rho^{(w)} h_s^2 + \tfrac{1}{2} \rho_b h_b^2 + \rho^{(w)} h_s h_b \right) \right) + \\ &g \left(\rho^{(w)} h_s + \rho_b h_b \right) \partial_x (Y_b) = -\tau_b \end{aligned} \tag{19}$$

where $\rho_m = \rho^{(w)}(1 + (s-1)C)$ is the average flow density and $C = C_b u_b h_b/(uh)$ is the flux-averaged concentration of the entire flow.

The complete system admits 4 unknowns: h, u, Y_b and C_b.

3 EXPERIMENTAL FACILITIES, INSTRUMENTATION EXPERIMENTAL PROCEDURES

The experimental characterization of α_c and $\alpha^{(w)}$, fundamental for the derivation of the layer velocity, is undertaken next.

The experiments were performed in an 11 m long and 40 cm wide prismatic recirculating tilting flume existing in the Laboratory of Fluid Mechanics of the University of Aberdeen. The side-walls are made of glass, enabling visualization and laser measurements. In order to achieve and maintain uniform flow conditions, a manually operated vane was placed at the outlet. A detailed description can be found in Cunningham 2000, pp. 47–55, and Ferreira 2005, pp. 57–59.

Five kinds of measurements were performed: (i) water and sediment discharges; (ii) water depth and bed elevation; (iii) instantaneous flow velocity; and (iv) velocity of the bedload particles.

Two orthogonal components of the instantaneous flow velocity were measured with a DANTEC 55X Modular Laser Doppler Anemometer. The transmitting optics features a 20 mW, monochromatic He-Ne laser. The sampling software enabled the collection of 12000 samples before writing to file. The LDA system was placed at about 6 m from the inlet. The sampling frequency varied with the hydraulic parameters between 200 Hz and 300 Hz.

The flow was recorded on video, with a 25 fps Panasonic video camera with adjustable shutter speed and lenses aperture. The maximum saltation height was accessed by analyzing side-view video footages. The paths and the velocities of individual gravel particles moving in the bedload layer were computed from video footages taken from above (details of the setup *in* Ferreira 2005, pp. 57–66).

Table 1. Summary of the characteristics of the experimental tests.

Name	Q (ls^{-1})	i_0 (–)	h_0 (cm)	u_* (ms^{-1})	$\Phi(\times 1000)$ (–)	Fr (–)
T_0	10.3	0.0014	7.46	0.033	–	0.40

T_9	17.3	0.0046	6.99	0.056	1.584	0.75

A total of 10 capacity, subcritical and uniform flow experimental tests were carried. Their main characteristics are shown in table 1. In this table, Q stands for the total discharge, i_0 for the bed slope, h_0 for uniform flow depth, Φ for the non-dimensional sediment discharge and Fr for the Froude number. The friction velocity, u_*, was computed from the linear profile of $\overline{u'w'}$ in the logarithmic sublayer. In order to determine sediment discharge, sediment samples were collected at the flume outlet.

The bed was composed of a gravel mixture with $d_{50} = 5.45$ mm, $d_{90} = 5.45$ mm and $\sigma_g = 5.45$. The sediment grains were transported exclusively as bedload and no appreciable bed forms were registered.

4 EXPERIMENTAL RESULTS

4.1 *Particle velocity*

The velocity of the particles of each size fraction, $u_{b_k}^{(g)}$, was determined with the help of a particle tracking algorithm (described in Ferreira 2005, p. 171–174). Figure 4 shows examples of trajectories of particles detected by the algorithm. The trajectories show an apron-like shape, typical of particles entrained by turbulent sweep events.

Copyright © 2006 Taylor & Francis Group plc, London, UK

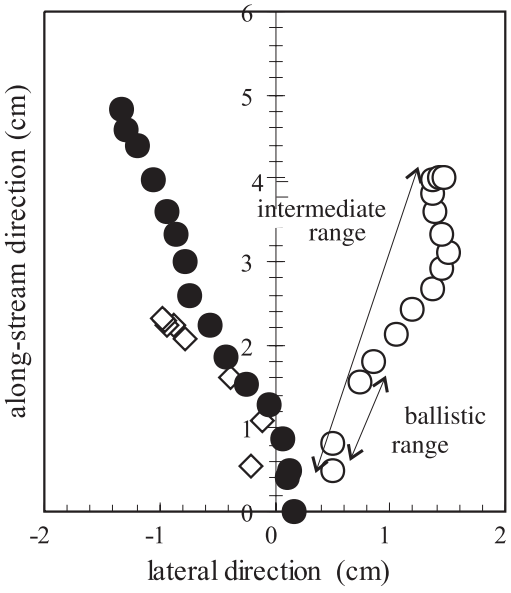

Figure 4. Paths of displaced gravel particles.

A typical path between the initial and the final rest positions encompasses, as seen in figure 4, saltation and rolling or sliding. During saltation, the displacement between two successive positions is larger than the displacement between to successive particle during rolling or sliding.

Nikora et al. (2002) categorized the movement of gravel particles in the bedload layer in three ranges: the ballistic, the intermediate and the global. the velocity histogram in ballistic range is narrow and the mode has a high value; in the intermediate range, the velocity histogram is wide and the mean velocity is much smaller than the peak velocity. The global range includes also the periods of rest that a particle may have in its downstream travel.

Saltation belongs to the to the ballistic range whereas the full particle path between rest positions, containing a succession of saltation, rolling and sliding reaches, pertains to the intermediate range. It is reasonable to assume that, for a given control volume, all types of movement will be present if the set of N moving particles is large enough. Thus, bedload should be defined as the product of the particle velocity, computed in the intermediate range, the depth-averaged sediment concentration and the thickness of the bedload layer, defined as the maximum saltation height.

The velocity of the particles, as defined in this study, is the ensemble average, over a large number of particles, of the path-averaged velocity in the along-stream direction. This definition is thus compatible with the concept of bedload explained above. Considering that the frame rate is constant, the path-averaged velocity is obtained by dividing the total particle displacement (see figure 4) by the time elapsed.

The results, for the size fractions characterized by $d = 1.5$, 2.4, 3.1, 4.0, 5.5 and 6.4 mm, are shown in figure 5. As discussed, the velocities shown in this figure pertain to the intermediate range. This observation will enable the comparison of the present experimental results with those of earlier studies, notably Fernandez Luque and van Beek (1976). Indeed, it is observable in figure 5 that the average velocity of each size fraction follows a linear trend, as was the case of Luque and van Beek's results.

All size fractions can be represented by the linear regression

$$u_b^{(g)} = 4.5\,(u_* - u_0) \tag{20}$$

where $u_0 = 0.029\,\mathrm{ms}^{-1}$.

It is recalled that Fernandez Luque and van Beek (1976) obtained $u_b^{(g)} = 11.5(u_* - 0.7u_{*c})$. Thus, equation (20) is similar to Fernandéz Luque & van Beek's with the conspicuous difference that the slope of the former is smaller than the slope of the latter. It is argued that the difference between both formulas is due to the fact that the measurements performed by Fernandez Luque and van Beek (1976) pertained to the ballistic range; indeed, they measured the velocity of particles during saltation events. Thus, it was considered that the formula proposed by Fernandéz Luque & van Beek would lead to an overestimation of the bedload by overestimating the average particle velocity. It is noted that Niño and Garcia (1994) observed $u_b^{(g)} = \alpha_c u_*$, α_c between 4 and 6, a formula that is in better agreement with equation (20).

4.2 *Water velocity*

The profiles of the time-averaged velocity corresponding to the experimental tests shown in table 1 can be seen in figure 6. These profiles are obtained by ensemble-averaging four distinct sets of time-averaged measurements for each height above the bed. Space averaging was not performed because the bed was mobile – the geometry of the bed would be different for each time-averaged profile. Thus, it is assumed that the ensemble average is equivalent to a space average.

The velocity profile is composed of three regions, described by as many mathematical expressions. In the roughness sublayer, the lower layer of the inner flow region, the velocity profile is approximately linear. In the upper parts of the inner flow region, the profile is logarithmic. In outer flow region the flow is described by a log-wake law (*cf.* Townsend 1976).

Assuming that the bedload layer is contained in the roughness sublayer, the depth-averaged velocity of

Copyright © 2006 Taylor & Francis Group plc, London, UK

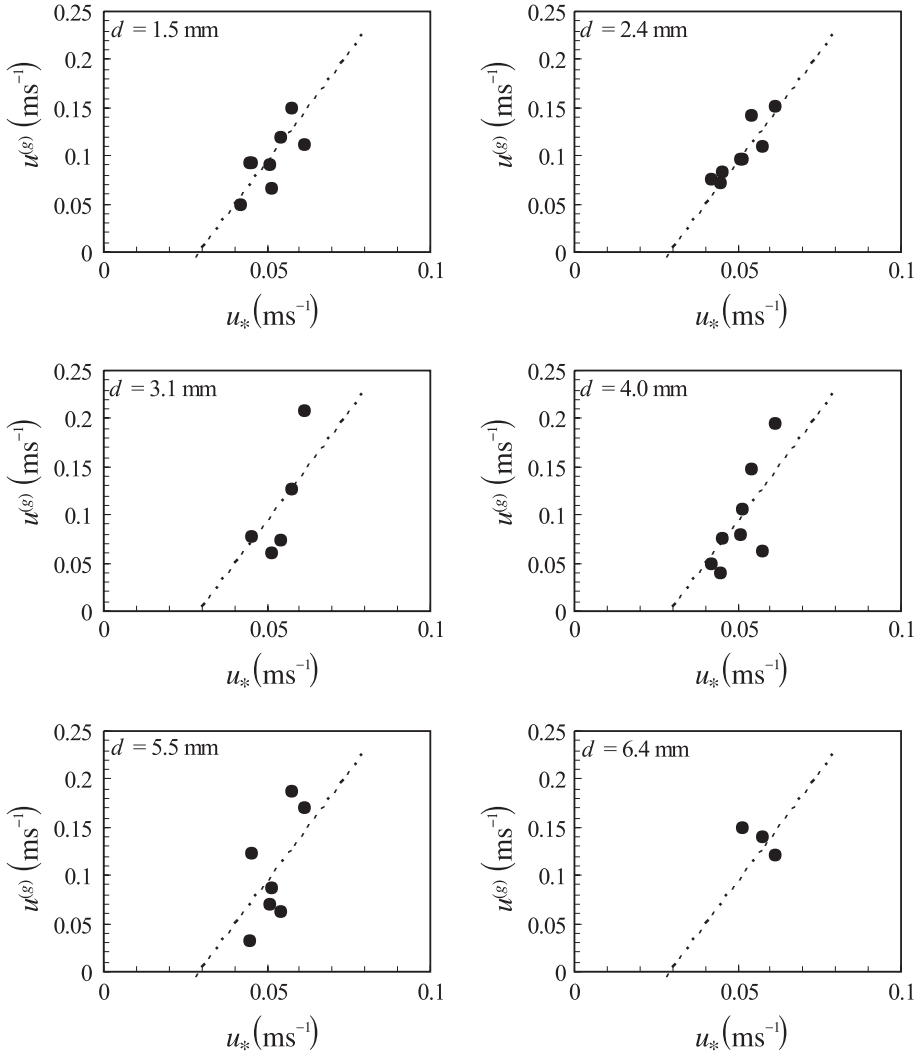

Figure 5. Ensemble average of the path-averaged velocity of the gravel particles of each size fraction (black dots). Dotted line stands for equation (20).

the water in the bedload layer can be estimated from the integration of the linear velocity profile seen in figure 6. Symbolically, it is

$$\frac{u^{(w)}(y)}{u_*} = C_1 \frac{y}{k_s} + C_2 \tag{21}$$

where k_s is the equivalent roughness height. The integration of equation (22) renders

$$\frac{u_b^{(w)}}{u_*} = \int_0^{h_b} \left\{ \frac{u^{(w)}(y)}{u_*} \right\} \mathrm{d}y = \frac{C_1}{2} \frac{h_b}{k_s} + C_2 \tag{22}$$

Ferreira 2005, p. 91, quantified the values of C_1, C_2 and k_s. From the profiles shown in figure 6 it was obtained $C_1 = 4.65$ and $C_2 = 4.49$. The equivalent roughness height was computed from the water-worked bed profiles and related to the mean height of the protruding particles, δ_a. It is assumed that $k_s = 2.5\delta_a$.

The values shown in table 2 suggests that k_s is approximately constant in the range of θ_{50} corresponding to the experimental tests carried out. Thus, let $k_s = 1.90 d_{90}$ where $d_{90} \approx 2.2 d_{50}$ (table 2). Substituting the values of the constants in equation (22) and considering that $h_b/d_{50} = 3$, a frequent value, the

T_5	6.86	3.45	6.17	1.67
T_6	5.97	3.50	6.26	1.64
T_7	6.65	3.46	6.24	1.71
T_8	6.24	3.44	6.20	1.69
T_9	6.14	3.43	6.17	1.65

depth-averaged water velocity in the bedload layer becomes

$$u_b^{(w)} = 7.1 u_* \tag{23}$$

Parameter α_* is obtained from equation (7), with $\alpha^{(w)} = 7.1$, $\alpha_c = 4.5$ and $u_0 = 0.029\,\mathrm{ms}^{-1}$. The continuum velocity of the bedload layer is retrieved from equation (8). The remaining closure equations are presented in the context of the model application.

5 APPLICATION – OVERFEEDING AT THE UPSTREAM REACH

5.1 *Test conditions*

Upstream overfeeding can be enforced by supplying sediment at the upstream reach while maintaining sediment recirculation. For that purpose, a conveyor belt with adjustable velocity was installed at the upstream reach of the flume described in section 3.

The bedload discharge was set by adjusting the thickness and the width of the sediment layer in the belt and the velocity of the motor.

The experimental procedure comprises two phases, recirculation and overfeeding. In the first phase, uniform and capacity conditions are obtained by running a recirculation test during 8 hours. Generalized deposition is enforced by imposing, at the upstream reach, a steady sediment discharge. The duration of the overfeed test was 15 hours.

The recirculation phase was characterized by $Q = 0.0138\,\mathrm{m}^3\mathrm{s}^{-1}$, $h_0 = 0.099\,\mathrm{m}$, $i_0 = 0.001$ and $u_* = 0.029\,\mathrm{ms}^{-1}$.

At the end of the recirculation phase, the bed was composed of a mixture of coarse sand and gravel characterized by $d_{50} = 2.02$ mm, $d_{90} = 5.61$ mm and $\sigma_g = 2.79$. The equivalent roughness height was $k_s = 4.61$ mm.

During the recirculation phase sediment transport was incipient. The sediment discharge imposed at the upstream end during the overfeeding phase was $Q_s \approx 2.5\,\mathrm{gs}^{-1}$. The composition of the feeding material was approximately equal to that of the bed surface.

5.2 *Closure equations and solution procedure*

In order to simulate the overfeeding test described in the preceding section, the model requires closure equations for the thickness of the bedload layer, for the bed shear stress and for the vertical flux of sediment between the bed and the bedload layer.

The thickness of the bedload layer, h_b, is addressed first. Since the physical system features no appreciable bed forms, h_b is expected to scale with the saltation height (see discussion in Ferreira 2005, p. 114–115). The later is expected to increase with the bed shear stress and with the bedload discharge. In this study, is is assumed that

$$\frac{h_b}{d_{50}} = 2\frac{10.5\theta_{50}}{1 + 0.2\theta_{50}} \tag{24}$$

The flux of sediment between the bedload layer and the bed is modeled by spatial lag equation, following Phillips and Sutherland (1989). It is proposed

$$\phi_{2,3}^{net} = -\left(C_b h_b u_b - q_b^*\right)/\Lambda \tag{25}$$

where Λ is the adaptation length and q_b^* is the equilibrium (capacity) volumetric bedload discharge. For the latter, a simple monomial equation, in the form of $q_b^* = m(u - \chi)^3$, was employed.

The friction coefficient may be expressed by a Keulegen-type law (Chow 1959, p. 204), given that it is assumed that only grain roughness exists. The particular law employed was

$$C_f = \left(5.75\mathrm{Log}\left(\frac{h}{k_s}\right) + 4.4\right)^{-2} \tag{26}$$

The constants were modified to achieve better matches to the measured values of $(u_*/u)^2$. The Shields parameter, θ_{50}, is computed from the definition $C_f u^2/(\rho^{(w)}(s-1)d_{50})$.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The solution procedure involves the discretization by an explicit 1st order finite volume discretization whose general form is

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n - \frac{\Delta t}{\Delta x}\left(\mathbf{F}_{i+\frac{1}{2}}^n - \mathbf{F}_{i-\frac{1}{2}}^n\right) + \Delta t \mathbf{G}_i^n \qquad (27)$$

where $\mathbf{U} = [h \;\; \rho_m uh \;\; \alpha_* C_b h_b \;\; Y_b(1-p)]$ is the vector of conservative dependent variables and $\mathbf{F}$ and $\mathbf{G}$ are, respectively, the corresponding flux and source terms vector (see equations 16, 17, 18 and 19). Inter-cell fluxes are calculated by Godunov's method. The length of the computational space and time steps are, respectively, Δx and Δt.

The proposed test represents a boundary-initial value problem. Initial conditions comprised steady total discharge, constant water depth and equilibrium sediment concentrations. Since the Froude number was smaller than one, two boundary conditions were imposed at the upstream section and one boundary condition was imposed at the downstream end. Constant total and sediment discharge hydrographs were imposed at the upstream end. A stage-discharge hydrograph derived from the proposed friction law was imposed at the downstream end.

5.3 *Comparison between experimental and numerical results*

The imposition of strong overfeeding at the upstream end originates a sediment wave, with steep front, that propagates downstream. Associated to this discontinuity in the bed profile there is necessarily a discontinuity in the water depth (see Ferreira tese Ha Ha) which may be a hydraulic jump should the Froude number of the flow over the sediment wave be larger than one.

The morphologic response of the stream can be seen in figure 7. Profiles of the measured sediment wave and water elevation are shown in this figure, at $t = 2.5$, 5.0, 7.5, 10 and 14 hours. In order to transport the sediment discharge imposed at the upstream reach the stream increases its slope and, hence, its transport capacity. A new equilibrium slope would be obtained at sufficiently large times.

The corresponding profiles obtained by the numerical solution of the model described in the previous sections are shown in figure 7(b), superimposed to the experimental results. In figure 7(a) the results of a de Vries type of model are also shown. Water and bed elevations are made non-dimensional by h_0, the depth of the uniform flow in the recirculation phase. Distances in the longitudinal direction are made non-dimensional by the work length of the flume for this test, $L_0 = 10$ m.

The adaptation length Λ and the parameters m and χ were fitted to achieve best results in the proposed model. The values employed were $\Lambda = 0.4$ m, $m \approx 0.0006\,\mathrm{m^{-1}s^2}$ and $\chi = 0.35\,\mathrm{ms^{-1}}$. The parameter

Solid thick lines (——) stand for computed bed elevation; thin lines (——) stand for the elevation of the free surface. Dashed lines with black dots (- - ● - -) stand for the measured bed elevation; dashed lines with open circles (- - ○ - -) stand for the measured free surface elevation.

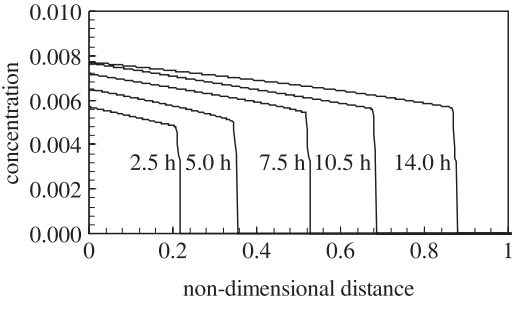

Figure 8. Profiles of the calculated concentrations in the bedload layer.

m acts mainly on the velocity of the wave front while Λ is relevant for the rate of deposition and, hence, for the shape of sediment wave. The same parameters were used in the de Vries-type model. In that model, the adaptation length was used in a lag equation that corrects the equilibrium bedload discharge to simulate non-equilibrium conditions. This procedure, described in Ferreira (1998), p.? - ?, represents an extra computational step, suitable for explicit schemes.

The computed concentrations in the bedload layer are plotted in figure 8. The profiles are monotone

Copyright © 2006 Taylor & Francis Group plc, London, UK

decreasing since, over the sediment wave, the water depth is not constant.

As the new equilibrium slope is attained, the concentration tends to a constant value. This is evident in the vicinity of the upstream reach where the C_b approached a constant value from $t = 10$ h onwards.

6 DISCUSSION AND CONCLUSIONS

The proposed model is based on the shallow-water equations complemented with mass conservation equations for the sediment constituent. It explicitly incorporates the inertia of the transported sediment by dividing the water column in two transport layers, each modeled as continuum, and by assigning the bedload layer a density and a velocity highly dependent on the concentration of sediment.

Should the concentration be zero, the proposed model converges essentially to the clear-water shallow-water equations. The same happens to models similar to that of Vries (1965), since they are obtained by complementing the shallow-water equations with Exner equation. Thus, it is expected that, for small concentrations of transported sediment, both types of models render similar results. Gravel transport is typically associated to small sediment concentrations. It is thus a matter of discussion if the dynamics of the transported sediment are negligible in the overall dynamics of the system or if it should be included in the morphological models.

The differences observed by comparing the results of models that share the equation for capacity bedload discharge must be interpreted as differences resulting from the structure of the models. The coefficients of the laws that describe bedload transport were fitted so that the results of the proposed model would fit the observed morphologic response. As seen in figure 7, the proposed model and the de Vries-type model render quite different solutions for the same transport laws. Hence, it is concluded that the structure of the models is indeed different, even for concentrations as low as those seen in figure 8. Furthermore, the dynamics of the bedload, as idealized in the proposed model, must be relevant for the morphological response of the stream.

While it appears to be clear that joint effect of the convective inertia of the transported sediment and the accumulation of sediment sediment mass in the bedload layer (the terms that are not present in the de Vries-type model), the present study did not address the relative importance of these terms. Furthermore, the application of the model to more realistic test cases requires the specification of the a physically based bedload transport formula applicable to poorly sorted sediment mixtures. Efforts should be undertaken to address experimentally these issues.

Energy dissipation downstream of dams established in alluvial beds

A. Sá Lopes, M.F. Proença & R. Maia
Departamento de Engenharia Civil, Faculdade de Engenharia da Universidade do Porto, Porto, Portugal

ABSTRACT: Energy dissipation behind the hydraulic structure of a mobile dam was experimentally studied with the aid of Laser-Doppler Anemometry (LDA), aiming to optimize the design and length of the dissipation devices, most commonly a stilling basin followed by rock fill alluvial bed protection.

Measurements of the flow field over the rock protection were carried out in order to prevent damages at the foundations of the structure as well as to protect the river bed from erosion, namely due to operational reasons. The characterisation of mean velocity and turbulence intensities were carried out for different flow conditions and different rock fill characteristic dimensions, using a physical model of the Crestuma dam, located in the Douro river.

The obtained results (namely values of bottom shear stress) provide a better insight of the rock fill protection behaviour and can help to achieve a cheaper and safer design of the rock fill protection.

1 INTRODUCTION

Energy dissipation of flood discharges is a very important issue that must be carefully analysed when bearing in mind the design and layout of hydraulic structures, namely dams. The usual formation of a hydraulic jump downstream the weir devices requires adequate protection of the river bed, at locations where energy dissipation occurs and where flow velocities present higher values, especially if the constructions are established in alluvial beds.

Stilling basins concrete slabs followed by rock fill bed protections are one of the most common devices that are used to allow weir discharges to be performed without damaging the construction foundation. Length and characteristics of the protected zone and, specially, the rock fill bed protection depend on flow conditions and have to be carefully defined in order to prevent erosion or scour of the river bed.

Flow velocity and bed shear stress values play an important role in the process and have been the basis for the establishment of different criteria, allowing initiation of movement prediction.

In the present work an experimental study of a physical model of the Crestuma dam was carried out. Flow field definition for different flow conditions and different bed rock protections were made using laser Doppler anemometry technique in order to allow the analysis of velocity flow characteristics in each situation. Rock fill protection behaviour, concerning scour and erosion occurrence, has been studied in relation to flow field type changes.

Bottom shear stress values have been calculated and compared with the literature (Shields diagram) in order to try to explain any possible erosion effects. Two different approaches to Shields diagram have been made, taking into account the existence or not of flow uniformity characteristics of the studied flow. In accordance, two different methods of evaluation of friction velocity values have been applied.

2 THEORETICAL FRAMEWORK

In 1936, Shields described the initial bed grain instability problem based on experimental data. Shields diagram was referred to plane beds with grains of uniform size and was modified in order to take into account the non uniform distribution of the mixtures of different grains and their orientation under flow conditions. The modified Shields diagram (Fig. 1) presents several curves instead of the original one, grading different levels of incipient motion of the particles as referred by Hoffmans et al. (1997).

For a particular situation the critical shear stress value can be obtained through the Shields parameters ψ and D_* definition, assuming:

$$\Psi = \frac{u_*^2}{\Delta g d} \quad and \quad D_* = d\left(\frac{\Delta g}{\nu^2}\right)^{\frac{1}{3}} \tag{1}$$

where Δ = relative density $((\rho_s/\rho) - 1)$; d = particle diameter $(d = d_{50})$; u_* = friction velocity;

Copyright © 2006 Taylor & Francis Group plc, London, UK

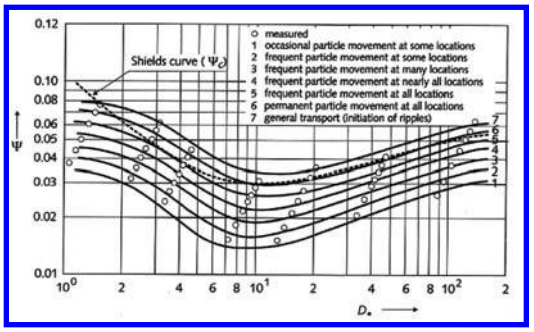

Figure 1. Modified Shields diagram (Hoffmans et al. 1997).

g = acceleration of gravity; ν = cinematic viscosity; ψ = mobility parameter; D_* = dimensionless diameter.

Shields diagram application requires the knowledge of flow and bed sediment characteristics.

Flow uniformity can be checked plotting u/U_{max} versus y'/h on different sections and verifying if the velocity profiles overlap on a single curve with the following law:

$$\frac{u(y')}{U_{max}} = A\ln(\frac{y'}{h}) + B \tag{2}$$

where u = mean flow velocity; y' = vertical distance to the bed flow, corrected according to rough bed situation; U_{max} = maximum velocity profile; h = flow depth; and, A and B constants.

The above equation will not be valid if the following conditions are not fulfilled (Rota criterion 1962, according to Cardoso 1990):

$$\left.\begin{aligned} &\frac{u_*}{U_{max}} = constant \\ &\beta = \frac{\rho hg(-I_0 + \frac{\delta h}{\delta x})}{\tau_0} = constant \\ &\frac{d(\frac{U_{max}\delta_*}{u_*})}{dx} = constant \end{aligned}\right\} \tag{3}$$

where I_0 is the bottom slope, δ_* and τ_0, are the boundary layer momentum thickness and the shear stress values, respectively. For β values: <-1, accelerated flow; $=-1$, uniform flow; >-1, decelerated flow.

Non-uniformity may then concern a set of flows which equilibrium is affected by the upstream flow conditions. Corresponding velocity profiles will vary along the flow.

Friction flow velocity evaluation must be done taking into account the referred flow characteristics.

For uniform flow, the general equation, most commonly used is:

$$u_* = (gRJ)^{\frac{1}{2}} \tag{4}$$

where R is the hydraulic radius and J the energy loss by unit length, that can be given by the Manning-Strickler expression:

$$J = \frac{U^2}{K_s^{\,2} R^{\frac{4}{3}}} \tag{5}$$

where K_s (=1/n) is the Strickler coefficient and U the mean sectional velocity. For uniform flows with small bottom gradient, R may be usually taken as h, the flow depth, and J as I_o, the bottom channel slope.

Regarding non-uniform flows using Saint Venant equations and according to Graf & Song (1995) and Graf & Altinakar (1998) the friction velocity can be given by:

$$u_*^2 = ghI_0 + (-gh\frac{\delta h}{\delta x}(1 - Fr^2)) \tag{6}$$

where I_0 is the bottom channel slope, x the velocity profile coordinate and Fr the Froude number, which is defined as:

$$Fr = \frac{U}{\sqrt{gh}}$$

3 EXPERIMENTAL SET UP

3.1 *Facilities and measuring equipment*

Experiments have been carried out in a water channel of the Hydraulics Laboratory of FEUP. The water channel, with a length of 32,3 m, a width of 1,0 m and a bottom slope of 0,5%, is provided with side windows allowing visual access to the test sections.

The channel is fed from a reservoir located at a higher level, provided with a water level control allowing a constant flow to be delivered to the channel.

Flow measurement values can be controlled, upstream through a flow meter, Sparling Waterhawk series 600, flangeless version, and downstream through a sluice crested weir whose discharge value is obtained measuring the water level by means of a Bestobell Mobrey MSP90 system.

Velocity measurements have been made using a one component fibre optics Laser System from Dantec, working in forward scatter mode.

A 100 MW Argon-Ion laser source, operating in multi-mode was used.

The main characteristics of the Laser Doppler Anemometer system are shown in table 1.

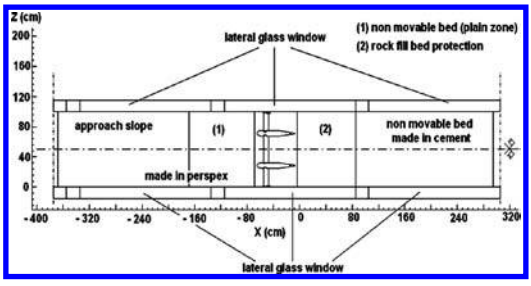

Figure 2. Crestuma model – plant.

The signal from the photomultiplier was band-pass filtered and processed by a TSI 1990c counter, operating in the single measurement per burst mode, with a frequency validation of 1% at 10/16 cycle comparison. A 1400 Dosteck card interfaced the counter with a computer, which provided all statistical quantities, using a purpose's built software.

3.2 *Physical model characteristics and similarity conditions*

In order to perform experimental work a physical model of Douro river Crestuma dam was built.

Crestuma dam is a mobile type dam founded on alluvial bed, whose flow discharges are made through double slicing gates installed on 8 spans of 28 m each and supported by 49 m length and 6 m width piles. The double slicing gates can move independently and allow discharges over or underneath their body or both simultaneously. Flow discharge energy dissipation is achieved on a concrete slab stilling basin with a length of 42 m from gate axis position, followed by the rock fill bed protection with a length of 80 m.

The model was made of perspex using a 1:80 geometric scale. Taking into account that gravitational forces are predominant in this case, the Froude number similarity was used for model construction.

Considering the above mentioned scale and taking into account the width of the water channel of Hydraulics Laboratory (1 m), the portion of Crestuma dam represented by the model includes one central span, two piles and two lateral incomplete spans (approximately half spans) as represented in Figure 2.

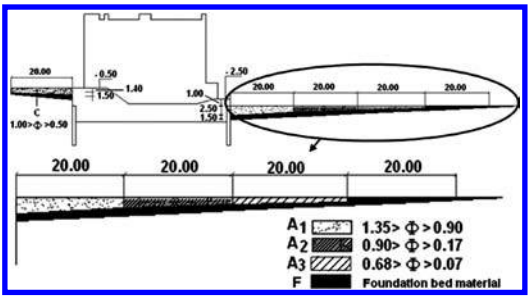

Figure 3. Crestuma dam rock fill bed protection characteristics.

Crestuma rock fill protection has a variable depth and includes different number of layers along its length as shown on Figure 3, where rock fill material dimensions are also indicated.

The concrete slab basin of the plant was modelled on Perspex and the rock fill protection by means of granite and sand grains with specific weights of:

- Granite grains – 26 KN/m^3
- Sand grains – 16 KN/m^3
- Wet sand grains – 18 KN/m^3

The four top layer sections used in the model were 25 cm length each and will be referred as section 1, 2, 3 and 4, corresponding to the above A1, A2, A3 and F designations. Section 4 corresponds to natural foundation bed material.

The bed grain size distribution used for the different sets of experiments corresponds to three different rock fill protection characteristics, A, B and C, as shown on table 2. The rock fill bed protection designated as type A corresponds to the scaled rock fill bed protection used in Crestuma dam. Type B section (increased) dimension was designed taking into account market maximum available dimensions of rock fill to be used in section 1 of the prototype. Type C section 1 element dimensions (the largest of all three) were determined using the following formula proposed by U.S. Corps of Engineers, and used on Crestuma project (LNEC, 1972):

$$d \geq k \frac{U^2}{2g} \frac{\gamma}{\gamma_s - \gamma}$$

where γ and γ_s are respectively the specific weights of water and rock material, k is dependent on flow turbulence and was taken equal to 1, 35.

Sections 2 and 3 element dimensions of types B and C rock protections have been evaluated regarding to grading correspondence to section 1 elements dimension used on type A (Crestuma Project) rock fill protection.

3.3 *Flow conditions*

As previously mentioned Crestuma gates allow different types of discharges. In the present work flow discharge was considered to be done always by the sections underneath the gates and keeping equal gate openings in all the three spans of the model.

Two different flow values have been considered, 11,5 l/s and 12,2 l/s, which main features are presented on table 3, where H_1 is the upstream water level and y_0 is the downstream water level.

The 11,5 l/s value corresponds to a flow situation where hydraulic jump is formed within the stilling basin slab. A small increase of 6% to 12,2 l/s, on the flow value, led to an hydraulic jump showing much more instable characteristics with an oscillatory behaviour and a tendency to move away from the stilling basin slab.

4 EXPERIMENTAL RESULTS

Taking into consideration the two referred flow conditions and the three different types of rock fill bed protection, four sets of measurements have been carried out.

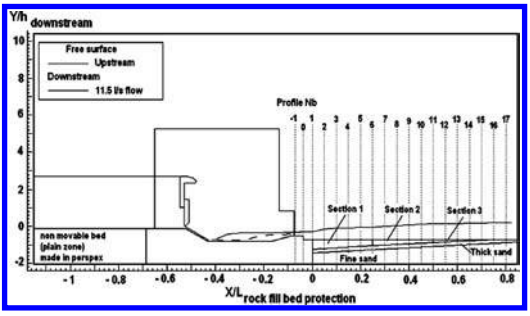

Figure 4. Location of measured profiles.

On each of them, mean and fluctuating velocity profiles have been measured at different flow sections behind the hydraulic structure, as shown on Figure 4.

The first set of experiments concerned a gate flow discharge value of 11,5 l/s and the use of a rock fill bed protection, designated as type A.

Mean and fluctuating values of the horizontal and of the vertical velocity components for the different profiles above referred have been measured and led to the results shown on Figures 5a and 5b. Values of velocities and depth presented are dimensionless taking as reference respectively the horizontal mean sectional velocity and the flow depth values of the stabilized flow on the sections downstream the rock fill bed protection.

As already stated the flow characteristics showed a quite stable hydraulic jump formed within the stilling basin slab. The highest velocity values were observed before entering the rock fill bed protection and no erosion was verified.

The second set of measurements concerned the same type A of rock fill bed protection but a higher gate flow discharge value of 12,2 l/s. Flow characteristics showed a quite unstable and oscillating hydraulic jump moving periodically away from the stilling basin slab.

The consequence of this type of flow gate discharge was the start of the formation of a scour hole on the rock fill bed protection, whose characteristics, concerning dimensions and location, are shown on Figure 6. Scour hole depth values were made dimensionless by considering the ratio to the downstream flow depth value. The scour hole was mostly located in front of the central gate span, along section 1 of the rock fill bed protection. Stabilization of sediment transport occurred, approximately, two hours after the starting of the test.

Mean and fluctuating horizontal velocity component values, after sediment transport stabilization, are presented on Figures 7a and 7b.

Figures 7a and b also represent longitudinal profiles of maximum scour and of maximum deposition,

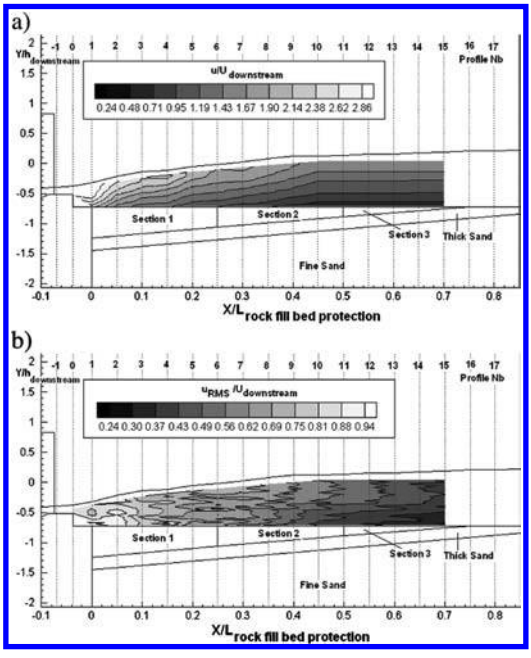

Figure 5. Evolution of the horizontal component values for 11,5 l/s flow and type A rock fill protection: (a) mean velocity and (b) rms (note: dark values are the lowest in range).

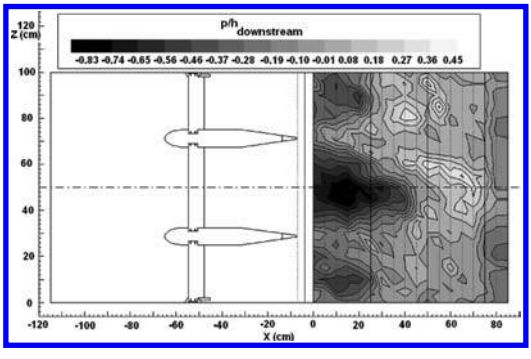

Figure 6. Scour hole caused by a 12,2 l/s gate discharge on type A rock fill bed protection.

the first corresponding to the central channel axis and the other to the pile axis, in accordance with eroded material being transported and deposited downstream, at different transverse rates and locations. The deposition of that material turned the velocity measurement on some downstream profiles impossible because measuring points were out of reach of laser beams. Moreover, only horizontal velocity component could be measured due to the very low flow depth associated with very high flow surface fluctuations and because of LDA system characteristics, namely beam separation at front lens probe.

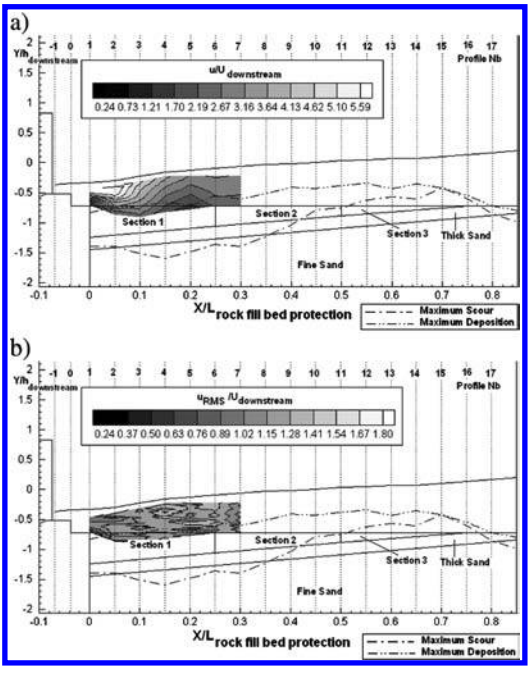

Figure 7. Evolution of the horizontal component values for 12,2 l/s flow and type A rock fill protection: (a) mean velocity and (b) rms (note: dark values are the lowest in range).

A comparison of velocity flow fields of 11,5 l/s and 12,2 l/s flows is presented on Figures 8a and b.

These figures enable to conclude that much higher velocity values and much more important velocity gradient values on the rock fill protection region have been achieved with the 12,2 l/s flow, due not only to the flow velocity values increase, but as well as to the tendency of movement of the hydraulic jump towards downstream.

The third set of experimental measurements was carried out with the same flow gate discharge of 12,2 l/s but using type B rock fill protection.

Scour process did not start immediately. Several oscillations could be noticed on the material of upstream measuring sections (1 and 2) of top layer rock protection during the first 24 h of the test, which have been followed by the formation of the scour hole presented on Figure 9.

The scour hole position moved downstream, in comparison with the situation previously reported for type A rock fill (Fig. 6), and it was now located at the end of section 1 and beginning of section 2 of the rock fill bed protection.

Mean and fluctuating horizontal component velocity measurements have been made before and after the scour hole formation and the results are presented on Figures 10a and 10b.

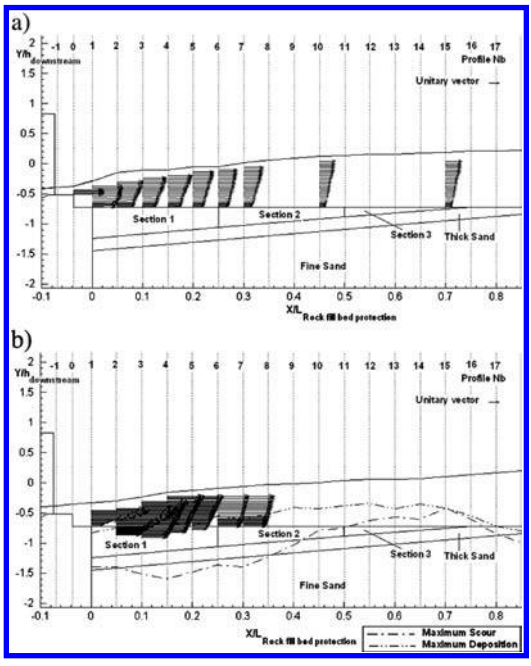

Figure 8. Flow fields for (a) 11,5 l/s and (b) 12,2 l/s gate flow discharges and for type A rock fill bed protection.

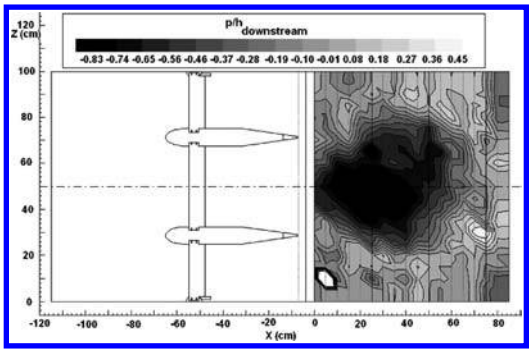

Figure 9. Scour hole caused by a 12,2 l/s gate discharge on type B rock fill protection.

As shown on these figures, the two experiments do show similar mean horizontal component velocity profiles at the beginning of the rock fill protection. Higher differences can be noticed on velocity profiles P5 to P8, corresponding to the end of section 1 and beginning of section 2 of the top rock fill layer protection. The analysis of Figures 11a and 11b, concerning corresponding horizontal component fluctuating velocity values, shows that after scour hole formation the highest fluctuation values have moved towards section 1 zone of bed protection whilst, before

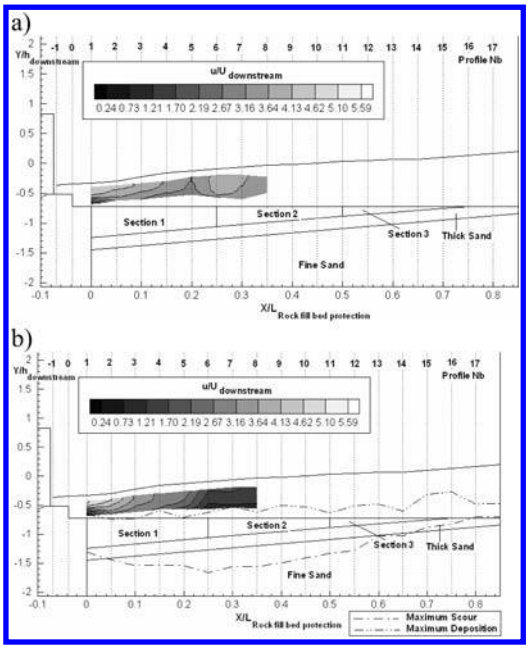

Figure 10. Evolution of horizontal component mean velocity values for 12,2 l/s flow and type B rock fill protection: (a) before and (b) after scour hole formation (note: dark values are the lowest in range).

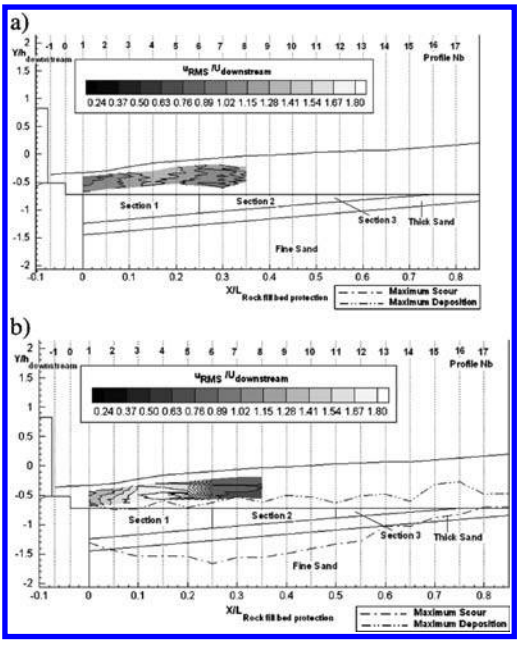

Figure 11. Evolution of horizontal component rms values for 12,2 l/s flow and type B rock fill protection: (a) before and (b) after scour hole formation (note: dark values are the lowest in range).

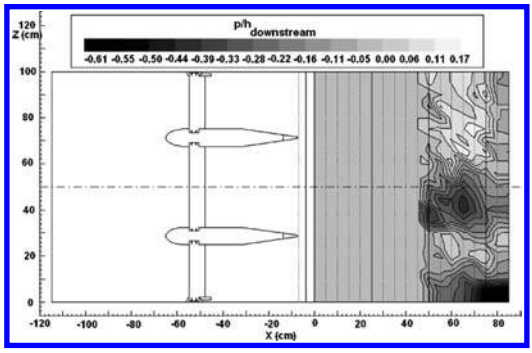

Figure 12. Scour hole caused by a 12,2 l/s gate discharge on type C rock fill bed protection.

erosion was noticed, those values were located by the end of section 1 and beginning of section 2.

The last set of measurements concerned the rock fill bed protection type C and again the use of the same gate flow value of 12,2 l/s.

During the corresponding tests no erosion was noticed on sections 1 and 2 of the rock fill protection. Only slight erosion of the material of section 3 could be observed. Related scour hole characteristics are presented in Figure 12.

Horizontal component mean and fluctuating velocity values are presented on Figures 13a and 13b.

It can be confirmed that mean velocity values are quite similar to the 11,5 l/s flow case. In what concerns fluctuating values, less instability was noticed in this case.

A comparison of the mean flow velocity fields for 12,2 l/s flow regarding rock fill types B (after sour occurrence) and C is made on Figures 14a and b.

This information complements Figure 8b, enabling to compare influence of rock fill protection dimension.

5 RESULT ANALYSIS

The results, earlier presented have been analysed bearing in mind the rock fill bed protection behaviour, concerning its characteristics and flow conditions.

Result analysis has been carried out considering Shields criterion for initiation of movement of gravel particles on a flat bed, using the modified Shields diagram, presented on Figure 1.

The application of Shields diagram and the mobility values calculation required the definition of the friction velocity values. That has been made considering the flows under study either as uniform or as non-uniform flows.

For uniform flows, friction velocity values, u_*, have been directly assessed by using the expressions

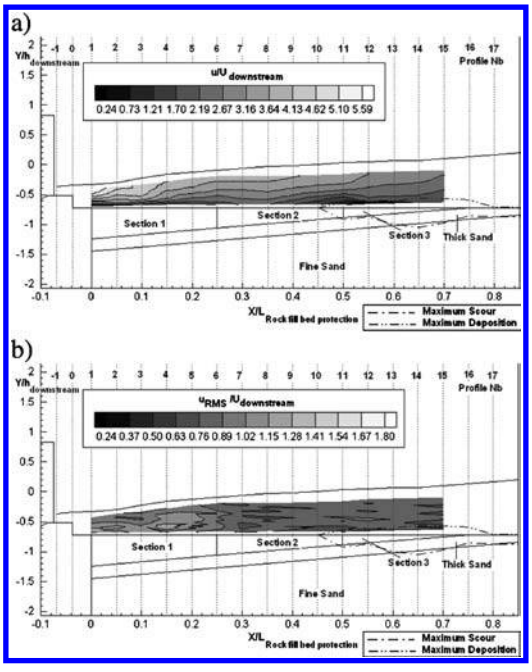

Figure 13. Evolution of horizontal component values for 12,2 l/s flow and type C rock fill protection: (a) mean velocity and (b) rms (note: dark values are the lowest in range).

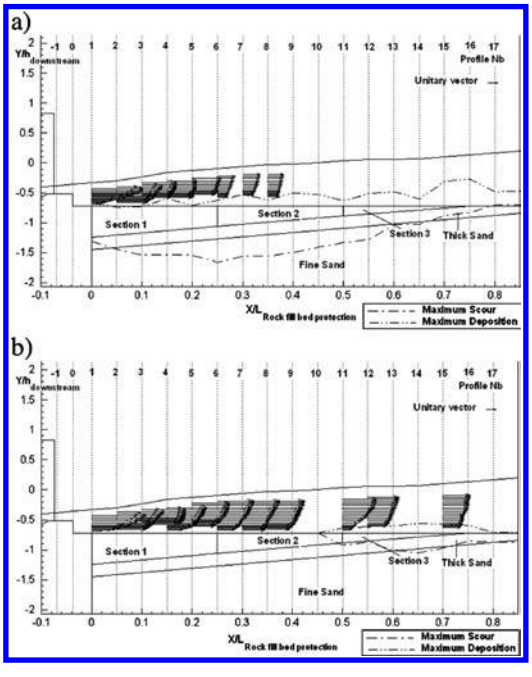

Figure 14. Flow fields for 12,2 l/s flow and (a) type B rock fill protection (after scour occurrence) and (b) type C rock fill protection.

Table 4. Friction velocity values evaluation for 12,2 l/s flow value and type C rock fill protection (uniform flow).

Profile	x (cm)	h (cm)	R (cm)	U (m/s)	J (m/m)	u_* (cm/s)
P1	0	2,4	2,3	0,821	7,49E-02	12,97
P2	5	2,6	2,5	0,758	5,77E-02	11,83
P3	10	3,0	2,8	0,729	4,44E-02	11,11
P4	15	3,4	3,2	0,652	3,04E-02	9,74
P5	20	3,6	3,4	0,599	2,39E-02	8,87
P6	25	3,8	3,5	0,592	1,67E-02	7,62
P7	30	4,0	3,7	0,623	1,74E-02	7,95
P8	35	4,2	3,9	0,630	1,67E-02	7,97
P11	50	4,6	4,2	0,519	9,27E-02	6,21

(4) and (5), and assuming Strickler coefficient as previously referred:

$$K_s = \frac{1}{n}$$

where, according to Chang (1988), n is given by:

$$n = 0{,}0482(d_{50})^{\frac{1}{6}}$$

That allowed bed shear stresses (τ_o) and Shield's parameters (D* and ψ) to be evaluated (based on equation 1) for flow profiles not affected by scour hole formation. Table 4 exemplifies the evaluation of u_* for 12,2 l/s flow, type C rock fill protection. For this same flow and types A and B rock fill bed protection, this method enabled only to evaluate those parameters for the entrance of the rock fill protection area (profile P1). Figure 15 (a, b and c) shows plots of the correspondent obtained values.

According to Figure 15a there will be no movement on the rock fill protection for the 11,5 l/s flow (for type A rock fill protection), being the nearest point to curve 1, of the modified Shields diagram, the one representative of profile P1. This curve corresponds to "occasional particle movement at some locations" (see legend of Figure 1). In fact, during the tests no erosion or scour was noticed, only some rock material instability was remarked.

Figure 15b enabled comparison of Shield diagram plots correspondent to profile P1 for this case (type A), for different flow conditions (Q = 11,5 l/s and 12,2 l/s). The point representative of the 12,2 l/s flow value was now located between curves 6 and 7 of Shields diagram, corresponding to "permanent moving of particles" and "general transport of ripples" situations, as was, in fact, confirmed during the tests.

Figure 15c compares Shield plots correspondent to all the rock fill protection types for 12,2 l/s flow.

For type B protection, where velocity profile P1 was measured before erosion occurrence, the diagram

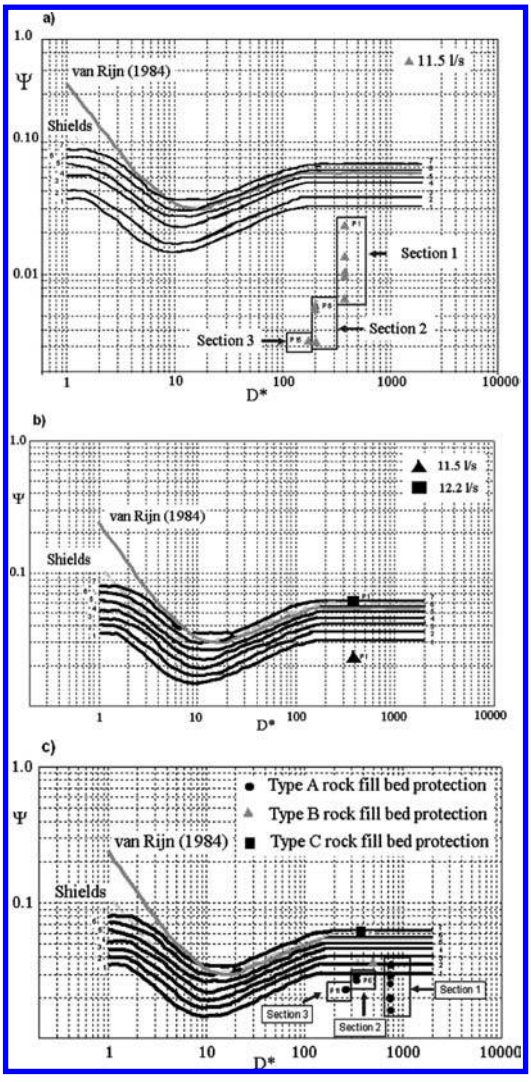

Figure 15. Modified shields diagram for: (a) 11,5 l/s flow and type A rock fill bed protection; (b) 11,5 l/s and 12,2 l/s and type A rock fill protection; (c) 12,2 l/s and types A, B and C rock fill protection (assuming uniform flow case).

indicated the situation of "frequent movement of particles in some locations", which was in agreement with the experimental results.

In which regards C type rock fill bed protection, Shields diagram enabled to conclude that there will be no particle movement of materials except on profile P1 location where there will be the tendency to "occasional to frequent movement of particles". In fact, it should be pointed out that, during the experiments, no erosion events of bed protection on sections 1 and 2 were recorded. However, on section 3, some scour has

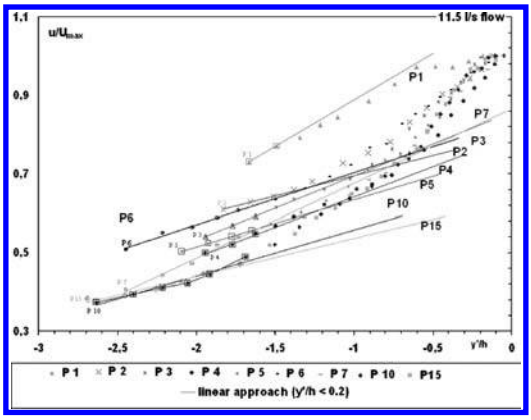

Figure 16. Uniformity flow analysis for 11,5 l/s flow.

Table 5. Rotta criterion parameters evolution for 12,2 l/s flow and for type A, B and C rock fill bed protections: (a) u_*/U_{max}; (b) β; (c) $U_{max}\delta^*/u_*$.

	Rock fill bed protection								
	Type A			Type B			Type C		
Profile	a)	b)	c)	a)	b)	c)	a)	b)	c)
P1	0,102	0,6	9,8	0,103	0,7	7,0	0,118	0,4	5,3
P2	–	–	–	–	–	–	0,121	1,4	4,8
P3	–	–	–	–	–	–	0,123	1,8	4,6
P4	–	–	–	–	–	–	0,119	1,2	5,8
P5	–	–	–	–	–	–	0,116	1,6	7,0
P6	–	–	–	–	–	–	0,101	2,2	8,3
P7	–	–	–	–	–	–	0,103	2,1	7,4
P8	–	–	–	–	–	–	0,105	1,6	6,9
P11	–	–	–	–	–	–	0,089	0,7	13,3

occurred, as it was shown in the previously referred Figure 12.

The above analysis was based on the assumption that the studied flows were uniform flows and thus the representation of their velocity profiles could be made using the logarithmic law defined by the expression (2).

Nevertheless, velocity profiles on the inner region, corresponding to the 11,5 l/s flow case have been plotted, and shown on Figure 16. For inner limit region, the value of $y'/h = 0.2$, often used, was considered. Those profiles enabled to conclude that the flow, was in fact not uniform.

The same conclusion could be withdrawn through Rotta criterion application, using the set of expressions (3) which values are shown on table 5 for the 12,2 l/s flow and the three rock fill bed protections studied, which confirms the non-uniformity of the flow.

Table 6. Friction velocity values evaluation for 12,2 l/s flow value and type C rock fill protection (non-uniform flow).

Profile	x (cm)	h (cm)	u_*^2 (cm^2/s^2)	u_* (cm/s)
P1	0	2,4	173,36	13,17
P2	5	2,6	78,32	8,85
P3	10	3,0	164,60	12,83
P4	15	3,4	66,87	8,18
P5	20	3,6	18,10	4,25
P6	25	3,8	27,37	5,23
P7	30	4,0	19,99	4,47
P8	35	4,2	12,91	3,59
P11	50	4,6	192,73	13,88

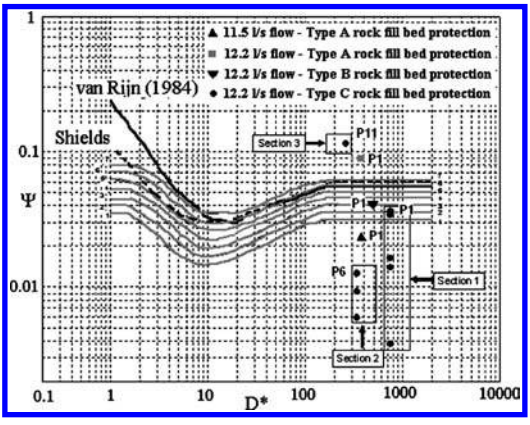

Figure 17. Modified Shields diagram for 11,5 l/s and 12,2 l/s flows and for type A, B and C rock fill bed protections, assuming the non uniform flow case.

Based on the data obtained from the velocity profiles measured and for the different test conditions, velocity friction values have then been recalculated using equation (6). Table 6 presents an example of those calculations for the same case as in table 4: 12,2 l/s flow and type C rock fill protection.

The same procedure has been applied to all the flow values and bed fill protection types and have been on the basis of Shields parameters recalculation for all set of flows and rock fill bed protections, which are shown on Figure 17.

The plotted values considering the non-uniformity conditions show to be in better agreement with the experiments. From the above figure, it can be concluded that for A and B rock type protections movement of materials shall occur, which was confirmed by the experiments, and that for C type only on section 3 of the rock fill protection, profile P11, erosion will occur, in accordance with what was, in fact, reported on experiments and shown on Figure 12. That occurrence could not be confirmed by Shields diagram when considering uniform flow case.

6 CONCLUSIONS

A physical model of Crestuma dam was made and tested for two flow values and for three different types of rock fill bed protections, in order to have a better insight on flow energy dissipation effect on those protections.

Laser Doppler Anemometry was used for flow velocity measurements in order to define the corresponding flow fields on the different test conditions. Velocity profiles measurements at different locations in the stilling basin and in the downstream rock fill bed protection, allowed the definition of the mean and turbulent flow field characteristics corresponding to each one of the different test conditions.

Two different limit flow discharges were studied, enabling the analysis of scour effects on different rock fill bed protections; one close to incipient motion of particles of (type A) rock fill bed protection and the other with scouring effects on the three different studied (growing in dimension, types A, B and C) rock fill types.

Critical shear stress criterion, using modified Shields diagram was applied to analyse the different types of rock fill bed protection behaviour. Subsequently, Shields parameters have been calculated assuming uniformity or non-uniformity behaviour of the flow.

Based on the above criterion scour occurrence was analysed and experimental results compared with the theoretical ones.

It could be concluded that, in general, the non-uniform flow approach led to better results on scour occurrence analysis.

Future work shall be made taking into account other different criteria for initiation of sediments movement in order to compare the obtained results.

ACKNOWLEGEMENTS

ABSTRACT: River dunes influence the hydraulic roughness and water levels in rivers. Especially during floods the interplay between dunes and the flow field could become significant. Therefore, it is desired to forecast the dimensions of dunes during such extreme and unsteady flood events. At present it is not yet feasible to predict the dimensions of dunes by computing the flow and sediment transport in full detail for operational spatial and temporal scales. In this paper, we present a morphodynamic model that simulates dune development, without computing all details in the flow field. The flow model is based on the 2D-vertical hydrostatic equations, with a constant eddy viscosity over depth. Flow separation and the sediment transport behaviour in the flow separation zone are included in a parameterized way. Results of the morphodynamic model using steady flow conditions, are in general agreement with flume experiments. A next step in the research will be to use forecasted dune dimensions for hydraulic roughness predictions.

1 INTRODUCTION

Water levels during floods in rivers are largely influenced by the flow resistance that results from flow over a dune-covered bed. A flood event itself determines the development of the dunes, leading to a complex interplay of bed formation and flow characteristics.

In current practice, in hydraulic flow models the roughness of the main channel is used as the calibration parameter to match observed water levels. Although the total flow resistance of the river is due to several different sources (e.g. vegetation or groynes), dunes have a large influence on the roughness because of energy dissipation behind steep dunes (e.g. Vanoni and Hwang 1967). During their development, the lee-side of a dune may become so steep that the flow cannot follow the bed surface any longer, forming a flow separation zone. The turbulence (eddies) generated in the flow separation zone slows the flow down. This process is often referred to as form roughness or form drag.

At present, there is still limited knowledge about the effect of dunes on the hydraulic roughness of a river, let alone about their development during floods. In order to understand flow resistance due to dunes, it is necessary to first understand their behaviour. If dune dimensions and their resulting resistance can be predicted as a function of flow conditions and sediment properties, this part of the total flow resistance may be excluded from the calibration of hydraulic models.

Several researchers proposed methods to forecast dune dimensions (e.g. dune length and dune height), based on a range of parameters like flow strength, water depth or sediment size. Part of the proposed methods are empirical (e.g. Julien and Klaassen 1995; Van Rijn 1984), while others are more theoretical (e.g. Kennedy 1969; Onda and Hosoda 2004). All these methods are designed to calculate equilibrium dune dimensions in steady, uniform flow. In that case a unique dune height and dune length exist for each specific combination of flow characteristics and sediment properties.

Observations have shown that changes in flow resistance are out of phase with flood intensity. Maximum dune dimensions occur later than the maximum discharge (e.g. Ten Brinke et al. 1999; Julien et al. 2002). Several researchers tried to include the observed time-lag between dune dimensions and flood intensity in their models to forecast dune dimensions (e.g. Allen 1976; Fredsøe 1979). However, as shown by Wilbers (2004), none of these predictors are able to predict dune dimensions during several floods in the River

Copyright © 2006 Taylor & Francis Group plc, London, UK

Rhine in the Netherlands adequately. Wilbers (2004) developed an empirical calculation method to forecast dune development under unsteady flow conditions, based on a method proposed by Allen (1976). This method is applied with success to three sections of the Rhine branches. However, a major drawback is that the method is not generally applicable. For every situation, initial dune dimensions have to be known and data are required to calibrate empirical coefficients. Furthermore, the method gives only limited insight in the physics behind dune development during floods.

To forecast the behaviour of dunes on a physical basis, the flow and sediment transport resulting from that flow has to be predicted. Yoon and Patel (1996) adopted a k-ω turbulence model enabling a detailed computation of the flow in the separation eddy. Results were shown to be in general agreement with the experimental data. Stansby and Zhou (1998) showed that the computation of the flow in the separation zone improved when a non-hydrostatic pressure (instead of hydrostatic) was applied. Nelson et al. (2005) have shown that a large eddy simulation model with non-hydrostatic pressure, in combination with a sediment transport model taking fluctuations of the bed shear stress on turbulent timescales into account, realistically models dune development. Such approaches require modelling all details in the flow field and especially the complex flow in the flow separation zone. A disadvantage of such methods is that they are complicated and require much computational effort. This becomes a problem when the flow calculation has to be done repeatedly for each bottom update.

As a first step towards predicting flow resistance caused by dunes on large spatial and long temporal scales, we propose a morphodynamic model to forecast dune development under steady flow conditions. We aim to develop the most basic morphodynamic model that still describes the most relevant processes to predict dune development.

Paarlberg et al. (2005) have shown that the morphodynamic model of Hulscher (1996), which is originally developed to simulate offshore sandwaves, can also be used to simulate river dunes in unidirectional flows. This morphodynamic model is numerically implemented by Németh et al. (2006) and Van Den Berg and Van Damme (2005), of which the latter is used in this research.

The numerical model is based on hydrostatic equations, implying that flow separation cannot be treated explicitly. To keep the model appropriate, we present an approach to include flow separation in a parameterized way. Following the approach of Kroy et al. (2002), the idea is to cut off the flow separation zone from flow computations and only compute the flow above this zone. Paarlberg et al. (2005) showed that the shape of the flow separation can be estimated on the basis of general dune dimensions. Although the predicted shape was in agreement with detailed measurements on turbulent flows over dunes, the parameterization was not tested in a morphodynamic model. Therefore, in this paper, the morphodynamic model is extended with a parameterization of sediment transport behaviour in the flow separation zone, and tested against flume data.

2 MODEL FOR GENTLE DUNES

To simulate dune development, flow and sediment transport due to this flow are modelled. A stationairy version of the code described in Van den Berg and Van Damme (2005) is used for computations. This model is based on earlier models by Hulscher (1996) and Németh and Hulscher (2003). In this section the model equations are discussed. Further, the numerical model is applied to a situation with gentle bed-slopes (i.e. streamlined flow without separation).

2.1 *Steady flow model*

Flow is simulated with the hydrostatic two-dimensional vertical (2DV) shallow water equations. The momentum equation in x-direction and the continuity equation read:

$$u\frac{\partial u}{\partial x} + w\frac{\partial u}{\partial z} = -g\frac{\partial \zeta}{\partial x} + A_v\frac{\partial^2 u}{\partial z^2} + gi \tag{1}$$

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \tag{2}$$

The velocities in the x- and z- directions (see Figure 1) are u and w, respectively. The water surface elevation is denoted by ζ, i is the average bottom slope,

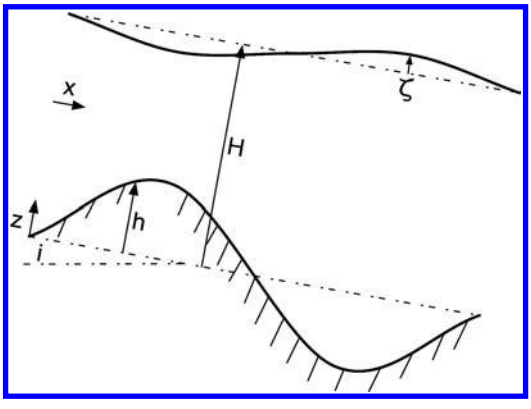

Figure 1. Definitions of H (average height of the water column), $h(x)$ (bottom disturbance) and $\zeta(x,t)$ (surface elevation).

Copyright © 2006 Taylor & Francis Group plc, London, UK

and g and A_v denote the acceleration due to gravity and the vertical eddy viscosity, respectively.

2.2 *Boundary conditions*

Two boundary conditions are imposed at the water surface ($z = H + \zeta$): (*i*) there is no flow through the surface, and (*ii*) there is no shear stress at the surface:

$$u\frac{\partial \zeta}{\partial x} = w \tag{3}$$

$$\frac{\partial u}{\partial z} = 0 \tag{4}$$

The boundary condition at the bed ($z = h$) is that there is no flow through the boundary:

$$u\frac{\partial h}{\partial x} = w \tag{5}$$

As a basic turbulence closure, a constant eddy viscosity is used. In combination with the fundamental property of boundary layers, the no-slip boundary condition leads to an over-prediction of the shear stress at the bed. Soulsby (1990) has made a comparison between different turbulence models for boundary layer flows. He also examined alternatives to the no-slip boundary conditions. It turns out that constant eddy viscosity in combination with a partial slip conditions results in a good representation of the vertical flow structure and the shear stress at the bed level.

The partial slip condition at the bed ($z = h$) is given by:

$$\tau_b = A_v\frac{\partial u}{\partial z} = Su_b \tag{6}$$

where τ_b is the volumetric bed shear stress [m^2/s^2]. The slip parameter S determines the resistance at the bed; $S \to \infty$ would amount to a no slip condition.

Paarlberg et al. (2005) calibrated the values of A_v and S using flume measurements of the actual velocity profile and the bottom shear stress.

2.3 *Sediment transport model and bed behaviour*

Only bedload sediment transport is considered in the model, since this is assumed to be the main transport mechanism behind dune development. A general bed load formula including bed slope effects is applied:

$$q_b = \alpha|\tau_b|^\beta\left[\frac{\tau_b}{|\tau_b|} - \lambda\frac{\partial h}{\partial x}\right] \tag{7}$$

where q_b is the volumetric bed load transport [$m^2\ s^{-1}$]. The proportionality constant α [$s^2\ m^{-1}$] describes how efficiently the sand particles are transported by the bed shear stress (Van Rijn 1993) and strongly determines the time-scale of bed evolution. Parameter β represents the nonlinear dependence of sediment transport on the bed shear stress. The bed slope parameter λ describes the downhill preference of moving sediment. Bed evolution follows from the Exner equation:

$$(1-\epsilon_p)\frac{\partial h}{\partial t} = -\frac{\partial q_b}{\partial x} \tag{8}$$

where ϵ_p is bed porosity (typically $\epsilon_p \sim 0.4$).

2.4 *Results*

The model presented in this section cannot treat flow separation, since the pressure distribution is hydrostatic. However, the model should be able to reproduce the main characteristics of dune development in the case of streamlined flow (no flow separation). Figure 2 shows results of a simulation with an initially small symmetrical bed disturbance and periodic boundary conditions. Used parameter values are specified in Table 1 (see also Paarlberg et al. 2005).

The figure shows that over time the dunes grow in amplitude and migrate in streamwise direction. Further, it can be observed that dune asymmetry (ratio of stoss- and lee-side slope) increases over time. These processes are well known processes in dune development, giving confidence in the used model equations. However, to enable determination of equilibrium dune dimensions the model needs to be extended to enable simulations in cases where flow separation occurs.

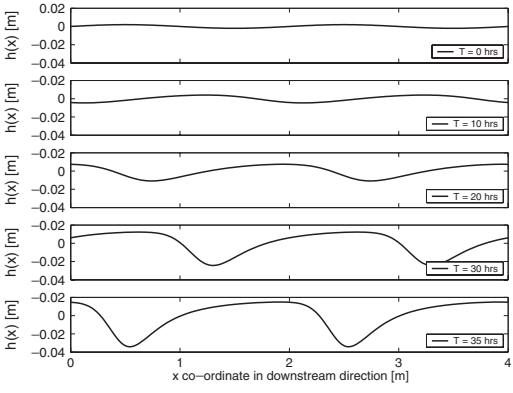

Figure 2. Development of small initial disturbance (2 mm). See Table 1 for model parameter settings. Flow is from left to right. T are flow hours.

3 FLOW SEPARATION

3.1 *Process of flow separation*

Flow over a river bed is driven by gravity. Seen in vertical direction the pressure gradient is linear between the watersurface (zero) and the bed ($\rho g h_l i$, with h_l the local water depth) for parallel and non-curved streamlines. This condition holds more or less for slowly accelerating flow over the stoss side of a dune.

If we consider flow over a dune, such as shown in the bottom panel of Figure 2, the pressure gradient in horizontal direction is positive (or adverse) at the lee-side of the dunes due to an increasing local water depth. This adverse pressure gradient is most pronounced in the region close to the bed. Here momentum is lowest, leading to a velocity profile with a $\partial u/\partial z$ of zero near the bottom. Even further downstream on the lee-side, where the adverse pressure gradient is larger, reverse flow is observed. As a result of the reversed flow, a flow separation zone will form behind steep dunes. Here, the location where the flow separates is termed the flow separation point (FSP).

Figure 3 shows flow over a typical dune with presence of a flow separation zone (FSZ). The flow reattaches to the bed at a typical distance of about 6 times the dune height at the flow reattachment point (FRP). The separating streamline (SSL) indicates the boundary between the recirculating flow cell, and the normal flow field. The zero velocity line (ZVL) connects the points where the horizontal velocity is zero. The abbreviations used in this section are included in Figure 3 for later reference.

3.2 *Parameterization of the shape of the flow separation zone*

Paarlberg et al. (2005) propose a parameterization of the shape of the flow separation zone, based on the approach of Kroy et al. (2002). They state that formation and migration of aeolian sand dunes do not very sensitively depend on the details in the FSZ. Since there is flow recirculation in the FSZ, it is assumed that computation of the flow field above the separating streamline is sufficient. Therefore, a parameterization of this separating streamline was developed by Paarlberg et al. (2005).

The main concepts of the parameterization are:

- The shape of separation zone is independent of flow conditions;
- The SSL can be represented by a 3rd order polynomial: $s(x) = s_3(x_*)^3 + s_2(x_*)^2 + s_1(x_*) + s_0$, with $x_* = x - x_s$ and x_s the position of the FSP;
- There is smooth connection at separation point giving s_1 and s_0;
- The (dimensionless) length of the separation zone can be estimated from (see Paarlberg et al. 2005 for determination of coefficients):

$$L_{fsz}/H_{dune} = 0.19\alpha_s + 5.66 \quad (9)$$

  where L_{fsz} the FSZ-length, H_{dune} the dune height at separation and α_s the local bed slope at separation (degrees);
- The angle of the SSL at the FRP is $-25°$ with the average bottom slope.

4 THE MORPHODYNAMIC MODEL

To include flow separation, the numerical model described in Section 2 is extended with the parameterization for flow separation as described in Section 3. Figure 4 shows a schematic representation of the morphodynamic model setup, which will be explained in this section. If there is no flow separation, the left part of Figure 4 is followed which is the model as described

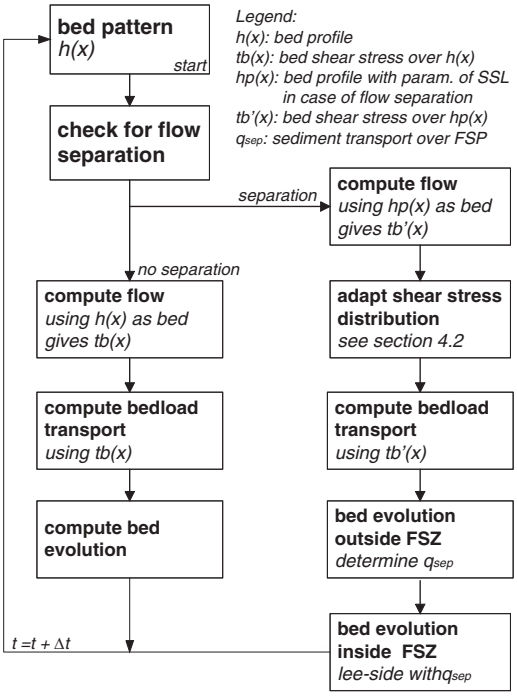

Figure 4. Schematic representation of the morphodynamic model.

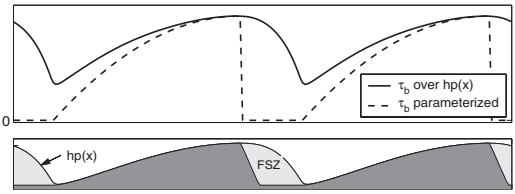

Figure 5. Parameterization of bed shear stress distribution over a dune. The bottom panel gives an arbitrary bed profile with flow separation zones (FSZ) indicted. The top panel gives the computed and parameterized bed shear stress distribution.

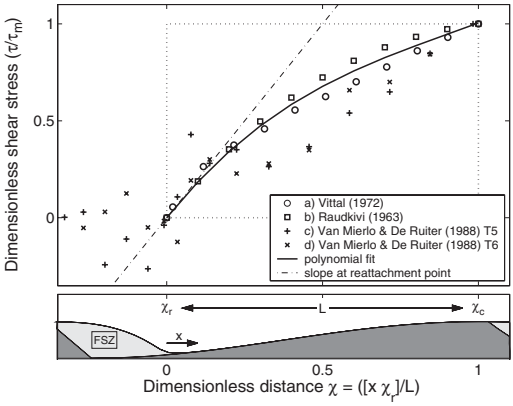

Figure 6. Measured bed shear stress distributions over dunes. For case (a) and (b) the data points are directly taken from reported literature; for case (c) and (d) the values are derived by assuming a logarithmic velocity profile close to the bed. The horizontal axis is scaled by $L = \chi_c - \chi_r$, being the horizontal length between the FRP and the next bedform top. The vertical axis is scaled by the maximum bed shear stress measured at the top (see also Table 2).

in Section 2. When flow separation does occur the model follows the right part in Figure 4.

4.1 *Flow separation criterion in the model*

In the flow solver, no pressure distributions are computed. The criterion for flow separation to occur is based on local bed gradients. Strong (negative) bed gradients result in an increase of adverse pressure gradient. In line with e.g. Kroy et al. (2002) we use the following separation criterion: separation occurs if the local bed gradient exceeds $-14°$ (with the mean bottom slope).

4.2 *Bed shear stress distribution over a dune*

In our approach, flow is computed over the SSL above the FSZ, and over the bed elsewhere. Thus the flow inside the FSZ is not computed explicitly. Figure 5 shows an example of the bed shear stress distribution over two identical dunes with flow separation.

Measurements show that the time-averaged bed shear stress approximates zero in the FSZ (see e.g. Van Mierlo and De Ruiter 1988). Furthermore, if bedload transport is dominant, the sediment flux in the FSZ is close to zero due to flow recirculation in the FSZ. The flow computation over the parameterized bed ($hp(x)$) is used to give a first estimate of the bed shear stress distribution over the dunes. Next, the average bed shear stress (and thus the flux) is set to zero inside the FSZ. This procedure results in two discontinuities in the shear stress distribution over a dune. At the FSP the bed shear stress goes to zero. In Section 4.3 will be shown that this is no problem because of the method used for bed evolution inside the FSZ. However, the discontinuity at the FRP must be resolved. Therefore, we need a parameterization for the distribution of the average bed shear stress over the stoss-side of the dunes.

Figure 6 shows measurements of (dimensionless) bed shear stress distributions over dunes (dune characteristics can be found in Table 2). At the FRP the measured time-averaged bed shear stress is zero, and downstream of the FRP the time-averaged bed shear stress gradually increases until it reaches a maximum at the dune crest. To mimic this behaviour a curve is

Table 2. Measurements that are used to obtain a bed shear stress distribution for the model. General dune and flow characteristics, used scaling parameters for Figure 6, and general flow characteristics are included.

	(a)	(b)	(c)	(d)
λ	0.6	0.39	1.6	1.6
Δ	0.03	0.03	0.08	0.08
L	0.51	0.25	1.16	1.16
τ_m	0.72	0.30	1.12	1.50*
i	$3.5{\cdot}10^{-4}$	$5.3{\cdot}10^{-4}$	$9.4{\cdot}10^{-4}$	$9.4{\cdot}10^{-4}$
H	0.200	0.130	0.290	0.372
q	0.070	0.037	0.099	0.171

λ: Dune length [m]; Δ: Dune height [m]; L: Distance between FRP and next crest position [m]; τ_m: Maximum bed shear stress [N/m^2] (the latter two parameters are used as scaling parameters in Figure 6); i: Average bottom slope [−]; H: Average water depth [m]; q: Specific discharge [m^2/s]; *: measured shear stress was slightly higher due to horizontal section just before top; (a): Vittal (1972); (b): Raudkivi (1963); (c,d): Van Mierlo and De Ruiter (1988).

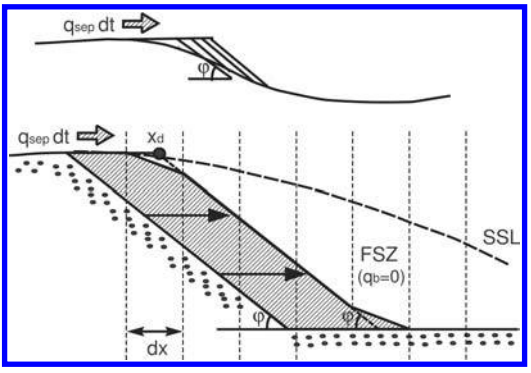

Figure 7. If flow separation occurs, a lee-side with an angle of repose (φ) is formed (top figure). The volumetric sediment transport ($q_{sep}dt$), where dt is the timestep, distributes evenly over the lee-side, as sketched in the lower figure. x_d is the horizontal position where the lee-side starts; dx is the horizontal grid distance. Due to interpolation to the grid in each time step, errors occur, which are compensated in the next time step.

fitted through these measurement points. Since we are interested in the shear stress on the stoss-side of a dune only measurements in the rectangular box in Figure 6 are used. The solid line in Figure 6 is a third order polynomial fit through the data, which fits quite well to the data. Therefore, we choose to approximate the bed shear stress distribution over a dune with a third order polynomial:

$$\tau'(\chi) = \begin{cases} 0 & \text{if } \chi < 0 \text{ (FSZ)} \\ a_3(\chi)^3 + a_2(\chi)^2 + a_1(\chi) + a_0 & \text{if } \chi_r \le \chi \le \chi_c \end{cases} \quad (10)$$

where χ is a dimensionless position along the dune (see Figure 6), and the coefficients $a_0 \ldots a_3$ are calibrated using the measurements. Parameter a_0 equals zero, since the bed shear stress is zero at the reattachment point (χ_r) and for a_1 holds at χ_r:

$$\left.\frac{d\tau'}{d\chi}\right|_{\chi_r} = 2\frac{\tau_m}{L}, \quad L = \chi_c - \chi_r \quad (11)$$

The coefficients a_2 and a_3 are calibrated by imposing smooth connection to the computed bed shear stress (and gradient in bed shear stress) at the crest of a dune.

4.3 *Bed evolution*

Bed evolution in the region outside the FSZ is determined by computing sediment transport and bed level changes by applying Eqs. (7) and (8). Since the time-averaged bed shear stress is set to zero inside the FSZ, there is no sediment transport in that zone. To schematize bed deformation in the FSZ, the material that passes the FSP is assumed to avalanche down the lee-side of the dunes and to be distributed evenly over the lee-side, with a lee-side angle at the angle of repose φ (for natural sand $\varphi \sim 30°$).

When performing this operation numerically, two small errors are made at each numerical timestep: (1) a "truncation error", being the difference between the volume that should be stored behind the dune and the amount that is actually stored; this error is kept within 1×10^{-6} m^2, and (2) a "rounding error" due to interpolation to the grid when the lee-side of the dune is set (this error is of order 1×10^{-5} m^2). The sum of both errors implies that either too few or too much sediment is stored at the lee-side of the dune. This error is computed and corrected in the next morphodynamic update.

As may be observed in Figure 2, using the flow separation criterion discussed in Section 4.1, the position where flow separation occurs for the first time in the model is somewhere halfway the lee-side of the dune. In the model, from this moment onward separation occurs at the crest of the dune, inducing avalanching of sediment over the top. This process occurs fast compared to the overall timescale of dune development (migration of about order 10 m/day, see e.g. Wijbenga and Van Nes 1986), and is illustrated in Figure 7. Effectively, it means that the lee-side does not deform from the moment that it reaches a slope at the angle of repose, and that the distance that the lee-side moves downstream is determined by the sediment volume over the separation point and the dune height.

5 RESULTS WITH FIXED DUNE LENGTH

In this section, the performance of the model from the previous section is presented. The eddy viscosity A_v and slip parameter S remain constant during the simulation. As bedforms develop over time, the roughness of the bed changes. Although the roughness (included in the model via the slip parameter S) is constant in a simulation, the average water depth H is changed to ensure a constant steady discharge. Simulations are made with periodic boundary conditions, putting restrictions on the wave length of simulated dunes (i.e. the dune length will remain constant).

5.1 *Bed evolution*

Simulations start with an initially flat bottom with very small disturbances. These disturbances develop into asymmetric features as shown in Section 2.4. Using the morphodynamic model discussed in the previous section, simulations can now be performed including the effect of flow separation. Parameter settings for the model runs presented here are the same as in Section 2.4. Figure 8 shows the long term evolution of two dunes, leading to typical dune shapes with a lee-side at the angle of repose.

After sufficiently long time, a (dynamic) equilibrium is obtained as shown in Figure 9. The equilibrium is referred to as dynamic because the dunes still migrate in downstream direction, while their height remains constant. The dune height (defined as the vertical distance between crest- and trough elevation averaged over the two dunes) steadily increases, attaining an equilibrium height after about 130 flow hours. The average water depth (H) shows a similar behaviour, as a result of increasing flow resistance due to a growing FSZ.

Determination of the migration velocity of the dunes is not straightforward, because the dune profile deforms, as well. For example, in cases without flow separation, the crest of the dunes migrates faster than the trough. Since simulations initially start with a sinusoidal disturbance in a periodic domain, we choose to apply a fast fourier transform to determine the migration velocity of the Fourier mode most prominently present in the bed. The phase difference between the Fourier components at two subsequent timesteps is translated into an estimate of the migration velocity. Figure 9c shows, apart from the "discontinuity", that the migration velocity decreases with increasing dune height. Larger dunes, with constant dune length, imply lower migration velocities, since more sediment has to be moved.

The discontinuities in Figure 9 are related to our implementation of flow separation. The system suddenly switches from a situation without flow separation to one with flow separation. When this switch

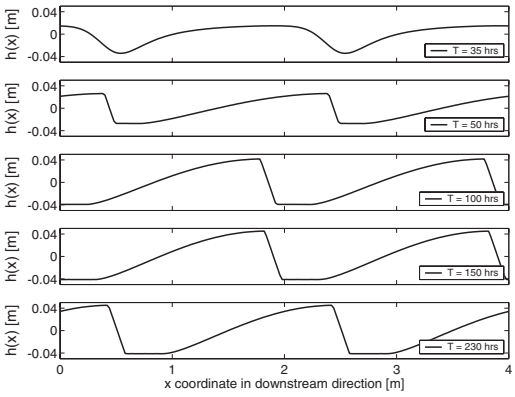

Figure 8. Long term development of two identical dunes. The top panel is the same as the last panel of Figure 2 with a different scale on the y-axis. T are flow hours.

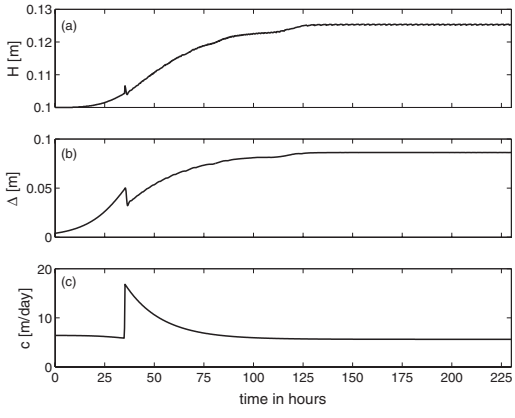

Figure 9. Development of average water depth H (a), dune height Δ (b), and migration velocity (c) over time for the simulation shown in Figure 8. The discontinuity is at the time where flow separation happens for the first time (after about 35 hours).

occurs, the system needs to adapt to the strong changes in bed shear stress distribution over the dunes. After about 35 flow hours, when flow separation occurs, the bed shear stress in the FSZ becomes zero and on the stoss side the bed shear stress gradient increases (i.e. Eq. (10)). From separation onwards, all the sediment transported over the FSP is stored in the FSZ behind the lee-side of a dune. This leads to a situation with a larger migration velocity, compared to a situation where the sediment was redistributed over a sinusoidal dune.

5.2 *Flow field and bed shear stress*

Figure 10 shows the bed velocity, the bed shear stress distribution and the velocity field in equilibrium after

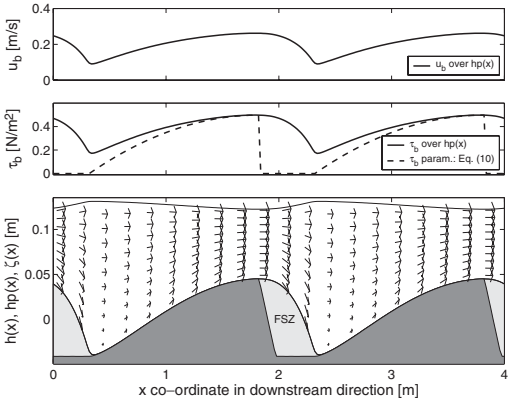

Figure 10. Bed velocity (top), bed shear stress (center) and velocity field (bottom) after 150 flow hours. Dark gray shading is the bed, light gray shade represents the FSZ, over which the flow is computed.

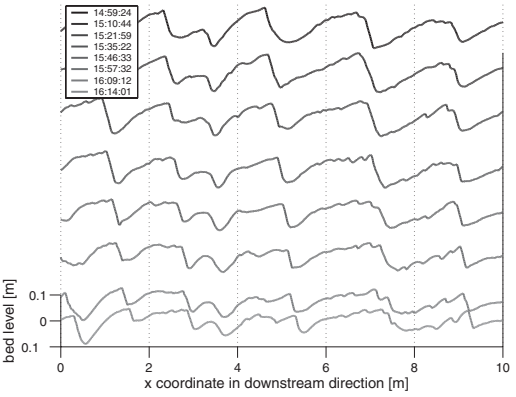

Figure 11. Bed profile measurements for TOW test T14 in equilibrium (Bakker et al. 1986). Test conditions: $q = 0.04\,\mathrm{m^2/s}$, $H = 0.106\,\mathrm{m}$, and $i = 1.06 \cdot 10^{-4}$. Time reads from top to bottom, and scale is indicated on the lower left side of the plot.

150 flow hours. The dunes occupy a considerable height of the water column ($\Delta/H \approx 0.7$ in equilibrium), and also water surface fluctuations are significant. The velocity at the bed increases over the stoss-side. Due to the partial slip condition, velocities near the bed differ from zero. Also we clearly see lower velocities at the bed compared to velocities at the surface.

5.3 *Comparison with measurements*

Between 1973 and 1980 a series of flume experiments with steady flow conditions and uniform sediment were carried out at the Delft Hydraulics Laboratory (Bakker et al. 1986). The measurements were performed in a flume which is 100 m in length and 1.5 m wide.

Figure 11 shows a series of recorded bed profiles for test T14 in equilibrium. The first 10 m of a 30 m long measurement section at the end of the flume are shown. In this experiment, which started with a bed profile resulting from a previous experiment, the following flow conditions hold in equilibrium: a specific discharge $q \approx 0.04\,\mathrm{m^2/s}$, an average water depth $H = 0.106\,\mathrm{m}$, and mean bottom slope $i = 1.06 \cdot 10^{-4}$. The energy slope is kept constant during the experiment by a weir at the downstream end of the flume. These conditions are comparable to the simulation that is performed. In the experiments, an equilibrium was attained after about 250 flow hours. In equilibrium, the average dune height is about 0.05 m, the average length about 1.7 m, and the migration rate is estimated at about 10 m/day. All these characteristics are in general agreement with our simulation, although the dune height seems somewhat over estimated by our simulation model. This may be due to our approximation of constant eddy viscosity over depth, or the imposed constant dune length.

6 DISCUSSION

The proposed model is simple and fast in application, but highly parameterized. Some of the parameters maybe estimated a priori. An estimation of the eddy viscosity A_v can be obtained from a relationship that follows from integration of an parabolic eddy viscosity profile in vertical direction:

$$A_v = \frac{1}{6}\kappa u_* H \tag{12}$$

in which κ is the Von Kármán constant (=0.407), and u_* is the shear velocity ($=\sqrt{gHi}$). Evaluating this equation for an initial water depth of $H = 10\,\mathrm{cm}$ results in $A_v = 1.56 \times 10^{-4}\,\mathrm{m^2/s}$. This is very close to the calibrated value (see Table 1). The slip parameter S is more difficult to estimate, and may depend on grain-size, water depth and energy slope; for now, this remains a parameter for calibration.

The parameter α appearing in the sediment transport relationship is set to 0.3 following Van Rijn (1993). According to Komarova and Hulscher (2000) its value can be estimated with:

$$\alpha = \frac{m}{(s-1)g} \tag{13}$$

where s is the specific grain density (=1.65), and m is an empirical coefficient, which may vary between 5.7 and 12 depending on the rate of sediment transport (Wiberg and Smith 1989). To arrive at a value of $\alpha = 0.3$, m should be about 5. Although this seems a

Copyright © 2006 Taylor & Francis Group plc, London, UK

quite low value, it is considered that the value of α primarily influences the rate of sediment transport and thus the timescale of bed evolution. It has only minor influence on the general bed behaviour.

In the proposed morphodynamic model, we do not account for turbulent fluctuations, and use the average bed shear stress to compute the sediment transport over the dunes. For sure we cannot reproduce all details of the complicated dune development process. However, our goal is to develop an appropriate model to reproduce general dune behaviour. Therefore, we believe that this approach is appropriate for our goals.

In the flow solver, no details of the turbulent flow inside the FSZ are computed. However, it is expected that there is an influence of the energy losses in the FSZ on the remainder of the flow field, since simulated water surface elevations above the FSZ are quite large. This influence is not included in the proposed model. It could be included by changing the boundary condition above the SSL (Eq. (6)) using a characteristic turbulent mixing length, e.g. the vertical distance between the ZVL and the SSL. This would require a depth-dependent eddy viscosity.

At the FRP the time-averaged bed shear stress is close to zero. However, experimental observations show that at the FRP much sediment is brought into transport. This is probably due to large fluctuations of the bed shear stress at the FRP. The influence could be included by imposing a fluctuation on the computed bed shear stress.

In our model, the dune length is assumed constant. However, e.g. Ten Brinke et al. (1999) observed that during dune development dunes do not only grow in amplitude, but their length also increases. Furthermore, a constant dune length has an influence on the model results, since a combination of dune height and dune length determines the steepness of the dunes (and thus influence the sediment transport via the slope parameter). Furthermore, a changing dune length is expected to be related to the influence of flow separation on equilibrium dune dimensions. Therefore, a next step in the model should certainly be to include a variable dune length in the model.

7 CONCLUSIONS

In this paper we present a morphodynamic model to simulate dune development. We focus on modelling processes that are most relevant to get a general idea of dune dimensions under certain flow conditions and sediment characteristics.

In cases where flow separation does not occur (i.e. when dunes have gentle slopes), the basis model qualitatively reproduces well known morphological behaviour: dunes grow in amplitude, migrate in streamwise direction, and become asymmetrical. These processes can be modelled using hydrostatic equations and a simple sediment transport model based on average bed shear stress.

Flow separation plays a key role in dune development. To keep the model appropriately, we follow an approach introduced by Kroy et al. (2002) to determine the shape of the flow separation zone on the basis of general dune dimensions (see also Paarlberg et al. 2005) and effectively cut off the flow separation zone from computations. The flow field is only computed above the flow separation zone and the sediment transport behaviour downstream of the reattachment point and in the flow separation zone, where no flow is computed, is parameterized. In the paper it is shown that the basis model, extended with this parameterization of flow separation is able to simulate dune development to equilibrium conditions, under steady discharge conditions. Moreover, the model is in general agreement with laboratory flume data.

Future work will focus on more detailed calibration and validation of the flow model, and the application of the model to unsteady flow conditions. Furthermore, the morphodynamic model will be extended to include variable dune length during the development process of dunes. When the model is applied to unsteady flood events, the dimensions of the dunes (length, height and steepness) and of the flow separation zone can be used to make predictions of the overall roughness that may be expected. This is very important for water manager to make accurate predictions of water levels.

ABSTRACT: The paper presents the important, both from practical and theoretical reasons, problem of forming river bed forms within sand-gravel mixtures. In natural rivers, due to the complicated nature of the discharge and changes in the water level, the bed forms are quite complicated structures. These features are changing in length and height and when present they change the hydraulics conditions. Up to now there are few papers concerning gravel bed forms found in rivers. Most of scientific papers focus only on sand riverbed forms. The present paper concentrates on the field measurements of sand-gravel bed forms found in the Raba River in Polish Carpathians. The research focuses here mostly on the geometrical parameters of these bed forms such as height, length, as well as granulometric characteristics of the sediment. Based on *in-site* measurements different hydraulics parameters were also determined. Special attention was given to the roughness coefficient, which is very important from a practical point of view for engineers working with river training works and hydraulics structures.

1 INTRODUCTION

Gravel sub aqueous bed forms (those with a median grain size greater than 2 mm), such as dunes and bed load sheets, which occur on river beds which are composed of sand and gravel mixtures are reported very rarely within the world literature. There is even less information on the hydrodynamic development of such gravel features. Reviewing the literature, equilibrium and non-equilibrium gravel dunes range in length from less than 0.6 m to greater than 100 m. Their heights range from less than 0.1 m to 16 m (Carling 1999). In general terms dunes have lengths that scale primarily with boundary layer thickness or water depth (Best 1996). Height (H) and length (L) data for the gravel dunes reported by some researchers (Carling 1999) are consistent with the H:L function reported by Ashley (1990) for equilibrium dunes developed in sand. Using Ashley's (1990) dune form criteria of height (>0.1 m) and length (>0.6 m) as a general guide it can be shown that gravel dunes have been correctly identified in the number of studies (e.g. Galay 1967, Dinehart 1992 and Carling et al. 2005). As far as gravel bed forms hydrodynamics is concerned, gravel dunes are suppose to develop for a range of Froude numbers up to 0.75. For the non-dimensional mean shear stress $\Theta = 0.25$ they should reach their maximum height and start to reduce in height at Shields parameter value $\Theta = 0.30$ (Carling 1999). The other bed forms which develop on the river bed are ripples. Their length is proportional to the grain size. They have heights up to a few tens of millimeters and lengths less than 0.6 m (Allen 1984). The reports from the literature about ripples which are developed in gravel are controvertible, being based mostly on length:height criteria. However ripples are suppose to develop only in the bed sediments not coarser than about 0.6 mm ($D_{50} < 0.6$ mm) in hydraulic smooth flow ($U * D < 10$) which is not associated with mobile gravel. However Gomez et al. (1989) reported some gravel bed forms which he called ripples, but Carling (1999) suggests that they were bed load sheets. Finally some scientists (e.g. Kuhnle 1986, Iseya and Ikeda 1987) report bedload sheets and define them as low-relief bedforms,

Copyright © 2006 Taylor & Francis Group plc, London, UK

that develop in mixture of coarse sand and gravel (D_{50} from 2 mm to 5 mm).These features are one or two grains in height and share some characteristic of incipient dunes (e.g. Bridge 1993). What is worthy of notice is that no bed load sheets developed in 100% gravels in experiments described by Iseya and Ikeda (1982) as well as Dietrich et al. (1989). At the same time in a mixture of gravel and sand, Whiting et al. (1988) describes bed sheets as stable bed forms, which could grow in thickness giving asymmetric dune like forms up to 0.10 m height, and that such bed forms give the bed instability from which incipient dunes can develop. The main objective of the present work is to understand how riverbed forms developed in the mixture of sand and gravel develop. The study site was in the upland part of the the Raba River below the Dobczyce Water Reservoir and close to the confluence with the Vistula River. The study is important firstly because of the need for a better understanding of the process of formation such features like sand-gravel bed forms. Secondly, dunes are responsible for flow resistance, which is significant, for example, when designing hydraulics structures or calculating flow residence times for water supply or pollutant dispersion. Thirdly, understanding of bed form forming process is important for geologists to interpret how sedimentary rocks were deposited, where ancient sedimentary assemblages are believed to be of alluvial origin.

2 MATERIALS AND METHODS

2.1 *Study location*

The Raba River – Figure 1 – (137 km long with a catchment area of 1537 km^2) is mostly (86%) situated in the Polish part of the Eastern Carpathian Mountains

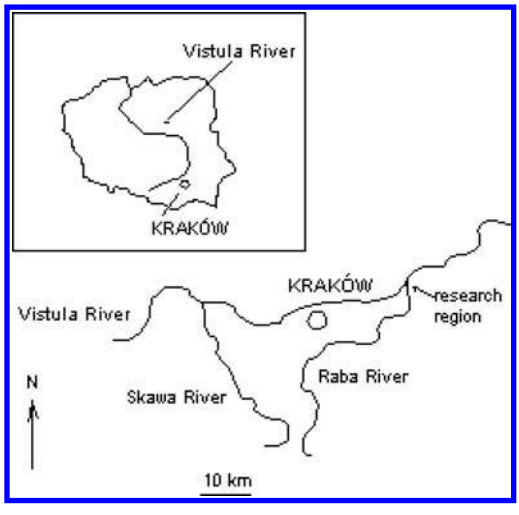

Figure 1. The location of the research region.

(the Wyspowy Beskid and the Zywiecki Beskid) which are Carpathian flysh. Its streambed, along the alluvial part, consists mostly of sandstone and mudstone bed-load pebbles and cobbles (from Magurian nappe). The typical structure of the lower Raba River alluvial plain, from the beginning of the 20th century consists of normally loose pebble gravels, open work pebble gravels, dilated framework pebble gravels, trough cross-stratified and parallel laminated medium to very coarse grained sands, massive find sands and muds (Wyzga 1993). The coarser grains which collect as armour on the river bed, also form a framework, the interstices of which are filled by a matrix of finer sediment. The Raba River, during the spring and early summer floods, experiences frequent bed load movement, which is reflected in many mobile gravel bars which form along the margins and centre of the river channel. The research region of the Raba River (reach 700 m long, close to the Uscie Solne municipality), where the Raba joins the Vistula River, is situated at the border of the uplands (14% of the catchment is situated in Carpathian intramontane and submontane depressions). The river loses here its mountainous character and is alluvial. The river bed sediment here is the mixture of sand and gravel. The river bed usually is characterised by an armour layer where the range of sediment is from 0.4 mm to 50 mm, with sand and gravel moving above it. In low to medium flows the water is very clear making the sediment transport processes visible to the eye. On the armouring layer sand and sand-gravel bedforms appear under certain range of hydraulics conditions. These bedforms are built up with sediment of the range from $D_{50} = 0.5$ mm up to 11 mm. The average slope of the whole Raba River is 0.00443, the slope of the whole lower part of the Raba is 0.00198 whereas the slope of the research reach, at the confluence, is 0.0006. The river channel at the research reach averages 50 m wide. According to Krzanowski (1972) the average annual flow is here 20.86 [$m^3 \cdot s^{-1}$] and the minimum annual flow is 2.71 [$m^3 \cdot s^{-1}$].

2.2 *Methods*

The research location was safely accessible from the Raba River banks on foot under low discharge and from a rubber boat under mean discharge conditions. The location was being visited daily during several sampling periods between 2001 and 2005. The work within the research reach concentrated on surveying the migration of several ripples, dunes and other sand and sand-gravel structures, measuring the water depth and the speed of the flow with a NAUTILUS 2000 magnetic current meter. Velocities of running water were recorded above all characteristic points of the bed-forms: crest, trough, along the stoss and lee slopes and finally above the flat bed. Such

Copyright © 2006 Taylor & Francis Group plc, London, UK

hydraulics parameters as Froude number, Reynolds number, shear velocity, shear stresses and drag coefficient were calculated. For sediment sampling the technique described by Church, McLean and Wolcot (1987) was applied. Samples were collected from a homogeneous body of sub-armour sediment, so as not to combine them with the distinct surface material. The sieving analysis for coarse grains was carried out by hand in the field using round-mesh sieves (Michalik 1990). Fine material was sieved in the laboratory. Water velocity measurements were based on Jarrett's (1990) recommendations regarding the taking of velocity profiles in river cross-sections. Bergeron and Abraham's (1992) methods were then applied to the field data, and shear velocity V_* values were calculated from the velocity profiles obtained near to the river-bed. Finally, shear stress τ values were calculated from:

$$\tau = V_*^2 \rho \quad [\mathrm{N\,m^{-2}}] \tag{1}$$

where:
V_* – shear velocity [m s^{-1}],
ρ – water density [kg m^{-3}].

To calculate various flow resistance coefficients the methods given by Wijbenga (1990) and Przedwojski et al. (1995) were used. The Darcy-Weisbach flow resistance coefficient was obtained from:

$$f = 8\,g\,J\,R / V^2 = 8\,(V_* / V)^2 \tag{2}$$

where: V – average cross-section velocity [m s^{-1}].

The Strickler formula for the roughness is as follows (Sobota 1994):

$$k = \frac{21.1}{\sqrt[6]{d}}, \quad n = \frac{1}{k} \tag{3}$$

where: k – Strickler coefficient, d – the roughness height which could be a grain dimension (e.g., D_{50}) or the height of the bed form [m], n – roughness coefficient.

The roughness given by Chézy with Manning's n could be written as follows (Sobota 1994):

$$C = \frac{1}{n} R_h^{1/6} \tag{4}$$

where: C – Manning coefficient, R_h – hydraulic radius [m], n – roughness coefficient[–].

The equation for roughness according to the findings of Chow (1959), which could be determinated after field measurements, is as follows:

$$n = \frac{(x-1)\,y^{\frac{1}{6}}}{6.78\,(x+0.95)} \tag{5}$$

where: $x = v_{0.8}/v_{0.2}$, y – maximum water depth in the cross section [m], $v_{0.2}$ – velocity value measured at $0.2y$ [m s^{-1}], $v_{0.8}$ – velocity value measured at $0.8y$ [m s^{-1}].

3 RESULTS AND DISCUSSION

For the reasons of brevity all results of investigations and calculations are presented in tabular and graphic manner. Every time the research reach in the field was visited geometrical survey of bedforms were conducted, velocity profiles were obtained close to the bed as well as higher within the flow and sediments samples for granulometric analysis were obtained (Figure 2). Every time after major flooding (it has happened twice during the measuring campaign) a geodetic survey was made to get the river bed altitude details (Figure 3).

Under low discharges (up to 3.9 m^3/sec) we noted that only sand ripples of heights (H) up to tens millimetres were developing and moving along the full width of the research reach, whereas pre-existing sand-gravel bedforms were immobile on the armoured bed.

When the discharge was larger (up to 11.4 m^3/sec) coarser bed load was moving, including overpassing coarser grains over the crests of the sand-gravel features which then began to migrate. Under the latter conditions sand ripples only developed close to the river banks where the flow velocity was lower than in the centre of the channel, whereas sand-gravel barchanoid dunes were developing along the whole width of the channel although predominantly in the centre. Figure 4 presents measured heights (H) of the investigated bedforms against their lengths (L).

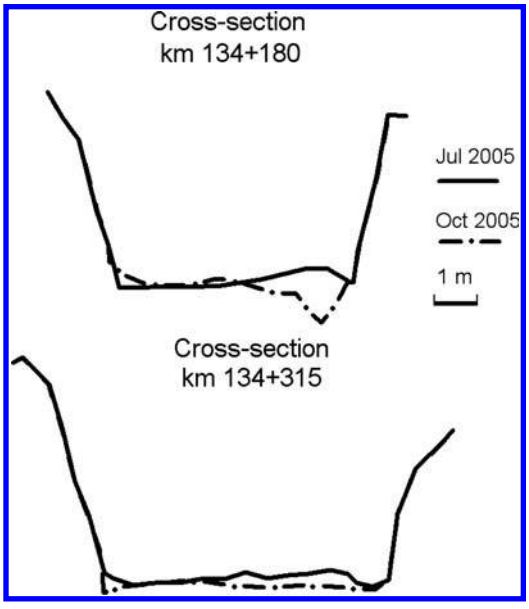

Figure 3. Examples of changes in the riverbed configuration after major flooding.

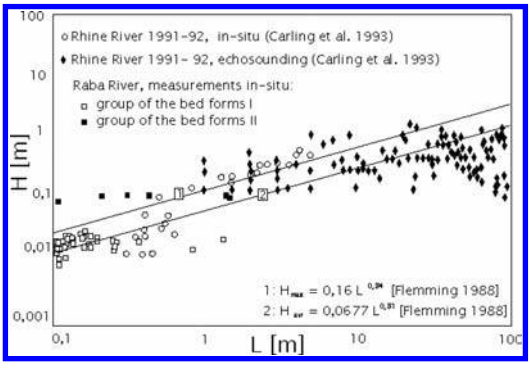

Figure 4. Height-length relation for the Raba River bedforms.

The Raba data are compared with Fleming (1988) central tendency and limit lines as well as with bigger sand dunes found on the bed of the River Rhine (Carling et al., 2000). The Raba data we divided in Figure 3 into two groups: Type 1 with the $1 < D_{50} < 2.4$ mm and $L < 0.6$ m which are here termed bed forms I and the second, Type 2 which are longer with $4 < D_{50} < 11$ mm which are termed bed forms II. The relation between Raba features describes the relation: $H = 0{,}05\,L^{0{,}35}$ ($r^2 = 0.47$; $F_{0.05\ (1;55)} = 3.95$; $\alpha = 0.05$; $n = 57$). The Raba type 1 bedforms are much shorter and smaller than the Rhine features and are also mostly below the upper limit given by Flemming (1988). Type 2 bedforms are steep and lie above Flemming's curve.

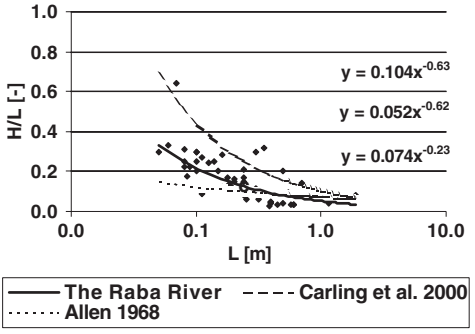

Figure 5. Steepness index (H/L) of the Raba River bedforms against their lengths (L).

Raba bedforms are steeper (Figure 5) then dunes described by Allen (1968) but flatter then the Rhine long sand dunes. Their H/L index $= 0.0518L^{0.622}$ ($r^2 = 0.71$; $F_{0.05\ (1;51)} = 7.24$; $\alpha = 0.05$; $n = 52$).

Also plotted are the geometrical lengths and height of the Raba features against water depth (Figure 6 a, b), they lie close to the Yalin (1964) middle curve as far as their length (L) is concerned but some of them are higher (H) than the maximum limitation. This may be because the higher bedforms has formed under a previous discharge when water depths were greater and have not yet fully readjusted their morphology.

Table 1 presents examples of hydraulics parameters calculated for sand-gravel dunes we found during the investigations. The shear stresses were not sufficient to disrupt the armouring layer of the sediment river bed. However, under the highest measured values coarse sediment movement occurred over the sand-gravel features and intensive sedimentation occurred at the toes of the bedforms. Also the sand ripples were transported, building and then decaying rapidly in different parts of the flat gravel armoured river bed. The smaller features were moving with a celerity of 5 cm/sec and larger with 2 cm/sec.

The Froude number was between 0.238 and 0.678 indicating that they are still in the developing or steady stage, below the transition stage. At the same time the D_{50} shows that they are fine-gravel to medium gravel (Gordon et al. 1992). Table 2 shows the different roughness coefficient values, for different ways of their calculations. As expected, when using the bed form height in the Strickler formula larger values of roughness values are obtained. Given that all the measurements were for low or medium discharges, it is possible that larger dunes would have developed under higher flows and thus a larger n value for discharge calculation, would be required. Consequently a traditional approach to estimating the roughness coefficient values would be inaccurate.

4 CONCLUSIONS

The following conclusions can be drawn from the analysis of the data:

1. Under the range of low discharges up to 3.9 m^3/sec only sand and very fine sand-gravel bedforms of $1 < D_{50} < 2.4$ mm of heights (H) up to tens millimetres can develop and move, whereas other existed sand-gravel features were preserved, sitting on the armoured bed.

2. When the discharge is growing up to 11.4 m^3/sec the sand-gravel dunes start to develop with $4 < D_{50} < 11$ mm. The movement of sediment along such features is under such discharges very low and mostly the crests are mobilized first.
3. The relation between height (H) and length (L) Raba River bedforms describes the relation: $H = 0.05\,L^{0.35}$ ($r^2 = 0.47$; $F_{0.05\,(1;55)} = 3.95$; $\alpha = 0.05$; $n = 57$). The Raba's bedforms are much shorter and smaller than the features measured at the bed of larger rivers (e.g. the Rhine). They are mostly below the limitation given by Flemming (1988).
4. The Raba bedforms are steeper and flatter then classical dunes described by Allen (1968). Also they are flatter then the features from bigger rivers (e.g.

Semi-empirical model to predict mobile bed evolution in presence of a side overflow

B. Rosier, J.-L. Boillat & A.J. Schleiss
Laboratory of Hydraulic Constructions (LCH), Swiss Fed. Inst. of Technology, Lausanne, Switzerland

ABSTRACT: Side weirs are a widely used device to control flow processes along a channel or river course. The lateral loss of water is responsible for the reduction of sediment transport capacity in the main-channel yielding to aggradation and the formation of a local sediment deposit in the downstream weir alignment. The reduced cross section generates backwater effects and additional contraction and expansion losses. As a consequence, the head over the side weir rises. Accompanied with supplementary roughness induced by the development of bed forms, the design discharge to be diverted over the weir is increased by this flow-sediment transport interaction. Based on a flume study, a semi-empirical model to predict the length and the global longitudinal shape of the aggraded reach as well as the position and height of the maximum bed elevation is developed. The longitudinal shape is fairly well represented by an adapted Maxwell-type distribution function.

1 INTRODUCTION

Within the framework of the multidisciplinary flood protection research project *DIFUSE* (*Di*gues *Fu*sibles et *S*ubmersible*s*, Fuse plugs and overflow dams at rivers), involving governmental offices, private companies and four research institutes, the *Laboratory of Hydraulic Constructions* (*LCH*) investigates the effects of a side overflow on sediment transport in a natural channel. The topic of the present paper constitutes one aspect of this study.

A side weir, also known as a lateral weir, is a free overflow weir set into the side of a channel which allows part of the liquid to spill over the side when the surface of the flow in the main channel rises above the weir crest. Hydraulic structures of this kind find their use in urban drainage systems, irrigation engineering, river restoration, and flood control management.

The flow over a side weir is a typical case of spatially varied flow with decreasing discharge. The main design objective is to estimate the total overflow discharge. The hydraulic behaviour of side weirs has been subject to numerous investigations. A review of literature indicated that the main focus of research within this field is laid on the determination of an appropriate discharge coefficient. Sharp-crested side weirs in a rectangular channel have been studied extensively by Nadesmoorthy & Thomson (1972), Subramanya & Awasthy (1972), Ranga Raju et al. (1979), Hager (1987), Singh et al. (1994), and Borghei et al. (1999).

All contributions have in common that a fixed channel bottom is assumed to describe side overflow intensity, since most studies refer to irrigation or drainage engineering. Especially in natural rivers a mobile bed is present and for the purpose of flood control management its morphological behaviour and aspects of bed load transport have to be taken into account.

The lateral loss of water is responsible for the reduction of sediment transport capacity in the mainchannel by decreasing the bottom shear stress. This yields to an elevation of the mean bed level and the formation of a local sediment deposit in the weir alignment. Consequently, the cross section is reduced and the upstream water level rises and the head over the side weir as well. In addition with supplementary roughness induced by the development of bed forms, the design discharge to be diverted over the side weir is increased in an unforeseen way.

In the present study, a semi-empirical model to describe the interaction between bed morphology and side weir discharge is developed. Based on laboratory experiments, the global longitudinal shape of the aggraded channel reach is modeled using a Maxwellian distribution function. For this purpose, the wavy cross-sectional averaged variation of the bed surface elevation is smoothed using an appropriate moving average. An adequate window length is obtained determining a characteristic periodic longitudinal bed surface elevation. Important parameters of the Maxwell-type distribution function such as location and height of the maximum bed surface elevation and a shape factor are expressed in terms of geometric channel and side weir variables

as well as hydraulic parameters and bed load transport relations.

2 EXPERIMENTAL SETUP

The tests were conducted in a rectangular 2.0 m wide, 30 m long and 1.2 m deep flume. The flume was subdivided longitudinally into two separate channels by a vertical 0.9 m high smooth wall. The first channel, being 1.5 m wide, represents the actual testing facility including the mobile bed ($d_{50} = 0.72$ mm, $d_m = 1.05$ mm) and the side weir on the right bank. The second one, 0.47 m wide, constitutes a lateral channel permitting to evacuate the diverted discharge. A general layout of the experimental setup is shown in Figure 1.

In order to determine the influence of lateral overflow on bed-load transport, the main channel discharge including flood hydrographs, channel slope, length and height of the lateral weir crest, and number of weirs were considered as test parameters. Table 1 gives an overview of the of test series used for analysis in the present paper.

The channel facility originally possesses a horizontal slope. The bottom slope bed for each experiment has been created by adjusting the mobile bed to the requested slope. Once the desired discharge has been introduced to the initially plane bed, sediment was fed into the upstream end of the flume via a conveyer belt. The quantities to be supplied were estimated according to the formula of Smart & Jäggi (1983) and adjusted during the test in order to maintain both, uniform flow and equilibrium transport conditions in the approach channel upstream of the side overflow. The side overflow discharge was determined using a sharp-crested weir located in the evacuation channel (Fig. 2) and equipped with an ultrasonic gauge.

Water depth was recorded continuously in the centreline of the main channel by the use of ultrasonic gauges (Fig. 2). The 2D velocity field was measured with an Ultrasonic Doppler Velocity Profiler (UVP) allowing to obtain instantaneously a 1D-velocity profile over the entire water depth (Metflow 2000). As far as the monitoring of the river bed morphology is concerned, digital photogrammetry has been applied to

obtain a digital elevation model (DEM) (Rosier et al. 2004).

3 ANALYSIS

3.1 *Variation of mean longitudinal bed surface elevation*

After introducing the flow to the initially flat bed, bed forms rapidly form. In Figure 3, a cut-out of the final bed situation for experiment B01 is shown. Furthermore, longitudinal bed elevation profiles for different lateral wise locations are presented in Figure 4, top). Two profiles are located on the right river bank ($y = 0.30$ m, $y = 0.60$ m), two on the left ($y = 0.90$ m, $y = 1.20$ m) and one in the centreline of the channel ($y = 0.75$ m). In addition, the cross sectional averaged longitudinal profile is presented (denoted "z-mean"). A detailed view of this profile is given in Figure 4 (bottom).

This profile is used to determine a characteristic periodic variation for the mean longitudinal bed surface elevation (in the following denoted as ω) which will serve later on as the moving window length to smooth the wavy profile.

The variation of the mean bed surface elevation has been determined manually by searching the profile record for the presence of lee slopes (Coleman & Melville, 1994). For a detected lee slope within a bed profile, the location of the corresponding ω-value was taken as being given by the upstream trough of the same bed feature. The trough elevation for the ω-bed feature was defined as the minimum bed elevation occurring between the location of the present one and that of the subsequent (downstream) one.

Similarly, the crest elevation was defined as the maximum bed elevation occurring between the location of the present ω-value and that of the previous (upstream) feature. The ω-length is determined as the longitudinal difference between two troughs.

Once ω-lengths are determined for the entire bed profile, mean values (ω_{mean}) for each test series are calculated. In Figure 5, averaged ω-lengths as well as hydraulic and geometric parameters are combined.

The corresponding Equation 1 is found to represent the mean ω-lengths for the entire data set in the best way. The R^2-value of Equation 1 is 0.97.

$$y = \frac{\omega_{mean}}{L_D} = 0.0025x^2 + 0.049x \quad (1)$$

where L_D = side weir length, Q_1 = upstream discharge, $y_1 - w_D = h_1$ = side weir head at the upstream weir corner, y_1 = water depth at the upstream weir corner, w_D = side weir crest height, g = acceleration due to gravity and S_0 = bottom slope (Fig. 6).

In this context it has to be mentioned that the side weir length for test series D is assumed to be

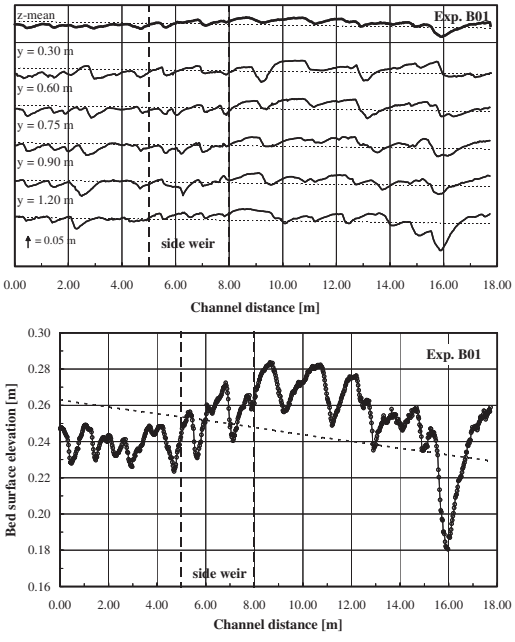

Figure 4. Top: Longitudinal bed surface profiles for different lateralwise locations and cross sectional averaged profile, denoted "z-mean". Bottom: Detailed view of the z-mean profile. The dotted lines represent the initially flat bed.

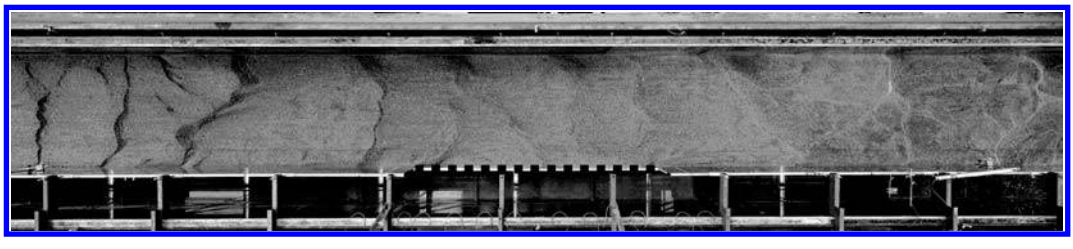

Figure 3. Cut-out ($x = 0.5$ m to $x = 12.5$ m) of the final bed morphology for experiment B01. The dotted line represents the side weir position. Flow is from left to right.

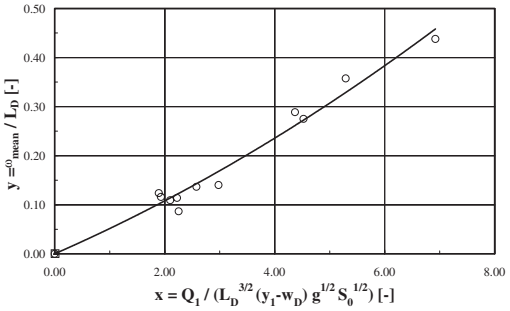

Figure 5. Combination of hydraulic and geometric parameters to describe the mean variation of the bed surface elevation ω_{mean}.

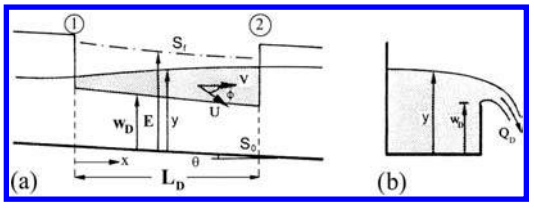

Figure 6. Definition sketch: (a) longitudinal section; (b) cross section (from Hager 1987, modified).

$L_D = 2 \times 2.5 = 5.0$ m, since the short 1.0 m long separation wall between the two weirs reveals no significant importance.

The data analysis further shows that a window length for the moving average of $\omega^* = 3.50$ m turns out to yield satisfying results. To obtain ω^* from Equation 1, the right term has to be multiplied by L_D ($\omega_{mean} = y\ L_D$) and a factor of 4.542, thus $\omega^* = 4.542 y\ L_D = 4.542 \omega_{mean}$.

3.2 *Shape of deposit*

In most of the experiments, the shape of the sedimentary deposit is characterized by a rather steep stoss slope and a milder lee slope. This type of shape is similar to the shape of flood hydrographs. Furthermore, the main parameters describing the deposit are the maximum bed elevation z_{max}, the corresponding position of the maximum bed elevation x_{max}, its volume and shape.

With regard to these aspects, a feasible and satisfying approach for the parameterisation of the deposit is represented by the Maxwell distribution function. This function is a probability distribution with applications often found in physics and chemistry (e.g. heat and gas transfer) as well as in hydrology to parameterize flood hydrographs (see above paragraph). The function is rather simple and straightforward since it is composed of only three dimensionless variables. In addition to that, it offers an analytical solution and is

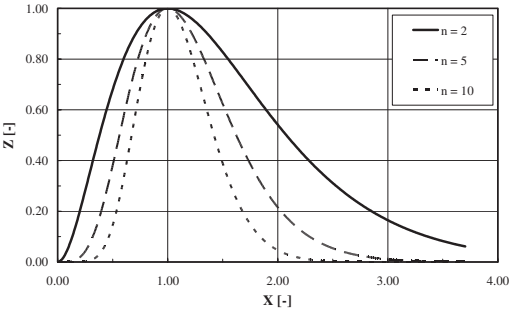

Figure 7. Dimensionless shape of the aggraded channel reach for different n-values.

continuous and derivable. An advantageous property is, in contrast to e.g. a Gaussian distribution, its boundedness. Another reason for having chosen this kind of function is the fact that it fits the experimental results in the best way.

Introducing the dimensionless parameters referring to the peak values (z_{max}, x_{max})

$$X = \frac{x}{x_{max}}, \quad Z = \frac{z}{z_{max}} \tag{2}$$

the aggraded channel reach can be described by the following Maxwell distribution function:

$$Z(X) = \left(X\ e^{1-X} \right)^n \tag{3}$$

In Equation 3 n represents the "shape parameter" of the deposit. In Figure 7, the function $Z(X)$ is presented for different n-values. It can be observed that the shape of the deposit becomes more peaked with increasing n. Furthermore, by definition, the maxima of both, X and Z, are located at 1.00.

3.3 *Data processing for determination of deposition shape*

Once the moving average according to section 3.1 is determined, the characterisation of the aggraded channel reach is assessed using the Maxwell-type distribution function introduced in section 3.2.

The procedure to obtain the Maxwell distribution function from the moving average is exemplarily described for experiment B01.

In a first step, the starting and ending point of the aggraded channel reach has to be identified. These points do not compulsory coincide with the initial bed although this should theoretically be the case and would be desirable. For the present data set, slight erosion or aggradation upstream or downstream, respectively, might be encountered in some experiments (e.g. in Figure 8 (top), the starting point of the

Copyright © 2006 Taylor & Francis Group plc, London, UK

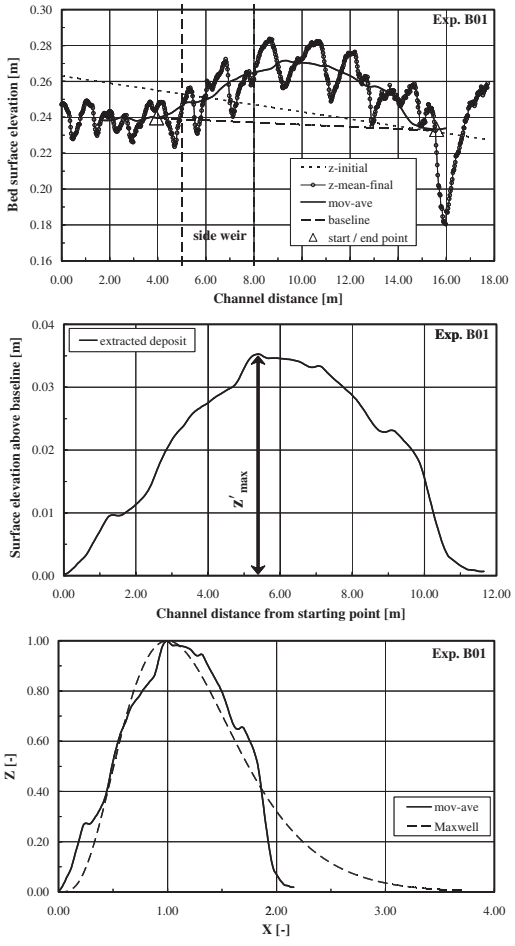

Figure 8. Top: Initial mobile bed, cross sectional averaged final bed, moving average corresponding to the cross sectional averaged final bed, starting and ending points of the aggraded reach and baseline connecting the two local minima defining the aggraded reach. Middle: Extracted deposit. Bottom: Normalised moving average and corresponding Maxwellian distribution function.

aggraded reach is located slightly lower than the corresponding initial bed). These phenomena are likely to be attributed to the fact that sediment supply is estimated and/or to the length of the testing facility. An error estimation reveals that the shape of the aggraded reach (moving average) and consequently the shape factor n are not significantly influenced by this vertical offset. However, the present analysis is conducted including possible vertical offset. For the establishment of design criteria to predict the diverted discharge which are based on the model of the aggraded reach, this vertical shift has to be taken into account, since a lower or higher starting/ending point of the deposit will affect the spilled discharge. As mentioned before, the overall shape of the deposit is rightly assumed and does not change significantly due to the vertical shift.

Due to the above reasons, the requested starting and endpoints are found by searching a local minimum of the moving average in the respective region (instead of taking the corresponding initial bed). For the starting point, the requested value is found where a clear and distinct aggradation compared to the upstream part of the moving average is evident. This location is characterised by a significant change of slope. For the ending point, the same procedure is applied.

Once these two local minima are identified, they are linked with a linear function being the tangent in each point. This tangent represents a reference level or baseline to obtain the difference between the values of the moving average and the baseline. By this procedure the aggraded channel reach is extracted and dissociated from the channel and the original data set, respectively.

In Figure 8 (top), the initial mobile bed, the cross sectional averaged bed, the moving average corresponding to the cross sectional averaged bed, and the starting and ending points of the aggraded reach as well as the connecting tangent (baseline or reference level) are represented. Figure 8 (middle) shows the extracted deposit.

In a further step, the maximum elevation z_{max} and the corresponding position x_{max} of the moving average are determined for and from the extracted deposit. Since the net aggradation maximum in the channel (initial bed level as reference level) differs from the maximum elevation of the extracted deposit (baseline as reference level), the corresponding x_{max}- and z_{max}-values in Equation 2 have to be substituted by x'_{max} and z'_{max}. Thereafter, the Maxwell distribution function is applied to these values (Fig. 8, bottom). The shape factor n is found by a trial-and-error procedure. The prediction accuracy or the optimal n-value, respectively, to describe the moving average is obtained using the least squares method (LSM). The least squares error analysis (Π) is performed for the vertical difference according to Equation 4:

$$\Pi = \sum_{i=1}^{n} \left[\left(Z_{mov-ave} \right)_i - \left(Z_{Maxwell} \right)_i \right]^2 = \min \qquad (4)$$

3.4 *Results for deposition shape*

According to the previous paragraphs, the shape factor n has been determined for the present data set (Table 1). Most values for n are located in a rather narrow range going from $n = 3.00$ to 5.40 (Fig. 9). The mean value for these experiments is $n = 4.27$.

Despite this close correlation, three values exceed this range. For experiment B04 a value of 1.30 is

Copyright © 2006 Taylor & Francis Group plc, London, UK

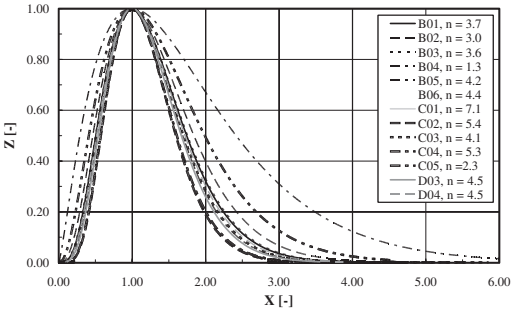

Figure 9. Shape factor n for the entire experimental data set (test series according to Table 1).

obtained, for C01 $n = 7.10$ and for C05 a value of $n = 2.30$ is determined. Referring to Figure 9, the shape factor for C01 and C05 are still in the range of the totality of the experiments. A reasonable physical explanation appears to be difficult to give. For experiment B04, owing the most considerable deviation, a possible explanation is the combination of a comparatively low discharge with a rather mild slope. These experimental conditions seem to emphasize the formation of a well pronounced and extended deposit.

4 MODEL DEVELOPMENT AND PROPOSED METHOD

As mentioned in paragraph 3.2, the shape factor n, the maximum bed elevation z_{max} (z'_{max}) and the position x_{max} (x'_{max}) of z_{max} (z'_{max}) are the main characteristic parameters to describe the aggraded reach (extracted deposit). In the following paragraphs each of these parameters will be assessed in order to develop a relationship able to describe the respective parameter.

In a first step, a description of the extracted deposit as shown in Figure 8 (middle) is developed. The objective of this analysis is to obtain an expression for n, z'_{max} and x'_{max}.

The second step is dedicated to the transfer of the extracted deposit to the channel. For this purpose, the maximum elevation z_{max} and its position x_{max} in the channel have to be known. The anchor point where the extracted deposit is integrated in the channel (origin coordinates of the deposit) refers to the side weir position in the channel and its crest height w_D, since these two values normally are fixed and their coordinates are known a priori.

A reflection of the problem of mutual interaction of lateral overflow and bed morphology leads to the conclusion that four components have to be taken into account:

– geometry of the channel
– geometry of the weir
– hydraulic parameters (flow)
– sediment transport (bed-load).

As mentioned above, the two dimensional or even three dimensional flow pattern tend to deposit bed-load material in the downstream weir alignment. The intensity of this effect certainly depends on the ratio between the flow discharge at the entrance and exit section of the channel reach bounded by the weir. Since the lateral outflow and consequently the flow discharge at the exit section are not known a priori, this ratio cannot directly be used finding suitable relationships. On the contrary, it is rather the very purpose of this study to determine the diverted outflow, hence knowing the exit discharge. Nevertheless, as will be shown in the following paragraph, a ratio of exit and entrance values will be used. This ratio refers to the bed-load transport intensity, thus indirectly dealing with exit and entrance flow discharges.

4.1 *Shape factor* n *for the extracted deposit*

The development of a relation determining n is based on the idea that the four components mentioned in the previous paragraph will be of importance.

Concerning sediment transport, the different sediment transport capacity upstream and upstream of the side weir is taken into account.

From the different empirical bed-load formulae the one proposed by Schoklitsch in 1934 is used (Graf, 1971):

$$q_{sb} = \frac{2.5}{s} S_e^{3/2} \left(q - q_{cr}\right) \tag{5}$$

where q_{sb} is the volumetric solid discharge per unit width, s the relative density ($s = \rho_s/\rho$), S_e the energy slope, q the liquid discharge per unit width and q_{cr} the critical discharge for incipient motion. It has to be noted that any other appropriate formula, e.g. the one of Smart & Jäggi (1983) could be used.

The critical liquid discharge q_{cr}, usually expressed by τ_{cr}, is given with the use of the Manning-Strickler formula such as:

$$q_{cr} = 0.26(s-1)^{5/3} \frac{d^{3/2}}{S_e^{7/6}} \tag{6}$$

where d is the grain size diameter (usually d_{50}).

The intensity of the solid discharge as bed-load can then be expressed in dimensionless form as:

$$\Phi \equiv q_{sb*} = \frac{q_{sb}}{\sqrt{(s-1)gd^3}} \tag{7}$$

Φ usually is referred to as Einstein – factor. Using Equation 7 upstream and downstream of the side weir,

Copyright © 2006 Taylor & Francis Group plc, London, UK

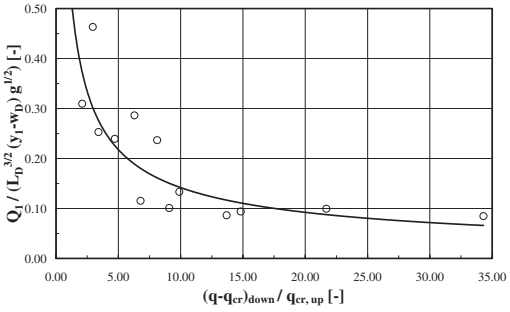

Figure 10. Relation between geometric side weir parameters, flow variables and incipient motion criteria yielding Eq. 8.

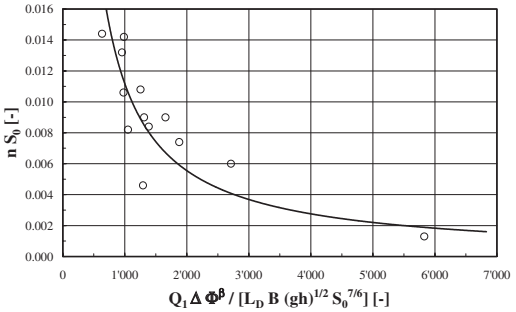

Figure 11. Relationship for the shape factor n (Eq. 9).

the ratio $\Delta\Phi = \Phi_{upstream}/\Phi_{downstream}$ of intensity of bed-load can be determined.

For the upstream part of the channel all variables occurring in Equation 7 are known or can be calculated. The Φ-values for the channel stretch downstream of the side weir are not known a priori, since the effect of the mobile bed on the diverted discharge and consequently the remaining discharge in the channel is not yet quantified.

Based on the present data set, a relation for $(q - q_{cr})_{downstream}/q_{cr,upstream}$ is developed. Since $q_{cr,upstream}$ can be calculated using Equation 6, the unknown term $(q - q_{cr})_{downstream}$ can be calculated. Knowing this term, Equation 5 yields q_{sb} and subsequently Φ for the downstream channel reach is known by applying Equation 7.

The proposed relation shown in Figure 10 reads:

$$\frac{Q_1}{L_D^{3/2}\left(y_1 - w_D\right)\sqrt{g}} = 0.59\left(\frac{\left(q - q_{cr}\right)_{down}}{q_{cr,up}}\right)^{-0.62} \quad (8)$$

The R^2-value is 0.73. To develop Equation 8, the measured water surface slope has been used instead of S_e. For a first approximation the initial bottom slope S_0 can be used but better results were obtained with the water surface slope which differs slightly from the initial bottom slope.

Finally, from Figure 11 the following relation to determine the shape factor n is obtained ($R^2 = 0.78$):

$$n\,S_0 = 11.85\left(\frac{Q_1\,\Delta\Phi^{\beta}}{\left(y_1 - w_D\right)^{3/2} B\sqrt{g}\,S_0^{7/6}}\,\frac{y_1 - w_D}{L_D}\right)^{-1.0} \quad (9)$$

where B is the channel width and β a correlation factor being 0.175.

It has to be noted that the Froude number influences bed form pattern. It is a well-known phenomenon that bed forms generated at low velocities are washed out at high velocities. Especially for test series C high Froude numbers close to unity have been observed (transition regime, washed-out dunes). The corresponding bed surface has been comparatively smooth with a roughness almost equal to grain roughness. For this reason, the Froude number is incorporated in Equation 9, expressed as $Q_1/[(y_1 - w_D)^{3/2}\ B\ g^{1/2}]$. The difference of this Froude number in comparison with the traditional Froude number is that it refers to the upstream side weir head instead of water depth. Thus, besides hydraulic parameters and channel geometry, a third component of the four components to be taken into account, namely the weir geometry, expressed in terms of w_D, could be incorporated.

Furthermore, the exponent 7/6 of the bottom slope is a well known value occurring in incipient motion criteria (e.g. Eq. 6).

4.2 *Maximum elevation z'_{max} of the extracted deposit*

A first attempt to find a relationship for $z'_{\max}$ has been a combination of $z'_{\max}$ and $y_{1,cr}$ on the one hand and q_{sb} and q_{cr} on the other. An approach of this kind has been used by Requena et al. (2005) to determine the vertical bed elevation shift at the beginning of a local river widening. The analysis using data from the present study did not yield any satisfactory relation.

Due to this reason, the functional relationship presented in Figure 12 has been developed in order to obtain the maximum elevation $z'_{\max}$ of the extracted aggraded channel reach. The ratio $(q - q_{cr})_{down}/q_{cr,up}$ on the x-axis can be obtained by the help of Equation 8.

It can be noted that the shape of the presented curve is similar to the shape of the Shields-curve.

4.3 *Position x_{max} of the extracted deposit*

Since by definition, $X = x/x_{max} = 1.00$ (or $X = x/x'_{max} = 1.00$ for the extracted deposit), one of the three

Copyright © 2006 Taylor & Francis Group plc, London, UK

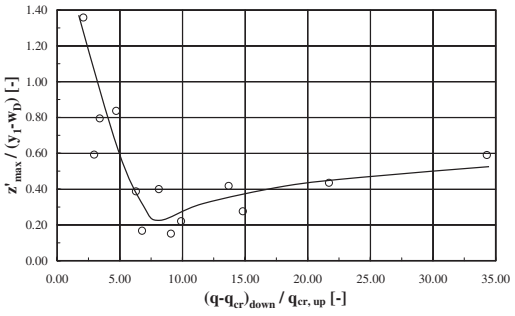

Figure 12. Relationship to determine z'_{max} for the extracted deposit.

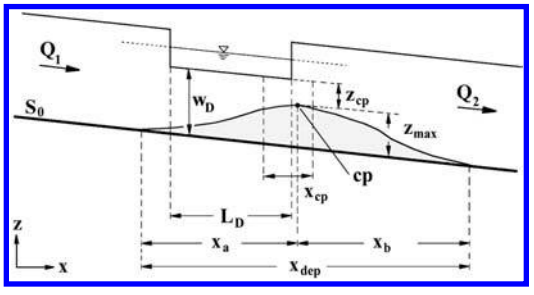

Figure 13. Definition sketch illustrating the position of the coupling point *cp* as well as its coordinates z_{cp} and x_{cp}.

unknown variables is known or can be constructed, respectively. For modelling purposes, beginning at $X = 1.00$, arbitrarily increments for $X < 1.00$ until $X = 0.00$ have to be chosen. For $X > 1.00$, discrete increments until a certain X-value depending on the underlying problem have to be chosen. For the present data set, $X = 4.00$ to 6.00 appears to be an appropriate range (cf. Fig. 9).

4.4 *Vertical reference point* z_{cp} *for coupling extracted deposit with channel geometry*

Once the shape of the extracted deposit is known, it has to be transferred to the channel. The reference point *cp* (*cp* meaning coupling point) is defined by the maximum bed elevation z_{max} and its position x_{max} in the channel (cf. Fig. 13). It is this point where the peak of the extracted deposit and the peak of the aggraded channel reach coincide.

A rather simple relationship for the vertical coordinate z_{cp} of the coupling point *cp* is obtained by using the sill height w_D as a reference. The resulting relation is given by Equation 10:

$$\frac{w_D - z_{cp}}{w_D} = 1/4 \quad \text{or} \quad z_{cp} = 0.75\, w_D \tag{10}$$

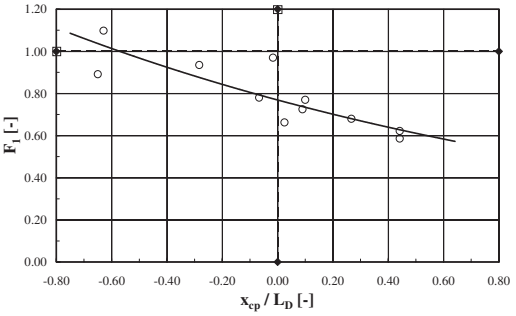

Figure 14. Influence of approach Froude number F_1 on the horizontal coordinate x_{cp} of the coupling point *cp*.

The advantage of the top crest as an anchor point is that the weir height can generally be assumed to be a fixed and known elevation given by the design procedure.

4.5 *Horizontal reference point* x_{cp} *for coupling extracted deposit with channel geometry*

For the horizontal coordinate of the coupling point, the downstream weir corner is used as a reference.

Values for the ratio x_{cp}/L_D obtained by the experiments are in the following range:

$$-0.65 < \frac{x_{cp}}{L_D} < 0.44 \tag{11}$$

Since the location of the maximum deposition constitutes a kind of control section, an improvement of Equation 11 can be achieved considering the approach-Froude number F_1. In Figure 14, it becomes evident that close to $F_1 = 1.0$ the negative range given in Equation 11 ($-0.65 \div 0.00$) serves as a reference whereas for lower Froude numbers ($0.50 < F_1 < 0.80$) the positive range should be applied ($0.00 \div 0.44$). By the use of Equation 12 extracted from Figure 14 an estimation of the respective ranges is possible:

$$F_1 = 0.77\, e^{-0.46\frac{x_{cp}}{L_D}} \tag{12}$$

At this point it has to be mentioned that the range of F_1 is rather narrow and comparatively high values are observed for some experiments (mainly test series C). This is not astonishing since the background of the present study is the use of side weirs in flood protection engineering. Nevertheless, it has to be kept in mind that for Froude numbers close to 1.00 both the flow and sediment transport regime might change. With respect to sediment transport, for the present

Copyright © 2006 Taylor & Francis Group plc, London, UK

data set, especially for test series C, the transition regime is observed. This means, dunes from the lower regime change to washed-out dunes for the transition regime and a comparatively smooth bed surface is achieved.

Moreover, the distance x_b between the end of the aggraded reach and the position x_{cp} of the maximum bed elevation z_{max} appears to follow Equation 13:

$$\frac{x_b}{L_D} = 2.024 \quad \text{for test series } B \tag{13a}$$

$$\frac{x_b}{L_D} = 1.042 \quad \text{for test series } C \text{ and } D \tag{13b}$$

The total deposition length x_{dep} can then be described by the following range:

$$0.5 < \frac{x_b}{x_{dep}} < 0.6 \tag{14}$$

meaning the position of the maximum bed elevation is located approximately in the center (50%) or slightly upstream of the center (60%) of the total deposition length. This behaviour is also represented in Figure 9, showing that the extracted aggraded reach is skewed to the left.

4.6 *Synopsis of model development and proposed method*

The aggraded reach can mainly be parameterized by its maximum elevation, the location of the maximum elevation and its shape.

The shape n is obtained by the help of Equation 9. Equations 5–8 are necessary to obtain the bed-load intensity ratio $\Delta\Phi$ in Equation 9.

The maximum elevation z'_{max} is provided using Figure 12 and Equation 8.

The position x'_{max} is designed using the definition $X = x/x_{\text{max}} = 1.00$ or $X = x/x'_{\text{max}} = 1.00$, respectively, of the Maxwell-type distribution function. In the upstream direction, distinct increments from 1.00 to 0.00 are constructed, in the downstream direction distinct increments from 1.00 to a requested value, e.g. 4.00 to 6.00, are build.

Once the aforementioned parameters are determined, the modeled deposit has to be transferred to the channel. For this reason, the horizontal and a vertical coordinates (x_{cp}, z_{cp}) of the coupling point cp are needed. The vertical coordinate is provided by Equation 10, the horizontal one by Equation 11 and Figure 14.

Knowing the position of x_{cp} (Eq. 11 and Fig. 14), the downstream length x_b of the aggraded reach is obtained by Equation 13. Using Equation 14, the total deposition length x_{dep} can be estimated.

5 DISCUSSION

The experimentally observed increased spilled discharge over a side weir due to morphological bed changes depends on the aggraded channel reach, form induced roughness and local energy losses created by the 3-dimensionality of the deposit(s).

The aggraded channel reach or the shape of the local deposit, respectively, appears to be satisfactorily modelled by a Maxwellian distribution function. The main parameters to describe the sedimentary deposit are the maximum elevation, the position of the maximum elevation and the shape. Based on these variables, four parameters are assumed to be of major influence: channel geometry, side weir geometry, flow parameters and bed-load transport. Relationships, taking into account a combination of these four parameters have been developed to describe the aggraded channel reach. An important parameter within these relationships is the ratio of flow discharge at the entrance and exit section of the channel reach bounded by the weir. Since the main objective of this study is to predict the diverted flow discharge taking into account the interaction with the mobile bed, this ratio cannot directly be implemented because neither the diverted discharge nor the discharge at the exit section are known a priori. Nevertheless, a ratio of entrance and exit flow discharges is indirectly incorporated by introducing entrance and exit bed-load intensities.

Since the Froude number plays an important role regarding flow and sediment transport regime it is implemented using the side weir head instead of flow depth.

Since the presented model results from an ongoing research project, the generality and application ranges of the present study, as for all experimental studies, are limited to the experimental conditions. Some parameters occurring in the model have no or no sufficient variation. For example, the grain diameter and the channel width have been constant throughout the test series and the weir height only changes slightly. With regard to the movable bed properties, fine material has been used. The choice of this material has been inspired by the Rhone river upstream of Lake Geneva in Switzerland. This reach is characterized by a bottom slope of $S_0 \approx 0.1\%$ and a gravel bed ($d_{50} = 15$ mm to $d_{50} = 35$ mm). In flood seasons, the slightly armoured bed surface is destroyed and rather fine material resulting among other sources from glacier abrasion is present. Thus, despite a certain lack of generality, similar effects as being observed in the present flume study might be expected in nature.

Copyright © 2006 Taylor & Francis Group plc, London, UK

The disadvantages of the present model mentioned above will be improved incorporating other flume and field data as well as numerical simulation techniques.

The superposition of form roughness constitutes a next step of the ongoing research project. While introducing form induced roughness using bed form geometry, the aggraded channel reach which has already been modelled has to be taken into account. Moreover, traditional approaches to determine bed form geometry and corresponding roughness (e.g. Van Rijn, 1984) do not seem to be appropriate in the side overflow influenced channel reach (Rosier et al., 2005).

Since the deposit is not homogeneously distributed over the entire cross section but varies in lateralwise direction, local energy losses created by contraction and expansion phenomena might have to be taken into account using a 2D morphological model, e. g. introducing the Bordat-Carnot formula. This implies a clear distinction of the local deposit close to the weir from the general aggradation of the channel reach and bed form patterns which is not that obvious because these morphological effects are superimposed. Thus, the intention of the present study is to present a rather simple 1D morphological model before increasing the complexity using a 2D model.

6 CONCLUDING REMARKS

In the present study the interaction of a side overflow with a mobile bed in a channel has been investigated experimentally.

Due to the lateral loss of water the sediment transport capacity is significantly reduced within a rather short channel reach resulting in sediment deposition. As a consequence, an elevated mean bed level and the formation of a local sedimentary deposit in the reach of the lateral side weir are observed. This leads to backwater effects and local energy losses.

For the prediction of side over flow discharge and modelling purposes, the extent and the shape of the aggraded channel reach have to be known.

The aggraded reach can be fairly well described using a Maxwell-type distribution function. The characteristic parameters are expressed in terms of geometric, flow and bed-load transport variables.

The transfer of the modelled deposit to the channel is achieved by a coupling point referring to the downstream weir coordinate and sill height.

By the help of the developed semi-empirical model, numerical simulations for steady flow conditions dedicated to the estimation of spilled discharge taking into account side weir induced morphological bed changes are possible.

NOTATION

The following symbols are used in this paper:

B = channel width
cp = coupling point to incorporate deposit in the channel
g = acceleration due to gravity
L_D = length of weir crest
n = shape parameter (Maxwell)
n_D = number of weirs
q = unit discharge
q_{cr} = critical unit discharge for incipient motion
q_{sb} = solid unit discharge
Q_1 = approach discharge
S_0 = bottom slope
S_e = energy slope
t = duration of experiment
w_D = sill height
x = distance along channel axis
x_{max} = location of maximum bed elevation (Maxwell)
x_{cp} = reference point in channel to incorporate deposit
x_{dep} = deposition length in channel
x_a = upstream deposition length until maximum
x_b = downstream deposition length from maximum
X = peak parameter of Maxwell distribution
y = lateralwise position in channel width
y_1 = water level at upstream weir corner
Z = peak parameter of Maxwell distribution
z = bed elevation
z_{max} = maximum bed elevation (Maxwell)
z_{cp} = reference point in channel to incorporate deposit
β = correlation factor in Eq. 9
ω = variation of longitudinal mean bed elevation
ω_{mean} = mean variation of longitudinal mean bed elevation
ω^* = window length of moving average
Φ = dimensionless solid discharge intensity.

ABSTRACT: The morphology, flow and process mechanics of river dunes has attracted much interest over many years. However, many of these studies have concentrated on investigating two-dimensional (2D) bed features and their associated flow structures and bed stress distributions. This morphological simplification imposes inherent limitations on our interpretation and understanding of dune form and flow dynamics, as natural dunes are invariably three-dimensional (3D) with an associated fully 3D flow structure. For example, studies over 2D forms neglect the significant effect that lateral flow and secondary circulation may have on the flow structure and thus dune morphology. This paper details a field investigation of the interactions between the 3D morphology, 3D turbulent flow structure and suspended sediment movement over large alluvial sand dunes in the Rio Paraná, NE Argentina. Fixed point and moving vessel surveys enabled the links between three-dimensionality, large-scale turbulence and sediment suspension over the dunes to be investigated.

1 INTRODUCTION

Dunes are ubiquitous forms in river channels, occurring within a wide range of bed sediment sizes. The presence of dunes on the bed significantly influences both the nature of the mean and turbulent flow structure, and consequently exerts a strong control on the entrainment, transport and deposition of bed sediment. As a result of their importance, the morphology, flow and mechanics of river dunes have attracted much interest over many years (e.g. McLean and Smith 1986, Yalin 1992, Nelson 1993, McLean et al. 1994, Bennett and Best 1995, Best 1996, Amsler and García 1997, Shimizu et al. 1999, Kostaschuk 2000, Best and Kostaschuk 2002, Carling et al. 2000, Yue et al. 2003)

This interest in dune flow and form dynamics has enabled elucidation of the main characteristics of flow associated with dunes, which are: (a) accelerating flow over the dune stoss side, (b) flow separation or deceleration (Best and Kostaschuk 2002) from the dune crest in the lee side, (c) flow reattachment at 4 to 6 dune heights downstream, (d) a shear layer between the separated flow zone and streamwise flow above, which expands as it extends downstream, and (e) an internal boundary layer that grows from reattachment beneath the wake along the stoss slope of the next dune downstream. Most of the studies that have contributed to describing these key flow features over dunes have however concentrated on simplified two-dimensional (2D) bedforms, with constant heights and straight crestlines transverse to the flow. Given that natural bedforms are invariably three-dimensional (3D) (e.g. Allen 1982, Baas 1994) this morphological simplification has imposed inherent limitations on our interpretation and understanding of dune form and flow dynamics.

Natural dunes often have variation in crestline planform curvature, crestline height, and crestline continuity (Allen 1982, Dalrymple and Rhodes 1995, Roden 1998), with phase differences between successive crests often producing variability in dune wavelength and steepness (Gabel 1993). This three-dimensionality has significant implications for understanding the flow structure over dunes. For example, simplified 2D

forms do not possess lateral flows and secondary circulation present in more three dimensional forms, which will have major impacts on the lee side flow structure, bed shear stress and overall dune dynamics. This complexity of bedform morphology in alluvial environments has been known for many years (e.g. Sorby 1859, Neill 1965, Allen 1968) and the considerable complications that the three-dimensionality of form can introduce into the flow structure over bedforms highlighted (e.g. Allen 1968). However, only recently have the full 3D effects of dune form been investigated in detail in the laboratory (Maddux et al. 2003a,b, Venditti 2003). Maddux et al. (2003a,b) investigated dunes in which the planform crestline was straight (i.e. orthogonal to the mean flow at all positions), but where the dune height varied in the cross-stream direction in the form of a full cosine wave. Successive crestlines were 180 degrees out of phase, creating three-dimensional forms where the crest height maxima was followed immediately downstream by a crest height minima. Maddux et al. (2003a) found that these spanwise variations in form significantly altered the flow compared to that found over 2D dunes with a similar crest height. Maximum streamwise velocity was found to be highest over the crestline nodes, rather than the maxima in crestline height, and a significant amount of momentum flux over the dune was transformed into secondary currents induced by topographic forcing due to the three dimensionality in dune height (Maddux et al. 2003a).

Venditti (2003) also performed laboratory investigations into the effects of dune three-dimensionality on flow structure in which dune planform curvature was altered, but crest height and the three-dimensional volume of the dunes were maintained. Results indicate that a convex downstream planform crestline (a lobe) possesses lower average velocities for a given discharge than straight-crested 2D dunes. However, lobes were found to produce a well-defined lee side separation zone, with an intense downstream wake structure and an enhanced level of turbulence with more vigorous mixing in the separation cell than observed over 2D straight-crested dunes. In contrast, dunes with a crestline that is concave downstream (a saddle) were found to have higher average flow velocities, weakly defined separation cells, and wakes that were not a significant component of the flow field (Venditti 2003). Venditti (2003) argues that lower mean velocities associated with the lobe were caused by higher turbulence intensities in the lee, as a result of flow divergence, whereas in the case of the saddle, convergence of flow in the lee of the dune results in lower turbulence intensities but higher average flow velocities.

The experiments of Maddux et al. (2003a,b) and Venditti (2003) demonstrate that even a simple three-dimensionality in dune form can significantly influence the average flow velocity and flow distribution, secondary currents and lateral flows, and the size and intensity of the separation zone, turbulence and downstream wake. There is thus a significant gap in the understanding of turbulent flow over fully 3D dunes and that there is a pressing need for studies and measurements over natural three-dimensional field dunes. This paper presents a first step towards this goal and details a study of a field of 3D dunes in the Rio Paraná, NE Argentina. A large (0.35 km wide, 1.2 km long) area of dunes was surveyed using a Multibeam Echo Sounder (MBES), providing high-resolution 3D detail of the river bed. Simultaneous with the MBES survey, 3D flow information was obtained with an acoustic Doppler current profiler (aDcp), including at-a-point velocity measurements over key areas of the channel bed. The present paper presents details of the methodology and results using this integrated approach that has enabled investigation of the interactions between the 3D morphology and 3D turbulent flow structure of large alluvial sand dunes. The turbulent flow structures over different sections of dunes with distinct 3D morphologies are also highlighted, and used to discuss the implications for understanding dune flow structure and dune dynamics.

2 FIELD SITE AND FIELD METHODS

The study area is a field of dunes in the Rio Paraná, 16 km north of the city of Corrientes, NE Argentina (Fig. 1). The Paraná River basin occupies 2,600,000 km^2, with a mean annual discharge of the Rio Paraná of 17,000 m^3 s^{-1} (Orfeo and Steveax 2002). At the field site, the Rio Paraná is approximately 2.5 km wide and 5–12 meters deep and, at the time of surveying in May 2004, the discharge of the full river section was about 11,000 m^3 s^{-1}. Measurements

of the 3D bathymetry and 3D flow structure were made from a small vessel simultaneously using a Reson™ SeaBat® 8101 Multi-Beam Echo Sounder (MBES) and an RDInstruments™ RioGrande® 600 kHz acoustic Doppler current profiler (aDcp). Both instruments were located together spatially and temporally using a Leica™ differential global positioning system (DGPS) in real time kinematic (RTK) mode, which produced an accuracy in relative position of +/−0.02 m and +/−0.03 m in the horizontal and vertical positions respectively, with the boat velocity being approximately 1 m s^{-1} during measurements.

The Reson SeaBat 8101 MBES is a 240 kHz system, which measures the relative water depth across a wide swath perpendicular to the track of the survey vessel. A transmit projector array on the sonar head transmits pulses of acoustic energy into the water column, with reflections from the water column and bed being 'heard' on a semicircular receive array. The SeaBat 8101 has 101 beams with a total across-track subtended angle of 210 degrees, permitting the MBES to measure a swath width ∼7.4 times the water depth. A combined motion and gyro sensor (a TSS® Meridian Attitude & Heading Reference System (MAHRS)) was used to provide full 3D motion and orientation data for the MBES processing, and the DGPS was set to output a pulse per second, which is used to remove all latency from the MBES processing. The MBES provides information on the river bed morphology at a centimetric resolution and millimetric precision over scales from ripples superimposed on dunes to the entire river reach, and provides an unparalleled methodology by which to examine the form of alluvial roughness.

Simultaneous with the MBES survey, the aDcp was used to quantify the 3D flow structure over the swath of dunes. The aDcp has a 4 beam (transducer) system, each with an orthogonal angle of 20 degrees in the vertical (RD Instruments 2001), and emits acoustic pulses of energy that are backscattered by particles in the water column. The Doppler shift principle is used to convert the change in frequency into weighted averages of components of flow velocity within each depth range bin. The aDcp was set to pulse (or 'ping') at 5 Hz, although measurements were then averaged over 12 pulses to increase the signal:noise ratio, and yielded instantaneous 3D velocity profiles at ∼0.54 Hz. Since all velocities measured by the aDcp are relative to the aDcp, and hence the boat velocity, these measured aDcp velocities must be corrected for this motion by removing the DGPS-derived boat velocity, thereby producing measurements of the flow velocity (cf. Yorke and Oberg 2002). Flow velocities were finally converted from beam coordinates into an Earth referenced coordinate system, using the simultaneous measurements made by the aDcp's 'on-board' attitude and gyro sensor. Since the boat velocity was ∼1 m s^{-1}, each profile was averaged over an area of diameter ∼1.5 m at the first sampling bin nearest the water surface. An inherent limitation of the aDcp is that since each beam is oriented at 20 degrees to the vertical, the measurements are being made, and averaged across, different volumes of fluid in the vertical profile. This limitation increases with depth of measurement, such that static measurements in 10 m of water produce readings at the bed that are averaged over an area of 9.7 m in diameter.

MBES and aDcp measurements were made along a total of 14 parallel streamwise transects, each approximately 25 m apart, and six spanwise cross-sections approximately 200 m apart. For analysis of the large scale turbulent structures associated with the dunes, aDcp measurements were then taken at two fixed (moored points) as guided by the MBES survey. This included a fixed point positioned close to a dune crest and a point over the dune lee.

3 RESULTS

3.1 *Bed morphology*

Figure 2 shows the quantified bathymetry of the full field of dunes surveyed by the MBES. Flow depth increases to the SSW corner of the survey area, with a corresponding increase in dune size, and is related to the presence of a large mid-channel bar upstream of the survey area. Overall, the dunes have a relatively complex 3D pattern throughout the surveyed area (Fig. 2), with the dunes being ∼1.2 to 2.5 m high and possessing a range of wavelengths from 45–85 m, yielding a range in the dune form index (or aspect ratio; height/wavelength) of ∼0.021–0.029.

A streamwise profile through the field of dunes (Fig. 3, see location on Fig. 2) shows that the vast majority of the dunes are highly asymmetric, with

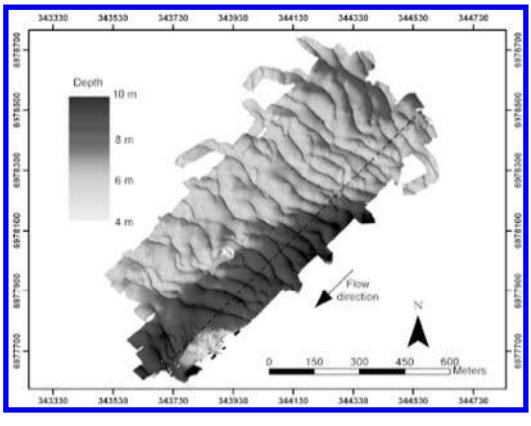

Figure 2. Bathymetric contour map of the dune field obtained using multibeam sonar.

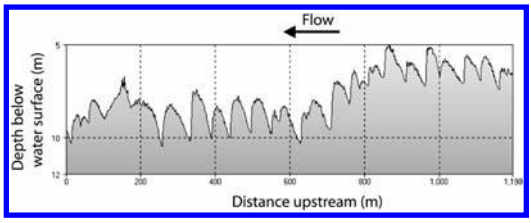

Figure 3. Profile of bed morphology, obtained with MBES, along the streamwise transect indicated in Fig. 2. Note the superimposed bedforms on the larger dunes and the crest-brink separation as shown by the gentle rounded nature of the surface close at the crest followed by a sharper break of slope into the lee.

lee side slope angles typically around ∼8.5 to ∼22 degrees. Dune stoss slope angles are much shallower, typically around ∼1.5 to 2.5 degrees.

The dunes have clearly identifiable crestlines in planform (Fig. 2), many of which are laterally continuous throughout the ∼200 m width of the survey area. However, there are several discontinuous crestlines in-between the more continuous crestlines, frequently resulting in bifurcation of individual crestlines (Fig. 2). Most crestline planform profiles also have zones of pronounced curvature, which produces saddles (where the planform crestline is concave downstream) and lobes (where the planform crestline is convex downstream) along individual crestlines. Venditti (2003) suggests that such distortion is related to maintaining the 3D bed, which exerts a significant control on sediment transport over individual dunes and thus downstream changes in bedform morphology. Indeed one would expect the variations in dune height, and shear stress profiles, produced by planform curvature of the crestlines to produce preferential sediment pathways along a particular dune, with a subsequent influence on the dune dynamics immediately downstream. The control of sediment transport directions by crestline curvature is likely to be important within the study reach, and further influenced by the locations of crestline bifurcations and crestline junctions (Fig. 2).

Numerous variations in the crest heights are present within the dune field in the study reach, even along laterally continuous crestlines (Fig. 2). Moreover, the lee side troughs of many of the dunes also have a large variability in their scour depth, with such variability being up to ∼1.5 m along an individual crest, which may be greater than the variation in the crest height between dunes. The variability in scour depth appears to be correlated to areas of planform crestline curvature, with saddle-shaped crests generally having greater, but more localized, areas of scour in their lee compared with straighter crested dunes (Fig. 2). Conversely, lobe-shaped crestlines appear to possess more laterally extensive but shallower lee side scour zones.

The stoss side slopes of the dunes in the reach are commonly convex up (Fig. 3). Most dunes also appear to have a distinct crest-brink parting (i.e. the highest point of the crest and the brinkline of any steeper slipface are not coincident), as indicated by the gentle rounded dips at the crest followed by a sharper break of slope into the lee (Fig. 3). This separation between the crest and the brink is known to have significant implications for shear and turbulence production in the lee side (Best and Kostaschuk 2002), with an influence on sediment movement over the dune crest into the lee side. Despite the variability in lee side angle across the field of dunes, most of the lee slope angles (∼>10 degrees) may be expected to produce a separation zone in the dune lee (e.g. Ogink 1988, van Rijn 1993, Wilbers 2002), with low-angle dunes also possessing intermittent flow separation (Best and Kostaschuk 2002). The presence of lee side flow separation is a significant feature of the dune dynamics, exerting significant controls on turbulence production and sediment transport (e.g. McLean et al. 1994, Bennett and Best 1995).

The different aspects of dune three-dimensionality revealed by this MBES survey therefore appear interrelated and may be expected to influence the dune flow dynamics (e.g. Venditti 2003). Planform crestline curvature seems related to variations in crestline height and patterns of leeside scour depth. Moreover, the linkages between crestlines in terms of crestline discontinuities, bifurcations and junctions also appear related to the influence of the upstream dune three-dimensionality, and in particular dune height and variations in lee side scour.

3.2 *Flow structure*

The flow structure obtained with the aDcp over three dunes identified from the MBES survey are shown in Figures 4, 5 and 6. The dunes selected for more detailed analysis possess: a straight crest, a lobe-shaped crest, and a saddle-shaped crest, and were formed within similar flow depths with relatively uniform local crestal heights (2.1–2.3 m). Importantly, the high-resolution bed morphology obtained from the MBES is used to place the individual dunes and their associated flow fields into their full three-dimensional morphological context.

The straight crested dune (Fig. 4) shows many features present over 2D fixed dunes (e.g. McLean et al. 1994, Bennett and Best 1995), including acceleration of streamwise flow along the stoss side of the dune, particularly at the crest, associated with a zone of positive vertical velocity slightly removed from the bed. This is followed by a significant deceleration of flow and a zone of high negative vertical velocity in the dune lee, with a separation zone present in the lee side as indicated by the ∼100 degree change in flow direction

Copyright © 2006 Taylor & Francis Group plc, London, UK

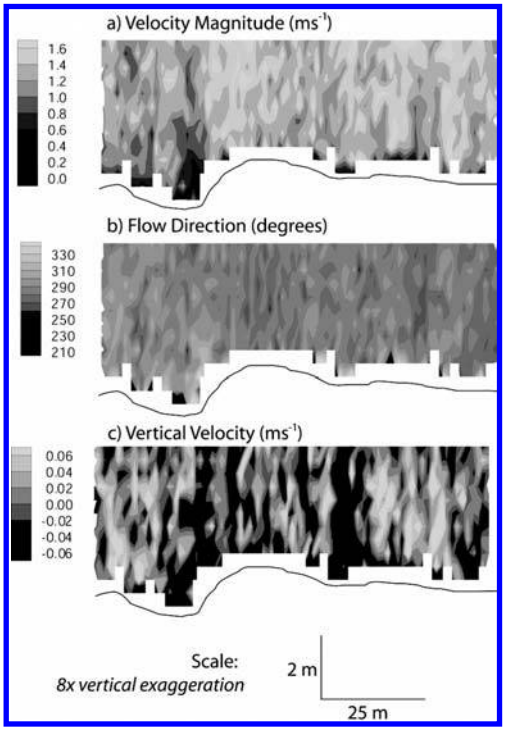

Figure 4. Flow velocity magnitude, direction and vertical velocity over a straight-crested dune. Flow is from right to left.

though the leeside scour (Fig. 4b). This flow separation is associated with a leeside angle of 18 degrees.

Over the saddle-shaped crestline (Fig. 5), a similar pattern of higher streamwise velocity over the stoss side and lower streamwise velocity in the dune lee is apparent, although the deceleration of velocity in the lee is not as marked as over the straight-crested dune. There is also a clear pattern of enhanced vertical velocity over the dune, with a zone of strong upwelling along the stoss side approaching the dune crest, and a stronger zone of downwelling throughout the region of lee side scour. The magnitude of the vertical velocity is also enhanced over the saddle-shaped crestline compared to the straight-crested dune, particularly in the region of downwelling in the dune lee. However, despite this clear pattern in vertical velocity, no flow separation zone is detected in the dune lee, probably due to the spatial sampling limitations of the aDcp. As the angle of the lee side slope over this saddle (14.5 degrees) would suggest that a permanent separation zone may be present, the non-detection of flow separation by the aDcp suggests that flow separation is probably spatially less extensive than associated with the straight-crested dune.

In the case of the lobe-shaped crestline (Fig. 6), the general flow pattern is once again similar to the other

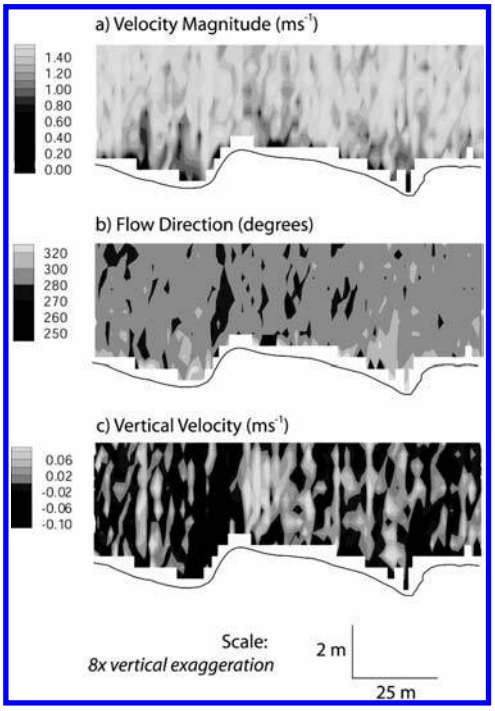

Figure 5. Flow velocity magnitude, direction and vertical velocity over a saddle-crested dune. Flow is from right to left.

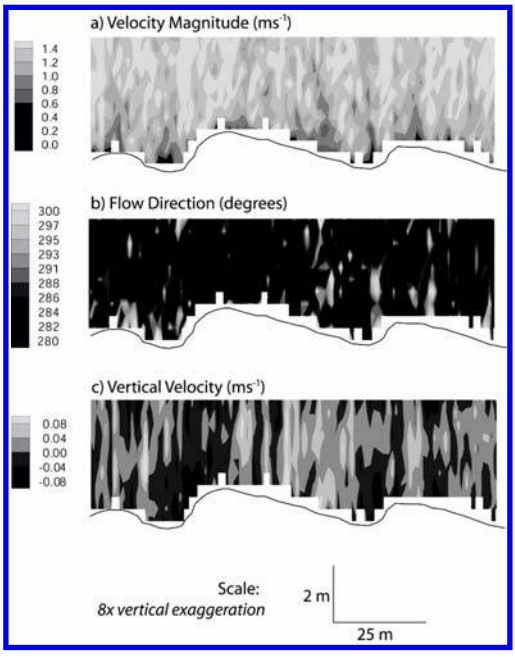

Figure 6. Flow velocity magnitude, direction and vertical velocity over a lobe-crested dune. Flow is from right to left.

Copyright © 2006 Taylor & Francis Group plc, London, UK

two cases, although the velocity over the whole dune is slightly lower (1.2 ms^{-1}). A small zone of decelerated flow is again prevalent in the lee side, with the vertical velocity again being enhanced over the dune form, and being greater than the straight-crested dune but less pronounced than in the saddle-shaped crest. Despite the high negative vertical velocity in the lee side, there is no measured flow reversal, with only a ~20 degrees deviation in flow direction detected in lee side. Again, since the lee side angle of the dune (14 degrees) would suggest the likelihood of permanent flow separation, this suggests that the separation zone is again smaller than over the straight-crested dune.

These results from a field study of mean flow over 3D dunes, and the recent physical modeling studies of Maddux et al. (2003a,b) and Venditti (2003), have several important implications for sediment entrainment, deposition, sediment transport rates, dune migration and thus the overall stability of a sand bed. The smaller separation zones and lower velocity gradients associated with the leeside of 3D dunes may be associated with a smaller level of large-scale turbulence, and thus amount of sediment entrained into suspension (e.g. Jackson 1976, Kostaschuk and Church 1993) than their 2D counterparts. Moreover, as form drag can be reduced by ~52% over a 3D irregular dune pattern (Venditti, 2003) and turbulence intensities are generally less over 3D dunes compared with 2D dunes (Maddux et al. 2003a), the spatially-averaged bed shear stress is likely to be less over the whole dune: sediment transport rates may thus be expected to be lower over a 3D dune than over a 2D dune profile. The effects of differential dune height, wavelength and form index associated with dune three-dimensionality, which will affect the presence, location and permanence of flow separation, and their influence on flow structure and sediment entrainment may thus be expected to be important in affecting flow resistance over dune-covered beds. More research in this area is vital to better understand dune dynamics.

3.3 *Large-scale turbulence analysis*

The acoustic backscatter signal from the aDcp was used as a proxy for suspended sediment concentration (see Shugar 2005). The backscatter from each of the four instrument beams was averaged for of the bins in the vertical. Time series from a location close to the bed (about 2 m from the bed) at both the dune crest and dune trough were used for comparisons (see Fig. 1 for location).

Wavelet analysis was used to compare the time series. The wavelet transform was designed to analyze time series containing nonstationary power over many different frequency scales (see Daubechies 1990). The wavelet transform used herein is the continuous version, where the transform is calculated for all scales

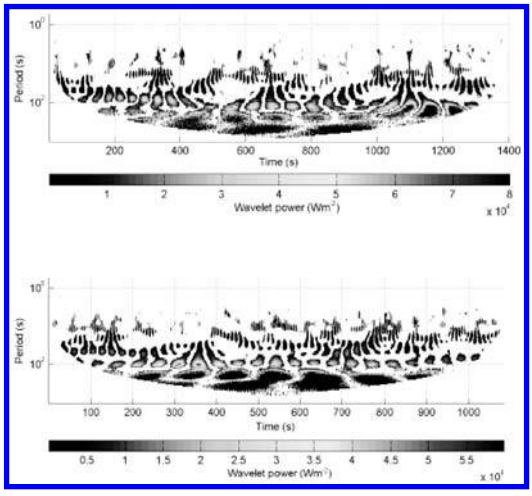

Figure 7. Wavelet power spectrums of calibrated suspended sediment concentration at (a) the dune crest and (b) at the dune trough. Both time series are taken 2 meters above the channel bed.

and positions in time. Wavelet analysis offers several advantages over more traditional spectral analyses based on the Fourier transform. The Fourier transform decomposes a signal into a series of sine and cosine waves, and expresses the signal in terms of the frequency (x) and power (y) of its constituent waves, without reference to when the frequencies occur. Furthermore, strong inhomogeneities in a turbulent series mean that the physical meaning of a Fourier decomposition is lost. Wavelet transforms however allow one to unfold a signal into both space and scale using analyzing functions called wavelets, which are localized in space (Farge 1992). A time series is decomposed into a set of scaled and translated versions of wavelet functions, with the scale of the wavelet varying with frequency. Thus, where a Fourier transform in the frequency domain yields a power value for each frequency and is inherently nonlocal, wavelet analysis produces power values for a set of locations in time and for a range of frequencies, the latter related to the scales of the wavelet function considered. Wavelet analysis is therefore useful in analyzing time series that contain nonstationary power at various frequencies and expresses a time series in three-dimensional space: time (x), scale/frequency (y) and power (z).

Figure 7 shows wavelet transforms for suspended sediment concentrations at 1 meter above (a) the crest surface and (b) trough locations over the dune. Wavelet analysis identifies coherent flow structures at a range of frequencies from 1 to 1×10^{-3} Hz, with structures having periods of ~100 seconds dominating the time

Copyright © 2006 Taylor & Francis Group plc, London, UK

series at both the crest and the trough, but with significantly lower wavelet power for the trough time series. Periodicities of flow structures with high suspended sediment content of 0.01 Hz are common, with both records exhibiting these larger, lower frequency structures. As these regions of enhanced suspended load correlate well with streamwise flow deceleration over both crest and trough, these events are interpreted as fluid ejections, which have a streamwise velocity lower than the average and are responsible for increased suspension of sediment. These results suggest that these larger scale structures (~100 s) move over the crest and are then transmitted through the lee side scour, with the lower wavelet power indicative of less coherence as the flow structure moves through the lee side.

4 CONCLUSIONS

Detailed measurements of bed morphology and three-dimensional flow structure over a field of sand dunes in the Rio Paraná, Argentina, have enabled an initial field testing of recent laboratory findings concerning 3D dune morphology and flow dynamics.

Dune morphology is complex with considerable variations in dune height, wavelength, scour depth and crestline curvature. For instance, dune three-dimensionality may induce larger changes in dune height than the variation present between different dunes. Variability in crestline direction and curvature along with crestline continuity are also present. Crestline discontinuities, bifurcations and junctions appear related to the influence of upstream dune three-dimensionality.

Three-dimensionality in dune morphology is also shown to significantly influence the flow structure. Both lobe and saddle shaped dune crestlines produce smaller regions of lee side flow separation, with higher vertical velocities when compared with a straight crested dune. These findings suggest that if the flow structure over 3D dunes is associated with smaller levels of large-scale turbulence, this may also result in less suspension of bed sediment, and thus sediment transport over the dune field may be reduced.

This field study also highlights that further research is clearly required into the interacting effects of dune curvature and dune height on flow structure, from a combination of laboratory and theoretical work aligned with targeted field investigations. An advance in understanding is also required on the influence of natural 3D dune geometry on macroturbulent flow structures and their spatial variability. Furthermore, detailed information is needed as to how dune migration rates and sediment transport are linked to the morphology of natural 3D dunes, which can then be linked though to an increased understanding of the temporal changes in 3D dune flow structure.

ACKNOWLEDGEMENTS

This research was enabled through award of grants NER/A/S/2001/00445 and NER/B/S/2003/00243 from the UK Natural Environment Research Council for which we are extremely grateful. We would like to gratefully acknowledge the outstanding and full support of RESON (www.reson.com), and John Fraser in particular. Additionally, we also extend thanks to the staff of CECOAL-CONICET (Corrientes, Argentina), and in particular Lolo Roberto and Luis Bonnetti, for their field support. Flow resistance associated to a schematic step-pool pattern

F. Canovaro & L. Solari
Department of Civil Engineering, University of Firenze, Italy

ABSTRACT: Flow resistance developed by macro-roughness represented by pebbles positioned on a granular layer according to a regularly spaced stripe pattern on steep bed slopes is here investigated. Flume experiments under various geometrical and hydraulic conditions are carried out and interpreted by means of a theoretical model. Results indicate that when the macro-roughness stripes are spaced according to some optimal wavelength, flow resistance is maximum. A statistical analysis of a large number of step-pool geometry data suggests that this spacing corresponds to one of the statistically most frequent wavelength observed in natural step-pool sequences.

1 INTRODUCTION

Step-pool are characteristic bedforms that widely take place in steep mountain streams, occurring when gradients ranges between 3% and 30%, even if not fully developed step-pool sequences have been observed for slopes down to 1% (Montgomery & Buffington, 1997; Lenzi, 2001). Step-pool pattern provides a fundamental role in mountain stream hydraulics, developing the major portion of flow resistance (Abrahams et al., 1995). This flow resistance is essentially due to a loss of kinetic energy, dissipated by roller eddies that occur when water flows over a step rise and plunges into the pool below, creating a tumbling flow (Peterson and Mohanty, 1960). As a result much of the energy which might be otherwise available for sediment erosion is lost, providing a bed stabilization (Ashida et al., 1976). Following this idea some authors (e.g. Davies & Sutherland, 1980; Whittaker & Jaeggi, 1982; Abrahams et al., 1995) have suggested that step-pool streams evolve toward a maximum flow resistance condition in the way to achieve a maximum bed stabilization. In particular Abrahams et al. (1995) suggests that maximum flow resistance occurs when $1 < H/L/S < 2$, where H is the step height, L the step-pool wavelength and S the average bed channel slope. Later field investigations (Wohl et al., 1997; Chartrand & Whiting, 2000; Zimmermann & Church, 2001) have somewhat extended the validity of Abrahams et al. (1995) results suggesting that, where average channel slope is below 5–7%, H/L/S is greater than 2. Notwithstanding several field and laboratory studies have been carried out about step-pool geometry (Whittaker & Jaeggi, 1982; D'Agostino & Lenzi, 1998; Chin, 1999; Chartrand & Whiting, 2000; Lenzi, 2001; Zimmermann & Church, 2001; Gomi et al., 2003; Curran & Wilcock, 2005), very few data (Lee & Ferguson, 2002; Aberle & Smart, 2003; Curran & Wilcock, 2005) are available about the behaviour of hydraulic quantities and so very little is known about the flow resistance developed by step-pool streams. This lack of hydraulic data is due to the difficulties of survey low-frequency high-magnitude formative discharges, especially when step-pool sequences occur in rugged, mountainous and often inaccessible terrain (Chin, 1999).

In the present work we investigate, by means of a theoretical analysis and a laboratory activity, flow resistance when macro-roughness elements are positioned according to a regularly spaced stripe pattern on a layer of relatively fine material, representing a step-pool-like bed arrangement. Experiments are carried out changing size of macro-roughness elements, spacing of the macro-roughness stripes, flow discharge and slope of the flume. Experimental results are interpreted by means of a theoretical model in order to investigate the behavior of flow resistance as a function of hydraulic variables and geometric properties of macro-roughness stripes. Results show that flow resistance reaches a maximum when the spacing between macro-roughness stripes is about 10 times the average macro-roughness height. A statistical analysis based on various field observations of step-pool geometry underlines that this spacing appears to be one of the most frequent occurring in step-pool bed morphology sequences, suggesting that natural mountains stream bed-forms evolve toward a bed configuration maximizing flow resistance.

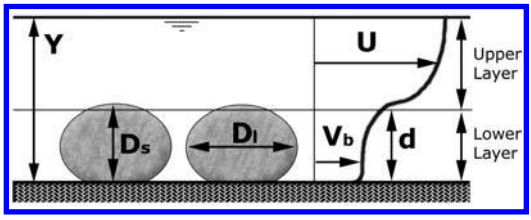

Figure 1. Sketch of a free surface flow over a bed with macro-roughness elements and notations.

2 THEORETICAL BACKGROUND

Flow resistance is herein evaluated by means of a theoretical model developed by Canovaro et al. (in prep.). According to this model, dimensionless Chezy coefficient C is calculated from the average longitudinal velocity profile in the case of steady flow and spatially averaged uniform conditions.

In order to obtain the longitudinal velocity profile, the flow region is assumed to be composed by two layers (Figure 1). A bottom layer, laying on the bed and containing the major part of the macro-roughness elements, in which the flow is dominated by the loss of momentum due to the drag around the obstacles. In such layer of thickness d the flow velocity V_b is relatively low, and approximately constant over the depth. An upper layer, extending up to the free surface, of height $Y-d$; in this layer, characterized by a mean flow velocity U, the flow velocity is relatively high and the major part of flow discharge occurs.

According to the double-layer approach herein adopted, the mean flow velocity profile is characterized by four variables: Y, U, d and V_b. Such quantities allow to estimate flow resistance in the case of macro-roughness flow conditions.

Taking into account a control volume of unit bed area extending from the bed to the water free surface, the two governing equations, continuity and momentum balance, read as follows:

$$q = (Y-d)U + d\psi V_b, \tag{1}$$

$$F_g = F_d + F_s, \tag{2}$$

where q is the flow discharge per unit width, F_g the streamwise water mass weight, F_d the macro-roughness-induced drag force, F_s the surface-induced friction, and ψ a reduction coefficient, being $\psi < 1$, for the bottom layer flow velocity V_b, taking into account the effective flow area among the macro-roughness elements. Therefore ψV_b denotes the mean (apparent) flow velocity in the lower layer. It is worth to notice that the ψ coefficient depends on the effective bed arrangement. For a regularly spaced stripe arrangement of the macro-roughness, the reduction factor is estimated as follows:

$$\psi = 1 - D_m D_l N_u \tag{3}$$

where D_m and D_l are the median axis diameter and the long axis diameter of macro-roughness elements respectively and N_u is the number macro-roughness elements arranged on an unit bed area along the channel.

The streamwise water mass weight component per unit bed area involved in equation (2) is expressed as follows:

$$F_g = \rho g Y S \left(1 - \frac{2 D_s \Gamma}{3Y}\right), \tag{4}$$

where S is the channel slope, Γ is the spatial density (defined as the ratio between the number of macro-roughness elements arranged in an unit bed area, and the maximum number that is possible to arrange in the same area: $\Gamma = N_u / N_{\max}$) and D_s is the short axis diameter of the macro-roughness elements. In eq. (4) the term into brackets acts as a reduction factor in order to exclude from calculations the control-volume fraction occupied by macro-roughness elements. This latter volume is calculated resembling macro-roughness elements to ellipsoids and estimating $N_{\max}$ as the ratio between the unit bed area and the area projection of ellipsoid to the bed.

The drag force per unit bed area can be written as follows:

$$F_d = \frac{1}{2} \rho C_D N_u A_f' V_b^2, \tag{5}$$

where ρ is the water density, C_D the drag coefficient and A_f' the area perpendicular to the flow interested by V_b for a single macro-roughness element, defined as follows:

$$A_f' = \begin{cases} \frac{\pi}{4} D_m d & \text{if} \quad d < D_s \\ \frac{\pi}{4} D_m D_s & \text{if} \quad d \geq D_s \end{cases}. \tag{6}$$

Note that in equation (5) the effective lower layer velocity V_b is employed instead of the apparent velocity ψV_b, being a more appropriate characteristic velocity for evaluating the macro-roughness element drag. Notwithstanding that drag coefficient should reasonably be a function of stripe spacing, due to the lack of information about step-pool stream hydraulics the drag coefficient C_D is assumed constant to 1.5 as suggested by other authors (Robertson et al., 1974; Bathurst, 1996).

Finally, the surface friction per unit bed area takes the following expression:

$$F_s = \rho U^2 \left[\frac{(1-\Gamma)}{C_G^2} + \frac{\Gamma}{C_P^2} \right], \tag{7}$$

being C_G and C_P the Chezy coefficients of a channel bed without macro-roughness elements ($\Gamma = 0$), and

Copyright © 2006 Taylor & Francis Group plc, London, UK

completely covered by macro-scale roughness ($\Gamma = 1$), respectively.

In the present study Y and U are obtained through an experimental activity, while d and V_b are unknowns to be determined by solving the governing equation system composed by the equations (1) and (2).

The mean flow velocity profile is then estimated as follows:

$$\overline{U} = \frac{(Y-d)U^2 + d(\psi V_b)^2}{q}. \quad (8)$$

The dimensionless Chezy coefficient is finally evaluated with the following:

$$C = \frac{\overline{U}}{\sqrt{F_g/\rho}}. \quad (9)$$

3 LABORATORY EXPERIMENTS

The experiments are carried out in a 10 m long, 36.5 cm wide and 50 cm deep glass-walled recirculating tilting flume. The measuring reach is 4 meter long with a bed covered by a layer of granular uniform material having a medium size of 7 mm. In order to dissipate flow disturbances, before the beginning of the measuring reach a transition reach composed by little quarry rubbles is positioned (figure 2). Three different sets of pebbles are used as macro-roughness elements, characterized by different medium axis values according to the Wentworth sedimentological scale Φ, as presented in table 1.

Macro-roughness elements are positioned according to a regularly spaced stripe pattern along the experimental reach. Each stripe is made by pebbles, placed over the granular layer with the long axis D_l in the flow direction and the short axis D_s perpendicular to the bottom of the flume.

For each set of pebbles the "wave length" L, i.e. the spacing between two following stripes, is varied from 6 to 160 cm. Experiments have been carried out for various flow discharges and channel slopes. No bed load occurred during the experiments.

For each run both total water depth Y and mean flow velocity U are measured; several time-averaged values of these quantities are taken during each run along the measuring reach. Water surface elevation is measured by means of a set of 40 piezometers placed below the granular layer; by averaging these 40 values one space-time averaged water depth value is obtained for each run.

Flow velocity is taken in 33 points according to a regular distribution along one wavelength across the middle stripe (figure 3), by means of a micro-propeller meter. As for the water surface elevation measurements, one space-time averaged velocity value is obtained for each run. Each value is the result of a 400 velocity time-averaging readings, corresponding to a measurement time of 10 seconds.

The experimental activity is composed by 147 runs divided into 17 experiments, each experiment is characterized by either different stripe height, bed slope or flow discharge. A summary of the performed experiments is reported in table 2.

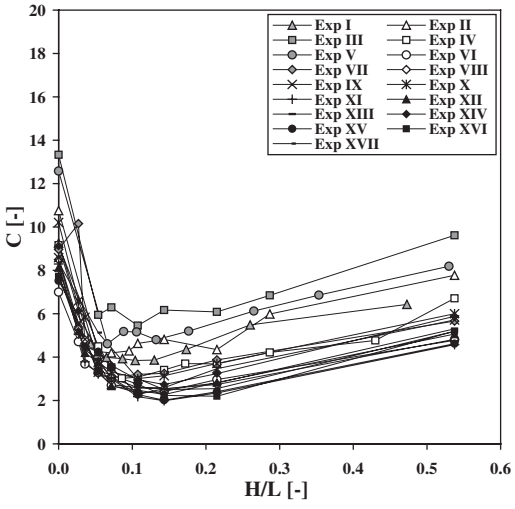

Figure 4. Chezy coefficient (C) as a function of ratio stripe height (H) to stripe wavelength (L).

4 EXPERIMENTAL RESULTS

Results obtained during the experimental activity described in the previous section are here presented.

In figures 4 and 5 dimensionless Chezy coefficient (C) and ratio of drag shear stress (τ_d), defined as the drag force F_d per unit bed area, to total shear stress (τ_g), defined as the total force F_g per unit bed area, are presented as functions of the ratio of stripe height (H) taken equal to D_s to macro-roughness stripe wavelength (L). Both plots show a non monotonic behaviour of the investigated quantities for all the experimental

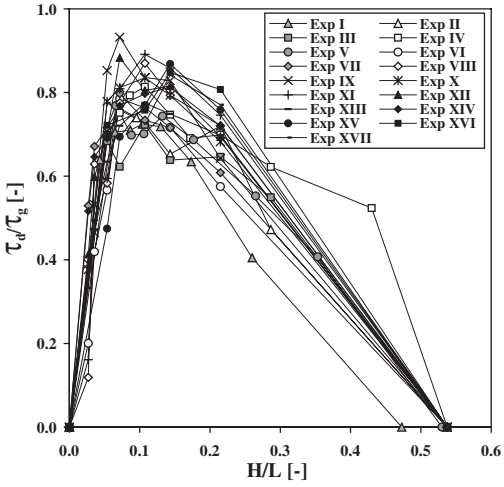

Figure 5. Ratio of drag shear stress (τ_d) to total shear stress (τ_g) as a function of the ratio stripe height (H) to stripe wavelength (L).

series. In particular it is apparent the existence of an "optimal" dimensionless spacing value (H/L), ranging around 0.15, maximising both flow resistance and ratio drag shear stress to total shear stress.

When maximum flow resistance conditions are attained C is about 2–3 times smaller than in the case of no macro-roughness presence ($H/L = 0$) but note that C is also smaller than in the case when the spacing between stripes is minimum ($L = D_l$).

When flow resistance is maximum, drag shear stress is about 80% of total shear stress, suggesting that in this condition stripes develop a fundamental role in energy dissipation while surface resistance plays an almost negligible role.

Notwithstanding the presence of some scattering in the data points, it seems that flow discharge, flume slope and stripe height do not significantly affect the value of the observed "optimal" dimensionless spacing H/L. On the other hand, for a given H/L, flow resistance seems to increase with stripe height and bed slope while it decreases with the flow discharge (compare figure 4 with table 2).

The presence of an "optimal" H/L value maximizing flow resistance has been also observed in other investigations (e.g. Johnson & Le-Roux, 1946; Wohl & Ikeda, 1998) devoted to study the influence on flow resistance C and on equivalent roughness size K_s of macro-roughness positioned according to a regularly spaced stripes pattern, under various geometric and flow conditions. In figures 6 and 7 two comparisons respectively with Wohl & Ikeda (1998) and Johnson & Le-Roux (1946) experiments in the case of macro-roughness composed by transverse rectangular ribs are presented. The comparisons show a fairly good

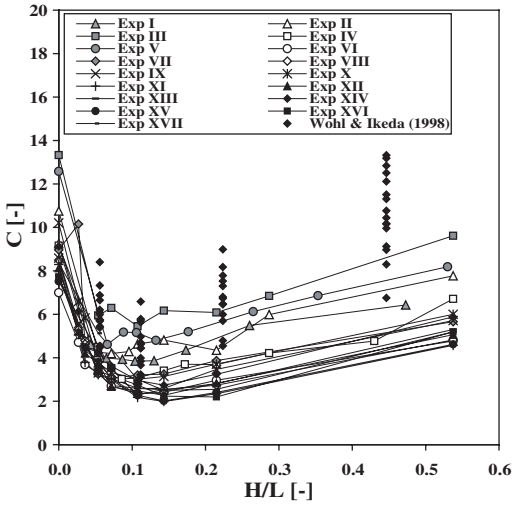

Figure 6. Comparison with Wohl & Ikeda (1998) experiments.

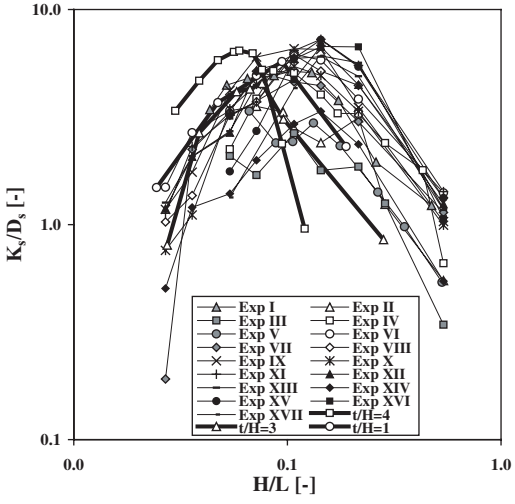

Figure 7. Comparison with Johnson & Le-Roux (1946) experiments (solid lines); for the present experiments t/H is around 2, being t equal to D_l and H equal to D_s.

agreement; in particular the presence of an "optimal" spacing value maximizing flow resistance is revealed in both cases when H/L is around 0.15 as found in the present study. These findings suggest that the present experiments are representative of a common behaviour in the dissipative mechanism associated to regularly spaced stripes.

The presence of a maximum in flow resistance was also found for macro-roughness spatial arrangements different from the one employed in the present study. Rouse (1965) indicates, in the case of a regular pattern of macro-roughness disposition, that the maximum flow resistance is achieved when macro- roughness spatial density (the sum of all basal areas of the macro-roughness elements arranged in an unitary bed area) is ranging between 0.15–0.20. As pointed out by Morris (1971) for flow in closed conduits, the presence of a maximum in flow resistance may be explained in terms of a different behaviour of flow motion in relation to the spacing value (or to the spatial density) of macro-roughness stripes. For high spacing values, when macro-roughness stripes are "isolated", motion might be regarded as a "non wake interfering"-like, while for low spacing values, the vortex generation and dissipation associated to a stripe is no complete before the flow meets the next stripe.

5 CONCLUDING REMARKS

The present investigation shows that maximum flow resistance in the case of macro-roughness positioned according to regularly spaced stripes occurs when the spacing between the stripes is about 10 times the stripe height. In this condition flow resistance consists almost entirely in form resistance, the latter is associated to the plunging of flow downstream each stripe and the formation of roller eddies developing in the pool between two successive stripes.

This mechanism can be commonly observed in natural step-pool sequences (Abrahams et al., 1995; Chin, 1998; Chartrand & Whiting, 2000) unless for high flow discharges when the step-pool shape is hidden. Even if the present regular spaced stripe pattern is only a rough schematization of a natural morphology, in the light of the above findings it seems reasonable to consider some general analogies between flow resistance developed by natural step-pool sequences and the laboratory results herein presented.

In figure 8 a statistical frequency distribution of natural step-pool gradient (H/L) based on 177 field and laboratory data about step-pool geometry, obtained from various authors (Whittaker & Jaeggi, 1982; Abrahams et al., 1995; D'Agostino & Lenzi, 1998; Chin, 1999; Chartrand & Whiting, 2000; Lenzi, 2001; Zimmermann & Church, 2001; Gomi et al., 2003; Curran & Wilcock, 2005) is presented.

It appears that the range of most common spacing values observed in step-pool sequences is very close to the "optimal" spacing value that maximizes flow resistance in the present flume experiments. This finding seems to suggest that natural step-pool sequences evolve toward a bed configuration maximizing flow resistance, in order to achieve a bed stabilization (Abrahams et al., 1995), since much of the energy which might otherwise be available for sediment erosion is lost (Ashida et al., 1976).

The latter results suggest to consider as representative of real step-pool sequences only the presentflume

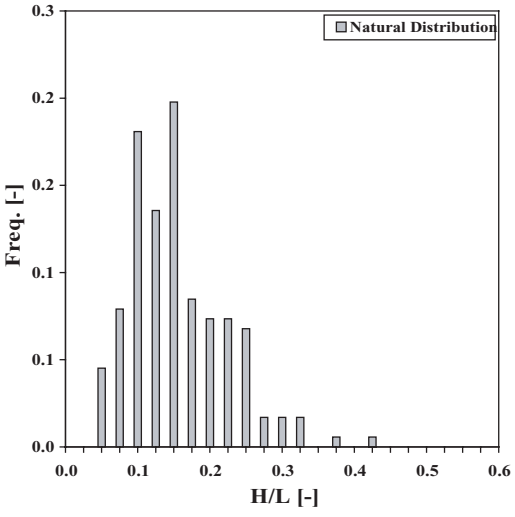

Figure 8. Statistical distribution of the ratio of step height H to step spacing L observed in natural step-pool beds.

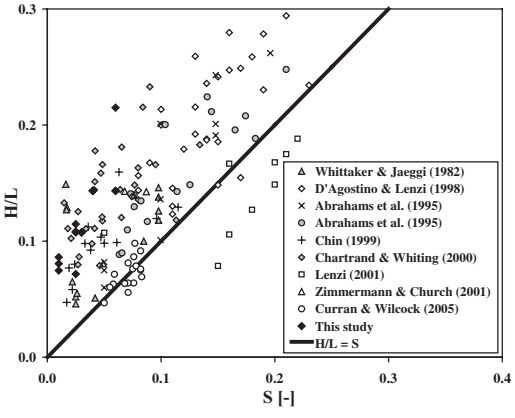

Figure 9. Flume and field measurements of step spacing L, step height H and channel slope S. The line represents $H/L = S$.

data whose macro-roughness geometry maximizes flow resistance.

In figure 9 a comparison between geometric characteristics of employed flume pattern and natural step-pool sequences, showing the local step-pool gradient H/L as a function of channel slope S, confirms the hypothesis of considering employed pattern as a laboratory model for step-pool sequences. From the plot it appears that the present flume ($S - H/L$) pairs fall in the same range of real step-pool sequence observed geometry. In figure 9 the line for $H/L = S$ is also reported, a somewhat different behavior is associated to the data reported by Lenzi (2001) as in general step-pool patterns are characterized by $H/L > S$.

Notwithstanding the present results refers to a rough representation of step-pool morphologies, the latter findings seem to suggest the present model may be extended to provide an interpretation of flow resistance developed by natural step-pool morphologies. These development are in progress.

ACKNOWLEDGEMENTS

The Authors are grateful to Prof E. Paris, University of Florence (Italy), for his valuable comments and suggestions. The Authors wish also to thank Elena Facchini and Luca Nelli, who have carried out a part of experimental activity herein presented.

Three-dimensional properties of laboratory sand waves obtained from two-dimensional autocorrelation analysis

ABSTRACT: A comprehensive data set of 3-D sand waves developing from a flat bed to equilibrium stage (known as the research program SWAT.nz – Sand Waves and Turbulence New Zealand) was obtained during investigations in a 5-ft-wide flume at The University of Auckland. The recorded sand bed is treated as a continuous field of sand-bed elevations, rather than subdivided into discrete sand waves. Aiming at 3-D interpretation of the random field of sand-bed elevations, 2-D autocorrelation analyses are introduced. It is shown that the 2-D autocorrelation function approach is a useful tool to depict 3-D characteristics of sand waves and their further potential is outlined.

1 INTRODUCTION

Best (2004) gives an up-to-date description of the complexity of the field of underwater bed morphology, and refers to the lack of knowledge of the interaction of 3-D dune shape and the surrounding flow field. He notes that a better understanding of the 3-D behavior of sand forms in uniform flow conditions is needed to provide information for future research aimed at combining the complex morphodynamic and hydraulic features, which are inherent during the development of sand waves.

In order to gain advances in the understanding of 3-D sediment and flow-field interaction, progress must be made in describing 3-D characteristics of subaqueous bed forms.

Allen (1968) provided an earlier classification scheme for the 3-D nature of bed forms. He observed visually the position of the crest line in a plane parallel to the water surface (planimetric view) and distinguished the crest line characteristics as straight, sinuous, caternary, linguoid, cuspate, or lunate.

Ashley (1990) proposes to use the term 'dune' for all large-scale subaqueous bed forms, the wide variety which are subject to effects such as sediment size, water levels, unsteady and reversing flows and channelization. As one of the characteristics to describe the term with more detail, the dunes were distinguished according to their shape into 2-D dunes, which develop at lower flow speeds, and 3-D dunes, which occur at higher speeds.

In contrast to previous technology that did not allow 3-D dune information to be gained very easily, the advances in the last decades now enable us to record and analyze 3-D dune fields.

2-D sand waves can be comfortably analyzed using one transect parallel to the flow, mostly recorded along the centre line of the channel. For 3-D dunes, an analysis technique covering the whole surface area should provide enlightening new information about the pattern.

Even though technological advances have enabled us to record 3-D surfaces, few researchers have previously tried to follow up this extended area of interpretation of submerged sediment waves.

One of the most recent works was by Venditti (2003). He describes features of the planimetric view of sand waves with the help of video analysis. He used the non-dimensional span Λ_{NDS} as a parameter (see Fig. 1) to describe the 3-D characteristics of bed forms.

A critical value of 1.2 for the non-dimensional span is proposed to distinguish between 2-D and 3-D bed forms. His work is based on the pioneering work of Allen (1968) nearly 40 years earlier. The use of

Copyright © 2006 Taylor & Francis Group plc, London, UK

spatial recognition software prevents this method gaining universal status, along with difficulties associated with identifying certain crest lines, which is a very subjective procedure (see Fig. 2).

In the present paper it is proposed to treat a recorded 3-D sand-bed elevation field as a random field rather than discrete sand waves, following Nikora et al. (1997) who used longitudinal and transverse spectra, correlation and structure functions to describe statistical sand wave dynamics.

2 EXPERIMENTAL INVESTIGATION

A 5-MHz Seatek ultrasonic ranging system, comprising 31 transducers (see Fig. 3), was employed for the measurements of the sand bed. The moving probe arrangement, which was traveling up-and-down the flume on a moving carriage and which measured the 3-D elevations of a developing sand bed, was introduced in Friedrich et al. (2005), a methodology paper describing experiments undertaken in a narrow 440-mm-wide flume. This paper utilizes data obtained during experiments in a larger 5-ft-wide flume. Brief explanatory notes illustrating additional to Friedrich et al. (2005) 5-ft-flume methodology are given below.

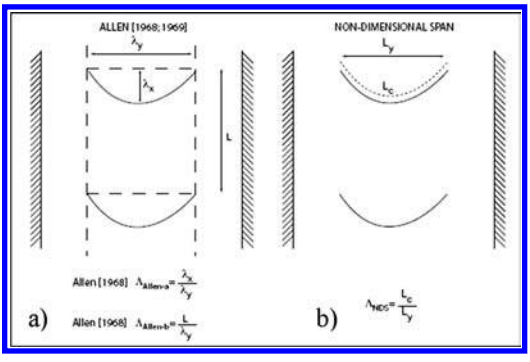

Figure 1. (a) Ratio Λ of λ_x (the stream wise distance that the lobes extend downstream) and λ_y (the cross-stream distance between lobes of a crest line), after Allen (1968), and (b) the non-dimensional span Λ_{NDS} for closing crest lines L_c and L_y, after Venditti (2003).

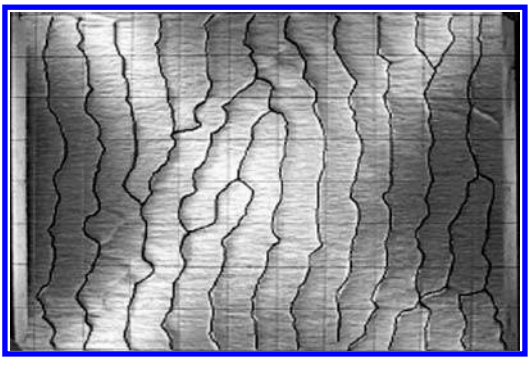

Figure 2. Identification of crest lines in order to determine the non-dimensional span, after Venditti (2003).

The 31 transducers were interrogated sequentially (starting from sensor 1 and finishing with sensor 31), with the same sequence repeated every 0.2-s. The sensors were mounted on a skewed grid (see Fig. 4) to allow for the movement of the carriage in the time interval between readings of the components of the sensor array. This ensured that measurements were obtained on an equivalent rectangular recording grid (Fig. 5). With a carriage velocity = 0.33-m/s, the rectangular recording grid shown in Figure 4 was generated.

Each mobile-bed experiment (flat sand bed to equilibrium bed forms) utilizing moving probes was carried out over several hours. Experimental parameters for these experiments are given in Table 1.

The sequence of operation was as follows. Initially, the moving carriage with submerged sensors traveled downstream for 56-s. Then the carriage was stationary

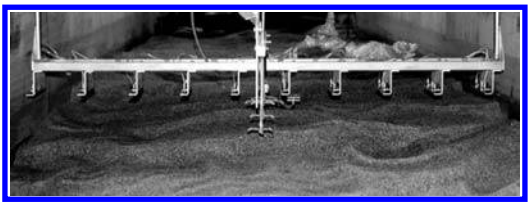

Figure 3. Arrangement of the moving probes across the 5-ft flume. Four Acoustic Doppler Velocimeters (ADVs) are placed in front of the acoustic sensors in the centerline of the flume to measure the flow field at different water depths.

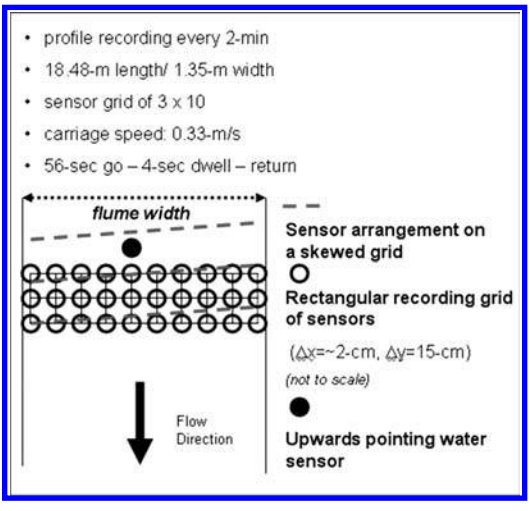

Figure 4. Moving probe arrangement for the 5-ft flume.

for a waiting period of 4-s, which was used to move the sensors up out of the water, in order to reduce the water surface disturbance when traveling upstream. Afterwards, the carriage traveled upstream for 56-s. After a further waiting period of 4-s, and submerging the sensors again, the carriage moved downstream into the second cycle. Each cycle duration was two minutes. The experiment was continued with repeated cycles until appropriate bed-form development had occurred. Recording of the bed profiles occurred only during the downstream-moving portion of each cycle, based on the configuration of the recording grid. The frequency of recording of bed profiles was one profile every two minutes. As one can see from Figure 4, sensor no. 31 was inverted and used to record the water surface elevation, meaning that only 30 sensors were used to record bed elevations. Overall, ten longitudinal profiles with a transverse resolution of 150-mm were recorded over each sweep of a length of 18.48-m.

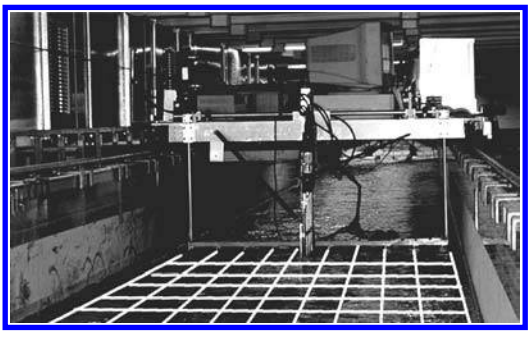

Figure 5. Schematic display of sand bed elevation recording grid in the 5-ft flume. Moving carriage is traveling downstream (recording) and upstream (sensors out of the water) along the flume over a length of 18.48-m.

3 METHODS

3.1 *Data processing*

Firstly, the ten longitudinal profiles recorded for each sweep along the flume were considered individually. Filtering methods were applied to remove faulty signals and to take into account the detection of suspended particles. Afterwards, interpolation procedures were used to fill the gaps in the profiles. The sand-bed elevation surfaces were detrended linearly for every individual snapshot. Then the following autocorrelation procedures were applied with the help of Matlab routines. The sand-bed elevations were considered as a 3-D random field.

3.2 *2-D Autocorrelation functions*

As a simple introduction to correlation functions, one can say: everything is related to everything else, but like things are more related than unlike things. For a vivid description of one case of correlation functions, the spatial auto-correlation function showing the correlation of a variable with itself through space), one can say:

- if there is any systematic pattern in the spatial distribution of a variable, it exhibits spatial autocorrelation;
- nearby or neighboring areas being more alike gives positive spatial autocorrelation;

- negative autocorrelation arises for patterns in which neighboring areas are unlike, and
- fully random signals or fields exhibit no spatial autocorrelation.

A full-dimensional correlation function $R(\Delta x, \Delta y, \tau)$ (spatial and temporal) is practically difficult to evaluate. In the past researchers used 1-D autocorrelation functions (spatial and temporal) to determine the wavelength of bed forms and the duration how long it takes for a bed form to move past a stationary object. Often a spatial or temporal longitudinal centerline flume profile of a sand bed has been used for the analysis (Andreotti et al. 2006; Callander 1978; Coleman & Eling 2000).

The normalized spatial 1-D autocorrelation function R at $\Delta x = k\delta x$ between two values of sand-bed elevation z at distances x_i and x_{i+k} along the flume ($i = 1$ to $N-k$, with N equal to the number of points in the data vector z along x) is defined as:

$$R(\Delta x,0,0) = \frac{\sum_{i=1}^{N-k}(z(x_i)-\bar{z})(z(x_{i+k})-\bar{z})}{\sigma^2} \quad (1)$$

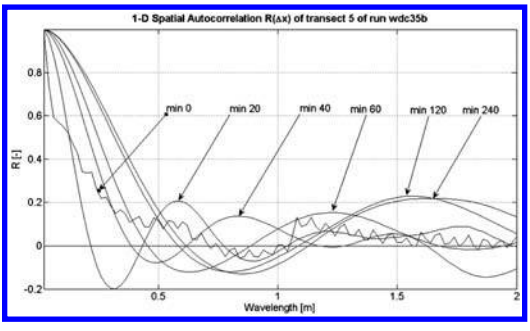

Figure 6. 1-D spatial autocorrelation function for selected times of run wdc35b centreline, developing from flattened sand bed.

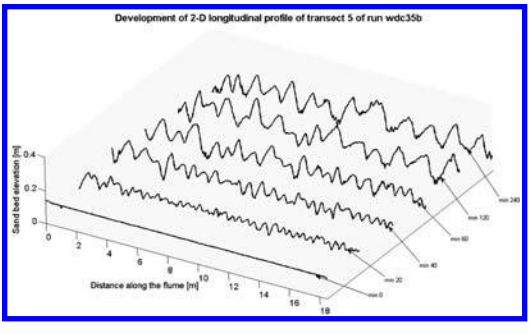

Figure 7. Corresponding centerline longitudinal sand bed profiles for the autocorrelation function of Figure 6.

With $\bar{z}$ being the mean value of the data vector z along the flume, and σ being the standard deviation. The wavelength can be generally obtained by the position of the first peak of the autocorrelation function. 1-D spatial autocorrelation functions (see Figure 6) and the corresponding bed profiles (see Figure 7) are shown below for selected times of run wdc35b.

Having recorded a random field along and across the flume, one can apply the 2-D spatial autocorrelation function defined as:

$$R(\Delta x,\Delta y,0) = \frac{\sum_{i=1}^{N-k}\sum_{j=1}^{M-l}(z(x_i,y_j)-\bar{z})(z(x_{i+k},y_{j+l})-\bar{z})}{\sigma^2} \quad (2)$$

with z being a 2-D data matrix along x and y, and the correlation being done at $\Delta x = k\delta x$ and $\Delta y = l\delta y$ between measurement points (i,j) and $(i+k, j+l)$. As a result, one obtains the 1st Quadrant ($(\Delta x >= 0, \Delta y >= 0)$ autocorrelation function of Figure 8.

Mirroring the information on the x and y axes results in the typical 2-D autocorrelation function, as is shown in Figure 9 for minute 240 of run wdc35b.

The locations of hills and troughs in all directions of the 2-D autocorrelation plot shows the 3-D character of the recorded sand bed.

For the evaluation of 2-D autocorrelation functions, the restricted width of the flume prevents a sufficient number of data points across the flume to see a fully developed autocorrelation function with pronounced fluctuating characteristic in all directions. For the start of sand wave development, starting from a flat sand bed, which is exposed to a uni-directional water flow, the sediment transport's main direction is downstream and therefore the crests of the developing sand waves keep roughly perpendicular to the flume wall (Fig. 10). Once a certain development is reached, either the flume walls or the flow depth act as a restricting factor in further growth of sand waves.

As one expects, a random sand-bed field that has crest lines parallel to the flow (see Fig. 10), as happens at the beginning of sand wave development or in flumes with a small width, will reveal a 2-D autocorrelation function as seen in Figure 11.

The 2-D autocorrelation function in itself shows a very 2-dimensional character, as the correlation across the flume is very similar at every transect across the flume. Only minor changes between the transects are displayed in an uneven outline across the autocorrelation function.

As soon as the crest lines start to bend and lose their parallel character, with individual transects across the flume showing more differences compared to each other, the typical peak and trough characteristics of the 2-D autocorrelation function (e.g. Fig. 9), revealing 3-D characteristics of the random field.

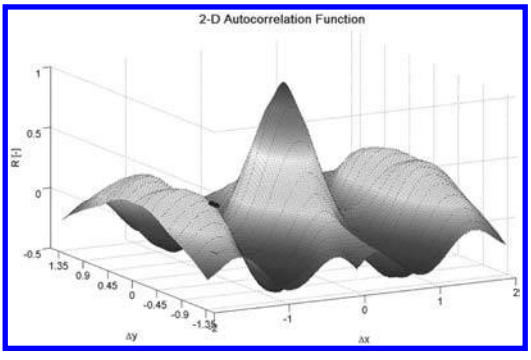

Figure 9. Typical 2-D spatial autocorrelation function displayed for all four quadrants. Minute 240 of run wdc35b is shown. Axes dimensions in m.

Figure 10. Recorded 6.25-m long and 0.175-m wide dune bed. Red indicates crests, and yellow troughs. The crest lines are parallel to each other and perpendicular to the flume wall. These measurements in a small 440-mm wide flume were discussed in Friedrich et al. (2005).

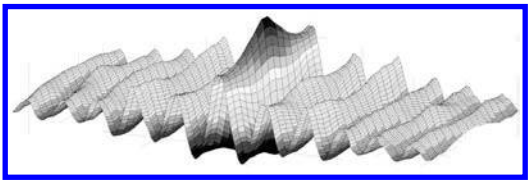

Figure 11. Schematic display of 2-D spatial autocorrelation function for a 2-D dune bed as shown in Figure 10. The autocorrelation function has a very pronounced 2-D character.

In an ideal case, the first peak of the contours along and across the flume could be used to determine the 3-D characteristics of a bed-form field, including the dominant wavelength along the flume and separation between individual bed forms across the flume. As the development of the bed forms across the flume is restricted by the flume walls, the bed forms are not free to spread out in that direction. Therefore one can not use the first peak in all directions to determine 3-D characteristics of bed forms. Nevertheless, by looking at the surface of the 2-D autocorrelation function (see Fig. 9) one can see, that the centre cone shows distinctive features, which relate to 3-D characteristics and changes in the texture of the observed sand bed field.

Based on the assumption that the slopes of the centre cone are constant between the correlation value of 1 and the first negative peak (see Fig. 6), a horizontal cut at any correlation level between roughly 0.7 and 0.2 results in obtaining an ellipse shape along the horizontal cut (see Fig. 12). The main objective for choosing the cut-off value is the closure of the ellipse, which is describing the centre cone. After the cut-off value is determined, ellipses describing bed-form parameters can be calculated, which provide information of the 3-dimensionality of the random field of sand bed elevations as well as information about the direction of the bed-from field.

Taking into account the uniformity of the slope of the cone, the ellipticity of the surface at the contour level will provide measured 3-dimensionality of the bed-form field.

3.3 *Determination of uniformity*

To determine the appropriate contour levels where the ellipse will be closed, contour plots such Figure 13 were visually evaluated.

From Figure 6 one can see that a correlation level of 0.4 ensures information on longitudinal levels even

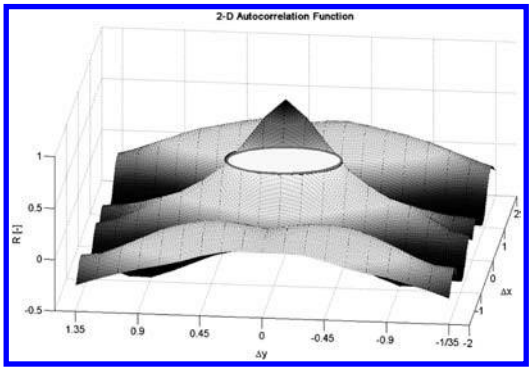

Figure 12. Ellipse shape of the horizontal cut of the centre cone of the 2-D autocorrelation functions (run wdc35b, min 240, correlation level 0.4).

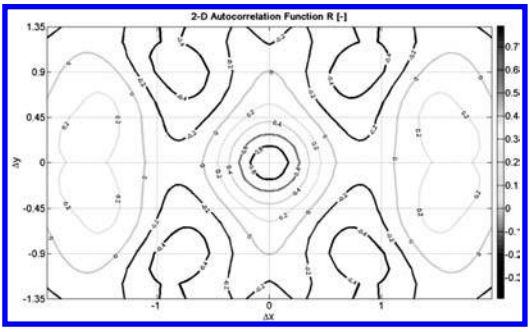

Figure 13. Typical contour plot at a certain time of a recorded sand-wave bed (min 240 of run wdc35b).

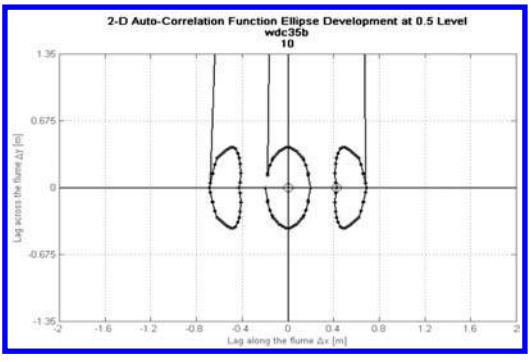

Figure 14. Determination of contours at a correlation level of 0.5. The fluctuating nature of the autocorrelation function causes several contours to display, where only the centre cone is important for the present calculations (run wdc35b, minute 10 of development).

for early times in the development of sand waves. Furthermore, this gains closed ellipses around the centre cone of 2-D autocorrelation functions in all directions. For the early minutes of development from a flat sand bed, there might however be no information about the shape of the centre cone, as the chosen level does not close completely around the centre cone for the 2-D dunes at that time.

Figure 14 shows that contours at the threshold level also exist outside the main centre cone, these contours being caused by the fluctuating nature of the 2-D autocorrelation function. In order to access the ellipticity of the centre cone, a routine was developed in Matlab to delete secondary cut-off contour-level information and yield only the shape of the central contour (see Fig. 15).

Determination of information about the ellipticity of the centre cone at a certain correlation level is done accordingly to Goring et al. (1999). Following their procedure for 2-D structure functions, we determined for the central ellipse (see Fig. 16):

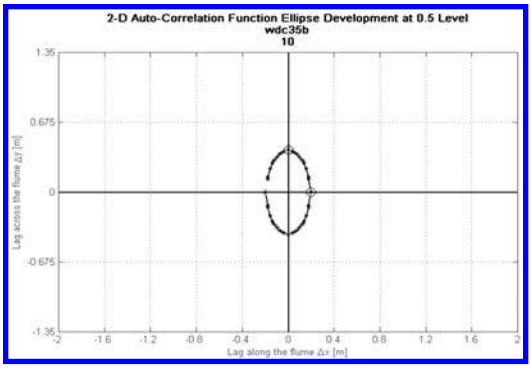

Figure 15. Filtering method applied for multiple correlation peaks as displayed in Figure 14. Afterwards only the outline of the centre cone is left (run wdc35b, minute 10 of development).

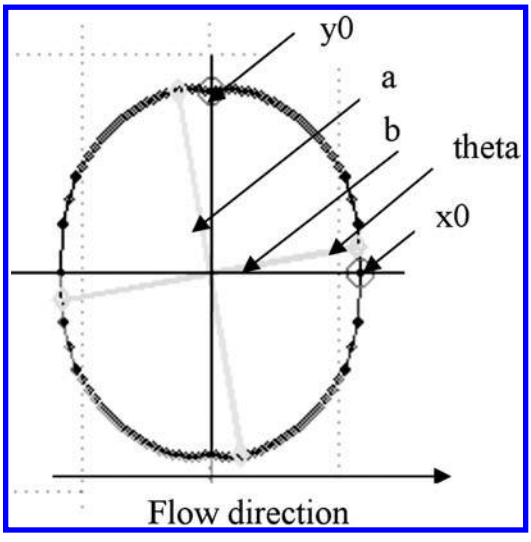

Figure 16. Schematic display of geometrical information describing the shape of the ellipse obtained when cutting through the centre cone of the 2-D autocorrelation function at a certain correlation level.

- *x0*, the longitudinal distance defined by the chosen correlation value.
- *y0*, the transverse distance defined by the chosen correlation value.
- *a*, the major axis of the ellipse at the chosen correlation value.
- *b*, the minor axis of the ellipse at the chosen correlation value.
- *theta*, the angle of rotation of the ellipse describing the cone shape.

3-D properties of the shape of the centre cone of the 2-D autocorrelation functions are principally described by the ratios $x0/y0$ and a/b, as well the

Copyright © 2006 Taylor & Francis Group plc, London, UK

angle of rotation of the ellipse, *theta*. Owing to the constant near-origin slopes of a correlation surface, the ratios and theta should not significantly depend on the threshold correlation levels selected. Indeed test have shown this to be the case.

4 RESULTS AND DISCUSSIONS

4.1 *General interpretation for all runs*

The experimental runs of Table 1, were analyzed using the 2-D autocorrelation function. Sand-bed elevation fields of a length of 18.48-m and a width of 1.35-m exist for every second minute over the run durations (from flat bed conditions) given in Table 1. For each 3-D bed surface recorded, the ellipticity of the centre cone of the 2-D autocorrelation surface was calculated.

Generally, three different cases of ellipticity can be distinguished according to their $x0/y0$ ratio (see Fig. 17):

(a) With a ratio of 1, the shape of the cone is circular and isotropy exists. This stage of isotropy is rarely achieved, as it indicates a uniform spread of the bed forms along as well as across the flume.

(b) A ratio of less than 1 typically occurs early on in development, when neither the flume width nor the water depth restrict sand wave development. This shape indicates the formation of 2-D dunes. They are characterized by crest lines perpendicular to the flow across the whole width of the flume. After a certain stage of development is reached, which is indicated by reaching a minima in the a/b ratio for the ellipse shape, the ellipse is growing again and 3-D dunes develop. With growing sand wave length, the flume walls act as a restricting factor and limit sand wave separation across the flume, keeping the ratio $x0/y0 < 1$. The flow field is constricted by the walls to emphasize uni-directional flow downstream.

(c) A ratio larger than 1 indicates that the flow depth, and not the flume walls, act as the restricting factor of the 3-D development of bed forms. Sand waves are broken up across the flume and a very pronounced 3-D sand bed field can develop.

One also needs to take into account the rotation of the ellipse (see) as well as the values of the size of the ellipse. The rotation *theta* indicates the main average direction of the crest lines, and the values of a and b indicate the relative major and minor magnitudes of the sand wave lengths.

Therefore, with the help of analyzing the elliptical shape of the centre cone of the 2-D autocorrelation function, results can be used to see the transition from 2-D to 3-D dunes. Furthermore, for bed-form development in the later stages, restrictions in the development of bed forms can be easily associated to either the flow depth or the flume walls. Both scenarios will be discussed in the following.

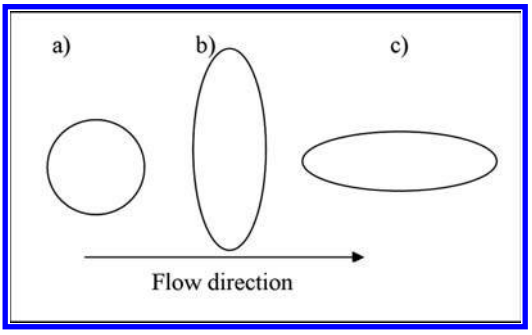

Figure 17. Different cases of ellipticity.

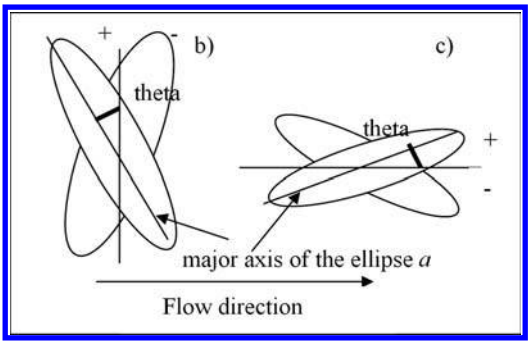

Figure 18. Rotation of the ellipse for cases (b) and (c) from Figure 17 indicates the main direction of the average crest line. Rotation *theta* is relative to the y axis for $x0/y0 < 1$ and the x axis for $x0/y0 > 1$.

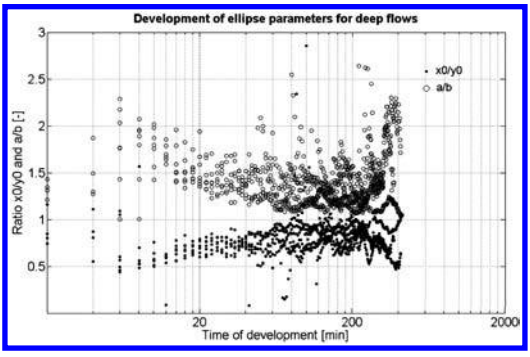

Figure 20. Ratios for the whole development all deep flows.

Figure 21. Typical developed bed forms for the deep flow. The main crest lines are still stretching over most of the flume width, with minor separation across the flume.

in a ratio of less than 1 for $x0/y0$ and a ratio of larger than 1 for a/b. Figure 19 and Figure 20 show the development of both ratios over time for selected runs. Figure 19 shows results for run wdc25b in detail. One can see, that at around minute 60, both ratios, $x0/y0$ and a/b, level off and a stage is reached where the bed forms have the most uniform character along and across the flume. It is proposed that at around that time, the transition from 2-D to 3-D dunes proceeds.

When one has a look at the complete development process for all runs (see Fig. 20), after the leveling-off stage, both ratios continue to fluctuate away from unity and even grow away again for some runs from a uniform distribution. This indicates the bed-surface development of a more 3-dimensional bed surface causing the crest lines to break up at the flume walls with occurrence of local scour. The growth of bed forms along the flume still continues. Figure 21 shows a typical sand bed after development for one of the deep flows.

Figure 22 shows contour plots of the sand-bed elevation of run wdc33a at different stages. At minute 12 of the bed-form development, one can see that the crest lines are still very perpendicular to the flume walls, and no major separation occurs across the flume.

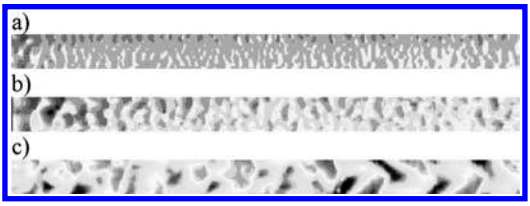

Figure 22. Snapshots (length = 18.48-m, width = 1.35-m) of sand bed elevations at (a) min 12, (b) min 30 and (c) min 230 for run wdc33a.

At minute 30, the crest lines are still mainly orthogonal to the flume walls, but minor separation across the flume starts. The transition from 2-D to 3-D sand waves proceeds. This is the stage where according to Figure 20 the most uniform stage of bed form development along and across the flume appears for the whole development. After this stage, the sand waves continue to grow along the flume, but are restricted in their growth across the flume by the flume walls, which is shown here in the snapshot of minute 230 of development.

4.2 *Differences in bed-form development associated with water depth*

As one can see from Table 1, the sand bed was exposed to two water depths, 0.15-m and 0.52-m. Results of the 2-D autocorrelation functions can be used to show the differences in development for these two different water depths.

For the shallow flow, the water depth acts as the restricting force in the development of the dunes, with the bed surface losing its one-directional character early on in the development stage. The shallow depth and the wide flume causes a more pronounced separation across the flume of bed forms early on.

This is reflected in ellipse shapes with ratios of $x0/y0$ larger than 1. Even for early stages, as soon as the flat sand bed is exposed to the water flow, bed forms separate across the flume, leading to 3-D dune development. For the deep flow, the flume walls act to restrict the development of the dunes, with no major separation of bed forms across the flume taking place and a transition from 2-D to 3-D dunes is the result.

Figure 23 shows ratios $x0/y0$ for all runs over time. As one can see, for the shallow flows the ratio $x0/y0$ essentially never goes to less than 1 over the whole time of development. Minor changes here are caused by having the sand bed exposed to different flow velocities. The rotation *theta* of the ellipse (see Fig. 23) shows either no rotation at all or a skewed fluctuation to a positive rotation. Both ellipse shape properties together indicate that the main average crest line keeps orthogonal to the flow with a slight skewness relative to the main flow direction.

Copyright © 2006 Taylor & Francis Group plc, London, UK

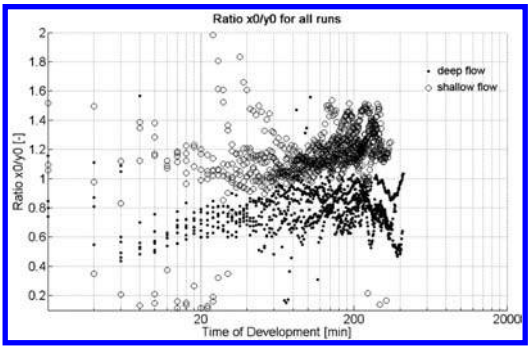

Figure 23. Ratio of *x0/y0* for all runs at correlation value 0.4.

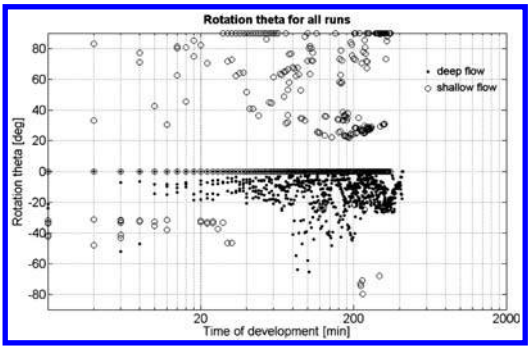

Figure 24. Angles of rotation of ellipse *theta* for all runs at correlation value 0.4.

On the contrary, for the deep flow, the ratio $x0/y0$ approaches unity very fast at the beginning of development, indicating a degree of 2-dimensionality for the early stage. Additionally the degree of rotation is close to 0 at the beginning of development, which indicates 2-D dunes, or 3-D dunes perpendicular to the flow. Theta increases slightly with increasing flow strength. The crest lines at the beginning of bed-form development remain predominantly perpendicular to the flume wall, whereas with the 2-D to 3-D transition, the crest lines begin to skew across the flume.

5 CONCLUSION

In this paper we have presented a new approach to gain 3-D sand-wave characteristics for sand beds developing from flat bed to equilibrium stage. The 2-D autocorrelation function has been applied on random fields of sand-bed elevations, each of a length of 18.48-m and a width of 1.35-m. The contours of the centre cone of the 2-D autocorrelation function become generally elliptical and the shape and degree of rotation varies as the bed develops.

For a shallow flow (ratio of flow depth to flume width less than 0.1), the major axis of the ellipse is oriented with the main direction of the flow field, which indicates 3-D development of the bed forms, from early on in the development stage. For a deeper flow (ratio of flow depth to flume width of 0.35), the major axis of the ellipse is orientated perpendicular to the main direction of the flow field, throughout the bed-form development. This indicates that the flume width is the restricting factor when it comes to the 3-D development of sand waves. As a deeper flow allows the sand waves to grow larger along the flume, this increase in growth potential is not supported across the flume with the flume walls acting to restrict development.

An automatic method to determine 2-D to 3-D dune transition is introduced. This paper's findings are preliminary. From the first tests, as introduced above, we suggest the following:

(a) $x0/y0 < 1$ indicates that the 3-D development of sand waves is wall-influenced; $x0/y0 > 1$ indicates that the 3-D development of the sand waves is flow-depth-influenced;
(b) *theta* tends generally to zero for 2-D wall influenced and 3-D sand waves. Some high *theta* values can be obtained for 3-D flow-depth-influenced runs, when ratio $x0/y0$ drops briefly below 1. For 3-D wall-influenced dunes, *theta* is skewed away from zero.
(c) for the deep flow, once the ratio $(x0/y0)/(a/b) > 0.9$, the 2-D to 3-D dune transition proceeds.

Generally it can be said, that the introduced technique requires more testing on a more varied data set, which is currently done at The University of Auckland, using additional data sets similar to Friedrich et al. (2005).

The application of 2-D autocorrelation functions of sand-bed surfaces requires further analysis, although the present results highlight that insights into 3-D characteristics of sand waves can be readily and objectively gained from this approach.

Spatial development of turbulent open channel flow over bottom with multiple dunes

N.Th. Fourniotis, A.A. Dimas & A.C. Demetracopoulos
Department of Civil Engineering, University of Patras

ABSTRACT: The spatial development of turbulent open channel flow over bottom with five consecutive, identical dunes is studied by numerical solution of the RANS equations utilizing either the $k-\varepsilon$ or the Spalart-Allmaras turbulence models and the VOF free-surface formulation. Results are presented for several dune sizes: (a) constant dune length to channel depth ratio $L/d = 5$ and dune heights $h/d = 0.15, 0.25, 0.35$, and (b) constant ratio $L/h = 20$ and dune heights as in (a). The mean free-surface level decreases, for all cases, in the flow direction over the dunes, while, locally over each dune, the free-surface amplitude increases with increasing dune height and increasing dune length. The spatial distribution of the wall shear stress presents a wave-like behavior and its amplitude increases with increasing dune height and decreasing dune length. Flow separation at each dune crest is followed by a recirculation region and reattachment at a distance $x_R/d \sim (h/d)^{3/2} \cdot (L/h)^{-4/3}$ from the dune crest.

1 INTRODUCTION

The interaction of river flow and sediment transport creates a variety of bed forms such as ripples, dunes, antidunes or other irregular shapes and obstacles. Their presence, in general, causes flow separation and recirculation, which can alter the overall flow resistance and, consequently, can affect sediment transport within the river and erosion of river banks. For dunes, in particular, the flow is characterized by an attached flow on their windward side, separation at their crest and formation of a recirculation eddy in their leeside. The eddy dimensions depend on the dune length L, the dune height h and other flow characteristics, i.e., water depth d, Froude number Fr and Reynolds number Re. The resulting shear stress and pressure distributions on the bed, as well as turbulence in the bulk of the fluid, determine the total flow resistance and the rates of sediment transport.

The turbulent open channel flow over bottom with sand dunes has been studied, under the assumption of a fixed bed without sediment movement, both experimentally and numerically. Experimental data are available by Raudkivi (1963, 1966) for dunes with $L/2 = 12.87$ and 17.23, Van Mierlo & De Ruiter (1988) for dunes with $L/h = 20$, Lyn (1993) for dunes with $L/h = 12.5$, Kadota & Nezu (1999) for dunes with $L/h = 20$, and others. In recent years, numerical studies seek to describe the developing turbulent flow by either a solution of the Reynolds-averaged Navier-Stokes (RANS) equations, along with a turbulence model, or a large-eddy simulation (LES), along with a subgrid scale model. In both cases, significant role plays the free-surface treatment.

Van der Knaap et al. (1990) studied the dune cases, considered experimentally by Van Mierlo & De Ruiter (1988), by solving the RANS equations and employing the $k-\varepsilon$ turbulence model with wall functions. The effect of sand-grain roughness was taken into account with the wall-function approach, while the free surface with the rigid lid approximation. They were able to obtain quite good predictions of the flow features, including mean velocity, separation and reattachment.

Mendoza & Shen (1990) studied the turbulent open channel flow over flat bottom with a single dune by solving the RANS equations and employing the $k-\varepsilon$ model but with an algebraic stress in place of the more common eddy-viscosity assumption. The bottom roughness was considered by the wall-function approach, while the free surface was approximated as a rigid lid. In the streamwise direction, either periodic or inflow/outflow conditions were applied. Their results compared well with the mean velocity, wall shear stress, wall pressure and turbulence data of Raudkivi (1963, 1966).

Yoon & Patel (1996) studied the turbulent open channel flow over a single dune by solving the RANS equations and employing the $k-\omega$ turbulence model without use of wall functions. Periodic conditions were applied in the streamwise direction, while the free surface was treated as a flat plane of symmetry (rigid lid). They considered dunes with $7.14 \leq L/h \leq 12.5$ and found that the total flow resistance increases with decreasing L/h. Their predictions were in general

Copyright © 2006 Taylor & Francis Group plc, London, UK

agreement with the experimental data of Van Mierlo & De Ruiter (1988).

Cheong & Xue (1997) studied the turbulent open channel flow over bottom with three dunes solving the RANS equations and employing a three-layer near-wall $k-\varepsilon$ model. They used a general curvilinear coordinate system, applied periodic conditions in the streamwise direction and treated the free surface as a frictionless, rigid lid, symmetry plane. Their mean velocity, wall shear stress and turbulence results compared well with the data reported by Raudkivi (1963, 1966) and Van Mierlo & De Ruiter (1988).

Yue et al. (2005) studied the turbulent open channel flow over a single dune by a large eddy simulation. Periodic conditions are applied in the streamwise direction, while the free surface motion was simulated using the level set method. They employed two subgrid scale models, namely, the dynamic Smagorinsky model and the dynamic two-parameter model, in order to assess model effects on the free surface flow. They examined the coherent structures induced by the dune and their interactions with the free surface. Their numerical predictions were in good agreement with experimental data.

In the present work, a numerical study of the two-dimensional, fully-turbulent, subcritical, free-surface flow over a bed with five consecutive, identical dunes is conducted. The dune shape defined by Kadota & Nezu (1999) is used, for cases with $14.29 \le L/h \le 33.33$ and $3 \le L/d \le 7$, which are typical values of those observed in river flows (Nezu & Nakagawa 1993). Our aim is to examine the effect of dune dimensions on the flow characteristics. The RANS equations are solved utilizing either the $k-\varepsilon$ or the Spalart-Allmaras (S-A) turbulence models. The free-surface shape is tracked by applying a modified volume of fluid (VOF) method (Hirt & Nichols 1981), while the numerical solution is based on a finite-volume discretization, using the commercial CFD code FLUENT (Fluent 2005). Inflow/outflow conditions are applied in the streamwise direction. The formulation is presented in the next section, the problem description and the computation setup are presented in section 3, while the results are presented in section 4 followed by the conclusions.

2 FORMULATION

For steady-state, incompressible, turbulent open channel flow, the governing equations are the RANS equations. In two-dimensional form, the continuity and momentum equations, respectively, are

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{1}$$

$$U_j \frac{\partial U_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial P}{\partial x_i} + \frac{1}{\rho}\frac{\partial \tau_{ij}}{\partial x_j} + g_i \tag{2}$$

where $i,j = 1,2$, x_1 is the streamwise coordinate, x_2 is the vertical coordinate, U_i is the time-averaged velocity component in x_i direction, ρ is the density, P is the dynamic pressure, g_i is the gravity force per unit volume and τ_{ij} is the Reynolds stress tensor, which represents the effects of the turbulent fluctuations in the fluid flow, defined as

$$\frac{\tau_{ij}}{\rho} = \nu\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) - \overline{u_i u_j} \tag{3}$$

where ν is the kinematic viscosity and u_i is the fluctuating part of the velocity.

The turbulent Reynolds stresses $-\overline{u_i u_j}$ are calculated using the Boussinesq relationship

$$-\overline{u_i u_j} = \nu_t\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) - \frac{2}{3}k\delta_{ij} \tag{4}$$

where k is the turbulent kinetic energy, δ_{ij} is the Kronecker delta function and ν_t is the eddy viscosity. For closure of the governing equations, a model of the turbulent Reynolds stresses has to be introduced. In the present study, the standard $k-\varepsilon$ two-equation model and the S-A one-equation model are used.

In the $k-\varepsilon$ model (Launder & Spalding 1974), the eddy viscosity of equation (4) is expressed in terms of the turbulent kinetic energy k and the turbulent dissipation rate ε via the Kolmogorov-Prandtl expression

$$\nu_t = C_\mu \frac{k^2}{\varepsilon} \tag{5}$$

where C_μ is a constant. The turbulent kinetic energy k and the turbulent dissipation rate ε are computed by the respective transport equations

$$U_i \frac{\partial k}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\frac{\nu_t}{\sigma_k}\frac{\partial k}{\partial x_i}\right) + P_k - \varepsilon \tag{6}$$

$$U_i \frac{\partial \varepsilon}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\frac{\nu_t}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial x_i}\right) + \frac{\varepsilon}{k}\left(C_1 P_k - C_2 \varepsilon\right) \tag{7}$$

where σ_k, σ_ε, C_1, C_2 are empirical constants and P_k is the production term, which is modeled in the standard fashion of the $k-\varepsilon$ model. The usual values of the constants are used: $C_\mu = 0.09$, $C_1 = 1.44$, $C_2 = 1.92$, $\sigma_k = 1.0$, and $\sigma_\varepsilon = 1.3$.

In the S-A model (Spalart & Allmaras 1992), the eddy viscosity is expressed in terms of a modified eddy viscosity $\tilde{\nu}$

$$\nu_t = \tilde{\nu} f_{v1} \tag{8}$$

Copyright © 2006 Taylor & Francis Group plc, London, UK

where $f_{u1} = r^3/(r^3 + C_{u1}^3)$ is a viscous damping function, $r = \tilde{\nu}/\nu$ and $C_{u1} = 7.1$. The modified eddy viscosity is computed by the transport equation

$$\rho\frac{D\tilde{\nu}}{Dt} = G_\nu - Y_\nu + \frac{1}{\sigma_{\tilde{\nu}}}\left[\frac{\partial}{\partial x_j}\left((\mu+\rho\tilde{\nu})\frac{\partial\tilde{\nu}}{\partial x_j}\right) + C_{b2}\rho\left(\frac{\partial\tilde{\nu}}{\partial x_j}\right)^2\right] \quad (9)$$

where $\sigma_{\tilde{\nu}} = 2/3$ and $C_{b2} = 0.622$ are empirical constants, while G_ν and Y_ν are the production and dissipation terms, respectively, which are modeled in the standard fashion of the S-A model.

A modified VOF method (Hirt & Nichols 1981) was employed for computing the free-surface elevation. The VOF formulation relies on the assumption that two or more fluids are immiscible. In open channel flow, a new field variable F is introduced, which is the water volume fraction. The governing equations for the water flow, under the free surface, and the air flow, above the free surface, are expressed in a single form as given by (1) and (2), but the physical properties that appear in (1) and (2) are defined by the volume-fraction-weighted average of the physical properties of air and water as follows

$$\rho = F\rho_{water} + (1-F)\rho_{air} \quad (10)$$

$$\mu = F\mu_{water} + (1-F)\mu_{air}. \quad (11)$$

According to the law of mass conservation of air and water, the volume fraction of the water satisfies the equation

$$\frac{\partial F}{\partial t} + U_i\frac{\partial F}{\partial x_i} = 0 \quad (12)$$

For the numerical implementation of VOF by a finite volume method, the water volume fraction F is defined in each computational cell as follows

$$F = \frac{\delta V_{water}}{\delta V_{cell}} \quad (13)$$

where δV_{cell} is the volume of the computational cell and δV_{water} is the fraction of the volume of the cell filled with water. Therefore, we have $F = 1$, $F = 0$ or $0 < F < 1$ when the cell is full of water, is full of air or contains a free surface, respectively.

3 PROBLEM DEFINITION AND COMPUTATION SETUP

In the present study, we consider the turbulent open channel flow over a train of five consecutive, identical dunes. Far from the dunes, where the channel bottom is flat, we have normal depth $d = 1$ m,

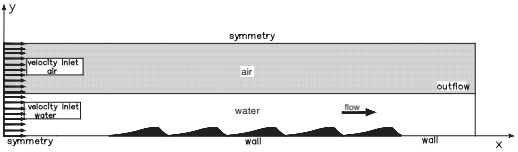

Figure 1. Computational domain of open channel flow with a train of five consecutive, identical dunes on the bottom.

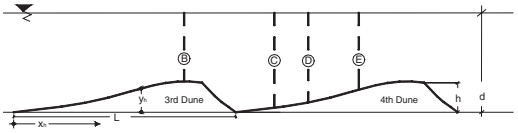

Figure 2. Dune shape parameter definitions and profile cross-sectional locations in the region of the 3rd and 4th dunes.

subcritical Froude number $Fr = 0.3$ and Manning coefficient $n = 0.02$. We consider water temperature 20°C where density is $\rho = 998.2\,\mathrm{Kg/m^3}$ and kinematic viscosity is $\nu = 1.005 \times 10^{-6}\,\mathrm{m^2/s}$. One-dimensional analysis of the flow gives channel slope $S = 0.35316 \times 10^{-3}$, mean velocity $U = 0.94$ m/s, Reynolds number $Re = 4dU/\nu = 3.74 \times 10^6$, which corresponds to fully turbulent flow, bulk friction velocity $U_* = (gdS)^{1/2} = 0.059$ m/s and wall roughness height $K_S/d = 0.018$, which corresponds to fully rough flow since $K_S^+ = U_* K_S/\nu = 1054$.

The numerical solution of the equations described in the previous section is based on a finite-volume discretization, using the commercial CFD code FLUENT (version 6.2.16). A sketch of the computational domain for the open channel flow over a train of five consecutive, identical dunes is shown in Figure 1. The VOF implementation requires the use of a multiphase flow domain with water and air. Initially, the water layer has uniform depth d, which is equal to the normal depth of the corresponding open channel flow over flat bottom. The thickness of the air layer is set to $4d$ so that the upper boundary of the computational domain does not affect the development of the water-air interface. In the present study, all lengths are presented normalized by d.

The five dunes along the bottom are located far from the inflow and outflow boundaries, so that the flow becomes fully developed before the first dune and fully developed again before the outflow boundary. In the present study, the total length of the computational domain is $200d$ and the first dune starts at $x/d = 90$ where $x = 0$ corresponds to the inflow plane and $y = 0$ to the flat bottom. The notation $x = x_1, y = x_2$ and $U = U_1$ is adopted in the rest of this paper.

The dune shape adopted in the present study is shown in Figure 2, and corresponds to the function (Kadota & Nezu 1999)

Table 1. Dune sizes and corresponding number of cells.

Dune case	h/d	L/d	Number of cells
1	0.15	3	169,010
2	0.15	5	199,515
3	0.25	5	200,220
4	0.35	5	105,030
5	0.35	7	200,080

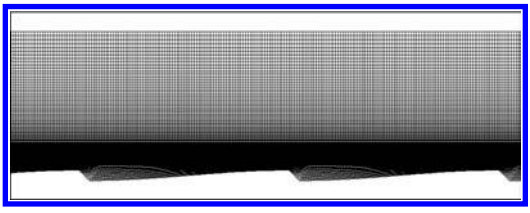

Figure 3. Mesh detail in the region between dunes for case 4.

$$\frac{y_h}{h}=\frac{1}{2}\left[1+\sin\left(\left(2X+\frac{1}{2}\right)\pi\right)\right] \tag{14}$$

where y_h is the dune profile height, h is the maximum dune height at the dune crest, $X=20x'/38$ for $-0.95<x'\le 0.0$, $X=10x'-9$ for $0\le x'\le 0.05$, $x'=x_h/L$ is the normalized local streamwise coordinate and L is the dune length. The five combinations considered, in the present study, are given in table 1.

The computational mesh is non-uniform along the two directions. Along the x direction, the grid size is $\Delta x/d=0.2$ for $0\le x/d\le 15$, it decreases linearly from $\Delta x/d=0.2$ to $\Delta x/d=0.1$ between $x/d=15$ and $x/d=90$, where the dunes start, and it increases linearly from $\Delta x/d=0.1$ to $\Delta x/d=0.2$ between the last dune and the outflow plane. Over the dunes, the grid size is $\Delta x/d=0.1$ upstream and $\Delta x/d=0.05$ downstream of the crest. In the y direction, the grid size on the wall is $\Delta y/d=0.04$, which is about twice the wall roughness height, and decreases gradually to $\Delta y/d=0.01$ at $y/d=1$. Then, the grid size increases gradually to $\Delta y/d=0.1$ at $y/d=5$ resulting in a coarser mesh in the air layer. The total number of cells for each case is given in table 1. The mesh for case 4 is shown in Figure 3.

FLUENT solves the governing equations sequentially using the control volume method. The governing equations are integrated over each control volume to construct discretized algebraic equations for the dependent variables. These discretized equations are linearized using an implicit method. As the governing equations are nonlinear and coupled, iterations are needed to achieve a converged solution. A donor-acceptor scheme is used to prevent numerical diffusion of F, the water volume fraction, and, thus, preserve a sharp interface. Schemes of the higher available level of accuracy are employed for the other variables with certain under-relaxation factors for promoting convergence. The discretization schemes are: PRESTO for pressure, QUICK for momentum, turbulent kinetic energy k and turbulent dissipation rate ε, and modified HRIC for the VOF implementation. The PISO scheme is utilized for the velocity-pressure coupling. For stable convergence, we use low under relaxation factors: 0.1 for pressure, momentum, turbulent kinetic energy, turbulent dissipation rate and volume fraction and 1.0 for density, body forces and turbulent viscosity. The continuity equation and transport equations of velocities, turbulence quantities and water volume fraction are solved in the steady-state mode until equilibrium conditions are achieved. A value of 10^{-7} is employed as convergence criterion for the sum of each normalized residual over the whole fluid domain for all the governing fluid flow equations, including the mass residuals.

There are four types of boundary conditions that are applied in this open channel flow problem; one for each of the four boundaries of the computational domain, namely, inflow plane, outflow plane, wall and air-layer boundary.

At the inflow plane, a uniform streamwise velocity distribution is prescribed for the water layer equal in magnitude to the mean velocity $U=0.94$ m/s obtained from the one-dimensional analysis. Uniform velocity distribution with the same magnitude is prescribed for the air layer as well. It has been observed that if no air is allowed to enter through the upstream boundary, or if the airflow rate is too small, then large recirculation regions of air may occur above the water. This reversal of air flow in the upstream direction of the channel causes computational instabilities (Ma et al. 2002).

The turbulent kinetic energy k and the turbulent dissipation rate ε at the inflow plane are specified, respectively, by the equations (e.g. Versteeg & Malalasekera 1995)

$$k=(IU)^2 \tag{15}$$

and

$$\varepsilon=C_\mu^{3/4}\frac{k^{3/2}}{0.1d} \tag{16}$$

where I is the turbulence intensity. In this paper, a value of three percent, $I=0.03$, is assumed for both the water and the air layer.

At the outflow plane, an overall mass balance correction and zero diffusion flux (zero normal gradients) for all flow variables are implemented. The water level at the outlet is not prescribed and is allowed

Copyright © 2006 Taylor & Francis Group plc, London, UK

to be predicted numerically according to the outflow boundary condition.

On the wall, the boundary condition is the no-slip condition, which is realized by a standard wall-function approach where the viscous sub-layer is not resolved. The wall-function, for the fully turbulent region outside the viscous sub-layer, is expressed as

$$\frac{U_P}{U_*} = \frac{1}{\kappa}\ln\left(Ey_P^+\right) - \Delta B \tag{17}$$

where U_P is the tangential velocity at the wall-adjacent cell, $U_* = (\tau_w/\rho)^{1/2}$ is the friction velocity, τ_w is the wall stress, $y_P^+ = U_* y_P/\nu$ is the node coordinate of the wall-adjacent cell in wall-coordinates, $\kappa = 0.41$ is the von Karman constant, $E = 9.793$ is an empirical constant and ΔB is a roughness parameter. In the fully rough regime ($K_S^+ > 90$), considered in the present study,

$$\Delta B = \frac{1}{\kappa}\ln\left(1 + C_S K_S^+\right) \tag{18}$$

where $C_S = 0.5$ is an empirical roughness constant (Fluent 2005).

For the wall treatment of turbulence quantities (Fluent 2005), the k transport equation (6) is solved at the wall-adjacent cells subject to the boundary condition

$$\frac{\partial k}{\partial n} = 0 \tag{19}$$

on the wall where n is the wall-normal direction, while ε is not computed by the solution of the transport equation (7) at the wall- adjacent cells but directly from

$$\varepsilon_P = \frac{C_\mu^{3/4} k_P^{3/2}}{\kappa y_P}. \tag{20}$$

At the upper boundary of the computational domain, above the air layer, symmetry boundary condition is applied. Symmetry condition is also prescribed at the channel bottom for $0 \le x/d \le 15$ to avoid a sudden transition from the uniform velocity profile at the inflow plane to the boundary layer development.

Initially, the computation assigns on all cells, both in the water and the air layers, velocity, turbulent kinetic energy and dissipation rate values equal to their counterparts at the inflow plane.

4 RESULTS AND DISCUSSION

First, the corresponding turbulent open channel flow with a flat bottom is considered for code validation, and to serve as a basis of comparison for the cases with dunes on the bottom. The wall stress distribution, for both turbulence models, is shown in Figure 4. The wall stress magnitude agrees with the one-dimensional prediction $\tau_w = \rho g d S = 3.46$ Pa after $x/d \approx 40$ where transition ends. The velocity profile at $x/d = 50$ and $x/d = 100$ is shown in Figure 5. In both locations, the results agree with the logarithmic law of a fully-developed, turbulent open channel flow. The turbulent viscosity ($\mu_t = \rho \nu_t$) profile is shown in Figure 6. The results follow the parabolic profile (Nezu & Nakagawa 1993) close to the bottom but deviate substantially from it close to the free surface due to the use of isotropic turbulence models ($k - \varepsilon$ and S-A) that over-predict the magnitude of vertical velocity fluctuations and, hence, the turbulent viscosity.

The turbulent open channel flow over the train of dunes is characterized by the modification of the free-surface level, the separation of the flow at the dune crest and the reattachment at the windward side of the next dune. Typical streamlines, for case 4, are shown in Figure 7.

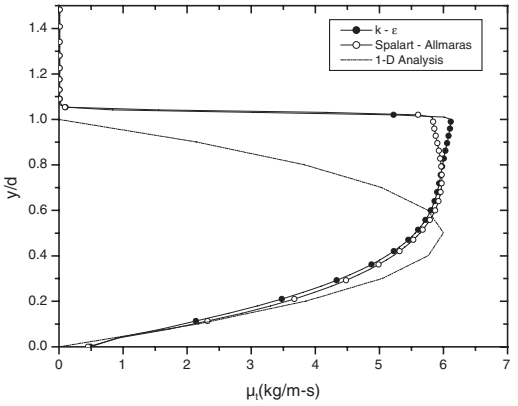

Figure 6. Turbulent viscosity profile at $x/d = 100$ in open channel with flat bottom.

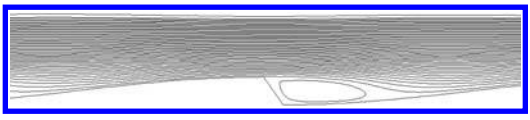

Figure 7. Streamlines in the region downstream of the 3rd dune for case 4.

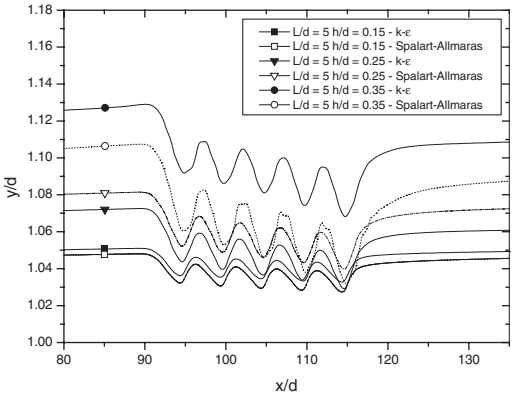

Figure 8. Free-surface elevation in the region over the dunes for cases 2, 3 and 4. The dune train is at $90 \leq x/d \leq 115$.

The free-surface profile, for each of the five dune configurations, is shown in Figures 8–9. In Figure 8, the free-surface profiles, for $L/d = 5$, are shown for all three h/d values. The mean free-surface level decreases, for all cases, in the flow direction over the dunes, while, locally over each dune, the amplitude of the free-surface elevation increases with increasing dune height. In Figure 9, the free-surface profiles, for $L/h = 20$, are shown for all three h/d values. Again, the mean free-surface level decreases, for all cases, in the flow direction over the dunes, while, locally over each dune, the amplitude of the free-surface elevation

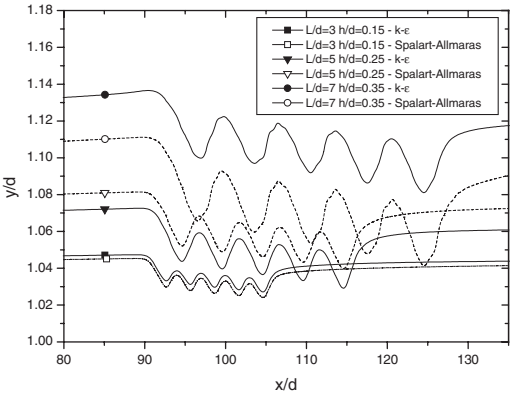

Figure 9. Free-surface elevation in the region over the dunes for cases 1, 3 and 5. The dune train starts at $x/d = 90$.

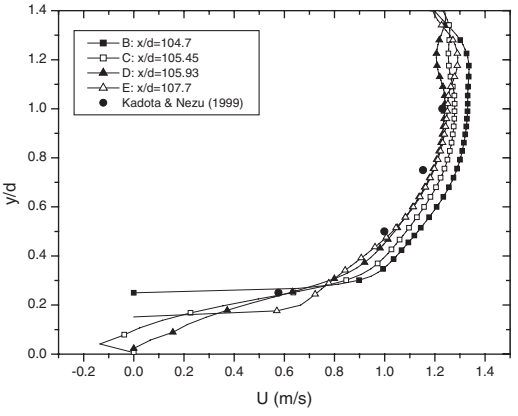

Figure 10. Streamwise velocity profile at cross-sections B, C, D and E for case 3 using the $k - \varepsilon$ model.

increases with increasing dune length. There is a small difference (less than 2%) in the mean free-surface level between the predictions of the two turbulence models.

The velocity profiles are presented at cross sections between the third and the fourth dune according to the sketch of Figure 2. Typical velocity distributions, for case 3, are shown in Figures 10–11. The flow accelerates (cross section B) over the windward side of the dune, separates at the dune crest, forms a recirculation region (cross section C) in the leeside of the dune, reattaches (cross section D) at a distance x_R from the dune crest and accelerates (cross section E) again. Kadota & Nezu (1999) considered experimentally the same dune with our case 3 but for $Fr = 0.29$ and $Re = 1.75 \times 10^4$. Their experimental data, for the velocity profile at reattachment (cross section D) where $U(y/d = 1) = 1.23$ m/s, are also shown in Figures 10–11. The agreement with the predictions of both turbulence models is very good. The velocity

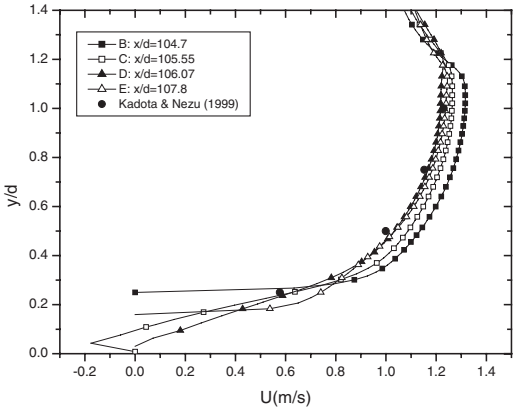

Figure 11. Streamwise velocity profile at cross-sections B, C, D and E for case 3 using the S-A model.

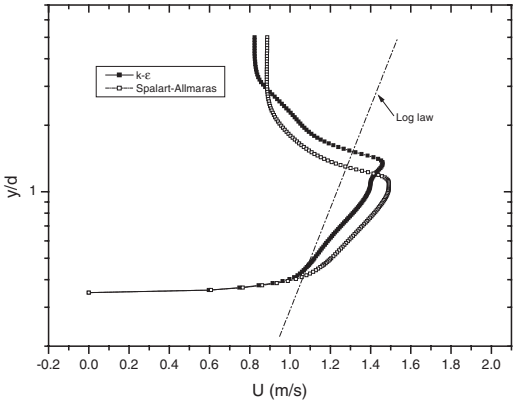

Figure 12. Streamwise velocity profile at the crest of the 3rd dune for case 5.

at the crest of the third dune, for case 5, is shown in Figure 12 and compared to the logarithmic law. The resulting velocity presents a steeper profile than the logarithmic law and is similar to the velocity profile observed in flat bottom boundary layer under favorable pressure gradient. The S-A model predicts a steeper profile than the $k-\varepsilon$ model.

The wall shear stress distribution, for each of the fine dune configurations, is shown in Figures 13–15. In Figure 13, the wall stress profiles, for $L/d=5$, are shown for all three h/d values. The profiles present a wave-like behavior that deviates substantially from the corresponding flat bottom case, while the amplitude increases with increasing dune height. In Figures 14–15, the wall stress profiles, for $L/h=20$, are shown for the lower and the higher h/d values. Again, the profiles present a wave-like behavior that deviates substantially from the corresponding flat bottom case, while the amplitude increases with decreasing dune length. The

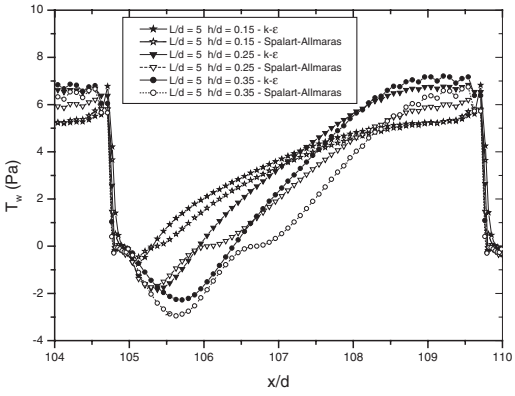

Figure 13. Wall stress distribution in the region downstream of the 3rd dune for cases 2, 3 and 4.

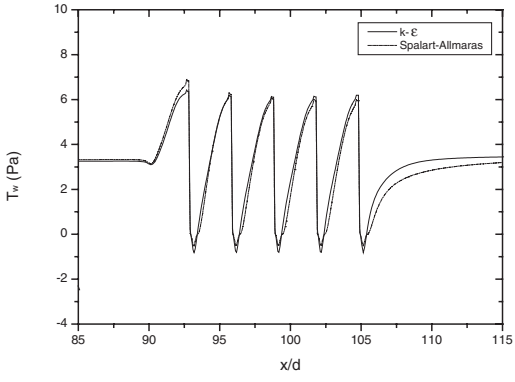

Figure 14. Wall stress distribution in the region over the dunes for case 1.

reattachment point is defined as the location on the windward side of the dune where the wall shear stress is zero.

The horizontal distance of the reattachment point from the dune crest is called reattachment length x_R. The S-A model predicts a longer reattachment length and lower wall shear stress on the windward side of the dunes than the $k-\varepsilon$ model. It should be noted here that the same grid was used for both models without tailor-refinement to any of the two models. The value of x_R obtained by the S-A model is always larger than the $k-\varepsilon$ one by as much as 25%. The predictions $x_R/h=4.72$ of the $k-\varepsilon$ model and $x_R/h=5.28$ of the S-A model, for case 3, compare with the value $x_R/h=5$ measured by Van Mierlo & De Ruiter (1988) for $Fr=0.23$ and $Re=4\times10^5$ and the value $x_R/h=4.05$ measured by Kadota & Nezu (1999) for $Fr=0.29$ and $Re=1.75\times10^4$. Based on the five configurations considered in the present study, the reattachment length x_R is found to correlate with

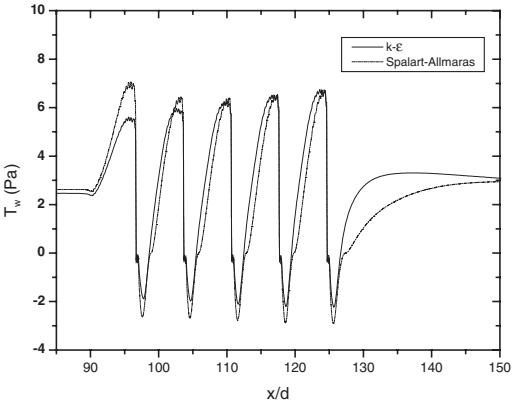

Figure 15. Wall stress distribution in the region over the dunes for case 5.

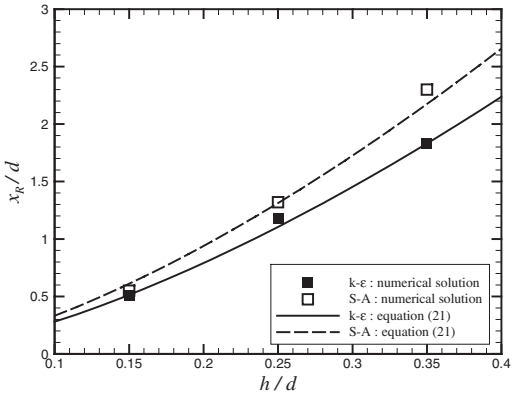

Figure 16. The correlation of the reattachment length to dune height and water depth for $L/h = 20$.

the channel depth d, the dune height h and the dune length L according to the following expression

$$\frac{x_R}{d} = a\left(\frac{h}{d}\right)^{\frac{3}{2}} \cdot \left(\frac{L}{h}\right)^{-\frac{4}{3}} \qquad (21)$$

where $a = 480$ for the $k - \varepsilon$ model and $a = 570$ for the S-A model. A comparison of the numerical results with (21) is shown in Figures 16–17.

5 CONCLUSIONS

The turbulent open channel flow over bottom with a train of five consecutive, identical dunes was studied by the numerical solution of the RANS equations using the $k - \varepsilon$ and Spalart-Allmaras turbulence models and the VOF free-surface treatment.

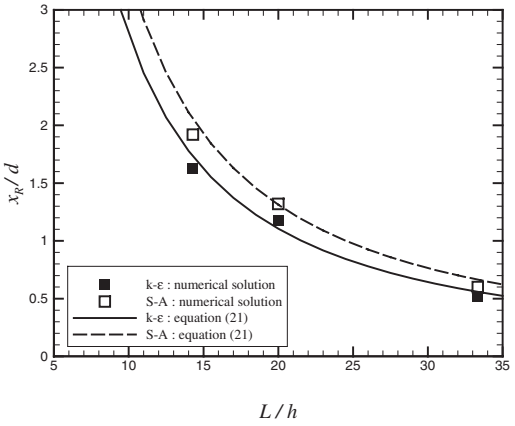

Figure 17. The correlation of the reattachment length to dune length and dune height for $L/d = 5$.

Our aim was to identify the effect of the dune dimensions on the flow characteristics. It was found that over the dunes, the mean free-surface level decreases, for all cases, in the flow direction, while, locally over each dune, the amplitude of the free-surface elevation increases with increasing dune height and increasing dune length. The spatial distribution of the wall shear stress presents a wave-like behavior and its amplitude increases with increasing dune height and decreasing dune length. The flow separation at each dune crest is followed by a recirculation region and reattachment at a distance $x_R/d \sim (h/d)^{3/2} \cdot (L/h)^{-4/3}$ from the dune crest.

The turbulence results are reasonable from about the half-depth point to the bottom and inaccurate from the half-depth point to the free surface. A modification to the synergy between the turbulence models and VOF is required to represent the reduced vertical velocity fluctuations that exist in turbulent flow close to a free-surface.

Bed forms and transport characteristics of a partly cohesive sediment

R. Banasiak & R. Verhoeven
Hydraulics Laboratory, Department of Civil Engineering, Ghent University, Belgium

ABSTRACT: In a laboratory study an artificial partly cohesive sediment made from mineral components was tested along with a noncohesive reference sediment. The experimental approach included the registration and analysis of bed form development, flow resistance, shear stress, total load transport (bed and suspended load) in a range of the Froude number up to 0.8. The paper highlights the essential differences between the mobility of noncohesive and partly cohesive sediment beds. In contrast to sand with typical bed configurations (ripples, dunes and washed-out dunes), the cohesive-like bed under erosion became covered with isolated ripples or with a rippled granular moving layer covering an intact substrate. The dimensions of bed forms for cohesive material were up to ten times smaller than in the case of sand. Consequently, significantly lower flow resistance was recorded for partly cohesive sediment. Although for both types of sediment the active sediment layer is composed of granular material only, the bed load transport rates as a function of effective shear stress were significantly smaller for the partly cohesive bed. On the other hand, no significant differences between studied sediments were found for the suspended load function.

1 INTRODUCTION

The dynamic response of a sediment bed to flow action depends not only upon the dominant grain size of the deposit but also on other fractions appearing even in small quantities. In particular, fine, cohesive particles of clay and silt have the potential to affect significantly the mobility of a sediment mixture. Sediments containing predominantly granular material and a certain amount of cohesive (in)organic fraction are termed to as semi- or partly cohesive sediments, and have been pointed out only over a decade ago in respect of sediments occurring in sewer pipelines (Crabtree, 1989). The partly cohesive sediment was described as a sediment that has a greater resistance to erosion than it would be anticipated from a purely granular one of similar grain size. According to Mitchener & Torfs (1996) the addition of a cohesive fraction to a sand bed influences both the critical shear stress and the mode of erosion. They reported about a limit content for the cohesive fraction that changes the erosion resistance from that of pure sand and which is related to the type of cohesive binder and to the size of the granular fraction. For instance, for kaolinite added to sand ($d_{50} = 230\,\mu m$) this limit is about 3% of clay. For Laponite clay added to sand (Alvarez-Hermandez, 1990), the transition between cohesionless and cohesive erosion behaviour occurred at between 5% and 15% clay content. Alvarez-Hermandez (1990) has also reported that once partly cohesive sediment is mobilized to motion, it behaves as a noncohesive sediment with a bed covered with bed forms.

Bed forms occurring during the erosion of sand with an addition of a cohesive fraction were also observed by other investigators during low flow conditions with deposited sediment bed in conduits (Skipworth, 1996, Tait et al. 1998, De Sutter, 2000, Banasiak et al. 2005). However, no verifiable data on the bedforms have been provided and rather little is known about the bed form dimensions and bed resistance in case of cohesion affected sediments. Most of the researchers focused instead on establishing critical shear stresses as a function of grain size composition and physical properties and on producing sediment transport functions or erosion formulas depending, however not distinctly, on the mode of erosion.

This study aims therefore to bring more recognition about sediment transport in transition between cohesive and noncohesive sediments. It focuses on the assessment of the bed surface response, the evaluation of the bed friction and shearing characteristics as a base for formulation of sediment transport formulas.

2 EXPERIMENTAL METHOD

2.1 *Experimental flume*

Experiments were conducted in a tilting 11 m long recirculating flume with a semi-circular cross-section

Copyright © 2006 Taylor & Francis Group plc, London, UK

and diameter of 0.39 m. The flume has a discharge maximum capacity of 40 l/s, and flows with water depths up to 0.15 m and velocities up to approximately 1 m/s can be realised. The flume internal surface was covered with an abrasive paper to imitate the hydraulic roughness of concrete pipes. The roughness coefficient k_w of the flume wall was determined experimentally to be 0.3 mm. The bed slope of the tilting flume was fixed at 0.002.

The flume was divided into three reaches. The upstream reach provided a 3 m length of the channel for the flow, bed forms, surface waves and sediment transport to stabilize. The second reach, the tested sediment section, was 4.2 m long. The downstream reach served as an outrun section to minimize the effect of the backwater in the testing zone.

The discharge was controlled by the adjustment of a computer controlled butterfly valve and measured by an electromagnetic discharge meter. Two hydrostatic pressure transducers measured the upstream and downstream water level at both ends of the tested sediment bed section. A slot type bed load trap was located at the end of the sediment bed section. It had a load cell which records the accumulated weight of trapped sediment. Material that entered this trap is considered as the bed load whilst the sediment remaining in the flow is regarded as suspended load. The latter was measured using a set-up pumping samples from five points over the vertical. Suspended sand transport rates are estimated by integrating products of velocity and concentration values. The velocities were measured by a 3D acoustic Doppler velocitymeter (ADV).

2.2 *Test performance*

Tests were conducted using sand and a mixture of sand and an artificial inorganic cohesive binder. The sand had a mean grain size of 0.19 mm and a standard deviation $\sigma = 1.4$. The cohesive-like mixture was made of the same sand with addition of kaolinite clay ($d_{50} = 6\,\mu$m) in a proportion of 6% by weight (of the dry mixture).

The sand and the wet prepared sediment mixture were placed in the pipe invert and leveled to obtain a sediment bed with a thickness of approximately 4 cm alone the pipe centreline. During the erosion tests the discharge was gradually increased up to its maximum and maintained constant sufficiently long to obtain uniform flow and steady sediment transport, for which the sediment transport controlling parameters were determined. The restriction for the test duration was imposed by the scouring at the beginning of the erodible section (no sediment feeding was provided). After each run, the deposit surface was measured using a laser distometer, and the bed was again prepared for a next test.

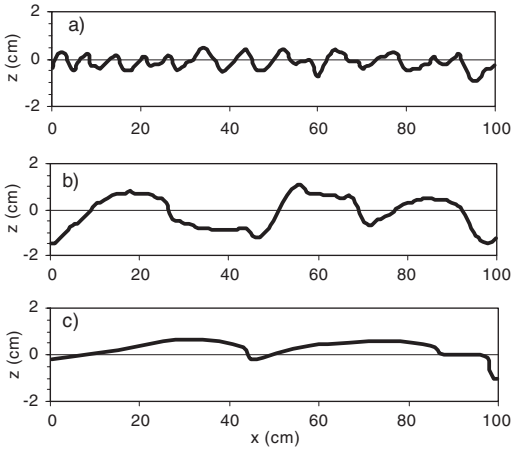

Figure 1. Bed forms for sand a) $U = 0.34$ m/s – ripples, b) $U = 0.61$ m/s – dunes and c) $U = 0.72$ m/s – washed-out dunes (U – mean cross-section flow velocity).

3 RESULTS

3.1 *Bed forms*

The bed forms development for sand are illustrated in Figure 1. As typical for noncohesive fine sand, at lower flow regime the bed formed into ripples with a gradual growth in size. After reaching a flow rate of $Q \approx 20$ l/s (Froude number Fr between 0.5 and 0.7) the bed formed into dunes, that can be seen in Figure 1b. Further increase of the flow strength and Froude number ($Fr > 0.7$) resulted in an increasing dune length together with a decrease of the form height, which means that the transition regime was reached; the bed flattened due to washing out (Fig. 1c).

Figure 2 presents the topography of the bed recorded after the tests with the partly cohesive sediment. It is visible that the bed formation consisted of low-relief features in the order of a few millimeters in height. These separated ripples on top of the substrate created a quite uniform pattern along the channel and moved individually downstream during the lower flow regime. For maximum flow rate the granular sediment layer covered the underlying substrate, and the ripple crests were flattened.

The average bed form sizes for both sediment types are depicted in Figures 3a,b. This comparison clearly indicates the effect of the cohesive strength on the bed formation; bed forms are nearly ten times smaller in the case of the mixture than those for pure sand. For a sand and clay mixture the ripple height varies little with flow rate. Also the bed form lengths are significantly reduced and no dunes are detected over the partly cohesive sediment bed; the ripples undergo directly the washing out at the transition regime and the bed smoothens.

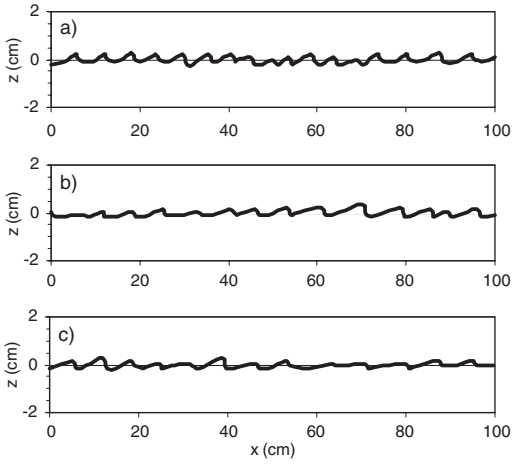

Figure 2. Bed forms for partly cohesive sediment bed: a) $U = 0.48$ m/s, b) $U = 0.63$ m/s, and c) $U = 0.73$ m/s.

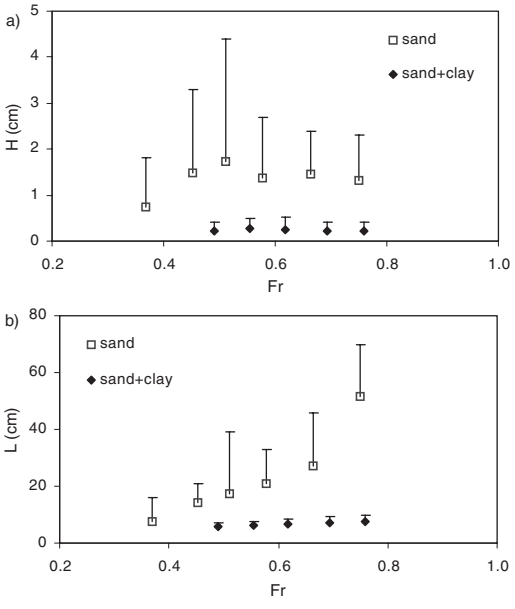

Figure 3. Bed form height a) and length b) (vertical bars indicate the maximum values).

3.2 *Bed roughness and shear stress*

Following the bed form size development, it can be expected that the bed form friction for cohesion affected sediment will change in respect of noncohesive sediment. In Figure 4 the equivalent sand roughness, k_s, normalized by the mean particle diameter of sand d_{50} is used and related to the Froude number Fr to show the variance of the bed resistance with flow

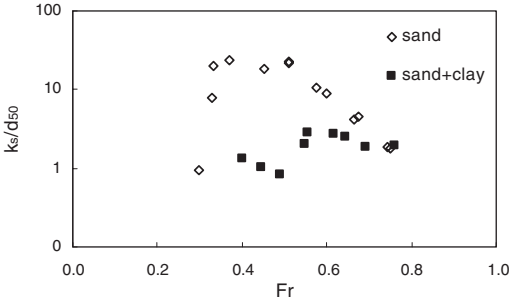

Figure 4. Bed friction against Froude number.

rate. The differences are again striking. The friction for sand bed increases up to a limit value $k_s/d_{50} = 23$ during appearance of dunes, and then diminishes as the dunes are washed out. For a cohesion affected bed the roughness height ratio is about 1 for a flat bed, which extends over a wider flow range due to increased critical shear stress (no motion), and increases to 2.9 as a maximum value once the bed forms develop under the shear stress exceeding the critical value.

When coping with a bed forms covered bed it is expedient to account for the part of the friction related to the presence of the bed forms. Here, the friction will be translated into the shearing on the bed. In a linear superposition of the resistance it is that the shear stress felt at the bed, called the skin friction shear stress, τ_b', is not equal to the spatially-averaged total bed shear stress, τ_b. The difference between the skin friction shear and the total shear is the form drag τ_b''

$$\tau_b = \tau_b' + \tau_b'' \tag{1}$$

This is the well know concept introduced by Einstein (1950). The reference plane-bed shear stress and bed form shear stress is calculated from

$$\frac{n'}{R_b^{1/6}}\sqrt{g} = \frac{\sqrt{\tau_b'/\rho}}{U} \tag{2}$$

$$\frac{n''}{R_b^{1/6}}\sqrt{g} = \frac{\sqrt{\tau_b''/\rho}}{U} \tag{3}$$

where g is the gravity constant, ρ – water specific density, U – the cross-section average flow velocity, and R_b – the hydraulic radius determined according to a side-wall elimination of Kleijwegt (1992).

The calculated total bed shear stress and the grain shear stress is shown in Figure 5. It is visible that whereas for sand the bed forms account for up to a half of the total shear stress, for partly cohesive sediment τ_b does not deviate so much from τ_b'; the form drag is then relatively small.

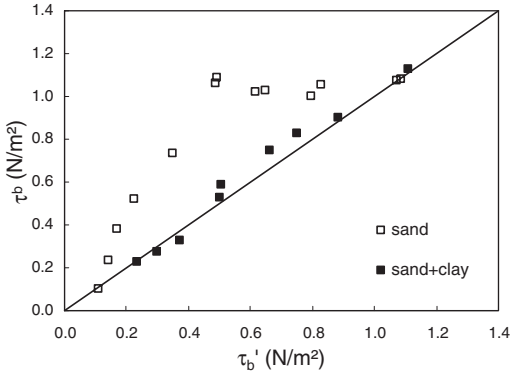

Figure 5. Bed and grain shear stress.

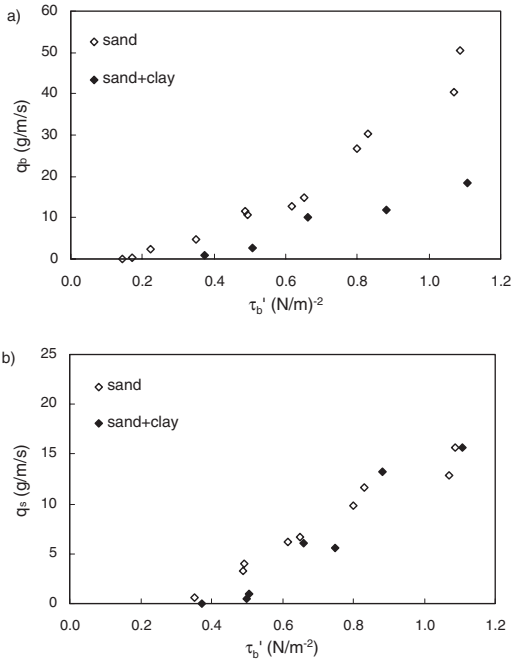

Figure 6. Bed a) and suspended b) load transport.

3.3 *Transport rates*

It is also interesting to have a look on the sediment transport intensities both for bed and suspended load. Figures 6a,b present sediment transport rates against the grain shear stress as this part of shear stress is deemed responsible for sediment transport. For the bed load data there is a clear influence of the cohesion on the sediment transport, both in respect to the beginning of motion and the transport intensity at a given shear rate.

For the suspended load (suspended sand) these differences are less pronounced. They appear mainly for lower flow rates; while the sand sheet layer develops over the cohesive substrate, the particles enter into suspension at nearly the same rate as in the case of a sand bed.

4 DISCUSSION

It is remarkable that the presence of a relatively small amount of cohesive binder has a big potential to modify the overall erosion behaviour of a sediment bed. In the current study, due to the addition of 6% of kaolinite clay the critical shear stress raised from $0.12\,N/m^2$ for pure sand to about $0.33\,N/m^2$. This resulted in a drastic change in the active layer thickness, bed topography along with friction factor and sediment transport rates. For a partly cohesive mixture the disturbance depth increased only slightly with flow intensity. This is important to recognize, since under the equilibrium sediment transport there is a little or no deepening erosion as it can be anticipated for cohesive sediment. In this sense the partly cohesive sediment behaves like a noncohesive one. The moving, continues or discountinues granular layer, depending on the flow regime, 'protects' the underlying cohesive layer against the erosion. The role of isolated small bed forms on the shearing over the bed is still to be clarified. The development of the active bed load layer and presence of bed forms over a cohesive bed type will certainly depend on the degree of cohesion. It will be conditioned by the rate of disintegration of grains from the bed and the transport capacity of the flow. Once the flow is able to carry the separated particles at a rate larger than the erosion rate, the moving granular layer will be vanishingly small and susceptible to suspension. On the other hand, once the cohesive strength is low, the fine particles will be easily washed out; the coarser particles will move as noncohesive sediment layer.

Because of the change in the mode of transport, it is reasonable that the bed load transport differs significantly between the two types of sediment, despite of the fact that the bed load consists of the same granular material. Apart of increased critical shear stress, the primary reducing factor for bed load transport is the reduction of active bed load layer thickness due to the cohesion in the substrate. Remarkably, no big difference is recorded regarding the suspended load except for the situation with ripples/early dunes for sand as for this flow conditions the cohesive bed was rather weakly developed.

An important issue in this study is the assessment of the friction factor during the sediment motion. Although the rise of this friction factor is not as big as for noncohesive sediment, it can be 3 times of that for a flat bed for the present bed. Consequently, there

Copyright © 2006 Taylor & Francis Group plc, London, UK

is need to account this rise due the presence of bed forms in the calculations of the effective shear stress relating the sediment transport. For certain flow conditions neglecting this can result in a 15% error in the shear stress, with as a consequence of about 50% error in the bed material transport prediction.

5 PARTLY COHESIVE SEDIMENT – THE DEFINITION

Based on the current observations and reported in literature, a definition for partly cohesive sediments is tempted. The characteristic feature for the sediment in transition between noncohesive and cohesive sediment is that it produces a granular top layer over an unremoulded substrate. On the one hand, this layer approaches in thickness and continuity the active bed load layer for noncohesive sediments, and on the other hand diminishes with increasing cohesion strength. If the cohesive fraction content of a mixture exceeds the upper transition value, the erosion rates can be modeled using the existing equations for cohesive sediments. For cohesive fraction content below the lower transition value, the mixture behaves as a noncohesive sediment and sand transport theories can be applied to predict the sediment transport rates. However, for transition sediments neither of these approaches seems to be correct. A modified non-cohesive prediction tool is needed and combined with an erosion describing formula. The knowledge of the shear stress distribution within this granular layer is desirable as well. On a longer time scale the erosion/transport mode will depend much on (non)equilibrium conditions for sediment transport.

6 CONCLUSIONS

The sediment mixture composition strongly influences the erosion behaviour of partly cohesive sediments. Addition of just a few percent of cohesive material can increase the critical shear stress of the sediment mixture and change its behaviour from noncohesive to cohesive-like. The conducted experiments demonstrated that sediments in general do not follow a strict distinction between noncohesive and cohesive types. There is a gradual change in the mode of sediment erosion/transport, bed forms development and friction characteristics. Obviously, more experiments are needed to relate the erosion behaviour to clay characteristics and to the characteristics of natural mixtures (muds).

Bed morphology and flow resistance in steep open channels with varying widths

R.B. Weichert[1], G.R. Bezzola[2] & H.E. Minor[1]
[1] *Laboratory of Hydraulics, Hydrology and Glaciology (VAW), Zürich, Switzerland*
[2] *Federal Office for the Environment FOEN, Switzerland*

ABSTRACT: Steep open channels are often characterised by bed forms in different scales. In the meso-scale, the typical bed features are usually described as successions of steps and pools. Depending on the channel width, the step-pool morphology can be superposed by macro-scale bed forms as e.g. bar structures. In steep headwater streams bed roughness is large relatively to flow depth. Consequently, flow field and flow resistance are significantly influenced by the bed morphology. In order to study the flow resistance in steep open channels, flume experiments were carried out at the Laboratory of Hydraulics, Hydrology and Glaciology (VAW) of the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland. The results show that for experiments where bar structures occurred, a significant influence of the macro-scale bed features on flow resistance could be ascertained. A new approach is proposed to compute flow resistance in steep-open channels with macro- and meso-scale bed features.

1 INTRODUCTION

The roughness scale, expressed by the ratio of flow depth to roughness height, h/d, controls the extent bed morphology affects flow field and energy dissipation. Usually, three different roughness scales are distinguished: small-scale, intermediate-scale and largescale. The flow in steep open channels is usually characterized by large-scale roughness, i.e. flow depths are in the same order of magnitude as the bed roughness heights. For these conditions, the local relation between the size of a bed element d and the flow depth h largely influences the turbulent flow field and therefore, the energy losses in the vicinity of the roughness elements. In addition, the roughness structure, such as the relative position of one boulder to another, leads to superpositioning of vortices resulting in a very complex and irregular flow field (Buffin-Belanger and Roy, 1998; Lawless and Robert, 2001) with spatially and temporally high variations in flow velocities, flow depths, air entrainment, water-surface slopes and energy gradients. Following this, the flow in steep boulder-bed channels resembles more a jet and wake type rather than a shear flow type (Bray, 1987).

2 BED MORPHOLOGY

Longitudinal stream profiles in mountainous regions usually do not exhibit a smoothly varying slope but reaches of alternately steeper and flatter slopes associated with shallower and deeper flow sections respectively (Leopold et al., 1964). Several authors recognised that these successions of steep- and gentle-gradient segments are found in a wide range of geomorphologic scales. Within the present paper, two different geomorphologic scales will be considered more in detail.

2.1 *Meso-scale: Steps and pools*

In the meso-scale, the accumulation of the largest bed elements results in organised bedforms, that are often situated approximately transverse to the direction of flow. Successive groups of boulders forming such transverse structures are separated by pools (see Figure 1), so these river segments are often called step-pool-systems (Zimmermann and Church, 2001; Mac-Farlane and Wohl, 2003).

In flows with small-scale roughness that are characterised by a flat and stable bed, the effective bed roughness is well described by a characteristic grain size of the bed material. In steep open channels with large-scale roughness, the roughness geometry determines the flow field, and vice versa. For these channels, the concept of a representative grain size fails, as a single linear dimension basing on a particle size is insufficient to describe the complex roughness geometry (Bathurst, 1978; Aberle, 2000). Alternatively, the standard deviation of the bed elevations, s, has been used as a parameter to describe the bed

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 1. Bedforms in steep open channels can be observed in different scales. Left: Steps and pools, right: Riffles and pools.

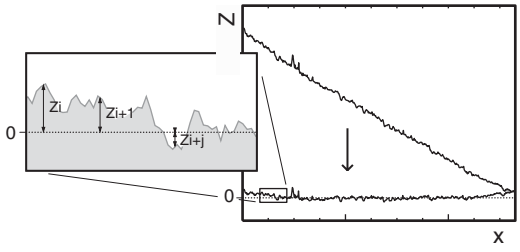

Figure 2. The standard deviation of the roughness heights is determined from a slope-detrended longitudinal profile.

roughness in rough channels (Furbish, 1987; Aberle, 2000; Aberle and Smart, 2003). From the residuals of slope-detrended longitudinal profiles (see Figure 2), the standard deviation of the bed elevations can be calculated as

$$s = \sqrt{\frac{1}{n_m - 1}\sum_{i=1}^{n_m}(z_i - z_m)^2}, \qquad (1)$$

where n_m denotes the number of measuring points, z_i is the elevation of point i, and z_m denotes the mean of the bed elevation level.

2.2 *Macro-scale: Riffles and pools*

In the macro-scale, successions of steeper and flatter sections are denoted as riffle-pool sequences and are often associated with bar features. In straight channels, these bar features are usually located alternately at the channel banks and have mainly been observed and described for gravel-bed streams (Leopold et al., 1964; Richards, 1976; Thompson, 2001). In general, the bed slopes of the riffle sections are steeper than the reach-averaged value and are charaterised by small flow depths and high flow velocities, whereas the pools are gently sloping sections with large flow depths and low flow velocities (see Figure 1).

As width is often constricted in steep open channels, riffles and pools in connection with alternate bars tend to be absent from or poorly developed in boulder-bed streams. Even for cases where sufficient width is available, a variable course often inhibits a rhythmic development of bar features. Nevertheless, bar features as well as meandering tendencies have also been described for boulder-bed channels (Leopold et al., 1964; Wohl et al., 1993).

3 FLOW RESISTANCE

For uniform flow conditions, the water-surface slope, friction slope, and energy gradient are parallel to the streambed and the cross-sectional area, hydraulic radius and flow depth remain relatively constant throughout the stream reach. In contrast to this, the flow in mountain torrents is highly nonuniform with zones of separation, acceleration and deceleration around the roughness elements. Following this, uniform flow conditions in steep open channels are not present at a local scale. However, considering a spatial average of the hydraulic parameters, the flow is usually assumed as quasi-uniform (Bathurst, 1978).

3.1 *Model of composite roughness*

For stable-bed channels, flow resistance can be considered to arise from skin friction and form resistance. Whereas skin friction can be described by the concept of bed shear stress, form resistance is better expressed by the sum of the hydrodynamic forces acting on the individual bed features. Nevertheless, form resistance is often expressed by a shear stress as well, so that the total bed shear stress, τ (or equivalently channel gradient, S) can be subdivided into a component assigned to skin friction, and a component that is attributed to the bed irregularities (Einstein and Barbarossa, 1952; Yalin, 1977).

Copyright © 2006 Taylor & Francis Group plc, London, UK

For losses due to isolated roughness elements, Einstein & Banks (1950) proved for a certain range of roughness concentrations that the total flow resistance could be expressed by the sum of resistances offered by the individual roughness elements, corresponding to the isolated roughness flow as defined by Morris (1959). However, in flows with large scale roughness, wake interferences are the standard case as bedforms exist in different orders of magnitude. These bedforms interfere with each other in such a complex way that the application of a linear superposition of roughness components does not reproduce the existent physical conditions. However, due to the lack of alternatives, this concept is also applied to steep open channels (Egashira and Ashida, 1991; Curran and Wohl, 2003).

3.2 *Meso-scale: Steps and pools*

The energy dissipating mechanisms in step-pool streams predominantly correspond to form resistance which includes form drag, wake interference, and free surface distortion. A fundamental understanding of flow resistance in step-pool channels requires the knowledge of the temporal and spatial variations of the energy dissipating mechanisms. Following this, the model of composite roughness basing on linear superposition of resistance components should not be considered to have a fundamental physical background, as it does not represent the variable conditions found in steep open channels.

A variety of flow resistance equations have been proposed that consider conditions typical for steep open channels. Most of these approaches in steep rough channels contain a characteristic grain size (Rickenmann, 1990; Vogel, 2003) to describe the bed roughness geometry which has been found to be unsuitable for the complex geometries of mountain torrents (Aberle and Smart, 2003; Weichert, 2006).

For step-pool channels, Aberle and Smart (2003) introduced the standard deviation of the roughness heights as characteristic roughness parameter (see Equation 1) and verified its validity by the analysis of experimental data. From this set of data the following flow resistance equation has been proposed, where U denotes the average velocity, U_* is the bed shear velocity, h expresses the average flow depth, and s the standard deviation of the roughness heights, as defined in Equation 1

$$\frac{U}{U_*} = 0.91\frac{h}{s}. \tag{2}$$

Aberle and Smart's considerations are based on experiments with small $W_f - d_{max}$-ratios (see Table 2), where W_f denotes the flume width and d_{max} is the maximum grain size. Hence, it can be assumed that macro-scale bed features were mainly absent.

3.3 *Macro-scale: Riffles and pools*

In case of gravel-bed rivers with macro-scale bed features, some attempts have been made to evaluate the flow resistance with the specific objective to identify the portion of total flow resistance that is directly attributed to the riffle-pool sequences (Parker and Peterson, 1980; Prestegaard, 1983; Hey, 1988). At low flow stages, bedforms in the macroscale become exposed and contribute substantially to the total flow resistance whereas at flood stages, they usually are submerged and contribute little to the total resistance. According to Parker and Peterson (1980), the mechanisms that contribute to the extra resistance include expansion losses in the lee of the bar fronts, antidune and standing wave formation when the flow is near critical or supercritical and dropstructure losses in the riffles when the flow is so shallow that they act as controls.

Both, Parker and Peterson (1980) and Prestegaard (1983) applied the concept of composite roughness where the energy slope is divided into a grain and a bar influenced component, S_{gr} and S_{fo}, respectively. Correspondingly, flow resistance is divided into its components as well, and the bar resistance component, expressed by a Chézy-coefficient c_{fo} is calculated by the difference between the total, measured flow resistance c and a grain resistance component c_{gr} calculated from the Keulegan-Equation

$$\frac{U}{U_*} = 2.5ln\frac{h}{k_s} + 6.0. \tag{3}$$

Parker and Peterson (1980) used field data to account for the influence of the bar features with

$$c_{fo} = 2.33 \cdot 10^{-6}\left(\frac{RS_{gr}}{s-1}\right)^{-1.744}. \tag{4}$$

Parker and Peterson (1980) proposed the hydraulic roughness parameter in Equation (3) to be $k_s = 2d_{90}$. This choice largely influences the derivation of Equation (4). Prestegaard (1983) used $k_s = d_{84}$. According to Hey (1988), this leads to a significant underestimation of the grain friction slope and an overestimation of the bar friction slope. Robert 1997 criticised that the approach of Parker and Peterson (1980) does not directly take into account the morphology of pools and riffles, as e.g. size and spacing of the bed features.

4 FLUME EXPERIMENTS

The purpose of the experiments described herein was to study the bed morphology, flow resistance and stability in steep open channels that exhibit steps and pools. The experiments were carried out in a rectangular flume of 13.40 m length and 0.60 m depth (see

Copyright © 2006 Taylor & Francis Group plc, London, UK

Figure 3). The width of the channel could be adjusted, so that different widths (0.15 m, 0.30 m, 0.60 m) were considered in the experiments. The sidewalls of the flume were made of glass and steel. The influence of the channel boundary was tested with a sidewall correction. However, due to the extreme bed roughness and relatively high ratios of channel width to flow depth the resistance was little affected by the sidewalls. As a consequence, for the evaluation of the present data set, no differentiation was made between the flow depth, h, and the hydraulic radius of the bed section, R.

A widely-graded sediment mixture was used that roughly corresponded to the Steinibach-torrent, Canton of Obwalden in the Swiss Alps with a scale of 1 : 20 (Table 1). This mixture in connection with the examined flume slopes of 5%, 9%, 13% guaranteed that a step-pool morphology developed.

The ratio of flume width to maximum grain size, W_f/d_{max}, is an important parameter with respect to the development of bed features in different scales. Within the present study, the W_f/d_{max}-ratio was varied between 3.3 and 13.2. A comparison with other step-pool flume studies (see Table 2) reveals that most of the previous investigations focussed on smaller W_f/d_{max}-ratios.

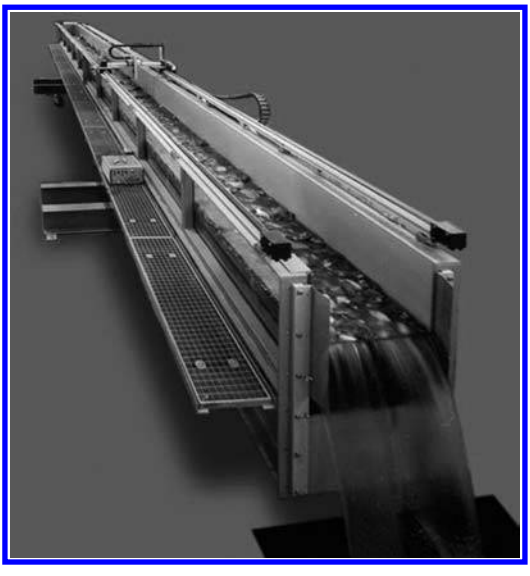

Figure 3. Flume used for the experiments.

Table 1. Grain size distribution applied in the flume experiments.

d_{16}	2 mm
d_{50}	6 mm
d_{65}	10 mm
d_{84}	19 mm
d_{90}	26 mm
d_{max}	45 mm
d_m	10 mm

After an experimental run, the channel bed was scanned by a laser displacement sensor in a predetermined regular, dense grid with sample intervals of $\Delta x = 0.02$ m in the main flow direction, and $\Delta y = 0.01$ m in the lateral direction. Compared to the maximum grain size, this is equivalent to $0.44\, d_{max}$ in the x-direction, and $0.22\, d_{max}$ in the y-direction. Depending on flume width, between 12 and 54 longitudinal profiles were recorded. The laser measurements were carried out at dry and wet bed conditions, respectively. At a dry bed, the laser data was used to obtain a detailed map of the bed topography. At a wet bed condition, the laser data was used to distinguish between wet and dry channel bed sections. Most of the experimental results were based on the analysis of longitudinal profiles obtained from the laser measurements. The discrimination between wet and dry sections allowed to adapt the analysis of the longitudinal profiles to the stream course. In this respect, an automated algorithm was developed and was applied to the digital elevation data. If no bar structures were present, the longitudinal profiles were taken in the lengthwise direction of the flume, parallel to the flume side walls. If bar features were present, the longitudinal profiles were defined by following the channel alignment (see Figure 4).

In addition to the laser sensor, an ultrasonic probe was installed at the positioning system in order to detect the free water surface. For a calm water surface, the probes gave a digital distance reading with a resolution of ± 0.5 mm. However, for the small relative submergences considered in the present study, a heavily disturbed, unsteady water surface existed. The measuring signal had a conical extension with an angle of propagation of 10 degree on each side of the 13 mm wide probe. The shortest distance within the considerable large detection area in a specific time interval was recorded. Following this, the ultrasonic devices were not considered to deliver highly accurate values of the local flow depth. However, preliminary tests revealed that averaging of the local values over a length of 8 cm $\equiv 1.8\, d_{max}$ was sufficient to remove the influence of the unsteady free surface.

5 ANALYSIS

5.1 *Bed morphology*

According to Leopold and Wolman (1957) river channels possess three characteristic fluvial morphologies: straight, meandering and braided. Bar structures alternately located on both banks may be a fundamental prerequisite for meandering or braiding, hence, they can be considered as a transition bed form from a straight channel to meandering or braiding. Several authors (Anderson et al., 1975; Jaeggi, 1983; da Silva, 1991) presented delimitation criteria for the different channel forms depending on the main parameters which are channel width, W, flow depth, h, channel gradient, S, and a characteristic grain size diameter, d. The delimitation diagrams proposed by several authors are mostly limited to observations of channel patterns at relatively small slopes compared to step-pool channels. As width, slope and discharge were varied within the flume experiments, the delineation criteria can be compared for steep open channels with slopes ranging up to 13%. Table 3 lists the observed morphologies for the different experimental runs. In Figure 5, the experimental data is compared with the delimitation criteria of da Silva (1991) and the modifications

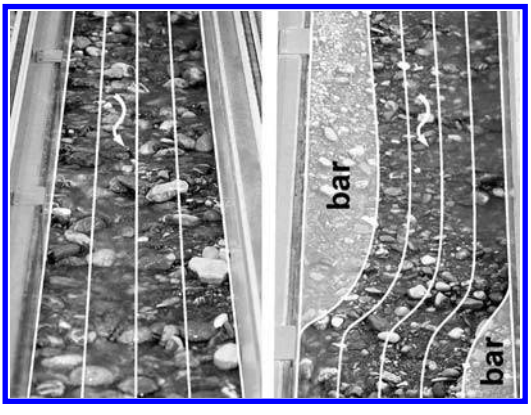

Figure 4. Evaluation of the longitudinal profiles depending whether bar features were present or not.

Table 3. Macro-scale structures observed in the flume experiments. Run denotations in brackets correspond to Figure 5. S denotes the flume slope, W_f the flume width, Q the discharge. The morphologies are abbreviated by *s*: straight, *db*: diagonal bars, and *b*: braided.

S [%]	W_f [cm]	**Q** [l/s]	**Morphology**

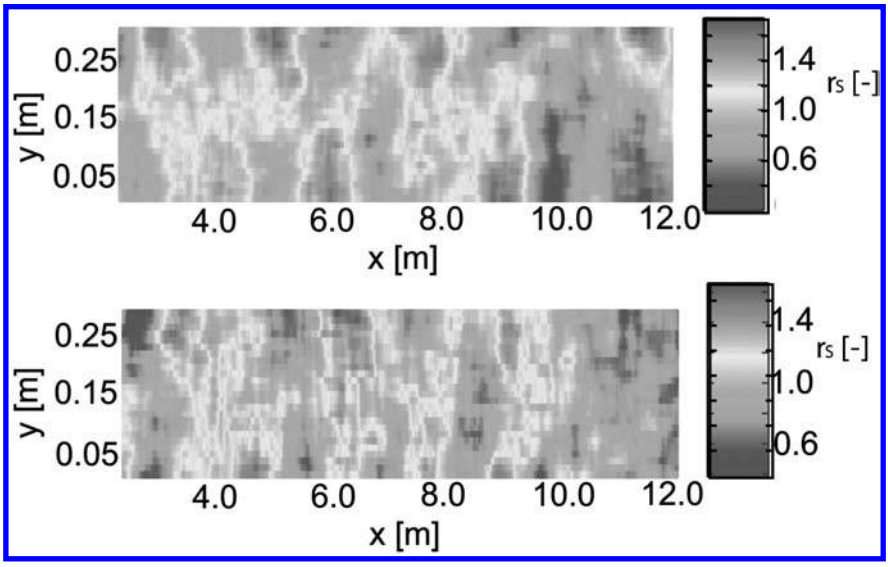

Figure 6. Ratio of the local slope to the average slope over the whole flume, $r_S = S/S_{reach}$ for the experiments with a flume slope of 9%, a flume width of 30 cm and a discharge of 5 l/s (above). The picture below represents a flume slope of 9%, a flume width of 30 cm and a discharge of 8 l/s.

proposed by Zarn (1997). It should be emphasised that in nature, the transitions from one bedform to another occur gradually rather than abruptly, as it is suggested from the diagram. Figure 5 in combination with Table 3 demonstrate that the predicted bedforms from the diagram are mostly consistent with the experimental data when the modifications by Zarn (1997) are taken into account. This result suggests an analogy for the formation processes of the macro-scale bed features in flat and steep channels.

In the present study, the classification of the morphologies is based on the visual impression of the planform morphology. In case of diagonal bars, this corresponds to a horizontal variation of the stream course. In addition to this horizontal oscillation, a vertical variation of the channel bed existed. In the following, the interconnection between the horizontal and the vertical variation of the bed is considered in more detail.

Figure 6 illustrates two contour plots, where the ratio, r_S, of the local slope to the reach-averaged slope (average over the whole flume length) is shown for every measuring point in the flume. The local slope was determined over a section length of 1 m. The upper part of the figure corresponds to the experiment with a flume slope of 9%, a flume width of 30 cm and a discharge of 5 l/s, whereas the figure below represents the experiment with a flume slope of 9%, a flume width of 30 cm and a discharge of 8 l/s. As listed in Table 3, bar structures were absent for both runs.

In contrast to the visual impression of the bed morphology, the slopes for the run with $Q = 5$ l/s clearly indicate alternately located bed features at the sidewalls. These features are associated with gradients steeper than the average ($r_S > 1$) and gradients smaller than the average slope in the reach-scale ($r_S < 1$). As a consequence, they are denoted as riffles and pools. The wavelengths, λ (defined in Figure 7) are approximately 3–5 flume widths, which are similar values as observed for gravel bed rivers. For the flume experiments in the present study, the discharge is increased in small increments starting from a plane bed. Hence, for small discharges, diagonal bar structures tend to form at every flume width investigated. As a consequence, the generation of the horizontal and the vertical structures are closely associated with each other. As already noted by Parker and Peterson (1980), riffles and pools are nothing more than juxtapoints of successive diagonal bar structures. With increasing discharge, the bar structures vanish, whereas the riffle-pool features prevail. However, at large discharges, these macro-scale bed features rearrange in the way, that the oppositely at the side walls located riffle-structures tend to join with each other. This results in transversely oriented macro-scale bed features (see Figure 6).

Although the described macro-scale bed features resemble riffle-pool sequences in gravel-bed rivers, they differ with respect to their appearance in the meso-scale. In gravel-bed rivers, the riffle sections usually exhibit meso-scale bedforms, whereas the pools are mainly free of bedforms. On the contrary, in boulder-bed streams meso-scale bedforms could be observed independently on the location (compare Figure 7).

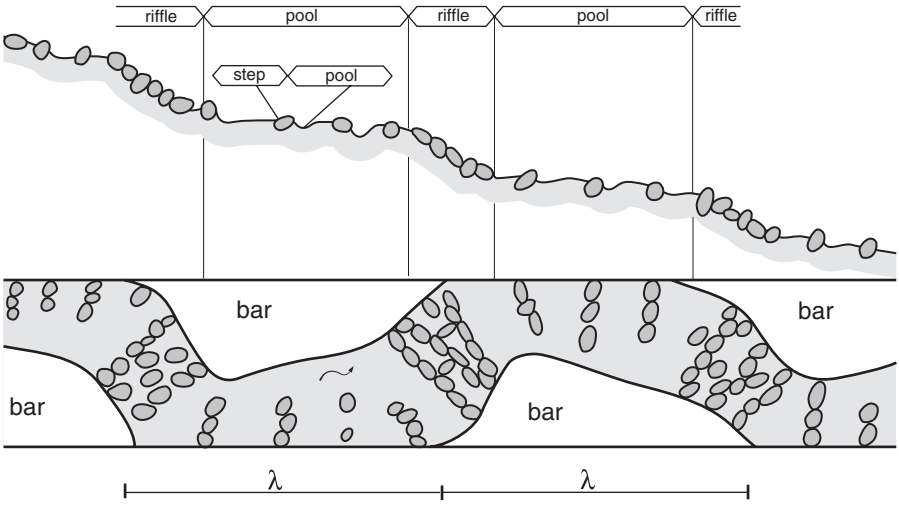

Figure 7. Macro-scale bed features as observed in the flume experiments.

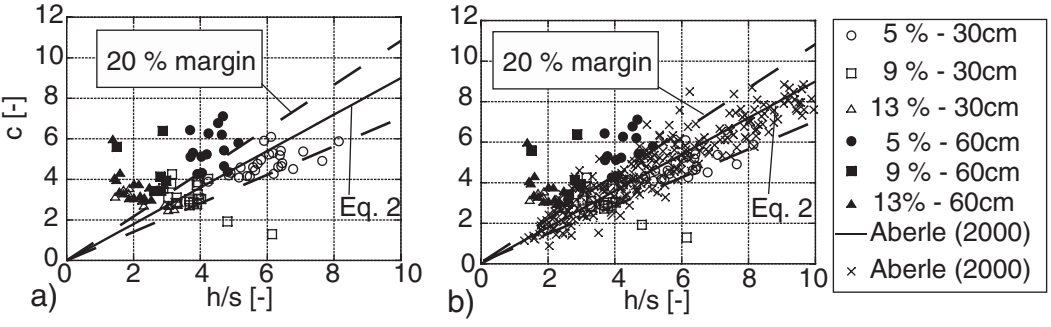

Figure 8. Comparison between the flow resistance equation of Aberle and Smart (2003) and the present data – (a) without the original data of Aberle and (b) with the original data of Aberle. The flow resistance, expressed by the Chézy-coefficient c, is illustrated depending on the relative submergence h/s. Herein, s denotes the standard deviation of the roughness heights.

However, in accordance to gravel-bed rivers, more of the coarse material could be found on the riffles than in the pools. Whereas the riffles exhibited meso-scale structures that correspond to boulder-glide sections or large steps, in the pools smaller step structures developed.

5.2 *Flow resistance*

In the following, the present data set is evaluated with respect to the flow resistance. The inadequacy of flow resistance equations that contain a characteristic grain size to describe the conditions of step-pool channels is discussed in Aberle (2000) or Weichert (2006). The present paper mainly focusses on a comparison between the flume data of this study and Equation 2 in order to evaluate the influence of the macro-scale bed features on the flow resistance.

Flow resistance can be expressed by the Chézy-coefficient, which is defined as

$$c = \frac{U}{\sqrt{ghS}} = \frac{q}{\sqrt{gh^3S}}. \quad (5)$$

For the following considerations, the bed area was divided into 5 sections, each with a length of 2.12 m, as the Chézy-coefficient is based on the assumption of quasi-uniform flow conditions which require an temporal and spatial averaging of the local parameters (flow depth, h, and channel gradient, S). The specific discharges were obtained by dividing the discharge Q by the channel width W (see Figure 10).

In Figure 8 the Chézy-values of the present data set are compared with Equation 2 proposed by (Aberle and Smart, 2003). For flume widths of 30 cm, the measured values fit relatively well with Equation 2. In contrast,

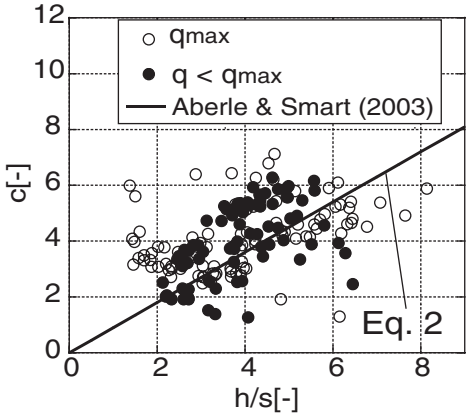

Figure 9. The influence of flow stage on the flow resistance.

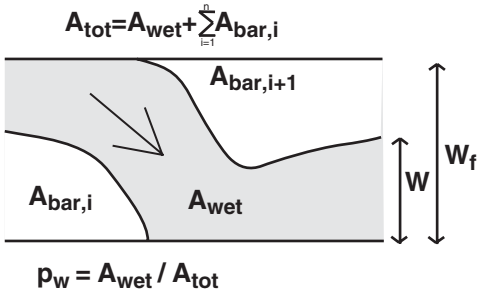

Figure 10. Definition sketch for p_w (see Equation 6).

the runs with a flume width of $W_f = 60$ cm deviate significantly from Aberle's approach. This behaviour indicates an influence of the macro-scale bar features on the flow resistance.

No difference could be established between the data of experiments at bedforming discharges or at smaller discharges (see Figure 9).

The influence of the macro-scale bar features on the flow resistance is analysed in Figure 11, where the ratio of the total, measured flow resistance, c, and the flow resistance of the meso-scale structures, c_{meso}, is shown. In this respect, c_{meso} is calculated with Equation (2) proposed by Aberle and Smart (2003). In order to account for the observed difference in flow resistance whether bar features were absent or not, the portion of the wetted area, A_{wet}, on the whole area of the channel bed, A_{tot}, is taken as a parameter to describe the pronouncement of the bed features in the macro-scale (see Figure 10). This means, the larger p_w, the smaller the influence of macro-scale bed features.

$$p_w = \frac{A_{wet}}{A_{tot}}. \tag{6}$$

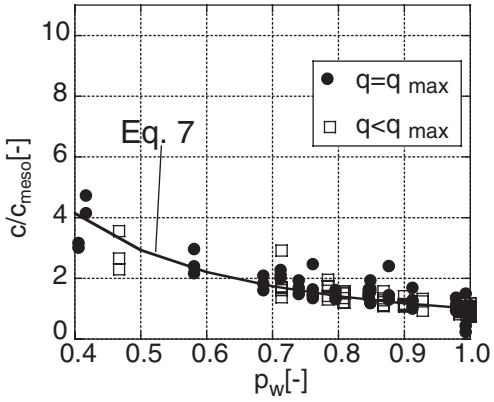

Figure 11. The influence of macro-scale bed features on the flow resistance.

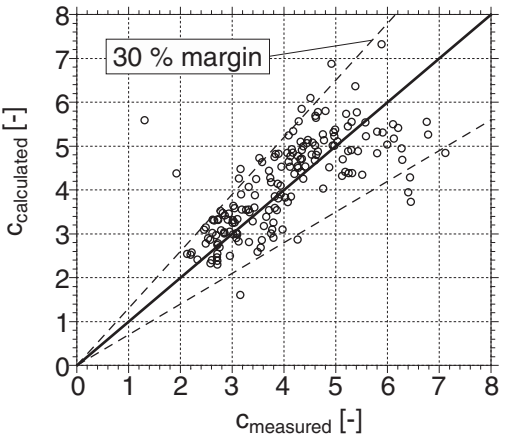

Figure 12. Comparison between measured Chézy-coefficients and those calculated with Equation 8.

In general, Figure 11 shows that the ratio c/c_{meso} decreases with increasing value of $p_w = A_{wet}/A_{tot}$. The best fit ($r^2 = 0.84$) of the data in Figure 11 is

$$\frac{c}{c_{meso}} = p_w^{-1.58} \tag{7}$$

for $p_w \geq 0.4$.

Expressing c_{meso} by Equation (2), the data of the present study is best described with

$$c = 0.91 \cdot p_w^{-1.58} \cdot \frac{h}{s}. \tag{8}$$

With this equation, the effects of the different geomorphologic scales are separatively but not additively taken into account. Whereas the standard deviation of

Copyright © 2006 Taylor & Francis Group plc, London, UK

the roughness heights, s, focusses on the mesoscale structures, the parameter, p_w accounts for the macroscale bed features. In Figure 12, the comparison between the measured and the calculated Chézy-coefficients demonstrate the adequacy of Equation 8 (compared to the errors of other flow resistance equations – see Weichert 2006) to consider the flow resistance in steep open channels.

In general, the results shown in Figure 11 are not evoked by a resistance-diminishing effect of the bar features. On the contrary, they demonstrate the effect of the bar features on the development of the mesoscale roughness structure. As a conclusion, the introduction of p_w in Equation 8 points out the necessity for an adequate description of the roughness structure when different geomorphologic scales are present.

Although the previous considerations showed the adequacy of the parameter p_w to explain the processes within the flume, a fundamental aspect concerns its applicability under field conditions. The parameter p_w is defined by the wetted channel bed area, A_{wet}, divided by the whole area of the channel bed, A_{tot} (see Figure 10). Whereas A_{wet} can be measured under field conditions, the question remains how to determine A_{tot}. Here, it is proposed to assess A_{tot} by considering the bankfull width of the channel. As the determination of the bankfull width is not a straight-forward issue in steep open channels, p_w can only be determined as an approximation.

6 CONCLUSIONS

Steep open channels are characterised by coarse, structured armour layers that are often denoted as step-pool systems. Additionally, the ratio of flume width to maximum grain size plays a significant role, as it determines the number of boulders required for a total blocking of the channel. For larger flume widths, the occurrence of macro-scale bed features could be observed, which influence all relevant processes. Following this, the description of the roughness structure depending on the existent geomorphologic scales is an important aspect regarding the assessment of all important processes. In this connection, the present study shows the suitability of the standard deviation of the roughness heights to describe the roughness geometry in the meso-scale.

The considered ratios of flume width to maximum grain size allowed for an assessment of the macroscale bed features. These structures are characterised by both a horizontal as well as a vertical variation of the channel bed. The horizontal, quasi-meandering tendency is evoked by bar features located alternately at the channel sides. These features could be identified with delimitation criteria as e.g. the one proposed by da Silva (1991), if the modificatons of Zarn (1997) are taken into account.

In addition to the horizontal oscillation, vertical variations express successions of steep and gentle gradient sections, i.e. riffle and pool sections. An important result of the present study concerns the observation that these features possibly occur although the horizontal oscillations are not apparent, i.e. for relatively small flume widths.

The macro-scale bed features significantly influence the flow resistance. For the conditions without macro-scale bed features, the flow resistance data of the present study can be predicted by the equation proposed by Aberle and Smart (2003). In contrast, the deviations increase when pronounced macro-scale bed features are present. Experiments with wellpronounced bar features had smaller values of the flow resistance. This effect can be attributed to differences in the meso-scale structure, that occur depending whether bar features are present or not. The effect of the macro-scale bar features can be taken into account with Equation 8 which is an extension of the approach proposed by Aberle and Smart.
